Biochemical confirmation of muscle damage by demonstration of increased serum CK or AST activity, in conjunction with appropriate clinical signs, provides the diagnosis.

DIFFERENTIAL DIAGNOSIS

- Ear tick (*Otobius megnini*) induced muscle cramping[16]
- Polysaccharide storage myopathy of Quarter horses
- Ionophore intoxication (monensin, lasalocid, salinomycin, narasin, maduramicin)[17]
- Equine lower motor neurone disease (acute form)
- *Cassia occidentalis* toxicosis
- Hyperkalemic periodic paralysis
- Laminitis
- Colic
- Pleuritis
- Aorto-iliac thrombosis.

TREATMENT

The treatment chosen depends on the severity of the disease. The **general principles** are rest, correction of dehydration and electrolyte abnormalities, prevention of complications including nephrosis and laminitis, and provision of analgesia.[18]

Mildly affected horses (heart rate <60 bpm, normal rectal temperature and respiratory rate, no dehydration) may be treated with rest and phenylbutazone (2.2 mg/kg, orally or IV every 12 h for 2–4 d). Horses should be given mild exercise with incremental increases in workload as soon as they no longer have signs of muscle pain. Access to water should be unrestricted.

Severely affected horses (heart rate >60 bpm, rectal temperature >39°C (102°F), 8–10% dehydrated, reluctant or unable to walk) should not be exercised, including walking back to their stable, unless it is unavoidable. Isotonic, polyionic **fluids**, such as lactated Ringer's solution, should be administered IV to severely affected horses to correct any hypovolemia and to insure a mild diuresis to prevent myoglobinuric nephropathy. Less severely affected horses can be treated by administration of fluids by nasogastric intubation (4–6 L every 2–3 h). Although it has been recommended that urine should be alkalinized by administration of mannitol and sodium bicarbonate (1.3% solution IV, or 50–100 g of sodium bicarbonate orally every 12 h) to minimize the nephrotoxicity of myoglobin, this therapy is not effective in humans at risk of myoglobinuric nephrosis.[19] Affected horses should not be given diuretics (e.g. furosemide).

Phenylbutazone (2.2–4.4 mg/kg, IV or orally, every 12–24 h), **flunixin meglumine** (1 mg/kg IV every 8 h) or **ketoprofen** (2.2 mg/kg IV every 12 h) should be given to provide **analgesia**. **Mild sedation** (acetylpromazine 0.02–0.04 mg/kg IM, or xylazine, 0.1 mg/kg IM, both with butorphanol, 0.01 to 0.02 mg/kg) may decrease muscle pain and anxiety. Tranquilizers with vasodilatory activity, such as acetylpromazine (acepromazine), should only be given to horses that are well hydrated. **Muscle relaxants**, such as methocarbamol, are often used but have no demonstrated efficacy.

Recumbent horses should be deeply bedded and repositioned by rolling every 2–4 h. Severely affected horses should not be forced to stand.

CONTROL

Prevention of the sporadic, idiopathic disease centers on insuring that horses are fed a balanced ration with adequate levels of vitamin E, selenium and electrolytes, and have a regular and consistent program of exercise. Despite lack of clear evidence for a widespread role for **vitamin E or selenium** deficiency in exertional rhabdomyolysis, horses are often supplemented with 1 IU/kg vitamin E and 2.5 μg/kg selenium daily in the feed. Care should be taken not to induce selenium toxicosis.

Sodium bicarbonate (up to 0.5 to 1.0 g/kg body weight daily in the ration) and other electrolytes are often added to the feed of affected horses, but their efficacy is not documented. **Phenytoin** has proven useful in the treatment of recurrent rhabdomyolysis. It is administered at a dose rate of 6–8 mg/kg, orally, every 12 h, and the dose adjusted depending on the degree of sedation produced (a reduced dose should be used if the horse becomes sedated) or lack of effect on serum CK or AST activity. Phenytoin can be administered to horses for months. **Dimethylglycine, dantrolene, altrenogest, and progesterone** are all used on occasion in horses with recurrent rhabdomyolysis, but again without demonstrated efficacy.

The feeding of high fat, low soluble carbohydrate diets is useful in the prevention of recurrent exertional rhabdomyolysis in Thoroughbred horses and polysaccharide storage myopathy in Quarter horses. The usefulness of this practice in preventing sporadic, idiopathic exertional rhabdomyolysis has not been demonstrated.

MASSETER MYONECROSIS

Degeneration of the masseter muscles causes dysphagia and trismus in adult horses.[1,2] The disease is associated with abnormally low serum or blood concentrations of vitamin E or selenium in some affected horses.[1] Muscles of locomotion and cardiac muscle can be affected in addition to disease of the masseter muscle. Clinical signs include dysphagia, trismus, weight loss, gait abnormalities, atrophy of the masseter muscle, teeth grinding or quidding of feed, and unexpected death. Horses with extensive involvement of other muscles can have myoglobinuria.[1] Signs of dysphagia and trismus are related to dysfunction of the masseter muscle. Gait abnormalities are related to disease in muscles of locomotion and unexpected death is probably due to the cardiac lesions. Serum activity of creatine kinase and aspartate aminotransferase is elevated in acute cases.[1] Necropsy examination reveals diffuse swelling, muscle pallor, and white streaking of masseter muscle in acutely affected animals.[1] Lesions are also detected in muscles of locomotion and myocardium in some horses.[1] Chronic cases have atrophy of affected muscle. Histological changes include swelling, fragmentation and loss of striations of myocytes in acute cases and degenerating fibers replaced by fibrosis in chronic cases.[1] Treatment is symptomatic and affected horses can require enteral or parenteral delivery of nutrients. Vitamin E and selenium status should be determined and administered if indicated. Prevention should focus on ensuring that horses in geographic regions in which vitamin E or selenium are deficient in feeds are supplemented with these micronutrients.

ATYPICAL MYOPATHY (MYOGLOBINURIA) IN GRAZING HORSES

A syndrome of acute myoglobinuria occurring in horses at pasture is reported from Great Britain and Europe,[1–4] and is suspected to occur in North America and Australia. Occurrence of the disease is sporadic but usually affects more than one animal in a band of horses. Localized outbreaks involving large numbers of horses are reported.[1,4] The case fatality rate is usually very high, approaching 100%.[1,4] The disease occurs more commonly in the autumn or winter although cases have been reported from most months of the year. There does not appear to be a breed or sex predilection to development of the disease. Younger horses might be at greater risk of the disease but this could simply reflect the age distribution of horses at pasture in areas in which the disease occurs. Atypical myopathy occurs almost exclusively in horses at pasture and is not associated with enforced exercise.

Clinical signs are those characteristic of acute rhabdomyolysis and include an abrupt onset of stiffness and reluctance to move. Progression to lateral recumbency is rapid, occurring within hours of the initial onset of signs. Recumbency is often the first indication of this disease observed in horses at pasture.[3] Horses forced to stand have tremors and difficulty walking. Lumbar and gluteal muscles can be firm. Affected horses are tachycardic and tachypneic. Respiratory distress, presumably secondary to degeneration of intercostal muscle and diaphragm, is common in recumbent horses in the terminal stages of the disease. There is discolored urine (pigmenturia). Affected horses die within 24–72 h of onset of clinical signs. Serum biochemical abnormalities include massively increased serum activities of creatine kinase, lactate dehydrogenase, and aspartate aminotransferase.[2–4] Serum concentrations of troponin T, a marker of myocardial damage, are above normal in most affected horses.[4] Serum concentrations of vitamin E and/or selenium and red cell activity of glutathione peroxidase are not consistently abnormally low.[2–4]

Necropsy examination does not reliably reveal gross evidence of muscle disease although there can be swelling, edema and localized hemorrhage into muscles. There are hemorrhagic or pale areas in the ventricular myocardium of some horses.[2] Histologic examination reveals the presence of widespread degeneration of myocytes, without inflammation, in muscles of locomotion and respiration.[2,3] Within a muscle group some fibers are severely affected while other neighboring fibers are apparently normal.[3] The ventricular myocardium has lesions of muscle degeneration in some horses.[2,4] Myoglobinuric nephrosis is a consistent finding in horses that die spontaneously or are euthanized in the terminal stages of the disease.

Definitive diagnosis is based on the presence of clinical signs of muscle disease, large elevations in serum activity of muscle derived enzymes and necropsy examination.

Treatment is supportive and largely ineffectual and should follow the guidelines provided under acute rhabdomyolysis. There are no documented effective control measures although ensuring normal vitamin E and selenium status is advisable.

LOW MILK FAT SYNDROME

The secretion of a normal volume of milk but with its milk fat reduced, often to less than 50% of normal, is a significant cause of wastage in high-producing cows. It occurs most commonly in cows on low-fiber diets, for example, lush, irrigated pasture or grain rations that are ground very finely or fed as pellets.[1] It is assumed that a decreased formation of acetate in the rumen is the cause of a depletion of fatty acid precursors and the fall in butterfat. Treatment is achieved by administration of sodium bicarbonate or magnesium oxide, which increase fiber digestibility and hence the propionate: acetate ratio.[2] Magnesium oxide also increases the activity of lipoprotein lipase in the mammary gland and increases uptake of triglycerides by the mammary gland from the plasma.[3]

EQUINE PARS INTERMEDIA DYSFUNCTION (ADENOMA OF THE PARS INTERMEDIA OF THE PITUITARY, EQUINE CUSHING'S DISEASE)

A slowly progressive disease of older horses caused by non-malignant hypertrophy and hyperplasia of melanotropes of the pars intermedia of the pituitary gland and characterized by polyuria, polydipsia, hirsutism, and laminitis.

ETIOLOGY

The disease appears to be attributable to degeneration of the periventricular hypophyseal dopaminergic neurons with subsequent development of a non-malignant functional tumor comprised of

melanotropes of the pars intermedia of the pituitary gland.[1]

Cushing's syndrome caused by adrenocortical tumors is exceedingly rare in horses.[2]

EPIDEMIOLOGY

The disease occurs worldwide in all breeds of horses and ponies. It is sporadic, non-infectious, and non-contagious. The prevalence of the disease is approximately 0.1%.[3] The case-fatality rate is high (approaching 100%) after a prolonged course because of the advanced age of most affected horses, the severity of the disease and the cost of palliative treatment.

There is no apparent sex or breed predisposition, although the disease might be more common in ponies. Affected animals are usually at least 7 years old, and the average age at presentation is 20 years.

PATHOGENESIS

There is a loss of inhibitory effect of dopamine with subsequent hypertrophy and hyperplasia of **melanotropes** of the pars intermedia of the pituitary gland which results in unchecked secretion of **pro-opiomelanocortin** and compression of the neurohypophysis, hypothalamus and optic chiasma. Production of pro-opiomelanocortin by melanotropes is not under the negative feedback control of glucocorticoids and as a result affected horses produce large quantities of pro-opiomelanocortin, melanocyte stimulating hormone, β-endorphin, and smaller but still excessive quantities of adreno-corticotropic hormone (ACTH).[4,5] Production of ACTH results in loss of the normal circadian rhythm in serum cortisol concentration and **hyperadrenocorticism,** and **secondary diabetes mellitus**. The space-occupying effects of the tumor can cause blindness because of compression of the optic chiasma, and **diabetes insipidus**, because of neurohypophyseal dysfunction.

CLINICAL FINDINGS

Affected horses exhibit one or more of hirsutism, hyperhidrosis, polyuria, polydipsia, polyphagia, and a docile demeanor. There is often central obesity, characterized by excessive fat deposition in the crest of the neck and in the supraorbital fossae. Rarely, affected horses are blind or have seizures. Hirsutism, the presence of a long, often curly hair coat that is not shed during the warmer months, is a relatively consistent and specific finding in affected horses. Laminitis is a frequent finding in horses with equine pars intermedia dysfunction, and as many as 70% of horses with idiopathic laminitis (i.e. not clearly associated with an inducing disease such as colic or diarrhea) have evidence of pars intermedia dysfunction.[6] Affected horses are often infertile and heal poorly.

CLINICAL PATHOLOGY

There is often mild neutrophilia and lymphopenia. Serum biochemical analysis may demonstrate **hyperglycemia** and an increase in alkaline phosphatase activity. Resting serum cortisol concentrations of affected and normal horses are similar and not useful in diagnosis. **Glucosuria** is often present.

DIAGNOSTIC CONFIRMATION

Antemortem diagnosis is achieved on the basis of clinical signs and one of several diagnostic tests. It is important that testing be based on the presence of clinical signs compatible with the disease in order to minimize the frequency of false positive diagnoses. Laboratory tests for the disease are not infallible and the results of these tests should be viewed only in the context of the horse's clinical signs. Further complicating diagnosis of equine pars intermedia dysfunction is the slow and progressive onset of the disorder. It is therefore likely that attempting a definitive dichotomous answer (disease present or disease absent) based on laboratory testing is unreasonable – some mildly affected horses will test normal while some apparently healthy horses with histologically normal pituitary glands will test positive.[7]

Laboratory tests used to diagnose pars intermedia dysfunction include measurement of serum or plasma cortisol, ACTH, glucose, or insulin concentrations, the ACTH stimulation test, the thyrotropin-releasing hormone stimulation test, measurement of urinary and salivary corticoid concentrations and combinations of these tests.[8] The most widely accepted laboratory tests are the overnight dexamethasone suppression test and measurement of serum ACTH concentration.[8] Other tests have been suggested, but either their sensitivity and specificity have not been determined, or they involve measurement of multiple variables or of hormones for which assays are not readily commercially available.[9,10] Measurement of basal serum insulin concentration is not a useful diagnostic test for equine pars intermedia dysfunction.[11] Measurement of urine or salivary cortisol concentrations has been suggested as a means of diagnosing equine pars intermedia dysfunction, but neither has been validated in a sufficient number of horses to permit assessment of their clinical utility.[12,13]

Diagnosis with a high degree of accuracy is achieved by the **overnight dexamethasone suppression test**.[4] After collection of a serum sample for measurement of cortisol, dexamethasone (40 μg/kg IM) is administered at about 5 p.m. A second blood sample is collected 15 h later, with the option to collect a third sample 19 h after dexamethasone administration. Normal horses will have a serum cortisol concentration of less than 1 μg/dL (28 nmol/L) in the second and third blood samples, whereas affected horses will not show a significant reduction in serum cortisol concentration from that of the initial sample. The sensitivity and specificity of this test are apparently high with both reported to be approximately 100%.[8] However, recent studies of healthy horses demonstrate that there is considerable seasonal variation in the dexamethasone suppression test, with all of 39 healthy aged ponies and horses having normal tests in January (winter) but 10 of the same 39 (26%) having abnormal tests in September (autumn).[7] These results suggest that these diagnostic tests should be interpreted with caution when conducted in the autumn.

Measurement of serum or plasma adrenocorticotropin (ACTH) concentration has been proposed as an accurate laboratory indicator of equine pars intermedia dysfunction.[14] The upper ACTH concentration from normal horses is 35–55 pg/mL.[14] However, there is considerable seasonal variation in aged normal horses, with all of 39 horses having plasma ACTH concentration <35 pg/mL in January (winter), and May (late spring) but in only three of the same 39 horses in September (autumn).[7] These results demonstrate the need for caution when assessing the diagnostic importance of plasma ACTH concentrations in aged horses.

The combined dexamethasone suppression/TRH stimulation test has reported sensitivity and specificity of 88% and 79%, respectively.[15] The test is performed by administering 40 μg/kg of dexamethasone phosphate (or similar dexamethasone salt) intravenously between 8 a.m. and 10 a.m. Cortisol concentration in serum is then measured 3 h later and thyroid releasing hormone (TRH, 1 mg) administered intravenously. Serum cortisol concentration is measured 30 min after TRH administration. Serum cortisol concentrations of heathy horses 30 min after TRH administration are unchanged from those at the time of TRH administration, while serum cortisol concentrations in horses with equine pars intermedia dysfunction increase by >66% of the baseline value.[15]

NECROPSY FINDINGS

The pituitary gland is usually enlarged due to the increased numbers of melanocorte cells comprising an adenoma of the pars intermedia.[18] The adrenal cortices are

usually of normal width but may be thickened in some cases. With the appropriate clinical history, the observation of a well-defined nodule within the pituitary gland is usually sufficient for confirmation of the diagnosis, but histology and immunohistochemical testing of the mass can be performed. There is only fair (kappa = 34%) agreement among pathologists for histologic diagnosis of the disease.[19]

DIFFERENTIAL DIAGNOSIS

- Insulin resistance
- Diabetes insipidus
  Both of these diseases are exceedingly rare in horses
- Obesity
- Psychogenic polydipsia or salt eating
- Chronic renal failure.

TREATMENT

Treatment is palliative. There is no effective treatment of the pars intermedia adenoma and the aim of treatment is to reduce secretion of the products of the melanotropes through the use of dopamine agonists or serotonin antagonists. Treatment must be continued for the life of the horse.

The **treatment of choice** is administration of pergolide, a dopamine agonist, at 1.7–5.5 µg/kg orally every 24 h. The recommended starting dose is 3.0 µg/kg once daily for 2 months, at which time clinical and laboratory (plasma ACTH concentration, dexamethasone suppression test) signs of the disease should be evaluated. This treatment is superior to cyproheptadine in terms of reducing plasma ACTH concentrations and improving clinical signs of disease[16] although this is not a uniformly reported observation.[17] Cyproheptadine, a serotonin antagonist, is administered at 0.25 mg/kg orally every 24 h for 1 month. If an acceptable response is achieved then this dose is continued, if not, then the dose is increased to 0.25 mg/kg every 12 h.

Symptomatic treatment should include clipping of the hair coat in spring, treatment of laminitis and wounds, and prevention of injuries and infection.

CONTROL

None.

DISORDERS OF THYROID FUNCTION (HYPOTHYROIDISM, HYPERTHYROIDISM, CONGENITAL HYPOTHYROIDISM, THYROID ADEMONA)

Disorders of thyroid function due to abnormalities in the thyroid gland, pituitary gland or hypothalamus are uncommon in the domestic species and are best documented for the horse. Thyroid disorders secondary to excessive or inadequate intake of iodine, or selenium deficiency are discussed under those headings.

ETIOLOGY

Disorders of thyroid function result in hypothyroidism or hyperthyroidism. Hypothyroidism can result from diseases of the thyroid gland (primary hypothyroidism), pituitary gland (secondary hypothyroidism due to reduced secretion of thyroid stimulating hormone), or hypothalamus (tertiary hypothyroidism, decreased thyrotropin [thyroid releasing hormone] secretion). Autoimmune thyroiditis has not been described in horses. Lymphocytic thyroiditis occurs in goats.[1] Consumption of propylthiouracil (4 mg/kg body weight orally once daily for 4–6 weeks) induces hypothyroidism in adult horses.[2,3] Administration of trimethoprim-sulfadiazine (30 mg/kg orally q . 24 h for 8 weeks), which can induce hypothyroidism in humans and dogs, does not impair thyroid function of most horses.[4]

Hereditary congenital hypothyroidism secondary to defects in thyroglobulin production occurs in sheep, goats, and Afrikander cattle.[5] The disease is inherited as an autosomal recessive trait.[5] The cause of congenital hypothyroidism in foals is uncertain, although ingestion of nitrates by the pregnant dam is strongly suspected.[6] Partial thyroidectomy of equine fetuses results in birth of foals with clinical and pathological characteristics similar to the spontaneous disease.[7]

Hyperthyroidism in horses is attributable to functional adenocarcinoma or adenoma of the thyroid gland[8,9] but most thyroid tumors, are not functional.[10,11]

EPIDEMIOLOGY

The frequency with which hypothyroidism occurs in adult horses is unknown. It is relatively common practice to administer thyroid hormone or iodinated casein to fat horses, those with laminitis, rhabdomyolysis, or anhidrosis, or to enhance fertility, but documentation of abnormal thyroid function in these animals is rare. None of 79 clinically normal brood mares had an abnormal response to thyroid stimulating hormone administration,[12] indicating that hypothyroidism is uncommon. Importantly, horses with non-thyroid related illness often have low concentrations of thyroid hormones in blood without evidence of thyroid dysfunction – this is referred to as the euthyroid sick or non-thyroidal illness syndrome and is not indicative of thyroid disease.[13]

Abnormalities of the thyroid gland were detected in 12% of 1972 **goats** examined in India.[1] Of thyroid glands examined from 1000 goats in India, 2.4% had colloid goiter, 39% parenchymatous goiter, 1.8% lymphocytic thyroiditis, and 2.1% were fibrotic.[1]

Congenital hypothyroidism in foals occurs in western Canada and the western and northern USA. One survey of necropsy records of almost 3000 equine fetuses and neonatal foals in western Canada found that 2.7% had histologic evidence of thyroid and musculoskeletal abnormalities consistent with congenital hypothyroidism.[14] Congenital hypothyroidism occurs in Dutch goats, Merino sheep, and Afrikander cattle.[5,15] Hypothyroidism is reported in an East Friesian ram.[16]

Hyperthyroidism is a sporadic disease of older horses for which other risk factors are not identified.[9,17]

Thyroid tumors are common in older horses with ~50% having adenomas evident on histologic examination of the thyroid gland.[11] The clinical course of such tumors is benign, although their size can be quite impressive. Thyroid adenocarcinoma is much less common but has a malignant course.[10,11]

CLINICAL FINDINGS

Clinical characteristics of hypothyroidism in adult horses are poorly defined, largely because of the difficulty of confirming the diagnosis and the pharmacological effect of exogenous thyroid hormones. Clinical abnormalities anecdotally attributed to hypothyroidism include exercise intolerance, infertility, weight gain, maldistribution of body fat, agalactia, anhidrosis, and laminitis, among others. Definitive association of these clinical syndromes with abnormalities of thyroid function is lacking.

Thyroidectomy of horses causes a reduction in resting heart rate and body temperature, docility, decreased food intake, increased cold sensitivity, dull hair

coat, and delayed shedding of hair.[18,19] Blood and plasma volumes of horses increased after removal of the thyroid glands.[19] Effects of thyroidectomy were reversed by administration of thyroxine, with the exception of blood and plasma volume which did not return to euthyroid values.[19] Thyroidectomized horses did not become obese or develop laminitis.

Induced hypothyroidism in goats is evident as a loss of body weight, facial edema, weakness, profound depression, and loss of libido.[20]

Congenitally hypothyroid foals have a prolonged gestation but are born with a short silky hair coat, soft pliable ears, difficulty in standing, lax joints, and poorly ossified bones. The foals are referred to as dysmature. Characteristic musculoskeletal abnormalities include inferior (mandibular) prognathism, flexural deformities, ruptured common and lateral extensor tendons, and poorly ossified cuboidal bones.[14]

Horses with **hyperthyroidism** are tachycardic, cachexia, and have hyperactive behavior.[9,17] There is usually detectable enlargement of the thyroid gland.

Thyroid adenomas are evident as unilateral, non-painful, enlargement of the thyroid gland of older (>15 years) horses. Thyroid adenocarcinoma presents as metastatic disease with both local and distant spread. Some affected horses have signs of hyperthyroidism, although this is unusual.

CLINICAL PATHOLOGY

Hematologic abnormalities in hypothyroid horses are not well documented. Induced-hypothyroidism in horses causes increases in serum concentrations of very low density lipoprotein, triglycerides, and cholesterol, and decreased concentrations of non-esterified fatty acids.[21] Induced hypothyroidism in goats caused hypoglycemia, hypercholesterolemia, and anemia.[20] Hypothyroidism in a ram caused hypercholesterolemia.[16]

Thyroid hormone assays

Assays are available for measurement of serum concentrations of T3, T4, free T4 (radioimmunoassay or equilibrium dialysis), and TSH.[13] Values of each of these analytes varies depending on the method of analysis, physiologic status of the animal, and administration of other compounds (Table 29.8). Serum concentrations of thyroid hormones is high at birth and declines with age.[22–25] There are statistically significant **diurnal variations** in serum concentrations of T3 and T4 in adult horses with lowest concentrations observed during the early morning hours, likely coincident with the time at which metabolic rate is lowest (Table 29.8).[26] **Feed restriction** for 3–5 days lowers serum concentrations of T3, T4, and fT4 in horses by 24–42%.[27] Administration of **phenylbutazone** decreases concentrations of fT4 (measured by equilibrium dialysis) and T4 by 4 days of treatment, and can persist for up to 10 days after discontinuation of phenylbutazone.[28] The decrease in T4 is suggested to be attributable to displacement of T4 from protein binding sites by phenylbutazone, but this does not explain the decrease in fT4. The clinical significance of phenylbutazone-induced decreases in thyroid hormones is uncertain, but should be considered when assessing thyroid function in horses.

Because of the number of analytical and physiological factors that affect serum thyroid hormone concentrations, values considered normal vary considerably, as illustrated by the finding that 44 of 79 clinically normal non-pregnant broodmares had serum T4 concentrations below the reference range, although responses to

Table 29.8 Serum or plasma concentrations of thyroid hormones and thyroid stimulating hormone (TSH) in foals and horses

Physiologic status	Serum or plasma T3	Serum or plasma T4	fT4[a]	TSH
Age				
Birth (<10 h)	991 ng/dL[24]	28.8 μg/dL[24]	12.1 ng/dL[24]	
	12.8 ± 7.4 mmol[23]	493 ± 58 nmol/L[23]		
	366 ± 222 ng/L[25]	13.3 ± 5.1 μg/dL[25]		
1–3 days	940 ng/dL[24]	28.0 μg/dL[24]	12.1 ng/dL[24]	
4 days	935 μg/dL[24]	11.2 μg/dL[24]	5.9 ng/dL[24]	
	7.8 ± 4.2 mmol[23]	232 ± 61 nmol/L[23]

fT4 = free T4; TSH = thyroid stimulating hormone. Mean ± SD or median (95% confidence interval). To convert μg/dL to nmol/L for T4 or fT4, multiply by 12.87. To convert ng/dL to nmol/L for fT3 or T3, multiply by 0.0154.
[a]fT4 determined by radioimmunoassay (RIA) or equilibrium dialysis (ED).

TRH were normal.[12] This example illustrates the need to determine reference ranges based on the methodology used and with well defined definition of the physiological state of the animals being tested.

Diagnosis of hypothyroidism is aided by demonstration of inappropriate responses of the thyroid gland to administration of TSH or TRH, although the use of these tests depends on determining the increase in serum T3 and/or T4 that is expected in normal horses and in horses with thyroid disease. Of 79 clinically normal mares, all had some increase in T3 and 77 had an increase in T4 2 hours after IV administration of 1 mg of TRH intravenously.[12] The mean increase in serum T3 concentration was 4.5 times that of resting values (from 0.62 ng/mL to 2.44 ng/mL), whereas serum T4 concentration increased to a mean of 2.1 times that of resting value (from 14.7 ng/mL to 28.6 ng/mL).[12] While responses to administration of TSH are reported, responses, other than complete lack of response, indicative of abnormal thyroid function have not been determined and the utility of the test has been questioned.[27]

The TSH response test involves administration of 5 IU of TSH intravenously. Blood samples are collected before, 30 min and 2 and 4 h after administration.[29] Serum concentrations of T3 and T4 in healthy horses double after administration of TSH. An alternative involves administration of 5 IU intramuscularly and collection of blood before and 3 and 6 h after a TSH administration.[30] TSH is currently unavailable.

The TRH response test requires administration of 0.5–1 mg of TRH intravenously. Serum concentrations of T3 and T4 at 2 and 4 h are double those before TRH administration in horses with normal thyroid function.[31]

Measurement of fT4 in serum is useful for assessment of thyroid function.[3] fT4 concentrations can be normal in horses with low concentrations of T3 and T4, and in this situation are likely indicative of normal thyroid function.

Measurement of serum concentrations of TSH is useful in determining thyroid responsiveness to endogenous TSH. Elevated TSH concentrations in horses with low serum concentrations of T3, T4, or fT4 is indicative of thyroid dysfunction.[13,32]

Diagnosis of hypothyroidism in horses should be based on the presence of compatible clinical signs, low serum concentrations of thyroid hormones (T3, T4, fT4); elevated concentrations of thyroid stimulating hormone, lack of an increase in serum concentrations of thyroid hormones in response to administration of thyroid releasing hormone (TRH), and increased TSH concentration in serum in response to TRH administration. Diagnosis of hypothyroidism should not be based solely on clinical signs, or on the measurement of resting (unstimulated) serum T3 or T4 concentrations. At a minimum, appropriate clinical signs and documentation of an abnormal response to stimulation testing (TSH or TRH) are essential for diagnosis of hypothyroidism in horses. Measurements of fT4 concentrations determined by equilibrium dialysis are useful in determining thyroid function in sick horses in which T3 and T4 concentrations are low as fT4 concentrations will be normal in horses without thyroid disease.[13]

Foals with congenital hypothyroidism have abnormally low concentrations of T3 and T4, and less than expected increases in serum concentrations of these hormones in response to TSH administration.[33]

Horses with hyperthyroidism have markedly elevated concentrations of T3 and T4.[9,17] Concentrations of T4 do not decline in response to administration of T3.[17] T3 (2.5 mg) is administered intramuscularly twice daily for 3 days and serum concentrations of T3 and T4 measured. T4 concentrations in serum of healthy horses decline by approximately 80% whereas those of horses with hyperthyroidism do not decline.

NECROPSY FINDINGS

Findings on necropsy examination of hypothyroid horses have not been reported. Foals with congenital hypothyroidism have histologic evidence of thyroid hyperplasia, but no gross signs of goiter.

TREATMENT

Treatment of confirmed hypothyroidism in horses is achieved by administration of levo-thyroxine (20 µg/kg PO q24 h).[34] Serum T3 concentrations peak in 1 h and then decline while concentrations of T4 peak in 2 h and persist for 24 h.[34] The clinical status of the horse should be monitored during treatment and serum concentrations of T3 and T4 measured every several months. Iodinated casein, which is no longer readily available in the USA, is administered at 5 g/450 kg body weight orally once daily. Administration of thyroxine or iodinated casein for treatment of low serum thyroid hormone concentrations in horses with nonthyroidal illness syndrome (euthyroid sick syndrome) should be done judiciously.

A response to thyroxine administration is not necessarily confirmation of hypothyroidism as thyroxine can have marked effects in horses with normal thyroid function. Administration of thyroxine (up to 96 mg/470 kg horse, orally once daily) increases serum concentrations of T4 and, to a lesser extent, fT4, and decreases concentrations of TSH.[35] The increases in T4 are associated with a loss of body weight, decreases in serum concentrations of triglycerides, cholesterol, and very low density lipoproteins, and an increase in whole body insulin sensitivity.[35,36] Thyroxine should be administered with caution to horses with normal thyroid function.

CONTROL

There are no recognized control measures for hypothyroidism in adult horses. Minimizing intake of nitrates by pregnant mares appears warranted, but definitive proof of the efficacy of this practice is lacking. Pregnant mares should not be fed fodder or supplements that interfere with thyroid function.

The inherited disorder in sheep, cattle, and goats can be prevented by selective breeding.

Diseases associated with nutritional deficiencies

30

Introduction

The following criteria are suggested for the assessment of the importance of nutrition in the etiology of a disease state in a single animal or in a group of animals:

- Is there evidence from an examination of the diet that a deficiency of a specific nutrient or nutrients may be occurring?
- Is there evidence from an examination of the animals that a deficiency of the suspected essential nutrient or nutrients could cause the observed disease?
- Does supplementation of the diet with the essential nutrient or nutrients prevent or cure the condition?

The difficulties encountered in satisfying these criteria and making an accurate and reliable diagnosis of a nutritional deficiency have increased as investigations have progressed into the area of trace elements and vitamins. The amounts of such substances as selenium present in feedstuffs and body tissues are exceedingly small and their estimation difficult and expensive. Because of these difficulties it is becoming more acceptable to describe individual syndromes as responsive diseases, i.e. which satisfy only the third of the above criteria. The practice leaves much to be desired but has the advantage that applicable control measures are more readily available.

EVIDENCE OF EXISTENCE OF DEFICIENCY

General evidence will include either evidence of deficiency in the diet, or abnormal absorption, utilization or requirement of the nutrient under consideration. Special evidence may be obtained by chemical or biological examination of the feed.

Diet

The diet for a considerable period prior to the occurrence of the disease must be considered because body stores of most dietary factors may delay the appearance of clinical signs. Specific deficiencies are likely to be associated with particular soil types, and in many instances soil and geological maps may predict the probable occurrence of a nutritional disease.[1] Diseases of plants may also indicate specific soil deficiencies, e.g. 'reclamation disease' of oats indicates a copper deficiency in the soil. Domination of the pasture by particular plant species may also be important, e.g. subterranean clover selectively absorbs copper, legumes selectively absorb molybdenum, and *Astragalus* spp. are selector plants for selenium.

Farming practices may have a marked bearing on the presence or absence of specific nutrients in livestock feed. For example, heavy applications of nitrogen fertilizer can reduce the copper, cobalt, molybdenum, and manganese content of the pasture. On the other hand, many applications of lime reduce plant copper, cobalt, zinc, and manganese levels, but increase the molybdenum content. Effects such as these are sufficiently severe to suggest that animals grazing the pasture might suffer trace element deficiency. Modern hay-making methods, with their emphasis on the artificial drying of immature forage, tend to conserve vitamin A but may result in a gross deficiency of vitamin D. Soil and pasture improvement by exaggeration of the depletion of nutrients, particularly trace elements, from marginally deficient soil may give rise to overt deficiency disease. Thus, local knowledge of farming and feeding practices in a particular area is of primary importance in the diagnosis of nutritional deficiency states.

Abnormal absorption

Even though a diet may contain adequate amounts of a particular nutrient, some other factor, by decreasing the absorption of the nutrient, may reduce the value of the dietary supply. For instance, excess phosphate reduces calcium absorption, excess calcium reduces the absorption of iodine, and absence of bile salts prevents proper absorption of the fat-soluble vitamins. Chronic enteritis reduces the absorption of most dietary essentials. The list of antagonisms that exist between elements grows all the time, most of them being interferences with absorption. For example, excess calcium in the diet interferes with the absorption of fluorine, lead, zinc, and cadmium, so that it may cause nutritional deficiencies of these elements, but it also reduces their toxic effects when they are present in the diet in excessive amounts.

Abnormal utilization of ingested nutrients

This may also have an effect on the development of conditioned deficiency diseases. For example, molybdenum and sulfate reduce copper storage, vitamin E has a sparing effect on vitamin A, and thiamine reduces the dietary requirements of essential fatty acids.

Abnormal requirement

Stimulation of the growth rate of animals by improved nutrition or other practices may increase their requirement of specific nutrients to the point where deficiency disease occurs. There seems to be little doubt that there is a genetic variation in mineral metabolism and it has even been suggested that it may be possible to breed sheep to 'fit' actual deficiency conditions, but the significance of the inherited component of an animal's nutritional requirement is unknown and probably small. It should not be overlooked, however, when policies of upgrading livestock in deficient areas are initiated.

EVIDENCE OF A DEFICIENCY ASSOCIATED WITH THE DISEASE

Evidence is usually available from experimental work to indicate the clinical signs and necropsy findings one can expect to be produced by each deficiency. Several modifying factors may confuse the issue. Deficiencies under natural circumstances are unlikely to be single and the clinical and necropsy findings will be complicated by those caused by deficiencies of other factors or by intercurrent infections. In addition, most of the syndromes are both variable and insidious in onset and the minimal nature of the necropsy lesions in many nutritional deficiency diseases adds further difficulty to the making of a diagnosis.

Special clinical and laboratory examinations of the animals are valuable aids to diagnosis in many instances. However, the ranges of blood or tissue concentrations of minerals and vitamins, or their biochemical markers, in normal animals and those values which indicate deficiency have not been well-established. In other words, the cut-off values above which animals are normal and below which they are abnormal or deficient have not been adequately determined in naturally occurring nutritional deficiencies. Experimentally induced nutritional deficiencies provide an indication of the changes that occur in the concentrations of a particular nutrient marker, but variations due to age, genotype, production cycle, length of time on the inadequate diet, previous body stores of the element and other stressors commonly complicate the results and render them difficult to interpret accurately and with repeatability.

In most cases, nutritional deficiencies affect a proportion of the herd or the flock at the same time and the clinicopathological examination should include both normal and clinically affected animals. Comparison of the laboratory results of normal and abnormal animals allows for more accurate and reliable interpretation and the making of a diagnosis.

EVIDENCE BASED ON CURE OR PREVENTION BY CORRECTION OF THE DEFICIENCY

The best test of the diagnosis in suspected nutritional deficiency is to observe the effects of specific nutrient additions to the ration. Confounding factors are frequently encountered. Spontaneous recoveries may occur and adequate controls are essential. Curative responses may be poor because of an inadequate dose rate, because of advanced tissue damage, or because the abnormality may have been only a predisposing factor or secondary to a complicating factor that is still present. Another common cause of confusion in therapeutic trials is the impurity of the preparations used, particularly when trace elements are involved. Finally, the preparations used may have intrinsic pharmacological activity and produce some amelioration of the disease without a deficiency having been present.

Monitoring of nutritional status

The feeds and feeding program have a major influence on reproductive performance, growth rate, and milk production and must be monitored regularly. The veterinarian must be aware of any changes in the feeding program that have occurred since the last farm visit or that are intended in the near future. On breeding farms, there are several different age groups of animals at different levels of growth and production. This requires close surveillance to avoid undernutrition or overnutrition. Scoring of the body condition of dairy cattle, beef cows, sheep, and pigs is becoming commonplace as an indicator of the adequacy of the diet. Veterinary clinical nutrition is now a veterinary medical specialty that should provide new and useful information for the practitioner working with a particular species or class of food animals. The American College of Veterinary Nutrition also provides consultants in veterinary nutrition who can be called on for advice in solving nutritional problems. An experienced and competent nutritionist should be consulted to assist with complex nutritional problems.

Nutritional management in dairy herds

Advising farms about nutrition is a key activity for dairy cattle practitioners. Feed costs constitute approximately 60% of the total cost of producing milk, and even minor improvements in feeding efficiency can be profitable. Some dairy practitioners function as the nutritional specialists for the dairy farms they serve. They may collect feed samples for nutrient analysis, formulate rations, and advise the farmer regarding crop and harvesting conditions. These veterinarians often devote a considerable amount of their professional time to nutritional management.

It is common for farms to employ a professional nutritionist or to use a nutritionist employed by a feed company or local cooperative. These professional nutritionists generally formulate the rations and submit feed samples for nutrient analysis. On these herds, the veterinarian can have an important role in ensuring that the diet described on paper is adequately formulated and delivered to the cows. Routine scheduled activities such as measuring the dry matter of forages, hand mixing total mixed rations (TMR) for one cow and comparing it with the machine-mixed TMR ('TMR test mix'), and scoring the feed bunk to assess feed sorting and dry matter intake are important procedures that help to ensure the successful delivery of a nutritional program. Assessing pasture conditions by periodic inspection of pasture is an important component of managing the nutritional program of herds that use management-intensive grazing. These quality control activities should be conducted routinely as part of the health and production management program.

There is probably no aspect of a dairy enterprise that has a wider impact than the feeding program. Dairy farm feeding

programs have direct effects on production and growth and set the stage for future productive potentials. Many health problems on a dairy relate in some way to the feeding program. Feed costs on the average dairy account for more than 60% of total operating expenses in the USA. A significant part of the average dairy's labor force devotes its time to planting, growing, harvesting, mixing, and feeding rations to a variety of animals. Investments in equipment used in feeding programs are an important part of the dairy's debt load. Small changes in feeding programs may bring about large changes in productivity, health, income, feed costs, labor allocation, and debt load. The total savings from small changes can be substantial. Without considering improved production or health effects, one study has shown that routine nutritional consultation by veterinarians can save 14% of total feed costs on dairies.

For all these reasons, veterinarians who intend to serve their dairy clients on a herd basis must become actively involved in the herd's feeding program. Dairy herds are commonly fed unbalanced, expensive rations. By serving as independent consultants, veterinarians can provide unbiased advice to their clients. Those veterinarians who wish to serve their clients at a herd level constantly find their attention focused on the feeding program. The next recumbent, hypocalcemic cow raises questions about dry cow feeding. The next anestrous, thin cow with smooth ovaries raises questions about early lactation energy levels in the ration and dry matter intake (DMI). The next time the herd average mature equivalent milk production falls by 500 lb, the problem generates the same sense of urgency as a cow with a prolapsed uterus. As a profession, dairy veterinary medicine must come to grips with the fact that it cannot truly serve client needs by practicing therapeutic medicine separately from nutritional consulting. Veterinarians must train themselves to deal with nutrition directly, consistently and knowledgeably.

In recent years, as herd size has increased, many dairies have come to rely on a team of advisors rather than only one or two. A nutritional consultant, local veterinarian, and outside consultant may all be providing advice to a dairy. In these circumstances, communication about the feeding program and resulting performance is critical. It is imperative that the veterinarian be knowledgeable about dairy nutrition and involved in ration formulation. The veterinarian needs to maintain their involvement as part of the advisory team.

Levels of nutritional service

Having decided to be involved in a dairy's feeding program, the veterinarian and client should first agree on the level of nutrition service that is to be provided. The level varies from herd to herd, depending on the veterinarian's expertise, the client's ability and interest, and the role being played by other consultants to the farm. There are essentially four levels of service that might be provided:

Level 1: Problem identification and analysis

At level 1, the veterinarian takes on the task of monitoring the dairy herd for indicators that there might be nutrition-related problems. Many areas need to be monitored: production, milk components, DMI, body scores, disease rates, growth rates, and feed costs. Based on these monitored areas, the veterinarian can call attention to problems as they arise, form and test hypotheses about likely causes, and interact with other farm service personnel as the problems are addressed.

Level 2: Ration analysis

At level 2, the veterinarian evaluates the nutritional adequacy of diets as they are fed to the cows. If problems of balance or economics are identified, they are referred to the appropriate person for reformulation. This level is difficult to sustain over time because, after a while, the person formulating the ration is likely to resent being 'second-guessed'. It can work well if the 'team approach' is part of the procedure on the dairy.

Level 3: Ration formulation

At level 3, the veterinarian takes on the responsibility of formulating the ration. To operate responsibly at this level, veterinarians need several additional skills beyond those traditionally taught at veterinary colleges. The veterinarian must know how to use a computer to formulate a balanced, deliverable, cost-effective ration. The veterinarian should have experience in the daily mechanics of how feeds are handled and how cows are fed. It requires an intimate knowledge of the farm and its personnel. The veterinarian must maintain daily contact with the feed industry, so that feed prices and availability can be factored into the farm's overall feeding program.

If not managed carefully, this level of service has several pitfalls. It lacks the on-farm follow-up, supervision of implementation, and monitoring of results that are included in level 4. There is a truism about feeding dairy cows that every cow has three rations: the one formulated, the one delivered, and the one actually eaten. The best feeding programs minimize the difference among these three rations. If the veterinarian's role stops at formulation, then mistakes can occur in delivery and feed bunk management that can doom the program to failure. If the program fails, the veterinarian's formulation is likely to be blamed.

Level 4: Total program consulting

Level 4 of nutritional service includes those aspects missing in level 3. The veterinarian plays an active role in implementing the feeding recommendations. Attention is paid to areas such as bunk management, cow comfort, feeding frequency and scheduling, quality control and consistency of feeding management. Working closely with the producer, plans for future forage production can be generated, including attention to factors such as timing the harvest for maximum feed value. The monitoring described in level 1 is sustained, and timely adjustments and feedback are provided to ensure that the rations are accomplishing the desired ends. In the long term, this is the level of service that is most desirable for both the veterinarian and the client. The producer benefits from the added supervision and support, and the veterinarian can assure the client that the program is carried out as designed. If the program is not working, it can be modified. Total program consulting can be accomplished with the veterinarian as a part of the team that would include the nutritionist, as well as by the veterinarian alone. With many larger herds, particularly, multiple outside consultants are used, and a team approach provides the owner with the best opportunity for expert advice. In many herds, the veterinarian is best suited to be the 'team leader'.

Nutritional management of the beef breeding herd

Good nutrition provides the essential basis for optimum productivity in cattle breeding operations. Despite this, nutritional expertise has not been a traditional strength of many food-animal veterinarians.

Throughout the world, beef-breeding operations are generally range or pasture based. These operations are conducted in diverse environments, with great variation in nutritional management. Even within the USA, the area of pasture or rangeland required to maintain a cow-calf unit may vary from 3 acres or more in the south-west to 1 or 2 acres in more intensive regions. In parts of Australia, the corresponding area may be measured in square miles. However, in general, the area of land, or amount of pasture, necessary for production is related to local economic realities. This, in turn, is related to levels of managerial and resource inputs that can differ with regions, markets, and enterprise priorities. Notwithstanding such caveats, there are a number of principles of good nutritional management that may be universally applied to cattle breeding operations. Regardless of region, an important consideration is that of maintaining or

improving production while reducing costs. In simple terms, financial return from a beef breeding operation is a function of number of calves, their weaning weight, and price. On the cost side of the ledger is the maintenance cost of the breeding females. This varies considerably, both within and between regions. Market price, in general, is usually unmanageable at the farm level. However, both the number of calves born and their weaning weights are strongly influenced by nutrition. For example, good nutritional management helps to ensure that as many females as possible are cycling at the start of the breeding season. This, in turn, helps to ensure that calves are born early with the result that they are older, and heavier, at weaning than later-born calves.

In general, nutrition is the most important limiting factor of beef breeding performance. For veterinarians, an understanding of the principles underlying the nutritional management of breeding females is necessary. Effective counseling and trouble-shooting does not necessarily require a higher degree in nutrition, although it should include sufficient knowledge and wisdom to know when such expertise is needed. A starting point is to have a working knowledge of the different energy measuring systems (total digestible nutrients (TDN), metabolizable energy (ME) and net energy, NE) that are commonly used, their applications for different classes of animals, activities and feedstuffs, and to identify one with which the veterinarian can work best. The Nutrient Requirements of Beef Cattle from the National Research Council (NRC) in the USA is a useful document revised in 2000. This is packaged with a computer program that includes ration formulators as well as a library of feeds and feedstuffs. A number of computer programs are now available for least-cost-ration formulation in beef herds.

Nutritional advice for beef feedlots

Feedlots frequently consult a qualified nutritionist to assist in the formulation of cost-effective diets. The veterinarian should communicate regularly with the nutritionist to be aware of the composition of the diets and any changes that are being planned. Because feed is the major portion of the cost per unit of body weight gain, it is imperative that the diet be the lowest-cost diet possible while providing nutrients that allow optimum growth and finishing. Most of the emphasis in feedlot nutrition has been on the development of cost-effective diets that support a maximum growth rate without any deleterious effects. Considerable information is available on the nutrient requirements for feedlot cattle and on the feeds and feeding systems used.

The precise specifications of the diets are the responsibility of the nutritionist, but the feedlot veterinarian frequently is in a position to evaluate the quality of the feed delivery system. This means checking to determine whether cattle are fed on time, whether the feed is mixed properly, and whether the feed intake is intermittent because of inclement weather or muddy ground surfaces. Any deviations should be communicated to the consulting nutrtionist.

Nutritional deficiency diseases are uncommon in feedlot cattle, because cattle usually receive a diet that contains the nutrients required for maintenance and promotion of rapid growth. Diets prepared according to the Nutrient Requirements of Beef Cattle should meet all the requirements under most conditions.

Specific nutrient deficiencies are extremely rare, because diets are prepared every few days or daily and it would be highly unusual for a feedlot to use a feedstuff deficient in a specific nutrient for a prolonged period. However, such a situation may occur in a small farm feedlot that prepares its own feedlot diet with little or no attention to the necessity for supplementation of homegrown feeds. Thus, there are only a few nutrition-related diseases that may affect a well-managed feedlot, but these diseases may cause large economic losses when they occur. They include the following:

- Carbohydrate engorgement (grain overload or D-lactic acidosis)
- Feedlot bloat or ruminal tympany
- Feeding errors (i.e. accidental incorporation of an excessive amount of a feed additive, such as monensin or urea, or sudden unintended changes in the ingredient composition of the diet).

Nutritional advice for swine-herds

Veterinarians involved in health management of swine-herds must be well informed about the nutrient requirements of the different age groups of pigs. Since feed constitutes 60–80% of the cost of producing a market pig, every effort must be made to increase the economic efficiency of feed use. Some surveys of well-managed pig farms in Alberta, Canada, found a 20% difference in feed costs, and it is estimated that in the industry the range in feed costs is likely to be near 50%. Reduction of the feed cost of the highest costing farm to that of the lowest costing farm would save that farm more than US$23 000 annually, which is equivalent to a cost reduction in production of $6.80/pig. The trend is to use complete feeds formulated by feed company nutritionists who are familiar with the nutrient composition of local feedstuffs. With complete diets, specific nutrient deficiencies are uncommon.

The major problem is the efficiency of utilization of the different feeds throughout the life cycle of the pig. The nutrient requirements of the pig at various phases of growth from birth to market weight and of breeding stock are well established. The remaining questions appear to be about the levels of feed that should be provided during the different phases of the growth of the pig in order to achieve optimum production and to yield the best carcass. Proper nutrition can greatly increase the efficiency of pig production, because feed represents such a large percentage of the cost involved. The following are some recommended practices for increasing efficiency of feed utilization with pigs:

- Provide well-balanced diets with adequate levels of amino acids, energy, vitamins, and minerals necessary to meet the particular demands of the pig at each stage of its life cycle. The diet depends on the demands, usually characterized as the growth rate or lean deposition. Feed intake is the supply function. Feed intake is limited by appetite, and thus other nutrients are matched to expected energy intake and subsequent growth
- Use least-cost formulation to the extent that it is feasible. The least-cost energy source in most of the pig-rearing areas is corn, and the most common protein source is soybean meal
- Restrict the level of a properly balanced diet for sows during gestation to avoid overfeeding. Sows that have lost excessive body weight in the previous lactation need supplemental feed during the dry period to avoid the thin-sow syndrome
- Ad-lib feeding for growing pigs is usually optimum, unless the genotype deposits excess fat during the latter stages of growth
- Market pigs as close to optimum slaughter weight as possible to maximize margin over feed costs
- Avoid feed wastage by using well-designed feeding systems and proper adjustment of those feeders
- Use pelleting of diets to increase digestibility, especially of small grains, and to decrease feed wastage. However, pelleting also predisposes pigs to gastroesophageal ulcers.

The feed efficiency of the pigs from weaning to market should be monitored regularly. It is often difficult to obtain accurate data on this item for specific groups of pigs, because the amount fed to each group may not be calculable when a

common feeding system is in use. However, the total amount of feed used and the total weight of pigs marketed will give an estimate of feed efficiency.

The National Research Council (NRC) in the USA provides an important service in establishing the nutrient requirements of swine and other species. The 10th revised edition of the Nutrient Requirements of Swine was published in 1998. The 200-page edition incorporates the wealth of new research information that has emerged over the past 10 years since the 8th edition, and addresses new areas such as modelling nutrient requirements and reducing nutrient excretion.

Even though the nutrient requirements of pigs are well known, they do continue to change because of changes in growth and production characteristics of pigs. Pigs with high lean-growth rates require higher levels of amino acids to support their increased rate of body protein deposition. Similarly, high milk-producing sows nursing large litters have increased amino acid requirements.

In the 10th edition, a new approach is used to produce estimates of nutrient requirements that take into consideration not only the pig's body weight, but also its accretion rate of lean (protein) tissue, gender, health status, and various environmental factors. To accurately estimate nutrient needs of gestating and lactating sows, there is a need to account for body weight, weight gain during gestation, weight loss during lactation, number of pigs in the litter, weight gain of the litter (a reflection of milk yield), and certain environmental factors.

A series of integrated mathematical equations was used to account for the many factors now known to influence nutrient requirements. These equations provide the framework for modeling the biological basis of predicting requirements. The NRC models predict the levels of nutrients (outputs) needed to achieve a certain level of production under a given set of environmental conditions (inputs).

Five principles were used to develop the models. The models: (1) were made for ease of use by people with varying levels of nutritional expertise and with limited information; (2) were developed for continued relevance for several years to come; (3) were intended to be structurally simple, so they could be understood readily by users; (4) were developed to be transparent so that all of the equations could be available to the user and (5) were firmly anchored to empirical data at the whole-animal level rather than being simply based on theoretical values. Three independent models were developed for growth, gestation, and lactation. The growth model estimates amino acid requirements of pigs from weaning to market weight, and the gestation and lactation models estimate energy and amino acid requirements of gestating and lactating sows.

Few revisions were made in the previously published mineral requirements. Based on recent findings, higher dietary requirements for sodium and chloride in the young pig were established. The manganese requirements were increased from 10 to 20 ppm for gestating and lactating sows.

Several changes were made in the feed composition tables. Nutrient composition of feeds was obtained from as many data bases as possible, including from the feed industry and from data sets outside the USA and Canada.

The information on water was expanded considerably, with more detailed information on the factors that influence water intake. There is additional new information on non-nutritive feed additives, such as antimicrobial agents, anthelmintics, microbial supplements, oligosaccharides, enzymes, acidifiers, flavors, odor control agents, antioxidant pellet binders, flow agents, high-mineral supplements, and carcass modifiers.

A new chapter on minimizing nutrient excretion is included in the 10th edition. It addresses environmental issues and the importance of reducing the excretion of nutrients, particularly nitrogen and phosphorus, which can potentially contribute to environmental pollution.

Nutritional advice for sheep flocks

The influence of nutrition on the reproductive performance of ewes has been a matter of concern to sheep farmers and sheep production research workers throughout the world. It is clear that the relationship between nutritional provision and nutrient requirements for optimum reproductive performance is seldom ideal because of the wide range of environmental conditions and the seasonality of breeding that most sheep breeds exhibit. Prolonged periods of undernutrition during mid-pregnancy are partly the result of the decline in feed availability and quality over that stage of the reproductive cycle.

Prolonged duration of moderate to severe undernutrition of ewes bearing twins in mid-pregnancy can reduce placental development causing significant reductions in lamb birth weight with increased mortality. Considerable progress has been made in understanding the principles of nutrition of sheep and in defining their nutrient requirements for maintenance, pregnancy, and lactation.

The sensitivity of lamb birth weight, particularly in twins and triplets, to the ewe's plane of nutrition during late pregnancy is well known. It has been established that mortality rates are high in lambs with birth weights below the breed norm, and that after birth the absolute growth rates are lower in surviving light lambs than in heavier lambs of the same breed. The plane of nutrition and the size of the placenta have been recognized as major determinants of the fetal growth rate. Fetal growth retardation in undernourished ewes has a placental component, and the factors that affect placental growth are relevant here.

The 21-week gestation can be divided into a number of periods to consider the effects of nutrition on reproduction within each period. In the first month of gestation, embryonic loss is the main sequel to inadequate nutrition. During this period, it is generally recommended that the BCS of the ewe be maintained at 2.5–3.5 (scale of 1 to 5) to minimize embryonic and early fetal losses. This is followed by a period of 2 months in which there is rapid growth of the placenta, but during which growth of the fetus in absolute terms is still small. Over this period, it is normal to advocate that losses in body weight should not exceed 5%. Finally, there is the phase from 90 days to parturition, in which gain in the mass of the fetus amounts to 85% of its birth weight; during this period, nutrient intake must be increased.

Placental development in the pregnant ewe begins about 30 days after conception, the number of placentomes associated with each fetus is fixed at this time, and the total weight of the placentomes increases until about 90 days of gestation, after which there is little change. The factors that influence the ultimate size of the placenta and its weight include hormonal and nutritional factors, prolonged environmental heating of pregnant ewes, parity of ewes, and possibly genotype, but the most important determinant is nutrition of the ewe. Moderately severe undernutrition during early pregnancy and midpregnancy significantly reduces placental weight at or near term and causes chronic intrauterine growth retardation.

The size of the placenta is a major determinant of fetal growth. In well-fed ewes, the fetal growth rate before 120 days of gestation is not correlated positively with placental weight, but fetal growth rate in the last 3 to 4 weeks of pregnancy is limited by the size of the placenta. Earlier placental influences on fetal growth are evident, however, when ewes are underfed. Placental weight and fetal growth rate are correlated positively during periods of maternal underfeeding, which starts before 90, at 95, or at 112 days of gestation. During the first 90 days of pregnancy, placental growth is reduced when ewes are moderately underfed. Low-weight fetuses in ewes with placenta weights near the bottom of the

normal range are affected with chronic and progressive hypoxemia and hypoglycemia, which affect fetal metabolism. The consequences are fetal death during late pregnancy, fetal hypoxemia during parturition, premature birth, and a high perinatal mortality rate caused by hypoglycemia and hypothermia.

The extent to which ewes maintained on a fixed ration draw on their own body reserves in an attempt to meet the energy costs of pregnancy is determined by fetal weight. In well-fed ewes, fetal growth rate remains constant until at least 120 days of gestation and decreases thereafter. However, its absolute growth rate increases markedly during the last 8 weeks of gestation, when fetal growth is most rapid, exceeding 100 g/day near birth. The growth rate among fetuses is highly variable, which accounts for birth weights ranging from 2 kg to over 7 kg. When ewes that have been well fed are severely underfed at any stage during the last 40 to 50 days of pregnancy, the fetal growth rate decreases within 3 days, by 30% to 70%. This illustrates that the mobilization of maternal reserves is substantially less than fetal requirements and emphasizes the importance of ensuring a continuous supply of good-quality feed during late pregnancy. The larger the fetal burden, the more susceptible a ewe is to hypoglycemia during underfeeding.

Re-feeding after severe underfeeding can reverse the reduced growth rate of fetuses, but the response depends on the duration of the underfeeding. If the period of underfeeding is 16 days or less, the growth rate increases when ewes are re-fed, but there is no change when re-feeding occurs after 21 days of severe underfeeding. Moderate underfeeding of pregnant ewes for 85 days reduces the fetal growth rate irreversibly, and refeeding them in late pregnancy does not cause the fetal growth rate to increase but does prevent further decreases after 120 days.

The major consequences of prenatal growth retardation are on lamb survival. The neonatal mortality of lambs increases markedly in many environments as the birth weight falls below 3–3.5 kg. Compared with normal lambs, low-birth-weight animals have reduced insulation because of the smaller number of wool fibers, greater relative heat loss because of their larger surface area per unit of body weight, and a reduced capability to maintain heat production because of their lower fat and energy reserves. All these factors increase their susceptibility to environmental stress and reduce their ability to compete with normal-sized siblings. Underfeeding during pregnancy can also reduce available body lipids in lambs by about 47% and also decreases the lactose, lipid, and protein available in colostrum during the first 18 h by about 50%. Newborn lambs have to draw on body reserves of glycogen in order to maintain heat production during the first 18 h after birth, and thus depend heavily on colostrum intake and supplemental feeding to avoid hypoglycemia and hypothermia.

The effects of maternal nutrition on udder development and on the production and yield of colostrum and milk in ewes have also been examined. In the last 30 days before birth, there is a marked increase in the rate of mammary tissue growth in the ewe. In well-fed ewes with one or two lambs, large volumes of colostrum accumulate in the mammary glands during the last few days of pregnancy and copious milk secretion begins soon after birth, with averages of 1800 to 2800 mL of colostrum and milk being produced during the first 18 h. Udder growth rates are proportional to fetal growth rates in that the greatest increase in udder weight occurs in the last 30 days of gestation and the weight of udder tissue is 30–40% of the total weight of the litter. Colostrum production is proportional to udder weight, and re-feeding of ewes a few days before lambing fills the udder tissue present but does not increase udder tissue weight. In underfed ewes, prenatal colostrum accumulation is reduced markedly, lactogenesis is delayed, and the total production of colostrum and milk during the first 18 h averages about 1000 mL. Subsequently, in both types of ewe, milk production increases, reaching a peak about 1–2 weeks after birth. Underfeeding ewes beginning at 105 days of gestation can reduce the total yield of colostrum during the first 18 h after birth by decreasing mammary tissue growth. Thus, the prepartum accumulation of colostrum and its sub-sequent rates of secretion are reduced. Improving the ewe's nutrition from 1 h after birth can increase the secretion rates of colostrum between 10 and 18 h.

The growth rate of lambs during the first few weeks of life is correlated positively with birth weight. Low planes of maternal nutrition during late pregnancy and early lactation are generally associated with low birth weights, milk yields, and postnatal growth rates, and high planes of nutrition with the opposite effects. A marked increase in the plane of maternal nutrition at birth can overcome the inhibitory effects on lactation and lamb growth rate of underfeeding in late pregnancy.

At breeding time, the aim is to achieve a body score of 3.0–3.5, which ensures maximum ovulation rate. For ewes with a BCS of 3.5 at breeding, it is desirable to allow them to lose no more than 5% of their body weight steadily, equivalent to approximately 0.5 to 1 unit of condition score during the second and third months of pregnancy. This mild degree of undernutrition enhances placental growth and establishes the basis for maximum fetal growth in the 4th and 5th months of pregnancy, the period during which the fetus achieves over 80% of its growth. During these final 2 months of pregnancy, there is a limit to the extent to which body fat reserves can be used, because excessive mobilization of depot fats as a consequence of inadequate dietary energy supply leads to pregnancy toxemia. In late gestation, the optimum BCS ranges from 2.5 to 3.0. In contrast, early lactation is a period in which body fat can be safely used to meet some of the high energy demands of lactation. During this period, a loss of BCS of 1.0 (equivalent to 5 kg fat for a 70 kg ewe at mating) is acceptable, and during lactation it ranges from 1.5 to 2.5. The replacement of the body fat that is used before the next breeding cycle is important in achieving a maximum ovulation rate and subsequently optimum reproductive performance.

Winter shearing of pregnant ewes during the final 10 weeks of pregnancy has been shown to cause a significant increase in lamb birth weight. Shearing pregnant sheep at 8 weeks before lambing leads to a chronic increase in energy requirements, which are met by oxidizing body fat depots without risks of clinical ketosis. Fetal growth is enhanced as a result of these metabolic adaptations.

The nutrient requirements for maintenance, breeding, pregnancy, and lactation of ewes have been catalogued, and optimum feeding strategies for the breeding ewe can be formulated. The evaluation of the ewes' ration during late gestation by monitoring plasma concentrations of the ketone body 3-OH butyrate has been described with accurate guidelines, which have been used as the basis for flock nutritional advice during late gestation.

The achievement of optimum reproductive performance involves changing feeding strategies and adjusting the nutrient value of the diet as necessary throughout the reproductive cycle to meet the needs of the particular stage. The requirements for metabolizable energy begin to increase steadily above maintenance levels beginning at between 8 and 12 weeks of pregnancy and continuing into late pregnancy and lactation. During early lactation, when the energy requirements of prolific ewes exceed those required by the voluntary consumption of all but the highest-quality diets, the body fat reserves are used and then replenished toward the end of lactation, when milk yield declines, and in the period leading up to rebreeding.

In contrast to the ability of the ewe, particularly in early lactation, to use body reserves when the intake of energy fails to

meet her needs, there is little scope for sustaining production by drawing on body protein. For example, lactating ewes can lose up to 7 kg of body fat during a 4-week period in early lactation, when energy intake is below requirements. For ewes on a low-protein intake, the maximum daily loss of protein was 26 g. Thus, it is important to meet the protein needs of the ewe at all times during pregnancy, but especially during late pregnancy, for fetal growth, udder development, and colostrum production. The estimates for protein are also based on the important principle of distinguishing between the needs of the rumen microflora for rumen-degradable protein and of the host animal for additional undegraded dietary protein when rumen-degradable protein fails to meet those requirements; this represents the minimum protein needs of the animal. In practice, the dietary allowances for late pregnancy and early lactation are higher than the sum of the rumen-degradable protein and undegradable protein.

The rapid growth of the fetus after 90 days of pregnancy requires an increased allowance of dietary energy, which can be met with concentrates if only hay is available. This is particularly true for ewes carrying twins or triplets. The daily dietary energy requirement of ewes of varying body weights and fetal number ranging from singletons to triplets has been described in conjunction with a monitoring program for dietary energy supply based on plasma concentration of the ketone body 3-OH butyrate. This system forms the basis of flock advisory visits made by veterinarians during late gestation in UK flocks. Correct nutrition during late gestation guarantees appropriate lamb birth weights despite litter size and sufficient accumulation of protective immunoglobulin in the udder.

DEFICIENCIES OF ENERGY AND PROTEIN

DEFICIENCY OF ENERGY

ETIOLOGY

Insufficient quantity or quality of feed is a common nutritional deficiency and practical problem of feeding livestock.[1,2] The term **protein-energy malnutrition** is used to describe a form of incomplete starvation in which energy and protein are present in the diet in suboptimal quantities. Protein and energy deficiencies usually occur concurrently in underfed livestock and often cannot be strictly separated.

EPIDEMIOLOGY

A deficiency of energy is the most common nutrient deficiency limiting performance of farm animals. There may be inadequate amounts of feed available, or the feed may be of low quality. Supplies of feed may be inadequate because of overgrazing, drought, snow covering, or it may be too expensive to be fed to the animals. Available feed may be of such low quality and digestibility that animals cannot consume enough to meet energy requirements. In some cases, forage may contain a high concentration of water, which limits total energy intake.

CLINICAL FINDINGS

The clinical findings of an energy deficiency depends on the age of the animal, whether or not it is pregnant or in lactation, the presence of concurrent deficiencies of other nutrients and environmental influences. In general, an insufficient supply of energy in **young animals** results in retarded growth and delay in the onset of puberty. In **mature animals**, there is a marked decline in milk production and a shortened lactation. A prolonged energy deficiency in pregnant beef heifers will result in a failure to produce adequate quantities of colostrum at parturition. In mature animals, there is also a marked loss of body weight, especially during high demands for energy as in late pregnancy and early lactation. There are **prolonged periods of anestrus** lasting up to several months, which has a marked effect on reproductive performance in the herd. Primigravid females are particularly susceptible to protein-energy malnutrition because of growth and maintenance requirements.[1] A **prolonged deficiency of energy during late gestation** may result in undersized, weak neonates with a high mortality rate. A **deficiency of energy during prolonged periods of cold weather**, especially in pregnant beef cattle, and ewes being wintered on poor quality roughage, may result in abomasal impaction. Heat loss from the animal to the environment increases remarkably during cold weather, and when ambient temperatures are below the critical temperatures, the animal responds by increasing metabolic rate to maintain normal body core temperature. If sufficient feed is available when temperatures are below the lower critical temperature, ruminants will increase their voluntary feed intake to maintain body temperature. If sufficient feed is not available, the animal will mobilize energy stored as fat or muscle to maintain body temperature and thus lose body weight. In the case of ruminants and horses, if the feed is of poor quality, for example, poor quality roughage, the increased feed intake may result in impaction of the abomasum and forestomachs in cattle and of the large intestine in the horse.

Cold, windy, and wet weather will increase the needs for energy and the effects of a deficiency are exaggerated, often resulting in weakness, recumbency and death. A sudden dietary deficiency of energy in fat, pregnant beef cattle and ewes can result in starvation ketosis and pregnancy toxemia. Hyperlipemia occurs in fat, pregnant or lactating ponies that are on a falling plane of nutrition.

Protein-energy malnutrition occurs in neonatal calves fed inferior quality milk replacers that may contain insufficient energy or added non-milk proteins which may be indigestible by the newborn calf. A major portion of the body fat present at birth can be depleted in diarrheic calves deprived of milk and fed only fluids and electrolytes for 4–7 days. Feeding only fluids and electrolytes to normal, healthy newborn calves for 7 days can result in a significant loss of perirenal and bone marrow fat, and depletion of visible omental, mesenteric and subcutaneous fat stores.[3] The amount of body fat present in a calf at birth is an important determinant of the length of time an apparently healthy calf can survive in the face of malnutrition. Calves born from dams on an adequate diet usually have sufficient body fat to provide energy for at least 7 days of severe malnutrition. The absence of perirenal fat in a calf at 2–4 days of age suggests inadequate reserves of fat at birth and chronic fetal malnutrition.[3]

DEFICIENCY OF PROTEIN

A deficiency of protein commonly accompanies a deficiency of energy. However, the effects of the protein deficiency, at least in the early stages, are usually not as severe as those of energy. Insufficient protein intake in young animals results in reduced appetite, lowered feed intake, inferior growth rate, lack of muscle development, and a prolonged time to reach maturity. In mature animals, there is loss of weight and decreased milk production. In both young and mature animals, there is a drop in hemoglobin concentration, packed cell volume, total serum protein, and serum albumin. In the late stages, there is edema associated with the hypoproteinemia. Ruminants do not normally need a dietary supply of essential amino acids, in contrast to pigs which need a natural protein supplement in addition to the major portion of total protein supplied by the cereal grains. The amino acid composition of the dietary protein for ruminants is not critical because the ruminal flora synthesize the necessary amino acids from lower quality proteins and non-protein sources of nitrogen.

CLINICAL FINDINGS

The clinical findings of an energy deficiency are similar to those of a protein deficiency and the clinical findings of both resemble many other specific nutrient deficiencies and subclinical disease. Protein-energy malnutrition in beef cattle occurs most commonly in late gestation and is characterized clinically by weakness, clinical recumbency, marked loss of body weight, a normal mental attitude, and a desire to eat.[1,2] Cows with concurrent hypocalcemia will be anorexic. If the condition occurs at the time of parturition, there will be an obvious lack of colostrum. Calves of these cows may attempt to vigorously suck their dams, attempt to eat dry feed, drink surface water or urine and bellow continuously. Affected cows and their calves may die within 7–10 days.

Protein-energy malnutrition is less common in dairy cattle because they are usually fed to meet the requirements of maintenance and milk production. Dairy calves fed inferior quality milk replacers during periods of cold weather will lose weight, become inactive, lethargic, and may die within 2–4 weeks. Affected calves may maintain their appetites until just before death. Diarrhea may occur concurrently and be confused with acute undifferentiated diarrhea due to the enteropathogenic viruses or cryptosporidiosis. Affected calves recover quickly when fed cow's whole milk.

Protein-energy malnutrition also occurs in sheep and, less commonly, in goats. Excessive dental attrition is a common cause in grazing sheep, which is exacerbated by the excessive ingestion of soil.

DIFFERENTIAL DIAGNOSIS

The diagnosis will depend on an estimation of the concentration of energy and protein in the feed, or a feed analysis, and comparing the results with the estimated nutrient requirements of the affected animals. In some cases, a sample of feed used several weeks earlier may no longer be available or the daily amount of feed intake may not be known. Marginal deficiencies of energy and protein may be detectable with the aid of a metabolic profile test. Specific treatment of livestock affected with protein-energy malnutrition is usually not undertaken because of the high cost and prolonged recovery period. Oral and parenteral fluid and electrolyte therapy can be given as indicated. The provision of high-quality feeds appropriate to the species is recommended.

PREVENTION

The prevention of protein-energy malnutrition requires the provision of the nutrient requirements of the animals according to age, stage of pregnancy and production, the environmental temperature and the cost of the feeds. Body-condition scoring of cattle and sheep can be used as a guide to monitor body condition and nutritional status. Regular analysis of feed supplies will assist in the overall nutritional management program. The published nutrient requirements of domestic animals are only guidelines to estimated requirements since they were determined in experimental animals selected for uniform size and other characteristics. Under practical conditions, all of the common factors that affect requirements must be considered.

Diseases associated with deficiencies of mineral nutrients

An enormous literature exists on the subject of mineral nutrient deficiencies in animals and it is not possible to review it all here. However, some general comments should be made. The era of large-scale deficiencies affecting very large numbers of animals and comprising single elements has now largely passed in developed countries. The diagnostic research work has been done and the guidelines for preventive programs have been outlined and put into action in the field, so that the major breakthroughs have already been made, and what remains is in many ways a tidying-up operation after large-scale control campaigns. The loose edges needing to be refined include correcting overzealous application of minerals, which can produce toxicoses, sorting out the relative importance of the constituent elements in combined deficiencies, which are characterized by incomplete response to provision of single elements, and devising means of detecting marginal deficiencies.

At least 15 mineral elements are nutritionally essential for ruminants. The macrominerals are calcium, phosphorous, potassium, sodium, chlorine, magnesium, and sulfur. The trace elements, or microminerals, are copper, selenium, zinc, cobalt, iron, iodine, manganese, and molybdenum. Improving trace element nutrition of grazing livestock, in a way that is cost effective and that meets consumer perceptions and preferences, is a continuing challenge.[1]

INCIDENCE AND ECONOMIC IMPORTANCE

Despite increasing experimental evidence that anomalies in trace element supply can influence growth, reproductive performance, or immunocompetence of livestock, few data exist from which the incidence and economic significance of such problems can reliably be assessed. Most published reports of the more readily recognized trace element-related diseases continue to provide insufficient quantitative information to assess their incidence and true economic impact. Despite these deficiencies in information, the FAO/WHO Animal Health Yearbooks indicate that, of the countries providing information on animal diseases, 80% report nutritional diseases of moderate or high incidence, and trace element deficiencies or toxicities are involved in more than half of those whose causes were identified. In the UK, it has been estimated that, despite the activities of its nutritional and veterinary advisory services and extensive policies of ration supplementation, characteristic clinical signs of copper deficiency develop annually in about 0.9% of the cattle population. In light of recently described evidence that copper deficiency can predispose to increased mortality due to infectious diseases in lambs, the

economic losses from copper deficiency may be grossly underestimated.

DIAGNOSTIC METHODS AND STRATEGIES

In developed countries with highly developed animal industries, the emphasis is on disease prevention rather than therapy, and elimination or economical control of trace element deficiencies is a matter of education rather than research. However, because copper, cobalt, selenium, and iodine deficiencies can affect reproductive performance, appetite, early postnatal growth, and immunocompetence on a herd or flock basis, increasing emphasis is being placed on diagnostic methods that will identify a developing risk long before specific clinical manifestations appear. In addition, it is not good enough to merely define the distribution of animal populations with an abnormal trace element status indicated by blood or tissue analysis, or to detect a deficiency of the trace element in the diet. The only feasible way of monitoring the pre-clinical stages of trace element deficiency is the identification of a biochemical indicator which reflects changes in the activity of the enzyme involved or the concentration in tissues of its substrate or products. The demand is growing for techniques that will predict when the likely pathological outcome of such anomalies justifies the introduction of protective measures. For example, recent observations indicate that a high proportion of grazing cattle become hypocupremic if maintained on forage, but fail to develop characteristic clinical signs of deficiency and, furthermore, only a small percentage of these animals exhibit any physiological response to the administration of copper. This illustrates the lack of understanding of the variables involved in the development of clinical manifestations of copper deficiency and whether they are induced by a simple dietary deficiency of copper or by specific copper antagonists present in the diet.[1] A relatively new and interesting area of development is the observation of genetic variation in dietary requirements for copper among different breeds of sheep and that sheep can be selected for a high or low concentration of plasma copper, which in turn will have profound physiological consequences in the low group. There is now evidence that heredity is involved in the utilization of trace elements by animals. A small amount is necessary, but a larger amount may be toxic, and there is a need to determine the optimal economic balance.

Thus, it is likely that trace element deficiencies are widespread, but their incidence and importance are probably underestimated because subclinical forms of deficiency can occur and go unnoticed for prolonged periods.

DEFICIENCIES IN DEVELOPING COUNTRIES

In developing countries, the trace element problem is confounded by the common deficiencies of energy, protein, phosphorus, and water, which affect postnatal growth and reproductive performance. Undernutrition is commonly accepted as the most important limitation to herbivore livestock production in tropical countries. However, mineral deficiencies or imbalances in soils and forages have long been held responsible for low production and reproduction problems among grazing tropical cattle. Cattle grazing forages in areas severely deficient in phosphorus, cobalt, or copper are even more limited by lack of these elements than either that of energy or protein.

PATHOPHYSIOLOGY OF TRACE ELEMENT DEFICIENCY

The physiological basis of trace element deficiency is complex.[1] Some elements are involved in a single enzyme, some in many more, and a lack of one element may affect one or more metabolic processes. Furthermore, there are wide variations in how individual animals respond clinically to lowered blood or tissue levels of a trace element. For example, two animals in a herd or flock with the same copper levels in their blood may be in different bodily condition. The susceptibility to clinical disease may be a function of the stage of physiological development at which they occur, genetic differences within a species, and interrelationships with other trace elements. There is now good evidence to show that the amounts of dietary copper adequate for some breeds of sheep were deficient for others, and even toxic to others.

A dietary deficiency does not necessarily lead to clinical disease. Several factors predispose the animal to clinical disease and they include:

- The age at which the deficiency occurs (for example fetal lambs are highly susceptible to demyelination due to copper deficiency in late fetal life)
- Differences in genotype requirements
- Discontinuous demands for trace elements because of changes in environment
- The challenge of infections, diet, and production demands
- Individual variations in response to the deficiency, the use of alternative pathways by the body in the face of a deficiency
- Size of the functional reserves.

The trace elements are involved as component parts of many tissues, and one or more enzyme activities and their deficiency leads to a wide variety of pathological consequences and metabolic defects. These are summarized in Table 30.1.

The **soil–plant–animal interactions** in relation to the incidence of trace element deficiencies in livestock are being examined. The soil and its parent materials

Table 30.1 Principal pathological and metabolic defects in essential trace element deficiencies[1]

Deficiency	Pathological consequence	Associated metabolic defect
Copper	Defective melanin production	Tyrosine/DOPA oxidation
	Defective keratinization; hair, wool	–SH oxidation to S–S
	Connective tissue defects	Lysyl oxidase
	Ataxia, myelin aplasia	Cytochrome oxidase
	Growth failure	?
	Anemia	?
	Uricemia	Urate oxidase
Cobalt	Anorexia	Methyl malonyl CoA mutase
	Impaired oxidation of propionate	Tetrahydrofolate methyl transferase
	Anemia	
Selenium	Myopathy; cardiac/skeletal	Peroxide/hydroperoxide destruction
	Liver necrosis	Glutathione peroxidase
	Defective neutrophil function	OH; O_2 generation
Zinc	Anorexia, growth failure	?
	Parakeratosis	Polynucleotide synthesis, transcription, translation?
	Perinatal mortality	
	Thymic involution	
	Defective cell-mediated immunity

are the primary sources of trace elements on which soil–plant–animal relationships are built. The natural ranges in concentration of most trace elements in soils are wide and range from deficient soils to those which are potentially toxic. The availability of trace elements to plants is controlled by their total concentration in the soil and their chemical form. Certain species of plants take up more trace elements than do others. The ingestion of soil can have a profound effect on trace element nutrition and metabolism. Geochemical surveys can now assist in the identification of areas in which livestock are exposed to excessive ingestion or deficiencies of trace elements.

The **dose–response trial** will continue to play a significant role in the delineation of trace element deficiencies because it is often difficult to determine the role of individual trace elements. A deficiency of one trace element may result in clinical disease, which may be indistinguishable from a deficiency of more than one trace element. Many of the trace element deficiencies may produce non-specific as well as specific effects.

A **dose–response trial** can be defined as the application of a test and a control substance to a group, or replicates, of individuals and the measurement of the response to the treatment. The requirements for a reliable dose–response trial include a careful appraisal of the basis for conducting the trial, a suitable form of the test substance for treatment, the careful selection of animals for the test, a reliable biochemical method for monitoring the response to the trace element, a measurable production response, an adequate system for measurement of the variable that may influence the response, and a means of measuring the economic impact.

The ***ad hoc*** **field observations** made by veterinarians who make a diagnosis of a trace element deficiency, followed by treatment or dietary changes, are subjective and usually lack controls but are nevertheless of value in indicating the magnitude and variability of response that might be expected in future experimental studies. Dose-response trials help to establish a link between a trace element and certain clinical signs; they may identify factors which modify the response to a trace element and, of paramount importance, give an indication of the economic importance of adequate supplementation of the element in the diet.

There are major problems in the diagnosis and anticipation of trace element deficiencies in grazing livestock. Because of the interplay between the constituents of the diet and the homeostatic mechanisms of the body, it is often impossible to predict from dietary composition alone whether a particular nutritional regimen will result in clinical disease. The assessment of the absorbable, rather than the total, concentration of elements in the diet is now considered to be more important in understanding the nutritional basis for the deficiencies.

LABORATORY DIAGNOSIS OF MINERAL DEFICIENCIES

The diagnosis of mineral deficiencies, particularly trace element deficiencies, will depend heavily on the interpretation of the biochemical criteria of the trace element status. This is because deficiencies of any one or more of several trace elements can result in non-specific clinical abnormalities, such as loss of weight, growth retardation, anorexia, and inferior reproductive performance.

The interpretation of biochemical criteria of trace element status are governed by three important principles: **relationship with intake, time, and function.**

1. **Relationship between the tissue concentrations of a direct marker and the dietary intake of the element** will generally be sigmoid in shape (a dose–response curve). The important point on the curve is the intake at which the requirement of the animal is passed, which is the intake of the nutrient needed to maintain normal physiological concentrations of the element and/or avoid impairment of essential functions. For several markers of trace element status, the position on the x-axis at which requirement is passed coincides with the end of the lower plateau of the response in marker concentration. Under these conditions, the marker is an excellent index of sufficiency and body reserves, but an insensitive index of a deficiency. If requirement is passed at the beginning of the upper plateau, the marker is a poor index of sufficiency, but a good index of deficiency. This principle allows direct markers to be divided into **storage** and **non-storage** types corresponding to the former and latter positions on the x-axis.
2. **Non-storage criteria can be divided into indicators of acute and chronic deficiency** and two types of relationships can be distinguished: a **rapid, early decline** in marker concentration followed by a plateau, and a **slow, linear rate** of decline. Markers with a slow, linear response will be good indices of a chronic deficiency, but unreliable indices of acute deficiency, because they cannot respond quickly enough. Conversely, the marker with a rapid, early decline will be a good index of acute deficiency, but an unreliable indicator for chronic deficiency if the low plateau is reached before functions are impaired. Those biochemical criteria that are based on metalloenzyme or metalloprotein concentrations in erythrocytes are of the slow type because the marker is incorporated into the erythrocyte before its release into the bloodstream, and thereafter its half-life is determined by that of the erythrocyte that is 150 days or more. Metalloenzymes or metalloproteins in the plasma with short half-lives provide markers of the rapid type.
3. A deficiency can be divided into four phases: depletion, deficiency (marginal), dysfunction, and clinical disease.

Depletion is a relative term describing the failure of the diet to maintain the trace element status of the body, and it may continue for weeks or months without observable clinical effects when substantial body reserves exist. When the net requirement for an essential element exceeds the net flow of absorbed element across the intestine then depletion occurs. The body processes may respond by improving intestinal absorption or decreasing endogenous losses. During the depletion phase, there is a loss of trace element from any storage sites, such as the liver, during which time the plasma concentrations of the trace element may remain constant. The liver is a common store for copper, iron, and vitamins A and B_{12}.

If the dietary deficiency persists, eventually there is a transition from a state of depletion to one of **deficiency**, which is marked by biochemical indications that the homeostatic mechanisms are no longer maintaining a constant level of trace elements necessary for normal physiological function. After variable periods of time, the concentrations or activities of trace element-containing enzymes will begin to decline leading to the phase of **dysfunction**. There may be a further lag period, the **subclinical phase**, before the changes in cellular function are manifested as **clinical disease**. The biochemical criteria can be divided, according to the phase during which they change, into indicators of marginal deficiency and dysfunction. The rate of onset of clinical disease will depend on the intensity of the dietary deficiency, the duration of the deficit and the size of the initial reserve. If reserves are non-existent, as with zinc metabolism, the effects may be acute and the separate phases become superimposed. The application of these principles to the interpre-

tation of biochemical criteria of trace element status are presented later in this chapter where applicable, under each mineral nutrient.

The **definitive etiological diagnosis** of a trace element deficiency will depend on the response in growth and health obtained following parenteral treatment or supplementation of the diet. The concurrent measurement of biochemical markers will aid in the interpretation and validation of those markers for future diagnosis. The strategies for anticipating and preventing trace element deficiencies include regular analysis of the feed and soil, which are not highly reliable; and monitoring samples from herds and flocks to prevent animals from entering the zone of marginal trace element deficiencies which precedes the onset of functional deficiency. The decision to intervene can be safely based on the conventional criteria of marginal trace element status.

COBALT DEFICIENCY

Cobalt deficiency is a disease of ruminants ingesting a diet deficient in cobalt, which is required for the synthesis of vitamin B_{12}. The disease is characterized clinically by inappetence and loss of body weight. Some effects on reproductive performance in sheep have been reported. Cobalt was first shown to be an essential nutrient for sheep and cattle as an outcome of Australian investigations in the 1930s of two naturally occurring diseases, **'coast disease'** of sheep, and **'wasting disease'** or **enzootic marasmus**, of cattle.[1]

Synopsis

Etiology Dietary deficiency of cobalt resulting in a deficiency of vitamin B_{12}.
Epidemiology Occurs primarily in cattle and sheep unsupplemented with cobalt worldwide where soils are deficient in cobalt. Associated with ovine white liver disease.
Signs Inappetence, gradual loss of body weight, pica, marked pallor of the mucous membranes. Wool and milk production decreased. Decreased lambing percentage.
Clinical pathology Cobalt, or vitamin B_{12} concentration of liver. Cobalt concentrations. Methylmalonic acid in plasma and urine. Formiminoglutamic acid in urine. Anemia.
Necropsy findings Emaciation, hemosiderosis of spleen.
Diagnostic confirmation Vitamin B_{12} and cobalt of liver.
Differential diagnosis list
Common causes of ill-thrift in ruminants:

- Copper deficiency
- General nutritional deficiency (protein and energy)
- Johne's disease
- Intestinal helminthiasis.

Treatment Oral dosing with cobalt or parenteral injections of vitamin B_{12}.
Control Dietary supplementation with cobalt. Cobalt-heavy pellets.

ETIOLOGY

The disease is caused by a deficiency of cobalt in the diet which results in a deficiency of vitamin B_{12}.

EPIDEMIOLOGY

Occurrence

The literature on the diagnosis, treatment, control of cobalt deficiency in ruminants in New Zealand has been reviewed.[2] The literature on the occurrence of cobalt deficiency, and the use of diagnostic tests in sheep, and their limitations and reference ranges for various age groups has also been reviewed.[3]

Cobalt deficiency occurs in Australia, New Zealand, the UK, North America, the Netherlands,[4] and probably occurs in many other parts of the world.[5] Where the deficiency is extreme, large tracts of land are unsuitable for the raising of ruminants, and in certain areas suboptimal growth and production may be limiting factors in the husbandry of sheep and cattle.

Historically, in severely cobalt deficient areas in New Zealand, ill-thrift was so marked that calves and lambs died. In those that survived, growth rates were markedly depressed and often zero over summer months compared with cobalt supplemented lambs.[6] In New Zealand, cobalt deficiency is now mainly confined to lambs, because severely deficient areas, where the deficiency occurred in adult sheep and cattle, and in lambs, have had cobalt fertilizer applied for many decades.[2] Cobalt responsive ill-thrift in lambs still occurs where cobalt fertilizer applications or vitamin B_{12} injections to lambs are haphazard. Live weight gains to supplementary vitamin B_{12} injections of up to 180 g/d have been reported.[6]

The concentration of cobalt in the soil can vary widely as, for example, in Irish cattle farms where the soil cobalt content varied between 0.2 and 18 mg/kg dry matter (DM), the forage had marginal to normal cobalt content, and low or very low blood vitamin B_{12} status was found in 55% of herds sampled.[7] However, the significance of the cobalt deficiency clinically is uncertain.[8]

Cattle and sheep are similarly affected and the signs are similar in both species. Cattle are slightly less susceptible than sheep, and lambs and calves are more seriously affected than adults. Cobalt/vitamin B_{12} deficiency occur in grazing lambs in the Netherlands and chronic hepatitis or ovine white liver disease are manifestations of the deficiency.[4] It has been described in beef cattle in the Netherlands.[9]

Although the disease occurs most commonly in ruminants at pasture in severely deficient areas, sporadic cases occur in marginal areas, especially after long periods of stable feeding. Bulls, rams, and calves are the groups most commonly affected, although dairy cows kept under the same conditions may develop a high incidence of ketosis.

A disease of moose called **'moose sickness'** occurs in Eastern North America is related to a cobalt- and vitamin B_{12} deficiency.[10] Affected moose are geographically localized mainly to the regions of the Tobeatic and Cape Breton Highlands of Nova Scotia in Canada. There are low concentrations of cobalt and vitamin B_{12} in liver and increased concentrations of methylmalonic acid in the plasma. There are striking similarities between the North American moose sickness and the 'mysterious' moose disease in Sweden, which is caused by molybdenosis.[10]

Frank deficiency is unlikely to occur in pigs, or in other omnivores or carnivores, because vitamin B_{12} is present in meat and other animal tissues, but there are some reports of improved weight gains following supplementation of the ration with cobalt. Horses appear to be unaffected.

Risk factors

Dietary and environmental factors

Pastures containing less than 0.07 and 0.04 mg/kg DM result in clinical disease in sheep and cattle, respectively. The daily requirement for sheep at pasture is 0.08 mg/kg DM of cobalt; for growing lambs the need is somewhat greater and at pasture levels of less than 0.10 mg/kg DM inefficient rates of gain are likely. For growing cattle, an intake of 0.04 mg/kg DM in the feed is just below requirement levels.[11] Variations in the cobalt content of pasture occur with seasonal variations in pasture growth and with drainage conditions. The increased incidence of the disease, which has been observed in the spring, may be related to domination of the pasture by rapidly growing grasses, which have a lower cobalt content than legumes. There is also a great deal of variation between years in the severity of the

losses encountered due to variations in the cobalt status of the animals. Forage grown on well-drained soils has a greater cobalt content than that grown on poorly drained soils of the same cobalt status. Plant growth is not visibly affected by a low cobalt content of the soil, but the addition of excessive quantities may retard growth.

Cobalt is also protective against the liver damage in sheep exposed to annual ryegrass.[12]

Primary cobalt deficiency occurs only on soils which are deficient in cobalt. Such soils do not appear to have any geological similarity, varying from wind-blown shell sands to soils derived from pumice and granite. Japanese soils composed largely of volcanic ash are seriously deficient. A survey in New Brunswick, Canada, revealed the average value for grass samples was 0.028 mg/kg DM, and for legume samples, 0.088 mg/kg DM, which justifies supplementation of ruminant diets with cobalt. The soils in New Brunswick are naturally acidic and with the heavy annual rainfall of 120 cm the cobalt content of the soil is decreased by leaching.

After the introduction of domestic livestock into New Zealand, it was realized that in some areas livestock did not thrive, or were affected with particular diseases not occurring in other areas. Large parts of New Zealand were subsequently discovered to be trace-element deficient (cobalt, selenium, and copper) and these deficiencies have been a significant part of the agricultural scene ever since.[6] Livestock grazing pastures grown on such soils may be deficient in one or more of these trace elements.

In New Zealand, soil types are categorized as severe, moderate or marginal. In total, of the land considered suitable for farming, about 1 million hectares in the North Island and 918,000 hectares in the South Island have been defined as cobalt deficient.[6]

Outbreaks of cobalt deficiency have occurred in cattle grazing on pastures on the granite-derived northern tablelands of New South Wales in Australia, and in sheep grazing pasture on soils derived from weathered rhyolite and ignimbrite, the former being inherently low in cobalt. Cobalt deficiency is now occurring in areas where it has never before been diagnosed, and in seasons of lush spring and summer pasture growth, cobalt deficiency should be suspected as a cause of unthriftiness. Lambs grazing cobalt-deficient pastures of the Northern Netherlands are 6.7 times more likely to die if unsupplemented with cobalt than supplemented lambs.[13] In the Netherlands, on farms with a history of ill-thrift caused by cobalt/vitamin B_{12} deficiency, the acetic acid-extractable soil cobalt content of the pastures was above the reference value for cobalt deficiency (≤0.30 mg Co/kg dried soil).[4] These concentrations are below the minimum requirement for sheep (0.07 mg/kg DM). The high soil pH (6.5) and the good drainage conditions on the farm were probably primary factors responsible for the low soil cobalt availability.

Although soils containing less than 0.25 mg/kg cobalt are likely to produce pastures containing insufficient cobalt, the relationship between levels of cobalt in soil and pasture is not always constant. The factors governing the relationship have not been determined, although heavy liming is known to reduce the availability of cobalt in the soil. Manganese appears to have a similar action, but the agricultural significance of the relationship is unknown.

Ovine white liver disease

A specific hepatic dysfunction of sheep has been described in New Zealand, Australia, the UK,[14] Norway,[15] and in grazing lambs in the Netherlands.[4] It has been called 'white liver disease' because of the grayish color of the liver. Clinically, it is manifested by photosensitization when the disease is acute, and anemia and emaciation when the disease is chronic. It seems likely that the disease is a toxic hepatopathy against which adequate levels of dietary cobalt are protective.[16]

Hepatic lipidosis in goats

Hepatic lipidosis has occurred in Omani goats in many parts of Oman for many years but the cause was unknown.[17,18] It is now known that low levels of serum vitamin B_{12} or low levels cobalt in the liver are associated with the liver lesion, and it can be experimentally reproduced using low levels of cobalt intake.[19] Abattoir surveys of goat livers found that hepatic lipidosis was one of the most frequent cause of their condemnation.[18] Because the goat is the predominant domesticated animal type raised for meat in the Sultanate of Oman, the condemnation of goat livers at slaughter represents a significant economic loss.[18]

Experimental reproduction of cobalt deficiency in sheep

Cobalt deficiency can be reproduced in sheep diet containing less than 70 μg/kg cobalt. Feeding a diet containing 4.5 μg/kg to lambs produced a severe vitamin B_{12} deficiency, characterized by subnormal plasma and liver concentrations of vitamin B_{12} and reduced growth rate, serous ocular discharge, alopecia, and emaciation, similar to naturally occurring outbreaks of cobalt deficiency in sheep.[20] Fatty degeneration of the liver was associated with reduced concentrations of vitamin B_{12} (14.5 pmol/g) at necropsy. Liver lesions included accumulation of lipid droplets and lipofuscin particles in hepatocyte, dissociation and necrosis of hepatocyte, and sparse infiltration by neutrophils, macrophages, and lymphocytes. Ultrastructural hepatocytic alterations included swelling, condensation and proliferation of mitochondria, hypertrophy of smooth endoplasmic reticulum, vesiculation and loss of arrays of rough endoplasmic reticulum, and accumulation of lipid droplets and lipofuscin granules in cytoplasm of hepatocytes. Co-factors are not a prerequisite to development of hepatic damage in cobalt-deficient sheep. Reduced activities of the vitamin B_{12} dependent enzymes, methylmalonyl CoA mutase and methionine synthesis, and lipid peroxidation are likely pathogenetic importance in the development of the lesions.

PATHOGENESIS

Cobalt is unique as an essential trace element in ruminant nutrition because it is stored in the body in limited amounts only and not in all tissues. In the adult ruminant, its only known function is in the rumen and it must, therefore, be present continuously in the feed.

The effect of cobalt in the rumen is to participate in the production of vitamin B_{12} (cyanocobalamin), and compared with other species the requirement for vitamin B_{12} is very much higher in ruminants. In sheep, the requirement is of the order of 11 μg/d, and probably 500 μg/d are produced in the rumen, most being lost in the process. Animals in the advanced stages of cobalt deficiency are cured by the oral administration of cobalt or by the parenteral administration of vitamin B_{12}. On cobalt-deficient diets, the appearance of signs is accompanied by a fall of as much as 90% in the vitamin B_{12} content of the feces, and on oral dosing with cobalt the signs disappear and vitamin B_{12} levels in the feces return to normal. Parenteral administration of cobalt is without appreciable clinical effect, although some cobalt does enter the alimentary tract in the bile and leads to the formation of a small amount of cobalamin.

The essential defect in cobalt deficiency in ruminants is an inability to metabolize propionic acid. A key biochemical pathway for propionic acid from rumen fermentation involves adenosyl cobalamin, one of several cobalt-containing coenzymes of the vitamin B_{12} complex that is required for the conversion of methylmalonyl coenzyme A to succinyl coenzyme A, both intermediates in the utilization pathway of propionate. Lack of vitamin B_{12} results in accumulation of methylmalonic acid which can be measured in the serum. The

clinical and pathological signs of cobalt deprivation are preceded by characteristic biochemical changes in tissues and fluids of the body. As soon as depletion begins, the concentration of cobalt and vitamin B_{12} fall in rumen fluid. Vitamin B_{12} values in serum also show an early decline, because they measure vitamin which is in transit, which is largely a reflection of the adequacy of current rumen synthesis, Serum vitamin B_{12} declines before liver vitamin B_{12} which confirms that the liver does not serve as an active storage pool.

A prolonged moderate cobalt deficiency in beef cattle (83 μg/kg) for 43 weeks results in several changes in lipid metabolism in addition to impaired growth.[21] There is severe accumulation of plasma homocysteine, and a marked increase of trace elements iron and nickel in the liver.[22]

The efficiency of cobalt in preventing staggers in sheep grazing pasture dominated by (*Phalaris tuberosa*) and possibly by canary grass (*Phalaris minor*) or rhompa grass, a hybrid *Phalaris* spp., is unexplained. A suggestion that a dietary deficiency of cobalt can lead to the development of polioencephalomalacia appears not to be valid.

The pathogenesis of **ovine white liver disease** is unclear. It is unknown if the disease is a simple cobalt deficiency, or a hepatotoxic disease in cobalt/vitamin B_{12}-deficient lambs. Marginal to deficient cobalt-deficient grass is essential for the development of the disease.[15] Cobalt fertilization of deficient pastures results in an increase in vitamin B_{12} in lambs.[16] Hepatic dysfunction occurs in affected sheep.[23] Affected lambs generally have higher serum levels of copper than in cobalt/vitamin B_{12}-supplemented lambs grazing the same pastures.[24] Dosing affected lambs with copper oxide needles resulted in toxic levels of liver copper.[25] It is suggested that the disease is a manifestation of B_{12} deficiency made worse by factors triggering early hepatic fatty change, resulting in more severe liver damage and loss of intracellular homeostasis, rendering the hepatocytes more vulnerable to other elements such as copper.[26] The amount of fructan in the pasture may be an important factor in the pathogenesis of the lesion.[11] One hypothesis suggests that the high level of fructan may initiate hepatic lipodystrophy, leading to hepatic insufficiency, growth reduction and ovine white liver disease.[11] Vitamin B_{12} is therapeutic.[27]

The pathological changes in lambs grazing cobalt-deficient pastures are related to blood concentrations of vitamin B_{12}, methylmalonic acid, and homocysteine, and lesions are confined mainly to the liver and brain.[28] Acute and chronic hepatitis are characteristic and the liver lesions are associated with polymicrocavitation of the brain.

Hepatic encephalopathy associated with cobalt deficiency and white liver disease has been described in lambs.[29] Symmetrical vacuolation and status spongiosus of the neuropil in the brain were characteristic and hyperammonemia secondary to the hepatic lesion is considered to be the cause of the brain lesions.

Caprine hepatic lipidosis has been induced experimentally using low intakes of low levels of dietary cobalt.[19] Goats provided with a diet which contains the minimum daily requirement of cobalt as specified for sheep not only developed a syndrome characterized by reduced weight gains, dry scruffy hair goat and a decline in erythrocyte indices but also lesions consistent with hepatic lipidosis. Goats fed diets containing levels of cobalt less than 0.1 mg/kg DM could experience even greater clinical and pathological consequences.

In **'Moose sickness'** there are low concentrations of cobalt and vitamin B_{12} in liver and increased concentrations of methylmalonic acid in plasma.[10]

CLINICAL FINDINGS

No specific signs are characteristic of cobalt deficiency. A gradual decrease in appetite is the only obvious clinical sign. It is accompanied by loss of body weight, emaciation, and weakness, and these are often observed in the presence of abundant green feed. Pica is likely to occur, especially in cattle. There is marked pallor of the mucous membranes and affected animals are easily fatigued. Growth, lactation, and wool production are severely retarded, and the wool may be tender or broken. In sheep, severe lacrimation with profuse outpouring of fluid sufficient to mat the wool of the face is one of the most important signs in advanced cases. Signs usually become apparent when animals have been on affected areas for about 6 months and death occurs in 3–12 months after the first appearance of illness, although severe wasting may be precipitated by the stress of parturition or abortion.

Cobalt deficiency in pregnant ewes can result in decreased lambing percentage, increased percentage of stillbirths, and increased neonatal mortality.[30] Lambs from deficient ewes are slower to start sucking, have reduced concentrations of serum colostral immunoglobulins, and have lower serum vitamin B_{12} and higher methylmalonic acid concentrations than lambs from cobalt-adequate dams.

'Moose sickness' in Nova Scotia is characterized by a loss of fear of man, weakness, and a staggering gait, apparent blindness, drooping of the ears, and emaciation and infestation by ticks.[10] A decreased intake of food, increasing lethargy and collapse, accompanied by loss of use of one or more limbs, precedes death.

CLINICAL PATHOLOGY

Biochemical criteria to determine cobalt and vitamin B_{12} status

Changes in the concurrent serum concentrations of methylmalonic acid and vitamin B_{12} of ewes and their lambs on cobalt deficient pastures, and their response to cobalt supplementation can be evaluated and monitored.[31] Those same changes can be evaluated during supplementation of lambs while suckling and after weaning on farms in the South Island of New Zealand considered to be cobalt-deficient.[32] These measurements are commonly done along with recording live weight gains, and analysis of pasture for cobalt content at the sampling times for blood MMA and vitamin B_{12}.

Growth responses to cobalt or vitamin B_{12} supplementation is anticipated when cobalt levels in herbage fall below 0.08–0.1 mg/K DM.[31]

Serum and hepatic cobalt and vitamin B_{12} concentrations

Serum cobalt. Cobalt concentrations in the serum of normal sheep are of the order of 1–3 μg/dL (0.17–0.51 μmol/L), and in deficient animals these are reduced to 0.03–0.41 μmol/L.

Serum vitamin B_{12}. Clinical signs of cobalt deficiency in sheep are associated with serum vitamin B_{12} levels of less than 0.20 mg/mL, and serum vitamin B_{12} levels are used as a laboratory test of cobalt status in animals. Levels of 0.2–0.25 μg/L are indicative of cobalt deficiency. These rise rapidly to 0.5–1.0 μg/L on treatment. The value of serum vitamin B_{12} assay as a diagnostic tool is in some doubt, but correctly interpreted they appear to be worthwhile. Serum vitamin B_{12} values greater than 0.2 μg/L are indicative of a normal vitamin B_{12} status in cattle. Deprivation of feed from sheep for 24 h results in a marked increase in serum vitamin B_{12}. The serum vitamin B_{12} levels of sheep at pasture are unreliable indicators of liver vitamin B_{12}.

Concurrent serum MMA and vitamin B_{12} concentrations. Concurrent changes in serum MMA and vitamin B_{12} concentrations in cobalt supplemented ewes and their lambs on cobalt-deficient farms were monitored. Serum concentrations of vitamin B_{12} fell below 250 pmol/L during early lactation, and as low as 100 pmol/L.[31] MMA concentration was maintained below 2 μmol/L in serum from supplemented ewes but increased to mean concentrations ranging from 7 to 14 μmol/L at the nadir of serum vitamin B_{12} concentration during

peak lactation.[31] A significant live weight response to supplementation occurred in ewes, and the vitamin B_{12} concentration in the ewe's milk and in the livers of their lambs more than doubled. Serum MMA concentration provides a more precise indication of responsiveness to vitamin B_{12} or cobalt supplementation than serum vitamin B_{12} concentrations in ewes and lambs. Neither very low serum vitamin B_{12} concentrations nor elevated MMA concentrations are necessarily indicative of responsiveness to supplementation in suckling lambs, but MMA gave an early indication of impending responsiveness. Supplementation of the ewe with a cobalt bullet appears to protect the growth performance of the lamb for 90 days and influence the subsequent serum vitamin B_{12} response in the lamb to vitamin B_{12} supplementation.[31]

In New Zealand, the serum vitamin B_{12} and MMA have been compared as indices of cobalt/vitamin B_{12} deficiency in lambs on cobalt-deficient farms, around lambing, and supplemented with either cobalt bullets, or short- or long-acting vitamin B_{12} preparations.[32] Serum MMA concentrations in excess of 9–14 μmol/L provide a more reliable diagnostic test for cobalt deficiency. However, there may be considerable variation between farms.

A critical evaluation of serum MMA and vitamin B_{12} concentrations for the assessment of cobalt deficiency in growing lambs in New Zealand indicates that the current reference ranges for vitamin B_{12} responsiveness are conservatively high and result in over-diagnosis of vitamin B_{12} deficiency in ill-thriftiness of sheep.[33] It would be preferable if vitamin B_{12} weight gain response trials were compared with reference curves.[34]

Serum concentrations of MMA allow better differentiation of a responsive condition than vitamin B_{12} concentrations. Serum MMA concentrations >13 μmol/L indicate responsiveness to supplementation while concentrations of <7 μmol/L indicate unresponsiveness. In the range 7–13 μmol/L, variation in response was observed and predictability of response is less certain but supplementation is advisable.

Hepatic cobalt. Normal hepatic cobalt levels in lambs range between 0.03 and 0.1 μg/g WW.[35] Levels below 0.02 μg/g WW (0.07 μg DM) are associated with clinical cobalt deficiency, and 0.015 μg/g WW (0.05 μg DM) is considered as a critical level. In lambs with clinical signs of ovine white liver disease, mean hepatic cobalt concentrations ranged from 0.013 to 0.024 μg/g WW. An average cobalt level below 0.025 μg/g WW in a sheep flock is considered marginal.[35] In a survey of the cobalt and copper concentrations of lamb livers at slaughter in Norway, the average hepatic levels of cobalt varied from <0.003 to 0.22 μg/g WW, and of copper from 5 to 240 μg/g WW.[35]

Serum methylmalonic acid

Because of some of the difficulties with the interpretation of serum vitamin B_{12} levels, other biochemical tests, especially methylmalonic acid (MMA) in plasma and urine as diagnostic and prognostic indicators and formiminoglutamic acid (FIGLU) tests are now used.[33,36] The determination of MMA has the potential to distinguish between subclinically and clinically affected animals, which serum vitamin B_{12} cannot do. Methylmalonic acid is ordinarily metabolized in ruminants by a vitamin B_{12} enzyme system. An elevated plasma concentration of MMA is a comparatively early indicator of functional vitamin B_{12} deficiency.[37] It is recommended that 10 μmol/L be an upper limit of normality for plasma MMA in barley-fed animals, and 5 μmol/L be the upper limit for grass-fed animals.[37] Measurement of serum MMA as diagnostic measures of cobalt status in cattle indicates that a level <2 μmol/L is normal, 2–4 μmol/L represents subclinical deficiency, and >4 μmol/L represents deficiency.[38] In a cobalt-deficient animal the methylmalonic content of urine is abnormally high and this has some merit as a test for the presence of the deficiency.[16] Cobalt-adequate lambs have plasma MMA levels of less than 5 μmol/L, urinary MMA less than 120 μmol/L and urinary MMA/creatinine values of less than 0.022 μmol MMA/mmol of urinary creatinine. An unequivocal result for methylmalonic acid is a concentration of greater than 30 μg/mL for ten animals selected randomly from a flock. If the urine is kept for more than 24 h it should be acidified to avoid degradation of the methylmalonic acid. Commercial kits are now available for assay of vitamin B_{12} in ruminant blood.

Formiminoglutamic acid

The concentration of formiminoglutamic acid in urine is a reliable indicator of the cobalt status of lambs. Levels of 0.08–20 μmol/mL in the urine of affected lambs return to 0 rapidly after treatment. However, the concentration of formiminoglutamic acid increases in the urine of lambs only in the later stages of cobalt deficiency when there is weight loss and ill-thrift. Animals with subclinical cobalt deficiency do not produce urinary formiminoglutamic acid at levels that would be useful diagnostically. Neither MMA nor formiminoglutamic acid is a normal constituent of urine and their presence in urine, without the need for a quantitative measurement, is probably a positive indication of cobalt deficiency.

Hematology

Affected animals are anemic, but their hemoglobin and erythrocyte levels are often within the normal range because of an accompanying hemoconcentration. The anemia is normocytic and normochromic. There is also a decrease in cellularity of the bone marrow in cobalt-deficient sheep. It is not repaired by the administration of vitamin B_{12} or by the parenteral administration of cobalt. Affected animals are also hypoglycemic (<60 mg glucose/dL plasma) and have low serum alkaline phosphatase levels (<20 U/L). The response to cobalt administration is matched by a very rapid return to normal of these levels. Unfortunately, there are too many other factors affecting their concentration for them to be of much value in diagnostic work.

NECROPSY FINDINGS

At necropsy, emaciation is extreme. The livers of sheep affected with white liver disease are pale and fatty. In most cases of cobalt deficiency, the spleen is dark due to the accumulation of hemosiderin. The microscopic changes of ovine white liver disease include hepatocellular dissociation and intracytoplasmic accumulations of lipid and ceroid-lipofuscin within hepatocytes. The ultrastructural changes of experimentally-induced ovine white liver disease have also been documented.[20]

Biochemical assays reveal very high iron levels in the liver and spleen, and low cobalt levels in the liver. In normal sheep, cobalt levels in the liver are usually above 0.20 mg/kg DM, but in affected sheep are typically less than 0.05 mg/kg DM. Liver cobalt levels in cattle fed excessive amounts of cobalt and thought to be affected by cobalt poisoning can be as high as 69 mg/kg DM.

Normal levels of vitamin B_{12} in the liver are of the order of 0.3 mg/kg, falling to 0.1 mg/kg in deficient lambs. In cattle, clinical signs occur with liver vitamin B_{12} levels of less than 0.10 mg/kg, and levels of more than 0.3 mg/kg of liver are necessary for optimum growth. Normal levels of the vitamin of cattle in New Zealand are 0.70–1.98 mg/kg of liver. After oral dosing with cobalt, the level of the element in the liver rises, but returns to the pretreatment level in 10–30 days. Since serum B_{12} levels reflect cobalt status, it is often useful to submit sera from surviving herdmates when attempting to confirm the diagnosis.

Samples for confirmation of diagnosis

- **Toxicology** – 50 g liver (ASSAY (Co)), 2 mL serum (ASSAY (B_{12}))
- **Histology** – formalin-fixed liver (LM).

DIFFERENTIAL DIAGNOSIS

Cobalt deficiency must be differentiated from other causes of 'ill-thrift' or 'enzootic marasmus'.

Ill-thrift

In young animals, in which this situation is most often encountered, nutritional deficiencies of copper, selenium, and vitamin D are possible causes of ill-thrift. Lack of total digestible nutrients is the most common cause of thin animals, but owners are usually aware of the shortage and do not present their animals for diagnosis. However, it does happen, especially with urban people who become farmers and are unaware of the actual needs of animals. So it is best to check the feed supply and also to check whether or not the animals have any teeth. These circumstances are seen so commonly in today's era of hobby farms that a new disease category 'hobby farm malnutrition' is warranted.

Internal parasitism

Careful necropsy or fecal examination will determine the degree of helminth infestation, but cobalt-deficient animals are more susceptible to parasitism and the presence of a heavy parasite load should not rule out the diagnosis of primary cobalt deficiency. It is also common for parasitic disease and cobalt deficiency to occur together in the one animal. It is then necessary to make two diagnoses and conduct two control programs. In sheep, special care is needed to differentiate the disease from Johne's disease. The differential diagnosis of anemia has been discussed elsewhere.

Dietary supplementation response

The most conclusive method of determining if animal production is being affected by the deficiency of a trace mineral is to measure the response of a production parameter, such as weight gain, milk production, wool production, or reproductive performance following supplementation of animals with the element under consideration.[39] However, if the degree of response can be related to a tissue level of the element, or its metabolites, then tissue analyses can replace the need for field trials, which require considerable expertise and resources and can take several months to monitor the results and obtain a quantitative outcome.

Growth response curve to supplementation

A new approach to defining mineral deficiencies is based on constructing response curves for any specified level of serum vitamin B_{12} that can be used to determine live weight response to supplementation and the probability of obtaining a response.[39] The technique closely relates the tissue mineral or biochemical indicator with the degree of production response to treatment. The advantages of this method over the traditional method have been described.[39] The results from published and unpublished cobalt/vitamin B_{12} weight response trials in young sheep grazing pasture in New Zealand have been reviewed.[39] No significant weight gain responses occurred to vitamin B_{12} or cobalt treatment in trials with serum vitamin B_{12} levels above 500 pmol/L or liver vitamin B_{12} levels greater than 500 nmol/kg. The fitted response curve approached 0 g/day at 500 pmol/L for serum vitamin B_{12} and 375 nmol/kg for liver vitamin B_{12}. The minimum vitamin B_{12} at which an economic response to treatment (10 μg/day BW gain) is not likely is 336 pmol/L for serum and 282 nmol/kg for liver.[39] Variable responses to cobalt or vitamin B_{12} include age, breed, sex, energy intake, concurrent disease, and length of pasture. Higher soil contamination on short pastures may result in increased cobalt intake and reduced response to vitamin B_{12} or cobalt. Serum vitamin B_{12} levels may also increase following prolonged yarding, and within 24–48 h after changes in dietary cobalt.

TREATMENT

Cobalt and vitamin B_{12}

Affected animals respond satisfactorily to oral dosing with cobalt or the IM injection of vitamin B_{12}. Oral dosing with vitamin B_{12} is effective, but much larger doses are required. Oral dosing with cobalt sulfate is usually at the rate of about 1 mg cobalt/d in sheep and can be given in accumulated doses at the end of each week. Intervals of 2 weeks between dosing are inadequate for the best possible response. On the other hand, the monthly dosing of lambs with oral doses of 300 mg cobalt is sufficient greatly to reduce deaths and permit some growth at suboptimal levels. The response to dosing is very quick, significant elevation of serum vitamin B_{12} levels being evident within 24 h. When large doses of cobalt are administered to some sheep, other undosed sheep on the same pasture may find sufficient additional cobalt on the pasture from the feces of their flockmates to meet their needs. No exact data are available on dose rates for cattle but ten times the prophylactic rate should be effective. Vitamin B_{12} should be given in 100–300 μg doses for lambs and sheep at weekly intervals. Vitamin B_{12} therapy is not likely to be used generally because of the high cost and the comparable effect of oral cobalt administration. However, vitamin B_{12} (hydroxocobalamin) may be a suitable therapeutic agent. One injection of 1 mg provides protection to lambs for 14 weeks, and for weaners, protection for up to 40 weeks. Treatment of lambs with ovine white liver disease with hydroxocobalamin results in an immediate beneficial response and treatment is repeated 10 days later.[14]

Cobalt toxicity

Overdosing with cobalt compounds is unlikely, but toxic signs of loss of weight, rough hair coat, listlessness, anorexia, and muscular incoordination appear in calves at dose rates of about 40–45 mg of elemental cobalt per 50 kg BW/d. Sheep appear to be much more resistant to the toxic effects of cobalt than are cattle. Pigs have tolerated up to 200 mg cobalt/kg of diet. At intakes of 400 and 600 mg/kg there is growth depression, anorexia, stiff legs, incoordination and muscle tremors. Supplementation of the diet with methionine, or with additional iron, manganese and zinc alleviates the toxic effects.

CONTROL

Supplement diet with cobalt

The recommended level of cobalt in the diet for sheep and cattle has for many years been about 100 μg/kg DM. Based on the levels of homocysteine and methylmalonic acid together with the vitamin B_{12} and hepatic folate status as predictors of the magnitude of cobalt-vitamin B_{12} status in assessing the cobalt requirements in cattle, the recommended levels of dietary cobalt to achieve maximum vitamin B_{12} levels are 250 μg/kg DM.[40] If such levels are not available, supplementation of the diet with cobalt is necessary. Calves reared on cobalt-deficient pastures require cobalt or vitamin B_{12} supplementation prior to weaning.[41]

Top dressing of pastures with cobalt

Cobalt deficiency in grazing animals can be prevented most easily by the top-dressing of affected pasture with cobalt salts. The amount of top-dressing required will vary with the degree of deficiency. Recommendations include 400–600 g/ha cobalt sulfate annually or 1.2–1.5 kg/ha every 3–4 years. The response to pasture treatment is slow, requiring some weeks to complete. Affected animals should be treated orally or by injection of vitamin B_{12} to obtain a quick, interim response.

In New Zealand, the requirement for cobalt of ruminants grazing on the pumice soils of the Central Plateau was established in the 1930s and top-dressing to increase the cobalt intake was widely practiced for many years. An on-farm survey conducted in 1978–1979 indicated that cobalt inputs could be halved because adequate reserves of soil cobalt had accumulated. However, the economic downturn in agriculture resulted in less use of cobalt, and follow-up surveys indicated a general overall decline in soil and pasture cobalt levels, which was pronounced in areas with a poor history of cobalt top-dressing. There is now a need to increase the soil level of cobalt to prevent cobalt deficiency in grazing ruminants. A regular cobalt input is required to build up reserves. This input requirement is about 350 g cobalt sulfate/ha for 7–10 years on

the most deficient areas. Individual farm to farm variation exists within an area and it is necessary to monitor their soil, pasture, and animal cobalt status. To achieve a level of cobalt of 0.08 mg/kg DM in pasture (the critical level for sheep) a soil cobalt level of 1.7 and 2.2 mg/kg DM is required for the yellow-brown pumice soils and yellow-brown loams, respectively.[42]

Supplementation of the diet with 0.1 mg cobalt/d for sheep and 0.3–1.0 mg/d for cattle is required, and can be accomplished by inclusion of the cobalt in salt or a mineral mixture. Cobalt can also be supplied to cattle in their drinking water supply.

Cobalt-heavy pellet

The use of 'heavy pellets' containing 90% cobalt oxide is an alternative means of overcoming the difficulty of maintaining an adequate cobalt intake in a deficient area. The pellet is in the form of a bolus (5 g for sheep, 20 g for cattle) which, when given by mouth, lodges in the reticulum and gives off cobalt continuously in very small but adequate amounts. Reports on their use in sheep and cattle indicate that they are effective. Administration of the pellets to lambs and calves less than 2 months old is likely to be ineffective because of failure to retain them in the undeveloped reticulum. The problem of cobalt deficiency in sucking animals can be overcome in part if the dams are treated because of the increased vitamin B_{12} content of their milk, but the daily intake of the lambs will still be much below the minimal requirement. In about 5% of animals, the pellets do not lodge in the reticulum and approximately 20% are rejected during the year after administration. If no response occurs, re-treatment is advisable. A further possible cause of failure is where pellets become coated with calcareous material, particularly if the drinking water is highly mineralized or if pasture top-dressing is heavy. The effects of pellet coating can be overcome by simultaneous dosing with an abrasive metal pellet. The cost is relatively high and, where top-dressing of pastures is practiced, addition of cobalt to the fertilizer is the cheaper form of administration. Pellets are preferred in extensive range grazing where top-dressing is impracticable and animals are seen only at infrequent intervals.

Controlled release glass boluses of cobalt

Boluses of controlled release glass containing cobalt are available for oral administration to cattle and sheep. The boluses are retained in the forestomachs for up to several months and slowly release cobalt.

Combine cobalt with administration of anthelmintics

Anthelmintics are convenient and efficient vehicles for supplementing the diet with selenium and cobalt on a regular basis, because both the selenium and cobalt status of lambs decline as they become dependent on forage, with its adherent nematode larvae, for their nutrients. As a result, the periods of highest incidence of cobalt and selenium deficiency and helminthiasis coincide. In one trial, there were lasting responses to selenium but transient, though significant, responses to the cobalt in the form of increases in plasma vitamin B_{12}. In some trials, the administration of a monthly bolus of 250 mg cobalt was more effective than the cobalt in the anthelmintic. The optimum level of cobalt supplementation of an anthelmintic ranges from 20 to 100 mg cobalt per treatment. When the anthelmintic is given at 3-weekly intervals, there may be a cumulative effect. A comparison of giving 500 µg cyanocobalamin subcutaneously to one group of lambs, with 2.5 mg cobalt orally in an anthelmintic to another group, revealed that even the lowest dose of cobalt in anthelmintics will be of some nutritional benefit.[43]

Vitamin B_{12} injections

The relationship in lambs between daily weight gains and vitamin B_{12} status in the serum and liver vitamin B_{12} concentrations is well defined. Lambs with serum vitamin B_{12} concentrations >335 pmol/L and liver vitamin B_{12} concentrations <280 nmol/kg fresh tissue are cobalt deficient and will show a marked increase in growth rates when supplemented with cobalt or vitamin B_{12}.

The subcutaneous injection of a soluble vitamin B_{12} in lambs was effective in increasing and maintaining the vitamin B_{12} status for about 24 days.[44] In cobalt deficient areas lambs should be given a 2 mg dose of vitamin B_{12} at least bimonthly to reduce the risk of vitamin B_{12} deficiency.[45]

A ***microencapsulated vitamin B_{12} in lactide/glycolide copolymers*** is able to increase and maintain vitamin B_{12} status of lambs for at least 210 days.[46] The treatment of ewes grazing cobalt deficient pastures 4–5 weeks prior to mating should ensure an increase in the storage of vitamin B_{12} in the fetal liver and an increase in the vitamin B_{12} content of colostrum and milk. The growth rates of cobalt deficient lambs, 4–6 weeks of age, were markedly improved by injections of 3.0, 4.5, or 6.0 mg of microencapsulated vitamin B_{12} and live weights were maintained for at least 260 days.[47] An injection of 3 mg microencapsulated vitamin B_{12} given to lambs at tailing will prevent cobalt deficiency and increase and maintain live weight gains in a flock for up to 8 months.

The vitamin B_{12} status of ewes can be increased during gestation and lactation by three injections of a long-acting preparation of vitamin B_{12} microencapsulated in an organic acid polymer given subcutaneously at 120 days prepartum (30 days after the ram had bred the ewes), 40 days prepartum, and 40 days post partum.[48] Compared with controls, serum and liver vitamin B_{12} concentrations of the treated ewes were increased by 70% during gestation. Fetal liver vitamin B_{12} concentrations were increased 270%. Over the lactation, ewe serum and milk vitamin B_{12} concentrations were increased at least 200% and 44%, respectively. The liver vitamin B_{12} stores of the newborn lambs from vitamin B_{12} treated ewes were depleted within 58 days. Ewes with a high vitamin B_{12} status will ensure an adequate supply of vitamin B_{12} to their lambs for at least the first 30 days of life.

A long-acting injectable microencapsulated vitamin B_{12} at a dose rate of 0.12–0.24 mg/kg BW will increase and maintain the vitamin B_{12} in dairy calves for at least 110 days.[2,49]

COPPER DEFICIENCY

Synopsis

Etiology Primary copper deficiency due to inadequate levels in diet. Secondary copper deficiency due to conditioning factors such as excess molybdenum and sulfur in the diet.
Epidemiology Primarily in young pastured ruminants (cattle, sheep, goats, and farmed deer) in spring and summer. Primary deficiency occurs in sandy soil and heavily weathered areas; secondary in peat or muck soil areas. Feed and water supplies may contain molybdenum, sulfate and iron salts, which interfere with copper metabolism. May be congenital in newborn lambs (swayback) if ewes deficient or delayed in nursing lambs (enzootic ataxia). Some breeds of sheep highly susceptible.
Signs Herd problem. Young growing ruminants on pasture. Unthriftiness, changes in hair color, chronic diarrhea in molybdenosis (secondary deficiency), chronic lameness, neonatal ataxia, anemia later stages of deficiency and falling disease in adult cattle.
Clinical pathology Low serum and hepatic copper. Ceruloplasmin. Anemia.
Necropsy findings Anemia, emaciation, hemosiderosis, osteodystrophy, demyelination in enzootic ataxia, myocardiopathy.
Diagnostic confirmation Low serum and hepatic copper and response to treatment.
Differential diagnosis list
Copper deficiency must be differentiated from herd problems associated with the following clinical findings:

- Unthriftiness due to intestinal parasitism
- Malnutrition due to energy-protein deficiency
- Lameness caused by osteodystrophy due to calcium, phosphorus, and vitamin D imbalance
- Anemia due to pediculosis
- Neonatal ataxia in lambs (congenital swayback and enzootic ataxia) from border disease; cerebellar hypoplasia (daft lamb disease); hypothermia; meningitis
- Sudden death due to other causes .

Treatment Copper sulfate orally; copper glycinate parenterally.
Control Provide source of copper by oral dosing or dietary supplementation in feed or on pasture. Parenteral administration of copper at strategic times. Copper oxide needles orally for prolonged effectiveness. Controlled-release boluses. Genetic selection. Removal of sulfates from water supply.

ETIOLOGY

Copper deficiency may be primary, when the intake in the diet is inadequate, or secondary (conditioned) when the dietary intake is sufficient but the utilization of the copper by tissues is impeded.

Primary copper deficiency

The amount of copper in the diet may be inadequate when the forage is grown on deficient soils or on soils in which the copper is unavailable.

Secondary copper deficiency

In secondary copper deficiency, the amount of copper in the diet is adequate, but conditioning dietary factors interfere with the utilization of the copper. Such secondary copper deficiencies are summarized in Table 30.2. The administration of copper is preventive and curative. The conditioning factor is known only in some instances, but a **dietary excess of molybdenum** is one of the most common. A high molybdenum intake can induce copper deficiency even when the copper content of the pasture is quite high and a higher copper intake can overcome the effect of the molybdenum. Conversely, supplementation of the diet with molybdenum can be used to counteract the copper intake when its content in the diet is dangerously high. There are species differences in response to high copper and molybdenum intake; sheep are much more susceptible to copper poisoning, cattle to excess molybdenum.

Zinc, iron, lead, and calcium carbonate are also conditioning factors and in New Zealand, the administration of selenium to sheep on copper-deficient pastures increases copper absorption and improves the growth rate of lambs. The use of zinc sulfate for the control of facial eczema may cause a depression of plasma copper levels, which can be alleviated by the injection of copper glycinate.

Dietary inorganic sulfate in combination with molybdenum has a profound effect on the uptake of copper by ruminants. Sheep consuming a complete diet, low in sulfur and molybdenum and with a modest 12–20 mg copper/kg dry matter (DM), may die from copper toxicity, while others grazing pasture of similar copper content but high in molybdenum and sulfur can give birth to lambs affected with the copper deficiency disease swayback.[1] An increase of sulfate concentration in a sheep diet from 0.1% to 0.4% can potentiate a molybdenum content as low as 2 mg/kg (0.02 mmol/kg) to reduce copper absorption to below normal levels. Additional sulfate in the diet also has a depressing effect on the absorption of selenium so that areas of a country with marginal copper and selenium levels in the soil may produce deficiency syndromes in animals if sulfate is added; this is likely to happen when heavy dressings of superphosphate are applied. Such combined deficiencies are becoming more common. The possibility of interaction between copper and selenium must also be considered because of the reported failure of animals to respond to treatment unless both elements are provided.

EPIDEMIOLOGY

Occurrence

Copper deficiency is endemic in ruminants worldwide and causes diseases of economic importance that may be severe enough to render large areas of otherwise fertile land unsuitable for grazing by ruminants of all ages, but primarily young, growing ruminants. Based on serum copper surveys of cattle herds in Britain, copper deficiency constitutes a serious problem requiring vigilance. It is estimated that characteristic clinical signs of copper deficiency develop annually in about 0.9% of the cattle population in the UK. In some surveys, the lowest levels of serum copper were in heifers being reared as heifer replacements. Although heavy mortalities occur in affected areas, the major loss is due to

failure of animals to thrive. Enzootic ataxia may affect up to 90% of a lamb flock in badly affected areas and most of these lambs die of inanition. In falling disease, up to 40% of cattle in affected herds may die.

Copper deficiency is the most common trace element deficiency in farmed deer in New Zealand.[2] The deficiency in deer is widespread and is a problem in many herds. It can be diagnosed from clinical signs such as enzootic ataxia and osteochondrosis.

Geographical distribution

Primary copper deficiency

The diseases caused by a primary deficiency of copper in ruminants are **enzootic ataxia** of sheep in Australia, New Zealand, and the USA, **licking sickness**, or *liksucht* of cattle in Holland and **falling disease** of cattle in Australia.

Copper deficiency occurs naturally in grazing livestock in many parts of the world. It has long been recognized as an endemic disease in the Salado's river basin in Buenos Aires Province, Argentina, affecting over 50% of the cattle population.[3] Some 81% of this wide area of 56 000 km^2 is devoted to breeding over 6.5 million head of beef cattle. The copper content in the grass is inadequate for most of the year and is most critical in autumn.[4]

A concurrent deficiency of both copper and cobalt occurs in Australia (**coast disease**) and Florida in the USA (**salt sickness**) and is characterized by the appearance of clinical signs of both deficiencies in all species of ruminants. The disease is controlled by supplementation of the diet with copper and cobalt.

In the USA, copper deficiency is not restricted to a single geographic region.[5] In a survey of 2007 beef cows and heifers from 256 herds, 1.7% were deficient and 38% were marginally deficient. In herds, 36% were marginally deficient and 0.8%, deficient. Approximately 50% of the producers reported use of copper supplements, but a significant portion of cattle from those herds were classified as marginally deficient or deficient.

A survey in Saskatchewan, Canada, found that 67% of slaughter cattle had liver levels lower than 10 mg copper/kg on a wet weight (WW). A survey of the copper status of the fetuses and livers from adult animals found that 20% of steers, 54% of pregnant cows, 52% of heifers, and 77% of non-pregnant cows had liver levels <25 mg/kg DM. The concentrations of copper in the liver of the fetuses were directly proportional to the liver copper concentrations in the dams. Liver copper levels of fetuses from dams with liver copper >25 mg/kg DM were higher than those in fetuses from dams with liver copper levels <25 mg/kg DM. During gestation, the level of copper progressively increased in the fetal liver and decreased in the maternal liver. The concentration of copper in fetal livers increased with increasing fetal age and at term, the newborn calf has high levels of liver copper to meet postnatal requirements because cows' milk is a poor source of copper. The magnitude of copper deficiency in some areas is extensive and emphasizes the importance of adequate copper nutrition in pregnant cattle in order to maintain adequate fetal levels of copper.

Copper deficiency has been diagnosed in Canada in a herd of captive musk-oxen, which had originated in the Northwest Territories.[6]

Copper deficiency may also cause anemia in sucking pigs and reduced growth rate and cardiac disease in growing pigs. Adult horses are unaffected, but abnormalities of the limbs and joints of foals reared in copper-deficient areas do occur. Osteochondrosis is associated with a copper deficiency in young, farmed red deer and wapiti X red deer hybrids in New Zealand.[7]

Secondary copper deficiency

The diseases caused by secondary copper deficiency, mostly due to high dietary intakes of molybdenum and sulfate, are listed in Table 30.2. They include syndromes characterized by diarrhea or by unthriftiness. **'Yellow calf'**, a disease of nursing calves occurs on Hawaii's rangeland where copper content of forages ranges from 2.6 to 11.8 mg/kg and the molybdenum from <1 to 39 mg/kg. **Swayback** of lambs in the UK has been classed as a secondary copper deficiency, but no conditioning factor has been determined. While swayback is a naturally occurring disease caused by a primary deficiency of copper, identical lesions occur experimentally by feeding molybdenum and sulfate to the ewes. There is some evidence that heavy lime dressing of a pasture may predispose to swayback. A wasting disease similar to **peat scours** and preventable by the administration of copper and unthriftiness ('pine') of calves, occur in the UK, but in both instances the copper and molybdenum intakes are normal. Molybdenum appears to be the conditioning agent in enzootic ataxia in the USA. A dietary excess of molybdenum is known to be the conditioning factor in the diarrheic diseases, peat scours in New Zealand, California, and Canada and 'teart' in Britain.

High concentrations of molybdenum in forage (21–44 mg/kg DM) have been identified in several reclaimed mining areas in British Columbia but cattle have grazed these areas for 12-week periods yearly for 3 years without developing secondary copper deficiency.[8] One-half of the animals received a copper supplement and there were no differences in weight gain, liver molybdenum, serum copper, and molybdenum and milk copper and molybdenum between the two groups. The results indicated that the upper tolerable dietary concentrations of 5–10 mg molybdenum described by the National Research Council and the minimum safe copper to molybdenum ratio of 2:1 are not universal.[8]

Moose sickness is a disease of moose (*Alces alces L.*) in Sweden.[9] The disease has also been known as **'Alvsborg disease'** and 'wasting disease'. About 4–5% of the moose population is affected annually. The appearance of the disease coincided with intensified liming of wetlands, lakes, and forests during the 1980s, undertaken to counteract the deleterious effects of acid rain. The increase in pH caused by the liming affected the availability of nutrients in the soil, reducing copper availability and increasing molybdenum.

Copper deficiency may be a factor contributing to the population decline of moose in North-western Minnesota.[10] In moose found dead, the copper concentrations based on criteria set for cattle, were deficient in 39.5% of livers, marginally deficient in 29.5% and adequate in 31%.[10]

Table 30.2 Secondary copper deficiency status

Disease	Country	Species affected	Copper level in liver	Probable conditioning factor
Swayback	Britain, USA	Sheep	Low	Unknown
Renguerra	Peru	Sheep	Low	Unknown
Teart	Britain	Sheep and cattle	Unknown	Molybdenum
Scouring disease	Holland	Cattle	Unknown	Unknown
Peat scours	New Zealand	Cattle	Low	Molybdenum
Peat scours	Britain	Cattle	Unknown, low level in blood	Unknown
Peat scours	Canada	Cattle	Unknown	Molybdenum

'Pine' (unthrifty)	Scotland	Calves	Low	Unknown

The lower concentrations of copper in moose from bog and forest areas compared with the agricultural and prairie areas of North-western Minnesota coincide with a lower calf-to-cow ratio in the north-west forest area compared with the northwestern prairies.

Seasonal incidence

Both primary and secondary copper deficiency occur most commonly in spring and summer coinciding with the lowest levels of copper in the pasture.

Large monthly variations occur in the serum levels of copper in both beef and dairy cattle and are commonly correlated with the rainfall; the higher the rainfall the lower the copper level.

The incidence of secondary copper deficiency may be highest at other times, depending upon the concentration of the conditioning factor in the forage. For example, the molybdenum content may be highest in the autumn when rains stimulate a heavy growth of legumes.

Risk factors

Several factors influence the plasma and tissue concentrations of copper, particularly in ruminants, including:

- Age of animal
- Demands of pregnancy and lactation
- Stage of growth
- Copper sources available to the animals
- Mineral composition of feed
- Season of the year
- Soil characteristics and its mineral composition
- Breed of animal
- Concentration of minerals, such as sulfur and molybdenum, which can interfere with the availability of copper.

Animal factors

Age susceptibility

Young animals are more susceptible to primary copper deficiency than adults. Calves on dams fed deficient diets may show signs at 2–3 months of age. As a rule, the signs are severe in calves and yearlings, less severe in 2-year-olds and of minor degree in adults. Enzootic ataxia is primarily a disease of sucking lambs whose dams receive insufficient dietary copper. Ewes with a normal copper status take some time to lose their hepatic reserves of copper after transfer to copper-deficient pastures and do not produce affected lambs for the first 6 months. The occurrence of the disease in sucklings and its failure to appear after weaning, point to the importance of fetal stores of copper and the inadequacy of milk as a source of copper. Milk is always a poor source of copper and when it is the sole source of nourishment the intake of copper will be low. Milk from normal ewes contains 20–60 μg/dL (3.1–9.4 μmol/L) copper, but under conditions of severe copper deficiency this may be reduced to 1–2 μg/dL (0.16–0.31 μmol/L).

Breed and species susceptibility

There are marked genetic differences in copper metabolism between breeds of sheep. The Welsh Mountain ewe can absorb copper 50% more efficiently than the Scottish blackface,[11] and the Texel cross blackface 145% more efficiently than pure blackface lambs.[11] The susceptibility to, or protection from, the effects of copper deficiency and also copper poisoning, is influenced from birth by genetic effects. These affect copper status of the lamb at birth, through the maternal environment controlled by the dam's genes and through the effect of the lamb's own genes. Later in life, the animal's own genes become the predominant influence determining its copper status on any given nutritional regimen. These genetic differences have physiological consequences reflected in differences in the incidence of swayback, both between and within breeds and in effects on growth and possibly on reproduction. The differences observed are due to genetic differences in the efficiency of absorption of dietary copper.

The genetic effects determining the copper status of the lamb are already present in utero and the effects are not controlled by the lamb's own genotype but by that of its dam. The maternal effect is still present at weaning at 9 weeks of age, but disappears after weaning when the genetic differences are due to the sheep's own genotype.

The existence of genes determining plasma copper has been shown by the successful continued selection for high and low concentrations in closed lines of a single breed type. Ram selection is made on the basis of plasma copper concentrations at 18 and 24 weeks of age. The proportion of the normal variation in plasma copper that is heritable is 0.3. The high-line female sheep retain more copper in the liver than the low-line females, caused by a positive correlation between the concentration of copper in plasma and the efficiency of absorption.

The genetic variation in the copper metabolism of sheep has important physiological consequences. Breeds show wide variation in their susceptibility to swayback; the incidence of swayback may vary from 0 to 40% between breeds within one flock and the incidence according to breed type is closely related to the differences in the concentration of copper in the liver than in blood. When these high and low female lines are placed on improved and limed pasture, which can induce a severe copper deficiency, soon after birth there are indications of swayback, general dullness, lack of vigor and mortality in the lambs. By 6 weeks of age, the mortality rate is higher in the lambs from the low copper line than in those from the high copper line. In addition, at 6 weeks of age, lambs from the low line are 2 kg lighter than those in the high line.

There are significant differences in the copper requirements and tolerance between goats and sheep.[12] The dietary copper requirements of goats are uncertain but may be higher than in sheep. Dietary levels of copper which could cause copper toxicity in sheep, do not cause toxicity in goats. Some limited data on growth performance indicates a stimulatory effect of 100–300 pap copper in the diet of Nubian goats. Extra copper accumulated in liver and to a lesser extent in other tissues and was excreted through the biliary system and into the feces.

Certain breeds of cattle, e.g. the Simmental and Charolais, may have higher copper requirements than other breeds, e.g. Angus and these differences may be related to differences in copper absorption in the gastrointestinal tract. Angus heifers have a lower minimal copper requirement than Simmental.[13] Based on liver copper, the control diets containing 4.4 mg or 6.4 mg of copper/kg DM did not meet the copper requirement of either breed during gestation and lactation or growth, Addition of 7 mg of copper/kg DM to the control diets met the copper requirements of both breeds.

Fetal liver copper

During gestation, the copper concentration increases progressively in the ovine and bovine fetal liver and decreases in the maternal liver. The developing bovine fetus obtains its copper by placental transfer and at birth, the liver concentration of copper is high and declines postnatally to adult levels within the first few months. Placental transfer is less efficient in sheep and lambs are commonly born with low liver reserves, making the neonatal lambs susceptible to copper deficiency. In copper-deficient cattle, the accumulation of liver copper in the fetus continues independent of the dam's liver copper until the fetus is about 180 days, then a gradual decline in fetal liver copper occurs. The liver copper concentration in fetuses from dams on a copper-adequate diet continues to increase and not decline at 180 days of gestation. All of this indicates an increase in copper requirements by the dam during pregnancy; during the last month of pregnancy, the daily requirement for copper in cattle increases to approximately 70% above the maintenance requirements, which means that the dietary allowance of 10 mg/kg DM needs to be increased up to 25 mg/kg

DM during pregnancy. The concentrations of copper, iron, manganese, and zinc are consistently lower than normal in the livers of aborted fetuses, indicating a nonspecific change in trace element status which is probably an effect of abortion and not a cause.

Colostrum is rich in copper, allowing the newborn with its preferential ability to absorb copper to increase hepatic stores. Later, the copper content of milk declines rapidly so that it is usually insufficient to meet the requirements of the sucking neonate for copper. The young milk-fed animal is able to absorb about 80% of its copper intake, but the efficiency of absorption declines with age as the rumen becomes functional, when only 2–10% of available copper is absorbed.

Dietary factors

Pasture composition

The absorption (or availability) of copper is influenced by the type of diet, the presence of other substances in the diet such as molybdenum, sulfur, and iron, the interaction between the type of diet and the chemical composition of the diet and the genetic constitution of the animals. Copper is well-absorbed from diets low in fiber, such as cereals and Brassicas, but poorly absorbed from fresh forage. Conservation of grass as hay or silage generally improves its availability. This explains why copper deficiency is a problem of the grazing animal and seen only rarely in housed ruminants receiving diets that are commonly adequate in copper.

Molybdenum and sulfur

Only small increases in the molybdenum and sulfur concentration of grass will cause major reductions in the availability of copper. This is especially notable in ruminants grazing improved pastures in which the molybdenum and sulfur concentrations were increased. The copper content of feedstuffs should be expressed in terms of available copper concentration, using appropriate equations, which permits a more accurate prediction of clinical disease and can be used for more effective control strategies.

The effect of changes in molybdenum and sulfur concentrations in grass on the availability of copper is changed by conservation. At a given concentration of sulfur, the antagonistic effect of molybdenum is proportionately less in hay than in fresh grass. At a low concentration of molybdenum, the effect of sulfur is more marked in silage than in fresh grass. The use of formaldehyde as a silage additive may weaken the copper sulfur antagonism and yield material of high availability. Thus, fields of herbage high in molybdenum should be used for conservation when possible and sulfuric acid should not be used as an additive for silage unless accompanied by a copper salt because it significantly raises the sulfur concentration of the silage.

Copper in diet

For general purposes, pasture containing <3 mg/kg DM of copper will result in signs of deficiency in grazing ruminants. Levels of 3–5 mg/kg DM can be considered as dangerous and levels >5 mg/kg DM (preferably 7–12) are safe unless complicating factors cause secondary copper deficiency. The complexity of minimum copper requirements, affected as they are by numerous conditioning factors, necessitates examination under each particular set of circumstances. For example, plant molybdenum levels are related directly to the pH reaction of the soil. Grasses grown on strongly acidic molybdenum-rich soils are characterized by low molybdenum values (<3 mg/kg DM), whereas those associated with alkaline molybdenum-poor soils may contain up to 17 mg/kg DM. Thus, it seems likely that conditioned copper deficiency can be related to regionally enhanced levels of plant available rather than soil molybdenum. Heavily limed pastures are often associated with a less than normal copper intake and a low copper status of sheep grazing them. Secondary copper deficiency is also recorded in pigs whose drinking water contains very large amounts of sulfate.

Dietary iron

A dietary intake of iron can interfere with copper metabolism.[14] Dietary levels of iron in the range of 500–1500 mg/kg DM, within the range of their fluctuation in silage and forage and higher levels, are a risk of inducing copper deficiency in ruminants, especially when the copper intake is marginal. Ruminants obtain iron from ingested soil and mineral supplements and, in areas where hypocuprosis is likely to occur, the risk can be minimized by avoiding the use of mineral supplements of high iron content, minimizing the use of bare winter pasture and avoiding the excessive contamination of silage with soil during harvesting.

Molybdenum-induced secondary copper deficiency in cattle occurred when motor oil containing molybdenum bisulfide was spilled on a pasture located on the side of a railway bed near the farm.

Stored feeds

Livestock that are housed have a slightly different dietary intake to those on pasture. Concentrates and proprietary feeds usually contain adequate copper. Pasture is less likely to contain sufficient copper, especially in early spring when the grass growth is lush and silage and haylage may be deficient. Hay is more mature and usually contains more of all minerals, so that animals housed for the winter are protected against copper deficiency for a few weeks after they come out onto pasture in the spring. Young, growing animals will be first affected. These comments should not be interpreted to mean that housed or feedlot animals cannot be affected by hypocuprosis; they can if the locally produced feed is copper-deficient, or more likely has a high concentration of molybdenum. Both are likely to be prevented, or less severe, if there is some supplementary feeding.

Soil characteristics

Copper deficiency

In general, there are two types of soil on which copper-deficient plants are produced. Sandy soils, poor in organic matter and heavily weathered, such as on the coastal plains of Australia and in marine and river silts, are likely to be deficient in copper as well as other trace elements, especially cobalt.

The second important group of soils is 'peat' or muck soils reclaimed from swamps and are soils more commonly associated with copper deficiency in the USA, New Zealand, and Europe. Such soils may have an absolute deficiency of copper, but more commonly, the deficiency is relative in that the copper is not available and the plants growing on the soils do not contain adequate amounts of the element.

The cause of the lack of availability of the copper is uncertain, but is probably the formation of insoluble organic copper complexes. An additional factor is the production of secondary copper deficiency on these soils due to their high content of molybdenum. A summary of the relevant levels of copper in soils and plants is given in Table 30.3.

Molybdenum excess

Pastures containing <3 mg/kg DM of molybdenum are considered to be safe, but disease may occur at 3–10 mg/kg DM if the copper intake is low. Pastures containing >10 mg/kg DM of molybdenum are dangerous unless the diet is supplemented with copper. Excess molybdenum may occur in soils up to levels of 10 and even 100 mg/kg. Perhaps more dangerous is the risk that overzealous application of molybdenum to pasture to increase bacterial nitrogen fixation may have similar effects, which are likely to be long-lasting.

In the UK, appreciable land is underlain by marine black shales rich in molybdenum, resulting in a high content of molybdenum in the soil and pastures and in a secondary copper deficiency that, potentially, limits livestock performance. Secondary (conditioned) copper deficiency is now recognized in cattle in many parts of Canada. Large areas of west-central Manitoba are underlain by molyb-

Table 30.3 Copper levels of soils and plants in primary and secondary copper deficiency

Condition	Area	Soil type	Soil copper (mg/kg)	Plant copper (mg/kg DM)
Normal	–	–	18–22	11
Primary copper deficiency	West Australia	Various	1–2	3–5
	New Zealand	Sand	0.1–1.6	3
	New Zealand	Peat	–	3
	Holland	Sand	–	<3
Secondary copper deficiency	New Zealand	Peat	5	7
	Britain	Peat	–	7–20
	Britain	Limestone	–	12–27
	Britain	Stiff clay	–	11
	Ireland	Shale deposits, peat marine, alluvial soils		
	Holland	Sand	–	>5
	Canada	Burned-over peat	20–60	10–25

deniferous shale bedrocks and the soil contain up to 20 mg/kg of molybdenum. However, in the same geographical location, hypocupremia may be associated with a primary deficiency of copper in the forage, or a secondary copper deficiency due to molybdenum in the forages.

In New Zealand, soil types have been identified which produce pastures that have molybdenum concentrations, varying from 3.5 to 20 mg/kg DM.[2] In some deer herds, copper deficiency may be molybdenum induced rather than due to low copper intake alone. Increasing the pasture molybdenum concentrations from 2 mg/kg DM to 4.6 mg/kg DM significantly reduced serum and liver copper concentrations in grazing red deer.[2] Reduced growth rate occurred when pasture molybdenum >10 mg/kg DM.

PATHOGENESIS

Effects on tissues

The consequences of hypocuprosis include a failure of copper metalloenzymes, many of which form part of the antioxidant defense system such as copper/zinc superoxide dismutase (Cu/Zn SOD) and ceruloplasmin.[15] Copper, as well as other essential trace elements, is an atypical antioxidant because it functions indirectly. Copper is a catalytic cofactor for Cu/Zn SOD and ceruloplasmin. Cu/Zn SOD catalyzes dismutation of the superoxide anion, producing molecular oxygen and hydrogen peroxide, with the latter product usually metabolized by glutathione peroxidase and catalase. The ferroxidase activity of ceruloplasmin mediates the oxidation of ferrous ions to the ferric state, thereby preventing ferrous ion-dependent formation of hydroxyl radicals via the Fenton reaction. Thus, in enabling Cu/Zn SOD and ceruloplasmin to function as described, copper can be classified as part of the antioxidant defense system of cells.

Copper deficiency can affect the antioxidant defense system resulting in oxidative damage to cellular components. The activity of Cu/Zn SOD and glutathione peroxidase is decreased in animals with copper deficiency. Copper deficiency in cattle has been associated with a decrease in Cu/Zn SOD, ceruloplasmin and cytochrome oxidase activity and with an increase in lipid peroxidation. Collectively, this indicates that copper deficiency weakens the antioxidant defense systems.[15]

Ceruloplasmin is the copper-containing enzyme through which copper exerts its physiological function. The pathogenesis of most of the lesions of copper deficiency has been explained in terms of faulty tissue oxidation because of failure of these enzyme systems. This role is exemplified in the early stages of copper deficiency by the changes in the wool of sheep.

Chromosomal abnormalities

The association between copper deficiency and DNA damage in cattle has been examined.[3,15] The Comet assay is a sensitive, reliable and rapid method for the detection of DNA double- and single-strand breaks and alkali-labile sites detection.[16] In naturally-occurring copper deficiency in Aberdeen Angus cattle in Argentina, cytogenetic analysis of peripheral lymphocyte cultures showed a significant increase in the frequency of abnormal metaphases in moderate to severe copper deficient groups. Thus, copper deficiency in cattle is associated with an increase in the frequency of chromosomal aberrations (clastogenic effect) as well as in DNA migration.

Wool

The straightness and stringiness of this wool is due to inadequate keratinization, probably due to imperfect oxidation of free thiol groups. Provision of copper to such sheep is followed by oxidation of these free thiol groups and a return to normal keratinization within a few hours.

Body weight

In the later stages of copper deficiency, the impairment of tissue oxidation causes interference with intermediary metabolism and loss of condition or failure to grow.

Diarrhea

The pathogenesis of copper deficiency in causing diarrhea is uncertain and there is little evidence that a naturally-occurring primary copper deficiency will cause diarrhea. There are no histological changes in gut mucosa, although villous atrophy is recorded in severe, experimentally produced cases. Diarrhea is usually only a major clinical finding in secondary copper deficiency associated with molybdenosis.

Anemia

The known importance of copper in the formation of hemoglobin accounts for the anemia in copper deficiency. The presence of hemosiderin deposits in tissues of copper-deficient animals suggests that copper is necessary for the reutilization of iron liberated from the normal breakdown of hemoglobin. There is no evidence of excessive hemolysis in copper-deficiency states. Anemia may occur in the later stages of primary copper deficiency, but is not remarkable in the secondary form unless there is a marginal copper deficiency, as occurs in peat scours in New Zealand. The unusual relationship in New Zealand between copper deficiency and postparturient hemoglobinuria is unexplained. Heinz body anemia in lambs with deficiencies of copper or selenium and moved from improved pasture to rape (*Brassica napus*) has been reported.

Bone

The osteoporosis that occurs in some natural cases of copper deficiency is caused by the depression of osteoblastic activity.[11] In experimentally induced primary copper deficiency, the skeleton is osteoporotic and there is a significant increase in osteoblastic activity. There is a marked overgrowth of epiphyseal cartilage, especially at costochondral junctions and in metatarsal bones. This is accompanied by beading of the ribs and enlargement of the long bones. There is also an impairment of collagen formation. When the copper deficiency is secondary to dietary excesses of molybdenum and sulfate, the skeletal lesions are quite different and characterized by widening of the growth plate and metaphysis and active osteoblastic activity.

Copper deficiency in foals causes severe degenerative disease of cartilage, characterized by breaking of articular and growth plate cartilage through the zone of hypertrophic cells, resulting in osteochondrosis of the articular-epiphyseal complex (A–E complex).[11] The incidence and severity of osteochondrosis in foals can be decreased by supplementation of the diets of mares during the last 3–6

months of pregnancy and the first 3 months of lactation. Foals from non-supplemented mares have separation of the thickened cartilage from the subchondral bone. Clinical, radiographic, and biochemical differences occur between copper-deficient and copper-supplemented foals and there may be a relationship between low copper intakes in rapidly growing horses, inferior collagen quality, biomechanically weak cartilage, and osteochondritis.[17]

Copper is essential for metalloenzyme lysyl oxidase, which produces aldehydic groups on hydroxylysine residues as a prerequisite for eventual cross-link formation in collagen and elastin. Similar lesions in foals have been attributed to zinc toxicity from exposure of affected animals to pasture polluted by smelters. Experimentally, the addition of varying amounts of zinc to the diet of foals containing adequate copper will result in zinc-induced copper deficiency, but there are no effects with zinc intakes up to 580 ppm and it is suggested that 2000 ppm or higher are necessary to affect copper absorption in horses.[18] Similar lesions of osteochondrosis have occurred in young farmed red deer and wapiti X red deer hybrids in New Zealand.[7]

Connective tissue

Copper is a component of the enzyme lysyl oxidase, secreted by the cells involved in the synthesis of the elastin component of connective tissues and has important functions in maintaining the integrity of tissues such as capillary beds, ligaments, and tendons.

Heart

The myocardial degeneration of falling disease may be a terminal manifestation of anemic anoxia, or be due to interference with tissue oxidation. In this disease, it is thought that the stress of calving and lactation contribute to the development of heart block and ventricular fibrillation when there has already been considerable decrease in cardiac reserve. Experimentally induced copper deficiency in piglets causes a marked reduction in growth and hematocrit and cardiac pathology and electrical disturbances.

Blood vessels

Experimentally produced copper deficiency has also caused sudden death due to rupture of the heart and great vessels in a high proportion of pigs fed a copper-deficient diet. The basic defect is degeneration of the internal elastic laminae. There is no record of a similar, naturally occurring disease. A similar relationship appears to have been established between serum copper levels and fatal rupture of the uterine artery at parturition in aged mares.

Pancreas

Lesions of the pancreas may be present in normal cattle with a low blood copper status. The lesions consist of an increase in dry matter content and a reduction in the concentrations of protein and copper in wet tissue. The cytochrome oxidase activity and protein:RNA ratio are also reduced. There are defects in acinar basement membranes, splitting, and disorganization of acini, cellular atrophy and dissociation and stromal proliferation.

Nervous tissue

Copper deficiency halts the formation of myelin and causes demyelination in lambs, probably by a specific relationship between copper and myelin sheaths. Defective myelination can commence as early as the midpoint of the fetus's uterine life. The focus of lesions in the white matter shifts from the cerebrum in lambs affected at birth (congenital swayback) to the spinal cord in delayed cases, which may reflect respective peaks of myelin development at those sites at 90 days' gestation and 20 days after birth. The postnatal development of delayed swayback has been confirmed through its control by copper supplementation after birth. In experimental animals, it has been shown that copper deficiency does interfere with the synthesis of phospholipids. While anoxia is a cause of demyelination, an anemic anoxia is likely to occur in highly deficient ewes and anemic ewes produce a higher proportion of lambs with enzootic ataxia, there is often no anemia in ewes producing lambs with the more common subacute form of the disease. Severely deficient ewes have lambs affected at birth and in which myelin formation is likely to have been prevented. The lambs of ewes less severely deficient have normal myelination at birth and develop demyelination in postnatal life.

Reproductive performance

There is no evidence that copper deficiency causes reproductive failure in dairy cows. Copper glycinate given to dairy cattle does not affect the average interval in days between calving and first observed heat, services per conception, or first service conception rate compared with untreated cows in the same population. Experimentally, the addition of molybdenum to the diet of heifers delayed the onset of puberty, decreased the conception rate and caused anovulation and anestrus in cattle without accompanying changes in copper status or in live weight gain. Thus, the presence of molybdenum rather than low copper status may affect reproductive performance of cattle. Geochemical data indicate that approximately 10% of the cultivated area of England and Wales has soils that may result in forage molybdenum concentrations similar to those used in the above experimental diet. It appears inadvisable to ascribe poor reproductive performance to subclinical hypocuprosis on the evidence of blood copper analysis alone. Other factors, such as management and energy and protein intake, should be examined.

Immune system

Copper is an essential trace mineral with an important role in the immune response but the precise mechanism is not well understood. In experimental secondary copper deficiency in cattle induced by molybdenum at 30 ppm and sulfate at 225 ppm, the intracellular copper content of peripheral blood lymphocytes, neutrophils, and monocyte-derived macrophages was reduced between 40% and 70%.[19] In copper deficient animals, the serum ceruloplasmin activity decreased to 50% of control values. Both the copper-zinc-superoxide dismutase and the cytochrome c oxidase activities are significantly reduced in leukocytes. Thus, copper deficiency alters the activity of several enzymes, which mediate antioxidant defenses and ATP formation. These effects may impair cell immune function, affecting the bactericidal capacity and making the animals more susceptible to infection.

Copper deficiency results in decreased humoral and cell-mediated immunity, as well as decreased non-specific immunity regulated by phagocytic cells, such as macrophages and neutrophils.[20,21] The decreased resistance to infection in sheep is amenable to treatment with copper and genetic selection. In lambs genetically selected for low and high concentrations of plasma copper, the mortality from birth to 24 weeks of age in the high line was half that in the low line. Most of the losses were due to a variety of microbial infections. Experimental viral and bacterial infections of cattle can cause a rapid, though transient, increase in serum ceruloplasmin and plasma copper in copper-replete animals, suggesting a major protective role for copper in infectious diseases. These changes in copper metabolism evolve from an interleukin-1 mediated increase in hepatic synthesis and release of ceruloplasmin, an acute phase protein. Copper concentrations in organs involved in immune regulations such as liver, spleen, thymus, and lung are substantially reduced by copper deficiency, suggesting that copper-deficient animals are at greater risk for infection than copper-adequate animals. However, experimental low copper diets with or without supplemental molybdenum does not alter the specific immunity of stressed cattle.[22]

The severity of copper depletion needed for immune dysfunction is less than

required to induce clinical signs of copper deficiency and endogenous copper may contribute to the regulation of both non-immune and immune inflammatory responses. Low molecular weight complexes may have an anti-inflammatory effect in animal models of inflammation and it is postulated that the elevation of plasma copper-containing components during inflammatory disease represents a physiological response.

In experimental coliform mastitis in dairy cattle, copper in the diet at 20 ppm reduced the clinical response but not duration of the mastitis compared with animals receiving 6.5 ppm beginning 60 days prepartum through 42 days of lactation.[23] Liver copper in the supplemented group was 162 and 33 ppm at calving and 256 and 45 ppm at 42 days post partum, respectively.

Copper deficiency in heifers in Northern India was associated with significant reduction in the candidacidal activity of neutrophils compared with copper supplemented animals.[24]

Sequence of clinical signs development

In experimental copper deficiency in calves, beginning at 6 weeks of age, subclinical and clinical abnormalities appear after the following intervals: hypocupremia at 15 weeks, growth retardation from 15 to 18 weeks, rough hair coat at 17 weeks, diarrhea at 20 weeks and leg abnormalities at 23 weeks. These signs correlate well with the onset of hypocupremia and are indicative of a severe deficiency. Even with these signs of deficiency, the histological abnormalities may be only minor in degree.

In experimental primary copper deficiency in calves, beginning at 12 weeks of age, clinical signs of the deficiency may not become apparent for about 6 months. Musculoskeletal abnormalities include a stilted gait, a 'knock-kneed' appearance of the forelimbs, overextension of the flexors, splaying of the hooves and swellings around the metacarpophalangeal and carpometacarpal joints. Changes in hair pigmentation occur after about 5 months and diarrhea between 5 and 7 months. The diarrhea ceased 12 h after oral administration of a small amount (10 mg) of copper.

Copper–molybdenum–sulfate relationship

The interaction between copper, molybdenum, and sulfur in ruminant nutrition is unique in its effects on health and production. Copper, molybdenum, and sulfur from organic or inorganic sources can combine in the rumen to form an unabsorbable triple complex, copper tetrathiomolybdate and deplete the host tissues of copper.[1]

Secondary or conditioned copper deficiency occurs when the dietary intake of copper is adequate, but absorption and utilization of the copper are inadequate because of the presence of interfering substances in the diet.[1] Molybdenum and sulfate alone or in combination can affect copper metabolism and the mechanisms by which this occurs are now being clarified. This effect also operates in the fetus and interferes with copper storage in the fetal liver. Besides the relationship with molybdenum, an interaction between the absorption of copper and selenium has been demonstrated, the administration of selenium to sheep on copper-deficient pastures causing an improvement in copper absorption.

The toxicity of any level of dietary molybdenum is affected by the ratio of the dietary molybdenum to dietary copper. The critical copper:molybdenum ratio in animal feeds is 2 and feeds or pasture with a lower ratio may result in conditioned copper deficiency. In some regions of Canada, the copper:molybdenum ratio will vary from 0.1 to 52.7. Higher critical ratios closer to 4.1–5.1 have been recommended for safety. The influence of dietary molybdenum on copper metabolism in ponies has been examined experimentally.

The copper status of growing calves can also be affected to a similar degree by the inclusion of appropriate levels of supplementary iron or molybdenum in the diet. Following such inclusion, the liver and plasma concentrations of copper will decline within 12–16 weeks to levels indicating severe copper deficiency. The clinical signs of copper deficiency, as indicated by reduced growth rate and changes in the hair texture and color, are evident after 16–20 weeks only in animals supplemented with molybdenum. The reduced growth rate was accompanied by a decreased feed intake and reduced efficiency of feed utilization.

Copper absorption

On the basis of a response to copper injections and no response to copper administered orally to sheep on a high molybdenum intake, it is suggested that interference occurs with the absorption of copper from the gut.

It is proposed that thiomolybdates form in the rumen from the reaction of dietary molybdenum compounds with sulfides produced from the reduction of dietary sulfur compounds by rumen bacteria. The thiomolybdates reduce the absorption of dietary copper from the intestine and also inhibit a number of copper-containing enzymes, including ceruloplasmin, cytochrome oxidase, superoxide dismutase and tyrosine oxidase.

Copper utilization

Sulfate and molybdate can interfere with mobilization of copper from the liver, inhibition of copper intake by the tissues, inhibition of copper transport both into and out of the liver and inhibition of the synthesis of copper-storage complexes and ceruloplasmin.

The clinical signs of hypocuprosis (such as steely wool) can occur in sheep on diets containing high levels of molybdenum and sulfate, even though blood copper levels are high. This suggests that under these circumstances copper is not utilizable in tissues and the blood copper rises in response to the physiological needs of the tissues for the element. In pigs, a copper–molybdenum complex can exist in animals and that in this form the copper is unavailable. This would interfere with hepatic metabolism of copper and the formation of copper-protein complexes such as ceruloplasmin.

Hepatic storage

The copper status of the liver depends on whether the animals are receiving adequate dietary copper. With adequate dietary levels, the liver copper levels are less in the presence of molybdate and sulfate. If the animals are receiving a copper-deficient diet such that copper is being removed from the liver, then the molybdate plus sulfate animals retain more copper in their liver than copper-deficient animals not receiving sulfate plus molybdate. This supports the hypothesis that molybdate and sulfate together impair the movement of copper into or out of the liver, possibly by affecting copper transport. Sulfate alone exerts an effect. An increase in intake reduces hepatic storage of both copper and molybdenum.

Phases of copper deficiency

The development of a deficiency can be divided into four phases:

1. Depletion
2. Deficiency (marginal)
3. Dysfunction
4. Disease.

During the depletion phase, there is loss of copper from any storage site, such as liver, but the plasma concentrations of copper may remain constant. With continued dietary deficiency, the concentrations of copper in the blood decline during the phase of marginal deficiency. However, it may be some time before the concentrations or activities of copper-containing enzymes in the tissues begin to decline and it is not until this happens that the phase of dysfunction is reached. There may be a further lag before the changes in cellular function are manifested as clinical signs of disease.

Summary
The overall effect of these interactions is as follows. Molybdate reacts with sulfides to produce thiomolybdates in the rumen. The subsequent formation of copper-thiomolybdate complexes isolates the copper from being biologically available.[1] The thiomolybdates reduce the effectiveness of enzymes containing copper and there are some significant interactions between copper, zinc, and iron.

CLINICAL FINDINGS

The general effects of copper deficiency are the same in sheep and cattle, but in addition to these general syndromes, there are specific syndromes more or less restricted to species and to areas. What follows is a general description of the disease caused by copper deficiency, in turn followed by the specific syndromes of enzootic ataxia, swayback, falling disease, peat scours, teart, and unthriftiness (pine).

Cattle

Subclinical hypocuprosis
No clinical signs occur, blood copper levels are marginal or below 57 mg/dL (9.0 mmol/L) and there is a variable response in productivity after supplementation with copper. Some surveys in copper-deficient areas found that about 50% of beef herds and 10% of dairy herds within the same area have low blood levels of blood copper associated with low copper intake from natural forages. The deficiency is likely to be suspected only if production is monitored and found to be suboptimal.

A perplexing feature of subclinical hypocuprosis is the wide variation in improved growth rate obtained when cattle of the same low copper status are given supplementary copper under field conditions.

General syndrome
Primary copper deficiency
Primary copper deficiency causes unthriftiness, loss of milk production, and anemia in adult cattle. The coat color is affected, red and black cattle changing to a bleached, rusty red and the coat itself becomes rough and staring. In severely deficient states, which are now uncommon, calves grow poorly and there is an increased tendency for bones to fracture, particularly the limb bones and the scapula. Ataxia may occur after exercise, with a sudden loss of control of the hindlimbs and the animal falling or assuming a sitting posture. Normal control returns after rest. Itching and hair-licking are also recorded as manifestations of copper deficiency in cattle. Although diarrhea may occur, persistent diarrhea is not characteristic of primary copper deficiency and its occurrence should arouse suspicion of molybdenosis or helminthiasis. In some affected areas, calves develop stiffness and enlargement of the joints and contraction of the flexor tendons causing the affected animals to stand on their toes. These signs may be present at birth or occur before weaning. Paresis and incoordination are not evident.

An increased occurrence of postparturient hemoglobinuria is also recorded, but only in New Zealand and may be unrelated to copper deficiency.

Secondary copper deficiency
This syndrome includes the signs of primary copper deficiency, except that anemia occurs less commonly, probably due to the relatively better copper status in the secondary state, anemia being largely a terminal sign in primary copper deficiency. For example, anemia occurs in peat scours of cattle in New Zealand, but in this instance, the copper intake is marginal. In addition to the other signs, however, there is a general tendency for diarrhea to occur, particularly in cattle. Because diarrhea is not a major sign in naturally occurring primary copper deficiency it is possible that it is due to the conditioning factor, which reduces the availability of copper. For example, the severity of the diarrhea is roughly proportional to the level of intake of molybdenum.

Falling disease
The characteristic behavior in falling disease is for cows in apparently good health to throw up their heads, bellow, and fall. Death is instantaneous in most cases, but some fall and struggle feebly on their sides for a few minutes with intermittent bellowing and running movement attempts to rise. Rare cases show signs for up to 24 h or more. These animals periodically lower their heads and pivot on the front legs. Sudden death usually occurs during one of these episodes.

Peat scours ('teart')
Persistent diarrhea with the passage of watery, yellow-green to black feces with an inoffensive odor occurs soon after the cattle go on to affected pasture, in some cases within 8–10 days. The feces are released without effort, often without lifting the tail. Severe debilitation is common, although the appetite remains good. The hair coat is rough and depigmentation is manifested by reddening or gray flecking, especially around the eyes, in black cattle. The degree of abnormality varies a great deal from season to season and year to year and spontaneous recovery is common. Affected animals usually recover in a few days following treatment with copper.

Unthriftiness (pine) of calves
The earliest signs are a stiffness of gait and unthriftiness. The epiphyses of the distal ends of the metacarpus and metatarsus may be enlarged and resemble the epiphysitis of rapidly growing calves deficient in calcium and phosphorus or vitamin D. The epiphyses are painful on palpation and some calves are severely lame. The pasterns are upright and the animals may appear to have contracted flexor tendons. The unthriftiness and emaciation are progressive and death may occur in 4–5 months. Grayness of the hair, especially around the eyes in black cattle, is apparent. Diarrhea may occur in a few cases.

Sheep

General syndrome
Primary copper deficiency
Abnormalities of the wool are the first observed signs and may be the only sign in areas of marginal copper deficiency. Fine wool becomes limp, glossy and loses its crimp, developing a straight, steely appearance. Black wool shows depigmentation to gray or white, often in bands coinciding with the seasonal occurrence of copper deficiency. The straight, steely defect may occur in similar bands and the staple may break easily. There appear to be some differences between breeds in susceptibility to copper deficiency, Merino sheep appearing to have a higher copper requirement than mutton sheep. The fleece abnormalities of Merino sheep in Australia have not been observed in Romney Marsh sheep in copper-deficient areas in New Zealand, but this may be due in part to the difficulty of detecting abnormality in wool that is normally rather straight and steely. Anemia, scouring, unthriftiness and infertility may occur in conditions of extreme deficiency, but in sheep, the characteristic findings are in the lamb, the disease enzootic ataxia being the major manifestation. Retardation of growth, diarrhea, delay to marketing, and increased mortality are common clinical findings in lambs genetically selected for low plasma copper and placed on improved and limed upland pastures. Osteoporosis, with increased tendency of the long bones to fracture, has also been recorded under conditions of copper deficiency insufficient to cause enzootic ataxia.

Swayback and enzootic ataxia in lambs and goat kids
These diseases have much in common, but there are differences in epidemiology and some subtle clinical ones.

Swayback is the only authentic manifestation of a primary nutritional deficiency of copper in the UK. The incidence can vary greatly among breeds of sheep, reflecting the genetic differences in copper metabolism both between and within breeds of sheep. The disease occurs in several forms.

A congenital form, cerebrospinal swayback, occurs only when the copper

deficiency is extreme. Affected lambs are born dead or weak and unable to stand and suck. Incoordination and erratic movements are more evident than in enzootic ataxia and the paralysis is spastic in type. Blindness also occurs occasionally. There is softening and cavitation of the cerebral white matter and this probably commences about day 120 of gestation.

Progressive (delayed) spinal swayback begins to develop some weeks after birth with lesions and clinical signs appearing at 3–6 weeks of age.

Postnatal acute fatal swayback may be a third form of the disease and appears to occur only in Wales. It resembles the more usual delayed form, but develops suddenly. There is a sudden onset of recumbency with death occurring 1–2 days later due to acute swelling of the cerebrum.

Enzootic ataxia affects only unweaned lambs. In severe outbreaks, the lambs may be affected at birth, but most cases occur in the 1–2-month age group. The severity of the paresis decreases with increasing age at onset. Lambs affected at birth or within the first month usually die within 3–4 days. The disease in older lambs may last for 3–4 weeks and survival is more likely, although surviving lambs always show some ataxia and atrophy of the hindquarters. The first sign to appear in enzootic ataxia is incoordination of the hindlimbs, appearing when the lambs are driven. Respiratory and cardiac rates are also greatly accelerated by exertion. As the disease progresses, the incoordination becomes more severe and may be apparent after walking only a few yards. There is excessive flexion of joints, knuckling over of the fetlocks, wobbling of the hindquarters and finally falling. The hindlegs are affected first and the lamb may be able to drag itself about in a sitting posture. When the forelegs eventually become involved recumbency persists and the lamb dies of inanition. There is no true paralysis, the lamb being able to kick vigorously even in the recumbent stage. The appetite remains unaffected.

Goats

Enzootic ataxia due to copper deficiency has been reported in young goat kids. The disease is similar in most respects to the disease in lambs. Kids may be affected at birth, or the clinical signs may be delayed until the animals are several weeks of age. Cerebellar hypoplasia is a frequent finding in goats.

Other species

Deer

Enzootic ataxia in red deer is remarkably different from the disease in lambs in that it develops in young adults well past weaning age, and in adults. The clinical signs include ataxia, swaying of the hindquarters, a dog-sitting posture and, eventually, inability to use the hindlimbs. Spinal cord demyelination and midbrain neuronal degeneration are characteristic. Osteochondrosis of young, farmed deer with copper deficiency is characterized by lameness, one or more swollen joints and an abnormal 'bunny-hopping' gait or 'cow-hocked' stance.[7] Copper deficiency in red deer in Australia during a period of drought caused loss of weight in lactating hinds after calving and steely hair coats (the hair had a lustre resembling that of so-called steely wool of copper-deficient sheep). Both adult and yearling stags had normal hair coats but those of the yearling hinds were patchy, with large areas of harsh, light colored, steely hair.[21] The high sulfur content of the diet and possible accidental iron ingestion from being fed on the ground may have resulted in secondary copper deficiency.

Pigs

Naturally occurring enzootic ataxia has occurred in growing pigs 4–6 months of age. Posterior paresis progresses to complete paralysis in 1–3 weeks. Dosing with copper salts had no effect on the clinical conditions, but hepatic copper levels were 3–14 mg/kg (0.05–0.22 mmol/kg). Copper deficiency in piglets 5–8 weeks of age has been reported and was characterized clinically by ataxia, posterior paresis, nystagmus, inability to stand, paddling movements of the limbs and death in 3–5 days. Demyelination of the spinal cord and degenerative lesions of the elastic fibers of the walls of the aorta and pulmonary arteries are present.

The inclusion of copper sulfate, at levels of 125–250 mg/kg of copper, in the diets of pigs 11–90 kg live weight and fed ad libitum, results in slight improvements in growth rate and feed efficiency, but has no significant effect on carcass characteristics. The supplemental copper causes a marked increase in liver copper concentration which poses a potential hazard and it is recommended that copper supplementation be limited to starter and grower diets fed to pigs weighing less than 50 kg live weight.

Horses

Adult horses are unaffected by copper deficiency, but there are unconfirmed reports of abnormalities of limbs of foals. Foals in copper-deficient areas may be unthrifty and slow-growing, with stiffness of the limbs and enlargement of the joints. Contraction of the flexor tendons causes the animal to stand on its toes. There is no ataxia or indication of involvement of the central nervous system. Signs may be present at birth or develop before weaning. Recovery occurs slowly after weaning and foals are unthrifty for up to 2 years.

Geophagia or soil eating in horses in Australia has been associated with larger concentrations of iron and copper in soil samples compared to paired control samples, suggesting that these elements provide the stimulus for geophagia.[25]

CLINICAL PATHOLOGY

The laboratory evaluation of the copper status of farm animals is complex because the biochemical values are often difficult to interpret and to correlate with the clinical state of the animal. Interpretation of the copper status of an individual animal is more difficult than of a herd.

The guidelines for the laboratory diagnosis of primary and secondary copper deficiency in cattle and sheep are summarized in Table 30.4.

Herd diagnosis. The diagnosis of copper deficiency in a herd of animals is based on a combination of collection and interpretation of the history, clinical examination of the affected animals, laboratory tests on serum and liver samples, and examination of the environment including analysis of the feed and water supplies and perhaps soil analysis.[11]

Table 30.4 Copper levels in body tissues and fluids in primary and secondary copper deficiency

Species and tissue	Normal level	Primary copper deficiency	Secondary copper deficiency
Cattle			
Blood plasma (μg/mL) (convert to SI units by multiplying by 15.7 which gives μmol/L)	1.26 ± 31	<0.5 and as low as 0.1–0.2	<0.5 and as low as 0.2–0.3
Adult liver (μmol/kg DM)	>100 (usually 200)	<20 and as low as 4	<10
Milk (mg/L)	0.05–0.20	0.01–0.02	–
Hair (mg/kg)	6.6–10.4	1.8–3.4	5.5
Sheep			
Blood plasma (μg/mL)	0.7–1.3	0.1–0.2	0.4–0.7
Adult liver (μmol/kg DM)	>200 (usually >350)	20	15–19

It is necessary to be especially careful when collecting specimens for copper analysis to avoid contamination by needles, copper distilled water, vial caps, cans for liver specimens and other possible sources of copper. An additional problem is the possible effect of intercurrent disease on plasma levels of copper.

Treatment response trial. A comparison of health and production variables in a group of animals treated with copper and a similar group not treated with copper, is also desirable. Variables include calf growth rates, calf mortality and reproductive performance.[26]

Copper status of herd. In order to assess the copper status of herd, a standard practice is to take blood samples at random from at least 10% of clinically affected animals and from 10% of normal animals. However, this may be inappropriate when there may be a wide variation in the serum copper concentration within a herd. In some cases, a 10% sample may be too large and in other cases too small. The minimal sample size for random samples from a finite population of a normal continuously distributed variable has been calculated as follows:

$$[n = t_2\, cv_2/[(\tilde{N}1)E_2\, t_2\, cv_2]]$$

Where n = minimal sample size; N = herd size; t = Student's t value; cv = coefficient of variation; and E = allowable error.

Initial testing can be used to estimate variability of serum copper concentration within a herd and a minimal sample size may be calculated. Each class of animal according to age groups, diet and production status should also be sampled. Follow-up samples should be taken from the same animals following therapy or the institution of control measures.

Laboratory diagnosis

Historically, the laboratory diagnosis of copper deficiency in cattle and sheep centered on the determination of serum or plasma copper and liver copper. However, serum copper levels alone are not reliable as indicators of copper status and liver samples collected either by liver biopsy or at slaughter should be used to accurately assess copper status in cattle. Clinically normal animals may have marginal levels of serum copper, or unthrifty animals may have marginal or deficient serum levels of copper. Furthermore, when either the normal animals with the marginal levels of copper or the unthrifty animals with the marginal or deficient levels are treated with copper there may or may not be an improvement in weight gain as might be expected in the former, or improvement in clinical condition in the latter.

Phases

The development of a deficiency can be divided into four phases[11] (Fig. 30.1):

1. Depletion
2. Deficiency (marginal)
3. Dysfunction
4. Disease.

During the depletion phase, there is loss of copper from any storage site, such as liver, but the plasma concentrations of copper may remain constant. With continued dietary deficiency, the concentrations of copper in the blood will decline during the phase of marginal deficiency. However, it may be some time before the concentrations or activities of copper-containing enzymes in the tissues begin to decline and it is not until this happens that the phase of dysfunction is reached. There may be a further lag before the changes in cellular function are manifested as clinical signs of disease.

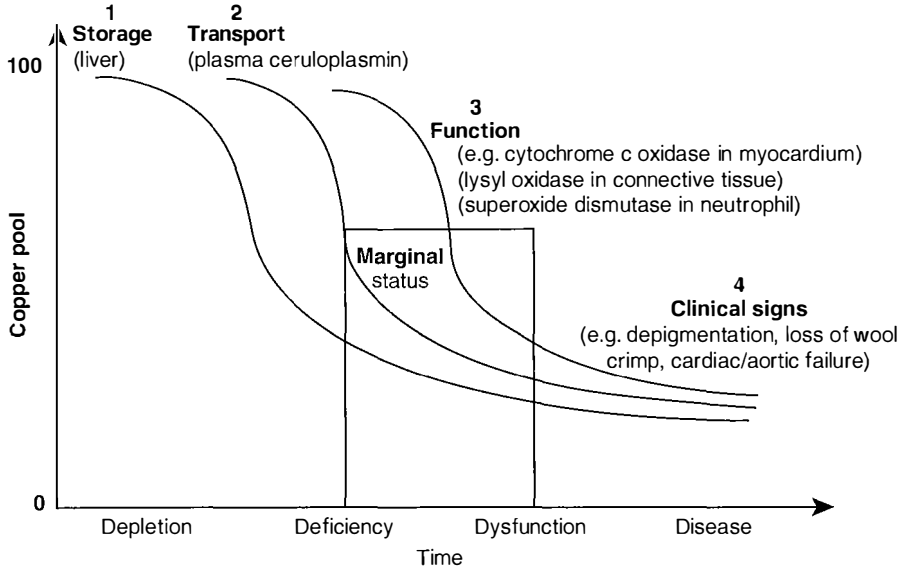

Fig. 30.1 The four phases of copper deficiency.

Interpretation of laboratory results

The three principles governing the interpretation of biochemical criteria of trace element status include:

- The relationships between the concentration of the marker and the intake of the element
- The time the animal is on an adequate diet
- Disturbances of tissue function.

From these principles, the concentrations of liver copper are insensitive indices of deficiency, but good indicators of excess. Plasma copper <57 μg/dL (9 μmol/L) is a good index of marginal deficiency, but values may have to fall to below 19 μg/dL (3 μmol/L) before there is a risk of dysfunction and loss of production in sheep and cattle. However, these are only guidelines. The range of values and the cut-off levels above which animals are normal, or below which they are deficient, have not been well-established. There is considerable biological variation dependent on the species, the breed of animal, the length of time over which the depletion has occurred and the presence of intercurrent disease.

Serum copper concentration in cattle is fairly specific for detection of low liver copper but only marginally sensitive when serum copper concentration of 0.45 μg/g is used as a test endpoint.[27] The value of serum copper concentration as a diagnostic indicator depends on the prevalence of copper deficiency in the particular area.

The interpretation of serum copper can change depending on what liver copper concentration is considered low.[28] With a liver copper <20 μg/g DM as indicative of copper deficiency, serum copper concentrations =9 mmol/L will be a good indicator of copper deficient status but concentrations >9 mmol/L will be a poor indicator of copper sufficient status. If 10 μg/g DM is used as liver copper cut-off, then serum concentrations >9 mmol/L are reliable as indicative of copper sufficient status but not on concentrations =9 mmol/L as indicative of copper deficiency.

Concentrations of copper in liver and blood may be of diagnostic value but should be interpreted with caution since clinical signs of copper deficiency may appear before there are significant changes in the levels of copper in the blood and liver. Conversely, the plasma levels of copper may be very low in animals that are otherwise normal and performing well. There is a tendency to overestimate the presence of copper deficiency because veterinarians use a diagnostic threshold for copper deficiency that is too high.[11,26] Among veterinary laboratories, there is a

wide variation in the normal range currently used for equine serum copper values.

Very low levels of both blood and liver copper in a group of animals need not be associated with clinical abnormalities. In a study in the Netherlands, in a group of dairy heifers, the copper status was determined at regular intervals over an 18-month period.[29] One group was supplemented with copper sulfate and the other was not. The copper and molybdenum levels in the grass were within normal limits as accepted in the Netherlands; copper 7–15 mg/kg DM and molybdenum <5 mg/kg DM. The levels of copper in both the blood and liver were much below the reference ranges used in the Netherlands (6–15 μmol/L in blood and >30 mg/kg DM in liver). No clinical signs of copper deficiency occurred and there were no differences in growth rate and reproductive performance.

Plasma and liver copper levels

Cattle and sheep

In cattle and sheep, plasma copper levels between 19 μg/dL and 57 μg/dL (3.0 and 9.0 μmol/L) represent marginal deficiency and levels below 19 μg/dL (3 μmol/L) represent functional deficiency or hypocuprosis. The internationally recognized threshold to assess copper deficiency is 9.4 μmol/L. In both species a value for plasma or serum of 11.0 μmol/L can be associated with a liver concentration from 789 to 3786 μmol/kg DM (50–240 mg/kg). By contrast, a value of 9.3 μmol/L will usually be associated with liver copper values of 315–789 μmol (20–50 mg/kg DM), which are regarded as marginally inadequate. Plasma copper levels of 49.9 μg/dL (7.85 μmol/L) or less are indicative of low liver copper levels. Plasma copper levels above 90.2 μg/dL (14.2 μmol/L) are usually associated with liver levels above 38.1 mg/kg (0.6 mmol/kg) DM. Of the two estimations, that on liver is the most informative as levels in blood may remain normal for long periods after liver copper levels commence to fall and early signs of copper deficiency appear. Levels of copper in adult liver above 200 mg/kg DM (3.14 mmol/kg) in sheep and above 100 mg/kg DM (1.57 mmol/kg) in cattle are considered to be normal. Levels of less than 80 mg/kg DM (1.5 mmol/kg) in sheep and less than 30 mg/kg DM (0.5 mmol/kg) in cattle are classed as low. Liver copper levels in fetuses and neonates are usually much higher than in adults and normal foals have had levels of 219 mg/kg (3.4 mmol/kg DM) compared with a normal of 31 mg/kg (0.49 mmol/kg DM) in adults.

Liver copper

Because the liver is a storage compartment for copper, the concentrations of liver copper indicate the state of depletion rather than deficiency. There is no particular threshold value for liver copper below which the performance and health of livestock are likely to be impaired. A broad range of values may, for example, coincide with the marginally deficient state, e.g. 5.1–20.3 mg (0.08–0.32 mmol) copper/kg liver DM. The concentration of hepatic copper in sheep is uniform and a single biopsy sample should be representative of the whole liver. The technique of liver biopsy for assessing the copper status of sheep has been evaluated. Frequency of biopsy does not affect copper concentration, the variability between successive samples is small and the biopsy procedure does not reduce body weight or rate of gain. Copper concentrations in the kidney cortex may be of more diagnostic value because concentrations are normally within a narrow range of 12.7–19.0 mg/kg DM (0.2–0.3 mmol/kg DM). Thus, concentrations below 12.7 mg/kg DM (0.2 mmol/kg DM) in the kidney may be a more reliable indicator of dysfunction than liver copper concentration.

The concentrations of copper in the livers of calves vary according to age and production class (dairy or beef) with no evidence of copper toxicosis or deficiency. In calves submitted for necropsy, the liver copper concentrations were as much as 60 mg/kg WW higher in dairy calves than beef calves.[30] The concentration increased for the first 2 months of age, then declined until 9 months of age, after which it began to increase. Thus, the diagnosis of copper imbalances based on liver copper concentration in calves should take into account the diagnostic covariates of age and production class.

Ceruloplasmin

The difficulty of interpreting plasma levels of copper led to the estimation of plasma levels of copper-protein complexes, especially ceruloplasmin. Ceruloplasmin contains greater than 95% of the circulating copper in normal animals. There is a highly significant correlation between plasma copper levels and plasma ceruloplasmin activity, which is a less complicated and more rapid procedure than plasma copper. The regression analyses indicate a strongly positive correlation coefficient of ceruloplasmin with serum of cattle and sheep of 0.83 and 0.92, respectively. The correlation between serum ceruloplasmin activity and hepatic copper concentrations in cattle was only 0.35, indicating an unreliable relationship. Normal plasma ceruloplasmin levels in sheep are in the region of 45–100 mg/L. Normal levels of serum ceruloplasmin activity in cattle range from 120 to 200 mg/L. The mean copper and ceruloplasmin levels are higher in plasma than serum; the percentage of copper associated with ceruloplasmin is less in serum (55%) than in plasma (66%). Normal plasma ceruloplasmin levels in sheep range from 4.5 to 10 mg/dL. In experimental primary copper deficiency in calves, rapid decreases occur in plasma ceruloplasmin activity at least 80 days before overt clinical signs of deficiency.

Erythrocyte dismutase

The measurement of the activity of erythrocyte superoxide dismutase (ESOD), a copper-containing enzyme, is now being evaluated as a procedure for the diagnosis of copper deficiency. The activity of this enzyme decreases more slowly than plasma or liver copper in copper-deficient animals and may be more closely correlated with the presence of imminence of hypocuprosis. In marginal deficiency, the ESOD value ranges from 2 to 5 U/mg hemoglobin and in functional deficiency the value is below 2.

Milk and hair copper

The levels of copper in milk and hair are also lower in deficient than in normal cattle and estimation of the copper content of hair is now acceptable as a diagnostic aid. It has the advantage of providing an integrated progressive record of nutritional intake. The levels of copper in bovine hair are more markedly depressed when extra molybdenum is fed.

Horses

A threshold level of plasma copper of 16 μmol/L is used to distinguish between the normal and subnormal values.[31] Liver copper from horses sampled at slaughter vary widely about a mean of 113.7 μmol/kg WW.[31] The threshold of 52.5 μmol/kg WW of copper in liver is proposed to distinguish deficient from marginal liver copper status. Many healthy horses have serum values between 12 and 16 μmol/L.

The mean hepatic copper concentrations of horses fed diets containing 6.9–15.2 mg copper/kg DM were 17.1–21.0 μg/g DM (0.27–0.33 μmol/g DM) tissue. The plasma copper concentrations ranged from 3.58 to 4.45 μg/dL (22.8–28.3 μmol/L). There was no simple mathematical relationship between plasma and hepatic copper concentrations. The range of serum copper concentrations in Thoroughbred horses at grass was 63–196 μg/dL (9.91–30.85 mmol/L) and in stabled Thoroughbreds the range was 47–111 μg/dL (7.40–17.47 mmol/L).

Farmed red deer (*Cervus elaphus*)

The suggested reference ranges for serum and liver copper concentrations to categorize the copper status of deer are: serum concentrations (μmol/L): <5, deficient; 5–8 marginal and; >8, adequate; and liver

copper concentrations (μmol/kg weight wet, WW): <60, deficient; 60–100, marginal and >100, adequate.[32] Enzootic ataxia and osteochondrosis occur when liver copper concentrations are <60 μmol/kg fresh tissue and serum copper concentrations are below 3–4 μmol/L.[33] Growth responses to copper supplementation are equivocal when blood copper concentrations are <3–4 μmol/L, but are significant when mean blood copper concentrations are 0.9–4.0 μmol/L. No antler growth or body weight response to copper supplementation occurs when blood ceruloplasmin (ferroxidase) levels averaged 10–23 IU/L (equivalent to serum copper concentrations of 6–13 μmol/L) and liver concentrations averaged 98 μmol/kg fresh tissue. This suggests deficient, marginal and adequate ranges for serum copper concentrations should be <5, 5–8 and >8 μmol/L, respectively and those for liver copper concentrations should be <60, 60–100 and >100 μmol/kg, respectively.[33]

Hematology

Anemia may occur in advanced cases of primary copper deficiency, hemoglobin levels being depressed to 50–80 g/L and erythrocytes to $2–4 \times 10^{12}$/L. A high proportion of cows in problem herds may have a Heinz-body anemia without evidence of hemoglobinuria and the severity of the anemia will be related to the hypocupremia.

NECROPSY FINDINGS

The characteristic gross findings in copper deficiency of ruminants are those of anemia and emaciation. Hair and wool abnormalities may be present as already described. Extensive deposits of hemosiderin can cause darkening of the liver, spleen and kidney in most cases of primary copper deficiency and in the secondary form if the copper status is sufficiently low. In lambs, there may be severe osteoporosis and long bone fractures. Osteoporosis is less evident in cattle, but can be confirmed radiographically and histologically. In naturally occurring secondary copper deficiency in cattle, associated with high dietary molybdenum and sulfate, there is widening of the growth plates due to abnormal mineralization of the primary spongiosa, resulting in a grossly rachitic appearance to the bones.

The most significant finding in enzootic ataxia is the degeneration of axons and myelin within the cerebellar and motor tracts in the spinal cord, a change only evident at the microscopic level. Chromatolysis of neurons in a variety of locations within the central nervous system is usually detectable. In a few extreme cases and in most cases of swayback, the myelin loss also involves the cerebrum, where there is destruction and cavitation of the white matter. There is marked internal hydrocephalus in such cases and the convolutions of the cerebrum are almost obliterated. Acute cerebral edema with marked brain swelling and cerebellar herniation, reminiscent of polioencephalomalacia, may also accompany the more typical myelopathy and multifocal cerebral leukomalacia in lambs with hypocuprosis.

In falling disease, the heart is flabby and pale. There is generalized venous congestion and the blood may appear watery. The liver and spleen are enlarged and dark. Histological examination reveals atrophy of the cardiac muscle fibers and considerable cardiac fibrosis. Deposits of hemosiderin are present in the liver, spleen and kidney.

Necropsy findings associated with copper deficiency in non-ruminant species are not well-documented. Degenerative changes with subsequent rupture of the aorta have been experimentally induced in pigs, but this has not been described as a naturally occurring disease. A myelopathy with white matter changes similar to those of enzootic ataxia has also been reported in 4–5-month-old copper-deficient pigs. Musculoskeletal changes similar to those described for calves have also been reported in foals with hypocuprosis.

Necropsy examinations should include assay of copper in viscera. The levels of copper in liver are usually low (see Table 30.4) and in secondary copper deficiency, there may be a high level of copper in the kidney and high levels of molybdenum in the liver, kidney and spleen. Copper levels in body tissues and fluids in primary and secondary copper deficiency are listed in Table 30.4.

Samples for confirmation of diagnosis

- **Toxicology** – 50 g liver, kidney (ASSAY (Cu) (Mo))
- **Histology** – formalin-fixed samples of: long bone (including growth plate), skin, liver, spleen. Enzootic ataxia/swayback: half of midsagittally-sectioned brain, lumbar and cervical spinal cord. Falling disease: heart (several sections), bone marrow, spleen (LM).

DIFFERENTIAL DIAGNOSIS

The clinical findings which are common in young, growing ruminants, include **a herd problem** of unthriftiness and progressive loss of weight, changes in hair coat color or texture of wool, chronic lameness, neonatal ataxia in lambs and kids and terminal anemia. In adult cattle on pasture with excess molybdenum, chronic diarrhea is characteristic. A combination of serum and liver copper and serum molybdenum, are major diagnostic aids in distinguishing between copper deficiency and the other diseases.

Several disease complexes that are herd or flock problems in cattle and sheep may resemble both primary and secondary copper deficiency. The emphasis is on many animals being affected at about the same time, with a chronic debilitating disease complex, under the same dietary and seasonal circumstances.

A scheme for the differential diagnosis of mineral and vitamin responsive disorders in beef cattle herds with suboptimal performance should include three major directions: malnutrition (lack of feed); chronic infectious disease; and, lack of specific micronutrients.[34]

Cattle

Unthriftiness and progressive **weight loss** may be due to protein-energy malnutrition and examination of the diet will reveal the cause.

Changes in hair coat color in young growing cattle is caused only by copper deficiency.

Chronic lameness in young growing cattle may be caused by a calcium, phosphorus and vitamin D imbalance, which is determined by examination of the diet and radiography of the long bones. The radiographic changes in cattle with secondary copper deficiency consist of widened irregular epiphyseal plates with increased bone density in the metaphysis and metaphyseal lipping. These findings are similar to those described for rickets and secondary nutritional hyperparathyroidism in cattle.

Chronic diarrhea in young cattle may be due to intestinal parasitism and fecal examination and response to therapy are diagnostic. Diarrhea in a group of adult cattle on pasture known to be high in molybdenum is probably due to secondary copper deficiency and response to therapy is diagnostic.

Winter dysentery of cattle, salmonellosis, coccidiosis, and mucosal disease are acute diseases characterized by diarrhea but are accompanied by other signs and clinicopathological findings which facilitate their identification. Many poisons, particularly arsenic, lead, and salt, cause diarrhea in ruminants but there are usually additional diagnostic signs and evidence of access to the poison. Assay of feed and tissues helps to confirm a diagnosis of poisoning.

A diagnosis of **peat scours** is usually made if there is an immediate response to oral dosing with a copper salt.

Falling disease occurs only in adult cattle and must be differentiated from other causes of sudden death. Poisoning by the gidgee tree (*Acacia Georginae*) produces a similar syndrome in cattle.

Sheep and goats

Unthriftiness and **abnormal wool** or hair as a flock or herd problem are characteristic of copper deficiency in sheep and goats, which must be differentiated from protein-energy malnutrition, intestinal parasitism, cobalt deficiency, and external parasites.

Lameness in a group of lambs several weeks of age must be differentiated from nutritional osteodystrophy due to a

calcium, phosphorus and vitamin D deficiency or imbalance, stiff lamb disease due to enzootic muscular dystrophy.

Neonatal ataxia caused by congenital swayback and enzootic ataxia in newborn lambs and kids due to maternal copper deficiency must be differentiated from border disease of newborn lambs, characterized by an outbreak of newborn lambs with hairy fleece and tremors, cerebellar hypoplasia (daft lamb disease) and hypothermia.

TREATMENT

The treatment of copper deficiency is relatively simple, but if advanced lesions are already present in the nervous system or myocardium complete recovery will not occur. Oral dosing with 4 g of copper sulfate for calves from 2 to 6 months of age and 8–10 g for mature cattle given weekly for 3–5 weeks is recommended for the treatment of primary or secondary copper deficiency. Parenteral injections of copper glycinate may also be used and the dosages are given under control.

The diet of affected animals should also be supplemented with copper. Copper sulfate may be added to the mineral-salt mix at a level of 3–5% of the total mixture. A commonly recommended mixture for cattle is 50% calcium–phosphorus mineral supplement, 45% cobalt-iodized salt, and 3–5% copper sulfate. This mixture is offered free of choice or can be added to a complete diet at the rate of 1% of the total diet.

CONTROL

Dietary requirements

The minimum dietary requirement for copper for cattle is 10 mg copper/kg DM and 5 mg/kg DM for sheep.

The requirement necessary to prevent subclinical or clinical copper deficiency will depend on the presence of interfering substances such as molybdenum, sulfur, and iron in the diet and possibly the genotype of the animal. Copper sulfate is considered a better supplement than copper oxide or injectable copper for cattle consuming diets containing excess molybdenum or molybdenum plus sulfur. Although there is a marked difference between breeds of sheep in their susceptibility to hypocuprosis, this would not seem to have an immediate practical application. The estimated copper requirement in the diet of mature ponies is 3.5 mg/kg DM. The levels of copper in liver samples of 50% of cull ewes and 40% of market lambs were high to toxic indicating that monitoring the dietary levels of copper is essential.[35]

The copper requirements may also vary according between breeds within a species. Angus heifers have a lower minimal copper requirement than Simmental heifers.[13] Based on liver copper, diets containing copper at 4.4 or 6.4 mg/kg DM, did not meet the requirement of either breed during gestation and lactation or growth. Supplementation of copper at 7 mg/kg DM to the control diets provided the requirements of both breeds.

There are significant differences in the copper requirements and tolerance between goats and sheep.[12] The dietary copper requirements of goats are uncertain but may be higher than in sheep. Dietary levels of copper which could cause copper toxicity in sheep, do not cause toxicity in goats. Some limited data on growth performance indicates a stimulatory effect of 100–300 ppm copper in the diet of Nubian goats. Extra copper accumulated in liver and to a lesser extent in other tissues and was excreted through the biliary system and into the feces.

Supplementation of diets with copper of feedlot cattle under some circumstances can affect performance. As little as 20 mg/kg DM of supplemental copper can reduce performance in finishing steers.[36] The addition of 10 or 20 mg/kg DM of supplemental copper to a high-concentrate diet containing 4.9 mg/kg DM alters lipid and cholesterol metabolism in steers but does not alter ruminal fermentation.[37] Decreasing cholesterol and altering fatty acid composition (saturated to unsaturated) in beef produced for human consumption has potential health benefits.

Copper can be supplied by several different methods as outlined below. The dose rates given are those recommended for the control of primary copper deficiency and these may have to be increased or treatment given more frequently in some instances of secondary copper deficiency. In these circumstances it is often necessary to determine the most satisfactory dosing strategy by a field trial.

Copper toxicity

The incidence of copper toxicity in dairy cattle in the UK has increased recently.[38] Apparent subclinical hepatopathy, with no clinical disease, due to excess copper intake in lactating dairy cattle has been described. On average, each cow received 963 mg copper daily from the mineral supplement alone. Calculation of the total dietary copper found that high producing cow had an estimated intake of 1325 mg copper daily, while each low producing cow received 1250 mg daily. The estimated copper requirements of the cows were 290 and 217 mg/cow per day, respectively. Thus oversupplementation of dairy cows with copper may be a significant problem in dairy herds without overt clinical signs of toxicity.

Copper sulfate

Oral dosing

Oral dosing with copper sulfate (5 g to cattle, 1.0 g to sheep, weekly) is adequate as prophylaxis and will prevent the occurrence of swayback in lambs if the ewes are dosed throughout pregnancy. Lambs can be protected after birth by dosing with 35 mg of copper sulfate every 2 weeks. However, regular oral dosing with copper sulfate is laborious and time-consuming and is no longer widely practiced.

Dietary supplementation

Mineral mixture in feed. The copper sulfate may be mixed with other minerals into a mineral premix, which is then incorporated into the concentrate part of the ration. The final concentration of copper is usually adjusted to provide an overall intake of at least 10 ppm of copper in the DM of the final ration. If the forage components of the ration contain much less than 10 ppm, the concentrate part of the ration may need to contain much larger concentrations of copper. Where a secondary copper deficiency is due to molybdenum in the forage, up to 1200 mg copper (approximately 5 g of hydrated copper sulfate) is added to the concentrate daily. When sheep are grazing toxic lupin stubble, the signs of lupinosis may be exacerbated by the supplementation of only 10 mg copper/kg DM as copper sulfate and therefore the supply of copper in the absence of suitable amounts of molybdenum and sulfur should be kept to a minimum.[39]

Salt-lick ad libitum. If animals are not receiving concentrates containing copper, an alternative is to provide free access to a mineral mixture or salt-lick containing 0.25–0.5% of copper sulfate for sheep and 2% for cattle, which will supply sufficient copper provided an adequate intake of the mixture is assured. The mineral mixture usually contains iodized salt, cobalt, calcium, phosphorus, and other trace minerals.

Top-dressing pastures. In some deficient areas, an effective method of administering copper is by the annual top-dressing of pasture with 10 kg/ha copper sulfate, although the amount required may vary widely with the soil type and the rainfall. Top-dressing may cause copper poisoning if livestock are turned onto pasture while the copper salt is still adherent to the leaves. Treated pasture should be left unstocked for 3 weeks or until the first heavy rain. It is also possible that chronic copper poisoning may result if the copper status of the soil increases sufficiently over a number of years.

Top-dressing grazing pastures of farmed red deer was compared with oral administration of copper oxide wire particles to some deer.[40] Top-dressing pastures with

copper sulfate at a rate of 12 kg/ha, but not 6 kg/ha, in mid-March was effective increasing the copper status of weanling hinds; while pastures top dressed the 12 kg/ha copper sulfate in mid-March and dosing hinds with 10 g copper oxide in late July were effective in increasing the copper status of pregnant hinds and in the case of the yearling hinds, significantly improved the copper status of their progeny from birth to weaning.

Drinking water supplementation. Addition of copper salts to drinking water is usually impractical because the solution corrodes metal piping and maintenance of the correct concentration of copper in large bodies of water is difficult. However, if the need is great, some way around these difficulties can usually be found and a system has been devised for automatic supplementation for short periods via the drinking water and has been effective in controlling copper deficiency in cattle. Copper pellets which provide 2–3 mg copper/L of water have been recommended for cattle. Calves can tolerate copper in milk replacers at a concentration of 50 ppm but there is no advantage in providing more than 10 ppm.

Molasses based mineral supplements. Copper can be provided in molasses-based supplements. However, the high sulfur concentrations in the molasses may affect the availability, through the formation ruminal thiomolybdates and result in lower liver copper concentrations. A dietary copper concentration greater than 10 ppm may be necessary to ensure absorption in beef cattle fed molasses-based supplements.[41]

Removal of sulfates

The removal of sulfates from drinking water by water purification, using a process of reverse osmosis, may have a positive effect on the copper status of beef cows. Cows drinking desulfated water had an increased availability of copper compared with those drinking water containing a large concentration of sulfates.

Parenteral injections of copper

To overcome the difficulty of frequent individual dosing or top-dressing of pasture, periodic parenteral injection of copper compounds that release copper gradually has given good results. They can be given at strategic times depending on the circumstances. They also have the advantage of avoiding fixation of copper by molybdenum in the alimentary tract. Injectable preparations of copper are now the method of choice for the prevention of swayback in lambs. The following have been evaluated under field conditions:

- Copper calcium ethylenediamine tetra-acetate (copper calcium edetate)
- Copper methionate
- Copper heptonate
- Copper glycinate
- Copper oxyquinoline sulfonate
- Copper phenylalanine complex.

The criteria used to judge these injections are minimal damage at the site of injections, satisfactory liver storage (90–100%) of the administered dose and a safe margin between therapeutic and toxic doses. The dose of copper in any of the compounds for cattle is 400 mg and for sheep 150 mg.

Copper heptonate at the rate of 25 mg of copper in 2 mL of preparation given by IM injection to ewes in mid-pregnancy was successful in preventing swayback in lambs. The IM injection of 1 or 2 mg Cu/kg BW as copper heptonate does not result in any signs of toxicity such as weakness, lethargy, or icterus. The copper is lost from the injection site within 7 days and most is transferred to the liver with little or no deposition in the skeletal muscle. The higher dose raised mean liver copper values to within the range of 13–52 mmol/kg DM, which is associated with copper toxicity.

In sheep on pasture of high molybdenum content, a single IM injection of copper heptonate providing 37.5 mg copper to adults or 25 mg copper to weaners increases the liver copper reserves for at least 9 and 3 months, respectively and is considered an acceptable alternative to copper oxide wire particles for preventing copper deficiency in sheep in southern Australia.[42]

Copper calcium edetate has the advantage of giving maximum copper storage very quickly – 1 week after injection – and blood levels are elevated within a few hours.

Because of the rapidity of the absorption, toxic effects can be encountered unless proper dose levels are observed. As well as deaths from serious overdosing, some deaths occur in groups of sheep for unexplained reasons. It is suggested that stress be minimized and simultaneous other therapy be avoided.

A marked local reaction occurs at the site of injection so that SC injection is preferable in animals to be used for meat, although to avoid an unsightly blemish, breeding animals should receive an IM injection. The injections are a small risk for precipitating blackleg in cattle on farms where this disease occurs. For sheep, a single injection of 45 mg of copper as copper glycinate in mid-pregnancy is sufficient to prevent swayback in the lambs.

The SC injection of copper calcium edetate or **copper oxyquinoline sulfonate** into sheep results in a rapid increase in the concentration of copper in whole blood, serum, and urine within the first 24 h. Following the injection of copper methionate, the concentration of copper in blood and serum rises steadily over a period of 10 days and there is no detectable increase in urinary copper. After the injection of any of the three compounds, there is a steady increase in serum ceruloplasmin activity over a period of 10–20 days, followed by a slow fall to preinjection activity by 40 days. The lower toxicity of copper injected as methionate compared with that as copper calcium edetate or copper oxyquinoline sulfonate is due to the slower absorption and transport of the copper to the liver and kidney. Death has occurred in sheep following the parenteral administration of diethylamine oxyquinoline sulfonate at recommended doses. Affected sheep manifested signs of hepatic encephalopathy and at necropsy, there was acute, severe, generalized, centrilobular hepatocellular necrosis. The use of copper disodium edetate at recommended doses in calves has also resulted in deaths associated with liver necrosis and clinical signs of hepatic encephalopathy.

Injectable **copper glycinate** is an excellent source of supplementary copper for increasing the concentration of copper in the serum of copper-deficient cattle and maintaining grazing cattle in an adequate copper status. One dose of copper glycinate will maintain adequate copper levels for about 60–90 days. The recommended dose in beef herds is 120 mg of copper for adult cattle and 60 mg of copper for calves. A supplemental source of copper is required for the calf during the pasture season because milk is a poor source of copper, particularly from copper-deficient cows and calves do not have the opportunity to increase or maintain body stores of copper while grazing. When the dam is severely hypocupremic in the spring, the calf is also severely hypocupremic or copper-deficient. Insufficient copper is secreted into the milk of copper-treated cows. Therefore, where the dam has not received an adequate copper intake during pregnancy, direct treatment of the calf will be required in early life. The copper reserves of newborn calves are increased in fetal liver at the expense of copper stores in the dam's liver, which are dependent on the availability of dietary or supplemental copper to the dam. Calves usually have sufficient liver copper at birth and do not need an injection of 50 mg until they are 6 weeks old. Because of the higher requirements for copper during the last trimester of pregnancy (demands of the fetal liver), a program of copper supplementation should involve the use of copper supplements, throughout the year as required.

One dose of copper glycinate is sufficient when cattle are grazing forage that contains no more than 3 mg/kg DM of

molybdenum and 3 g/kg DM of sulfur. With higher levels of molybdenum and sulfur, repeated injections of copper glycinate are recommended. The injectable copper may be supplemented by the use of copper sulfate in a mineral supplement at a level of 1%. The inclusion of copper sulfate in the mineral supplement may be adequate for cows, but the calves may not consume an adequate amount of mineral and injectable copper. The level of supplementation required to prevent a drop in serum copper over the pasture season will depend upon the concentration of dietary molybdenum and sulfur and their effect upon the coefficient of absorption of copper.

Injectable copper complex compounds have been evaluated as supplementary copper for grazing beef cattle under Canadian conditions. Copper edetate at 100 mg of copper, copper glycinate at 120 mg, and copper methionate at 120 mg were used and were equally effective in improving copper status of copper-deficient cattle and maintaining them in an adequate copper status for 90 days. The copper methionate was least acceptable because of the incidence and severity of reactions at the site of injection.

The use of injectable copper edetate in horses has been investigated as a method of increasing liver copper in foals at birth to reduce the incidence and severity of developmental bone and joint disease in newborn foals. The administration of 100 mg and 250 mg copper edetate IM to mares during the 9th and 10th months of gestation had no effect on the liver concentration of their foals at birth.[43]

Copper phenylalanine in a single injection to dairy cows in Uruguay maintained serum copper levels at an adequate level for at least 100 days.[44]

Controlled-release glass

Death due to poisoning is one of the dangers of parenteral administration because it is difficult to control the rate at which the supplement releases the copper, especially if the controlling mechanism is chemical binding. Methods used to control the release include the development of soluble controlled-release glass for oral administration to sheep and cattle. The copper is slowly released, absorbed, and stored in the liver. Initial field evaluations indicate that the boluses may not contain sufficient copper to maintain normal levels of copper for a sufficient length of time compared to the use of copper oxide needles.

Boluses of a soluble copper-containing controlled-release glass have been developed and evaluated. The boluses are based on a phosphate-type glass into which appropriate quantities of trace elements are incorporated. The boluses lodge in the rumen and release copper at a slow rate. They can provide additional supplies of copper to ruminants at an almost uniform rate for many months. One commercial product contains selenium and cobalt and in one experiment increased ceruloplasmin activity for at least 1 year. In one field study, the administration of two commercial soluble glass boluses containing copper and selenium, the selenium levels were increased from marginal to adequate, but adequate copper levels were not maintained.

A soluble glass bolus containing copper, cobalt, and selenium given to extensively grazed sheep in the North East of Scotland, under two different situations: lowland finishing lambs and upland sheep in their non-productive year between being a lamb and being a productive ewe (gimmer) was able to prevent or correct deficient and/or marginal cobalt and selenium status of sheep throughout the trial period. The bolus has little measured effect on the already adequate blood indicators of copper status, although the liver copper concentrations of the bolused sheep were higher.[45]

Copper oxide needles

Copper oxide needles or wire particles (fragments of oxidized copper wire up to 8 mm in length and 0.5 mm in diameter) are used for oral dosing and one of the most effective and safest methods for the control of copper deficiency in ruminants. Its major advantages are prolonged effectiveness and low cost. A single treatment can be effective for an entire summer or winter season. The needles are retained in the forestomachs and abomasum for up to 100 days or more and the copper is slowly released, absorbed and stored in the liver.

Sheep

A dose of 0.1 g/kg live weight (5 g) in sheep is safe and does not induce copper toxicity in the susceptible North Ronaldsay breed. The response in liver copper concentrations is dose-dependent. In sheep given doses ranging from 2.5 to 20 g per animal, the liver copper concentrations will peak 10 weeks after administration and will thereafter decline in a linear fashion over the next 40 weeks.

The administration of a single dose of 2 g cupric oxide needles orally to lambs between 3 and 5 weeks of age is an effective method for the prevention of induced hypocuprosis manifested as ill-thrift in lambs grazing pastures improved by liming and reseeding. The treatment maintained the lambs in normocupremia, provided adequate liver copper reserves, prevented clinical signs of hypocuprosis and produced a live weight gain advantage. The administration of the needles to ewes in the first half of pregnancy is also effective for the prevention of swayback in their lambs. The administration of cupric oxide needles to ewes at parturition is effective in preventing hypocupremia for up to 17 weeks in animals on pasture previously shown to cause a molybdenum-sulfur-induced copper deficiency. The treatment of the ewes at parturition also resulted in higher concentrations of copper in the milk in the initial weeks of lactation.

However, this increase in milk copper will not be effective in preventing hypocupremia and hypocuprosis in the lambs, which can be treated with cupric oxide needles at 6 weeks of age. Because some breeds of sheep may have a propensity to concentrate excess quantities of copper in the liver, it is important to adhere to the recommended dosage. Cupric oxide needles at a dose of 4 g per animal have also been used for the prevention of swayback in goats and to maintain liver copper levels for up to 5 months in farmed red deer grazing on a marginally copper-deficient pasture.

Copper oxide needles given to ewes in early pregnancy increases their liver copper status through gestation and early lactation and the copper status of their lambs from birth to 36 days old.[46] Serum copper concentration was not affected by treatment but a marked rise was observed in all lambs between birth and 10 weeks of age.

Cattle

A single dose of 20 g of copper oxide needles to hypocupremic suckler cows was sufficient to maintain adequate copper status for at least 5 months. The use of 20 g of copper oxide needles to young cattle weighing 190 kg effectively prevented growth retardation and severe hypocupremia, which occurred in an undosed control over a 70-day trial period. The currently recommended doses for beef cattle are 5 g for calves, 10 g for yearlings and 20 g for heavier or adult cattle, which will give protection for at least 6 months. A single oral dose of 20 g of copper oxide needles at the beginning of the grazing season is effective in increasing or maintaining stores of copper in the liver of grazing cows and calves consuming low-copper, high-molybdenum forage, and high-sulfate water supplies. The use of 50 g of needles in adult cows (55 kg BW) sustained higher levels of plasma concentrations than the SC injection of copper glycinate and 100, 200, or 300 g of needles given orally did not cause clinical effects.

Farmed red deer

The administration of 20 g boluses of copper-oxide wire particles to rising 2-year-old red deer stags did not significantly alter velvet antler weight, daily velvet antler growth rate, days from casting to removal, grade or value, or stag live weight gain.[47] Copper supplementation

increased mean serum ceruloplasmin (ferroxidase) concentrations by approximately 10 IU/L. Mean liver copper concentrations in control deer was 99 µmol/kg and ranged from 194 to 386 µmol/kg in the treated groups.

Field trials on New Zealand deer farms using 5 g of copper oxide wire particles given to deer 4–7 months old found no effect on live weight gain despite evidence of hypocupremia in 38% of non-supplemented animals, which gained weight at similar rates to those which had adequate plasma copper levels.[48] This suggests that the extent of the hypocupremia was either not sufficiently severe, or not maintained for a long enough period to cause copper deficiency resulting in live weight gain. This indicates that deer farmers need to reassess the need for copper supplementation in young deer.

Copper oxide powder

Copper oxide powder administered in the form of experimental, sustained-release rumen boluses significantly increased blood and liver copper concentrations in growing sheep, in out-wintered suckler cows during late pregnancy and early lactation and in growing cattle at grass in the summer periods over periods of at least 170 and 123 days, respectively.

Genetic selection

It is now possible to manipulate trace element metabolism by genetic selection in farm animals. Within a period of 5 years, selection of sheep based on plasma concentration of copper resulted in two divergent sets of progeny, one with a high level of copper status, the other with a low level, which resulted in clinical manifestations of copper deficiency in the low level and protection in the high level.

General guidelines

Several rules of thumb are important and useful.

- A dietary intake of copper equivalent to 10 mg/kg DM will prevent the occurrence of primary copper deficiency in both sheep and cattle
- Diets containing less than 5 mg/kg DM will cause hypocuprosis
- Diets with copper:molybdenum ratios of less than 5:1 are conducive to conditioned (secondary) hypocuprosis
- The newborn calf is protected against neonatal hypocuprosis by donations from the dam, but newborn lambs assume the same copper status as the ewe
- Cattle are more susceptible to copper deficiency than are sheep.

IODINE DEFICIENCY

Synopsis

Etiology Primary dietary deficiency of iodine or secondary to conditioning factors such as calcium, *Brassica* plants, or bacterial pollution of water.
Epidemiology In all species, most common in continental land masses. Neonatal animals. Diets of dams deficient in iodine or containing conditioning factors such as certain plants.
Signs Goiter as palpable enlargement of thyroid gland. Neonatal mortality due to stillbirths, weak neonates may not be able to suck and die in few days, alopecia at birth, myxedema.
Clinical pathology Blood iodine levels.
Necropsy findings Thyroid enlargement, alopecia, myxedema.
Diagnostic confirmation Goiter and iodine deficiency.
Differential diagnosis list
- Weak calf syndrome
- Abortion
- Congenital defects.
- Hypothyroidism

Treatment Not usually undertaken.
Control Insure dietary intake of iodine in pregnant animals

ETIOLOGY

Iodine deficiency may be due to deficient iodine intake or secondarily conditioned by a high intake of calcium, diets consisting largely of *Brassica* spp., or gross bacterial pollution of feedstuffs or drinking water. A continued intake of a low level of cyanogenetic glycosides, e.g. in white clover, is commonly associated with a high incidence of goitrous offspring. Linamarin, a glycoside in linseed meal, is the agent producing goiter in newborn lambs born from ewes fed the meal during pregnancy. A continued intake of the grass *Cynodon aethiopicus* with low iodine and high cyanogenetic glucoside contents may cause goiter in lambs. Rapeseed and rapeseed meal are also goitrogenic.

Goiter or hypothyroidism in newborn lambs occurs when pregnant ewes have a low iodine intake or ingest goitrogens [1]

EPIDEMIOLOGY

Occurrence

Goiter caused by iodine deficiency occurs in all of the continental land masses. It is not of major economic importance because of the ease of recognition and correction, but if neglected may cause heavy mortalities in newborn animals. **The most common cause of iodine deficiency in farm animals is the failure to provide iodine in the diet**. The sporadic occurrence of the disease in marginal areas attracts most attention. An epidemiological survey in Germany found up to 10% of cattle and sheep farms, and 15% of swine herds

were affected with iodine deficiency, which were both primary and secondary due to the presence of nitrates, thiocyanates, or glucosinolates in the diet.[2]

The importance of subclinical iodine deficiency as a cause of neonatal mortality could be much greater than clinical disease. For example, in southern Australia, ewes supplemented with iodine by the single injection of iodine in oil, have had less mortality in the lambs, have grown larger lambs, or performed the same as controls. In New Zealand, subclinical iodine deficiency has been recognized in a sheep flock in which fertility and lamb perinatal mortality occurred and corrected by supplementation of the ewes with iodine.[3,4] The annual cost associated with iodine deficiency in one Manawata Romney flock was conservatively estimated at $6.00 per ewe.[3] Iodine supplementation has been shown to reduce perinatal mortality and increased lambing percentage by 14–21% in pasture-fed ewes.[3] Thus subclinical iodine deficiency can affect reproductive performance and perinatal lamb mortality rates.[3]

Young animals are more likely to bear goitrous offspring than older ones and this may account for the apparent breed susceptibility of Dorset Horn sheep, which mate at an earlier age than other breeds.

A survey of crossbred cows in the Punjab of India, found that 35.9% of cows were iodine deficient with considerable geographic variation from 0 to 86% within Punjab.[5] The cardinal clinical signs of iodine deficiency were absent and basal plasma T3 (triiodothyronine) and T4 (plasma thyroxine) concentrations and their ratio did not differ between deficient and control cows. The response to injection of 1 mL of 78% ethiodized oil can prevent the deficiency for more than 70 days.[5]

Risk factors

Dietary and environmental factors

A simple deficiency of iodine in the diet and drinking water may occur and is related to geographical circumstances. Areas where the soil iodine is not replenished by cyclical accessions of oceanic iodine include large continental land masses and coastal areas where prevailing winds are offshore. In such areas, iodine deficiency is most likely to occur where rainfall is heavy and soil iodine is continually depleted by leaching. Over a 3-year period, several calves were born with goiter in a dairy herd located 200 km from the sea on sandy soil.[6] The calves were born from first-calf heifers which had not received any iodine supplementation.

Soil formations rich in **calcium** or lacking in humus are also likely to be relatively deficient in iodine. The ability of soil to retain iodine under conditions of heavy rainfall is directly related to their humus content, and limestone soils are, in general, low in organic matter. A high dietary intake of calcium also decreases intestinal absorption of iodine, and in some areas, heavy applications of lime to pasture are followed by the development of goiter in lambs. This factor may also be important in areas where drinking water is heavily mineralized.

There are several situations in which the relationship between iodine intake and the occurrence of goiter is not readily apparent. Goiter may occur on pasture containing adequate iodine; it is then usually ascribed to a secondary or conditioned iodine deficiency. A diet rich in plants of the ***Brassica* spp.**, including cabbages and brussels sprouts, may cause simple goiter and hypothyroidism in rabbits, which is preventable by administered iodine. Severe iodine deficiency can occur when ewes are fed Brassica crops for long periods. Brassicas such as swedes, turnips, and kale have low iodine content and contain goitrogens, and may result in weak newborn lambs with enlarged thyroid glands.[7] Goiter occurred in 85% of lambs examined at necropsy, born from ewes on the Brassica crop and not supplemented with iodine.

Diffuse hyperplastic goiter has occurred in calves in beef cows in Japan which were on pasture or being fed feed containing *Rorippa indica*, Hiern, genus Brassica, family Crucifera, 'Inugarash', which contains thiocyanate.[8] The iodine content of the waters on affected farms was low at 0.361 μg/L and 0.811 μg/L and that of the pastures, 87 and 121 μg/kg, on two different farms.

Hypothyroidism has also been produced in rats by feeding rapeseed, and in mice by feeding rapeseed oil meal. Feeding large quantities of kale to pregnant ewes causes a high incidence of goiter and hypothyroidism, also preventable by administering iodine in the newborn lambs. The goitrogenic substance in these plants is probably a glucosinolate capable of producing thiocyanate in the rumen. The thiocyanate content, or potential content, varies between varieties of kale, being much less in rape-kale, which also does not show the two-fold increase in thiocyanate content other varieties show in autumn. Small young leaves contain up to five times as much thiocyanate as large, fully formed leaves. Some of these plants are excellent sources of feed, and in some areas, it is probably economical to continue feeding them, provided suitable measures are taken to prevent goiter in the newborn. Although kale also causes mild goiter in weaned lambs this does not appear to reduce their rate of gain.

A diet high in linseed meal (20% of ration) given to **pregnant ewes** may result in a high incidence of goitrous lambs, which is preventable with iodine or thyroxine. Under experimental conditions, groundnuts are goitrogenic for rats, the goitrogenic substance being a glycoside-arachidoside. The goitrogenic effect is inhibited by supplementation of the diet with small amounts of iodine. **Soybean byproducts** are also considered to be goitrogenic. **Gross bacterial contamination of drinking water** by sewage is a cause of goiter in humans in countries where hygiene is poor. There is a record of a severe outbreak of goitrous calves from cattle running on pasture heavily dressed with crude sewage. Prophylactic dosing of the cows with potassium iodide prevented further cases. Feeding sewage sludge is also linked to the occurrence of goiter.

Goiter in lambs may occur when permanent pasture is plowed and resown. This may be due to the sudden loss of decomposition and leaching of iodine-binding humus in soils of marginal iodine content. In subsequent years the disease may not appear. There may be some relation between this occurrence of goiter and the known variation in the iodine content of particular plant species, especially if new pasture species are sown when the pasture is plowed. The maximum iodine content of some plants is controlled by a strongly inherited factor and is independent of soil type or season. Thus, in the same pasture, perennial rye grass may contain 146 μg iodine per 100 g dry matter (DM) and Yorkshire for grass only 7 μg/100 g DM. Because goiter has occurred in lambs when the ewes are on a diet containing less than 30 μg iodine per 100 g DM, the importance of particular plant species becomes apparent. A high incidence of goiter associated with heavy mortality has been observed in the newborn lambs of ewes grazing on pasture dominated by white clover and by subterranean clover and perennial rye-grass.

Congenital goiter has been observed in foals born to mares on low iodine intake, but also to mares fed an excessive amount of iodine during pregnancy.

PATHOGENESIS

Iodine deficiency results in a decreased production of thyroxine and stimulation of the secretion of thyrotropic hormone by the pituitary gland. This commonly results in hyperplasia of thyroid tissue and a considerable enlargement of the gland. Most cases of goiter of the newborn are of this type. The primary deficiency of thyroxine is responsible for the severe weakness and hair abnormality of the affected animals. Although the defect is described as hairlessness, it is truly hypoplasia of the hairs, with many very slender hairs present and a concurrent absence and

diminution in size of hair follicles. A hyperplastic goiter is highly vascular and the gland can be felt to pulsate with the arterial pulse and a loud murmur may be audible over the gland. Colloid goiter is less common in animals and probably represents an involutional stage after primary hyperplasia.

Other factors, particularly the ingestion of low levels of cyanide, exert their effects by inhibiting the metabolic activity of the thyroid epithelium and restricting the uptake of iodine. Thiocyanates and sulfocyanates are formed during the process of detoxication of cyanide in the liver and these substances have a pronounced depressing effect on iodine uptake by the thyroid. Some pasture and fodder plants, including white clover, rape and kale, are known to have a moderate content of cyanogenetic glucosides. These goitrogenic substances may appear in the milk and provide a toxic hazard to both animals and man. The inherited form in cattle is due to the increased activity of an enzyme that deiodinates iodotyrosines so rapidly that the formation of thyroxine is inhibited.

Iodine is an essential element for normal fetal brain and physical development in sheep. A severe iodine deficiency in pregnant ewes causes reduction in fetal brain and body weight from 70 days of gestation to parturition. The effects are mediated by a combination of maternal and fetal hypothyroidism, the effect of maternal hypothyroidism being earlier than the onset of fetal thyroid secretion.[9] There is also evidence of fetal hypothyroidisms, and absence of wool growth and delayed skeletal maturation near parturition.

CLINICAL FINDINGS

Although loss of condition, decreased milk production, and weakness might be anticipated, these signs are not usually observed in adults. Loss of libido in the bull, failure to express estrus in the cow, and a high incidence of aborted, stillborn or weak calves have been suggested as manifestations of hypothyroidism in cattle, whereas prolonged gestation is reported in mares, ewes, and sows.

A high incidence of **stillbirths and weak, newborn animals** is the most common manifestation of iodine deficiency. Partial or complete **alopecia** and palpable enlargement of the thyroid gland are other signs that occur with varying frequency in the different species. Affected foals have a normal hair coat and little thyroid enlargement, but are very weak at birth. In most cases, they are unable to stand without support and many are too weak to suck. Excessive flexion of the lower forelegs and extension of lower parts of the hindlegs has also been observed in affected foals. Defective ossification has also been reported, the manifestation is collapse of the central and third tarsal bones leading to lameness and deformity of the hock. Enlargement of the thyroid also occurs commonly in adult horses in affected areas, Thoroughbreds and light horses being more susceptible than draft animals.

In **cattle**, the incidence of thyroid enlargement in adults is much lower than in horses and the cardinal manifestations are gross **enlargement of the thyroid gland and weakness in newborn calves**. If they are assisted to suck for a few days, recovery is usual, but if they are born on the range during inclement weather, many will die. In some instances, the thyroid gland is sufficiently large to cause obstruction to respiration. Affected calves have a thick neck and appear to be suffocating.[6] Lethargy, weakness, and difficulty in consuming colostrum are common. Partial alopecia is a rare accompaniment.

In **pigs**, the characteristic findings are birth of **hairless, stillborn or weak piglets often with myxedema** of the skin of the neck. The hairlessness is most marked on the limbs. Most affected piglets die within a few hours of birth. Thyroid enlargement may be present but is never sufficiently great to cause visible swelling in the live pig. Survivors are lethargic, do not grow well, have a waddling gait and leg weaknesses due to weakness of ligaments and joints.

Adult **sheep** in iodine-deficient areas may show a high incidence of thyroid enlargement but are clinically normal in other respects. Newborn lambs manifest weakness, extensive alopecia, and palpable, if not visible, enlargement of the thyroid glands. The gestation length of ewes may be increased and increased perinatal mortality, especially in inclement weather.[1] Marginal iodine deficiency can result in non-specific production losses from embryonic mortality or high perinatal lamb death and are difficult to diagnose.[3]

Goats present a similar clinical picture, except that all abnormalities are more severe than in lambs. Goat kids are goitrous and alopecic. The degree of alopecia varies from complete absence of hair, through very fine hair, to hair that is almost normal.

Animals surviving the initial danger period after birth may recover, except for partial persistence of the goiter. The glands may pulsate with the normal arterial pulse and may extend down a greater part of the neck and cause some local edema. Auscultation and palpation of the jugular furrow may reveal the presence of a murmur and thrill, the 'thyroid thrill', due to the increased arterial blood supply of the glands.

Experimental hypothyroidism produced in horses by surgical excision of the gland results in a syndrome of poor growth, cold sensitivity, long, dull hair coat, docility, lethargy, edema of hindlimbs, and a coarse, thick appearance of the face. The rectal temperature is depressed and blood cholesterol levels are high. Administration of thyroprotein reverses the syndrome. Congenital hypothyroidism has been induced in guinea pigs using a low-iodine diet to compare the developmental abnormalities which occur in horses with congenital hypothyroidism.[10] Many of the abnormalities in guinea pig pups from the experimentally treated dams were similar to those described in foals.

Goiter has occurred in newborn foals whose mares were supplemented with excess iodine during the last 24 h of pregnancy.[11]

CLINICAL PATHOLOGY

Several criteria have been used for the laboratory diagnosis of iodine deficiency in sheep.[12] They include thyroid weight, lamb thyroid to body weight ratio, comparison of serum T4 (serum thyroxine) concentrations in lamb and dam (T4 concentrations are lower in the lamb than in the dam when iodine deficiency is present, serum T4 concentrations in the ewe and pasture iodine concentrations.[12] In New Zealand, pasture iodine, and serum thyroxine (T4) and tri-iodothyronine (T3) concentrations of ewes were unreliable in predicting the occurrence of increased litter size and reduced perinatal mortality in response to iodine supplementation.[12] Newborn lambs from ewes unsupplemented with iodine, had mean thyroid weight (g) to body weight (kg) ratio of 0.40 g/kg or greater.[12] Other tests are concentrations of iodine in plasma, milk, and urine all of which measure current iodine status.

Estimations of iodine levels in the blood and milk are reliable indicators of the thyroxine status of the animal. Organic or protein-bound iodine is estimated in serum or plasma and used as an index of circulating thyroid hormone, provided access to exogenous iodine in the diet, or as treatment, is adequately controlled. There may be between-breed differences in blood iodine levels but levels of 2.4–14 μg of protein-bound iodine per 100 mL of plasma appear to be in the normal range. In ewes, an iodine concentration in milk of below 8 μg/L indicates a state of iodine deficiency. Bulk tank milk iodine content should be greater than 300 μg/L.

Levels of thyroxine in the blood have not been used much to measure thyroid gland sufficiency in animals. Work in ewes has shown that normal lambs at birth have twice the serum thyroxine levels of their dams, but goitrous lambs have levels

less than those of their dams. However, low mean thyroxine levels (50 nmol/L is normal) are not a definitive indication of iodine deficiency because of the variety of factors affecting thyroxine levels. These levels fall rapidly soon after birth and approximate the dam's levels at 5–6 weeks of age.

Changes in serum thyroid hormone levels in newborn calves have been used as a diagnostic index in endemic goiter but their high variation has been unreliable.[13] The T4/T3 ratio of calves with goiter was lower than in healthy calves and adult cows, and may be a useful diagnostic aid.

In determining the iodine status of an area, iodine levels in soil and pasture should be obtained but the relationship between these levels, and between them and the status of the grazing animal, may be complicated by conditioning factors.

NECROPSY FINDINGS

Macroscopic thyroid enlargement, alopecia and myxedema may be evident. The weights of thyroid glands have diagnostic value. In full-term normal calves the average fresh weight is 6.5 g, in lambs 2 g is average. Newborn lambs from ewes unsupplemented with iodine, had mean thyroid weight (g) to body weight (kg) ratio of 0.40 g/kg or greater.[12] In calves with severe thyroid hypertrophy, the gland may be heavier than 20 g.[6]

The iodine content of the thyroid will also give some indication of the iodine status of the animal. At birth, a level of 0.03% of iodine on a wet weight basis (0.1% on dry weight) can be considered to be the critical level in cattle and sheep. On histological examination, hyperplasia of the glandular epithelium may be seen. Follicles depleted of colloid, infolded and lined by columnar epithelium are indicative of hypothyroidism in lambs born from ewes unsupplemented with iodine.[1]

The hair follicles will be found to be hypoplastic. Delayed osseous maturation, manifested by absence of centers of ossification, is also apparent in goitrous newborn lambs.

Samples for confirmation of diagnosis

- **Toxicology** – 1 thyroid gland (ASSAY (Iodine))
- **Histology** – skin, thyroid (LM).

DIFFERENTIAL DIAGNOSIS

Iodine deficiency is easily diagnosed if goiter is present but the occurrence of stillbirths without obvious goiter may be confusing. Abortion due to infectious agents in cattle and sheep must be considered in these circumstances. In stillbirths due to iodine deficiency, gestation is usually prolonged beyond the normal period, although this may be difficult to determine in animals bred at pasture. Inherited defects of thyroid hormone synthesis are listed under the heading of inherited diseases. Hyperplastic goiter without gland enlargement has been observed in newborn foals in which rupture of the common digital extensor tendons, forelimb contracture, and mandibular prognathism also occur. The cause of the combination of defects in unknown.

TREATMENT

Treatment of neonates with obvious clinical evidence of iodine deficiency is usually not undertaken because of the high case fatality rate. When outbreaks of iodine deficiency occur in neonates, the emphasis is usually on providing additional iodine to the pregnant dams. The recommendations for control can be adapted to the treatment of affected animals.

CONTROL

The recommended dietary intake of iodine for cattle is 0.8–1.0 mg/kg DM of feed for lactating and pregnant cows, and 0.1–0.3 mg/kg DM of feed for non-pregnant cows and calves.

Pastures in New Zealand which contain 0.24 mg iodine/kg DM provide an adequate intake for dairy cows.[14] The injection of iodine (iodized oil) IM three times at a dose of 2370 mg iodine/dose at the start of lactation and at 100-intervals increased iodine concentrations in milk to 58 μg/L for at least 98 days after each treatment.[14] Two iodine injections at 100-day intervals increased milk iodine concentrations to 160 μg/L and 211 μg/L at least 55 days after each treatment but had no effect on serum thyroid hormone concentrations. Iodine supplementation had no effect on milk, milkfat, or milk protein yield. Increasing iodine concentration in milk by IM injection of iodine could provide a method for increasing iodine intakes of humans, especially children.

Iodine can be provided in salt or a mineral mixture. The loss of iodine from salt blocks may be appreciable and an iodine preparation that is stable but contains sufficient available iodine is required. Potassium iodate satisfies these requirements and should be provided as 200 mg of potassium iodate per kg of salt. Potassium iodide alone is unsuitable, but when mixed with calcium stearate (8% of the stearate in potassium iodide) it is suitable for addition to salt – 200 mg/kg of salt.

Individual dosing of pregnant ewes, on two occasions during the 4th and 5th months of pregnancy, with 280 mg potassium iodide or 370 mg potassium iodate has been found to be effective in the prevention of goiter in lambs when the ewes are on a heavy diet of kale. For individual animals, weekly application of tincture of iodine (4 mL cattle, 2 mL pig and sheep) to the inside of the flank is also an effective preventive. The iodine can also be administered as an injection in poppy seed oil (containing 40% bound iodine): 1 mL given IM 7–9 weeks before lambing is sufficient to prevent severe goiter and neonatal mortality in the lambs. Control of goiter can be achieved for up to 2 years. The gestation period is also reduced to normal. A similar injection 3–5 weeks before lambing is less efficient.

The administration of long-acting injectable iodine (iodized oil) at a dose of 390 mg iodine to ewes, 5 weeks pre-mating, prevented goiter in newborn lambs from ewes fed swedes or swedes/turnips/kale as winter supplement.[7]

A device to release iodine slowly into the forestomachs, while still retaining its position there, has given good results in preventing congenital goiter in lambs when fed to ewes during late pregnancy.

IRON DEFICIENCY

Synopsis

Etiology Dietary deficiency of iron.
Epidemiology Young animals on milk diet; most commonly nursing piglets which have not received supplemental iron. Housed nursing lambs. Occurs in veal calves fed milk with limited quantities of iron. Continued blood loss due to hemorrhage (lice, blood sucking helminths). Subclinical iron deficiency occurs in calves and foals of doubtful significance. May be more susceptible to infectious diseases.
Signs Pale white skin of well grown nursing piglets, dyspnea, pallor of mucosae, sudden death may occur. Stillbirths if sows iron deficient. Secondary infectious diseases.

Clinical pathology Subnormal levels of hemoglobin of serum iron, microcytic hypochromic anemia.
Necropsy findings Pallor, thin watery blood, anasarca, dilated heart, enlarged liver.
Diagnostic confirmation Low serum hemoglobin and serum iron with microcytic hypochromic anemia. Response to iron therapy.
Differential diagnosis Other causes of anemia. See Chapter 9.
Treatment Parenteral and oral iron salts.
Control Insure adequate iron intake. Parenteral iron dextran to nursing piglets and lambs.

ETIOLOGY

Iron deficiency is usually primary and most likely to occur in newborn animals whose sole source of iron is the milk of the dam, milk being a poor source of iron. Deposits of iron in the liver of the newborn are insufficient to maintain normal hemopoiesis for more than 2–3 weeks, and are particularly low in piglets.

EPIDEMIOLOGY

Iron-deficiency states are not common in farm animals except in the very young confined to a milk diet.

Iron deficiency anemia occurs in nursing piglets for three reasons:

1. They do not have access to soil, which is a main source of iron for young farm animals
2. They grow rapidly and their absolute requirements for iron are high
3. Milk is a poor source of iron.

The administration of iron dextran to the piglets at a few days of age is preventive and is a routine health management strategy in modern pig production. If they do not receive supplemental iron dextran, clinical disease occurs usually when the piglets are 3–6 weeks old. The losses that occur include those due to mortality, which may be high in untreated pigs and to failure to thrive. Under modern pig production systems, piglets do not have access to sufficient dietary iron until they are weaned to a dry diet containing supplemental iron. Thus, the need for parenteral iron dextran at a few days of age. Even piglets raised outdoors with access to soil perform better when supplemented with iron.[1] Iron injected piglets raised outdoors are heavier at weaning, there is less preweaning morbidity and mortality and they have higher blood hemoglobin concentrations compared to non-supplemented piglets.[1]

Iron deficiency in pigs increases the severity of *Trichuris suis* and *Ascaris suum* infections.[2]

Iron deficiency anemia occurs in nursing lambs that are housed and do not have access to soil, do not consume much feed other than their dam's milk for the first 7–10 days of life, and grow at 0.4 kg/d.[3] The parenteral administration of iron dextran at 24 h of age prevents the anemia.[3] Abomasal bloat occurs in these lambs with lower serum iron concentration and iron dextran injections is preventive, as well as having a significant effect on weight gain, red blood cell and iron parameters.[4]

Continued blood loss by hemorrhage in any animal may result in subclinical anemia and iron deficiency. Cattle heavily infested with sucking lice may develop serious and even fatal anemia. The chronic form is characterized by a non-regenerative anemia with subnormal levels of serum iron, and treatment with iron is necessary for an optimal response. Horses carrying heavy burdens of bloodsucking strongylid worms often have subnormal hemoglobin levels and respond to treatment with iron. On occasions veal calves, and possibly young lambs and kids, may also suffer from an iron deficiency.

Good quality veal is traditionally pale in color and is produced by feeding calves an all-liquid milk replacer diet with a low concentration of available iron.[5,6] The pallor of veal is due largely to low concentrations of myoglobin and other iron-containing compounds in muscle. Milk replacers containing only 10 mg iron/kg DM results in marked anemia and reduced growth performance.[6] Feeding milk replacers with 50 mg iron/kg DM is considered, physiologically, the optimum amount of iron for veal calves but may be too high for acceptable carcass yield in some countries.[6] A severe iron deficiency with reduced growth rate in veal calves may be associated with a higher incidence of infectious disease because of an impaired immune system.[7] The objective in veal calf management is to walk the narrow line between the maximum production of white meat and a degree of anemia insufficient to interfere with maximum production.

Subclinical iron-deficiency anemia also occurs in newborn calves and kids but there is debate as to whether the condition has practical significance. In newborn calves affected with a normochromic, normocytic, and poikilocytic anemia the levels of serum iron are not significantly different from normal calves.[8] It has been proposed that severe poikilocytosis in calves is associated with abnormalities of hemoglobin composition and protein 4.2 in the erythrocyte membrane, and iron deficiency is the cause of moderate poikilocytosis in calves.[9]

Clinicopathological anemia, without clinical signs, is most likely to occur when calves are born with low hemoglobin and hematocrit levels, a relatively common occurrence in twins. It is possible that suboptimal growth may occur during the period of physiological anemia in early postnatal life. There is some evidence for this in calves in which hemoglobin levels of 11 g/dL at birth fall to about 8 g/dL between the 30th and 70th days and only begin to rise when the calves start to eat roughage. The daily intake of iron from milk is 2–4 mg in calves, and their daily requirement during the first 4 months of life is of the order of 50 mg, so that iron supplementation of the diet is advisable if the calves are fed entirely on milk. Even when hay and grain are fed to calves and lambs in addition to milk, there is a marked growth response to the administration of iron-dextran preparations at the rate of 5.5 mg/kg BW. The dietary iron requirement for fast-growing lambs is between 40 and 70 mg/kg BW, and growth rate is suboptimal on diets of less than 25 mg/kg BW.

Low serum iron concentration and low serum ferritin have been observed in hospitalized young foals.[10] Hemoglobin concentrations and packed cell volume decrease in foals from values at birth, which are similar to those for adult horses, to mean values during the first weeks and months of life below those reported in adults. Serum iron concentration, total iron-binding capacity, and packed cell volume decreased during the foal's first 24 h of life.[11] Based on the studies of foals from birth to 1 year of age, the potential for iron deficiency developing under 5 weeks of age is possible because 65% of foals had minimum ferritin concentrations = 45 ng/mL, and 81% of foals had these minimum values recorded between 2 and 4 weeks.

Competition horses are frequently given iron supplementation to treat anemia and to improve performance despite the fact that neither application has any scientific basis.[10] In contrast, iron overload and toxicity have occurred in competition horses.[12,13] Some studies have shown high total plasma iron in British 3-day event team horses prior to transport (77 μmol/L compared with normal levels of 24 μmol/L. Immediately after traveling for 3 days on the road, the plasma levels had declined to 29 μmol/L.[14] The iron-binding antioxidant activity, an indicator of transferrin saturation, had also declined, suggesting greater saturation of available transferrin in the plasma or a decreased capacity to sequester iron. The saturation of mechanisms to sequester iron, such as may occur with excessive supplementation, may predispose the horses to iron-catalyzed oxidant injury.[14] The total iron intake exceeded the normal recommendation of between 550 and 600 mg/d. Anemia (or a low packed cell volume) is not synonymous with iron deficiency but is frequently associated with disease processes. Poor performance in an iron-

deficient animal is more likely due to a reduction in the activity of metabolically active iron-containing enzymes rather than a reduction in oxygen transport. In addition, iron deficiency is unlikely to occur in healthy horses.

Calcium carbonate added to the diet of weaned and finishing pigs may cause a conditioned iron deficiency and a moderate anemia but this effect is not apparent in mature pigs. Manganese may exert a similar antagonistic effect.

PATHOGENESIS

More than half the iron in the animal body is found as a constituent of hemoglobin. A relatively small amount is found in myoglobin and in certain enzymes which play a part in oxygen utilization.

Piglets at birth have hemoglobin levels of about 90–110 g/L. A physiological fall to 40–50 g/dL occurs in all pigs, the lowest levels occurring at about the 8th–10th day of life. Levels of iron in the liver at birth are unusually low in this species and cannot be increased appreciably by supplementary feeding of the sow during pregnancy. The IM injection of iron-dextran preparations to sows during late pregnancy does elevate the hemoglobin levels of the piglets during the first few weeks of life but not sufficiently to prevent anemia in them. Piglets with access to iron show a gradual return to normal hemoglobin levels starting at about the 10th day of life, but in pigs denied this access the hemoglobin levels continue to fall.

One of the important factors in the high incidence of anemia in piglets is the rapidity with which they grow in early postnatal life. Piglets normally reach four to five times their birth weight at the end of 3 weeks, and 15 times their birth weight at the end of 8 weeks. The daily requirement of iron during the first few weeks of life is of the order of 15 mg. The average intake in the milk from the sow is about 1 mg/d and the concentration in sow's milk cannot be elevated by feeding additional iron during pregnancy or lactation. Apart from the specific effect on hemoglobin levels, iron-deficient piglets consume less creep feed, and after the first 3 weeks of life make considerably slower weight gains than supplemented piglets. Although specific pathogen-free pigs show a less marked response to the administration of iron than pigs reared in the normal manner, it is obvious that they need supplementary iron to prevent the development of anemia. Iron-deficient piglets appear to be more susceptible to diarrhea at about 2 weeks of age than are piglets that have received iron. A marked impairment of gastric secretion of acid and chloride and atrophic gastritis occurs in iron-deprived piglets. Villous atrophy of the small intestine and changes in the gastrointestinal flora also occur in iron-deficient piglets which may contribute to the increased susceptibility to diarrhea.

In iron deficient piglets, lymphocyte activity is impaired resulting in a decrease in circulating B-lymphocyte numbers and decreased immunocompetence.[15]

Severe iron deficiency in veal calves is characterized by impaired growth and reduced feed intake and utilization. The growth rate is reduced only when hemoglobin concentrations fall below 70 g/L.[16] The reduced growth rate may be due to reduction in the half-life of growth hormone.

CLINICAL FINDINGS

The highest incidence of iron deficiency anemia in piglets occurs at about 3 weeks of age, but it can occur up to 10 weeks of age.

Affected pigs may be well grown and in good condition, but the growth rate of anemic pigs is significantly lower than that of normal pigs and feed intake is reduced. A mild diarrhea may occur but the feces are usually normal in color. Dyspnea, lethargy and a marked increase in amplitude of the apex beat of the heart can be felt after exercise. The skin and mucosae are pale and may appear yellow in white pigs. Edema of the head and forequarters, giving the animal a fat, puffed-up appearance may be present. A lean, white hairy look is probably more common. Death usually occurs suddenly, or affected animals may survive in a thin, unthrifty condition. A high incidence of infectious diseases, especially enteric infection with *Escherichia coli*, is associated with the anemia, and streptococcal pericarditis is a well-recognized complication. Under experimental conditions, similar signs occur in calves and there is, in addition, an apparent atrophy of the lingual papillae. A high incidence of stillbirths is recorded in the litters of sows suffering from iron-deficiency anemia.

CLINICAL PATHOLOGY

In normal piglets there is a postnatal fall of hemoglobin levels to about 8 g/L and sometimes to as low as 4–5 g/L during the first 10 days of life. In iron-deficient pigs there is a secondary fall to 20–40 g/L during the 3rd week. The hemoglobin level at which clinical signs appear in pigs is about 40 g/L.[17] Erythrocyte counts also fall from a normal of $5–8 \times 10^{12}$/L down to $3–4 \times 10^{12}$/L and may be a better index of iron status than hemoglobin levels. Iron-deficiency anemia in piglets is a microcytic hypochromic anemia. In chronic blood loss anemia in cattle infested with sucking lice, there is a non-regenerative anemia and a decrease in serum iron levels. Serum levels of iron considered to be normal in sheep and cattle are 100–200 μg/dL (17.9–35.8 μmol/L). In newborn calves, the levels are 170 μg/dL (30.4 μmol/L) at birth and 67 μg/dL (12.0 μmol/L) at 50 days of age. Serum ferritin concentration is an index for monitoring pre-latent iron deficiency of calves.[18]

The borderline of iron-deficiency anemia of veal calves at 16–20 weeks of age has been defined as a hemoglobin concentration of 9 g/L and a saturation of total iron binding capacity of 10%.[19]

NECROPSY FINDINGS

The carcass is characterized by pallor, watery blood and moderate anasarca. The heart is always dilated, sometimes extremely so. The cardiac dimensions in severely anemic neonatal pigs indicate that dilatation and hypertrophy occur consistently. The liver in all cases is enlarged, and has a mottled tan-yellow appearance. Histological examination of the bone marrow reveals maturation asynchrony of the erythroid line and a lack of hemosiderin stores. Other microscopic changes described include periacinar hepatocellular changes typical of hypoxia and decreased numbers of parietal cells in the gastric mucosa.

Samples for confirmation of diagnosis

- **Toxicology** – 50 g liver (ASSAY (Fe)) (Note that serum ferritin from surviving littermates is a better indicator of iron status)
- **Histology** – liver, heart, bone marrow, stomach (LM).

DIFFERENTIAL DIAGNOSIS

Confirmation of the diagnosis will depend upon hemoglobin determinations and curative and preventive trials with administered iron. The possibility that anemia in piglets may be caused by copper deficiency should not be overlooked especially if the response to administered iron is poor. Isoimmunization hemolytic anemia can be differentiated by the presence of jaundice and hemoglobinuria, and the disease occurs in much younger pigs. Eperythrozoonosis occurs in pigs of all ages and the protozoan parasites can be detected in the erythrocytes.

TREATMENT

The recommendations for the prevention of the disease are set out below and can be followed when treating clinically affected animals. Horses with poor racing performance often have suboptimal blood levels of hemoglobin and a blood loss anemia due to parasitism, and respond well to treatment with iron. Treatment is usually parenteral and consists of organic iron preparations such as iron-dextran, iron-

sorbitol-citric acid complex, iron saccharate, or gluconate. These must be given exactly as prescribed by the manufacturer as some are quite irritant, causing large sloughs when injected IM. The dose rate is 0.5–1 g elemental iron in one injection per week. When given IV, or even IM, some horses show idiosyncratic reactions and literally drop dead. Vitamin B_{12} (cyanocobalamin) is often used in the same injection at a dose rate of 5000 μg/week in a single dose. Other additives, especially folic acid and choline, are also used but with little justification. Oral treatment with iron sulfate or gluconate at a dose rate of 2–4 g daily for 2 weeks is as effective and much cheaper, but lacks the style of the parenteral injection. It has the disadvantage of being unpalatable and is best dispensed in liquid form to be mixed with molasses and poured onto dry feed.

CONTROL

Preventive measures must be directed at the neonatal piglets because treatment of the sows before or after farrowing is generally ineffective, although some results are obtained if the iron preparations are fed at least 2 weeks before farrowing. Ferric choline citrate appears to have some special merit in this field. Allowing the nursing piglets access to pasture or dirt yards, or periodically placing sods in indoor pens, offer adequate protection. Where indoor housing on impervious floors is necessary, iron should be provided at the rate of 15 mg/d until weaning either by oral dosing with iron salts of a commercial grade or by the IM injection of organic iron preparations. These methods are satisfactory, but the results are not usually as good as when piglets are raised outdoors. However, indoor housing is practiced in many areas to avoid exposure to parasitic infestation and some bacterial diseases, especially erysipelas. If sods are put into pens care must be taken to insure that these diseases are not introduced.

Dietary supplementation

Sows

Feeding sows a diet supplemented with 2000 mg iron/kg DM of diet will satisfactorily prevent iron-deficiency anemia in the piglets. The piglets will ingest about 20 g of sows feces per day, which will contain sufficient iron and obviate the need for IM injection of iron-dextran. The piglets grow and thrive as well as those receiving the iron-dextran.

Veal calves

Milk replacers for veal calves may contain up to 40 mg/kg DM of iron for the first months, but commonly only 10–15 mg/kg DM for the finishing period. The best indicator of the onset of anemia in calves on vealer diets is loss of appetite, which is a more sensitive indicator than biochemical measurement.

Heifer calf herd replacements

The National Research Council recommends that milk replacers fed to herd replacements or dairy beef contain 100 mg/kg of DM, with an upper limit of 1000 mg/kg DM.[17] The pre-ruminant calf can tolerate between 2000 and 5000 ppm DM iron in milk replacer.[17]

Oral dosing

Daily dosing with 4 mL of 1.8% solution of ferrous sulfate is adequate. Iron pyrophosphate may also be used (300 mg/d for 7 days). To overcome the necessity for daily dosing, several other methods of administering iron have been recommended. A single oral treatment with iron-dextran or iron-galactan has been recommended, provided an excellent creep feed is available, but the method seems unnecessarily expensive. With this oral treatment it is essential that the iron be given within 12 h of birth because absorption has to occur through the perforate neonatal intestinal mucosa; later administration is not followed by absorption. Reduced iron (British Veterinary Codex) can be administered in large doses because it does not cause irritation of the alimentary mucosa. A single dose of 0.5–1 g once weekly is sufficient to prevent anemia. Alternatively, the painting of a solution of ferrous sulfate on the sow's udder has been recommended (450 g ferrous sulfate, 75 g copper sulfate, 450 g sugar, 2 L water – applied daily) but has the disadvantage of being sticky and of accumulating litter. Pigs raised on steel gratings can derive enough iron from them to avoid the need for other supplementation. Excessive oral dosing with soluble iron salts may cause enteritis, diarrhea, and some deaths in pigs. High intakes of ferric hydroxide cause diarrhea, loss of weight, and low milk production in cattle. The presence of diarrhea in a herd prevents absorption of orally administered iron, and treatment by injection is recommended in this circumstance.

Intramuscular injection of iron preparations

Suitable preparations must be used and are usually injected IM in piglets on one occasion only, between the 3rd and 7th day of life. Iron-dextran, fumarate, and glutamate are most commonly used. A dose of 200 mg of a rapidly absorbed and readily utilizable form of iron within the first few days of life will result in greater body weights at 4 weeks of age than piglets given only 100 mg.[20] Multiple injections give better hemoglobin levels but have not been shown to improve weight gain and, thus, a second injection at 2–3 weeks of age may not be economical. A total dose of 200 mg is usually recommended as being required to avoid clinically manifest iron-deficiency anemia, but in order to avoid any chance of a subclinical deficiency the feed should contain additional iron at the level of 240 mg/kg. A new preparation (Heptomer) contains 200 mg/mL of iron, permitting a full dose in one injection. Contrasting information is that one injection of 100 mg of iron is adequate for baby pigs. Acute poisoning and rapid death occurs in piglets given iron-dextran compounds parenterally if the piglets were born from sows which were deficient in vitamin E and selenium during gestation. This is discussed under iron-dextran poisoning. In normal piglets, the iron-dextran compounds are safe and are usually not toxic even on repeated injection. These preparations are ideal for treatment because of the rapid response they elicit and the absence of permanent discoloration of tissues after their use if given during the first month of life. A combination of sodium selenite and iron-dextran has been given to piglets at 3 days of age and is superior to treatment with iron alone when the piglets are deficient in selenium.

Iron supplementation should also be administered to suckling piglets raised outdoors.[1]

Iron deficiency anemia in housed lambs is preventable by the IM injection of 300 mg iron dextran at 24 h of age.[3] At 12 and 24 days after treatment, the hematological values in the treated group were significantly different from the unsupplemented group, and at weaning, the treated lambs were 1.0 kg heavier than untreated lambs.[3] An oral iron supplement given to these housed lambs improved red cell and iron parameters but did not improve performance.[21]

Comparable doses of parenteral iron-dextran compounds have been used for the treatment of iron-deficiency or iron-loss anemias in other species, but accurate doses have not been established and the use of these preparations in cattle and horses is expensive. In addition, iron-dextran preparations given IM to horses may cause death within a few minutes after administration. The most inexpensive method of supplying iron is to use ferrous sulfate orally at a dose of 2–4 g daily for 2 weeks to adult cattle and horses with iron-deficiency anemia.

Iron injection of beef calves in the first week after birth will result in an increase in packed cell volume (PVC), hemoglobin (Hb), mean corpuscular volume (MCV), and mean corpuscular hemoglobin (MCH) which persists for 12 weeks. However, weight gains during the first 18 weeks of life were not affected.

SODIUM CHLORIDE DEFICIENCY

A dietary deficiency of sodium is most likely to occur:

- During lactation, as a consequence of losses of the element in the milk, in rapidly growing young animals fed on low-sodium, cereal-based diets
- Under very hot environmental conditions where large losses of water and sodium occur in the sweat and where the grass forage and the seeds may be low in sodium
- In animals engaged in heavy or intense physical work and in animals grazing pastures on sandy soils heavily fertilized with potash, which depresses forage sodium levels.[1]

Naturally occurring salt deficiency causing illness in grazing animals is uncommon except under certain circumstances. The most commonly cited occurrences are on alpine pastures and heavily fertilized pasture leys. Pasture should contain at least 0.15 g/100 g dry matter (DM) and clinical signs are evident after about 1 month on pasture containing 0.1 g/100 g DM. Under experimental conditions, lactating cows give less milk until the chloride deficiency is compensated. After a period of up to 12 months there is considerable deterioration in the animal's health and anorexia, a haggard appearance, lusterless eyes, rough coat, and a rapid decline in body weight occur. High-producing animals are most severely affected and some may collapse and die. The oral administration of sodium chloride is both preventive and rapidly curative. Experimental sodium depletion in horses for up to 27 days has no deleterious effect on general health.

In **dairy cattle on a sodium-deficient diet** there is polyuria, polydipsia, salt hunger, pica, including licking dirt and each other's coats, drinking urine, loss of appetite and weight, and a fall in milk production.[2] Urination is frequent and the urine has a lower than normal specific gravity and the urine concentrations of sodium and chloride are decreased and the potassium increased. The salivary concentration of sodium is markedly decreased, the potassium is increased, and the salivary sodium:potassium ratio is decreased. The concentration of serum sodium and chloride are also decreased, but the measurement of urinary or salivary sodium concentration is a more sensitive index of sodium intake than plasma sodium concentration.[2] Of these, it is urinary sodium which is depressed first and is therefore the preferred indicator in cattle[3] and horses.[4] The polyuria associated with severe sodium depletion may be an antidiuretic hormone insensitivity due to lack of an effective countercurrent mechanism and hyperaldosteronism.[2]

Supplementation of salt to dairy cows on a pumice soil in New Zealand resulted in a 12.8% increase in milk yield with unaltered composition.[5] The cows were grazing ryegrass/clover pastures averaging 0.05% sodium whereas the recommended concentration for dairy cows is 0.12%. Measurement of the sodium content of the pasture is the most simple and reliable method of diagnosing salt deficiency compared to saliva sodium:potassium ratio. It is considered likely that sodium deficiency will become more prevalent on dairy farms in the future and that there cost-effective benefits to using salt where deficiencies occur.

Experimental restriction of chloride in the diet of dairy cows in early lactation results in a depraved appetite, lethargy, reduced feed intake, reduced milk production, scant feces, gradual emaciation and severe hypochloremia and secondary hypokalemic metabolic alkalosis.[6] Lethargy, weakness, and unsteadiness occur after about 6 weeks on the chloride-deficient diet.[7] Bradycardia is also common. The concentration of chloride in cerebrospinal fluid is usually maintained near normal, while the serum concentrations decline.[8] The experimental induction of a severe, total body chloride deficit by the provision of a low-chloride diet and the daily removal of abomasal contents results in similar clinical findings to those described above and lesions of nephrocalcinosis.[9]

The **diagnosis of salt deficiency** is dependent on the clinical findings, analysis of the feed and water supplies, serum levels of sodium and chlorine and determination of the levels of sodium in the saliva, urine, and feces of deficient animals.[10] The concentration of sodium in saliva is a sensitive indicator of sodium deficiency. In cattle receiving an adequate supply of sodium and chlorine, the sodium levels in saliva vary from 140 to 150 mmol/L, in deficient cattle the levels may be as low as 70–100 mmol/L.[10] The levels of sodium in the urine are low, with a reciprocal rise in potassium.[4] The serum sodium levels are less reliable, but licking begins when the level falls to 137 mmol/L and signs are intense at 135 mmol/L.

The biochemical methods have been evaluated to estimate the sodium intake of dairy cows.[11] Groups of cows were given 10–20, 30–50, or 70–100 g salt per day, and two groups were given salt ad libitum either in bowls or in salt blocks. The concentrations of sodium and potassium were measured in serum and urine. Cows receiving 70–100 g salt daily, and those in the ad libitum group, had higher urinary sodium concentrations than the other groups. Those receiving 10–20 g day had a higher urinary ratio of potassium:sodium in their urine than all other groups, in which the ratio decreased as the level of supplementary salt increased.

Experimentally induced sodium deficiency in young pigs causes anorexia, reduced water intake and reduced weight gains.[12]

The provision of salt in the diet at a level of 0.5% is considered to be fully adequate for all farm animal species. Under practical conditions, salt mixes usually contain added iodine and cobalt. In some situations the salt mixes are provided on an ad libitum basis rather than adding them to the diet. However, voluntary consumption is not entirely reliable. The daily amount consumed by animals having unrestricted access to salt can be highly variable and often wasteful. Two factors influencing voluntary salt intake include the physical form of the salt and the salt content of the water and feed supplies. Some cattle consume much more loose than block salt, though the lower intakes of block salt may be adequate. Also, animals dependent on high saline water for drinking consume significantly less salt than when drinking non-saline water. Voluntary salt consumption is generally high in cows on low-sodium pastures, which are low inherently or as a result of heavy potash fertilization. Lactating gilts may require 0.7% salt in their diets[13] and energy efficiency in feedlot cattle may be improved by feeding high levels (5% of diet) of salt in the diet of finishing steers.[14]

MAGNESIUM DEFICIENCY

A nutritional deficiency of magnesium plays a role in causing lactation tetany in cows and hypomagnesemic tetany of calves, and these diseases are dealt with in Ch. 28 on metabolic diseases. In both diseases, there are complicating factors that may affect the absorption and metabolism of the element.

Hypomagnesemia may occur in up to 50% of adult horses hospitalized for severe gastrointestinal disease such as colic, acute diarrhea, and infectious respiratory disease.[1] Young horses were able to regulate serum total magnesium concentrations more efficiently than adult horses which were more likely to be hospitalized longer, but the mortality rate was not higher.

Magnesium is an essential constituent of rations for recently weaned pigs.[2] Experimentally induced deficiency causes weakness of the pasterns, particularly in the forelegs, causing backward bowing of the legs, sickled hocks, approximation of the knees and hocks, arching of the back, hyperirritability, muscle tremor, reluctance to stand, continual shifting of weight from limb to limb, and eventually tetany and death. A reduction in growth rate, feed consumption and conversion, and levels of magnesium in the serum also occur. The requirement of magnesium for pigs weaned at 3–9 weeks of age is 400–500 mg/kg of the total ration.

ZINC DEFICIENCY (PARAKERATOSIS)

Synopsis

Etiology Dietary deficiency of zinc and factors which interfere with zinc utilization.
Epidemiology Growing pigs, cattle and sheep. Excess of calcium favors disease in pigs.
Signs
Pigs Loss of body weight gain. Symmetrical, crusty skin lesions (parakeratosis) over dorsum and ears, tail; become thick and fissured. No pruritus.
Ruminants Alopecia, over muzzle, ears, tail-head, hindlegs, flank, and neck. Stiff gait and swelling over coronets. Loss of wool and thickened skin in sheep. Infertility in rams. Poor growth in goats and skin lesions.
Clinical pathology Serum zinc levels lower than normal.
Necropsy findings Parakeratosis.
Diagnostic confirmation Histology of skin lesions and serum zinc levels.

Differential diagnosis list

- Sarcoptic mange in cattle and pigs
- Exudative epidermitis in piglets.

Treatment Add zinc to diet.
Control Supplement zinc in diet.

ETIOLOGY

Pigs

A zinc deficiency in young, growing pigs can cause parakeratosis, but it is not due to a simple zinc deficiency. The availability of zinc in the diet is adversely affected by the presence of phytic acid, a constituent of plant protein sources such as soybean meal.[1] Much of the zinc in plant protein is in the bound form and unavailable to the monogastric animal such as the pig.[2] The use of meat meal or meat scraps in the diet will prevent the disease because of the high availability of the zinc. Another unique feature of the etiology of parakeratosis in swine is that an excess of dietary calcium (0.5–1.5%) can favor the development of the disease, and the addition of zinc to such diets at levels much higher (0.02% zinc carbonate or 100 mg/kg zinc) than those normally required by growing swine prevents the occurrence of the disease. The level of copper in the diet may also be of some significance, increasing copper levels decreasing the requirement for zinc. A concurrent enteric infection with diarrhea exacerbates the damage done by a zinc deficiency in pigs.

Ruminants

A primary zinc deficiency due to low dietary zinc in ruminants is rare but does occur.[3] Many factors influence the availability of zinc from soils, including the degree of compaction of the soil, and the nitrogen and phosphorus concentration. The risk of zinc deficiency increases when soil pH rises above 6.5 and as fertilization with nitrogen and phosphorus increases. Some legumes contain less zinc than grasses grown on the same soil, and zinc concentration decreases with aging of the plant. Several factors may deleteriously affect the availability of zinc to ruminants and cause a secondary zinc deficiency. These include the consumption of immature grass, which affects digestibility, the feeding of late-cut hay, which may be poorly digestible, and the presence of excessive dietary sulfur. The contamination of silage with soil at harvesting can also affect the digestibility of zinc.[3]

EPIDEMIOLOGY

Pigs

Parakeratosis in pigs was first recorded in North America in rapidly growing pigs, particularly those fed on diets containing growth promoters. The disease occurs most commonly during the period of rapid growth, after weaning and between 7 and 10 weeks of age. From 20 to 80% of pigs in affected herds may have lesions, and the main economic loss is due to a decrease in growth rate. In general, the incidence is greater in pigs fed in dry lot on self-feeders of dry feed than in pigs with access to some pasture, which is preventive and curative.

A low level of dietary zinc intake during pregnancy and lactation of gilts can result in skin lesions, stressful parturition, and an increased incidence of intrapartum mortality of piglets and deleterious effects on neonatal growth.[4]

It has been suggested that parakeratosis occurs because very rapidly growing pigs outstrip their biosynthesis of essential fatty acids, and when the diet is high in calcium the digestibility of fat in the diet is reduced at the same time. The net effect in rapidly growing pigs could be a relative deficiency of essential fatty acids.

Ruminants

There are naturally occurring cases in cattle, sheep, and goats. The disease is well-recognized in Europe, especially in calves. It is common in some families of cattle and an inherited increased dietary requirement for zinc is suspected. The inherited disease occurs in Friesian and Black Pied cattle and is known as lethal trait A46.[5] Signs of deficiency appear at 4–8 weeks of age. The main defect is an almost complete inability to absorb zinc from the intestine; zinc administration is curative.

The disease in **cattle** has been produced experimentally on diets low in zinc, and naturally occurring cases have responded to supplementation of the diet

with zinc.[3] Calves remain healthy on experimental diets containing 40 mg/kg zinc, but parakeratosis has occurred in cattle grazing pastures with a zinc content of 20–80 mg/kg (normal 93 mg/kg) and a calcium content of 0.6%. There is also an apparently improved response in cattle to zinc administration if copper is given simultaneously. Parakeratosis has also been produced experimentally in goats and sheep.

Zinc nutrition may be involved in the immune responses of feedlot calves.[6] When calves are stressed by transportation or challenged with the infectious bovine rhinotracheitis virus, they tend to have reduced fevers, higher dry matter intake and less body weight loss when fed organic zinc and manganese sources than the corresponding oxide forms.

Outbreaks of the disease have occurred in **Sudanese Desert ewes** and their lambs fed on a zinc-deficient diet of Rhodes grass containing less than 10 mg/kg of zinc. The disease has also been diagnosed in **mature sheep and goats** and the cause of the deficiency could not be determined. A marginal zinc deficiency, characterized by subnormal growth and fertility and low concentration of zinc in serum, but without other clinical signs, can occur in sheep grazing pastures containing less than 10 mg/kg zinc.[7]

In Germany, skin lesions have occurred in alpacas and llamas with low zinc and copper status.[8] In the affected herd, the average serum zinc and copper levels were 0.17 and 0.49 μg/mL for alpacas and 0.22 and 0.38 μg/mL for llama, respectively. The levels considered normal in llamas is 0.30 μg for zinc and 0.40–0.70 μg copper per mL.

PATHOGENESIS

The pathogenesis of zinc deficiency is not well-understood. Zinc is a component of the enzyme carbonic anhydrase, which is located in the red blood cells and parietal cells of the stomach, and is related to the transport of respiratory carbon dioxide and the secretion of hydrochloric acid by the gastric mucosa. Zinc is also associated with RNA function and related to insulin, glucagon, and other hormones. It also has a role in keratinization, calcification, wound healing, and somatic and sexual development. Because it has a critical role in nucleic acid and protein metabolism a deficiency may adversely affect the cell-mediated immune system.

A zinc deficiency results in a decreased feed intake in all species[7] and is probably the reason for the depression of growth rate in growing animals and body weight in mature animals. Failure of keratinization resulting in parakeratosis, loss and failure of growth of wool and hair and lesions of the coronary bands probably reflect the importance of zinc in protein synthesis. There are lesions of the arteriolar walls of the dermis. The bones of zinc-deficient ruminants reveal abnormal mineralization and reduction of zinc concentration in bones. Retarded testicular development occurs in ram lambs, and complete cessation of spermatogenesis suggests impairment of protein synthesis.

CLINICAL FINDINGS

Pigs

A reduced rate and efficiency of body weight gain is characteristic. Circumscribed areas of erythema appear in the skin on the ventral abdomen and inside the thigh. These areas develop into papules 3–5 mm in diameter, which are soon covered with scales followed by thick crusts. These crusts are most visible in areas about the limb joints, ears and tail and are distributed symmetrically in all cases. The crusts develop fissures and cracks, become quite thick (5–7 mm) and easily detached from the skin. They are crumbly and not flaky or scaly. No greasiness is present except in the depths of fissures. Little scratching or rubbing occurs. Diarrhea of moderate degree is common. Secondary subcutaneous abscesses occur frequently, but in uncomplicated cases, the skin lesions disappear spontaneously in 10–45 days if the ration is corrected.

Ruminants

In the naturally occurring disease in cattle, in severe cases, parakeratosis and alopecia may affect about 40% of the skin area. The lesions are most marked on the muzzle, vulva, anus, tailhead, ears, backs of the hindlegs, kneefolds, flank, and neck. Most animals are below average body condition and are stunted in growth. After treatment with zinc, improvement is apparent in 1 week and complete in 3 weeks. Experimentally produced cases exhibit the following signs:

- Poor growth
- A stiff gait
- Swelling of the coronets, hocks, and knees
- Soft swelling containing fluid on the anterior aspect of the hind fetlocks
- Alopecia
- Wrinkling of the skin of the legs, scrotum and on the neck and head, especially around the nostrils
- Hemorrhages around the teeth
- Ulcers on the dental pad.

The experimental disease in cattle is manifested by parakeratotic skin, mainly on the hindlimbs and udder, and similar lesions on teats, which tend to become eroded during milking. The fetlocks and pasterns are covered with scabby scales. There is exudation first with matting of hair, then drying and cracking. The skin becomes thickened and inelastic. Histologically, there is parakeratosis. Clinical signs develop about 2 weeks after calves, and lambs go onto a deficient diet so that there is no evidence of storage of zinc in tissues in these animals. In goats, hair growth, testicular size, and spermatogenesis are reduced, and growth rate is less than normal. Return to a normal diet does not necessarily reverse these signs and the case fatality rate is high. There is a marked delay in wound healing.

Sheep

The natural disease in sheep is characterized by loss of wool and the development of thick, wrinkled skin. Wool-eating also occurs in sheep and may be one of the earliest signs noticed in lambs after being on a zinc-deficient diet for 4 weeks. Induced cases in lambs have exhibited reduced growth rate, salivation, swollen hocks, wrinkled skin and open skin lesions around the hoof and eyes. The experimental disease in goats is similar to that in lambs.

One of the most striking effects of zinc deficiency in **ram lambs** is impaired testicular growth and complete cessation of spermatogenesis. Diets containing 2.44 mg/kg dry matter (DM) caused poor growth, impaired testicular growth, cessation of spermatogenesis, and other signs of zinc deficiency within 20–24 weeks. A diet containing 17.4 mg/kg DM of zinc is adequate for growth, but a content of 32.4 mg/kg DM is necessary for normal testicular development and spermatogenesis. On severely deficient experimental diets, other clinical signs in young rams are:

- Drooling copious amounts of saliva when ruminating
- Parakeratosis around eyes, on nose, feet, and scrotum
- Shedding of the hooves
- Dystrophy and shedding of wool, which showed severe staining
- Development of a pungent odor.

In naturally occurring cases in rams the animals stood with their backs arched and feet close together.

A marginal zinc deficiency in ewes may be characterized by only a reduction in feed intake and a slightly reduced body weight, and no other external signs of disease. This is important because, in grazing ruminants, the lack of external signs indicates that zinc deficiency could easily pass undetected.

Infertility in ewes

Infertility in ewes and a dietary deficiency of zinc have not been officially linked, but

a zinc-responsive infertility has been described in ewes. Again, attention is drawn to the need for response trials when soil and pasture levels of an element are marginal.

An **experimental zinc deficiency in pregnant ewes** results in a decrease in the birth weight of the lambs and a reduced concentration of zinc in the tissues of the lambs; these effects are due to the reduced feed intake characteristic of zinc deficiency.[7] The zinc content of the diet did not significantly influence the ability of the ewes to become pregnant or maintain pregnancy. The combination of pregnancy and zinc deficiency in the ewe leads to highly efficient utilization of ingested zinc, and the developing fetus will accumulate about 35% of the total dietary intake of zinc of the ewe during the last trimester of pregnancy. The disease is correctable by the supplementary feeding of zinc.

Goats

Experimentally induced zinc deficiency in goats results in poor growth, low food intake, testicular hypoplasia, rough dull coat with loss of hair, and the accumulation of hard, dry, keratinized skin on the hindlimbs, scrotum, head, and neck. On the lower limbs the scabs fissure, crack, and produce some exudate. In naturally occurring cases in pygmy goats there was extensive alopecia, a kyphotic stance, extensive areas of parakeratosis, abnormal hoof growth, and flaky, painful coronary bands. A zinc-responsive alopecia and hyperkeratosis in Angora goats has been described. Affected animals had recurrent pruritus, hyperemia, exfoliation, fleece loss over the hindquarters, face and ears, and a decline in reproductive performance.

Immediately before parturition in cows, there is a precipitate fall in plasma zinc concentration, which returns to normal slowly after calving. The depression of zinc levels is greater in cows that experience dystocia. This has led to the hypothesis that dystocia in beef heifers may be caused in some circumstances by a nutritional deficiency of zinc and that preparturient supplementation of the diet with zinc may reduce the occurrence of difficult births. This phenomenon does not appear to occur in sheep. The level of serum zinc increased in cattle during the season of facial eczema when sporidesmin intoxication causes depletion of liver zinc.[9]

CLINICAL PATHOLOGY

Skin scraping

Laboratory examination of skin scrapings yields negative results, but skin biopsy will confirm the diagnosis of parakeratosis.

Zinc in serum and hair

Serum zinc levels may have good diagnostic value. Normal levels are 80–120 μg/dL (12.2–18.2 μmol/L) in sheep and cattle. Calves and lambs on deficient diets may have levels as low as 18 μg/dL (3.0 μmol/L). Normal serum zinc levels in sheep are above 78 μg/dL (12 μmol/L), and values below 39 μg/dL (6 μmol/L) or less are considered as evidence of deficiency.[7] There is a general relationship between the zinc content of the hair and the level of zinc in the diet, but the analysis of hair is not considered to be a sufficiently accurate indicator of an animal's zinc status. In experimental disease in piglets, there is a reduction in serum levels of zinc, calcium, and alkaline phosphatase, and it is suggested that the disease could be detected by measuring the serum alkaline phosphate and serum zinc levels. Levels of zinc in the blood are very labile and simple estimations of it alone are likely to be misleading. For example, other intercurrent diseases commonly depress serum calcium and copper levels. In addition, zinc levels in plasma fall precipitately at parturition in cows; they are also depressed by hyperthermal stress. After 1 week on a highly deficient diet, serum zinc levels fall to about 50% of normal, or pretreatment levels.

NECROPSY FINDINGS

Necropsy examinations are not usually performed, but histological examination of skin biopsy sections reveals a marked increase in thickness of all the elements of the epidermis. Tissue levels of zinc differ between deficient and normal animals but the differences are statistical rather than diagnostic.

DIFFERENTIAL DIAGNOSIS

Sarcoptic mange may resemble parakeratosis, but is accompanied by much itching and rubbing. The parasites may be found in skin scrapings. Treatment with appropriate parasiticides relieves the condition.

Exudative epidermitis is quite similar in appearance, but occurs chiefly in unweaned pigs. The lesions have a greasy character that is quite different from the dry, crumbly lesions of parakeratosis. The mortality rate is higher.

TREATMENT

In outbreaks of parakeratosis in swine, zinc should be added to diet immediately at the rate of 50 mg/kg DM (200 mg of zinc sulfate or carbonate per kg of feed). The calcium level of the diet should be maintained at between 0.65 and 0.75%. The injection of zinc at a rate of 2–4 mg/kg BW daily for 10 days is also effective. Zinc oxide suspended in olive oil and given IM at a dose of 200 mg of zinc for adult sheep and 50 mg of zinc for lambs will result in a clinical cure within 2 months. The oral administration of zinc at the rate of 250 mg zinc sulfate daily for 4 weeks resulted in a clinical cure of zinc deficiency in goats in 12–14 weeks.

CONTROL

Pigs

The calcium content of diets for growing pigs should be restricted to 0.5–0.6%. However, rations containing as little as 0.5% calcium and with normal zinc content (30 mg/kg DM) may produce the disease. Supplementation with zinc (to 50 mg/kg DM) as sulfate or carbonate has been found to be highly effective as a preventive and there appears to be a wide margin of safety in its use, diets containing 1000 mg/kg DM added zinc having no apparent toxic effect. The standard recommendation is to add 200 g of zinc carbonate or sulfate to each tonne of feed. Weight gains in affected groups are appreciably increased by the addition of zinc to the diet. The addition of oils containing unsaturated fatty acids is also an effective preventive. Access to green pasture, reduction in food intake, and the deletion of growth stimulants from rations will lessen the incidence of the disease but are not usually practicable.

Ruminants

For cattle, the feeding of zinc sulfate (2–4 g daily) is recommended as an emergency measure followed by the application of a zinc-containing fertilizer. As an alternative to dietary supplementation for ruminants, an intra-ruminal pellet has been demonstrated in sheep. It was effective for 7 weeks only and would not be satisfactory for long-term use. The creation of subcutaneous depots of zinc by the injection of zinc oxide or zinc metal dust has been demonstrated. The zinc dust offered a greater delayed effect. A soluble glass bolus containing zinc, cobalt, and selenium was able to correct experimentally induced zinc deficiency in sheep.[10] The bolus supplied the daily requirement of the sheep for zinc with no detrimental effect on their copper status.

Zinc-methionine, an organic zinc supplement for dairy goats improved udder health and enhanced the absorption of nitrogen and increased nitrogen retention.[11]

MANGANESE DEFICIENCY

A dietary deficiency of manganese (Mn) may cause infertility and skeletal deformities both congenitally and after birth.

ETIOLOGY

A primary deficiency occurs endemically in some areas because of a geological deficiency in the local rock formations.[1] Apart from a primary dietary deficiency of manganese, the existence of factors depressing the availability of ingested manganese is suspected. An excess of calcium and/or phosphorus in the diet is known to increase the requirements of manganese in the diet of calves,[2] and is considered to reduce the availability of dietary manganese to cattle generally.

Congenital chondrodystrophy in calves has been associated with a manganese deficiency,[3] and an outbreak of congenital skeletal defects in Holstein calves due to manganese deficiency has been reported.[4]

EPIDEMIOLOGY

Soils containing less than 3 mg/kg of manganese are unlikely to be able to support normal fertility in cattle. In areas where manganese-responsive infertility occurs, soils on farms with infertility problems have contained less than 3 mg/kg of manganese, whereas soils on neighboring farms with no infertility problems have had levels of more than 9 mg/kg. A secondary soil deficiency is thought to occur and one of the factors suspected of reducing the availability of manganese in the soil to plants is high alkalinity. Thus, heavy liming is associated with manganese-responsive infertility. There are three main soil types on which the disease occurs:

- Soils low in manganese have low output even when pH is less than 5.5
- Sandy soils where availability starts to fall
- Heavy soils where availability starts to fall at pH of 7.0.

Many other factors are suggested as reducing the availability of soil manganese but the evidence is not conclusive. For example, heavy liming of soils to neutralize sulfur dioxide emissions from a neighboring smelter is thought to have reduced the manganese intake of grazing animals.

Herbage on low manganese soils, or on marginal soils where availability is decreased (possibly even soils with normal manganese content), is low in manganese. A number of figures are given for critical levels. It is suggested that pasture containing less than 80 mg/kg of manganese is incapable of supporting normal bovine fertility, and that herbage containing less than 50 mg/kg is often associated with infertility and anestrus. The Agricultural Research Council feels that, although definite figures are not available, levels of 40 mg/kg dry matter (DM) in the diet should be adequate. Other authors state that rations containing less than 20 mg/kg DM may cause anestrus and reduction in conception rates in cows and the production of poor quality semen by bulls. Most pasture contains 50–100 mg/kg DM. Skeletal deformities in calves occur when the deficiency is much greater than the above; for example, a diet containing more than 200 mg/kg DM is considered to be sufficient to prevent them.

Rations fed to pigs usually contain more than 20 mg/kg DM of manganese, and deficiency is unlikely unless there is interference with manganese metabolism by other substances.

There are important variations in the manganese content of seeds, an important matter in poultry nutrition.[1] Maize and barley have the lowest content. Wheat or oats have three to five times as much, and bran and pollard are the richest natural sources with 10–20 times the content of maize or wheat. Cows' milk is exceptionally low in manganese.

PATHOGENESIS

Manganese plays an active role in bone matrix formation, and in the synthesis of chondroitin sulfate, responsible for maintaining the rigidity of connective tissue. In manganese deficiency, these are affected deleteriously and skeletal abnormalities result. Only 1% of manganese is absorbed from the diet and the liver removes most of it, leaving very low blood levels of the element.[3]

CLINICAL FINDINGS

In cattle, the common syndromes are infertility, calves with congenital limb deformities, and calves which manifest poor growth, dry coat, and loss of coat color. The deformities include knuckling over at the fetlocks, enlarged joints and, possibly, twisting of the legs. The bones of affected lambs are shorter and weaker than normal and there are signs of joint pain, hopping gait, and reluctance to move.

A severe congenital chondrodystrophy in Charolais calves occurred on one farm.[3] The limbs were shortened and the joints enlarged. The pregnant cows were fed on apple pulp and corn silage both of which were low in manganese.

An outbreak of congenital skeletal malformations in Holstein calves was characterized clinically by small birth weights (average 15 kg). Abnormalities included joint laxity, doming of the foreheads, superior brachygnathia, and a dwarflike appearance due to the short long-bones. The features of the head were similar to those of the wildebeest. The majority of affected calves were dyspneic at birth, and snorting and grunting respiratory sounds were common. Affected calves failed to thrive and most were culled due to poor performance.

A manganese-responsive infertility has been described in ewes and is well known in cattle. In cattle, it is manifested by slowness to exhibit estrus, and failure to conceive, often accompanied by subnormal size of one or both ovaries. Subestrus and weak estrus have also been observed.

Functional infertility was once thought to occur in cattle on diets with calcium to phosphorus ratios outside the range of 1:2 to 2:1. This was not upheld on investigation but may have been correct if high calcium to phosphorus intakes directly reduced manganese (or copper or iodine) availability in diets marginally deficient in one or other of these elements.

In pigs, experimental diets low in manganese cause reduction in skeletal growth, muscle weakness, obesity, irregular, diminished or absent estrus, agalactia and resorption of fetuses or the birth of stillborn pigs. Leg weakness, bowing of the front legs and shortening of bones also occur.

CLINICAL PATHOLOGY

The blood of normal cattle contains 18–19 μg/dL (3.3–3.5 μmol/L) of manganese (Mn), although considerably lower levels are sometimes quoted. The livers of normal cattle contain 12 mg/kg (0.21 mmol/kg) of manganese and down to 8 mg/kg (0.15 mmol/kg) in newborn calves, which also have a lower content in hair. The manganese content of hair varies with intake. The normal level is about 12 mg/kg (0.21 mmol/kg) and infertility is observed in association with levels of less than 8 mg/kg (0.15 mmol/kg). In normal cows, the manganese content of hair falls during pregnancy from normal levels of 12 mg/kg (0.21 mmol/kg) in the first month of pregnancy to

4.5 mg/kg (0.08 mmol/kg) at calving. All of these figures require much more critical evaluation than they have had, before they can be used as diagnostic tests.

Although tissue manganese levels in normal animals have been described as being between 2 and 4 mg/kg (0.04 and 0.07 mmol/kg), in most tissue[1] there appears to be more variation between tissues than this. However, tissue levels of manganese do not appear to be depressed in deficient animals, except for ovaries in which levels of 0.6 mg/kg (0.01 mmol/kg) and 0.85 mg/kg (0.02 mmol/kg) are recorded in contrast to a normal level of 2 mg/kg (0.04 mmol/kg).

There is then no simple, single diagnostic test permitting detection of manganese deficiency in animals. Reproductive functions, male and female, are most sensitive to manganese deficiency and are affected before possible biochemical criteria, e.g. blood and bone alkaline phosphatase, and liver arginase levels, are significantly changed. The only certain way of detecting moderate deficiency states is by measuring response to supplementation. Clinical findings in response to treatment which may provide contributory evidence of manganese deficiency are set out below.

NECROPSY FINDINGS

In congenital chondrodystrophy in calves, the limbs are shortened and all the joints are enlarged. Histologically, there is poor cartilage maturation with excessive amounts of rarefied cartilage matrix. There are degenerative changes in the chondrocytes and severe reduction in the mucopolysaccharide content of all body hyaline cartilage.[3,4]

TREATMENT AND CONTROL

The NRC estimated the maintenance requirement (0.002 of available Mn/kg BW) of dairy cows from dietary concentrations of Mn reported to cause Mn deficiency in cattle.[5] Based on NRC of 2001[2] equations, the maintenance requirement for Mn represents 82% of the total Mn requirement for a nonlactating, late gestation cow and 53% for a cow producing 40 kg/d of milk. Fecal loss of endogenous Mn is assumed to comprise the entire maintenance requirement. Assuming typical DMI, a diet with approximately 14 mg Mn/kg DM will meet the requirement for a 700 kg non-lactating cow during the last month of lactation. Recent research has determined that Mn intake had to equal 580 mg/d to meet the metabolic fecal Mn requirement. The corresponding dietary concentration, assuming DMIs of 21 and 12 kg/d for lactating and dry cows, respectively, were 28 and 49 mg/kg DM. These concentrations are approximately 1.6 and 2.7 times higher than those needed to meet the Mn requirements for lactating and dry cows, respectively, as calculated using the 2001 NRC dairy nutrient requirements model.[5]

For pigs, the recommended dietary intakes are 24–57 mg manganese per 45 kg BW. Expressed as a proportion of food intake, the recommended dietary level is 40 mg/kg DM in feed. The manganese requirements for gestation and lactation are 20 ppm of the diet.[6]

POTASSIUM DEFICIENCY

Naturally occurring dietary deficiency of potassium is thought to be rare. However, calves fed on roughage grown on soils deficient in potassium, or in which the availability of potassium is reduced, may develop a clinical syndrome of poor growth, anemia, and diarrhea. Supplementation of the diet with potassium salts appears to be curative. A similar syndrome has been produced experimentally in pigs[1] that manifested poor appetite, emaciation, rough coat, incoordination, and marked cardiac impairment as indicated by electrocardiographic examination. The optimum level of potassium in the diet of young, growing pigs is about 0.26%, and in ruminants 0.5% (i.e. 65 mg/kg BW).[2] Electrocardiographic changes have also been observed in cattle on potassium-deficient diets and these are probably related to the degeneration of Purkinje fibers of the myocardium which occurs on such diets. Similar changes have been recorded on diets deficient in magnesium or vitamin E.

An intake of potassium above requirement is more likely to occur than a deficiency and, although very large doses of potassium are toxic, ruminants are capable of metabolizing intakes likely to be encountered under natural conditions.[3] It seems probable, however, that potassium interferes with the absorption of magnesium and heavy applications of potash fertilizers to grass pastures may contribute to the development of the hypomagnesemia of lactation tetany.

Hypokalemia in cattle may occur secondary to anorexia, diarrhea, upper gastrointestinal obstruction, right-side displacement and torsion of the abomasum, and impaction of the abomasum. In most cases, the hypokalemia is not severe enough to cause weakness and recumbency. Hypokalemia resulting in severe weakness and recumbency has occurred in dairy cattle treated with isoflupredone acetate for ketosis.[4] Serum potassium levels were below 2.3 mEq/L. Cows ranged in age from 2 to 7 years, all had a history of moderate to severe ketosis and had calved within the previous 30 days. Most had been treated with insulin, glucose IV, and propylene glycol orally. Affected cows were recumbent, profoundly weak, appeared flaccid, and lay in sternal or lateral recumbency. They were unable to support the weight of their heads off the ground and they were commonly held in their flanks. Anorexia was common. Cardiac arrhythmias were detectable on auscultation, and atrial fibrillation was confirmed on electrocardiography. Treatment included IV and oral administration of potassium chloride and fluid therapy, but the response was ineffective. Most affected cattle died or were euthanized. At necropsy, muscle necrosis was present in the pelvic limbs, and histological examination of non-weight bearing muscle revealed multifocal myonecrosis with macrophage infiltration and myofiber vacuolation, which is characteristic of hypokalemic myopathy in man and dogs. It is important to note that myopathy was also present in muscles not subject to ischemia or recumbency.

Potassium excretion by the kidneys is via secretion by the distal tubular cells. Aldosterone or other steroids with mineralocorticoid activity enhance distal tubular secretion of potassium by increasing permeability of the tubular luminal membranes to potassium and increasing losses of potassium in the urine. Glucocorticoids are often used to treat ketosis; the most commonly used are dexamethasone and isoflupredone acetate. Dexamethasone has little mineralocorticoid activity compared with prednisone and prednisolone, which are related chemically to isoflupredone. It is recommended for the treatment of ketosis in dairy cattle at a single dose of 10–20 mg IM, and repeated if necessary, 12–24 h later. Field observations indicate that repeated doses of isoflupredone acetate decreases plasma concentrations of potassium by 70–80%, which suggests a strong mineralocorticoid activity. It is recommended that isoflupredone be used judiciously and animals be monitored for plasma potassium and any evidence of weakness and recumbency. Treatment with oral potassium chloride may be required, but may be ineffective.

SELENIUM AND/OR VITAMIN E DEFICIENCIES

Several diseases of farm animals are associated with a deficiency of either selenium or vitamin E alone or in combination, usually in association with predisposing factors such as dietary polyunsaturated fatty acids, unaccustomed exercise and rapid growth in young animals. These are summarized in Table 30.5. All of these diseases are described under one heading because both selenium and vitamin E are important in the etiology, treatment and control of the major diseases caused by their deficiencies.

They are also known as selenium-vitamin E-responsive diseases because, with some exceptions, they can be prevented by adequate supplementation of the diet with both nutrients.

The term '*selenium-responsive disease*' has created some confusion relative to the selenium-deficiency diseases. In some regions of the world, particularly New Zealand and in parts of Australia and North America, diseases such as ill-thrift in sheep and cattle and poor reproductive performance respond beneficially to selenium administration. While these usually occur in selenium-deficient regions, they may not be due solely to selenium deficiency. Thus, there are some reasonably well-defined selenium-deficiency diseases and some ill-defined 'selenium-responsive' diseases.

ETIOLOGY

The selenium- and vitamin E-responsive or deficiency diseases of farm animals are caused by diets deficient in selenium and/or vitamin E, with or without the presence of conditioning factors such as an excessive quantity of polyunsaturated fatty acids in the diet. Almost all of the diseases that occur naturally have been reproduced experimentally using diets deficient in selenium and/or vitamin E. Conversely, the lesions can usually be prevented with selenium and vitamin E supplementation. In certain instances, as for example in hand-fed dairy calves, the incorporation of excessive quantities of polyunsaturated fatty acids was a major factor in the experimental disease and this led to the conclusion that certain myopathic agents were necessary to produce the lesion, which is no longer tenable. The presence of polyunsaturated fatty acids in the diet may cause a conditioned vitamin E deficiency because the vitamin acts as an antioxidant. In the case of naturally occurring muscular dystrophy in calves, lambs and foals on pasture, the myopathic agent, if any, is unknown and selenium is protective. However, selenium is not protective against the muscular dystrophy associated with the feeding of cod liver oil to calves.

Selenium is an essential nutrient for animals and diseases due to selenium inadequacy in livestock are of worldwide distribution.[1,2]

Synopsis

Etiology Dietary deficiencies of selenium and vitamin E and conditioning factors like dietary polyunsaturated fatty acids.

Epidemiology

- **Enzootic muscular dystrophy** occurs in young growing calves, lambs, goat kids, and foals born to dams in selenium-deficient areas and unsupplemented. Occurs worldwide and common in Australasia, UK, Great Plains of North America where soils are deficient in selenium. Vitamin E deficiency in animals fed poor quality forage and diets high in polyunsaturated fatty acids. Outbreaks of muscular dystrophy precipitated by exercise.
- **Mulberry heart disease** in finishing pigs.
- **Selenium-responsive diseases** occur in Australasia and are not obvious clinically but respond to selenium supplementation. Selenium and vitamin E deficiency may be involved in reproductive performance, retained placenta in cattle, resistance to infectious disease like bovine mastitis. Controversial.

Signs Muscular dystrophy characterized by groups of animals with stiffness, weakness, recumbency, severe in myocardial form. Mulberry heart disease characterized by outbreaks of sudden death in finishing pigs.

Clinical pathology Increased plasma levels of creatine kinase. Low serum levels of selenium and vitamin E. Glutathione peroxidase activity.

Necropsy findings Bilaterally symmetrical pale skeletal muscle, pale streaks in myocardial muscle. Hyaline degeneration of affected muscle.

Diagnostic confirmation Low selenium and vitamin E in diet and tissues, increased creatine kinase and muscle degeneration.

Differential diagnosis list

Acute muscular dystrophy in calves and yearlings

- *Haemophilus somnus* septicemia
- Pneumonia.

Subacute enzootic muscular dystrophy:

- **Musculoskeletal diseases** polyarthritis, traumatic or infectious myopathies (blackleg), osteodystrophy, and fractures of long bones
- **Diseases of the nervous system**: spinal cord compression, Haemophilus somnus meningoencephalitis and myelitis, organophosphatic insecticide poisoning
- **Diseases of the digestive tract**: carbohydrate engorgement resulting in lactic acidosis, shock, dehydration and weakness.
- **Muscular dystrophy in lambs and kids**: Enzootic ataxia and swayback
- **Muscular dystrophy in foals**: Traumatic injury to the musculoskeletal system and polyarthritis; meningitis; traumatic injury to the spinal cord.

Treatment Vitamin E selenium parenterally.

Control Selenium and vitamin E supplementation of diet, strategic oral and/or parenteral vitamin E and selenium to pregnant dams or young animals on pasture.

Biological functions of selenium and vitamin E

Glutathione peroxidases and tissue peroxidation

Selenium is a biochemical component of the enzyme glutathione peroxidase (GSH-PX).[3] The activity of the enzyme in erythrocytes is positively related to the blood concentration of selenium in cattle, sheep, horses, and pigs and is a useful aid for the diagnosis of selenium deficiency and to determine the selenium status of the tissues of these animals. The enzyme from the erythrocytes of both cattle and sheep contains 4 g atoms of

Table 30.5 Diseases considered to be associated with a deficiency of either selenium or vitamin E or both (including 'selenium-responsive' diseases)

Cattle	Horse	Pigs	Sheep
Nutritional (enzootic) muscular dystrophy Retained fetal membranes Resistance to mastitis	Nutritional muscular dystrophy (feeds)	Mulberry heart disease Hepatosis dietetica Exudative diathesis Iron hypersensitivity Nutritional muscular dystrophy Anemia	Nutritional (enzootic) muscular dystrophy Ill-thrift (selenium responsive) Reproductive inefficiency (selenium responsive) Bone marrow abnormalities

selenium per mol of enzyme.[1] Selenium is also a component of thyroid gland hormones.

Plasma GSH-PX protects cellular membranes and lipid-containing organelles from peroxidative damage by inhibition and destruction of endogenous peroxides, acting in conjunction with vitamin E to maintain integrity of these membranes.[2] Hydrogen peroxide and lipid peroxides are capable of causing irreversible denaturation of essential cellular proteins, which leads to degeneration and necrosis. GSH-PX catalyzes the breakdown of hydrogen peroxide and certain organic hydroperoxides produced by glutathione during the process of redox cycling. This dependence of GSH-PX activity on the presence of selenium offers an explanation for the interrelationship of selenium, vitamin E and sulfur-containing amino acids in animals. The sulfur-containing amino acids may be precursors of glutathione, which in turn acts as a substrate for GSH-PX and maintains sulfhydryl groups in the cell. Selenium is also a component of several other proteins such as selenoprotein of muscle, selenoflagellin, Se-transport proteins and the bacterial enzymes, formate dehydrogenase, and glycine reductase. Selenium also facilitates significant changes in the metabolism of many drugs and xenobiotics. For example, selenium functions to counteract the toxicity of several metals such as arsenic, cadmium, mercury, copper, silver, and lead.

The arachidonic cascade, phagocytosis, and the immune response

Glutathione peroxidase may be involved in the arachidonic acid cascade.[3] Eicosanoids are important mediators of immune and reproductive function.

Vitamin E

Vitamin E is an antioxidant that prevents oxidative damage to sensitive membrane lipids by decreasing hydroperoxide formation. The vitamin has a central role in protection of cellular membranes from lipoperoxidation, especially membranes rich in unsaturated lipids, such as mitochondria, endoplasmic reticulum, and plasma membranes.

Interrelationships between selenium and vitamin E

An important interrelationship exists between selenium, vitamin E and the sulfur-containing amino acids in preventing some of the nutritional diseases caused by their deficiency. If vitamin E prevents fatty acid hydroperoxide formation and the sulfur amino acids (as precursors of GSH-PX) and selenium are involved in peroxide destruction, these nutrients would produce a similar biochemical result, that is, lowering of the concentration of peroxides or peroxide-induced products in the tissues.[1,2] Protection against oxidative damage to susceptible non-membrane proteins by dietary selenium, but not by vitamin E, might explain why some nutritional diseases respond to selenium but not to vitamin E. On the other hand, certain tissues or subcellular components may not be adequately protected from oxidant damage because they are inherently low in GSH-PX even with adequate dietary selenium. Damage to such tissues would be expected to be aggravated by diets high in unsaturated fatty acids and to respond adequately to vitamin E but not to selenium. The variations in GSH-PX activity between certain tissues, such as liver, heart, skeletal, and myocardial muscles, would explain the variations in the severity of lesions between species.

There are both selenium-dependent GSH-PX and non-selenium-dependent GSH-PX activities in the tissues and blood. The non-selenium-dependent enzyme does not contain selenium and does not react with hydrogen peroxide but shows activity toward organic hydroperoxide substrates. The spleen, cardiac muscle, erythrocytes, brain, thymus, adipose tissue, and striated muscles of calves contain only the selenium-dependent enzyme. The liver, lungs, adrenal glands, testes, and kidney contain both enzymes. Hepatic tissue contains the highest level of non-selenium-dependent enzyme.

Vitamin E can prevent a toxic reaction to oral iron (ferrous sulfate) or iron dextran IM. When 0.1 ppm of selenium and 50 IU vitamin E/kg are added to the gestation of sows, glutathione peroxidase activity increased in 2-day-old pigs, especially if the iron injection is given prior to colostrum ingestion.[4]

EPIDEMIOLOGY

Enzootic nutritional muscular dystrophy (NMD)

Occurrence

This muscular dystrophy occurs in all farm animal species, but most commonly in young, rapidly growing calves, lambs, goat kids, and foals born from dams that have been fed for long periods, usually during the winter months, on diets low in selenium and vitamin E.[5] It is an important cause of mortality in goat kids from birth to about 3 months of age.[1] Goat kids may require more selenium than lambs or calves, which may explain the higher incidence of the disease in kids. The disease in kids may also be associated with low α-tocopherol levels and normal selenium status. The literature on selenium and vitamin E deficiency in sheep and goats has been reviewed.[2]

NMD in horses occurs most commonly in foals to about 7 months of age.[6] In reported cases, the concentration of selenium in the blood of the mares was subnormal, the concentrations of selenium and vitamin E in the feedstuffs were subnormal, the level of unsaturated fatty acids in the feed was high and vitamin E and selenium supplementation prevented the disease. The disease is not well-recognized in adult horses, but sporadic cases of dystrophic myodegeneration are recorded in horses from 5 to 10 years of age. Some baseline data for selenium and vitamin E concentration in horses from breeding farms is available.[1]

The disease also occurs in grain-fed yearling cattle. Stressors such as being turned outdoors after winter housing, walking long distances, the jostling and movement associated with vaccination, and dehorning procedures and the like are often precipitating factors. The disease has occurred in steers and bulls 12–18 months of age under feedlot conditions. There may even be laboratory evidence of subclinical myopathy in normal animals in a group from which an index case occurred. Outbreaks of severe and fatal NMD have occurred in heifers, at the time of parturition, which were previously on a diet deficient in both selenium and vitamin E. The disease may also occur sporadically in adult horses that are deficient in selenium. Muscular dystrophy has occurred in Bohemian Red Poll mature dairy cows in the Czech Republic moved from a stanchion barn into loose box housing which resulted in increased locomotor activity and stress associated with the change in housing conditions.[7]

Myopathy and hepatic lipidosis in weaned lambs deficient in vitamin E without concurrent selenium deficiency has been described.[8]

There are two major syndromes of myopathy:

- An acute form: myocardial dystrophy, which occurs most commonly in young calves and lambs and occasionally foals
- A subacute form: skeletal muscular dystrophy, which occurs in older calves and yearling cattle.

The two forms are not mutually exclusive.

Geographical distribution

NMD occurs in most countries of the world but is common in the UK, the USA, Scandinavia, Europe, Canada, Australia, and New Zealand. In North America, it is common in the north-east and north-west and uncommon on the relatively high selenium soils of the Great Plains, where selenium toxicity has occurred. It is one of

most common deficiency diseases of farm livestock in the USA.[1] In the Czech Republic, the incidence of selenium deficiency in cattle is high and most frequently diagnosed in heifers, feeder bulls, grazed beef cattle, and dairy cows in the dry period.[9] Surveys of live cattle in the Czech Republic and in cattle tissues obtained at slaughter have found significant deficiency of selenium.[10,11] Poor selenium status, as assessed from blood, muscle, and liver selenium concentrations, was found in 80%, 70%, and 73% of the tested animals, respectively.[11] White muscle disease has occurred in lambs in Turkey where the levels of selenium in the hay and soil are deficient.[12] The mean values of selenium in the soil and hay were 0.03 ppm and 0.07 ppm, respectively.

NMD is endemic in grazing goats on the Mexican plateau because of selenium deficiency in the soil and forages.[13] In two different locations of the plateau, the concentration of selenium in the soil was 0.047 and 0.051 ppm, in the forages 0.052 and 0.075 ppm, in the serum of goats, 0.02 and 0.21 ppm, respectively.[13] The pH of the soil was 6.1 and 5.9, respectively. The mean concentration of selenium in the serum of kids with clinical signs of NMD was 36% lower compared with kids from the same farm which were normal.

Based on bulk tank milk selenium concentrations compared with serum selenium concentrations in dairy herds in Prince Edward Island, Canada, 59% of the herds were at some point marginal or deficient in selenium, which places them at risk of disease and suboptimal production.[14] The periods of greatest risk were in the fall and winter when 5% and 4%, respectively, of herds fell in the range of true deficiency. Herds in which selenium supplementation was provided from a commercial dairy concentrate, were over 4 times more likely to be selenium-adequate than herds not using this method and adjusted average daily milk yield was 7.6% greater in herds determined to be selenium-adequate when compared with selenium-marginal herds.

Soils and therefore the pastures they carry, vary widely in their selenium content, depending largely on their geological origin. In general, soils derived from rocks of recent origin, e.g. the granitic and pumice sands of New Zealand, are notably deficient in selenium. Soils derived from igneous rocks are likely to be low in selenium. Sedimentary rocks, which are the principal parent material of agricultural soils, are richer in selenium. Forage crops, cereal grains, and corn grown in these areas are usually low in selenium content (below 0.1 mg/kg dry matter, DM), compared with the concentration in crops (above 0.1 mg/kg DM) grown in areas where the available soil selenium is much higher and usually adequate. The disease occurs in pigs, usually in association with other more serious diseases, such as mulberry heart disease and hepatosis dietetica.

Selenium in soil, plants and animals

Selenium in soils. Soils containing <0.5 mg/kg of selenium are likely to support crops and pastures with potentially inadequate selenium concentrations (<0.05 mg/kg DM).[1,3]

Selenium in plants. Plants vary in their uptake of selenium but selenium is not a requirement for plant growth.[3] The selenium content of different pasture species on the same soil type does vary widely but slow growing and more deeply rooting species contained slightly higher concentrations.[3] In New Zealand, the most deficient soils consist of rhyolitic pumice in the central volcanic plateau of the North Island. Peat soils in the Waikaito River Valley are also deficient. North Island coastal sands and stony soils in the several locations are considered to be selenium-responsive, while most of the South Island is at least marginally deficient.

In the USA, the States of the Pacific North-west and of the north-eastern and south-eastern seaboard are generally low in selenium.[5] In Canada, western prairie grains generally contain relatively high levels of selenium, whereas in the eastern provinces, soils and feedstuffs usually have low selenium concentrations. Most soils in the Atlantic provinces of Canada are acidic and, consequently, the forages are deficient in selenium. Most forage samples contain less than 0.10 mg/kg DM of selenium and enzootic nutritional muscular dystrophy is common throughout the region.

Surveys in the UK found that the selenium status may be low in sheep and cattle fed locally produced feedstuffs without any mineral supplementation. In some surveys, up to 50% of farms are low in selenium, which places a large number of animals at risk. There are also differences in the selenium concentrations of different feeds grown in the same area. For example, in some areas 75% of cattle fed primarily corn silage, or 50% of the cattle fed sedge hay, might be receiving diets inadequate in selenium.

Several factors influence the availability of soil selenium to plants.

- **Soil pH:** alkalinity encourages selenium absorption by plants – and the presence of a high level of sulfur, which competes for absorption sites with selenium in both plants and animals, are two factors reducing availability
- Variation between plants in their ability to absorb selenium; **'selector' and 'converter' plants** are listed under the heading of selenium poisoning; legumes take up much less selenium than do grasses
- **Seasonal conditions also influence the selenium content of pasture**, the content being lowest in the spring and when rainfall is heavy. Blood selenium in dairy cows in the USA were lower during the summer and fall than during the winter and spring.[15] In this way, a marginally deficient soil may produce a grossly deficient pasture if it is heavily fertilized with superphosphate, thus increasing its sulfate content, if the rainfall is heavy and the sward is lush and dominated by clover as it is likely to be in the spring months.

Environmental sulfur from various anthropogenic activities has been suspected to be a significant factor in contributing to several health problems in livestock.[1] Livestock producers near natural sour gas desulfurization plants have reported that sulfur emissions are responsible for an increased occurrence of nutritional muscular dystrophy, weak calves, and retarded growth. Experimentally, a moderate increase in dietary sulfur does not impair selenium and copper status, or cause related disease in cattle.

Selenium in animals. There may be wide variations in the serum selenium concentrations and glutathione peroxidase activities in cattle grazing forages of various selenium concentrations within the same geographical area. The selenium status of beef cows can vary between geographical areas within a region of a country, which is likely due to variations in selenium concentration of the soil and plants in these areas. Beef herds from areas with adequate soil levels of selenium, herds provided with supplemental feed on pasture and herds in which pregnancy diagnosis was done, had higher average herd blood selenium values than other herds.

Vitamin E

Vitamin E deficiency occurs most commonly when animals are fed inferior quality hay or straw or root crops. Cereal grains, green pasture, and well-cured fresh hay contain adequate amounts of the vitamin.

α-Tocopherol levels are high in green grasses and clovers, but there are wide variations in the concentrations from one area to another. The serum α-tocopherol levels are higher in calves born from cows fed grass silage than in those born from cows fed the same grass as hay. Many factors influence the α-tocopherol content of pasture and hence the animals' intake.

The level of α-tocopherol in pasture declines by up to 90% as it matures. Levels as low as 0.7 mg/kg DM have been reported in dry summer pastures grazed by sheep. The α-tocopherol content of ryegrass and clover pasture ranges from 22 to 350 mg/kg DM and 90–210 mg/kg DM, respectively. After harvesting and storage, the α-tocopherol content of pasture and other crops may fall further, sometimes to 0. Preservation of grain with propionic acid does not prevent the decline. Thus, the dietary intake of α-tocopherol by cattle and sheep may be expected to vary widely and lead to wide variations in tissue levels. The plasma vitamin E status of horses is highest from May to August in Canada when fresh grass is being grazed and lowest when the horses are being fed harvested or stored feed during the same period. Plasma vitamin E levels in dairy cows in the USA were higher during the summer and fall than during the winter and spring.[15]

Outbreaks of NMD may occur in yearling cattle fed on high-moisture grain treated with propionic acid as a method of inexpensive storage and protection from fungal growth. There is a marked drop in the vitamin E content of acid-treated grain and an increase in the levels of peroxides of fat, which is consistent with a loss of naturally occurring antioxidants such as the tocopherols (secondary vitamin E deficiency). In these situations, the levels of selenium in the feed were below 0.05 mg/kg DM, which is inadequate and emphasizes the interdependence of selenium and vitamin E. The α-tocopherol content of moist grain (barley and maize) stored for 6 months, with or without propionic acid, falls to extremely low levels compared with conventionally stored grain in which the α-tocopherol levels usually persist over the same length of time. Selenium-deficient barley treated with sodium hydroxide to deplete it of vitamin E can be used to induce NMD when fed to yearling cattle. The disease may occur in sucking lambs with low plasma α-tocopherol levels and an adequate selenium status, which indicates that the sparing effect of each nutrient may not occur over the broad spectrum of clinical deficiencies.

Polyunsaturated fatty acids (PUFAs) in diet

Diets rich in PUFA such as cod liver oil, other fish oils, fishmeal used as a protein concentrate, lard, linseed oil, soybean, and corn oils have been implicated in the production of NMD, particularly in calves fed milk replacers containing these ingredients. The disease can be reproduced experimentally in young ruminant cattle, 6–9 months of age, by feeding a diet low in vitamin E and selenium and adding a linolenic acid. There are widespread lesions of myodegeneration of skeletal and myocardial muscles.[16] Fresh spring grass containing a sufficient concentration of linolenic acid to equal the amount necessary to produce NMD in calves may explain the occurrence of the naturally occurring disease in the spring months. The oxidation during rancidification of the oils causes destruction of the vitamin, thus increasing the dietary requirements (a conditioned vitamin E deficiency) and the presence of myopathic agents in the oils may also contribute to the occurrence of the disease. A secondary vitamin E deficiency occurs when NMD develops on rations containing vitamin E in amounts ordinarily considered to be adequate, but the disease is prevented by further supplementation with the vitamin. The lack of specificity of vitamin E in the prevention of muscular dystrophy in some circumstances is indicated by its failure and by the efficiency of selenium, as a preventive agent in lambs on lush legume pasture.

Other myopathic agents in diet

Not all of the myopathic agents that may be important in the development of NMD in farm animals have been identified. Unsaturated fatty acids in fish and vegetable oils may be myopathic agents in some outbreaks of NMD of calves and lambs. Lupinosis-associated myopathy in sheep is a substantial skeletal muscle myopathy encountered in weaner sheep grazing lupin stubbles infected with the fungus *Phomopsis* spp.[17] Affected sheep have a stiff gait, walk reluctantly, stand with their back humped and their feet under the body, and have difficulty getting to their feet.

Unaccustomed exercise

Historically, NMD occurred most commonly in rapidly growing, well-nourished beef calves 2–4 months of age, shortly following unaccustomed exercise. This was commonplace in countries where calves were born and raised indoors until about 6–8 weeks of age when they were turned out onto new pasture in the spring of the year. This has been a standard practice in small beef herds in the UK, Europe, and North America. A similar situation applies for ewes that lambed indoors and the lambs were let out to pasture from 1 to 3 weeks of age. Thus, unaccustomed activity in calves and lambs running and frolicking following their turnout onto pasture is an important risk factor but is not necessarily a prerequisite for the disease. In lambs, the vigorous exertion associated with running and sucking may account for the peracute form of myocardial dystrophy in young lambs on deficient pastures and from deficient ewes. In older lambs up to 3 months of age, outbreaks of acute NMD and stiff-lamb disease may be associated with the driving of flocks long distances. A similar situation applies for calves that are moved long distances from calving grounds and early spring pastures to lush summer pastures. The wandering and bellowing that occurs in beef calves weaned at 6–8 months of age may precipitate outbreaks of subacute NMD. Degenerative myopathy of yearling cattle (feedlot cattle, housed yearling bulls and heifer replacements) is now being recognized with increased frequency. The disease resembles subacute NMD of calves and in the UK is often seen when yearlings are turned outdoors in the spring of the year after being housed during the winter and fed a poor quality hay or straw or propionic acid-treated grain. Unaccustomed exercise is a common precipitating factor. However, the disease has occurred in housed yearling bulls with no history of stress or unaccustomed exercise but whose diet was deficient in selenium and vitamin E.

In horses subjected to exercise, there is an increase in erythrocyte malondialdehyde, a product of peroxidation, but selenium supplementation has no beneficial effect. There is inconclusive evidence that a selenium-vitamin E deficiency causes NMD in adult horses. There is no evidence that paralytic myoglobinuria and the 'tying-up' syndrome are due to a deficiency of selenium and vitamin E.

Congenital nutritional muscular dystrophy

Congenital NMD is rare in farm animals. Isolated cases have been reported.[18]

Similarly, NMD can occur in calves and lambs only a few days of age but rarely. Selenium readily crosses the bovine placenta and fetal selenium is always higher than the maternal status.[9] There is no evidence that the weak-calf syndrome is associated with selenium deficiency. Long-term parenteral supplementation with neither selenium alone nor in combination with vitamin E had any effect on the incidence of the weak-calf syndrome.

An investigation of aborted bovine fetuses with lesions of heart failure, specifically cardiac dilatation or hypertrophy along with a nodular liver and ascites compared with aborted fetuses without such lesions and non-aborted fetuses from the abattoir found myocardial necrosis and mean selenium levels of 5.5 μmol/kg in the fetuses with heart lesions, 6.5 μmol/kg in the fetuses without heart lesions and 7.5 μmol/kg selenium in the fetuses from the abattoir.[19] This suggests that selenium deficiency in bovine fetuses may cause myocardial necrosis and heart failure.

Normal levels of selenium in liver and kidney tissue of bovine fetuses derived from the abattoir were 7.5 ± 5.2 μmol/kg and 4.4 ± 1.1 μmol/kg, respectively.

In pigs, NMD has been produced experimentally on vitamin E- and selenium-deficient rations but is usually only a part of the more serious complex of mulberry heart disease and hepatosis dietetica.

Vitamin E-Selenium Deficiency (VESD) syndrome

Mulberry heart disease, hepatosis dietetica, exudative diathesis and nutritional myopathy, also known as the **VESD syndrome** (vitamin E and selenium deficiency) occur in pigs, usually as serious diseases. Nutritional muscular dystrophy may also occur in pigs. The occurrence of edema in various tissues has also been suggested as a possibility of Se or vitamin E deficiency. Impaired spermatogenesis and increased susceptibility to the effects of swine dysentery have also been suggested as responses to reduced levels of these two substances. There is a suspicion that the problems have become more common as the pig grows more quickly, the requirements have increased and the demands for anti-oxidants is increased at the same time that the provision of fat soluble vitamins is increasingly difficult. In addition, there is very small difference between the therapeutic and toxic levels of Se and Se toxicosis has occurred in an attempt to prevent Se deficiency. A more recent complication is the realization that we have been using inorganic Se to provide Se in the diet but that in the plant most of the Se is organic in the form of L-selenomethionine, a Se analogue of the amino acid methionine.[20] In the pig as in other species they are believed to serve as antagonists to toxic free radicles and act in concert with other substances such as Vitamin C. Little is known about their metabolism in the pig. In the pig, there is very little transfer of fat soluble products across the placenta so there is very little reserve of vitamin E in the new born pig. Immediately after birth, the young pig gets its vitamin E from the colostrum and milk of the sow. If the sow has low body stores or is fed a ration low in vitamin E then the piglet will be very low in vitamin E when it is weaned. Each can substitute for the other in a limited way in the pig. In the pig the diet has the most influence. Diets rich in polyunsaturated fatty acids, copper, Vitamin A or mycotoxins may reduce the availability of vitamin E. As dietary vitamin A levels increase, serum and liver α-tocopherol concentrations decline, suggesting a reduced absorption and retention of α-tocopherol when weaned pigs were fed high dietary vitamin A levels.[21] Se antagonists or crops from inherently low soil Se fields may also make the situation worse. In pigs, NMD has been produced experimentally on vitamin E- and Se-deficient rations but is usually only a part of the more serious complex of mulberry heart disease and hepatosis dietetica. Microangiopathy is most common in weaned pigs[22] and may be particularly related to vitamin E deficiency.[23]

There is conflicting evidence on the effect of the anti-oxidative vitamins C and E on the reproductive performance of sows. In some studies,[24,25] increasing dietary vitamin E in the diet during gestation may have increased the litter size and reduced the pre-weaning piglet mortality. A similar response has been seen following intramuscular injection of sows with vitamin E and Se[26,27] but the injection of vitamin C has produced no improvement.[28,29] A recent study[30] has confirmed that there was no effect on reproductive performance of sows and growth performance of piglets when supplemented by both vitamin E and C. Vitamin E and Se given to immature gilts for flushing purposes led to the formation of fewer but larger *corpora lutea* after ovulation, probably due to the progression of a smaller number of follicles to the ovulatory stage.[31] Vitamin E and the Se increased the development of the uterus but did not influence the number of piglets at farrowing.

VESD occurs naturally in rapidly growing pigs, usually during the post-weaning period (3 weeks to 4 months), particularly during the early finishing period. The lowest concentration of vitamin E in piglets was day 45 after farrowing[32] but it may be that the Se status of the newborn piglets may be more important for their health than their vitamin E status. The first 3–4 weeks following the move to the finishing house is the most dangerous period for a low vitamin E level[33] and it is important to remember that there is considerable individual variation. Serum vitamin E declines after weaning and even with vitamin E supplementation it takes 2–3 days for levels to rise.[34,35] There appears to be a temporary decreased absorption of the vitamin in the immediate post-weaning period and this in turn leads to the reduction of the stored vitamin E reserves. It is usually associated with diets deficient in both Se and vitamin E and those that may contain a high concentration of unsaturated fatty acids. Such diets include those containing mixtures of soybean, high-moisture corn and the cereal grains grown on soils with low levels of Se. The feeding of a basal ration of cull peas, low in Se and vitamin E, to growing pigs can cause the typical syndrome and low tissue levels of Se are present in pigs with spontaneously occurring hepatosis dietetica. It has been shown that feeding diets that contain linseed oil unfortunately reduced the vitamin E levels in the diet but increased the skatole levels.[36] However, there are reports of naturally occurring mulberry heart disease of pigs in Scandinavia in which the tissue levels of Se and vitamin E are within normal ranges compared with normal pigs.[37] In Ireland, in spite of supplementation of pig rations with vitamin E and Se at levels higher than that necessary to prevent experimental disease, spontaneous mulberry heart disease may still occur.[23] Affected pigs have lower tissue vitamin E levels than control pigs, which suggests an alteration in α-tocopherol metabolism unrelated to dietary Se and PUFA contents.

Natural occurrence of the disease complex in pigs is not uncommonly associated with diets containing 50% coconut meal, fish-liver oil emulsion, fish scraps with a high content of unsaturated fatty acids, or flaxseed, which produces yellow and brown discoloration of fat preventable by the incorporation of adequate amounts of α-tocopherol or a suitable antioxidant. The quality of the dietary fat does not necessarily influence blood vitamin E levels, but the presence of oxidized fat reduces the resistance of the red blood cells against peroxidation. The higher requirement for vitamin E by pigs fed oxidized fat may be due to the low vitamin E content in such fat. It has recently been shown[38] that the inclusion of 0.3 ppm Se to the diet of post-weaning piglets resulted in better performance than non-Se supplemented diets irrespective of the level of vitamin E in the ration (up to 200 ppm).

Mulberry heart disease

This is the most common form of Se and vitamin E deficiency of pigs. It occurs most commonly in rapidly growing feeder pigs (60–90 kg) in excellent condition being fed on a high-energy diet low in vitamin E and Se. The true causal mechanism is not known but it can be prevented by supplementation with vitamin E. It can also occur when it would appear that the level in the diet and in the serum or tissues appear to be satisfactory. The diets most commonly incriminated are soybean, corn, and barley. Mean liver concentrations of vitamin E were lower in pigs with MHD than in pigs that died of causes other than MHD.[39] The α-tocopherol content of corn is usually low and it is virtually absent from solvent-extracted soybean meal. Both are low in Se. The use of high-moisture corn may further exacerbate the tocopherol deficiency. The level of PUFAs in the diet was thought to be an important etiological factor but this is now not considered to be a

necessary prerequisite. Outbreaks of the disease may occur in which 25% of susceptible pigs are affected and the case mortality rate is about 90%. The disease has occurred in young piglets and in adult sows.

Hepatosis dietetica

Hepatosis dietetica appears to be less common than mulberry heart disease but the epidemiological characteristics are similar. It appears to be less common since the Se levels in supplements were raised to 0.3 ppm. It affects young growing pigs up to 3–4 months of age. NMD in pigs usually occurs in cases of mulberry heart disease and hepatosis dietetica but it has occurred alone in gilts.

Selenium-responsive disorders

A variety of diseases have been known as selenium-responsive disorders[3,40] because they respond beneficially to the strategic administration of selenium. These include: **ill-thrift** in lambs and calves on pasture; **lowered milk production** in cows; **white muscle disease** in lambs, calves, and kids; **lowered fertility** and **embryonic death** in sheep and cattle; **retained fetal membranes, metritis, poor uterine involution**, and **cystic ovaries** in cows; subclinical **mastitis** and **impaired immune function** in cattle; and **prematurity**, **perinatal death**, and **abortion** in cattle.[3] Of these, only ill-thrift, lowered fertility, lowered milk production, and white muscle disease have been reported in New Zealand.[3] The literature on the roles of selenium deficiency in grazing ruminants in New Zealand and a rational approach to diagnosis and prevention has been reviewed.[3]

The pathogenesis of these selenium-responsive diseases is not well understood but it would appear that the selenium deficiency is only marginal. Most investigations into selenium-responsive diseases have occurred in selenium-deficient areas in which diseases such as NMD of calves and lambs occur. The evidence that selenium deficiency in breeding ewes can result in a decline in reproductive performance has not been substantiated experimentally. Reproductive performance was not affected in ewes on a selenium-depleted diet.

Selenium-responsive unthriftiness in sheep has received considerable attention in New Zealand where the response to selenium administration has been most dramatic compared with Australia where the syndrome has also been recognized but where the response is much smaller. The oral administration of selenium to lambs in these areas results in greater body weight gains from weaning to 1 year of age compared with lambs not receiving selenium supplementation. The mean fleece weight of selenium-treated lambs is also greater.

The diagnosis of selenium-responsive unthriftiness depends on analyses of the soil, pasture and animal tissues for selenium and response trials to selenium supplementation. A deficiency state might be encountered when the selenium content of the soil is below 0.45 mg/kg, the pasture content below 0.02 mg/kg DM, the liver content below 21 μg/kg (0.27 μmol/kg) (WW), and wool concentrations below 50–60 μg/kg (0.63–0.76 μmol/kg). For the blood in selenium-responsive unthriftiness of sheep the following criteria are suggested:

Mean blood selenium status (μg/dL)
Deficient = 1.0
Doubtful 1.1–1.9
Normal ~2.0.

The GSH-PX activity is a good index of the selenium status of sheep with a selenium-responsive disease. If measured on a regular basis, it can provide an indication of the selenium status of grazing sheep in individual flocks. Single measurements of GSH-PX activity may fail to detect recent changes in grazing area, differences in pasture species and pasture composition and alterations in the physiological state of the animals.

Subclinical selenium insufficiency

Subclinical insufficiencies of selenium in grazing ruminants are widespread over large areas of southern Australia.[1] The plasma concentrations of affected sheep flocks are low, there are no obvious clinical signs of insufficiency in the ewes and there are significant responses in wool production and fiber diameter to selenium supplementation. The incidence of estrus and fertility is not affected by selenium supplementation. Live weights at birth, in mid-lactation, and at weaning were increased in lambs born to selenium-supplemented and crossbred ewes and in lambs born as singletons. Clean fleece weight at 10 months of age was increased by 9.5% and fiber diameter by 0.3 μm in lambs born to ewes that had received supplementary selenium. Differences in fleece weight and live weight were not detected at 22 months, suggesting that subclinical selenium insufficiency in early life did not permanently impair productivity if selenium status subsequently increased.

Temporal variations in glutathione peroxidase activity in sheep can be used to identify seasons of the year with the highest risk of selenium deficiency.[41] In the Mediterranean area, lambs born in the spring/summer are at higher risk to selenium-deficiency related diseases.[41] Lambs born in autumn/winter are from ewes gestating during the summer, when supplementation with cereal grains is provided.

Selenium is a component of type-I iodothyronine deiodinase, which catalyzes the extrathyroidal conversion of thyroxine (T4) to the more active tri-iodothyronine (T3). Sheep grazing pastures low in selenium frequently have higher circulating T4 and lower circulating T3 concentrations than sheep receiving selenium supplementations.

When ewes grazing pastures low in selenium were supplemented thiocyanate (to cause iodine insufficiency), iodide and selenium, there was no evidence of clinical deficiencies. Growth rates of lambs were not affected by thiocyanate of their dams during mid-pregnancy, but plasma T3 and T4 concentrations were depressed in ewes receiving thiocyanate. The iodide supplementation increased thyroid hormone concentrations in ewes, but depressed plasma T3 concentrations in lambs. Supplementation of sheep grazing pastures low in selenium with both selenium and thyroid hormones improved wool characteristics, live weight gain, and blood selenium, but there was no evidence of an interaction between the selenium and the hormones. Thus, it seems unlikely that the decline in the quantity of T3 produced, or of T4 utilized for T3 production, in selenium-deficient sheep is responsible for the observed differences in the productivity of selenium-deficient and supplemented sheep. The thyroids have a major role in regulating thermogenesis and lambs born to ewes supplemented with iodide tend to have higher rectal temperatures during cold stress. The thermoregulatory ability of the perinatal lamb is not adversely affected by subclinical selenium deficiency.

In a survey of the status of vitamin E and selenium of the livers of cull ewes and market lambs raised in Ontario, selenium was present at marginal levels in 3.3% of cull ewe samples and in 43% of market lamb samples.[16] Vitamin E was low to deficient in 10% of cull ewe samples and in 90% of market lamb samples. In cull ewes, there was a strong relationship between selenium and vitamin E. A large percentage of samples with marginal selenium values had adequate vitamin E, which may indicate that the sheep had access to high levels of vitamin E but received inadequate levels of supplement containing selenium.

An evaluation of the trace mineral status of beef cows in Ontario found that 96% of cull cows were deficient in blood selenium.[42,43] Based on analysis of serum samples from cattle in Iowa and Wisconsin, subclinical selenium deficiency is common in the cattle population.[44] The serum levels may be adequate for reproductive performance but marginal for optimal resistance to mastitis or for adequate transfer of selenium to the calf.

Reproductive performance

The published information on the effects of vitamin E and selenium deficiency or of dietary supplementation with one or the other or both on reproductive performance in farm animals are conflicting and controversial. Reproductive performance is complex and dependent on the interaction of many factors. Reproductive inefficiency is likewise complex and it is difficult to isolate one factor like a deficiency of vitamin E or selenium as a cause of reproductive inefficiency. Conversely, it is difficult to prove that supplementation with these nutrients will ensure optimum reproductive performance.[45]

Sheep

The evidence about the effect of selenium and vitamin E deficiency on reproductive performance in sheep is conflicting. Observations in the 1960s concluded that selenium deficiency caused embryonic deaths 20–30 days after fertilization in ewes. But supplementation of ewes, low or marginal in selenium status, with selenium did not improve reproductive performance. Experimental studies using selenium-deficient diets in ewes have been unable to find any adverse effects of selenium depletion on ewe conception rates, embryonic mortality, or numbers of lambs born. The parenteral administration of selenium to pregnant ewes between 15 and 35 days after mating resulted in a reduced embryonic survival rate and is not recommended during the first month of pregnancy.[46]

Cattle

Vitamin E supplementation can have significant effects on the health and some aspects of fertility in lactating dairy cows.[17] When used at four times the current recommendations. Vitamin E supplementation of dairy has its most beneficial effect of reducing the incidence of mastitis when used at rates of at least 1000 IU per day during the dry period and early lactation. The primary effect of vitamin E supplementation is on the immune system. The importance of selenium and vitamin E for the maintenance of optimum reproductive performance is not clear.[47] The IM injection of dairy cattle with selenium and vitamin E 3 weeks prepartum did not have any effect on average days to first estrus or first service, average days to conception, services per conception, or number of uterine infusions required. The prepartum IM injection of vitamin E and selenium 3 weeks prepartum increased the percentage of cows pregnant to first service, reduced the number of services per conception, decreased the incidence of retained placenta and reduced the interval from calving to conception. In a randomized field trial in a large dairy herd in the USA, oral supplementation of pregnant first-calf dairy heifers with selenium using a commercially available sustained-release intra-ruminal selenium bolus, increased blood selenium concentrations in treated animals at 30 days after treatment until after calving.[48] However, based on data analyzed mid-lactation and late lactation, there were no differences between treated and control groups in somatic cell count, days not pregnant, total milk production, or times bred. The use of an intra-ruminal pellet of selenium at two different levels in dairy herds in New Zealand was evaluated in yearling heifers.[49] The recommended dose was effective in elevating whole blood GSH-PX activity and selenium concentrations to over 10 times those of control animals. Milk production was increased and there was a trend to decreased somatic cell counts. There were no differences in calving-first-service or calving-conception intervals, or in the percentage of animals pregnant to first or all services. In other observations, following the treatment of dairy cows with oral selenium pellets there was an improvement in first service conception rate and significantly higher blood levels of GSH-PX. The inconsistent results obtained following the use of selenium and vitamin E in pregnant cows may be related to the selenium status of the animals; in some herds the blood levels are marginal and in others the levels are within the normal range.

Winter-fed lactating Norwegian dairy cows were found to have an adequate plasma levels of vitamin E and marginal-to-adequate levels of blood selenium. Silage was the most important source of vitamin E and selenium-supplemented commercial concentrates the most important source of selenium. No significant differences in vitamin E or selenium status was found between cows with or without recorded treatments of mastitis, parturient paresis, or reproductive abnormalities.[50]

Retained fetal placenta

A high incidence (more than 10%) of retained fetal membranes has been associated with marginal levels of plasma selenium compared with herds without a problem. In some cases, the incidence could be reduced to below 10% by the injection of pregnant cattle with selenium and vitamin E about 3 weeks prepartum, while in other studies similar prepartum injections neither reduced the incidence nor improved reproductive performance. A single injection of selenium 3 weeks prepartum can reduce the number of days postpartum required for the uterus to reach minimum size and to reduce the incidence of metritis and cystic ovaries during the early postpartum period. The parenteral administration of a single injection of 3000 mg vitamin E prepartum to dairy cows of all ages decreased the incidence of retained placenta and metritis to 6.4% and 3.9%, respectively, in the treated group, compared with 12.5% and 8.8%, in the control group.[51] The injection, 20 days pre-partum, of 50 mg of selenium and 680 IU of vitamin E reduced the incidence of retained fetal membranes in one series, but did not in another series. The plasma selenium concentration at parturition ranged from 0.02 to 0.05 ppm in control cows in which there was an incidence of 51% retained membranes and from 0.08 to 0.1 ppm in treated cows in which the incidence was reduced to 9%. A dietary level of 0.1 mg/kg DM selenium is recommended to minimize the incidence of the problem. The complex nature of the etiology of retained fetal membranes also requires a well-designed experimental trial to account for all of the possible factors involved.

Resistance to infectious disease

Many studies have examined the role of selenium and vitamin E resistance to infectious disease. Most of the evidence is based on in vitro studies of the effects of deficiencies of selenium or vitamin E or supplementation with the nutrients on leukocyte responses to mitogens, or on the antibody responses of animals to a variety of pathogens. The status of selenium and vitamin E in an animal can alter antibody response, phagocytic function, lymphocyte response and resistance to infectious disease. The administration of vitamin E and selenium during the dry period can influence mammary gland health and milk cell counts in dairy ewes.[52] In general, a deficiency of selenium results in immunosuppression and supplementation with low doses of selenium augments immunological functions. A deficiency of selenium has been shown to inhibit:

- Resistance to microbial and viral infections
- Neutrophil function
- Antibody production
- Proliferation of T and B lymphocytes in response to mitogens
- Cytodestruction of T lymphocytes and natural killer lymphocytes [53]

Vitamin E and selenium have interactive effects on lymphocyte responses to experimental antigens.[54]

Vitamin E supplementation of transport-stressed feedlot cattle is associated with reduced serum acute-phase protein concentrations compared with control animals.[55] Supplementation of the diet of cattle arriving in the feedlot with vitamin E had beneficial effects on humoral immune response and recovery from respiratory disease.[56]

The parenteral administration of selenium and vitamin E during pregnancy in dairy cows has a positive effect on the increase of selenium and vitamin E concentrations in blood, increase of selenium and immunoglobulins concentrations in colostrum and an increase of T3 concentration in blood on the day of parturition.[57] In addition, there was a trend toward a decreased incidence of clinical mastitis.

Neutrophil function

Selenium deficiency can affect the function of polymorphonuclear neutrophils (PMNs), which are associated with physiological changes in GSH-PX levels. In calves on an experimental selenium-deficient diet, the oxygen consumption and the activities of GSH-PX are lower than normal in neutrophils. The feeding of 80–120 mg of selenium/kg of mineral mixture provided ad libitum is an effective method of increasing blood selenium in a group of cattle and optimizing the humoral antibody response experimentally. It is suggested that blood selenium levels over 100 μg/L are necessary to maintain optimum immunocompetence in growing beef cattle.[58] In selenium-deficient goats, the production of leukotriene B_4, a product of neutrophil arachidonic acid lipoxygenation and a potent chemotactic and chemokinetic stimulus for neutrophils, is decreased, resulting in dysfunction of the neutrophils. A deficiency of selenium in pregnant sows impairs neutrophil function and vitamin E deficiency impairs function of both neutrophils and lymphocytes, which may result in increased susceptibility of their piglets to infectious diseases.[59] It is suggested that selenium supplementation be maintained at 0.3 mg/kg of the diet.

Neutrophils from postparturient dairy cows with higher levels of selenium have greater potential to kill microbes and cattle with greater superoxide production may have higher milk production.[49] Vitamin E is a fat-soluble membrane anti-oxidant which enhances the functional efficiency of neutrophils by protecting them from oxidative damage following intracellular killing of ingested bacteria. Peripartum immunosuppression in dairy cows is multifactorial but is associated with endocrine changes and decreased intake of critical nutrients. Decreased phagocytosis and intracellular killing by neutrophils occur in parallel with decreased dry matter intake and decreased circulating vitamin E. Since neutrophils are the primary mechanism of uterine defense and mammary health, the role of vitamin E on the health of dairy cows during the transition period have been examined. Compared with control cows given a placebo, the parenteral administration of vitamin E 1 week prepartum had no effect on the incidence of retained placenta, clinical mastitis, metritis, endometritis, ketosis, displaced abomasum or lameness.[60] However, there was a decreased incidence of retained placenta in cows with marginal pretreatment vitamin E status. An increase in α-tocopherol of 1 μg/mL in the last week prepartum reduced the risk of retained placenta by 20%.[61] In addition, serum non-esterified fatty acid concentration ≥ 0.5 mEq/L tended to increase the risk of retained placenta by 80% and in the last week pre-partum, a 100 ng/mL increase in serum retinol was associated with a 60% decrease in the risk of early lactation clinical mastitis.[61]

Immune response

The effects of selenium deficiency and supplementation on the immune response of cattle to experimental infection with the infectious bovine rhinotracheitis virus and sheep to parainfluenza-3 virus, indicates that a deficiency can affect the humoral response and supplementation enhances the response. The administration of selenium either alone or in combination with vitamin E can improve the production of antibodies against *E. coli* in dairy cows.[62] Pigs fed a vitamin E- and selenium-deficient diet develop an impaired cell-mediated immunity as measured by lymphocyte response to mitogenic stimulations. Supplementation of the diets of young pigs with selenium at levels above those required for normal growth have increased the humoral response, but not in sows. The wide variations in antibody responses that occur in these experiments indicate that there is a complex relationship between the selenium status of the host, humoral immune responses and protective immunity. The concept of using selenium supplementation to enhance antibody responses in sheep to vaccines is probably unfounded. However, the administration of sodium selenite to sheep vaccinated against enzootic abortion (*Chlamydophila abortus*) increased the antibody response but not when given with vitamin E.[63]

Vitamin E can stimulate the immune defense mechanisms in laboratory animals and cattle, experimentally. In most cases, the immunostimulatory effects of additional vitamin E are associated with supplementation in excess of levels required for normal growth. The parenteral administration to calves of 1400 mg of vitamin E weekly increases their serum vitamin E concentrations and lymphocyte stimulation indices. Similarly in growing pigs, a serum vitamin E concentration above 3 mg/L was necessary to achieve a significant response of the lymphocytes to stimulation with mitogens.

General resistance

These changes may render selenium-deficient animals more susceptible to infectious disease, but there is no available evidence to indicate that naturally occurring selenium and vitamin E deficiencies are associated with an increase in the incidence or severity of infectious diseases. Neutrophils from selenium-deficient animals lose some ability to phagocytose certain organisms, but how relevant this observation is in naturally occurring infections is unclear. Field studies of the incidence and occurrence of pneumonia in housed calves found that selenium status was not a risk factor.

Transfer of selenium and vitamin E to the fetus, colostrum, and milk

Selenium. In sheep, selenium is transferred across the placenta to the fetus and maternal selenium status during gestation is positively associated with fetal and newborn lamb selenium status.[2] Supplementation of gestating ewes with selenium will improve the selenium status of the lambs at birth. However, after birth the selenium of the lamb is depleted quickly by about 18 days after birth. Thus, continued intake of selenium by the lamb is necessary to maintain normal selenium status during the postnatal period. The colostrum of ewes contains higher levels of selenium than ewe milk. The selenium content of ewe's milk decreases rapidly after parturition, reaching a stable level by 1 week post partum. Supplementation of ewes during lactation results in higher milk selenium concentration and higher blood selenium in lambs. Supplementation of ewes has been shown to prevent nutritional myodegeneration in nursing lambs in selenium-deficient flocks.[2]

There is a highly significant relationship between blood selenium of cattle and milk selenium concentration.[64] As in sheep, in cattle, selenium is transferred across the placenta to the fetus and across the mammary barrier into the colostrum and milk.[9]

Pigs. The maternal intake of selenium affects fetal liver selenium and newbom piglets have lower liver selenium concentrations compared with their dams, regardless of selenium intake of sows during gestation.[65] Thus compared with cattle and sheep, the relatively high concentration of selenium needed in the diets of young rapidly growing piglets may be partially a function of limited placental transport or hepatic deposition of selenium and why the piglet is more susceptible to selenium deficiency than the sow.

Vitamin E. The transfer of vitamin E across the placenta to the fetus in sheep and cattle is limited.[2] Plasma levels of vitamin E in the fetus and in newborn lambs

(before ingestion of colostrum) are lower than in the ewe.[2] Vitamin E supplementation of the ewe in late gestation results in insignificant increases of the serum vitamin E in the lamb. However, supplementation of the ewe in the last month of pregnancy increases the vitamin E content of colostrum and milk.[2] Colostrum of the ewe is a rich source of vitamin E for the neonatal lamb, containing 5–11 times more vitamin E than milk at 1 week post partum. The parenteral administration of sodium selenite to ewes at lambing increases the vitamin E content of milk of ewes over the first 5 weeks of lactation, indicating a potential positive effect of selenium repletion on vitamin E transfer to milk.[2]

Neonatal morbidity and mortality

Based on some preliminary observations of the selenium content of hair samples of young calves, higher selenium levels in newborn calves may have some protective effect against morbidity due to neonatal disease. Similarly, neonatal piglets with high blood levels of GSH-PX activity may be more resistant to infectious diseases or other causes of neonatal mortality. Administration of vitamin E and selenium to dairy cows in late pregnancy resulted in the production of increased quantities of colostrum and the calves have increased quantities of GSH-PX at birth and 28 days of age, but the improved selenium status did not provide any improvement in passive immunity or growth.[66] Supplementing selenium to beef cows grazing selenium-deficient pastures with a salt mineral mix containing 120 mg selenium/kg of mix increased the selenium status of the cows and increased the serum IgG concentration, or enhanced transfer of IgG from serum to colostrum and increased the selenium status of the calves.[67] The parenteral administration of 0.1 mg Se and 1 mg of vitamin E/kg BW at mid-gestation did not affect the production of systemic or colostral antibodies. Supplementation of dairy cows at dry-off with selenium at 3 mg/d as selenite via an intraruminal bolus resulted in sufficient transfer of selenium to meet a target concentration of more than 2.2 μg of selenium/g of liver DM in newborn calves.[68]

Mastitis in dairy cattle

There is some evidence that a dietary deficiency of vitamin E may be associated with an increased incidence of mastitis in dairy cattle.[18] An increased incidence of mastitis during the early stages of lactation coincides with the lowest plasma concentration of vitamin E. Supplementation of the diet of dairy cows beginning 4 weeks before and continuing for up to 8 weeks after parturition with vitamin E at 3000 IU/cow per day, combined with an injection of 5000 IU, 1 week before parturition, prevented the suppression of blood neutrophil and macrophage function during the early postpartum period compared with controls. The vitamin E prevented the suppression of blood neutrophils during the postpartum period.[69] Cows in both the treated and control groups were fed diets containing selenium at 0.3 ppm of total dry matter. When selenium status in dairy cows is marginal, plasma concentrations of α-tocopherol should be at least 3 μg/mL.[70] Cows receiving a dietary supplement of about 1000 IU/d of vitamin E had 30% less clinical mastitis than did cows receiving a supplement of 100 IU/d of vitamin E.[70] The reduction was 88% when cows were fed 4000 IU/d of vitamin E during the last 14 days of the dry period.[70]

The selenium status of dairy cows may also have an effect on the prevalence of mastitis and mammary gland health.[57] Dairy herds with low somatic cell counts had significantly higher mean blood GSH-PX and higher whole blood concentrations of selenium than in herds with high somatic cell counts. The prevalence of infection due to *Streptococcus agalactiae* and *Staphylococcus aureus* was higher in herds with the high somatic cell counts compared with those with the low somatic cell counts. This suggests that phagocytic function in the mammary gland may be decreased by a marginal selenium deficiency. In a survey of cattle in herds in Switzerland, those with chronic mastitis had lower serum levels of selenium than healthy control herds. Experimental coliform mastitis in cattle is much more severe in selenium-deficient animals than selenium-adequate animals. The severity was in part due to the increased concentrations of eicosanoids.

Milk neutrophils from cows fed a selenium-deficient diet have significantly reduced capacity to kill ingested *Escherichia coli* and *Staph. aureus*, compared with cells from cows fed a selenium-supplemented diet. However, other experimental results are not as convincing.

Blood abnormalities

In young cattle from areas where NMD is endemic and particularly at the end of winter housing, the erythrocytes have an increased susceptibility to hemolysis following exposure to hypotonic saline. During clinical and subclinical white muscle disease in calves, there is a significant increase in both the osmotic and the peroxidative hemolysis of the erythrocytes. This defect is thought to be the result of alterations in the integrity of cell membranes of which tocopherols are an essential component. Abnormalities of the bone marrow associated with vitamin E deficiency in sheep have been described and abnormal hematological responses have been described in young growing pigs on an experimental selenium- and vitamin E-deficient diet. Vitamin E deficiency in sheep results in increased hemolytic susceptibility of erythrocytes, which may provide a basis for a single functional test for vitamin E deficiency in sheep.

Anemia characterized by a decreased packed cell volume, decreased hemoglobin concentration and Heinz body formation has been observed in cattle grazing on grass grown on peaty muck soils in the Florida everglades. Selenium supplementation corrected the anemia, prevented Heinz body formation, increased the body weight of cows and calves and elevated blood selenium.

Equine degenerative myeloencephalopathy

Equine degenerative myeloencephalopathy, which may have an inherited basis, has been associated with a vitamin E deficiency. The vitamin E status is low in some affected horses and supplementation with the vitamin was associated with a marked reduction in the incidence of the disease. However, serum vitamin E and blood GSH-PX activities determined in horses with histologically confirmed diagnosis of the disease compared with age-matched controls failed to reveal any differences and the findings did not support a possible role for vitamin E deficiency as a cause. Foals sired by a stallion with degenerative myeloencephalopathy and with neurological deficits consistent with the disease during their first year of life had lower plasma levels of α-tocopherol when the levels were determined serially beginning at 6 weeks to 10 months of age than age-matched controls. Absorption tests with vitamin E revealed that the lower α-tocopherol levels were not due to an absorption defect.

Equine motor neuron disease

This is a neurodegenerative disease of the somatic lower motor neurons resulting in a syndrome of diffuse neuromuscular disease in the adult horse.[71] Case-control studies found the mean plasma vitamin E concentrations in affected horses were lower than that of control horses. Adult horses are affected with the risk peaking at 16 years of age. In addition to the role of vitamin E depletion, other individual and farm-level factors, contribute to the risk of developing the disease.

Generalized steatitis

Steatitis in farm animals and other species may be associated with vitamin E and/or selenium deficiency. Most cases in horses have involved nursing or recently weaned foals. Generalized steatitis in the foal has

been described as either generalized cachexia due to steatitis alone, or as a primary myopathy or myositis with steatitis of secondary importance. The terms used have included steatitis, generalized steatitis, fat necrosis, yellow fat disease, polymyositis, and muscular dystrophy. The relationships between steatitis and vitamin E and selenium deficiency in the horse are not clear and there may be none. Many more clinical cases must be examined in detail before a cause–effect relationship can be considered.

PATHOGENESIS

The literature on the antioxidant roles of selenium and vitamin E have has been reviewed.[2] Dietary selenium, sulfur-containing amino acids and vitamin E act synergistically to protect tissues from oxidative damage.[1,2] GSH-PX, which is selenium-dependent, functions by detoxifying lipid peroxides and reducing them to non-toxic hydroxy fatty acids. Vitamin E prevents fatty acid hydroperoxide formation. High levels of PUFAs in the diet increase the requirements for vitamin E and, with an inadequate level of selenium in the diet, tissue oxidation occurs, resulting in degeneration and necrosis of cells. Vitamin E protects cellular membranes from lipoperoxidation, especially membranes rich in unsaturated lipids, such as mitochondric, endoplasmic reticulum and plasma membranes. Thus, dietary PUFA are not a prerequisite for the disease. Diets low in selenium and/or vitamin E do not provide sufficient protection against the 'physiological' lipoperoxidation that occurs normally at the cellular level.

The relative importance of selenium, vitamin E and sulfur-containing amino acids in providing protection in each of the known diseases caused by their deficiency is not clearly understood. Selenium has a sparing effect on vitamin E and is an efficient prophylactic against muscular dystrophy of calves and lambs at pasture, but does not prevent muscular dystrophy in calves fed on a diet containing cod liver oil. The current understanding of the biochemical function of selenium and its relation to vitamin E and the mechanisms of action of selenium and vitamin E in protection of biological membranes has been reviewed.[72]

Nutritional muscular dystrophy

A simplified integrated concept of the pathogenesis of the NMD would be as follows. Diets deficient in selenium and/or vitamin E permit widespread tissue lipoperoxidation leading to hyaline degeneration and calcification of muscle fibers. One of the earliest changes in experimental selenium deficiency in lambs is the abnormal retention of calcium in muscle fibers undergoing dystrophy and selenium supplementation prevents the retention of calcium. Unaccustomed exercise can accelerate the oxidative process and precipitate clinical disease. Muscle degeneration allows the release of enzymes, such as lactate dehydrogenase, aldolase and creatine phosphokinase, the last of which is of paramount importance in diagnosis. Degeneration of skeletal muscle is rapidly and successively followed by invasion of phagocytes and regeneration. In myocardial muscle, replacement fibrosis is the rule.

In calves, lambs, and foals, the major muscles involved are skeletal, myocardial and diaphragmatic. The myocardial and diaphragmatic forms of the disease occur most commonly in young calves, lambs, and foals, resulting in acute heart failure, respiratory distress, and rapid death, often in spite of treatment. The skeletal form of the disease occurs more commonly in older calves, yearling cattle, and older foals and results in weakness and recumbency, is usually less severe and responds to treatment. The biceps femoris muscle is particularly susceptible in calves and muscle biopsy is a reliable diagnostic aid.

In foals with NMD, there is a higher proportion of type IIC fibers and a lower proportion of type I and IIA fibers than in healthy foals. The type IIC fibers are found in fetal muscle and are undifferentiated and still under development. During the recovery period, fibers of types I, IIA, and IIB increase and the proportion of type IIC fibers decreases. A normal fiber type composition is present in most surviving foals 1–2 months after the onset of the disease.

Acute NMD results in the liberation of myoglobin into the blood, which results in myoglobinuria. This is more common in horses, older calves, and yearling cattle, than in young calves whose muscles have a lower concentration of myoglobin. Hence, the tendency to myoglobinuria will vary depending on the species and age of animal involved.

Subclinical selenium insufficiency

Selenium deficiency affects thyroid hormone metabolism and may explain the cause of ill-thrift. The conversion of the iodine-containing hormone, thyroxine (T4) to the more potent triiodothyronine (T3) is impaired in animals with low selenium status and iodothyroninedeiodinase is a selenoprotein which mediates this conversion.[72]

VESD syndrome and others

The pathogenesis of mulberry heart disease, hepatosis dietetica, exudative diathesis, and muscular dystrophy of pigs is not yet clear. Vitamin E and Se are necessary to prevent widespread degeneration and necrosis of tissues, especially liver, heart, skeletal muscle, and blood vessels. Se and vitamin E deficiency in pigs results in massive hepatic necrosis (hepatosis dietetica), degenerative myopathy of cardiac and skeletal muscles, edema, microangiopathy, and yellowish discoloration of adipose tissue. Myocardial and hepatic calcium concentrations are increased in pigs with mulberry heart disease.[73,74] In addition, there may be esophagogastric ulceration, but it is uncertain whether or not this lesion is caused by a Se and/or vitamin E deficiency. Anemia has also occurred and has been attributed to a block in bone marrow maturation, resulting in inadequate erythropoiesis, hemolysis or both. However, there is no firm evidence that anemia is a feature of Se and vitamin E deficiency in pigs. The entire spectrum of lesions has been reproduced experimentally in pigs with natural or purified diets deficient in Se and vitamin E, or in which an antagonist was added to inactivate vitamin E or Se. However, in some studies, the Se content of tissues of pigs that died from mulberry heart disease was similar to that of control pigs without the disease.

The extensive tissue destruction in pigs may account for the sudden death nature of the complex (mulberry heart disease and hepatosis dietetica) and the muscle stiffness that occurs in some feeder pigs and sows of farrowing time with muscular dystrophy. The tissue degeneration is associated with marked increases in serum enzymes related to the tissue involved. An indirect correlation between vitamin E intake and peroxide hemolysis in pigs on a deficient diet suggests that lipoperoxidation is the ultimate biochemical defect in pigs and that vitamin E and Se are protective.

CLINICAL FINDINGS

Acute enzootic muscular dystrophy

Affected animals may collapse and die suddenly after exercise without any other premonitory signs. The excitement associated with the hand-feeding of dairy calves may precipitate peracute death. In calves under close observation, a sudden onset of dullness and severe respiratory distress, accompanied by a frothy or blood-stained nasal discharge, may be observed in some cases. Affected calves, lambs, and foals are usually in lateral recumbency and may be unable to assume sternal recumbency even when assisted. When picked up and assisted to stand, they feel and appear limp. However, their neurological reflexes are normal. Their eyesight and mental attitude are normal and they are usually thirsty and can swallow unless the tongue is affected. The heart rate is usually increased up to 150–200/min and often with arrhythmia, the respiratory rate is increased up to 60–72/min and loud breath sounds are audible over the entire

lung fields. The temperature is usually normal or slightly elevated. Affected animals commonly die 6–12 h after the onset of signs in spite of therapy. Outbreaks of the disease occur in calves and lambs in which up to 15% of susceptible animals may develop the acute form and the case fatality approaches 100%.

Subacute enzootic muscular dystrophy

This is the most common form in rapidly growing calves, 'white muscle disease' and in young lambs, 'stiff-lamb disease'. Affected animals may be found in sternal recumbency and unable to stand but some make an attempt to stand. If they are standing, the obvious signs are stiffness, trembling of the limbs, weakness and, in most cases, an inability to stand for more than a few minutes. The gait in calves is accompanied by rotating movements of the hocks and in lambs a stiff, goose-stepping gait. Muscle tremor is evident if the animal is forced to stand for more than a few minutes. On palpation the dorsolumbar, gluteal and shoulder muscle masses may be symmetrically enlarged and firmer than normal (although this may be difficult to detect). Most affected animals retain their appetite and will suck if held up to the dam or eat if hand-fed. Major involvement of the diaphragm and intercostal muscles causes dyspnea with labored and abdominal-type respiration. The temperature is usually in the normal range but there may be a transient fever (41°C, 105°F) due to the effects of myoglobinemia and pain. The heart rate may be elevated, but there are usually no rhythmic irregularities. Following treatment, affected animals usually respond in a few days and within 3–5 days they are able to stand and walk unassisted.

In some cases, the upper borders of the scapulae protrude above the vertebral column and are widely separated from the thorax. This has been called the 'flying scapula' and has occurred in outbreaks in heifers from 18 to 24 months of age within a few days after being turned out in the spring following loose-housing throughout the winter. The abnormality is due to bilateral rupture of the serratus ventralis muscles and has been reported in a red deer.[75] Occasionally, the toes are spread and there is relaxation of carpal and metacarpal joints or knuckling at the fetlocks and standing on tip-toe, inability to raise the head, difficulty in swallowing, inability to use the tongue and relaxation of abdominal muscles. Choking may occur when the animals attempt to drink. In 'paralytic myoglobinuria' of yearling cattle, there is usually a history of recent turning out on pasture following winter housing. Clinical signs occur within 1 week and consist of stiffness, recumbency, myoglobinuria, hyperpnea, and dyspnea. Severe cases may die within a few days and some are found dead without premonitory signs. In rare cases, lethargy, anorexia, diarrhea and weakness are the first clinical abnormalities recognized, followed by recumbency and myoglobinuria.

Congenital muscular dystrophy has been described in a newborn calf.[18] The calf was still recumbent 13 h after birth, had increased serum creatine kinase and decreased serum vitamin E and selenium levels. Recovery occurred following supportive therapy and vitamin E and selenium.

Subcapsular liver rupture in lambs has been associated with vitamin E deficiency in lambs usually under 4 weeks of age.[76] Affected lambs collapse suddenly, become limp, and die within a few minutes or several hours after the onset of weakness.

In **foals, muscular dystrophy** occurs most commonly during the first few months of life and is common in the first week.[6] The usual clinical findings are failure to suck, recumbency, difficulty in rising and unsteadiness and trembling when forced to stand. The temperature is usually normal but commonly there is polypnea and tachycardia. The disease in foals may be characterized by an acute, fulminant syndrome, which is rapidly fatal, or a subacute syndrome characterized by profound muscular weakness. Failure of passive transfer, aspiration pneumonia, and stunting are frequent complications. In the subacute form, mortality rates may range from 30 to 45%.[6]

In **adult horses with muscular dystrophy**, a stiff gait, myoglobinuria, depression, inability to eat, holding the head down low, and edema of the head and neck are common. The horse may be presented initially with clinical signs of colic.

In **pigs, muscular dystrophy** is not commonly recognized clinically because it is part of the more serious disease complex of mulberry heart disease and hepatosis dietetica. However, in outbreaks of this complex, sucking piglets, feeder pigs and sows after farrowing, may exhibit an uncoordinated, staggering gait suggestive of muscular dystrophy.

Subclinical nutritional muscular dystrophy occurs in apparently normal animals in herds at the time clinical cases are present. The serum levels of creatine phosphokinase levels may be elevated in susceptible animals for several days before the onset of clinical signs; following treatment with vitamin E and selenium the level of serum enzymes returns to normal. Grossly abnormal electrocardiograms occur in some animals and may be detectable before clinical signs are evident.

Vitamin E selenium deficiency in pigs

Usually they occur separately but rarely MHD and HD occur together and even more rarely, you may find that there is NMD as well. There is a suspicion that the occurrence of two or more together has recently become more common but this in fact may be due to the greater awareness of both conditions. Two or more requires the supplementation with both Vitamin E and Se.

Mulberry heart disease

Usually seen in pigs from a few weeks to 4 months of age. These pigs are nearly always the best of the group and it may be that this rate of growth increases the demand for vitamin E and Se.

In mulberry heart disease, affected animals are commonly found dead without premonitory signs. More than one pig may be found dead. When seen alive, animals show severe dyspnea, cyanosis and recumbency and forced walking can cause immediate death. In some outbreaks, about 25% of pigs will show a slight inappetence and inactivity, these are probably in the subclinical stages of the disease. The stress of movement, inclement weather, or transportation will precipitate further acute deaths. The temperature is usually normal, the heart rate rapid and irregularities may be detectable. The feces are usually normal. A good 'classical outbreak' has been described.[77]

Hepatosis dietetica

In hepatosis dietetica, most pigs are found dead. Very few cases show other signs. In occasional cases, before death there will be dyspnea, severe depression, vomiting, staggering, diarrhea and a state of collapse. Some pigs are icteric. Outbreaks also occur similar to the pattern in mulberry heart disease. Muscular dystrophy is almost a consistent necropsy finding in both mulberry heart disease and *hepatosis dietetica* but is usually not recognized clinically because of the seriousness of the two latter diseases. Clinical muscular dystrophy has been described in gilts at 11 months of age. About 48 h after farrowing, there was muscular weakness, muscular tremors, and shaking. This was followed by collapse, dyspnea, and cyanosis. There were no liver or heart lesions. In experimental Se and vitamin E deficiency in young growing pigs, a subtle stiffness occurs along with a significant increase in the creatinine phosphatase (CPK) and serum glutamic-oxaloacetic transaminase (SGOT) values.

CLINICAL PATHOLOGY

Myopathy

Plasma creatine kinase (CK)

This is the most commonly used laboratory aid in the diagnosis of NMD. The enzyme is highly specific for cardiac and skeletal

muscle and is released into the blood following unaccustomed exercise and myodegeneration. In cattle and sheep, its half-life is 2–4 h and plasma levels characteristically decline quickly unless there is continued myodegeneration, but remain a good guide to the previous occurrence of muscle damage for a period of about 3 days. The normal plasma levels of CK (IU/L) are: sheep 52 ± 10; cattle 26 ± 5; horses 58 ± 6; and pigs 226 ± 43. In cattle and sheep with NMD, the CK levels will be increased usually above 1000 IU/L, commonly increased to 5000–10 000 IU/L and not uncommonly even higher. Following turnout of housed cattle onto pasture the CK levels will increase up to 5000 IU/L within a few days. The CK levels will usually return to normal levels within a few days following successful treatment. Persistent high levels suggest that muscle degeneration is still progressive or has occurred within the last 2 days. Measurement of plasma CK activity could be used to monitor recovery of animals treated for nutritional myopathy.

Aspartate aminotransferase

Aspartate aminotransferase (AST) activity is also an indicator of muscle damage, but is not as reliable as the CK because increased AST levels may also indicate liver damage. The AST activity remains elevated for 3–10 days because of a much longer half-life than CK. In acute cases, levels of 300–900 IU/L in calves and 2000–3000 IU/L in lambs have been observed. In normal animals of these species, serum levels are usually less than 100 IU/L.

The magnitude of the increase in AST and CK is directly proportional to the extent of muscle damage. Both are elevated initially; an elevated AST and declining CK would suggest that muscle degeneration is no longer active. The levels of both enzymes will be increased slightly in animals that have just been turned out and subjected to unaccustomed exercise, horses in training and in animals with ischemic necrosis of muscle due to recumbency caused by diseases other than muscular dystrophy. However, in acute muscular dystrophy, the levels are usually markedly elevated.

Selenium status

Although information on the critical levels of selenium in soil and plants is accumulating gradually, the estimations are difficult and expensive. Most field diagnoses are made on the basis of clinicopathological findings, the response to treatment and control procedures using selenium. The existence of NMD is accepted as presumptive evidence of selenium deficiency, which can now be confirmed by analyses of GHS-PX and the concentrations of selenium in soil, feed samples, and animal tissues. Tentative critical levels of the element are as follows:

- **Forages and grains**: A content of 0.1 mg/kg DM is considered adequate
- **Soil**: Soils containing less than 0.5 mg/kg are likely to yield crops inadequate in selenium concentration[5]
- **Animal tissues, blood and milk**: The concentration of selenium in various tissues are reliable indicators of the selenium status of the animal. There is a positive correlation between the selenium content of feed and the selenium content of the tissues and blood of animals ingesting that feed and the values fluctuate with the dietary intake of the element.[5]

Three tests can be used to assess selenium status in cattle and sheep: serum and whole blood selenium and glutathione peroxidase activity.[78] Serum selenium responds more rapidly to the administration of selenium than whole blood selenium. There is a similar delay in glutathione peroxidase activity to selenium supplementation. Blood or serum selenium status is most consistently measured at the herd-level. Interlaboratory differences in thresholds for deficiency exist and results should be considered based on laboratory-specific guidelines.

The recommended blood selenium reference ranges for New Zealand livestock have been used in several publications (see Table 30.7).[40,79,80]

Reference ranges for selenium and vitamin E in serum, blood, and liver of sheep and goat in the USA are available.[2]

Selenium status in horses

In New Zealand, the reference ranges for blood used for selenium status in horses are: adequate >1600 nmol/L (128 ng/mL); marginal 450–1600 nmol/L (36–128 ng/mL); and deficient <450 nmol/L (36 ng/mL).[81]

Kidney cortex and liver

Normal liver selenium concentrations range from 1.2 to 2.0 μg/g DM, regardless of species or age.[82] Levels of 3.5–5.3 μg/g (44–67 nmol/g) DM in the kidney cortex and 0.90–1.75 μg/g (11–22 nmol/g) DM in the liver of cattle are indicative of adequate selenium. Levels of 0.6–1.4 μg/g (8–18 nmol/g) in the kidney cortex and 0.07–0.60 μg/g (0.9–8 nmol/g) in the liver represent a deficient state.

The selenium content of bovine fetal liver samples collected at an abattoir contained 0.77 μg/mL WW and 0.13 μg/mL WW, from dairy breeds and beef breeds of cattle, respectively.[83] Mean liver selenium levels from aborted bovine fetuses with myocardial lesions were 5.5 μmol/kg, 6.5 μmol/kg in fetuses without myocardial lesions and 7.5 μmol/kg in fetuses from the abattoir, which suggests that selenium deficiency may be the cause of abortion.[84]

Blood and milk

Blood and milk levels of selenium are used as indicators of selenium status in cattle and the effect of dietary supplementation.[85] Serum selenium values increase gradually with age from starting ranges for neonates of 50–80 ng/mL for calves and sheep and 70–90 for foals and pigs.[82] Expected or normal values for adults are in the ranges of 70–100 for cattle, 120–150 for sheep, 130–160 for horses, and 180–220 for pigs.

Dams of affected calves have had levels of 1.7 ng/mL (22 nmol/L) (blood) and 4.9 ng/mL (62 nmol/L) (milk); their calves have blood levels of 5–8 ng/mL (63–102 nmol/L). Normal selenium-supplemented cows have 19–48 ng/mL (241–609 nmol/L) in blood and 10–20 ng/mL (127–253 nmol/L) in milk and their calves have blood levels of 33–61 ng/mL (419–774 nmol/L). Mean selenium concentrations in the blood of normal mares have been 26–27 ng/mL (329–342 nmol/L). In Thoroughbred horses, selenium concentrations in serum range from 39.5 to 118.5 mg/mL (40–160 ng/mL) (0.5–2.0 μmol/L) and there are significant differences between various stables of horses.

Bulk tank milk

The bulk tank milk selenium levels are closely related to the mean herd blood and milk levels and have the potential to be a low-cost, non-invasive means of evaluating herd selenium levels in order to determine selenium deficiency in the dairy herd.[64,86] Bulk tank selenium concentrations are an accurate reflection of the herd selenium status over the range of selenium intakes typical of dairy herds in an area.

Glutathione peroxidase

There is a direct relationship between the GSH-PX activity of the blood and the selenium levels of the blood and tissues of cattle, sheep, horses, and pigs.[1] The normal selenium status of cattle is represented by whole blood selenium concentration of 100 ng/mL (1270 nmol/L) and blood GSH-PX activity of approximately 30 mU/mg hemoglobin.

There is a high positive relationship (r = 0.87–0.958) between blood GSH-PX activity and blood selenium concentrations in cattle. Blood selenium levels less than 50 ng/mL are considered as selenium-deficient, while levels between 50 and 100 ng/mL (126.6 nmol/L) are marginal and greater than 100 ng/mL are adequate.[1] Comparable whole blood levels of GSH-PX are deficient if less than 30 mU/mg

hemoglobin, marginal if 30–60 mU/mg and adequate if greater than 60 mU/mg hemoglobin.[1] There is some evidence of variation in GSH-PX activities between breeds of sheep; levels may also decrease with increasing age. Low levels in some breeds of sheep may also be a reflection of adaptation to low selenium intake because of low levels of selenium in the soil and forages.

The GSH-PX activity is a sensitive indicator of the level of dietary selenium intake and the response to the oral or parenteral administration of selenium.[5] Because selenium is incorporated into erythrocyte GSH-PX only during erythropoiesis, an increase in enzyme activity of the blood will not occur for 4–6 weeks following administration of selenium. Plasma GSH-PX will rise more quickly and will continue to increase curvilinearly with increasing dietary selenium levels because it is not dependent on incorporation of the selenium into the erythrocytes. The liver and selenium concentration and serum GSH-PX activity may respond to changes in dietary selenium more rapidly than either whole blood selenium or erythrocyte GSH-PX activity. The response in GSH-PX activity may depend upon the selenium status of the animals at the time when selenium is administered. Larger increases in the enzyme activity occur in selenium-deficient animals. The GSH-PX activity in foals reflects the amount of selenium given to the mare during pregnancy.

The sandwich ELISA is a simplified method for the estimation of GSH-PX activity and selenium concentration in bovine blood and can be used for rapid screening of the selenium status of a large number of cattle.[87] The GSH-PX activity of whole blood samples has been used to assess the selenium status of cattle in the Czech Republic.[88]

The GSH-PX activity can be determined rapidly using a spot test which is semi-quantitative and can place a group of samples from the same herd or flock into one of three blood selenium categories: deficient, low marginal and marginal adequate.[89] A commercial testing kit known as the Ransel Kit is now available. Because of the instability of GSH-PX plasma, GSH-PX activity in sheep, cattle, and pigs should be measured in fresh plasma or stored at –20°C (–4°F). For absolute measurements, it is suggested that pigs plasma GSH-PX activity be measured immediately after separation from the blood cells, or be assayed within 24 h under specified laboratory conditions.

Vitamin E status

Vitamin E occurs in nature as a mixture of tocopherols in varying proportions. They vary widely in their biological activity so that chemical determination of total tocopherols is of much less value than biological assay. Tocopherol levels in blood and liver provide good information on the vitamin E status of the animal. However, because of the difficulty of the laboratory assays of tocopherols, they are not commonly done and insufficient reliable data are available. Analysis of liver from clinically normal animals on pasture reveal a mean α-tocopherol level of 20 mg/kg WW for cattle and 6 mg/kg WW for sheep. The corresponding ranges were 6.0–53 mg/kg WW for cattle and 1.8–17 mg/kg WW in sheep. The critical level below which signs of deficiency may be expected are 5 mg/kg WW for cattle and 2 mg/kg WW for sheep. Tocopherol levels in the serum of less than 2 mg/L in cattle and sheep are considered to be critical levels below which deficiency diseases may occur. However, if the diet contains adequate quantities of selenium, but not an excessive quantity of PUFAs, animals may thrive on low levels of serum tocopherols. In growing pigs, the serum vitamin E levels are between 2 and 3 mg/L. In summary, there are insufficient reliable data available on the vitamin E status on animals with NMD to be of diagnostic value.

The mean plasma vitamin E levels in clinically normal horses of various ages and breeds were 2.8 μg/mL.[90] The optimal method for storing equine blood prior to α-tocopherol analysis is in an upright position in the refrigerator for up to 72 h. If a longer period is needed, the serum or plasma should be separated, blanketed with nitrogen gas and frozen in the smallest possible vial; the α-tocopherol in these samples will be stable at –16°C (3°F) for at least 3 months.

A summary of the GSH-PX activity, tocopherol and selenium levels in blood and body tissues of animals deficient in selenium appears in Table 30.6. Normal values are also tabulated for comparison.[91] Both the abnormal and normal values should be considered as guidelines for diagnosis because of the wide variations in levels between groups of animals. The level of dietary selenium may fluctuate considerably, which may account for variations in GSH-PX. Selenium reference ranges to determine selenium status of sheep and cattle in New Zealand are shown in Table 30.7.

In the early stages of the subclinical form of NMD in lambs, there may be a decrease in serum selenium and glutathione peroxidase activity and an increase in the activity of aspartate aminotransferase (AST), creatine kinase (CK), and lactate dehydrogenase (LDH) compared with healthy lambs.[92] The LDH-isoenzyme activity is useful for detection of subclinical forms of NMD because of significant increases in the activity of the LDH_5-muscle fraction.

Farmed red deer

Reference range data for liver and blood selenium in red deer are limited.[93,94] White muscle disease has occurred in young deer with blood and liver selenium concentrations of 84–140 nmol/L and 240–500 nmol/kg fresh tissue, respectively. No growth rate response to selenium supplementation occurred in 1-year-old deer when blood selenium concentrations were less than 130 nmol/L, the range in which a growth rate response would be expected in sheep.

Table 30.6 Glutathione peroxidase (GSH-PX) activity and selenium levels in blood and body tissues of animals deficient in selenium.

Species	Clinical state or degree of deficiency	Erythrocyte GSH-PX activity μmol/min at 37°C/g hemoglobin	Serum selenium (μg/mL)	Liver selenium (μg/g DM)
Cattle	Normal or adequate	19.0–36.0	0.08–0.30	0.90–1.75
	Marginal	10.0–19.0	0.03–0.07	0.45–0.90
	Deficient	0.2–10.0	0.002–0.025	0.07–0.60
Sheep	Normal or adequate	60–180	0.08–0.50	0.90–3.50
	Marginal	8–30	0.03–0.05	0.52–0.90
	Deficient	2–7	0.006–0.03	0.02–0.35
Pigs	Adequate	100–200	0.12–0.30	1.40–2.80
	Deficient	<50	0.005–0.60	0.10–0.35
Horse	Adequate	30–150	0.14–0.25	1.05–3.50
	Deficient	8–30	0.008–0.055	0.14–0.70

Table 30.7 Selenium reference range to determine selenium status of sheep and cattle in New Zealand

	Deficient	Marginal	Adequate
Sheep			
Blood selenium (nmol/L)	<130	130–250	>250
Liver selenium (nmol/kg fresh tissue)	<250	250–450	>450
Cattle			
Blood selenium (nmol/L)	<130	130–250	>250
Liver selenium (nmol/kg fresh tissue)	<600	600–850	>850
Serum selenium (nmol/L)	<85	85–140	>250
Blood glutathione peroxidase (Ku/L – 25°C)	<0.5	0.5–2.0	>2.0

Pigs

An increase in the activity of several plasma enzymes occurs in Se and vitamin E deficiencies of pigs. The measurement of AST, CPK, lactic acid dehydrogenase, and isocitrate dehydrogenase can be used to detect the onset of degeneration of skeletal and myocardial muscles and liver. However, these are not commonly used for diagnostic purposes because of the acuteness of the illness. The determination of the levels of Se in feed supplies, tissues, and blood of affected pigs is much more useful as an aid to diagnosis and for guidelines for supplementation of the diet.

In Se-vitamin E deficiency in pigs, serum Se values of less than 2.5 ng/mL (3.2 nmol/L), hepatic Se of less than 0.10 mg/kg (1.3 μmol/kg), plasma α-tocopherol values of <0.40 μg/mL and hepatic α-tocopherol concentrations of <0.75 μg/g of tissue are common. In a recent study, the vitamin E level was <2 ppm in 25% of pigs with gross and microscopic lesions of MHD.[39] In a recent study results suggested that supplementation with a surfeit level of vitamin E reduced the response to endotoxin, i.e. a reduced response to the peak levels of IL-6.[95]

The diagnostic criteria for the VESD complex in pigs in New Zealand indicate that liver vitamin E concentrations >10 μmol/kg are adequate, with <2.5 μmol/kg associated with deficiency. Corresponding estimates for serum vitamin E are >2.5 μmol/L and <0.8 μmol/L, respectively. Liver Se concentrations of >2200 nmol/kg are adequate, with 1100–2200 nmol/kg being in the marginal range and <1100 nmol/kg being deficient. Deficiency levels for blood are in the range of 400–1500 nmol/L. These values must be interpreted along with the concentration of PUFAs in the diet.

There is a close relationship between blood vitamin E and resistance of erythrocytes against lipid peroxidation. The supplementation of the diet of pigs with vitamin E will increase both the serum levels of vitamin E and the resistance of the erythrocytes to lipid peroxidation.[96]

NECROPSY FINDINGS

The gross appearance of the muscle lesions is quite constant, but the distribution of affected muscles varies widely in different animals. Affected groups of skeletal muscle are bilaterally symmetrical and contain localized white or gray areas of degeneration and necrosis. These areas may be in streaks, involving a large group of muscle fibers that run through the center of the apparently normal muscle or as a peripheral boundary around a core of normal muscle. In the diaphragm, the distribution of damaged bundles gives the tissue a radially striated appearance. The affected muscle is friable and edematous and may be mineralized. Secondary pneumonia often occurs in cases where the muscles of the throat and chest are affected. In cases with myocardial involvement, white areas of degeneration are visible, particularly under the endocardium of the left ventricle in calves and of both ventricles in lambs. The lesions may extend to involve the interventricular septum and papillary muscles and have a gritty character consistent with mineralization. Pulmonary congestion and edema is common.

Histologically, the muscle lesions in all species are **non-inflammatory**. Hyaline degeneration is followed by coagulation necrosis and variable degrees of mineralization.

Other than a variable degree of muscular atrophy, gross lesions are not seen in horses with **equine motor neuron disease**. Confirmation of the diagnosis relies on histological identification of characteristic degeneration and loss of motor neurons of the spinal cord ventral horns. However, a very strong presumptive diagnosis can be achieved by microscopic confirmation of neurogenic atrophy in the sacrocaudalis dorsalis muscle or axonal degeneration in the spinal accessory nerve.[97]

A generalized **steatitis** has been described in newborn foals less than 2 months of age. The microscopic appearance of this yellow-brown fat consists of necrotic fat infiltrated by neutrophils, macrophages and giant cells. Steatitis and nodular panniculitis have also been reported in a 3-year-old vitamin E/selenium-deficient mare.[98] Supplemental vitamin E is believed to protect against steatitis in foals.

In **mulberry heart disease** the carcass is in good condition. All body cavities contain excessive amounts of fluid and shreds of fibrin. In the peritoneal cavity, the fibrin is often in the form of a lacy net covering all the viscera. The liver is enlarged, mottled and has a characteristic nutmeg appearance on the cut surface. The lungs are edematous and excessive fluid in the pleural cavities is accompanied by collapse of the ventral lung field. The pericardial sac is filled with gelatinous fluid interlaced with bands of fibrin. Beneath the epicardium and endocardium are multiple hemorrhages of various sizes. Usually, this hemorrhage is more severe on the right side of the heart. This gives the heart the typical mottled appearance which is caused by areas of necrosis and areas of hemorrhage. Histologically, the characteristic lesion is widespread myocardial congestion, hemorrhage, and myofiber degeneration. Multiple fibrinous microthrombi are within the myocardial capillaries and, occasionally, degenerative changes are visible in walls of small arterioles in many organs, including the heart. Malacia of cerebral white matter, or more rarely the molecular layer of the cerebellum, may occur and is attributable to microvascular damage. It should be stressed that, in some cases, the disease course is so rapid that morphologic changes are not discernible in the myocardial cells. Since it can be extremely difficult to distinguish mulberry heart disease from *S. suis* septicemia histologically, it is prudent to also attempt bacteriologic culture when attempting to confirm the diagnosis.

In **hepatosis dietetica**, the liver is swollen and has a mottled to mosaic-like appearance throughout its lobes. Many of the lobules are distended and reddish in color. There is in fact an irregular distribution of hepatic necrosis and hemorrhage. The gall bladder may be edematous and there may also be myocardial necrosis and pulmonary edema. Typically, the disease course is so rapid that jaundice does not develop. Histologically, there is a distinct lobular distribution of hemorrhage, degeneration, and necrosis.

In **NMD** of pigs, the lesions are often only visible at the microscopic level and consist of areas of bilaterally distributed areas of muscular degeneration. The changes include hyalinization, loss of striations and fragmentation of myofibers. The sections are difficult to cut because of the presence of calcium in the myocytes.

A mild degree of NMD may accompany some cases of *hepatosis dietetica*.

Samples for confirmation of diagnosis

- **Toxicology** – 50 g liver (ASSAY (Se) (Vitamin E))
- **Histology** – formalin-fixed skeletal muscle (multiple sites), heart (both left and right ventricular walls), brain (including cerebral hemisphere) (LM). May require special stains to show the presence of calcium in the sections
- **Bacteriology** (for mulberry heart disease only) – heart, liver, swab from pericardial sac (CULT).

DIFFERENTIAL DIAGNOSIS

Nutritional muscular dystrophy
NMD is most common in young rapidly growing animals fed a selenium-vitamin E-deficient ration or whose dams were on a deficient, unsupplemented ration throughout the winter months. Characteristically, the disease is sudden in onset and several animals are affected initially or within a few days, particularly following unaccustomed exercise. In the acute form, generalized weakness and a state of collapse are common. In the subacute form, the major clinical findings are stiffness in walking, long periods of recumbency or total recumbency, inability to stand, a normal mental attitude and appetite and no abnormal neurological findings to account for the recumbency. The CP levels are markedly elevated.

Calves and yearlings
Acute enzootic muscular dystrophy in calves with myocardial involvement must be differentiated from other diseases causing generalized weakness, toxemia and shock. These include:

- **Septicemias**: Haemophilus septicemia resulting in weakness, recumbency and fever
- **Pneumonia**: Pneumonic pasteurellosis causing dyspnea, toxemia, fever and weakness.

Subacute enzootic muscular dystrophy in which skeletal muscle lesions predominate must be differentiated from other diseases of young calves and yearlings characterized clinically by paresis and paralysis. The subacute form is more common in yearlings and young cattle and is characterized by recumbency with other body systems being relatively within normal ranges. The other diseases include:

- **Musculoskeletal diseases**: Polyarthritis, traumatic or infectious myopathies (blackleg), osteodystrophy and fractures of long bones
- **Diseases of the nervous system**: Spinal cord compression, Hemophilus meningoencephalitis and myelitis, organophosphatic insecticide poisoning
- **Diseases of the digestive tract**: Carbohydrate engorgement resulting in lactic acidosis, shock, dehydration, and weakness.

Lambs and kids
In lambs with 'stiff-lamb' disease, there is stiffness and a stilted gait, affected animals prefer recumbency, they are bright and alert and will suck the ewe if assisted. The serum levels of CPK and SGOT are also markedly elevated. Differentiation may be necessary from enzootic ataxia and swayback, but in these two diseases, stiffness is not characteristic but rather weakness and paresis.

Foals
In foals, NMD must be differentiated from acute diseases of the musculoskeletal and nervous system causing abnormal gait, weakness and recumbency. They include:

- Polyarthritis
- Meningitis
- Traumatic injury to the spinal cord.

Mulberry heart disease
Mulberry heart disease must be differentiated from other common causes of sudden death in pigs in which the diagnosis is made at necropsy and include:

- Acute septicemias due to salmonellosis, erysipelas, pasteurellosis and anthrax
- Porcine stress syndrome
- Gut edema
- Intestinal volvulus, heat exhaustion, suffocation during transportation.

TREATMENT

Because of the overlapping functions of selenium and vitamin E and because it is not always possible to know the relative etiological importance of one nutrient or the other in causing some of the acute conditions already described, it is recommended that a combined mixture of selenium and α-tocopherol be used in treatment. α-Tocopherol is the most potent form of the tocopherols and is available in a number of pharmaceutical forms, which also vary in their biological activity. It has become necessary to express the unitage of vitamin E in terms of international units of biological activity (1 IU:1 mg synthetic racemic a-tocopherol acetate. Natural D-α-tocopherol acetate 1 mg: 1 IU and natural D-α-tocopherol 1 mg: 0.92 IU).

Nutritional muscular dystrophy

For treatment of NMD in calves, lambs, and foals a mixture containing 3 mg selenium (as sodium or potassium selenite) and 150 IU/mL of DL-α-tocopherol acetate, given IM at 2 mL/45 kg BW is recommended. One treatment is usually sufficient. Animals with severe myocardial involvement will usually not respond to treatment and the case mortality rate is about 90%. However, all in-contact animals in the herd (calves, lambs, and foals) should be treated prophylactically with the same dose of selenium and vitamin E. They should be handled carefully during treatment to avoid precipitating acute muscular dystrophy. Animals with subacute skeletal muscular dystrophy will usually begin to improve by 3 days following treatment and may be able to stand and walk unassisted within 1 week.

Animals sometimes do not respond to either vitamin E or Se or treatment with both.

In outbreaks of mulberry heart disease, hepatosis dietetica and related Se and vitamin E deficiency diseases in pigs, all clinically affected pigs and all pigs at risk should be treated individually with a combination of Se and vitamin E parenterally at first to prevent any further sudden death. It can then be followed by oral administration.

CONTROL

The control and prevention of the major diseases caused by selenium and vitamin E deficiencies can generally be accomplished by the provision of both nutrients to susceptible animals fed on deficient rations. The following points are relevant and applicable to most situations:

Provide selenium and vitamin E
Maternal transfer to newborn
Selenium is potentially toxic
Selenium in milk supplies
Dietary requirement of selenium
High sulfate diets
Glutathione peroxidase activity
Different methods of supplementation.

Provide selenium and vitamin E

Over the years, both the vitamin E levels and Se levels in the diets have increased but particularly the former. This is in response to the more rapid growth rates of pigs but also the realization that pigs are coping with many more oxidative disease states. Outdoor pigs usually have sufficient of both unless the soil is Se deficient. A recent Chinese paper[99] has suggested that dietary zinc at 85 mg/kg, Se at 0.40 mg/kg, and vitamin E at 45 IU/kg is appropriate for crossbred sows.

While Se alone is protective against a greater spectrum of diseases than is vitamin E, there are situations in which vitamin E is more protective. Both Se and vitamin E should be provided when the diets are deficient in both nutrients, but this may not apply in every situation. Most of the emphasis has been on Se supplementation at the expense of vitamin E, which is more expensive and less stable. Most injectable vitamin E and Se preparations are adequate in Se but insufficient in vitamin E.

There have been several attempts to supplement weaner pigs with a vitamin E preparation. Besides individual injections, it

is possible to supplement weaner pigs with water supplementation.[100] Pigs will usually drink even if they are not eating. A recent study[101] showed that the supplementation of drinking water with high doses of vitamin E (150 mg of Dl-α-tocopherol acetate) was effective in maintaining serum vitamin E levels over the weaning period. This was even true when over the weaning period the intake of food was very low (it can be as low as 0.2–0.3 kg) and there is a temporary malabsorption in the intestine. It takes about 100 IU/L of water to provide a good vitamin E blood serum value.

Maternal transfer to newborn

Diseases caused by selenium deficiency are preventable by the administration of selenium to the dam during pregnancy or directly to the young growing animal. Selenium is transported across the placenta and provides protection for the neonate. Oral supplementation with selenium in beef cattle will provide enough to maintain blood levels in the dam and for adequate transfer to the fetus, which can sequester selenium when the levels are low in the dam. The colostrum of selenium-supplemented cattle also contains an adequate amount of selenium to prevent severe selenium-deficiency diseases.[68] However, by 7 days after parturition, the levels in milk may be inadequate to maintain adequate serum levels in calves. The strategic administration of selenium and vitamin E before the expected occurrence of the disease is also a reliable method of preventing the disease.

Selenium is potentially toxic

Se is toxic and any treatment and control program using it must be carefully monitored.[102] Se injected into or fed to animals concentrates in liver, skeletal muscle, kidney, and other tissues and withdrawal periods before slaughter must be allowed. There is some concern that Se may be a carcinogen for man. The only tissues that appear likely to consistently accumulate more than 3–4 mg/kg of Se are the kidney and liver and these are very unlikely to constitute more than a very small part of the human diet. There have been no reports of untoward effects of Se on human health when it has been used at nutritional levels in food-producing animals. The incorporation of Se into commercially prepared feeds for some classes of cattle and pigs has been approved in some countries. A recent case in Norway showed the hazards of Se contamination in the case of an iron supplement.[103] Se toxicosis has been fairly regularly reported.[104–106]

Pigs that are deficient may be more susceptible to other diseases. Pigs with NMD often have the appearance of pneumonic pigs because the diaphragm is weak and the pigs are dyspneic.

Deficient and small pigs may be more susceptible to the effects of iron and when this is given by injection there may be large numbers of dead piglets as a result of iron toxicity. In these cases, the heart lesions resemble those of MHD.

Selenium in milk supplies

The use of selenium in the diet of lactating dairy cows has caused concern about possible adulteration of milk supplies. However, the addition of selenium to the diets of lactating dairy cows at levels that are protective against the deficiency diseases does not result in levels in the milk that are hazardous for human consumption. The feeding of excessive quantities of selenium to dairy cattle would cause toxicity before levels became toxic for man.

Dietary requirement of selenium

The dietary requirement of selenium for both ruminants and non-ruminants is 0.1 mg/kg DM of the element in the diet. There may be nutritionally important differences in the selenium status between the same feeds grown in different regions and between different feeds within a region. Even within a region featuring high selenium concentrations, some feeds may contain levels of selenium below the 0.1 mg/kg minimum requirement for livestock. Thus a selenium analysis of feeds appears necessary in order to supplement livestock appropriately. Some geographical areas are known to be deficient in selenium and the feeds grown in these areas must be supplemented with selenium and vitamin E on a continuous basis. Some reports indicate that surveys have found that dairy producers are providing insufficient supplementary selenium in the ration to meet the recommended selenium intake for lactating dairy cows.[14] Long-term administration of organic selenium in the form of selenium yeast provides higher blood and tissue concentrations than repeated parenteral administration of recommended therapeutic doses of inorganic selenium.[71]

High sulfate diets

Avoidance of high sulfate diets is desirable, but provision of adequate Se overcomes the sulfate effect.

Glutathione peroxidase activity

Whole blood GSH-PX activity is a way of monitoring Se status but is not as reliable in pigs as in sheep and cattle.

Pigs. In growing pigs, both Se and vitamin E at 30 IU/kg DM of feed are necessary for the prevention of the diseases caused by diets deficient in vitamin E and Se. Supplementation of the diet of the sow will result in an adequate transfer to the piglets. Satisfactory protection of the diseases of pigs caused by vitamin E Se deficiency depends on the correct balance between Se, α-tocopherol, PUFAs in the diet and the presence of a suitable antioxidant to conserve the α-tocopherol.[107]

Different methods of supplementation

The prevention of the major diseases caused by selenium and vitamin E deficiencies can be achieved by different methods, including:

- Dietary supplementation in the feed or water supplies
- Individual parenteral injections
- Oral administration
- Pasture top-dressing.

The method used will depend on the circumstances of the farm, ease of administration, cost, the labor available, severity of the deficiency that exists and whether or not the animals are being dosed regularly for other diseases such as parasitism. The subcutaneous injection of barium selenate, the administration of an intra-ruminal pellet and the addition of selenium to the water supply were compared in cattle; each method was effective for periods ranging from 4 to 12 months.

Dietary supplementation

The inclusion of selenium and vitamin E in the feed supplies or salt and mineral mixes has been generally successful in preventing the major diseases caused by deficiencies of these two nutrients.

Selenium dose

Individual injections

Injections of Se and vitamin E have been used successfully for prevention, particularly in circumstances where the diet cannot be easily supplemented. Following IM injections of sodium selenite into calves, lambs, and piglets, the Se concentration of the tissues, particularly the liver, increases and then declines to reach preinjection levels in 23 days in calves and 14 days in lambs, and piglets. Adequate sources of vitamin E also must be provided. Injectable preparations of Se and vitamin E are usually adequate in Se and deficient in vitamin E and it may not be possible to correct a marginal deficiency of vitamin E in pregnant beef cattle, for example, by IM injection of a Se and vitamin E preparation which contains an inadequate concentration of vitamin E.[108] The current label dose of injectable Se, 0.055 mg Se/kg BW, which is therapeutically adequate for NMD, is not sufficient for long-term Se supplementation of cattle on a Se-deficient diet.[109] Copper and Se supplementation by parenteral administration can be combined when both deficiencies are present.[110]

Subcutaneous injections

Cattle and sheep. A slow-release preparation of barium selenate for SC injection is now available for use in cattle and sheep.[89] A SC injection of 1 mg selenium/kg BW to ewes 3 weeks before breeding elevated the selenium level in milk during lactation and increased the selenium concentration and GSH-PX in the blood of the lambs during the period when they are at greatest risk from selenium-deficiency diseases.[111] At a dose of 1 mg selenium/kg BW to pregnant ewes, the GSH-PX activity is increased and maintained at adequate levels for up to 5 months. There is adequate transfer of selenium to the lambs, providing protection for up to 12 weeks of age, which covers the period when lambs are at greatest risk. A dose of 1.2 mg selenium/kg BW provided adequate selenium status for as long as two consecutive lambing seasons. Barium selenate at 1 mg selenium/kg BW SC provides protection in young sheep for at least 3 months and is not associated with risk of selenium toxicity or unacceptable residues of selenium in tissues other than the site of injection.[89] A dose of 1 mg selenium/kg BW (barium selenate) to cattle SC increased the GSH-PX activity within 4 weeks and was maintained at high levels for up to 5 months.

Pigs. The SC injection of barium selenate of pregnant sows at 0.5–1.0 mg selenium/kg BW resulted in a significant difference in GSH-PX activity in the piglets from treated sows compared with untreated controls. The SC injection of barium selenate at 2.5 mg selenium/kg BW into pigs weighing 20 kg also maintained blood levels of selenium and GSH-PX activity during the most rapid growing period. The relative safety of barium selenate is due to its slow rate of release from the site of injection. By comparison, when selenium is administered as a soluble salt, such as sodium selenite, acute toxicity may occur at doses of 0.45 mg selenium/kg BW. Treatment with barium selenate increases the concentration of selenium in blood, liver and muscle and persists for at least 4 months. One disadvantage of barium selenate is that a large residue persists at the site of injection for long periods. The use of sodium selenite also increases tissue and blood concentrations of selenium, but they begin to decline by 23 days. The bovine liver rapidly removes approximately 40% of injected selenium salts (soluble) from the systemic plasma, binds it to a plasma component and within 1 h of injection releases it back into circulation.

Farmed red deer. A long-acting barium sulfate given subcutaneously to red deer on pasture, at 0.5, 1.0, or 2.0 mg Se/kg BW, elevated blood selenium concentrations from 105 nmol/L pre-injection for at least 377 days with peak levels of 1894, 1395, and 818 nmol/L for high, medium, and low doses, respectively.[112] Pastures contained 10–30 mg Se/kg DM. There was no significant difference in growth rate between treated and control deer. The preparation produced fewer and less severe subcutaneous tissue reactions than previous preparations. Young growing deer seem less sensitive to selenium deficiency as measured by weight gain, than sheep and cattle, suggesting that reference ranges for those species are not appropriate for deer.

Oral selenium and anthelmintics

Oral dosing using sodium selenite is sometimes combined with the administration of anthelmintics and vaccinations. The dose should approximate 0.044 mg/kg BW. A routine program in a severely deficient area comprises three doses of 5 mg of selenium (11 mg sodium selenite) each to ewes, one before mating, one at mid-pregnancy and one 3 weeks before lambing and four doses to the lambs. The first dose to lambs (of 1 mg) is given at docking and the others (2 mg each) at weaning and then at 3-month intervals. A 100-day controlled release anthelmintic capsule containing 13.9 mg of selenium will protect lambs from selenium deficiency for at least 180 days.[113]

Both selenium and cobalt can be incorporated into an anthelmintic program. The levels of GSH-PX activity may be monitored on a regular basis following the drenching with selenium and provide a good indication of selenium availability and selenium status of grazing sheep.

Pasture top-dressing

The application of sodium selenate as a top-dressing to pasture is now practiced and permitted in some countries. Top-dressing at the approved rate of 10 g selenium/ha is effective for 12 months and has a toxicity margin of safety of about 20 times. Sodium selenate is now used in preference to sodium selenite because only about one-fifth is required to raise the pasture level of selenium to the same concentrations provided by sodium selenite. Top-dressing severely deficient pumice soils in New Zealand prevented deficiency for at least 12 months, sheep were protected against white muscle in lambs and reproduction performance and weight gains were improved. It is recommended that sodium selenate be applied annually to all selenium-deficient soils at the rate of 10 g selenium/ha added to the superphosphate fertilizer, or as prills of sodium selenate alone. Top-dressing is an economical alternative to individual animal dosing, particularly in severely deficient areas with a high stocking rate. At the approved rate, no adverse effects are anticipated in human or animal health or on the environment.

Muscular dystrophy

Under most conditions, NMD of calves and lambs can be prevented by providing selenium and vitamin E in the diets of the cow or ewe during pregnancy at 0.1 mg/kg DM of actual selenium and α-tocopherol at 1 g/d per cow and 75 mg/d per ewe. If possible, the supplementation should be continued during lactation to provide a continuous source of selenium to the calves and lambs. Under some conditions the level of 0.1 mg/kg DM may be inadequate. In some circumstances, the optimal selenium concentration in the feed is considerably higher than 0.1 mg/kg DM and levels up to 1.0 mg/kg DM in the feed result in increases in GSH-PX activity which may be beneficial; however, the cost-effectiveness has not been determined. Pregnant ewes being fed on alfalfa hay may require selenium at a level of up to 0.2 mg/kg DM to prevent white muscle disease in their lambs. Young growing cattle, particularly beef cattle likely to receive hay and straw deficient in selenium and those which are fed high-moisture grain, should receive a supplement of selenium at the rate of 0.1 mg/kg DM and α-tocopherol at 150 mg/d per head. If selenium-supplemented concentrates are used as part of a feeding program for dairy cows, it is not necessary to provide additional selenium by parenteral injection.

Lambs are born with a low serum level of vitamin E but the concentration increases rapidly after the ingestion of colostrum.[1] Supplementation of pregnant ewes with α-tocopherol, either as a single IM dose (500 mg 2 weeks before lambing) or orally (150 mg daily during 3–4 weeks before lambing) results in a marked increase in the levels of the vitamin in the serum and colostrum. The vitamin E concentration in colostrum was 5–11 times higher than in milk 1 week after lambing.

Vitamin E supplementation of the feed of weaner sheep by oral drench or feed additive is effective in increasing plasma α-tocopherol concentrations. This is the most practical method for housed sheep and prevents subclinical myopathy.[114] The IM oily injection was slow to increase plasma levels of tocopherols and did not prevent myopathy in grazing experiments. Vitamin E supplements have no beneficial effects on wool quality or quantity in grazing sheep and unless certain flocks are susceptible to vitamin E deficiency myopathy it is not recommended.

Beef cattle and sheep

Salt-mineral mixture. NMD can be prevented in unweaned beef calves and lambs by the inclusion of selenium

(14.8 mg/kg) and vitamin E (2700 IU/kg) in the mineral supplement provided ad libitum to the pregnant cows and ewes on a selenium-deficient ration during the latter two-thirds of gestation and for the first month of lactation. Under most conditions this will provide selenium at 0.1 mg/kg DM in the diet.

The provision of **sodium selenite in a salt-mineral mixture** to provide 90 mg of selenium/kg salt-mineral mixture on a year-round basis, even under range conditions, increased GSH-PX activity levels into normal ranges in beef cows for 3 months when fed to extremely deficient animals. Calves of these cows had increased weaning weights and decreased incidence of infectious diseases, but the trial was uncontrolled. The provision of 30 mg selenium/kg salt-mineral mixture was insufficient to raise the GSH-PX activity levels to normal ranges. Peak blood selenium levels were achieved in weaned beef calves supplemented with 80 and 160 mg selenium/kg in free-choice salt-mineral mixtures for a period of 108 days. In some jurisdictions, it may be necessary for the veterinarian to prescribe a supplement containing higher levels than those permitted by legislation. A level of 25 mg/kg selenium of a salt-mineral mixture provided ad libitum for sheep will result in sufficient levels of selenium in the dam's blood and milk to prevent selenium deficiency diseases. Each ewe must consume from 8 to 12 g of the salt-mineral mixture per day.

Selenium deficiency in grazing and forage fed cattle is widespread in the United States and other countries.[115] Calves may be severely depleted of selenium and selenium-dependent glutathione peroxidase but exhibit no clinical signs of deficiency unless they are subjected to an oxidant or other types of stress. Nursing beef calves may be at risk of selenium deficiency if their dams are not supplemented with selenium. Even when sodium selenite is used in a free-choice mineral supplement designed to deliver 2 mg of selenium daily, calves are still at risk for selenium deficiency for up to 90 days. Selenium supplementation of pregnant beef cows with seleno-yeast in a free-choice mineral mixture increased the whole blood selenium and GSH-PX activity of both cows and calves much superior to sodium selenite.[115]

The supplementation of beef cattle in late gestation with oral vitamin E, 1000 IU/head per day, influenced the vitamin E status of cows which calved in late winter to a greater extent than cows calving in late summer because of the high vitamin E content in the pasture-based summer diet.[116] Calves from supplemented cows had higher serum vitamin E levels than calves from unsupplemented cows. Winter-born calves from supplemented Hereford cows had heavier 205-day adjusted weaning weights than did winter-born calves from unsupplemented cows. Supplementation did not affect vitamin E or IgG concentrations in cows which calved in late summer and it did not affect calf growth.

Dairy cattle

Selenium. The legal commercial selenium supplementation of complete rations for dairy cattle in the USA has recently been increased from 0.1 to 0.3 mg/kg DM of complete feed.[117] At this rate, a lactating cow consuming 20 kg of DM/d would consume about 6 mg supplemental selenium in addition to that naturally present in the feedstuffs. Current recommendations indicate that selenium intake for lactating and gestating dairy cattle should range from 5 to 7 mg/d for adequate concentrations in serum or plasma which would range from 70 to 100 ng of selenium/mL serum. Such supplementation should result in improved selenium status of the newborn, improved concentration of selenium in colostrum and improved health of the calves. The effects of selenium supplementation in dairy cattle on reproductive performance is equivocal. Some studies over a period of two lactations revealed no effect on reproductive performance, while others report an improvement in dairy cattle in a district considered to be marginally deficient in selenium. Intakes of inorganic selenium as sodium selenite in amounts of 50 mg/d for 90 days or 100 mg/d for 28 days by adult dairy cows (10–30 times the nutritional requirement) did not cause any health problems.[118] The toxic dose for cattle ranges from 0.25 to 0.5 mg/kg BW.

Milk replacers for dairy calves should contain a suitable antioxidant and be supplemented with 300 IU/kg DM of α-tocopherol acetate at the rate of 0.1 mg/kg DM of the milk replacer.

Vitamin E. Dietary or parenteral supplementation of vitamin E to dairy cows during the peripartum period has consistently improved the function of neutrophils and macrophages.[117] However, the effects of supplementation of dry dairy cows with vitamin E in the feed or parenteral administration of vitamin E before parturition on the incidence of disease have been variable. The amount of supplemental vitamin E fed per day during the prepartum period has ranged from 1000 to 3000 IU/day. Feeding 1000 IU/day of supplemental vitamin E to dry cows when adequate selenium was supplemented reduced the incidence of retained placenta. The prepartum subcutaneous injection of dairy cows with 3000 IU of vitamin E, 1 week before expected calving had no significant difference on the incidence of retained placenta, clinical mastitis, metritis, endometritis, ketosis, displaced abomasum, or lameness.[60] Vitamin E administered to cows with marginal pretreatment vitamin E status had a reduced risk of retained placenta. In cows, with adequate serum vitamin E, there was no reduction in the incidence of any disease.[60,61]

Based on health and immune function in cows, plasma concentrations of α-tocopherol in peripartum cows should be approximately 3 μg/mL. To maintain these blood values, dry cows and heifers fed stored forages during the last 60 days of gestation require approximately 1.6 IU of supplemental vitamin E/kg BW (approximately 80 IU/kg DMI). Increased intake of vitamin E of cows and heifers during the prepartum period also increases the vitamin E in colostrum. Milk is not a major source of vitamin E but colostrum contains high concentrations of α-tocopherol (3 to 6 μg/mL. For lactating cows, being fed stored forages, to reduce the incidence of mastitis, the recommendation for vitamin E is 0.8 IU/kg BW (approximately 20 IU/kg DMI).[117] When fresh forage is fed, there is less need for supplemental vitamin E. The intake of polyunsaturated fatty acids increases the vitamin E requirement and additional vitamin E may be required when protected unsaturated fats are fed.

NMD in the neonate

The injection of Se 0.06 mg/kg BW into piglets under 1 week of age, repeated at weaning time and into the sow 3 weeks before farrowing will be effective. The minimum lethal dose of Se for piglets is 0.9 mg/kg BW, which provides a reasonably wide range of safety. A high concentration of Se in the diet of pregnant sows in the last half of gestation has been associated with hemorrhagic lesions on the claws of newborn piglets.[119]

While selenium alone is protective against a greater spectrum of diseases than is vitamin E, there are situations in which vitamin E is more protective. Both selenium and vitamin E should be provided when the diets are deficient in both nutrients, but this may not apply in every situation. NMD can occur in ruminants with vitamin E deficiency and an adequate selenium status. Most of the emphasis has been on selenium supplementation at the expense of vitamin E, which is more expensive and less stable. Most injectable vitamin E and selenium preparations are adequate in selenium but insufficient in vitamin E.

Selenium responsive reproductive performance and growth

Sheep

In selenium deficient situations, reproductive performance of ewes may be improved by selenium or selenium and vitamin E. Survival of lambs, live weights

at birth and at weaning may be increased by selenium supplementation. Single injections of selenium before mating and lambing had no significant effects on estrus, fertility, prolificacy, and the number of lambs born and reared to 28 days in 2-year-old ewes.[120] Two consecutive injections of selenium (before mating and lambing) significantly increased the incidence of estrus, fertility, and lamb body weight at 28 days and daily weight gains for 28 days in 3-year-old ewes compared with controls. The injection of selenium plus vitamin E did not significantly improve reproductive performance in 2- nor 3-year-old ewes in the flock not considered selenium deficient.

Weak-calf syndrome

The parenteral injection of selenium and iodine to pregnant cattle in Ireland did not significantly reduce the incidence of the weak-calf syndrome, which is often attributed to a selenium deficiency.

Pigs

The injection of selenium 0.06 mg/kg BW into piglets under 1 week of age, repeated at weaning time and into the sow 3 weeks before farrowing will be effective. The minimum lethal dose of selenium for piglets is 0.9 mg/kg BW, which provides a reasonably wide range of safety. A high concentration of selenium in the diet of pregnant sows in the last half of gestation has been associated with hemorrhagic lesions on the claws of newborn piglets.[121]

Horses

Little information is available on the need of horses for selenium but the optimum intake is 6 mg/week or 2.4 μg/kg BW daily. The oral supplementation of 1 mg selenium/d increases blood selenium concentrations above levels associated with myodegeneration in horses and foals. In New Zealand, for horses on pasture, the injection of barium selenate, at a dose of 0.5 mg Se/kg BW, aseptically at a deep intramuscular site was efficacious in correcting the selenium status of mares grazing pasture with a selenium content of 0.01 to 0.07 mg/kg DM.[81] Some local swelling will occur.

To ensure nutritional adequacy and to have an adequate safety margin, adult Standardbred horses should receive 600–1800 mg DL-α-tocopherol daily in their feed. The parenteral administration of vitamin E and selenium to mares in late pregnancy and to their foals beginning at birth, will increase blood selenium to adequate levels. In selenium-deficient areas or when mares are fed selenium-deficient hay, the prepartum injections of selenium and vitamin E are indicated followed by intermittent injection of the foals, or supplementation of the diet with selenium at 0.1 mg/kg DM.

Intra-ruminal selenium pellets

Sheep

Intra-ruminal selenium pellets, similar to those used in cobalt deficiency, have produced satisfactory blood levels of selenium for up to 4 years in ewes at pasture.[89] A satisfactory pellet is composed of 0.5 g elemental selenium and finely divided metallic iron. The technique is efficient, but not completely, due to wide variations between animals in the absorption rate of the selenium. The average delivery of selenium is 1 mg/d and there is no danger of toxicity. In sheep grazing selenium-deficient pastures, the ruminal pellets increase the selenium status and weight gains compared with controls. About 15% of treated sheep reject the pellets within 12 months and in varying degrees the pellets acquire deposits of calcium phosphate. Sheep fed pellets recovered from sheep have low selenium levels, which suggests a low release of selenium from pellets that have been in the rumen of other sheep for several months. The peak levels of selenium occur 3 months after administration; there is a rapid decline in activity between 5 and 13 months. Sustained-released boluses containing sodium selenite, cobalt sulfate, potassium iodide, manganese sulfate, zinc oxide, and sulfate and vitamins A, D, and E have also been formulated to provide long-term maintenance of selenium.

A zinc, cobalt, and selenium soluble glass bolus administered to ram lambs increased the selenium status of the animals and increased sperm motility, percentage of live sperm and sperm responding to hypo-osmotic swelling test (an assay to determine plasma membrane permeability).[122]

High density compressed pellets containing both sodium selenite and cobalt carbonate have been developed for cattle and sheep.[43] The sheep pellet weighs 6 g and contains 276 mg Se and 765 mg Co. A 6 g bolus given to ewes before mating resulted in improved lambing perfomance, an increase in the percentage of twin lambs.[43]

Cattle

A selenium pellet containing 10% selenium and 90% iron grit is available for cattle and will maintain plasma selenium and GSH-PX activity above the critical level for up to 2 years.[123] When given to beef cows in the last 3 months of pregnancy, the selenium levels in milk are higher than in controls and the selenium status of the calves was sufficient to prevent NMD. The use of these pellets at two, three, and four times the recommended dose in growing cattle weighing 300–350 kg did not cause toxicosis and the selenium levels in the tissues at slaughter were not a risk for humans.

Use of the intra-ruminal selenium pellets in dairy cattle in New Zealand resulted in improved growth and milk production in herds where the selenium status was below the adequate range, but there was no effect on udder health and reproductive performance.

High density compressed pellets containing both sodium selenite and cobalt carbonate have been developed for cattle and sheep.[43] For cattle, the pellets weigh 18 g and contain 4.6% selenium and 12.75% cobalt (828 mg Se and 2295 mg Co). In both beef cows and growing cattle, the boluses increased blood glutathione peroxidase activity for at least 1 year.

A sustained-release intra-reticular bolus is an osmotic pump designed to release 3 mg selenium into the reticulorumen. It is intended to provide selenium supplementation for 120 days in grown heifers and pregnant beef cattle.

Selenium toxicity and residues

Selenium intoxication can occur following the administration of toxic amounts of a selenium salt. The use of selenium selenite instead of sodium selenate and giving a dose of five times the intended dose resulted in a high mortality within several hours after administration.[1] Animals deficient in selenium are more susceptible to selenium toxicosis than those that are selenium-adequate. The pharmacokinetics of selenium toxicity in sheep given selenium selenite parenterally has been examined. When oral preparations of selenium and monensin are given concurrently as part of a routine dietary management practice, there is greater risk of selenium intoxication than if the selenium is given alone. Administration of monensin sodium at a constant, safe dosage enhanced the toxicity of selenium as demonstrated by increased severity of the signs of intoxication, fatalities, tissue selenium concentrations and intensified gross, histopathological, and biochemical changes. There is some concern about selenium supplementation of beef cattle being a potential source of contamination for nearby aquatic systems, but there is no evidence that this has occurred.

Selenium responsiveness

The response to selenium supplementation is proportional to the degree of deficiency and supplementation of animals that have adequate selenium intakes is unlikely to significantly improve growth rate. In New Zealand, for selenium-deficient lambs, the potential for a growth response to selenium supplementation is strongly related to blood selenium concentration.[79] Economically significant live weight gains of >10 g/d can occur when initial blood

selenium concentrations are <130 nmol/L. This is the basis for the development of reference curves using blood selenium concentration to diagnose selenium deficiency and predict growth responses to lambs.[79]

Although many methods of supplementation of selenium are efficacious, they can differ widely in their cost and convenience of administration. The objective of any micronutrient supplementation program should be to optimize the return on investment.[40] The least cost option which provides adequate supplementation for the required period should be recommended initially.

Veterinarians are the professionals in the best position to offer advice on cost-effectiveness supplementation.[40] To retain this position, they must provide sound recommendations based on micronutrient analysis of animal tissue and defensible reference ranges which are supported by production response data. Monitoring micronutrient status in animal tissue should be encouraged so as to ensure that regulatory requirements are met and that deficiency and excessive use are avoided. Circumvention of veterinary involvement in the diagnosis and treatment of micronutrient supplementation can lead to greater use of supplements when not indicated, higher costs to farmers and low cost-benefit ratios for the industry.

Depot and bolus preparations have revolutionized the treatment of deficiencies of cattle and sheep that are grazed extensively where there is little opportunity for frequent administration (Table 30.8). The relatively short duration of a single drench or injection of selenium salts such as sodium selenite should be noted. The use of fertilizer applications selenium prills is gaining widespread acceptance on farms with high stocking rates.

DIETARY DEFICIENCY OF PHOSPHORUS, CALCIUM, AND VITAMIN D AND IMBALANCE OF THE CALCIUM:PHOSPHORUS RATIO

A dietary deficiency or disturbance in the metabolism of calcium, phosphorus, or vitamin D, including imbalance of the calcium:phosphorus ratio, is the principal cause of the **osteodystrophies.** The interrelation of these various factors is often very difficult to define and because the end result in all these deficiencies is so similar the precise etiological agent is often difficult to determine in any given circumstance.

In an attempt to simplify this situation, the diseases in this section have been dealt with in the following order:

Calcium deficiency (hypocalcicosis)
- Primary: an absolute deficiency in the diet
- Secondary: when the deficiency is conditioned by some other factor, principally an excess intake of phosphorus

Phosphorus deficiency (hypophosphatosis)
- Primary: an absolute deficiency in the diet
- Secondary: when the deficiency is conditioned by some other factor; although in general terms an excessive intake of calcium could be such a factor, specific instances of this situation are lacking

Vitamin D deficiency (hypovitaminosis-D)
- Primary: an absolute deficiency intake of the vitamin
- Secondary: when the deficiency is conditioned by other factors of which excess carotene intake is the best known.

In different countries with varying climates, soil types and methods of husbandry, these individual deficiencies are of varying importance. For instance in South Africa, northern Australia, and North America the most common of the above deficiencies is that of phosphorus; vitamin D deficiency is uncommon. In Great Britain, Europe and parts of North America, a deficiency of vitamin D can also be of major importance. Animals are housed indoors for much of the year, they are exposed to little ultraviolet irradiation, and their forage may contain little vitamin D. Under such conditions, the absolute and relative amounts of calcium and phosphorus in the diet need to be greater than in other areas if vitamin D deficiency is to be avoided. In New Zealand, where much lush pasture and cereal grazing is used for feed, the vitamin D status is reduced not only by poor solar irradiation of the animal and plant sterols, but in addition, an anti-vitamin D factor is present in the diet possibly in the form of carotene.

Now that the gross errors of management with respect to calcium and phosphorus and vitamin D are largely avoided, more interest is devoted to the marginal errors; in these, diagnosis is not nearly so easy and the deficiency can be evident only at particular times of the year. The conduct of a response trial in which part of the herd is treated is difficult unless they are hand-fed daily; there are no suitable reticular retention pellets or long-term injections of calcium or phosphorus because the daily requirement is so high. Two methods suggest themselves:

1. Analysis of ash content of samples of spongy bone from the tuber coxae
2. The metabolic profile method.

The latter program may have some value as a monitoring and diagnostic weapon in the fields of metabolic disease, nutritional deficiency and nutritional excesses.

Absorption and metabolism of calcium and phosphorus

In ruminants, dietary calcium is absorbed by the small intestine according to body needs. Whereas young animals with high growth requirements absorb and retain calcium in direct relation to intake over a wide range of intakes, adult male animals, irrespective of intake, absorb only enough calcium to replace that lost by excretion into urine and intestine, retaining none of it. Calcium absorption is increased in adult animals during periods of high demand, such as pregnancy and lactation, or after a period of calcium deficiency, but a substantial loss of body stores of calcium appears to be necessary before this increase occurs. The dietary factors influencing the efficiency of absorption of calcium include the nature of the diet, the absolute and relative amounts of calcium and phosphorus present in the diet and the presence of interfering substances. Calcium of milk is virtually all available for absorption, but calcium of forage-containing diets has an availability of only about 50%. The

addition of grain to an all-forage diet markedly improves the availability of the calcium.

Phosphorus is absorbed by young animals from both milk and forage-containing diets with a high availability (80–100%), but the availability is much lower (50–60%) in adult animals. Horses fed diets containing adequate amounts of calcium and phosphorus absorb 50–65% of the calcium, and slightly less than 50% of the phosphorus present in a variety of feedstuffs. In grains, 50–65% of the phosphorus is in the phytate form which is utilizable by ruminants, but not as efficiently by non-ruminants like the horse and pig. An average availability of 70% has been assumed for phosphorus in early weaning diets for young pigs, and a value of 50% in practical cereal-based feeds as supplied to growing pigs, sows and boars.

The metabolism of calcium and phosphorus is influenced by the parathyroid hormone calcitonin and vitamin D. Parathyroid hormone is secreted in response to hypocalcemia and stimulates the conversion of 25-dihydroxycholecalciferol to 1,25-dihydroxycholecalciferol (1,25-DHCC). Parathyroid hormone and 1,25-DHCC together stimulate bone resorption and 1,25-DHCC alone stimulates intestinal absorption of calcium. Calcium enters the blood from bone and intestine, and when the serum calcium level increases above normal, parathyroid hormone is inhibited and calcitonin secretion stimulated. The increased calcitonin concentration blocks bone resorption and the decreased parathyroid hormone concentration depresses calcium absorption.

CALCIUM DEFICIENCY

Calcium deficiency may be primary or secondary, but in both cases, the end result is an osteodystrophy, the specific disease depending largely on the species and age of the animals affected.

Synopsis

Etiology Primary dietary deficiency of calcium uncommon. Secondary calcium deficiency due to marginal calcium intake and high phosphorus intake.
Epidemiology Sporadic. Not common if diets adequate.
Signs Poor growth and dentition. Tetany may occur in lactating ewes. Inappetence, stiffness, fracture of long bones. Specific diseases include: rickets, osteomalacia and osteodystrophia fibrosa.
Clinical pathology Serum calcium and phosphorus. Radiography.
Necropsy findings Osteoporosis; low ash content of bone.
Diagnostic confirmation Histology of bone and bone ash analyses.
Differential diagnosis list See differential diagnosis of each specific disease.
Treatment Calcium salts parenterally and orally.
Control Adequate calcium and phosphorus levels in diet.

ETIOLOGY

A primary deficiency due to a lack of calcium in the diet is uncommon, although a secondary deficiency due to a marginal calcium intake aggravated by a high phosphorus intake is not uncommon. In ponies, such a diet depresses intestinal absorption and retention of calcium in the body and the resorption of calcium from bones is increased. The effects of reduced calcium intake and parathyroidectomy are understandably additive in pigs, but parathyroid insufficiency seems an unlikely natural phenomenon.

EPIDEMIOLOGY

Calcium deficiency is a sporadic disease occurring in particular groups of animals rather than in geographically limited areas. Although death does not usually occur, there may be considerable loss of function and disabling lesions of bones or joints.

Horses in training, cattle being fitted for shows, and valuable stud sheep are often fed artificial diets containing cereal or grass hays which contain little calcium and grains which have a high content of phosphorus. The secondary calcium deficiency that occurs in these circumstances is often accompanied by a vitamin D deficiency because of the tendency to keep animals confined indoors. Pigs are often fed heavy concentrate rations with insufficient calcium supplement. Dairy cattle may occasionally be fed similarly imbalanced diets, the effects of which are exaggerated by high milk production.

There are no well-established records of calcium deficiency in grazing sheep or cattle, but there are records of low calcium intake in feedlots accompanied by clinical osteodystrophy. There is also a well-recognized field occurrence of calcium deficiency in young sheep in southeast Australia. Outbreaks can affect many sheep and are usually seen in winter and spring, following exercise or temporary starvation. In most outbreaks the characteristic osteoporosis results from a long-term deprivation of food due to poor pasture growth. Occasional outbreaks occur on green oats used for grazing. The calcium intake in some cases is as low as 3–5 g/week in contrast to the requirement of 3–5 g/d.

High protein intake and rapid growth have been suggested as contributory factors in the development of skeletal problems in young horses. However, a concentration of dietary protein of 20%, which is significantly above the NRC recommended level of 14%, is neither helpful nor harmful to growing horses. The high protein intake did not affect the rate of growth, height, and circumference of cannon bones compared with horses receiving the lower 14% diet. The high protein diet did not result in hypercalciuria and did not affect calcium absorption or calcium retention.

In females there is likely to be a cycle of changes in calcium balance, a negative balance occurring in late pregnancy and early lactation and a positive balance in late lactation and early pregnancy and when lactation has ceased. The negative balance in late pregnancy is in spite of a naturally occurring increased absorption of calcium from the intestine at that time, at least in ewes.

PATHOGENESIS

The main physiological functions of calcium are the formation of bone and milk, participation in the clotting of blood and the maintenance of neuromuscular excitability. In the development of osteodystrophies, dental defects and tetany the role of calcium is well understood but the relation between deficiency of the element and lack of appetite, poor growth, loss of condition, infertility and reduced milk flow is not readily apparent. The disinclination of the animals to move about and graze and poor dental development may contribute to these effects.

Experimentally, feeding young lambs a diet low in calcium and phosphorus for 12 weeks results in soft and pliable ribs with thickening of the costochondral junctions, reduction in feed intake by about 34%, significant changes in plasma calcium and phosphorus concentrations and changes in dry matter digestibility.[1] Feeding repletion diets results in complete remineralization of rib bones, but only partial remineralization of the metatarsal bones.

Nutritional factors other than calcium, phosphorus and vitamin D may be important in the production of osteodystrophies, which also occur in copper deficiency, fluorosis and chronic lead poisoning. Vitamin A is also essential for the development of bones, particularly those of the cranium.

CLINICAL FINDINGS

The clinical findings, apart from the specific syndromes described later, are less marked in adults than in young animals, in which there is decreased rate or cessation of growth and dental maldevelopment. The latter is characterized by deformity of the gums, poor development of the incisors, failure of permanent teeth to erupt for periods of up to 27 months and abnormal wear of the permanent teeth due to

defective development of dentine and enamel, occurring principally in sheep.

A calcium deficiency may occur in lactating ewes and sucking lambs whose metabolic requirements for calcium are higher than in dry and pregnant sheep. There is a profound fall in serum calcium. Tetany and hyperirritability do not usually accompany hypocalcemia in these circumstances, probably because it develops slowly. However, exercise and fasting often precipitate tetanic seizures and parturient paresis in such sheep. This is typical of the disease as it occurs in young sheep in southeast Australia. Attention is drawn to the presence of the disease by the occurrence of tetany, convulsions and paresis but the important signs are ill-thrift and failure to respond to anthelmintics. Serum calcium levels will be as low as 5.6 mg/dL (1.4 mmol/L). There is lameness, but fractures are not common even though the bones are soft. A simple method for assessing this softness is compression of the frontal bones of the skull with the thumbs. In affected sheep, the bones can be felt to fluctuate.

Pigs fed on heavy concentrate rations may develop a hypocalcemic tetany, which responds to treatment with calcium salts. Tetany may also occur in young growing cattle in the same circumstances.

Inappetence, stiffness, tendency of bones to fracture, disinclination to stand, difficult parturition, reduced milk flow, loss of condition, and reduced fertility are all non-specific signs recorded in adults.

SPECIFIC SYNDROMES

Primary calcium deficiency

No specific syndromes are recorded.

Secondary calcium deficiency

Rickets, osteomalacia, osteodystrophia fibrosa of the horse and pig and degenerative arthropathy of cattle are the common syndromes in which secondary calcium deficiency is one of the specific causative factors. In sheep, rickets is seldom recognized, but there are marked dental abnormalities. Rickets has been produced experimentally in lambs by feeding a diet low in calcium.

CLINICAL PATHOLOGY

Because of the effect of the other factors listed above on body constituents, examination of specimens from living animals may give little indication of the primary cause of the disturbance. For example, hypocalcemia need not indicate a low dietary intake of calcium. Data on serum calcium and phosphorus and plasma phosphatase levels, radiographical examination of bones and balance studies of calcium and phosphorus retention are all of value in determining the presence of osteodystrophic disease, but determination of the initial causative factor will still depend on analysis of feedstuffs and comparison with known standard requirements. The levels of serum calcium may be within the normal range in most cases.[2] However, in spite of evidence to the contrary it seems that calcium deficiency is followed, at least in sheep, by a marked fall in serum calcium levels to as low as 3.5 mg/dL (0.87 mmol/L). In an uncomplicated nutritional deficiency of calcium in sheep, there is only a slight reduction in the radiopacity of bone, in contrast to sheep with a low phosphorus and vitamin D status which show marked osteoporosis. The response to dietary supplementation with calcium is also of diagnostic value.

NECROPSY FINDINGS

True primary calcium deficiency is extremely rare but when it does occur, severe osteoporosis and parathyroid gland hypertrophy are the significant findings. The cortical bone is thinned and the metaphyseal trabeculae appear reduced in size and number. The ash content of the bone is low because the bone is resorbed before it is properly mineralized.

Calcium deficiency secondary to other nutritional factors is common and typically induces the form of osteodystrophy known as osteodystrophia fibrosa (see subsequent description). In most instances, the confirmation of a diagnosis of hypocalcinosis at necropsy includes an analysis of the diet for calcium, phosphorus, and vitamin D content.

Samples for confirmation of diagnosis

Toxicology – long bone (ASSAY (ash)); feed (ASSAY (Ca) (P) (Vit D))
Histology – formalin-fixed section of long bone (including metaphysis), parathyroid (LM).

DIFFERENTIAL DIAGNOSIS

A diagnosis of calcium deficiency depends upon proof that the diet is, either absolutely or ralatively, insufficient in calcium, that the lesions and signs observed are characteristic and that the provision of calcium in the diet alleviates the condition. The diseases that may be confused with calcium deficiency are described under the diagnosis of each of the specific disease entities described below.

The close similarity between the dental defects in severe calcium deficiency of sheep and those occurring in chronic fluorosis may necessitate quantitative estimates of fluorine in the teeth or bone to determine the cause.

TREATMENT

The response to treatment is rapid and the preparations and doses recommended below are effective as treatment. Parenteral injections of calcium salts are advisable when tetany is present. When animals have been exposed to dietary depletion of calcium and phosphorus over a period of time, it is necessary to supplement the diet with calcium and phosphorus during dietary mineral repletion.[1]

CONTROL

The provision of adequate calcium in the diet, the reduction of phosphorus intake where it is excessive and the provision of adequate vitamin D are the essentials of both treatment and prevention. Some examples of estimated minimum daily requirements for calcium, phosphorus, and vitamin D are set out in Table 30.9. These are estimated minimum requirements and may need to be increased by a safety factor of 10% to allow for variation in individual animal requirements, the biological availability of nutrients in the feedstuffs and the effect which total amount of feed intake has on absolute intake of minerals. For example, the use of a complete pigs ration on a restricted basis may require that the concentration of both calcium and phosphorus be increased in order for that ration to deliver the actual total quantity of calcium and phosphorus necessary to meet a particular requirement for growth, pregnancy, or lactation. The information in Table 30.9 is presented merely as a guideline. When investigating a nutritional problem of formulating rations, it is recommended that the most recently available publications on the nutrient requirements of domestic animals be consulted.

Ground limestone is most commonly used to supplement the calcium in the ration, but should be prepared from calcite and not from dolomite. Variations in availability of the calcium in this product occur with variations in particle size, a finely ground preparation being superior in this respect. Bone meal and dicalcium phosphate are more expensive and the additional phosphorus may be a disadvantage if the calcium: phosphorus ratio is very wide. Alfalfa, clover, and molasses are also good sources of calcium but vary in their content. The optimum calcium:phosphorus ratio is within the range of 2:1 to 1:1. In cattle, absorption of both elements is better at the 2:1 ratio. For optimum protection against the development of urolithiasis in sheep a ratio of 2–2.5 calcium to 1 phosphorus is recommended.

The dustiness of powdered limestone can be overcome by dampening the feed or adding the powder mixed in molasses. Addition to salt or a mineral mixture is subject to the usual disadvantage that not all animals partake of it readily when it is provided free-choice, but this method of

Table 30.9 Some examples of estimated daily requirements of calcium, phosphorus and vitamin D

Species, kg body weight and function	Calcium	Phosphorus	Vitamin D
	(g/animal)

3 months old	0.69	0.44	
6 months old	0.82	0.51	
12 months old	0.43	0.28	

supplementation is often necessary in pastured animals. High-producing dairy cows should receive the mineral mixture in their ration as well as having access to it in boxes or in blocks.

PHOSPHORUS DEFICIENCY

Phosphorus deficiency is usually primary and is characterized by pica, poor growth, infertility and, in the later stages, osteodystrophy. Hypophosphatemia in dairy cattle is also associated with increased fragility of red blood cells and postparturient hemoglobinuria.

Synopsis

Etiology Usually a primary deficiency in diet; may be conditioned by vitamin D deficiency.
Epidemiology Primary phosphorus deficiency occurs worldwide. Soils and crops commonly deficient in phosphorus. Primary deficiency may occur in lactating dairy cattle in early lactation. Occurs under range conditions in beef cattle and sheep. In pigs not supplemented with sufficient phosphorus.
Signs Young animals grow slowly; develop rickets. Adults develop osteomalacia, unthriftiness, weight loss, reduced feed consumption, reluctance to move, leggy appearance, fractures, impaired fertility. Recumbency in high-producing cows on marginally phosphorus-deficient diet.
Clinical pathology Serum phosphorus. Phosphorus content of diet.
Necropsy findings Rickets and osteomalacia; lack of mineralization of bones.
Diagnostic confirmation Histology of bone lesions; bone ash analyses.
Differential diagnosis Those diseases resembling rickets and osteomalacia.
Treatment Phosphates parenterally and orally and vitamin D.
Control Supplement diets with adequate phosphorus, calcium, and vitamin D.

ETIOLOGY

Phosphorus deficiency is usually primary under field conditions but may be exacerbated by a deficiency of vitamin D and possibly by an excess of calcium.

EPIDEMIOLOGY

Geographical occurrence

In contrast to calcium deficiency, a dietary deficiency of phosphorus is widespread under natural conditions.[1] It has a distinct geographical distribution depending largely upon the phosphorus content of the parent rock from which the soils of the area are derived, but also upon the influence of other factors, such as excessive calcium, aluminum, or iron, which reduce the availability of phosphorus to plants. Large areas of grazing land in many countries are of little value for livestock production without phosphorus supplementation. In New Zealand, for example, where fertilization of pasture with superphosphate has been practiced for many years, phosphorus deficiency may still occur in dairy herds because of inadequate maintenance of

application over several years.[2] There is evidence also that the quality of the superphosphate declined over a period of several years. Soil reserves of phosphorus may also be low because of high phosphate retention soils. Animals in affected areas mature slowly and are inefficient breeders and additional losses due to botulism and defects and injuries of bones may occur. Apart from areas in which frank phosphorus deficiency is seen, it is probable that in many other areas a mild degree of deficiency is a limiting factor in the production of meat, milk, and wool.

Heavy leaching by rain and constant removal by cropping contribute to phosphorus deficiency in the soil and the low phosphorus levels of the plant cover may be further diminished by drought conditions. Pastures deficient in phosphorus are classically also deficient in protein.

Cattle

The literature on phosphorus nutrition of grazing cattle has been reviewed.[3] The degree of naturally occurring phosphorus deficiency in grazing cattle, the lack of uniformity in response to phosphorus supplementation and the suggested phosphorus requirements have resulted in considerable confusion in the United States and worldwide. Much of the confusion arises because animals have the ability to draw on skeletal phosphorus reserves when dietary phosphorus levels are inadequate. The mechanisms which control skeletal phosphorus withdrawal, the conditions which trigger withdrawal and the rate and extent of withdrawal without affecting animal performance are not well understood.

The earliest report of naturally occurring phosphorus deficiency in grazing cattle was at Armoedsvlakte in the Northern Cape of South Africa. The disease was called aphosphorosis and animals with the disease demonstrated a depraved appetite characterized by the desire to eat wood, bones, rocks, and other such materials. In severe deficiencies, cattle often died from botulism from eating bones from old carcasses contaminated with *Clostridium botulinum*. In advanced states of aphosphorosis, animals developed a stiffness in the forelegs resulting in a characteristic lameness referred to as 'styfsiekte' in South Africa, 'creeps' in Texas and 'pegleg' in Australia.[3]

A primary dietary deficiency of phosphorus in dairy cattle within the first several weeks of lactation can result in postparturient hemoglobinuria. In high-producing dairy cows, small restrictions in dietary phosphorus intake compared with National Research Council recommendations can result in acute recumbency in early lactation.[4]

Under range conditions, milking cows are most commonly affected, but under intensive conditions, it is the dry and young stock receiving little supplementation which will be affected. The incidence of the disease varies: it is most common in animals at pasture during drought seasons but can also be a serious problem in housed cattle fed on hay only.

A survey of the mineral status of bones of cattle at abattoirs in western New South Wales, Australia, found evidence of osteodystrophy based on ash density.[5] They represented cattle attempting to grow in a poor season, often female and in poor body fat condition and light in body weight and mostly from red soils known to be deficient in phosphorus.

The dietary requirements of phosphorus are given in Table 30.10. Cattle constantly grazing pasture in the southern hemisphere appear to require somewhat less phosphorus in their diet (0.20% is probably adequate) than do higher-producing, partly housed livestock. The dietary requirements of phosphorus recommended by the National Research Council for beef cows weighing 450 kg may exceed the basic requirements.[6] Over a period of several gestations a daily allowance of 12 g of phosphorus/day/animal was adequate for beef cows.[6,7] Cattle given a phosphorus-deficient diet did not develop detectable signs of phosphorus deficiency until they had been on a severely deficient diet for 6 months.

Sheep and horses

Sheep and horses at pasture are much less susceptible to the osteodystrophy of phosphorus deficiency than are cattle and their failure to thrive on phosphorus-deficient pasture is probably due in part to the low protein content of the pasture. In fact, there has been no clear demonstration of a naturally occurring phosphorus deficiency in sheep, nor is there any record of infertility in sheep caused by phosphorus deficiency.

There is some limited evidence that the serum inorganic phosphorus levels in Thoroughbred racehorses may be related to certain feeding regimens and to racing performance.[8] Horses fed cubed or pelleted dietary supplement have serum inorganic phosphate concentrations consistently below an accepted mean of 1.032 mmol/L.[8] It is suggested that a rapid rate of passage of the ingesta may affect absorption of phosphorus. Other observations indicate that some of the best track performers had significantly lower inorganic serum phosphorus concentrations compared with some of the worst performers.

Pigs

A primary deficiency can occur in pigs kept in confinement and not provided with sufficient dietary phosphorus. Lactating sows are more commonly affected than growing pigs. In some situations, in the cereal grains, the phytate levels are so high and phytase levels so low, rickets and osteomalacia are common in the pig population.[9]

Secondary phosphorus deficiency

This is of minor importance compared with the primary condition. A deficiency of vitamin D is not necessary for the development of osteodystrophy, although with suboptimal phosphate intakes deficiency of this vitamin becomes critical. Excessive intake of calcium does not result in secondary phosphorus deficiency, although it may cause a reduction in weight gains, due probably to interference with digestion and may contribute to the development of phosphorus deficiency when the intake is marginal. The presence of phytic acid in plant tissues, which renders phosphate unavailable to carnivora, is a major consideration in pigs but of only minor importance in herbivora, except that increasing intakes of calcium may reduce the availability of phytate phosphorus even for ruminants. Rock phosphates containing large amounts of iron and aluminum have been shown to be of no value to sheep as a source of phosphorus. A high intake of magnesium, such as that likely to occur when magnesite is fed to prevent lactation tetany, may cause hypophosphatemia if the phosphorus intake of dairy cows is already low.

Table 30.10 Approximate levels of phosphorus in soil and pasture (quoted as phosphate radical) at which phosphorus deficiency occurs in cattle

	Levels at which deficiency does not occur	Levels at which deficiency does occur
Soil	0.005%	0.002%
Pasture	0.3%	0.2% – osteophagia <0.01 % – rickets and osteomalacia
Daily intake (cattle)	40–50 g	25 g

All figures are on a dry matter (DM) basis and soil phosphate is citrate-soluble.

Hypophosphatemia has been induced in pigs by experimental supplementation of their diets with aluminum hydroxide.[10] After 3 weeks, severe hypophosphatemia, intense hypercalcemia, decreased growth rate, and a lower concentration of 2,3-diphosphoglycerate in the erythrocytes developed.[10]

PATHOGENESIS

From 80 to 85% of the phosphorus of the body is located in the skeleton where it occurs as hydroxyapatite in a 1.0:1.7 ratio with calcium. These two minerals provide bone strength necessary for normal activities, such as grazing.[3] Bone phosphorus also functions as an important phosphorus reservoir for resorption when body requirements temporarily exceed dietary intake. From 17 to 42% of bone could be resorbed in cattle and sheep in times of phosphorus deficiency.

Phosphorus is also essential for a broad range of enzymatic reactions, especially those concerned with energy metabolism and transfer. Phosphorus is also essential for the transfer of genetic information and is a vital component of various buffering systems. Phospholipids are necessary for maintenance of cell wall structure and integrity and as a integral components of myelin.

Rumen microbes have a phosphorus requirement apart from the animal's requirement which must be met for optimum rumen microbial activity to occur.

Phosphorus is essential for the laying down of adequately mineralized bones and teeth and a deficiency will result in their abnormal development. Inorganic phosphate, which may be ingested as such, or liberated from esters during digestion or in intermediary metabolism, is utilized in the formation of proteins and tissue enzymes and is withdrawn from the plasma inorganic phosphate for this purpose.

Experimentally, female beef cattle fed diets containing <6 g of phosphorus/day developed an insidious and subtle complex syndrome characterized by weight loss, rough hair coat, abnormal stance, and lameness.[6] Spontaneous fractures occurred in the vertebrae, pelvis, and ribs. Some affected bones were severely demineralized and the cortical surfaces were porous, chalky white, soft, and fragile. The osteoid tissue was not properly mineralized.

Experimental acute depletion of phosphorus in cattle results in a marked decline in serum inorganic phosphorus and affected animals display an avid appetite for old bones.[11] The signs include:

- Failure to gain weight and maintain body condition
- Reduced bone weight
- Osteopenia radiographically
- Evidence of reduced bone formation.

Prolonged phosphorus deficiency was associated with increased plasma concentrations of total calcium and 1,25-dihydroxyvitamin D and reduced plasma concentrations of parathyroid hormone.

The pathophysiological effects of low dietary phosphorus in pigs have been examined.[9] Determination of the serum concentrations of parathyroid hormone, 1,25-$(OH)_2$ D and osteocalcin were monitored in Romanian Landrace pigs originating from herds with dietary P deficiency. Serum P concentrations were negatively correlated with those of 1,25-$(OH)_2$ D. In lactating animals and sucklings, the linear relationships were not present. Serum P concentrations positively correlated with those of PTH and 1,25-$(OH)_2$ D concentrations were negatively correlated. The serum concentrations of 1,25-$(OH)_2$ D and osteocalcin were positively correlated. Milk P concentrations ranging from 3.10 to 7.49 mmol/L were correlated positively with urinary P concentrations ranging from 0.26 to 11.37 mmol/L. In conclusion, similar to other species, P homeostasis is achieved in pigs by feedback mechanisms between P, PTH, and 1,25-$(OH)_2$ D and osteocalcin production is induced by 1,25-$(OH)_2$ D

Inorganic phosphate also plays an important role in the intermediary metabolism of carbohydrate and of creatine in the chemical reactions occurring in muscle contraction. This may be of importance in those cows that are recumbent after calving and have hypophosphatemia. The loss of phosphorus in the phospholipids of milk due to the onset of profuse lactation may be the crucial factor in the development of postparturient hemoglobinuria. An increased susceptibility to bloat has been postulated as an effect of phosphorus deficiency.

CLINICAL FINDINGS

Primary phosphorus deficiency is common only in cattle. Young animals grow slowly and develop rickets. In adults there is an initial subclinical stage followed by osteomalacia. In cattle of all ages a reduction in voluntary intake of feed is a first effect of phosphorus deficiency and is the basis of most of the general systemic signs. Retarded growth, low milk yield, and reduced fertility are the earliest signs of phosphorus deficiency. For example, in severe phosphorus deficiency in range beef cattle, the calving percentage has been known to drop from 70 to 20%. Although it is claimed that relative infertility occurs in dairy heifers on daily intakes of less than 40 g of phosphate, the infertility being accompanied by anestrus, subestrus, and irregular estrus and delayed sexual maturity this has not been borne out by other experimental work, which indicates that fertility is independent of the calcium or phosphorus content or the calcium:phosphorus ratio of the diet in cattle. The effects of malnutrition on fertility are likely to be general and the infertility may often be related to lack of total energy intake rather than to specific deficiency. The development and wear of teeth are not greatly affected, in contrast with the severe dental abnormalities that occur in a nutritional deficiency of calcium. However, malocclusion may result from poor mineralization and resulting weakness of the mandible.

In the experimental production of phosphorus deficiency in beef cows, several months on a deficient diet are necessary before clinical signs develop.[7] The clinical signs included general unthriftiness, marked body weight loss, reduced feed consumption, reluctance to move, abnormal stance, bone fractures, and finally impaired reproduction. The detectable signs of phosphorus deficiency developed in the following sequence:

- Loss of body weight and condition
- Decreased whole blood phosphorus associated with increased whole blood calcium concentration
- Allotriophagia
- Abnormal stance, locomotion and recumbency.[6]

In a severely deficient area, a characteristic conformation develops and introduced cattle revert to the district type in the next generation. The animals have a leggy appearance with a narrow chest and small girth, the pelvis is small, and the bones are fine and break easily. The chest is slab-sided due to weakness of the ribs and the hair coat is rough and staring and lacking in pigment. In areas of severe deficiency, the mortality rate may be high due to starvation, especially during periods of drought when deficiencies of phosphorus, protein and vitamin A are exaggerated. Osteophagia is common and may be accompanied by a high incidence of botulism. Cows in late pregnancy often become recumbent and, although they continue to eat, are unable to rise. Such animals present a real problem in drought seasons because many animals in the area may be affected at the same time. Parenteral injections of phosphorus salts are ineffective and the only treatment that may be of benefit is to terminate the pregnancy by the administration of corticosteroids or by cesarean section.

Acute recumbency in high-producing dairy cows on a marginally phosphorus-deficient diet may become recumbent in early lactation.[4] Affected animals are recumbent and cannot stand. They may be bright and alert and their vital signs are within normal range.

Although sheep and horses in phosphorus-deficient areas do not develop clinically apparent osteodystrophy they are often of poor stature and unthrifty and may develop perverted appetites. An association between low blood phosphorus and infertility in mares has been suggested but the evidence is not conclusive. The principal sign in affected sows is posterior paralysis.

CLINICAL PATHOLOGY

Serum phosphorus

Blood levels of phosphorus are not a good indicator of the phosphorus status of an animal because they can remain at normal levels for long periods after cattle have been exposed to a serious deficiency of the element. Serum inorganic phosphorus levels are affected by such factors as age of animal, milk yield, stage of pregnancy, season of year, breed, feeding patterns, and dietary phosphorus. The times of sampling in a herd must be standardized to reduce the effect of diurnal variation in serum concentrations of inorganic phosphorus. Attention is drawn to the need to use standard methods of collection because of the effect that technique can have on phosphorus levels in blood. In cattle, the recommended procedure is to collect blood from the coccygeal vein and preserve it in buffered trichloroacetic acid. Hair does not reflect the status either. However, a marked hypophosphatemia is a good indicator of a severe phosphorus deficiency. The mild-to-moderate deficiencies, which are the most common ones, are usually accompanied by normal blood levels of phosphorus. Generally, clinical signs occur when blood levels have fallen from the normal of 4–5 mg/dL (1.3–1.7 mmol/L) to 1.5–3.5 mg/dL (0.5–1.2 mmol/L) and a response to phosphate supplementation in body weight gain can be anticipated in cattle that have blood inorganic phosphorus levels of less than 4 mg/dL (1.3 mmol/L). Levels may fall as low as 1 mg/dL (0.3 mmol/L) or less in severe clinical cases. Serum levels of calcium are usually unaffected.

Phosphorus content of diet

Estimation of the mineral content in pasture and drinking water is a valuable aid in diagnosis, but has major difficulty in representing what the animal has actually been taking in. A technique has been devised for determining phosphorus intake of sheep by estimating the phosphorus content of feces. A pool of three pellets from each of 30 sheep is used as a sampling technique.

Bone ash concentrations

Determination of total bone ash concentrations and bone calcium and phosphorus concentrations from sample of rib can provide useful diagnostic information and comparison to normal values.[12]

There is usually a marked deterioration in the radiopacity of the bones. However, the bone content of phosphorus is still considered the most accurate indication of phosphorus status.

NECROPSY FINDINGS

The necropsy findings are those of the specific diseases, rickets and osteomalacia.

DIFFERENTIAL DIAGNOSIS

A diagnosis of phosphorus deficiency depends upon evidence that the diet is lacking in phosphorus and that the lesions and signs are typical of those caused by phosphorus deficiency and can be arrested or reverted by the administration of phosphorus. Differentiation from those diseases that may resemble rickets and osteomalacia is dealt with under those headings.

TREATMENT

The preparations and doses recommended under control can be satisfactorily used for the treatment of affected animals. In cases where the need for phosphorus is urgent, as in postparturient hemoglobinuria and in cases of parturient paresis complicated by hypophosphatemia, the intravenous administration of sodium acid phosphate (30 g in 300 mL distilled water) is recommended.

CONTROL

Phosphorus (P) deficiencies in grazing livestock can be prevented by direct treatment of the animal through supplementing the diet or the water-supply, or indirectly by approximate fertilizer treatment of the soils. Hand-fed animals are supplemented with P in their diets.

Phosphorus requirements

Cattle

The phosphorus requirements for cattle in various stages of the production cycle have varied widely worldwide.[3] Accurate P requirements must be established for all classes of cattle grazing under various conditions before producers can determine whether diets are adequate in P to meet animal needs or whether P supplements must be provided to optimize production.[3] Apparent P requirements vary for a variety of reasons: differences among breeds of cattle, P availability in the feed, whether animals are pen fed or free grazing, possible interactions between nutrients, and the effects of disease and parasitism.

Dairy cattle

There is widespread belief among producers and consultants that reproductive performance in dairy cows can be improved by feeding phosphorus above recommended levels.[4] The current NRC recommendations for early lactation (90 days in milk) diets are 0.36% P (DM basis) for cows milking 45 kg/d and 0.35% P for cows milking 35 kg/d. The NRC recommends up to 0.42% for the highest producing cows during the first few weeks of lactation.

Several studies indicate that dietary P at 0.38 to 0.40% is sufficient for high producing dairy cows.[13,14] This concentration of P can be obtained with no supplementation or minimum supplementation of P, depending on feed ingredients. Dietary P at 0.31% can support high milk production but cannot sustain comparable high yield when cows proceed into late lactation. Cows conserve P when fed diets low in P by reducing P excretion in feces and urine. They may experience some negative balance in the first few weeks of lactation due to mobilization of P from bone, but this mobilized P can be restored in later lactation.

However, there has been a lack of information about the minimum intake level of P on which dairy cows can maintain health and milk production. In essence, the current requirements developed in various countries are mainly based on studies with non-lactating sheep and goats.

Environmental implications of phosphorus feeding of livestock

In the European Union and the USA, phosphorus (P) losses from dairy manure to the environment are becoming a more severe pollution problem.[15,16] Ideally, P is recycled into the soil/plant/animal system from which only the P incorporated into the animal system escapes. In a sustainable dairy farming system, the amount of P expelled in the form of manure must be limited to that amount which crops need for maximum growth. However, due to high livestock intensities, overapplication of P from manure occurs, leading to P accumulation in the soil and finally leaching, thus causing eutrophication of lakes. Reducing P intake by dairy cows and thus also that excreted in the manure will contribute to reducing environmental pollution.

In Delaware County of New York, more P enters dairy farms than is exported in milk, meat, or crops sold, thus resulting in a net annual accumulation of P on the farm ranging from 19 to 41 kg/cow.[17] Purchased feed is the single largest source of imported P on dairy farms, accounting for 65–85% of the 28–51 kg imported annually per cow for typical commercial dairy herds in New York. Similar amounts

have been reported for dairy farms in the Netherlands.[18]

Dairy farms in the states of New York, Pennsylvania, Delaware, Maryland, and Virginia, fed P to lactating cows averaging 34% above the NRC recommendations.[19] In 84% of the survey farms, ration formulation was provided by professionals rather than producers themselves. Most producers were feeding more P than cows needed because it was recommended by these consultants. Surveys in the USA show that dairy diets are formulated to contain approximately 0.45–0.50% P (DM basis), an amount that is about 20% in excess.[16] This oversupplementation of P is costing the US dairy industry about US$100 million (in 1999). Most lactating dairy cow diets could have their P content reduced by 20%.[16] This would result in a 25–30% reduction in P content of manure and a similar reduction in the amount of land required to accommodate the manure. Phosphorus is the most expensive nutrient in typical mineral-vitamin formulations for dairy cattle. Feeding a diet containing 0.45% P versus one containing 0.55% would save about $0.05/cow daily; for a 100 cows over 1 year, would save about $1825.00

Three factors which lead to excessive feeding of P include the notion that increasing P intake would improve reproduction, the absence of lactation trials showing the absolute minimum of P required to support milk production and the aggressive marketing of P supplements.[16]

Simulation models of the long-term effects of changes in feeding, cropping, and other production strategies on P loading and the economics of 100-cow and 800-cow dairy farms in south-eastern New York found that the most easily implemented change was to reduce the supplemented mineral P fed to that required to meet the current NRC recommended amounts, which would provide an annual increase in farm profit of about $22.00 per cow.[20] Dairy farms in some areas can maintain a long-term P balance by: feeding P according to the NRC requirements; a cropping strategy and land base use supplies all of the forage needed; all animals are fed a high forage diet; replacement heifers are produced on the farm.

The effects of feeding low amounts of phosphorus to high yielding dairy cows has been examined.[21] Lactating dairy cows were fed diets containing 67, 80, and 100%, respectively, of the phosphorus requirements recommended by the Dutch Committee on Mineral Nutrition for a period of 21 months. Nearly 5 months after the beginning of the feeding trial, the milk yield and milk lactose content of the 67% group decreased significantly. After 2 years, on the 80% diet, post-parturient hemoglobinuria occurred in one high producing cow. It was concluded that rations for high yielding dairy cows should not contain phosphorus content lower than 3.0 g/kg DM. The P supply with the 80% ration was considered to be just sufficient.

The supplementation of dietary P above levels recommended by the NRC (0.38% considered adequate or 0.48% excessive) did not improve duration or intensity of estrus in dairy cows under Wisconsin conditions.[4] Large lactation studies have shown that feeding P in excess of 0.37% of diet DM, which corresponds closely to the NRC P requirements, did not affect milk production, milk composition, or animal health.[22] Digestion studies and P retention data also support the NRC recommendations.[23] Biochemical markers of bone turnover in the dairy cow during lactation and the dry period are being used to measure bone formation and resorption during a complete lactation in dairy cattle.[24]

Based on calculation of P losses and the true absorption coefficient using data on saliva production, saliva-P content, and the efficiency of P absorption under conditions in the Netherlands, the P requirement recommended for dairy cows: P requirement (g/d per 600 kg cow) = $19 + 1.43 \times$ kg milk. The recommendation is up to 22% lower than the current recommendation for high yielding dairy cows used in the UK.[15]

The overfeeding of P has important environmental implications. Phosphorus excretion increases linearly as P intake is increased above the requirement. Once P requirements are met, all of the excess dietary P is excreted in the feces. This excess P accumulates in the environment, primarily by the recycling of manure to land as fertilizer for crop production. The surface runoff of this excess P promotes the eutrophication of surface waters. (Eutrophication is the accidental or deliberate promotion of excessive growth of one kind of organism to the disadvantage of other organisms in the ecosystem.) Therefore, close monitoring of P inputs in the livestock industry is important to reduce the risk of eutrophication of lakes and streams. Reducing dietary intake closer to requirement will require frequent and accurate feed analysis, quantification of dry matter intake and ration management to ensure that formulated diets are mixed and delivered to the cows properly. Phosphorus reduction will be achieved by precision of feeding of dairy cattle.[17] Portable and rapid tests are now available to determine the level of P in dairy cattle manure.[25] These hand-held tools can yield real-time measurements of dissolved P and total P in manure.

As part of the US Environmental Protection Agency's concentrated animal feeding operation (CAFO) final rule, all CAFOs will be required to develop and implement a **nutrient management plan**.[26] The emphasis on better management of nutrients appropriately targets a critical environmental issue associated with animal production. The concentration of animals in livestock feeding operations, often separate from feed grain production, requires importing of substantial qualities of feed nutrients. Due to inefficiencies of nutrient utilization in livestock production, quantities of nitrogen and phosphorus in manure greater than can be utilized in local crop production often result. In a survey of 994 dairy farms in Pennsylvania, only 20% of the farms reported manure nutrient testing, compared with over 90% which did soil testing.[27] Farm advisors and their services can be of vital importance in assisting producers make conscientious management decisions for enhanced nutrient utilization. Ration balancing involved the services of feed and mineral representatives on 85% of the farms, independent consultants on 12% and veterinarians only on 5% of farms. Nutrient management strategies and efforts must address the specific needs of farms with different animal densities and nutrient balances in order to be effective and applicable on the majority of farms.

Under field conditions, the difficulty usually encountered is that of providing phosphorus supplements to large groups of cattle grazing under extensive range conditions. The new recommendations for dairy cattle in 2001, are to provide phosphorus at 0.36–0.4% of dry matter intake.[28] These are lower than the previous recommendation of 0.5% of dry matter intake.

Bone meal, dicalcium phosphate, disodium phosphate, and sodium pyrophosphate may be provided in supplementary feed or by allowing free access to their mixtures with salt or more complicated mineral mixtures. The availability of the phosphorus in feed supplements varies and this needs to be taken into consideration when compounding rations. The relative biological values for young pigs in terms of phosphorus are: dicalcium phosphate or rock phosphate 83%, steamed bone meal 56%, and colloidal clay or soft phosphate 34%. It is suggested that in deficient areas adult dry cattle and calves up to 150 kg BW should receive 225 g bone meal/week, growing stock over 150 kg BW 350 g/week, and lactating cows 1 kg weekly, but experience in particular areas may indicate the need

for varying these amounts. The top-dressing of pasture with superphosphate is an adequate method of correcting the deficiency and has the advantage of increasing the bulk and protein yield of the pasture, but is often impractical under the conditions in which the disease occurs.

The addition of phosphate to drinking water is a much more satisfactory method provided the chemical can be added by an automatic dispenser to water piped into troughs. Adding chemicals to fixed tanks introduces errors in concentration, excessive stimulation of algal growth, and precipitation in hard waters. Monosodium dihydrogen phosphate (monosodium orthophosphate) is the favorite additive and is usually added at the rate of 10–20 g/20 L of water. Superphosphate may be used instead but is not suitable for dispensers, must be added in larger quantities (50 g/20 L) and may contain excess fluorine. A reasonably effective and practical method favored by Australian dairy farmers is the provision of a supplement referred to as 'super juice'. Plain superphosphate at a rate of 2.5 kg in 40 L of water is mixed and stirred vigorously in a barrel. When it has settled for a day the 'super juice' is ready for use and is administered by skimming off the supernatant and sprinkling 100–200 mL on the feed of each cow.

Beef cattle

The literature on the phosphorus nutrition of grazing beef cattle in the USA and other parts of the world has been reviewed.[3] There has been a notable lack of research into the P requirements of grazing beef cattle of various age groups, under varying soil and forage conditions which has created considerable confusion and disagreement about the P requirements. The effects of P fertilizer on forage P levels and seasonal changes in P concentration are well understood, but the availability of P in different forage species, at different stages of maturity and grown under different management schemes and environmental conditions is not well understood.

The details of the phosphorus requirements for beef cattle of various age groups are available in the National Research Council. (2000) Nutrient Requirements of Beef Cattle, 7th revised ed., updated 2000.[29]

Feedlot cattle

The phosphorus requirement of finishing feedlot calves is <0.16% of diet dry matter (DM) or 14.2 g/d.[30] Typical grain-based feedlot cattle diets do not require supplementation of inorganic mineral P to meet P requirements. Plasma P, performance and bone characteristics indicate that P requirements are less than the predicted requirements and should be modified. Supplementation of mineral P in finishing diets is an unnecessary economic and environmental cost for beef feedlot producers and should discontinue.

Pigs

The estimated dietary requirements for phosphorus for maximum growth and feed efficiency of pigs at 3–5, 5–10, 10–20, 20–50, 50–80, and 80–120 kg, as a percentage of diet (90% DM) are 0.70, 0.65, 0.60, 0.50, 0.45, and 0.40%, respectively.[31] The form in which phosphorus exists in natural feedstuffs influences the efficiency of its utilization. In cereal grains, grain by-products, and oilseed meals, about 60–75% of the phosphorus is organically bound in the form of phytate which is poorly available to the pig. The biological availability of P in cereal grains is variable ranging from less than 15% in corn to approximately 50% in wheat which has naturally occurring phytase enzyme. The phosphorus in inorganic phosphorus supplements also varies in bioavailability. The P in ammonia, calcium, and sodium phosphates is highly available.[31]

Toxicity of supplements

The use of phosphate supplements in the diet is not without hazards. Phosphoric acid is directly toxic and should not be used and monosodium phosphate is unpalatable to many animals; the depression of appetite that results may discount the improved feed utilization it provides. Superphosphate used as fertilizer can cause toxicosis in ruminants.[32] Clinical signs in sheep include teeth grinding, diarrhea, nervous system depression, apparent blindness, stiffness, and ataxia and high fatality rate.[32]

VITAMIN D DEFICIENCY

Vitamin D deficiency is usually caused by insufficient solar irradiation of animals or their feed and is manifested by poor appetite and growth and in advanced cases by osteodystrophy.

Synopsis

Etiology Lack of ultraviolet solar irradiation and/or deficiency of preformed vitamin D in diet.
Epidemiology Uncommon because diets are supplemented. Occurs in animals in countries with relative lack of UV irradiation especially in winter months; animals raised indoors for long periods. May occur in young grazing animals in winter months. May be antivitamin D factor.
Signs Reduced productivity; poor weight gain; reduced reproductive performance. Rickets in young; osteomalacia in adults.
Clinical pathology Serum calcium and phosphorus. Plasma vitamin D.

Necropsy findings Lack of mineralization of bone.
Diagnostic confirmation Histology of bone lesions.
Differential diagnosis list See Rickets and osteomalacia.
Treatment Administer vitamin D parenterally and oral calcium and phosphates.
Control Supplement diets with vitamin D. Injections of vitamin D when oral supplementation not possible.

ETIOLOGY

A lack of ultraviolet solar irradiation of the skin, coupled with a deficiency of preformed vitamin D complex in the diet, leads to a deficiency of vitamin D in tissues.

EPIDEMIOLOGY

Although the effects of clinically apparent vitamin D deficiency have been largely eliminated by improved nutrition, the subclinical effects have received little attention. For example, retarded growth in young sheep in New Zealand and southern Australia during winter months has been recognized for many years as responding to vitamin D administration.

However, general realization of the importance of this subclinical vitamin D deficiency in limiting productivity of livestock has come only in recent years. This is partly due to the complexity of the relations between calcium, phosphorus, and the vitamin and their common association with protein and other deficiencies in the diet. Much work remains to be done before these individual dietary essentials can be assessed in their correct economic perspective.

Ultraviolet irradiation

The lack of ultraviolet irradiation becomes important as distance from the equator increases and the sun's rays are filtered and refracted by an increasing depth of the earth's atmosphere. Cloudy, overcast skies, smoke-laden atmospheres, and winter months exacerbate the lack of irradiation. The effects of poor irradiation are felt first by animals with dark skin (particularly pigs and some breeds of cattle) or heavy coats (particularly sheep), by rapidly growing animals and by those that are housed indoors for long periods. The concentration of plasma vitamin D_3 recorded in grazing sheep varies widely throughout the year. During the winter months in the UK, the levels in sheep fall below what is considered optimal, while in the summer months the levels are more than adequate.[1] There is a marked difference in vitamin D status between sheep with a long fleece and those that have been recently shorn, especially in periods of maximum sunlight. The higher blood levels of vitamin D in the latter group are probably due to their greater exposure to sunlight. Pigs reared under intensive farming conditions and animals being prepared for shows are small but important susceptible groups.

Dietary vitamin D

The importance of dietary sources of preformed vitamin D must not be underestimated. Irradiated plant sterols with anti-rachitic potency occur in the dead leaves of growing plants. Variation in the vitamin D content of hay can occur with different methods of curing. Exposure to irradiation by sunlight for long periods causes a marked increase in anti-rachitic potency of the cut fodder, whereas modern hay-making technique with its emphasis on rapid curing tends to keep vitamin D levels at a minimum. Grass ensilage also contains very little vitamin D.

Based on a survey of the concentrations of vitamin D in the serum of horses in the UK, the levels may be low.[2] In the absence of a dietary supplement containing vitamin D, the concentration of 25-OH D_2 and 25-OH D_3 are, respectively, a reflection of the absorption of vitamin D_2 from the diet and of biosynthesis of vitamin D_3.

Information on the vitamin D requirements of housed dairy cattle is incomplete and contradictory. It appears, however, that in some instances natural feedstuffs provide less than adequate amounts of the vitamin for optimum reproductive performance in high-producing cows.[3]

Grazing animals

The grazing of animals, especially in winter time, on lush green feed including cereal crops, leads to a high incidence of rickets in the young. An antivitamin D factor is suspected because calcium, phosphorus and vitamin D intakes are usually normal, but the condition can be prevented by the administration of calciferol. Carotene, which is present in large quantities in this type of feed, has been shown to have antivitamin D potency but the existence of a further rachitogenic substance seems probable. The rachitogenic potency of this green feed varies widely according to the stage of growth and virtually disappears when flowering commences. Experimental overdosing with vitamin A causes a marked retardation of bone growth in calves. Such overdosing can occur when diets are supplemented with the vitamin and may produce clinical effects.[4]

The importance of vitamin D to animals is now well-recognized and supplementation of the diet where necessary is usually performed by the livestock owner. Occasional outbreaks of vitamin D deficiency are experienced in intensive systems where animals are housed and in areas where specific local problems are encountered, e.g. rickets in sheep on green cereal pasture in New Zealand.

PATHOGENESIS

Vitamin D is a complex of substances with anti-rachitogenic activity. The important components are as follows:

- Vitamin D_3 (cholecalciferol) is produced from its precursor 7-dehydrocholesterol in mammalian skin and by natural irradiation with ultraviolet light
- Vitamin D_2 is present in sun-cured hay and is produced by ultraviolet irradiation of plant sterols. Calciferol or viosterol is produced commercially by the irradiation of yeast. Ergosterol is the provitamin
- Vitamin D_4 and D_5 occur naturally in the oils of some fish.

Vitamin D produced in the skin or ingested with the diet and absorbed by the small intestine is transported to the liver. In the liver, 25-hydroxycholecalciferol is produced, which is then transported to the kidney where at least two additional derivatives are formed by 1-α-hydroxylase.[5] One is 1,25-dihydroxycholecalciferol (DHCC) and the other is 24,25-DHCC. Under conditions of calcium need or calcium deprivation the form predominantly produced by the kidney is 1,25-DHCC. At present, it seems likely that 1,25-DHCC is the metabolic form of vitamin D most active in eliciting intestinal calcium transport and absorption and is at least the closest known metabolite to the form of vitamin D functioning in bone mineralization. The metabolite also functions in regulating the absorption and metabolism of the phosphate ion and especially its loss from the kidney. A deficiency of the metabolite may occur in animals with renal disease, resulting in decreased absorption of calcium and phosphorus, decreased mineralization of bone, and excessive losses of the minerals through the kidney. A deficiency of vitamin D *per se* is governed in its importance by the calcium and phosphorus status of the animal.

Because of the necessity for the conversion of vitamin D to the active metabolites, there is a lag period of 2–4 days following the administration of the vitamin parenterally before a significant effect on calcium and phosphorus absorption can occur. The use of synthetic analogs of the active metabolites such as 1-α-hydroxycholecalciferol (an analog of 1,25-DHCC) can increase the plasma concentration of calcium and phosphorus within 12 h following administration[6] and has been recommended for the control of parturient paresis in cattle.

Maternal status

Maternal vitamin D status is important in determining neonatal plasma calcium concentration. There is a significant correlation between maternal and neonatal calf plasma concentrations of 25-OH D_2, 25-OH D_3, 24,25-$(OH)_2$ D_2, 24,25-$(OH)_2$ D_3 and 25,26-$(OH)_2$ D_3. This indicates that the vitamin D metabolite status of the neonate is primarily dependent on the 25-OH D status of the dam.[7] The maternal serum concentrations of calcium, phosphorus, and magnesium do not determine concentrations of these minerals found in the newborn calf. The ability of the placenta to maintain elevated plasma calcium or phosphorus in the fetus is partially dependent on maternal 1,25-$(OH)_2$ D status. Parenteral cholecalciferol treatment of sows before parturition is an effective method of supplementing neonatal piglets with cholecalciferol via the sow's milk and its metabolite via placenta transport.[6]

Calcium:phosphorus ratio

When the calcium:phosphorus ratio is wider than the optimum (1:1 to 2:1), vitamin D requirements for good calcium and phosphorus retention and bone mineralization are increased. A minor degree of vitamin D deficiency in an environment supplying an imbalance of calcium and phosphorus might well lead to disease, whereas the same degree of vitamin deficiency with a normal calcium and phosphorus intake could go unsuspected. For example, in growing pigs, vitamin D supplementation is not essential provided calcium and phosphorus intakes are rigidly controlled, but under practical circumstances, this may not be possible.

The minor functions of the vitamin include maintenance of efficiency of food utilization and a calorigenic action, the metabolic rate being depressed when the vitamin is deficient. These actions are probably the basis for the reduced growth rate and productivity in vitamin D deficiency. Some evidence suggests that vitamin D may have a role in the immune system.[8] Local production of 1,25-$(OH)_2$ D by monocytes may be important in the immune function, particularly in the parturient dairy cow.

CLINICAL FINDINGS

The most important effect of lack of vitamin D in farm animals is reduced productivity. A decrease in appetite and efficiency of food utilization cause poor weight gains in growing stock and poor productivity in adults. Reproductive efficiency is also reduced and the overall effect on the animal economy may be severe.

In the late stages lameness, which is most noticeable in the forelegs, is accompanied in young animals by bending of the long bones and enlargement of the joints. This latter stage of clinical rickets may occur simultaneously with cases of osteomalacia in adults. An adequate intake of vitamin D appears to be necessary for the maintenance of fertility in cattle, particularly if the phosphorus intake is low. In one study in dairy cattle, the first ovulation after parturition was advanced significantly in vitamin D-supplemented cows.[3]

CLINICAL PATHOLOGY

Serum calcium and phosphorus

A pronounced hypophosphatemia occurs in the early stages and is followed some months later by a fall in serum calcium. Plasma alkaline phosphatase levels are usually elevated. The blood picture quickly returns to normal with treatment, often several months before the animal is clinically normal. Typical figures for beef cattle kept indoors are serum calcium 8.7 mg/dL (10.8 normal), 2.2 mmol/L (2.7 normal); serum inorganic phosphate 4.3 mg/dL (6.3 normal), 1.1 mmol/L (1.6 normal); and alkaline phosphatase 5.7 units (2.75 normal).

Plasma vitamin D

The normal ranges of plasma concentrations of vitamin D and its metabolites in the farm animal species are now available[9] and can be used to monitor the response of the administration of vitamin D parenterally or orally in sheep.[10,11] The serum concentrations of vitamin D in the horse have been determined.[2]

NECROPSY FINDINGS

The pathological changes in young animals are those of rickets, while in older animals there is an osteomalacia. In all ages, a variable amount of osteodystrophia fibrosa may develop and distinction of the origin of these osteodystrophies based on only gross and microscopic examination is impractical. A review of management factors and a nutritional analysis of the feed is essential. The samples for confirmation of the diagnosis at necropsy are as per calcium deficiency.

DIFFERENTIAL DIAGNOSIS

A diagnosis of vitamin D deficiency depends upon evidence of the probable occurrence of the deficiency and response of the animal when vitamin D is provided. Differentiation from clinically similar syndromes is discussed under the specific osteodystrophies.

TREATMENT

It is usual to administer vitamin D in the dose rates set out under control. Affected animals should also receive adequate calcium and phosphorus in the diet.

CONTROL

Supplementation

The administration of supplementary vitamin D to animals by adding it to the diet or by injection is necessary only when exposure to sunlight or the provision of a natural ration containing adequate amounts of vitamin D is impractical.

A total daily intake of 7–12 IU/kg BW is optimal. Sun-dried hay is a good source, but green fodders are generally deficient in vitamin D. Fish liver oils are high in vitamin D, but are subject to deterioration on storage, particularly with regard to vitamin A. They have the added disadvantage of losing their vitamin A and D content in premixed feed, of destroying vitamin E in these feeds when they become rancid and of seriously reducing the butterfat content of milk. Stable water-soluble vitamin A and D preparations do not suffer from these disadvantages. Irradiated dry yeast is probably a simpler and cheaper method of supplying vitamin D in mixed grain feeds.

Stable water-soluble preparations of vitamin D are now available and are commonly added to the rations of animals being fed concentrate rations. The classes of livestock that usually need dietary supplementation include:

- Calves raised indoors on milk replacers
- Pigs raised indoors on grain rations
- Beef cattle receiving poor quality roughage during the winter months
- Cattle raised indoors for prolonged periods and not receiving sun-cured forage containing adequate levels of vitamin D. These include calves raised as herd replacements, yearling cattle fed concentrate rations, bulls in artificial insemination centers and purebred bulls maintained indoors on farms
- Feedlot lambs fed grain rations during the winter months or under totally covered confinement
- Young growing horses raised indoors or outdoors on rations that may not contain adequate concentrations of calcium and phosphorus. This may be a problem in rapidly growing, well-muscled horses receiving a high level of grain.

Because there is limited storage of vitamin D in the body, compared to the storage of vitamin A, it is recommended that daily dietary supplementation be provided when possible for optimum effect.

Injection

In situations where dietary supplementation is not possible, the use of single IM injections of vitamin D_2 (calciferol) in oil will protect ruminants for 3–6 months. A

dose of 11 000 units/kg BW is recommended and should maintain an adequate vitamin D status for 3–6 months.

In mature non-pregnant sheep weighing about 50 kg, a single IM injection of 6000 IU/kg body weight produced concentrations of 25-hydroxyvitamin D_3 at adequate levels for 3 months.[11] The parenteral administration of vitamin D_3 results in both higher tissue and plasma levels of vitamin D_3 than does oral administration and IV administration produces higher plasma levels than does the IM injection.[12] The timing of the injection should be selected so that the vitamin D status of the ewe is adequate at the time of lambing.[11] The vitamin D_3 status of lambs can be increased by the parenteral administration of the vitamin to the pregnant ewe.[13] Dosing pregnant ewes with 300 000 IU of vitamin D_3 in a rapidly available form, approximately 2 months before lambing, provides a safe means of increasing the vitamin D status of the ewe and the newborn lambs by preventing seasonally low concentrations of 25-hydroxyvitamin D_3.[14] In adult sheep there is a wide margin of safety between the recommended requirement and the toxic oral dose, which provides ample scope for safe supplementation if such is desirable.[10] In adult sheep given 20 times the recommended requirements for 16 weeks there was no evidence of pathological calcification.[10] Oral dosing with 30–45 units/kg BW is adequate, provided treatment can be given daily. Massive oral doses can also be used to give long-term effects, e.g. a single dose of 2 million units is an effective preventive for 2 months in lambs. Excessive doses may cause toxicity, with signs of drowsiness, muscle weakness, fragility of bones, and calcification in the walls of blood vessels. The latter finding has been recorded in cattle receiving 10 million units/d and in unthrifty lambs receiving a single dose of 1 million units, although larger doses are tolerated by healthy lambs.

VITAMIN D TOXICITY

Vitamin D toxicity has occurred in cattle,[1] horses[2], and pigs[3] following the parenteral or oral administration of excessive quantities of the vitamin.

In cattle, large parenteral doses of vitamin D_3 15–17 million IU, results in prolonged hypercalcemia, hyperphosphatemia and large increases in plasma concentrations of vitamin D_3 and its metabolites.[1] Clinical signs of toxicity occur within 2–3 weeks and include marked anorexia, loss of body weight, dyspnea, tachycardia, loud heart sounds, weakness, recumbency, torticollis, fever and a high case fatality rate.[1] Pregnant cows 1 month before parturition are more susceptible than non-pregnant cows.

Hypercalcemia and hypervitaminosis D in 17-day-old lambs being fed a milk replacer has been described.[4] The vitamin D content of the milk replacer was not excessive; there was no explanation for the abnormalities in the lamb which recovered when the milk replacer was changed. Serum concentrations of calcium were high at 23.61 mg/dL and 23.09, respectively in two lambs.

Accidental vitamin D_3 toxicity has occurred in horses fed a grain diet that supplied 12 000–13 000 IU/kg BW of vitamin D_3 daily for 30 days,[2] equivalent to about 1 million IU vitamin D_3/kg of feed. Clinical findings included anorexia, stiffness, loss of body weight, polyuria, and polydipsia. There was also evidence of hyposthenuria, aciduria, soft-tissue mineralization, and fractures of the ribs.[2] Calcification of the endocardium and the walls of large blood vessels are characteristic.

Severe toxicity in pigs occurs at a daily oral dose of 50 000–70 000 IU/kg BW. Signs include a sudden onset of anorexia, vomiting, diarrhea, dyspnea, apathy, aphonia, emaciation, and death.[2] Clinical signs are commonly observed within 2 days after consumption of the feed containing excessive vitamin D. At necropsy, hemorrhagic gastritis and mild interstitial pneumonia are commonly present.[3] Arteriosclerosis with calcification of the heart base vessels may also be visible macroscopically in poisoned cattle. Osteoporosis with multiple fractures has been observed in subacute to chronic hypervitaminosis D in pigs. Histologically, there is widespread soft tissue mineralization, with a predilection for the lung and gastric mucosa, as well as elastin-rich tissue, such as blood vessels. Changes in bone vary with the duration of exposure to toxic levels of the vitamin.

Assay of the various metabolites of vitamin D in tissues is difficult. The diagnosis is therefore usually confirmed by correlating microscopic changes with a history of exposure to toxic levels of vitamin D.

Samples for confirmation of diagnosis

- **Toxicology** – 500 g of suspect feed (ASSAY (Vit D))
- **Histology** – formalin-fixed lung, stomach/abomasum, proximal aorta, lung, bone (LM).

RICKETS

Rickets is a disease of young, growing animals characterized by defective calcification of growing bone. The essential lesion is a failure of provisional calcification with persistence of hypertrophic cartilage and enlargement of the epiphyses of long bones and the costochondral junctions (so-called 'rachitic rosary'). The poorly mineralized bones are subject to pressure distortions.

Synopsis

Etiology Deficiencies of any or combination of calcium, phosphorus, and vitamin D.
Epidemiology Young growing animals. No longer common. In calves on phosphorus-deficient diets (range or housed). In grazing lambs due to lack of solar irradiation. Rare in foals and pigs.
Signs Stiff gait and lameness, enlargement of ends of long bones, curvature of long bones, prolonged periods of recumbency. Delayed dentition.
Clinical pathology Elevated alkaline phosphatase; low serum calcium and phosphorus. Lack of density of bone radiographically.
Necropsy findings Abnormal bones and teeth. Bone shafts are soft, epiphyses enlarged. Ratio of bone ash to organic matter is decreased.
Diagnostic confirmation Histology of bone, especially epiphyses.
Differential diagnosis list
- Epiphysitis
- Congenital and acquired abnormalities
- Infectious synovitis.

Treatment Vitamin D injections, calcium and phosphate orally.
Control Supplement deficient diets with calcium, phosphorus, and vitamin D.

ETIOLOGY

Rickets is caused by an absolute or relative deficiency of any or a combination of calcium, phosphorus, or vitamin D in young, growing animals. The effects of the deficiency are also exacerbated by a rapid growth rate.

An inherited form of rickets has been described in pigs. It is indistinguishable from rickets caused by nutritional inadequacy.

EPIDEMIOLOGY

Clinical rickets is not as important economically as the subclinical stages of the various dietary deficiencies that produce it. The provision of diets adequate and properly balanced with respect to calcium, phosphorus and sufficient exposure to sunlight, are mandatory in good livestock production. Rickets is no longer a common disease because these requirements are widely recognized, but the incidence can be high in extreme environments, including purely exploitative range grazing, intensive feeding in fattening units and heavy dependence on lush grazing, especially in winter months.

Rickets is a disease of young, rapidly growing animals and occurs naturally under the following conditions.

Calves

Primary phosphorus deficiency in phosphorus-deficient range areas and vitamin D deficiency in calves housed for long periods are the common circumstances. Vitamin D deficiency is the most common form of rickets in cattle raised indoors for prolonged periods in Europe and North America. Grazing animals may also develop vitamin D deficiency rickets at latitudes where solar irradiation during winter is insufficient to promote adequate dermal photobiosynthesis of vitamin D_3 from 7-dihydrocholesterol. Rickets has occurred in yearling steers in New Zealand wintered on swede (*Brassica napus*) crop deficient in phosphorus.[1]

In young, rapidly growing cattle raised intensively indoors a combined deficiency of calcium, phosphorus and vitamin D can result in leg weakness characterized by stiffness, reluctance to move, and retarded growth. In some cases, rupture of the Achilles tendon and spontaneous fracture occur.[2] The Achilles tendon may rupture at the insertion of, or proximal to, the calcaneus.

Lambs

Lambs are less susceptible to primary phosphorus deficiency than cattle, but rickets does occur under the same conditions. Green cereal grazing and, to a lesser extent, pasturing on lush ryegrass during winter months may cause a high incidence of rickets in lambs; this is considered to be a secondary vitamin D deficiency. An outbreak of vitamin D deficiency rickets involving 50% of lambs aged 6–12 months grazing new grass and rape occurred during the early winter months in Scotland.[3] In the South Island of New Zealand, where winter levels of solar irradiation are low, rickets occurs in hoggets grazing green oats, or other green crops, which have been shown to contain high levels of rachitogenic carotenes.[1] A vitamin D responsive rickets has occurred in twin lambs 3–4 weeks of age.[4]

Pigs

Rickets in young pigs occurs in intensive fattening units where the effects of diet containing excessive phosphate (high cereal diets) are exacerbated by vitamin D and calcium deficiencies.

Foals

Rickets is uncommon in foals under natural conditions, although it has been produced experimentally.

PATHOGENESIS

Dietary deficiencies of calcium, phosphorus, and vitamin D result in defective mineralization of the osteoid and cartilaginous matrix of developing bone. There is persistence and continued growth of hypertrophic epiphyseal cartilage, increasing the width of the epiphyseal plate. Poorly calcified spicules of diaphyseal bone and epiphyseal cartilage yield to normal stresses, resulting in bowing of long bones and broadening of the epiphyses with apparent enlargement of the joints. Rapidly growing animals on an otherwise good diet will be first affected because of their higher requirement of the specific nutrients.

CLINICAL FINDINGS

The subclinical effects of the particular deficiency disease will be apparent in the group of animals affected and have been described in the earlier general section. Clinical rickets is characterized by:

- **Stiffness in the gait**
- **Enlargement of the limb joints,** especially in the forelegs
- **Enlargement of the costochondral junctions**
- **Long bones show abnormal curvature,** usually forward and outward at the carpus in sheep and cattle
- **Lameness and a tendency to lie down for long periods.**

Outbreaks affecting 50% of a group of lambs have been described.[3] Arching of the back and contraction, often to the point of virtual collapse, of the pelvis occur and there is an increased tendency for bones to fracture.

Eruption of the teeth is delayed and irregular, and the teeth are poorly calcified with pitting, grooving, and pigmentation. They are often badly aligned and wear rapidly and unevenly. These dental abnormalities, together with thickening and softness of the jaw bones, may make it impossible for severely affected calves and lambs to close their mouths. As a consequence, the tongue protrudes and there is drooling of saliva and difficulty in feeding. In less severely affected animals, dental malocclusion may be a significant occurrence. Severe deformity of the chest may result in dyspnea and chronic ruminal tympany. In the final stages, the animal shows hypersensitivity, tetany, recumbency and eventually dies of inanition.

CLINICAL PATHOLOGY

The plasma alkaline phosphatase is commonly elevated, but serum calcium and phosphorus levels depend upon the causative factor. If phosphorus or vitamin D deficiencies are the cause, the serum phosphorus level will usually be below the normal lower limit of 3 mg/dL. The serum concentrations of 25-hydroxyvitamin D_3 and 25-hydroxyvitamin D_2 are markedly decreased in vitamin D-deficient rickets compared with the normal values of >5 ng/mL.[3] Serum vitamin D concentrations as low as 0.4 ng/mL have been reported in lambs with vitamin D responsive rickets.[4] Serum calcium levels will be low only in the final stages. In leg weakness of young, rapidly growing cattle, the serum concentration of 25-hydroxyvitamin D may be non-detectable and the serum levels of calcium and inorganic phosphorus may be low.[2]

Radiographic examination of bones and joints is one of the most valuable aids in the detection of rickets. Rachitic bones have a characteristic lack of density compared with normal bones. The ends of long bones have a 'woolly' or 'moth-eaten' appearance and have a concave or flat, instead of the normal convex, contour. Surgical removal of a small piece of costochondral junction for histological examination has been used extensively in experimental work and should be applicable in field diagnosis.

NECROPSY FINDINGS

Apart from general poorness of condition, the necropsy findings are restricted to abnormal bones and teeth. The bone shafts are softer and larger in diameter, due in part to the subperiosteal deposition of osteoid tissue. The joints are enlarged and on cutting, the epiphyseal cartilage can be seen to be thicker than usual. Histological examination of the epiphysis is desirable for final diagnosis. In sheep, the best results are obtained

from an examination of the distal cartilages of the metacarpal and metatarsal bones.

A valuable diagnostic aid is the ratio of ash to organic matter in the bones. Normally the ratio is three parts of ash to two of organic matter but in rachitic bone this may be depressed to 1:2, or 1:3 in extreme cases. A reduction below 45% of the bone weight as ash also suggests osteodystrophy. Because of the difficulty encountered in repeating the results of bone ash determinations, a standardized method has been devised in which the ash content of green bone is determined, using either the metacarpus or metatarsus and the ash content related to the age of the animal, as expressed by the length of the bone. Although normal standards are available only for pigs, the method suggests itself as being highly suitable for all species.

Samples for confirmation of diagnosis

Toxicology – long bone (ASSAY (ash)); 500 g feed (ASSAY (Ca) (P) (Vit D))

Histology – formalin-fixed long bone (including growth plate) (LM).

DIFFERENTIAL DIAGNOSIS

Rickets occurs in young, rapidly growing animals and is characterized by stiffness of the gait and enlargement of the distal physes of the long bones, particularly noticeable on the metacarpus and metatarsus as circumscribed painful swellings. A history of a dietary deficiency of any of calcium, phosphorus, or vitamin D will support the clinical diagnosis. Radiographic evidence of widened and irregular physes suggests rickets. Copper deficiency in young cattle under 1 year of age can also result in clinical, radiographic and pathological findings similar to rickets. Clinically, there is an arched back, severe stiffness of gait, reluctance to move, and loss of weight. There are marked swellings of the distal aspects of metacarpus and metatarsus and radiographically there is a widened zone of cartilage and lipping of the medial and lateral areas of the physeal plate. Copper concentration in plasma and liver are low and there is usually dietary evidence of copper deficiency.

Epiphysitis occurs in rapidly growing yearling cattle raised and fed intensively under confinement. There is severe lameness, swelling of the distal physes and radiographic and pathological evidence of a necrotizing epiphysitis. The etiology is uncertain but thought to be related to the type of housing.

Congenital and acquired abnormalities of the bony skeletal system are frequent in newborn and rapidly growing foals. Rickets occurs, but only occasionally. 'Epiphysitis' in young foals resembles rickets and is characterized by enlargements and abnormalities of the distal physes of the radius, tibia, third metacarpal and metatarsal bones and the proximal extremity of the proximal phalanx. There may or may not be deviation of the limbs caused by uneven growth rates in various growth plates. The suggested causes include improper nutrition, faulty conformation and hoof growth, muscle imbalance, overweight and compression of the growth plate. Recovery may occur spontaneously or require surgical correction.

Rickets in pigs is uncommon and the diagnosis may be difficult. The disease is usually suspected in young, rapidly growing pigs in which there is stiffness in the gait, walking on tiptoes, enlargements of the distal ends of long bones, and dietary evidence of a marginal deficiency of calcium or phosphorus. The radiographic and pathological findings may suggest a rickets-like lesion.

Mycoplasmal synovitis and arthritis clinically resemble rickets of pigs. There is a sudden onset of stiffness of gait, habitual recumbency, a decrease in feed consumption, and enlargements of the distal aspects of the long bones which may or may not be painful, spontaneous recovery usually occurs in 10–14 days. The locomotor problems in young, growing pigs raised in confinement and with limited exercise must be considered in the differential diagnosis. In performance testing stations, up to 20% of boars may be affected with leg weakness.

Rickets in lambs must be differentiated from chlamydial and erysipelas arthritis, which are readily diagnosed at necropsy.

TREATMENT AND CONTROL

Recommendations for the treatment of the individual dietary deficiencies (calcium, phosphorus and vitamin D) are presented under their respective headings. Lesser deformities recover with suitable treatment but gross deformities usually persist. A general improvement in appetite and condition occurs quickly and is accompanied by a return to normal blood levels of phosphorus and alkaline phosphatase. The treatment of rickets in lambs with vitamin A, vitamin D_3, calcium borogluconate solution containing magnesium and phosphorus parenterally and supplementation of the diet with bone meal and protein resulted in a dramatic response.[3] Recumbent animals were walking within a few days.

OSTEOMALACIA

Osteomalacia is a disease of mature animals affecting bones in which endochondral ossification has been completed. The characteristic lesion is osteoporosis and the formation of excessive uncalcified matrix. Lameness and pathological fractures are the common clinical findings.

Synopsis

Etiology Absolute or relative deficiency of any one or combination of calcium, phosphorus, and vitamin D in adult animals.
Epidemiology Primarily in cattle and sheep on phosphorus-deficient diets. In feedlot animals due to excessive phosphorus without complementary calcium and vitamin D.
Signs Reduced productivity, licking and chewing inanimate objects, stiff gait, moderate non-specific lameness, shifting from leg to leg, crackling sounds while walking, arched back, lying down for long periods. 'Milk lameness' in high-producing dairy cows on deficient diet.
Clinical pathology Increased alkaline phosphatase, decreased serum phosphorus levels. Decreased density of long bones radiographically.
Necropsy findings Decreased density of bones, erosions of articular cartilages.
Diagnostic confirmation Histology of bones.
Differential diagnosis list
- Chronic fluorosis
- Polysynovitis and arthritis
- Spinal cord compression.

Treatment As for calcium, phosphorus, and vitamin D deficiency.
Control Adequate supplementation of diet.

ETIOLOGY

In general, the etiology and occurrence of osteomalacia are the same as for rickets except that the predisposing cause is not the increased requirement of growth but the drain of lactation and pregnancy.

EPIDEMIOLOGY

Osteomalacia occurs in mature animals under the same conditions and in the same areas as rickets in young animals, but is recorded less commonly. Its main occurrence is in cattle in areas seriously deficient in phosphorus. It is also recorded in sheep, again in association with hypophosphatemia. In pastured animals, osteomalacia is most common in cattle, and sheep raised in the same area are less severely affected. In feedlot animals, excessive phosphorus intake without complementary calcium and vitamin D is likely as a cause, especially if the animals are kept indoors. It also occurs in sows that have recently weaned their pigs after a long lactation period (6–8 weeks) while on a diet deficient usually in calcium. A marginal deficiency of both phosphorus and vitamin D will exaggerate the condition. Intensively-fed yearling cattle with inadequate mineral supplementation

may be affected with spontaneous fractures of the vertebral bodies, pelvic bones and long bones, leading to recumbency.[1] Simply handling the animals through a chute for routine activities such as tuberculin testing may precipitate the fractures

PATHOGENESIS

Increased resorption of bone mineral to supply the needs of pregnancy, lactation and endogenous metabolism leads to osteoporosis, and weakness and deformity of the bones. Large amounts of uncalcified osteoid are deposited about the diaphyses. Pathological fractures are commonly precipitated by sudden exercise or handling of the animal during transportation.

CLINICAL FINDINGS

Ruminants

In the early stages, the signs are those of phosphorus deficiency, including lowered productivity and fertility and loss of condition. Licking and chewing of inanimate objects begins at this stage and may bring their attendant ills of oral, pharyngeal, and esophageal obstruction, traumatic reticuloperitonitis, lead poisoning, and botulism.

The signs specific to osteomalacia are those of a painful condition of the bones and joints and include a stiff gait, moderate lameness often shifting from leg to leg, crackling sounds while walking, and an arched back. The hindlegs are most severely affected and the hocks may be rotated inwards. The animals are disinclined to move, lie down for long periods and are unwilling to get up. The colloquial names 'pegleg', 'creeps', 'stiffs', 'cripples', and 'bog-lame' describe the syndrome aptly. The names 'milkleg' and 'milk-lameness' are commonly applied to the condition when it occurs in heavily milking cows. Fractures of bones and separation of tendon attachments occur frequently, often without apparent precipitating stress. In extreme cases, deformities of bones occur and when the pelvis is affected dystocia may result. Finally, weakness leads to permanent recumbency and death from starvation.

Pigs

Affected sows are usually found recumbent and unable to rise from lateral recumbency or from the dog-sitting position. The shaft of one femur or the neck of the femur is commonly fractured. The fracture usually occurs within a few days following weaning of the pigs. The placing of the sow with other adult pigs usually results in some fighting and increased exercise, which commonly precipitates the pathological fractures.

CLINICAL PATHOLOGY

In general, the findings are the same as those for rickets, including increased serum alkaline phosphatase and decreased serum phosphorus levels. Radiographic examination of long bones shows decreased density of bone shadow.

NECROPSY FINDINGS

It can be difficult to discern any gross changes as the epiphyses are seldom enlarged and the altered character of cancellous bone may not be macroscopically visible. Cortical bone may be somewhat thinned and erosions of the articular cartilages have been recorded in cattle suffering from primary phosphorus deficiency. The parathyroid glands may be enlarged. Histologically, abnormal osteoid covers trabeculae and a degree of fibrous tissue proliferation is often evident. Analysis reveals the bones to be lighter than normal with a low ratio of ash to organic matter.

Samples for confirmation of diagnosis

Toxicology – long bone (ASSAY (ash)); 500 g feed (ASSAY (Ca) (P) (Vit D))

Histology – formalin-fixed bone, parathyroid (LM).

DIFFERENTIAL DIAGNOSIS

The occurrence of non-specific lameness with pathological fractures in mature animals should arouse suspicion of osteomalacia. There may be additional evidence of subnormal productivity and reproductive performance and dietary evidence of a recent deficiency of calcium, phosphorus, or vitamin D.

A similar osteoporotic disease of cattle in Japan has been ascribed to a dietary deficiency of magnesium. The cattle are on high-concentrate, low-roughage diets, have high serum calcium and alkaline phosphatase levels, but a low serum magnesium level. The osteoporosis is observable at slaughter and clinical signs observed are those of intercurrent disease, especially ketosis, milk fever, and hypomagnesemia. Reproductive and renal disorders occur concurrently.

In **cattle** it must be differentiated from **chronic fluorosis** in mature animals, but the typical mottling and pitting of the teeth and the enlargements on the shafts of the long bones are characteristic. In some areas, e.g. northern Australia, where the water supply is obtained from deep sub-artesian wells, the two diseases may occur concurrently. Analysis of water supplies and foodstuffs for fluorine may be necessary in doubtful cases.

In sows, **osteomalacia** with or without pathological fractures must be differentiated from **spinal cord compression** due to a vertebral body abscess and chronic arthritis due to erysipelas.

TREATMENT AND CONTROL

Recommendations for the treatment and control of the specific nutritional deficiencies have been described under their respective headings. Some weeks will elapse before improvement occurs and deformities of the bones are likely to be permanent.

OSTEODYSTROPHIA FIBROSA

Osteodystrophia fibrosa is similar in its pathogenesis to osteomalacia, but differs in that soft, cellular, fibrous tissue is laid down as a result of the weakness of the bones instead of the specialized uncalcified osteoid tissue of osteomalacia. It occurs in horses, goats, and pigs.

ETIOLOGY

A **secondary calcium deficiency due to excessive phosphorus feeding is the common cause in horses** and probably also in pigs. The disease can be readily produced in horses on diets with a ratio of calcium:phosphorus of 1:2.9 or greater, irrespective of the total calcium intake. Calcium:phosphorus ratios of 1:0.9 to 1:1.4 have been shown to be preventive and curative. With a very low calcium intake of 2–3 g/d and a calcium: phosphorus ratio of 1:13 the disease may occur within 5 months. With a normal calcium intake of 26 g/d and a calcium:phosphorus ratio of 1:5, obvious signs appear in about 1 year, but shifting lameness may appear as early as 3 months. The disease is reproducible in pigs on similar diets to those described above and also on diets low in both calcium and phosphorus. The optimum calcium:phosphorus ratio is 1.2:1 and the intake for pigs should be within the range of 0.6–1.2% of the diet.

EPIDEMIOLOGY

Osteodystrophia fibrosa is principally a disease of horses and other Equidae and to a lesser extent of pigs. It has also occurred in goats. Among horses, those engaged in heavy city work and in racing are more likely to be affected because of the tendency to maintain these animals on unbalanced diets. The major occurrence is in horses fed a diet high in phosphorus and low in calcium. Such diets include cereal hays combined with heavy grain or bran feeding. Legume hays, because of their high calcium content, are preventive.

The disease may reach endemic proportions in army horses moved into new territories, whereas local horses, more used to the diet, suffer little. Although horses may be affected at any age after weaning it is the 2–7-year age group that suffer most, probably because they are the group most likely to be

exposed to the rations that predispose to the disease.

A novel occurrence has been recorded of an endemic form of the disease affecting large numbers of horses at pasture. The dietary intake of calcium and phosphorus and their proportions, were normal. The occurrence was thought to be due to the continuous ingestion of oxalate in specific grasses: *Cenchrus ciliaris*, *Panicum maximum* var. *trichoglume*, *Setaria anceps*, *Brachiaria mutica* and *Pennisetum clandestinum*.

PATHOGENESIS

Defective mineralization of bones follows the imbalance of calcium and phosphorus in the diet and a fibrous dysplasia occurs. This may be in response to the weakness of the bones or it may be more precisely a response to hyperparathyroidism stimulated by the excessive intake of phosphorus. The weakness of the bones predisposes to fractures and separation of muscular and tendinous attachments. Articular erosions occur commonly and displacement of the bone marrow may cause the development of anemia.

CLINICAL FINDINGS

Horse

As in most osteodystrophies, the major losses are probably in the early stages before clinical signs appear or on diets where the aberration is marginal. In horses, a shifting lameness is characteristic of this stage of the disease and arching of the back may sometimes occur. The horse is lame, but only mildly so and in many cases, no physical deformity can be found by which the seat of lameness can be localized. Such horses often creak badly in the joints when they walk. These signs probably result from relaxation of tendon and ligaments and appear in different limbs at different times. Articular erosions may contribute to the lameness. In more advanced cases severe injuries, including fracture and visible sprains of tendons, may occur but these are not specific to osteodystrophia fibrosa, although their incidence is higher in affected than in normal horses. Fracture of the lumbar vertebrae while racing has been known to occur in affected horses.

The more classical picture of the disease has largely disappeared because cases are seldom permitted to progress to this advanced stage. Local swelling of the lower and alveolar margins of the mandible is followed by soft, symmetrical enlargement of the facial bones, which may become swollen so that they interfere with respiration.[1] Initially these bony swellings are firm and pyramidal and commence just above and anterior to the facial crests. The lesions are bilaterally symmetrical. Flattening of the ribs may be apparent and fractures and detachment of ligaments occur if the horse is worked. There may be obvious swelling of joints and curvature of long bones. Severe emaciation and anemia occur in the final stages.

Pigs

In pigs, the lesions and signs are similar to those in the horse and in severe cases, pigs may be unable to rise and walk, show gross distortion of limbs and enlargement of joints and the face. In less severe cases, there is lameness, reluctance to rise, pain on standing and bending of the limb bones, but normal facial bones and joints. With suitable treatment, the lameness disappears, but affected pigs may never attain their full size. The relationship of this disease to atrophic rhinitis is discussed under the latter heading.

Goats

An outbreak of the disease has been recorded in goats receiving a diet of wheat straw (60%) and 40% barley for 89 months.[2] The ratio of calcium to phosphorus in the diet was 1:1.8. Affected goats were 9–10 months of age with a history of stunted growth, lameness, diarrhea, and tongue protrusion. Clinically there was symmetrical enlargement of the face and jaws, tongue protrusion, prominent eyeballs, and tremor. The enlarged bones were firm and painful on palpation. The hindlimbs were bent outwards symmetrically from the tarsal joints.

CLINICAL PATHOLOGY

There are no significant changes in blood chemistry in horses affected with severe osteodystrophia fibrosa. However, the serum calcium level will tend to be lower than normal, the serum inorganic phosphorus higher than normal, and the alkaline phosphatase activity higher than normal. The levels of diagnostic alkaline phosphatase have not been determined. Affected horses may be unable to return their serum calcium levels to normal following the infusion of a calcium salt. Radiographic examination reveals increased translucency of bones.

NECROPSY FINDINGS

The entire skeleton is abnormal in this severe form of metabolic bone disease, but the change is most notable in the mandibular, maxillary, and nasal bones, which may appear thickened and distorted. The fleshy tissue that replaces normal cancellous bone in these sites is also present in the metaphyses of the long bones. Microscopically, there is proliferation of fibrous tissue and markedly increased osteoclast activity along thinned and abnormally oriented bony trabeculae. The parathyroid glands are enlarged. It must be remembered that osteodystrophia fibrosa is a lesion, not a disease. The pathway to this lesion usually involves a dietary imbalance in calcium and phosphorus, but the kidneys should also be examined to rule out the possibility of renal secondary hyperparathyroidism.

Samples for confirmation of diagnosis

- **Toxicology** – bone (ASSAY (ash)); 500 g feed (ASSAY (Ca) (P) (Vit D))
- **Histology** – formalin-fixed bone, parathyroid gland, kidney (LM).

DIFFERENTIAL DIAGNOSIS

In the early stages, the diagnosis may be difficult because of the common occurrence of traumatic injuries to horses' legs. A high incidence of lameness in a group of horses warrants examination of the ration and determination of their calcium and phosphorus status. An identical clinical picture has been described in a mare with an adenoma of the parathyroid gland. Inherited multiple exostosis has been described in the horse.

In pigs, osteodystrophia can be the result of hypovitaminosis A and experimentally as a result of manganese deficiency.

TREATMENT AND CONTROL

A ration adequately balanced with regard to calcium and phosphorus (calcium:phosphorus should be in the vicinity of 1:1 and not wider than 1:1.4) is preventive in horses and affected animals can only be treated by correcting the existing imbalance. Even severe lesions may disappear in time with proper treatment. Cereal hay may be supplemented with alfalfa or clover hay, or finely ground limestone (30 g daily) should be fed. Dicalcium phosphate or bone meal are not as efficient because of their additional content of phosphorus.

'BOWIE' OR 'BENTLEG'

This is a disease of lambs of unknown etiology. There is a characteristic lateral curvature of the long bones of the front legs, but the lesions differ from those of rickets. It has been observed only on unimproved range pasture in New Zealand. The cause is unknown, although phosphorus deficiency has been suggested.

Improvement of the pasture by top-dressing with superphosphate and sowing-improved grasses is usually followed by disappearance of the disease. Only sucking lambs are affected and cases occur only in the spring at a time when rickets does not occur. Up to 40% of a group of lambs may be affected without breed differences in incidence. A

similar syndrome has been produced by the feeding of wild parsnip (*Trachemene glaucifolia*) and, experimentally, by the feeding of a diet low in both calcium and phosphorus.

The disease has also been reported from South Africa where it occurs primarily in ram lambs and develops from as early as 3 months up to 1 year of age.[1] There is gradual bending of the forelimbs with hooves turned inwards and the carpal joints turned outwards. Animals of the South African Mutton Merino breed had significantly higher plasma phosphorus concentrations than those of the Merino and Dohne Merino breeds. The plasma calcium:phosphorus ratio was lower in affected lambs and their ewes and this converse ratio is thought to result in an induced plasma ionized calcium deficiency leading to improper calcification of bone.

Some tenderness of the feet and lateral curvature at the knees may be seen as early as 2–3 weeks of age and marked deformity is present at 6–8 weeks with maximum severity at weaning. The forelimbs are more commonly affected than the hindlimbs. Medial curvature occurs in rare cases. The sides of the feet become badly worn and the lateral aspects of the lower parts of the limbs may be injured and be accompanied by lameness. The lambs grow well at first, but by the time of weaning, affected lambs are in poor condition because of their inability to move about and feed properly. A rather similar syndrome has been observed in young Saanen bucks, but the condition showed a tendency to recover spontaneously.

At necropsy, in spite of the curvature of the limbs, there is no undue porosis and although the epiphyseal cartilages are thickened, they are supported by dense bone. There may be excessive synovial fluid in the joints and, in the later stages, there are articular erosions. Increased deposition of osteoid is not observed.

Supplementation of the diet with phosphorus or improvement of the pasture seems to reduce the incidence of the disease. Dosing with vitamin D or providing mineral mixtures containing all trace elements is ineffective.[2]

DEGENERATIVE JOINT DISEASE

Degenerative arthropathy occurs in cattle of all breeds, but reaches its highest incidence as a sporadic disease of young beef bulls. The disease has been identified as hip dysplasia because of the pre-existing shallow contour of the acetabulum. It is considered to be inherited as a recessive characteristic and exacerbated by rapid weight gain in young animals. The occurrence of the condition in these animals is usually associated with rearing on nurse cows, housing for long periods, provision of a ration high in cereal grains and byproducts (i.e. a high phosphorus:calcium ratio), and possibly with an inherited straight conformation of the hindlegs. Although the disease occurs in all beef breeds, there is a strong familial tendency which appears to be directly related to the rate of body weight gain and the straightness of the hindleg. If the potential for rapid weight gain is being realized in animals being force fed, the rate of occurrence appears to be dependent on their breeding and animals in the same herd that are allowed to run at pasture under natural conditions are either not affected or are affected at a much later age. Thus, animals in a susceptible herd may show signs as early as 6 months of age if they are heavily hand-fed and raised on dairy cow foster mothers. In the same herd, signs do not appear until 1–2 years of age if supplementary feeding is not introduced until weaning and not until 4 years if there is no significant additional feeding.

Clinically there is a gradual onset of lameness in one or both hindlegs. The disease progresses with the lameness becoming more severe over a period of 6–12 months. In some animals, there is a marked sudden change for the worse, usually related to violent muscular movements, as in breeding or fighting. In severely affected animals, the affected limb is virtually useless and, on movement, distinct crepitus can often be felt and heard over the affected joints. This can be accomplished by rocking the animal from side to side or having it walk while holding the hands over the hip joints.

An additional method of examination is to place the hand in the rectum close to the hip joint, while the animal is moved. Passive movement of the limb may also elicit crepitus, or louder clinking or clicking sounds. The hip joints are always most severely affected, but in advanced cases, there may be moderate involvement of the stifles and minimal lesions in other joints. Affected animals lie down most of the time and are reluctant to rise and to walk. The joints are not swollen, but in advanced cases, local atrophy of muscles may be so marked that the joints appear to be enlarged. There is a recorded occurrence in which the lesions were confined mainly to the front fetlocks.

Radiographic examination may provide confirmatory or diagnostic evidence.

At **necropsy,** the most obvious finding is extensive erosion of the articular surfaces, often penetrating to the cancellous bone and disappearance of the normal contours of the head of the femur or the epiphyses in the stifle joint. The synovial cavity is distended, with an increased volume of brownish, turbid fluid; the joint capsule is much thickened and often contains calcified plaques. Multiple, small exostoses are present on the periarticular surfaces. When the stifle is involved the cartilaginous menisci, particularly the medial one, are very much reduced in size and may be completely absent. In cattle with severe degenerative changes in the coxofemoral joint, an acetabular osseous bulla may be present at the cranial margin of the obturator foramen.[1]

Adequate calcium, phosphorus, and vitamin D intake and a correct calcium: phosphorus ratio in the ration should be insured. Supplementation of the ration with copper at the rate of 15 mg/kg has also been recommended for the control of a similar disease.

Degenerative joint disease of cattle is recorded on an enzootic scale in Chile and is thought to be due to gross nutritional deficiency. The hip and tarsal joints are the only ones affected and clinical signs appear when animals are 8–12 months old. There is gross lameness and progressive emaciation. An inherited osteoarthritis is described under that heading. Sporadic cases of degenerative arthropathy, with similar signs and lesions, occur in heavy-producing, aged dairy cows and are thought to be caused by long-continued negative calcium balance. Rare cases also occur in aged beef cows but are thought to be associated with an inherited predisposition. In both instances the lesions are commonly restricted to the stifle joints.

Diseases associated with deficiencies of fat-soluble vitamins

VITAMIN A DEFICIENCY (HYPOVITAMINOSIS-A)

A deficiency of vitamin A may be caused by an insufficient supply of the vitamin in the ration or its defective absorption from the alimentary canal. In young animals, the manifestations of the deficiency are mainly those of compression of the brain and spinal cord. In adult animals, the syndrome is characterized by night blindness, corneal keratinization, pityriasis, defects in the hooves, loss of weight and infertility. Congenital defects are common in the

offspring of deficient dams. Vitamin A may also provide a protective effect against various infectious diseases and enhance many facets of the immune system.

Synopsis

Etiology Dietary deficiency of vitamin A or its precursors.
Epidemiology Primary vitamin A deficiency in animals fed diet deficient in vitamin A or its precursors. Common in cattle grazing dry pastures for long periods. Occurs when diet of hand-fed animals is not supplemented with vitamin A.
Signs Cattle: Night blindness. Loss of body weight. Convulsions followed by recovery. Episodes of syncope. Permanent blindness with dilated pupils and optic disc edema. Pigs: Convulsions, hindleg paralysis, congenital defects.
Clinical pathology Low levels plasma vitamin A.
Necropsy findings Squamous metaplasia of interlobular ducts of parotid gland. Compression of optic nerve tracts and spinal nerve roots. Degeneration of testes.
Diagnostic confirmation Low levels of plasma vitamin A and squamous metaplasia of interlobular ducts of parotid glands.
Differential diagnosis list
Cattle
- Polioencephalomalacia
- Hypomagnesemic tetany
- Lead poisoning
- Rabies
- Meningoencephalitis
- Peripheral blindness due to bilateral ophthalmitis.

Pigs
- Salt poisoning
- Pseudorabies
- Viral encephalomyelitis
- Spinal cord compression due to vertebral body abscess.

Treatment Vitamin A injections.
Control Feed diets with adequate carotene. Supplement diet with vitamin A. Parenteral injections of vitamin A at strategic times.

ETIOLOGY

Vitamin A deficiency may be primary disease, due to an absolute deficiency of vitamin A or its precursor carotene in the diet, or a secondary disease in which the dietary supply of the vitamin or its precursor is adequate, but their digestion, absorption, or metabolism is interfered with to produce a deficiency at the tissue level.

EPIDEMIOLOGY

Primary vitamin A deficiency

Primary vitamin A deficiency is of major economic importance in groups of young growing animals on pasture or fed diets deficient in the vitamin or its precursors.[1] In the UK, primary vitamin A deficiency occurs in housed cattle fed a ration containing little or no green forage.[2] Animals at pasture receive adequate supplies of the vitamin, except during prolonged droughts, but animals confined indoors and fed prepared diets may be deficient if not adequately supplemented. For example, a diet of dried sugar beet pulp, concentrates and poor quality hay can result in hypovitaminosis-A in confined beef cattle.

Ruminants on pasture

Primary vitamin A deficiency occurs in beef cattle and sheep on dry range pasture during periods of drought. Clinical vitamin A deficiency does not always occur under these conditions because hepatic storage is usually good and the period of deprivation not sufficiently long for these stores to reach a critically low level.[3] Young sheep grazing natural, drought-stricken pasture can suffer serious depletion of reserves of the vitamin in 5–8 months, but normal growth is maintained for 1 year at which time clinical signs develop. Adult sheep may be on a deficient diet for 18 months before hepatic stores are depleted and the disease becomes evident. Cattle may subsist on naturally deficient diets for 5–18 months before clinical signs appear. However, during the annual dry season (October–June), herds of cattle, sheep and goats in the Sahelian region of West Africa are managed on dry grasses and shrubby ligneous plants, which fail to provide maintenance levels of crude protein and vitamin A. These substandard conditions result in vitamin A deficiency characterized by night blindness, xerophthalmia, retarded growth rates, reproductive failures, and increased mortality.[4] The pastoral herders associate the cure of night blindness with the consumption of green vegetation and will purposefully herd livestock into green vegetation areas when available. Certain ethnic groups of pastoral herders depend on ruminant milk as their principal source of vitamin A and night blindness in lactating and pregnant women as well as in young children appears after the onset of night blindness in their cattle and sheep during the latter half of the dry season. Therefore, increasing vitamin A levels in the milk of cows may alleviate the clinical signs of vitamin A deficiency in herder families.

Primary vitamin A deficiency is still relatively common in beef cattle that depend on pasture and roughage for the major portion of their diet. Beef calves coming off dry summer pastures at 6–8 months of age are commonly marginally deficient.

Maternal deficiency

A maternal deficiency of vitamin A can result in herd outbreaks of congenital hypovitaminosis-A in calves.[5] In one such occurrence, out of 240 heifers fed a vitamin A-deficient ration, 89 calves were born dead, 47 were born alive but blind and weak and died within 1–3 days after birth. Blindness with dilated pupils, nystagmus, weakness, and incoordination were characteristic. In another occurrence in the UK, 25% of the calves born from maternally vitamin A deficient heifer dams had ocular abnormalities.[2]

The status of the dam is reflected in that of the fetus only in certain circumstances, in that carotene, as it occurs in green feed, does not pass the placental barrier and a high intake of green pasture before parturition does not increase the hepatic stores of vitamin A in newborn calves, lambs, or kids and only to a limited extent in pigs. However, vitamin A in the ester form, as it occurs in fish oils, will pass the placental barrier in cows. Feeding of these oils, or the parenteral administration of a vitamin A injectable preparation before parturition, will cause an increase in stores of the vitamin in fetal livers. Antepartum feeding of carotene and the alcohol form of the vitamin does, however, cause an increase in the vitamin A content of the colostrum. Young animals depend on the dam's colostrum for their early requirements of the vitamin which is always highest in colostrum and returns to normal levels within a few days of parturition. Pigs weaned very early at 2–4 weeks may require special supplementation. Pregnant beef cows wintered on poor quality roughage commonly need supplementation with vitamin A throughout the winter months to insure normal development of the fetus and an adequate supply of the vitamin in the colostrum at parturition.

Adequacy of supplements

The addition of vitamin A supplements to diets may not always be sufficient to prevent deficiency. Carotene and vitamin A are readily oxidized, particularly in the presence of unsaturated fatty acids. Oily preparations are thus less satisfactory than dry or aqueous preparations, particularly if the feed is to be stored for any length of time. Pelleting of feed may also cause a serious loss up to 32% of the vitamin A in the original feedstuff.

Heat, light, and mineral mixes are known to increase the rate of destruction of vitamin A supplements in commercial rations. In one study, 47–92% of the vitamin A in several mineral supplements was destroyed after 1 week of exposure to the trace minerals, high relative humidity, sunlight and warm temperatures.[6]

Feedlot cattle

The disease still occurs in feedlot cattle in some parts of North America when feedlot cattle are fed rations low in

carotene or vitamin A over a period of several months.[7] The onset of clinical signs in growing feedlot cattle is typically seen 6–12 months after feeding a diet deficient in carotene or vitamin A. Small farm feedlots may feed their cattle a cereal grain such as barley and barley straw with no vitamin supplementation[8] or inadequate supplementation.[9] Grains, with exception of yellow corn, contain negligible amounts of carotene and cereal hay is often a poor source. Any hay cut late, leached by rain, bleached by sun, or stored for long periods loses much of its carotene content. The carotene content of yellow corn also deteriorates markedly with long storage. Moreover, under conditions not yet completely understood, the conversion by ruminants of carotene present in feeds such as silage may be much less complete than was formerly thought.

In feedlot cattle, the disease is most common in steers fed the same ration as heifers which may remain clinically normal.[6,7] It is suggested that sexual dimorphism may be due to the production of vitamin A by the corpus luteum of heifers.[7]

Pigs

Young pigs on a deficient diet may show signs after several months, but as in other animals, the length of time required before signs appear is governed to a large extent by the status before depletion commences. As a general rule it can be anticipated that signs will appear in pigs fed deficient rations for 4–5 months, variations from these periods probably being due to variations in the vitamin A status of the animal when the deficient diet is introduced. Congenital defects occur in litters from deficient sows, but the incidence is higher in gilts with the first litter than in older sows. It is presumed that the hepatic stores of vitamin A in older sows are not depleted as readily as in young pigs. Feeding white maize bran without supplementation can result in congenital defects in litters and paralysis in adult pigs.[10]

Horses

Adult horses may remain clinically normal for as long as 3 years on a deficient diet.

Secondary vitamin A deficiency

Secondary vitamin A deficiency may occur in cases of chronic disease of the liver or intestines because much of the conversion of carotene to vitamin A occurs in the intestinal epithelium and the liver is the main site of storage of the vitamin. Highly chlorinated naphthalenes interfere with the conversion of carotene to vitamin A and animals poisoned with these substances have a very low vitamin A status. The intake of inorganic phosphorus also affects vitamin A storage, low phosphate diets facilitating storage of the vitamin. This may have a sparing effect on vitamin A requirements during drought periods when phosphorus intake is low and an exacerbating effect in stall-fed cattle on a good grain diet. However, phosphorus deficiency may lower the efficiency of carotene conversion. Vitamins C and E help to prevent loss of vitamin A in feedstuffs and during digestion. Additional factors which may increase the requirement of vitamin A include high environmental temperatures, a high nitrate content of the feed, which reduces the conversion of carotene to vitamin A and rapid rate of gain. Both a low vitamin A status of the animal and high levels of carotene intake may decrease the biopotency of ingested carotene.

The continued ingestion of mineral oil, which may occur when the oil is used as a preventive against bloat in cattle, may cause a depression of plasma carotene and vitamin A esters and the carotene levels in buffer fat. Deleterious effects on the cattle are unlikely under the conditions in which it is ordinarily used because of the short period for which the oil is administered and the high intake of vitamin A and carotene.

PATHOGENESIS

Vitamin A is essential for the regeneration of the visual purple necessary for dim-light vision, for normal bone growth and for maintenance of normal epithelial tissues. Deprivation of the vitamin produces effects largely attributable to disturbance of these functions. The same tissues are affected in all species. However, there is a difference in tissue and organ response in the different species and particular clinical signs may occur at different stages of development of the disease. The major pathophysiological effects of vitamin A deficiency are as follows.

Night vision

Ability to see in dim light is reduced because of interference with regeneration of visual purple.

Cerebrospinal fluid pressure

An increase in CSF pressure is one of the first abnormalities to occur in hypovitaminosis-A in calves. It is a more sensitive indicator than ocular changes and, in the calf, it occurs when the vitamin A intake is about twice that needed to prevent night blindness. The increase in CSF pressure is due to impaired absorption of the CSF due to reduced tissue permeability of the arachnoid villi and thickening of the connective tissue matrix of the cerebral dura mater. The increased CSF pressure is responsible for the syncope and convulsions, which occur in calves in the early stages of vitamin A deficiency. The syncope and convulsions may occur spontaneously or be precipitated by excitement and exercise. It is suggested that the CSF pressure is increased in calves with subclinical deficiency and that exercise further increases the CSF pressure to convulsive levels.

Bone growth

Vitamin A is necessary to maintain normal position and activity of osteoblasts and osteoclasts. When deficiency occurs there is no retardation of endochondral bone growth, but there is incoordination of bone growth in that shaping, especially the finer molding of bones, does not proceed normally. In most locations this has little effect but may cause serious damage to the nervous system. Overcrowding of the cranial cavity occurs with resulting distortion and herniations of the brain and an increase in CSF pressure up to four to six times normal. The characteristic nervous signs of vitamin A deficiency, including papilledema, incoordination and syncope, follow. Compression, twisting and lengthening of cranial nerves and herniations of the cerebellum into the foramen magnum, causing weakness and ataxia and of the spinal cord into intervertebral foraminae results in damage to nerve roots and localizing signs referable to individual peripheral nerves. Facial paralysis and blindness due to constriction of the optic nerve, are typical examples of this latter phenomenon. The effect of excess vitamin A on bone development by its interference with vitamin D has been discussed elsewhere. Dwarfism in a group of pigs in a swine herd was suspected to be due to vitamin toxicosis.[11]

Epithelial tissues

Vitamin A deficiency leads to atrophy of all epithelial cells, but the important effects are limited to those types of epithelial tissue with a secretory as well as a covering function. The secretory cells are without power to divide and develop from undifferentiated basal epithelium. In vitamin A deficiency these secretory cells are gradually replaced by the stratified, keratinizing epithelial cells common to non-secretory epithelial tissues. This replacement of secretory epithelium by keratinized epithelium occurs chiefly in the salivary glands, the urogenital tract (including placenta but not ovaries or renal tubules) and the paraocular glands and teeth (disappearance of odontoblasts from the enamel organ). The secretion of thyroxine is markedly reduced. The mucosa of the stomach is not markedly affected. These changes in epithelium

lead to the clinical signs of placental degeneration, xerophthalmia and corneal changes.

Experimental vitamin A deficiency in lambs results in changes in the epithelium of the small intestine characterized by vesicular microvillar degeneration and disruption of the capillary endothelium.[12] Diarrhea did not occur.

Embryological development

Vitamin A is essential for organ formation during growth of the fetus. Multiple congenital defects occur in pigs and rats and congenital hydrocephalus in rabbits on maternal diets deficient in vitamin A. In pigs, administration of the vitamin to depleted sows before the 17th day of gestation prevented the development of eye lesions but administration on the 18th day failed to do so. A maternal deficiency of vitamin A in cattle can result in congenital hypovitaminosis-A in the calves, characterized by blindness with dilated pupils, nystagmus, weakness, and incoordination. Constriction of the optic canal with thickening of the dura mater results in ischemic necrosis of the optic nerve and optic disc edema resulting in blindness. Retinal dysplasia also occurs. Thickening of the occipital and sphenoid bones and doming of the frontal and parietal bones with compression of the brain also occur. Dilated lateral ventricles may be present and associated with increased CSF pressure.

Immune mechanisms

The effects of vitamin A and β-carotene on host defense mechanisms have been uncertain and controversial for many years.[13] Some workers claim that the incidence and severity of bacterial, viral, rickettsial and parasitic infections are higher in vitamin A-deficient animals.[13] It is possible that vitamin A and β-carotene afford protection against infections by influencing both specific and non-specific host defense mechanisms. The protective effect of vitamin A may be mediated by enhanced polymorphonuclear neutrophil function but this effect is also influenced by the physiological status of the animal such as lactation status in dairy cattle.[14] Experimentally, a severe vitamin A deficiency in lambs is associated with alterations in immune function, but the exact mechanism is unknown.[15]

CLINICAL FINDINGS

In general, similar syndromes occur in all species, but because of species differences in tissue and organ response, some variations are observed. The major clinical findings are set out below.

Night blindness

Inability to see in dim light (twilight or moonlit night) is the earliest sign in all species, except in the pig in which it is not evident until plasma vitamin A levels are very low. This is an important diagnostic sign.

Xerophthalmia

True xerophthalmia, with thickening and clouding of the cornea, occurs only in the calf. In other species a thin, serous mucoid discharge from the eyes occurs, followed by corneal keratinization, clouding and sometimes ulceration, and photophobia.

Changes in the skin

A rough, dry coat with a shaggy appearance and splitting of the bristle tips in pigs is characteristic, but excessive keratinization, such as occurs in cattle poisoned with chlorinated naphthalenes, does not occur under natural conditions of vitamin A deficiency. Heavy deposits of bran-like scales on the skin are seen in affected cattle. Dry, scaly hooves with multiple, vertical cracks are another manifestation of skin changes and are particularly noticeable in horses. A seborrheic dermatitis may also be observed in deficient pigs but is not specific to vitamin A deficiency.

Body weight

Under natural conditions, a simple deficiency of vitamin A is unlikely to occur and the emaciation commonly attributed to vitamin A deficiency may be largely due to multiple deficiencies of protein and energy. Although inappetence, weakness, stunted growth and emaciation occur under experimental conditions of severe deficiency, in field outbreaks severe clinical signs of vitamin A deficiency are often seen in animals in good condition. Experimentally, sheep maintain their body weight under extreme deficiency conditions and with very low plasma vitamin A levels.

Reproductive efficiency

Loss of reproductive function is one of the major causes of loss in vitamin A deficiency. Both the male and female are affected. In the male, libido is retained but degeneration of the germinative epithelium of the seminiferous tubules causes reduction in the number of motile, normal spermatozoa produced. In young rams, the testicles may be visibly smaller than normal. In the female, conception is usually not interfered with, but placental degeneration leads to abortion and the birth of dead or weak young. Placental retention is common.

Nervous system

Signs related to damage of the nervous system include:

- **Paralysis** of skeletal muscles due to damage of peripheral nerve roots
- **Encephalopathy** due to increased intracranial pressure
- **Blindness** due to constriction of the optic nerve canal.

These defects occur at any age but most commonly in young, growing animals and they have been observed in all species except horses.

Paralysis

The paralytic form is manifested by abnormalities of gait due to weakness and incoordination. The hindlegs are usually affected first and the forelimbs later. In pigs, there may be stiffness of the legs, initially with a stilted gait or flaccidity, knuckling of the fetlocks and sagging of the hindquarters. Complete limb paralysis occurs terminally.

Convulsions

Encephalopathy, associated with an increase in CSF pressure, is manifested by convulsions, which are common in beef calves at 6–8 months, usually following removal from a dry summer pasture at weaning time. Spontaneously, or following exercise or handling, affected calves will collapse (syncope) and during lateral recumbency a clonic-tonic convulsion will occur, lasting for 10–30 s. Death may occur during the convulsion or the animal will survive the convulsion and lie quietly for several minutes, as if paralyzed, before another convulsion may occur. Affected calves are usually not blind and the menace reflex may be slightly impaired or hyperactive. Some calves are hyperesthetic to touch and sound. During the convulsion there is usually ventroflexion of the head and neck, sometimes opisthotonos and, commonly, tetanic closure of the eyelids and retraction of the eyeballs. Outbreaks of this form of hypovitaminosis-A in calves have occurred and the case fatality rate may reach 25%.[9] The prognosis is usually excellent; treatment will effect a cure in 48 h but convulsions may continue for up to 48 h following treatment.

Seizures and acute death attributable to hypovitaminosis-A and hypovitaminosis-D have occurred in feeder pigs fed ground red wheat and whole milk and housed in a barn with no exposure to sunlight.[16] Lethargy, inappetence, diarrhea, and vomiting and progression to convulsions were characteristic.

Blindness

The ocular form of hypovitaminosis-A occurs usually in yearling cattle (12–18 months old) and up to 2–3 years of age. These animals have usually been on marginally deficient rations for several months. Night blindness may or may not have been noticed by the owner. The cattle have usually been fed and housed for long periods in familiar surroundings and the clinical signs of night blindness may have been subtle and not noticeable.

The first sign of the ocular form of the disease is blindness in both eyes during daylight. Both **pupils** are **widely dilated and fixed** and will not respond to light. Optic disc edema may be prominent and there may be some loss of the usual brilliant color of the tapetum. Varying degrees of peripapillary retinal detachment, papillary and peripapillary retinal hemorrhages, and disruption of the retinal pigment epithelium may also be present.[6] The **menace reflex** is usually totally absent, but the **palpebral and corneal reflexes** are present. The animal is aware of its surroundings and usually eats and drinks, unless placed in unfamiliar surroundings. The CSF pressure is increased in these animals, but not as high as in the calves described earlier. Convulsions may occur in these cattle if forced to walk, or if loaded onto a vehicle for transportation. The prognosis for the ocular form with blindness is unfavorable and treatment is ineffective because of the degeneration of the optic nerves. Exophthalmos and excessive lacrimation are present in some cases.

Congenital defects

These have been observed in piglets and calves. In calves, the defects are limited to congenital blindness due to optic nerve constriction and encephalopathy. In piglets, complete absence of the eyes (**anophthalmos**), or small eyes (**microphthalmos**), incomplete closure of the fetal optic fissure, degenerative changes in the lens and retina, and an abnormal proliferation of mesenchymal tissue in front of and behind the lens are some of the defects encountered. Ocular abnormalities in newborn calves from maternally vitamin A deficient heifers included corneal dermoid, microphthalmos, aphakia (absence of lens) and in some cases, both eyes covered by haired skin.[2]

Other congenital defects attributed to vitamin A deficiency in pigs include cleft palate and harelip, accessory ears, malformed hindlegs, subcutaneous cysts, abnormally situated kidneys, cardiac defects, diaphragmatic hernia, aplasia of the genitalia, internal hydrocephalus, herniations of the spinal cord, and generalized edema. Affected pigs may be stillborn, or weak and unable to stand, or may be quite active. Weak pigs lie on their sides, make slow paddling movements with their legs, and squawk plaintively.

Other diseases

Increased susceptibility to infection is often stated to result from vitamin A deficiency.[9,13] The efficacy of colostrum as a preventive against diarrhea in calves was originally attributed to its vitamin A content, but the high antibody content of colostrum is most important.

Anasarca. Edema of the limbs and brisket have been associated with vitamin A deficiency in feedlot cattle, especially steers.[17] The pathogenesis is not understood. The edema can be extensive, include all four limbs, ventral body wall and extending to the scrotum. Heifers were unaffected.

CLINICAL PATHOLOGY

Plasma vitamin A

Vitamin A levels in the plasma are used extensively in diagnostic and experimental work. Plasma levels of 20 μg/dL are the minimal concentration for vitamin A adequacy.[18] Papilledema is an early sign of vitamin A deficiency which develops before nyctalopia and at plasma levels below 18 μg/dL. Normal serum vitamin A concentrations in cattle range from 25 to 60 μg/dL. In pigs, levels of 11.0 μg/dL have been recorded in clinical cases, with normal levels being 23–29 μg/dL.[16] In experimental vitamin A deficiency in lambs, serum levels declined to 6.8 μg/dL (normal lambs at 45.1 μg/dL).[12]

The clinical signs may correlate with the serum concentrations of vitamin A.[8] In one outbreak, feedlot cattle with serum concentrations between 8.89 and 18.05 μg/dL had only lost body weight, those between 4.87 and 8.88 μg/dL had varying degrees of ataxia and blindness and those below 4.88 μg/dL had convulsions and optic nerve constriction.[8] Clinical signs can be expected when the levels fall to 5 μg/dL.[9] For complete safety, optimum levels should be 25 μg/dL or above.

Plasma retinol

Some information on the plasma retinol values in stabled Thoroughbred horses is available. The mean plasma level of retinol in 71 horses 2–3 years of age was 16.5 μg/dL. The serum retinol levels in racing Trotters in Finland are lower than during the summer months, which is a reflection of the quality of the diets.[19]

Plasma carotene

Plasma carotene levels vary largely with the diet. In cattle, levels of 150 μg/dL are optimum and, in the absence of supplementary vitamin A in the ration, clinical signs appear when the levels fall to 9 μg/dL. In sheep, carotene is present in the blood in only very small amounts even when animals are on green pasture.

Hepatic vitamin A

A direct relationship between plasma and hepatic levels of vitamin A need not exist since plasma levels do not commence to fall until the hepatic stores are depleted. A temporary precipitate fall occurs at parturition and in acute infections in most animals. The secretion of large amounts of carotene and vitamin A in the colostrum of cows during the last 3 weeks of pregnancy may greatly reduce the level of vitamin A in the plasma.

Hepatic levels of vitamin A and carotene can be estimated in the living animal from a biopsy specimen. Biopsy techniques have been shown to be safe and relatively easy, provided a proper instrument is used. Hepatic levels of vitamin A and carotene should be of the order of 60 and 4.0 μg/g of liver, respectively. These levels are commonly as high as 200–800 μg/g. Critical levels at which signs are likely to appear are 2 and 0.5 μg/g for vitamin A and carotene, respectively.

Cerebrospinal fluid

CSF pressure is also used as a sensitive indicator of low vitamin A status. In calves, normal pressures of less than 100 mm of saline rise after depletion to more than 200 mm. In pigs, normal pressures of 80–145 mm rise to above 200 mm in vitamin A deficiency. An increase in pressure is observed at a blood level of about 7 μg vitamin A/dL plasma in this species. In sheep, normal pressures of 55–65 mm rise to 70–150 mm when depletion occurs. In the experimentally induced disease in cattle, there is a marked increase in the number of cornified epithelial cells in a conjunctival smear and distinctive bleaching of the tapetum lucidum as viewed by an ophthalmoscope. These features may have value as diagnostic aids in naturally occurring cases.

NECROPSY FINDINGS

Gross changes are rarely observed at necropsy. Careful dissection may reveal a decrease in the size of the cranial vault and of the vertebrae. Compression and injury of the cranial and spinal nerve roots, especially the optic nerve, may be visible. In outbreaks in which night blindness is the primary clinical sign, atrophy of the photoreceptor layer of the retina is evident histologically, but there are no gross lesions.

Congenital ocular abnormalities in newborn calves from vitamin A deficient heifer dams included aphakia, absence of a uveal tract and aqueous humour, microphalmos, bony outgrowths of the occipital bone, compression of the cerebellum and cardiac abnormalities similar to the tetralogy of Fallot.[2]

Squamous metaplasia of the interlobular ducts of the parotid salivary gland is strongly suggestive of vitamin A deficiency in pigs, calves, and lambs, but the change is transient and may have disappeared 2–4 weeks after the intake of vitamin A is increased. This microscopic change is

most marked and occurs first, at the oral end of the main parotid duct. Abnormal epithelial cell differentiation may also be observed histologically in a variety of other sites such as the tracheal, esophageal, and ruminal mucosae, preputial lining, pancreatic ducts, and urinary epithelium. Hypovitaminosis-A has also been associated with an increased incidence of pituitary cysts in cattle. Secondary bacterial infections, including pneumonia and otitis media, are also common, due at least in part to the decreased barrier function of the lining epithelia.

The abnormalities that occur in congenitally affected pigs have already been described.

Samples for confirmation of diagnosis

Toxicology – 50 g liver, 500 g feed ASSAY (Vit A)
Histology – formalin-fixed parotid salivary gland (including duct), rumen, pituitary, pancreas, brain (including optic nerves), cervical spinal cord (including nerve roots); Bouin's-fixed eye (LM).

DIFFERENTIAL DIAGNOSIS

When the characteristic clinical findings of vitamin A deficiency are observed, a deficiency of the vitamin should be suspected if green feed or vitamin A supplements are not being provided. The detection of papilledema and testing for night blindness are the easiest methods of diagnosing early vitamin A deficiency in ruminants. Incoordination, paralysis, and convulsions are the early signs in pigs. Increase in CSF pressure is the earliest measurable change in both pigs and calves. Laboratory confirmation depends upon estimations of vitamin A in plasma and liver, the latter being most satisfactory. Unless the disease has been in existence for a considerable time, response to treatment is rapid. For confirmation at necropsy, histological examination of parotid salivary gland and assay of vitamin A in the liver, are suggested.

The salient features of the differential diagnosis of diseases of the nervous system of cattle are summarized in Table 32.3.

Cattle

Convulsive form of vitamin A deficiency in cattle must be differentiated from:

- **Polioencephalomalacia**: characterized by sudden onset of blindness, head-pressing, and tonic-clonic convulsions, usually in grain-fed animals but also in pastured animals ingesting an excess of sulfate in water and grass
- **Hypomagnesemic tetany**: primarily in lactating dairy cattle on pasture during cool windy weather; characterized by hyperesthesia, champing tonic-clonic convulsions, normal eyesight and tachycardia, and loud heart sounds
- **Lead poisoning**: in all age groups, but most commonly in pastured calves in the spring; characterized by blindness, tonic-clonic convulsions, champing of the jaw, head-pressing, and rapid death
- **Rabies**: in all age groups; characterized by bizarre mental behavior, gradually progressive ascending paralysis with ataxia leading to recumbency, drooling saliva, inability to swallow, normal eyesight, and death in 4–7 days.

Ocular form of vitamin A deficiency in cattle must be differentiated from those diseases of cattle characterized by central or peripheral blindness:

- **Central blindness**:
  Polioencephalomalacia
  Lead poisoning
  Meningoencephalitis.
- **Peripheral blindness**:
  Bilateral ophthalmitis due to ocular disease.

Loss of body condition in cattle, failure to grow and poor reproductive efficiency are general clinical findings not limited to vitamin A deficiency.

Pigs

Convulsive form of vitamin A deficiency in pigs must be differentiated from:

- Salt poisoning
- Pseudorabies
- Viral encephalomyelitis
- Organic arsenic poisoning.

Paralytic form of vitamin A deficiency in pigs must be differentiated from:

- Spinal cord compression due to vertebral body abscess.

Congenital defects similar to those caused by vitamin A deficiency may be caused by deficiencies of other essential nutrients, by inheritance or by viral infections in early pregnancy in all species. Maternal vitamin A deficiency is the most common cause of congenital defects in piglets. Final diagnosis depends upon the necropsy findings, analysis of feed and serum vitamin A of the dams.

TREATMENT

Vitamin A

Animals with curable vitamin A deficiency should be treated immediately with vitamin A at a dose rate equivalent to 10–20 times the daily maintenance requirement. As a rule, 440 IU/kg BW is the dose used. Parenteral injection of an aqueous rather than an oily solution is preferred. The response to treatment in severe cases is often rapid and complete, but the disease may be irreversible in chronic cases. Calves with the convulsive form due to increased CSF pressure will usually return to normal in 48 h following treatment. Cattle with the ocular form of the deficiency and that are blind will not respond to treatment and should be slaughtered for salvage.

Hypervitaminosis-A

Daily heavy dosing (about 100 times normal) of calves causes reduced growth rate, lameness, ataxia, paresis, exostoses on the planter aspect of the third phalanx of the fourth digit of all feet, and disappearance of the epiphyseal cartilage. Persistent heavy dosing in calves causes lameness, retarded horn growth and depressed CSF pressure. At necropsy, exostoses are present on the proximal metacarpal bones and the frontal bones are thin. Very high levels fed to young pigs may cause sudden death through massive internal hemorrhage and excessive doses during early pregnancy are reputed to result in fetal anomalies. However, feeding vitamin A for prolonged periods at exceptionally high levels is unlikely to produce severe embryotoxic or teratogenic effects in pigs.

CONTROL

Dietary requirement

The minimum daily requirement in all species is 40 IU of vitamin A/kg BW, which is a guideline for maintenance requirements. In the formulation of practical diets for all species, the daily allowances of vitamin A are commonly increased by 50–100% of the daily minimum requirements. During pregnancy, lactation, or rapid growth the allowances are usually increased by 50–75% of the requirements. The supplementation of diets to groups of animals is governed also by their previous intake of the vitamin and its probable level in the diet being fed. The rate of supplementation can vary from 0 to 110 IU/kg BW/d (1 IU of vitamin A is equivalent in activity to 0.3 μg of retinol; 5–8 μg β-carotene has the same activity as 1 μg of retinol).

Nutrient studies have indicated that pre-ruminant Holstein calves being fed milk replacer should receive 11 000 IU of vitamin A/kg DM for optimum growth and to maintain adequate liver vitamin A stores.[20]

The amounts of the vitamin to be added to the ration of each species to meet the requirements for all purposes should be obtained from published recommended nutrient requirements of domestic animals. Some examples of daily allowances of vitamin A for farm animals are set out in Table 30.11.

Supplementation method

The method of supplementation will vary depending on the class of livestock and the ease with which the vitamin can be given. In **pigs**, the vitamin is incorporated directly into the complete ration, usually through the protein supplement. In **feedlot and dairy cattle** receiving complete feeds, the addition of vitamin A to the diet is simple. In **beef cattle**, which may

Table 20.11 Daily dietary allowances of vitamin A

Animal	Vitamin A (IU/kg BW daily)
Cattle	
Growing calves	40
Weaned beef calves at 6–8 months	40
Calves 6 months to yearlings	40
Maintenance and pregnancy	70–80
Maintenance and lactation	80
Feedlot cattle on high energy ration	80
Sheep	
Growth and early pregnancy and fattening lambs	30–40
Late pregnancy and lactation	70–80
Pigs	
Growing pigs	40–50
Pregnant gilts and sows	40–50
Lactating gilts and sows	70–80
Horses	
Working horse	20–30
Growing horse	40
Pregnant mare	50
Lactating mare	50

be fed primarily on carotene-deficient roughage during pregnancy, it may not be possible to supplement the diet on a daily basis. However, it may be possible to provide a concentrated dietary source of vitamin A on a regular basis by feeding a protein supplement once weekly. The protein supplement will contain 10–15 times the daily allowance, which permits hepatic storage of the vitamin.

Parenteral injection

An alternative method to dietary supplementation is the IM injection of vitamin A at intervals of 50–60 days at the rate of 3000–6000 IU/kg BW. Under most conditions, hepatic storage is good and optimum plasma and hepatic levels of vitamin A are maintained for up to 50–60 days. In pregnant beef cattle the last injection should not be more than 40–50 days before parturition to insure adequate levels of vitamin A in the colostrum. Ideally, the last injection should be given 30 days before parturition but this may not be practical under some management conditions. However, the most economical method of supplementing vitamin A is, in most cases, through the feed and when possible should be used.

The use of injectable mixtures of vitamins A, D, and E is not always justifiable. The injection of a mixture of vitamins A, D, and E of feeder cattle in northern Australia prior to transport did not, contrary to anecdotal evidence, reduce weight loss associated with transportation.[21] Cattle in Queensland and north-western Australia have very high concentrations of hepatic vitamin A and in fact, drought-stricken cattle in the terminal stages of malnutrition have also had high liver concentration. The indiscriminate use of vitamin A preparations in cattle is a public health concern because some bovine livers may contain high levels of vitamin A which are potentially teratogenic for pregnant women.[22]

Oral vitamin A

The oral administration of a single bolus of vitamin A at a dose of 2.8 mg/kg BW to debilitated Sahelian cattle during the dry season was effective in raising the milk levels of vitamin A and was as effective as adding 10 g of the powder to the drinking water.[4] Both the powder and bolus products provided high levels of vitamin A in milk within 3 days of treatment and according to herder testimonials, night-blind people consuming milk from cattle previously treated with either oral vitamin A preparation were no longer affected with night blindness.

VITAMIN K DEFICIENCY

A primary deficiency of vitamin K is unlikely under natural conditions in domestic animals because of the high content of substances with vitamin K activity in most plants and the substantial synthesis of these substances by microbial activity in the alimentary canal. Sporadic cases may occur when impairment of the flow of bile reduces the digestion and absorption of this fat-soluble vitamin. Experimentally produced vitamin K deficiency in piglets is manifested by hypersensitivity, anemia, anorexia, weakness, and a marked increase in prothrombin time. The minimum daily requirement for newborn pigs is 5 µg/kg BW and the minimum curative injection dose is four times larger.

A hemorrhagic disease of recently weaned pigs from 6 to 15 weeks of age is considered to be associated with vitamin K deficiency.[1] Affected pigs fail to grow, become pale, develop large subcutaneous hematomas and exhibit lameness and epistaxis.[1] Excessive and fatal hemorrhage following routine castration may occur in pigs from 30 to 40 days of age, but not at 15–20 days of age.[2] Subcutaneous massive hemorrhage is more common in pigs at 40–70 days of age. Prothrombin time and activated partial thromboplastin time are prolonged along with decreased levels of vitamin K-dependent factors II, VII, IX, and X.[2] At necropsy, hemorrhages are extensive in the muscles of the hindlimbs, forelimbs, and axillary and mandibular region.

Vitamin K, or vitamin K_2, given at a dose of 3 mg/kg BW IM as a single dose will restore the blood coagulation defects to normal.[3] Vitamin K_3 added to the feed at a rate of 25 mg/kg for 4 days was also effective. The cause of the vitamin K deficiency was considered to be related to the use of antibacterial drugs in the feed but this has not been substantiated.

The most important therapeutic use of vitamin K in domestic animals is in sweet clover poisoning where toxic quantities of coumarin severely depress the prothrombin levels of the blood and interfere with its clotting mechanism. Industrial poisons used in rodent control which contain anticoagulants of the coumarin type, e.g. warfarin, cause fatal hypothrombinemia; vitamin K is an effective antidote. For warfarin-induced anticoagulation in the horse, the administration of 300–500 mg of vitamin K_1 SC every 4–6 h until the prothrombin time returns to baseline values is recommended.[4]

Diseases associated with deficiencies of water-soluble vitamins

Water-soluble vitamins, including vitamin C and the B complex, are of minor importance in ruminants (except for vitamin B_{12}) because of their synthesis in the alimentary tract of these animals.

The dairy cow's requirements for the B-complex vitamins were established in the 1940–1950s. At that time, vitamin requirements were defined as the smallest dietary amount necessary to prevent clinical signs of deficiency.[1] It was demonstrated that even when fed a vitamin-free diet, the synthesis of B-complex vitamins by the rumen microflora was sufficient to avoid deficiencies. Consequently, it was concluded that a dietary supply of B-complex vitamins was unnecessary in ruminants. However, there is now evidence that in high-producing dairy cows the requirements for biotin, nicotinic acid, folic acid, and vitamin B_{12} are increased under certain circumstances and the amounts supplied by the diet and by ruminal synthesis are not always adequate to maximize health and productivity of dairy cows.[1]

Niacin requirements per feed unit are higher with high-energy feeds. Niacin increases the number of ruminal protozoa and in cows with clinical or subclinical ketosis, repeated doses of niacin lead to a rapid decrease of non-esterified fatty acids. Dietary supplementation of niacin at 6 mg/d, have improved milk production.

Biotin supplementation of 20 mg/head per day in early lactation can result in improved hoof horn health. After 5 months of biotin supplementation, there is an improvement in the quality and resistance of cow heel and sole horns but 10 months of supplementation is required before an improvement in quality of coronary horn is observed.

Folic acid is essential for cell division and growth for protein synthesis. Supplementation of folic acid may increase milk production but there is insufficient data available to make a recommendation.

Vitamin B_{12} requirements are usually met by ruminal microflora synthesis if the dietary supply cobalt is adequate. High concentrate diets can modify bacterial synthesis of the vitamin and metabolic utilization of propionate increases the demand for *Vitamin B_{12}*.

Thiamin, nicotinic acid, riboflavin, pantothenic acid, pyridoxine, biotin, and folic acid are all synthesized by microbial activity. Nicotinic acid and vitamin C are synthesized by other means. The young calf or lamb, in the period before ruminal activity begins, is likely to receive inadequate supplies of these vitamins and deficiency states can be produced experimentally. In the pre-ruminant stage, colostrum and milk are good sources of the water-soluble vitamins, ewes' milk being much richer than cows' milk. The production of signs of deficiency of the B vitamins in horses by the feeding of deficient diets has raised some doubts as to the availability of the B vitamins synthesized in the large intestine in this species.

Vitamin C is synthesized by all species and is not an important dietary essential in any of the domestic animals. Synthesis occurs in tissues and, although blood levels fall after birth, in the newborn calf they begin to rise again at about 3 weeks of age. However, a dermatosis of young calves has been associated with low levels of ascorbic acid in their plasma and responds to a single injection of 3 g of ascorbic acid. A heavy dandruff, followed by a waxy crust, alopecia and dermatitis commences on the ears and spreads over the cheeks, down the crest of the neck and over the shoulders. Some deaths have been recorded, but spontaneous recovery is more usual.

There is some interest in the administration of high doses of ascorbic acid orally to horses to counteract the effects of stress and minimize the effects of infections. A single oral dose of 20 g of ascorbic acid does not result in any increase in plasma concentrations. However, daily administration of either 4.5 g or 20 g results in significant increases in plasma concentrations.[2]

THIAMIN DEFICIENCY (HYPOTHIAMINOSIS)

The disease caused by deficiency of thiamin in tissues is characterized chiefly by nervous signs.

ETIOLOGY

Thiamin deficiency may be primary, due to deficiency of the vitamin in the diet, or secondary, because of destruction of the vitamin in the diet by thiaminase. A primary deficiency is unlikely under natural conditions because most plants, especially seeds, yeast, and milk contain adequate amounts.

Thiamin is normally synthesized in adequate quantities in the rumen of cattle and sheep on a well-balanced roughage diet. The degree of synthesis is governed to some extent by the composition of the ration, a sufficiency of readily fermentable carbohydrate causing an increase of synthesis of most vitamins of the B complex and a high intake in the diet reducing synthesis. The etiology of polioencephalomalacia has been discussed in detail under that heading. Microbial synthesis of thiamin also occurs in the alimentary tract of monogastric animals and in young calves and lambs, but not in sufficient quantities to avoid the necessity for a dietary supply, so that deficiency states can be readily induced in these animals with experimental diets. Thiamin is relatively unstable and easily destroyed by cooking.

The coccidiostat amprolium is a thiamin antagonist and others are produced by certain plants, bacteria, fungi, and fish.

EPIDEMIOLOGY

One of the best examples of secondary thiamin deficiency is inclusion of excess raw fish in the diet of carnivores, resulting in destruction of thiamin because of the high content of thiaminase in the fish.

Two major occurrences of secondary thiamin deficiency are recorded. In horses, the ingestion of excessive quantities of **bracken fern** (*Pteridium aquilinum*) and **horsetail** (*Equisetum arvense*) causes nervous signs because of the high concentration of thiaminase in these plants. The disease has been induced in a pig fed bracken rhizomes and the possibility exists of it occurring under natural conditions. It has also been reported in horses fed large quantities of turnips (*Beta vulgaris*) without adequate grain. The second important occurrence of thiamin deficiency is in the etiology of polioencephalomalacia and is discussed under that heading.

A thiaminase-induced subclinical thiamin deficiency causing suboptimal growth rate of weaner lambs has been described.[1] Higher levels of thiaminase activity were present in the feces and rumen contents of lambs with poor growth rate compared with normal lambs. *Bacillus thiaminolyticus* was isolated from the feces and ruminal fluids of affected lambs and supplementation of thiaminase-excreting lambs with

IM injections of thiamine hydrochloride was associated with significantly improved growth rate.[1]

Thiamin deficiency occurs in sheep being subjected to live export from Australia to the Middle East.[2] Sheep that died or were clinically ill and euthanized had significantly lower hepatic and ruminal thiaminase concentrations than clinically healthy control sheep. A high proportion had thiamin concentrations comparable with those found in sheep that die with polioencephalomalacia. The evidence indicates that the thiamin deficiency is a primary one associated with deprivation of feed during transportation to the pre-embarkation feedlots. The low feed intake and failure of the ruminal microbes to adapt, thrive and synthesize a net surplus of thiamin during alterations in the ruminal environment are considered to be major contributing factors.

PATHOGENESIS

The only known function of thiamin is its activity as a cocarboxylase in the metabolism of fats, carbohydrates and proteins and a deficiency of the vitamin leads to the accumulation of endogenous pyruvates. Although the brain is known to depend largely on carbohydrate as a source of energy, there is no obvious relationship between a deficiency of thiamin and the development of the nervous signs which characterize it. Polioencephalomalacia has been produced experimentally in pre-ruminant lambs on a thiamin-free diet. There are other prodromal indications of deficiency disease. For example, there is a decrease in erythrocyte precursors and in erythrocyte transketolase. Additional clinical signs also in the circulatory and alimentary systems, but their pathogenesis cannot be clearly related to the known functions of thiamin. Subclinical thiamin deficiency due to thiaminases in the alimentary tract is associated with low erythrocyte transketolase activities and elevated thiamin pyrophosphate effects, which may explain the poor growth rate.[1]

CLINICAL FINDINGS

Bracken fern (*Pteridium aquilinum*) and horsetail (*Equisetum arvense*) poisoning in the horse

Incoordination and falling and bradycardia due to cardiac irregularity, are the cardinal clinical signs of bracken fern poisoning in the horse. These signs disappear after the parenteral administration of thiamin. Similar clinical effects occur with horsetail. Swaying from side to side occurs first, followed by pronounced incoordination, including crossing of the forelegs and wide action in the hindlegs. When standing, the legs are placed well apart and crouching and arching of the back are evident. Muscle tremor develops and eventually the horse is unable to rise. Clonic convulsions and opisthotonos are the terminal stage. Appetite is good until late in the disease when somnolence prevents eating. Temperatures are normal and the heart rate slow until the terminal period when both rise to above normal levels. Some evidence has also been presented relating the occurrence of hemiplegia of the vocal cords in horses with a below normal thiamin status. Neither plant is palatable to horses and poisoning rarely occurs at pasture. The greatest danger is when the immature plants are cut and preserved in meadow hay.

Experimental syndromes

These syndromes have not been observed to occur naturally but are produced readily on experimental rations.

In **pigs**, inappetence, emaciation, leg weakness and a fall in body temperature, respiratory rate, and heart rate occur. The electrocardiogram is abnormal and congestive heart failure follows. Death occurs in 5 weeks on a severely deficient diet. In calves, weakness, incoordination, convulsions, and retraction of the head occur and in some cases anorexia, severe scouring and dehydration.

Lambs 1–3 days old placed on a thiamin-deficient diet show signs after 3 weeks. Somnolence, anorexia, and loss of condition occur first, followed by tetanic convulsions.

Horses fed amprolium (400–800 mg/kg BW daily) developed clinical signs of thiamin deficiency after 37–58 days. Bradycardia with dropped heart beats, ataxia, muscle fasciculation and periodic hypothermia of hooves, ears, and muzzle were the common signs, with blindness, diarrhea, and loss of body weight occurring inconstantly.

CLINICAL PATHOLOGY

Blood pyruvic acid levels in horses are raised from normal levels of 2–3 μg/dL to 6–8 μg/dL. Blood thiamin levels are reduced from normal levels of 8–10 μg/dL to 2.5–3.0 μg/dL. Electrocardiograms show evidence of myocardial insufficiency. In pigs, blood pyruvate levels are elevated and there is a fall in blood transketolase activity. These changes occur very early in the disease. In sheep subjected to export, liver and rumen thiamin concentrations and erythrocyte transketolase activities, were all below levels found in clinically normal sheep.[2]

NECROPSY FINDINGS

No macroscopic lesions occur in thiamin deficiency other than non-specific congestive heart failure in horses. The myocardial lesions are those of interstitial edema and lesions are also present in the liver and intestine.

In the experimental syndrome in pigs, there are no degenerative lesions in the nervous system, but there is multiple focal necrosis of the atrial myocardium accompanied by macroscopic flabbiness and dilatation without hypertrophy of the heart.

DIFFERENTIAL DIAGNOSIS

Diagnosis of secondary thiamin deficiency in horses must be based on the signs of paralysis and known access to bracken fern or horsetail. A similar syndrome may occur with poisoning by:

- *Crotalaria* spp.
- Perennial ryegrass
- *Indigofera enneaphylla*
- Ragwort (*Senecio jacobaea*).

It is accompanied by hepatic necrosis and fibrosis. The encephalomyelitides are usually accompanied by signs of cerebral involvement, by fever and failure to respond to thiamin therapy.

TREATMENT

In clinical cases the injection of a solution of the vitamin produces dramatic results (5 mg/kg BW given every 3 h). The initial dose is usually given IV followed by IM injections for 2–4 days. An oral source of thiamin should be given daily for 10 days and any dietary abnormalities corrected.

CONTROL

The daily requirement of thiamin for monogastric animals is, in general, 30–60 μg/kg BW. The addition of yeast, cereals, grains, liver, and meat meal to the ration usually provides adequate thiamin.

RIBOFLAVIN DEFICIENCY (HYPORIBOFLAVINOSIS)

Although riboflavin is essential for cellular oxidative processes in all animals, the occurrence of deficiency under natural conditions is rare in domestic animals because actively growing green plants and animal protein are good sources and some synthesis by alimentary tract microflora occurs in all species. Synthesis by microbial activity is sufficient for the needs of ruminants but a dietary source is required in these animals in the pre-ruminant stage. Milk is a very good source. Daily requirements for pigs are 60–80 μg/kg BW and 2–3 g/tonne of feed provides adequate supplementation. The trend towards confinement feeding of pigs has increased the danger of naturally occurring cases in that species.

On experimental diets the following syndromes have been observed:

- **Pigs**: slow growth, frequent scouring, rough skin, and matting of the hair coat with heavy, sebaceous exudate are characteristic. There is a peculiar crippling of the legs with inability to walk and marked ocular lesions, including conjunctivitis, swollen eyelids, and cataract. The incidence of stillbirths may be high
- **Calves**: anorexia, poor growth, scours, excessive salivation and lacrimation, and alopecia occur. Areas of hyperemia develop at the oral commissures, on the edges of the lips, and around the navel. There are no ocular lesions.

NICOTINIC ACID DEFICIENCY (HYPONIACINOSIS)

Nicotinic acid or niacin is essential for normal carbohydrate metabolism. Because of the high content in most natural animal feeds, deficiency states are rare in ordinary circumstances, except in pigs fed rations high in corn. Corn has both a low niacin content and a low content of tryptophan, a niacin precursor. A low protein intake exacerbates the effects of the deficiency, but a high protein intake is not fully protective.

In ruminants, synthesis within the animal provides an adequate source. Even in young calves, signs of deficiency do not occur and because rumen microfloral activity is not yet of any magnitude, extra-ruminal synthesis appears probable.

The oral supplementation of niacin in the diet of periparturient dairy cows may result in an increase in serum inorganic phosphorus and a decrease in serum potassium, calcium, and sodium concentrations. Niacin has been used to study the effects of artificially induced ketonemia and hypoglycemia in cattle.

The daily requirements of niacin for mature pigs are 0.1–0.4 mg/kg BW, but growing pigs appear to require rather more (0.6–1 mg/kg BW) for optimum growth.

Experimentally induced nicotinic acid deficiency in pigs is characterized by inappetence, severe diarrhea, a dirty yellow skin with a severe scabby dermatitis and alopecia. Posterior paralysis also occurs. At necropsy, hemorrhages in the gastric and duodenal walls, congestion and swelling of the small intestinal mucosa, and ulcers in the large intestine are characteristic and closely resemble those of necrotic enteritis caused by infection with *Salmonella* spp.

Histologically, there is severe mucoid degeneration followed by local necrosis in the wall of the cecum and colon. Experimental production of the disease in pigs by the administration of an anti-metabolite to nicotinamide causes ataxia or quadriplegia, accompanied by distinctive lesions in the gray matter of the cervical and lumbar enlargements of the ventral horn of the spinal cord. The lesions are malacic and occur in the intermediate zone of the gray matter. The identical lesions and clinical picture have been observed in naturally occurring disease.

The oral therapeutic dose rate of nicotinic acid in pigs is 100–200 mg; 10–20 g/tonne of feed supplies sufficient nicotinic acid for pigs of all ages. Niacin is low in price and should always be added to pig rations based on corn.

PYRIDOXINE (VITAMIN B_6) DEFICIENCY (HYPOPYRIDOXINOSIS)

A deficiency of pyridoxine in the diet is not known to occur under natural conditions. Experimental deficiency in pigs is characterized by periodic epileptiform convulsions and at necropsy by generalized hemosiderosis with a microcytic anemia, hyperplasia of the bone marrow, and fatty infiltration of the liver. The daily requirement of pyridoxine in the pig is of the order of 100 μg/kg BW or 1 mg/kg of solid food, although higher levels have been recommended on occasions. Certain strains of chickens have a high requirement for pyridoxine and the same may be true of pigs.

Experimentally induced deficiency in calves is characterized by anorexia, poor growth, apathy, dull coat and alopecia. Severe, fatal epileptiform seizures occur in some animals. Anemia with poikilocytosis is characteristic of this deficiency in cows and calves.

PANTOTHENIC ACID DEFICIENCY (HYPOPANTOTHENOSIS)

Pantothenic acid is a dietary essential in all species other than ruminants, which synthesize it in the rumen. Deficiency under natural conditions has been recorded mainly in pigs on rations based on corn.

In pigs, a decrease in weight gain due to anorexia and inefficient food utilization occurs first. Dermatitis develops with a dark brown exudate collecting about the eyes and there is a patchy alopecia. Diarrhea and incoordination with a spastic, goose-stepping gait are characteristic. At necropsy, a severe, sometimes ulcerative, colitis is observed constantly, together with degeneration of myelin.

Calcium pantothenate (500 μg/kg BW/d) is effective in treatment and prevention. As a feed additive, 10–12 g/tonne is adequate.

Experimentally induced pantothenic acid deficiency in calves is manifested by rough hair coat, dermatitis under the lower jaw, excessive nasal mucus, anorexia and reduced growth rate, and is eventually fatal. At necropsy, there is usually a secondary pneumonia, demyelination in the spinal cord and peripheral nerves and softening and congestion of the cerebrum.

BIOTIN (VITAMIN H) DEFICIENCY (HYPOBIOTINOSIS)

Biotin or vitamin H, has several important biochemical functions. It is a cofactor in several enzyme systems involved in carboxylation and transcarboxylation reactions and consequently has a significant effect on carbohydrate metabolism, fatty acid synthesis, amino acid deamination, purine synthesis, and nucleic acid metabolism. Biotin is found in almost all plant and animal materials and, being required in very small quantities, is unlikely to be deficient in diets under natural conditions, especially as microbial synthesis occurs in the alimentary tract.

Cattle

Biotin is now considered a significant factor in lameness of cattle.[1] Biotin is important for the differentiation of epidermal cells which are required for normal production of keratin and hoof horn tissue. Biotin also acts as a co-factor in carboxylase enzymes and is an important factor in both gluconeogenesis and fatty acid synthesis. Significant differences in the fatty acid profile of horn tissue of cattle with claw lesions have been observed. Biotin supplementation reduces clinical white line disease, reduces horn lesions, and improves horn quality by strengthening the intercellular cementing material between keratinocytes.[2] Improved hoof integrity in intensively managed dairy cows has occurred following biotin supplementation.[3] However, a long period of supplementation is required before the effect of the vitamin on hoof health care is expressed. In addition, there may be improved milk production, milk composition, and cow fertility with biotin supplementation.

Biotin is synthesized in the rumen and absolute biotin deficiency has not been recognized. However, ruminal synthesis of biotin may be compromised by acidic conditions in the rumen, which may increase the need for supplementation of biotin in the diet of high-producing dairy cows. In the dairy cow in the periparturient period and early lactation, the levels of biotin may decrease. A decrease in plasma biotin levels of dairy cows at 25 days in milk (DIM), returning to constant levels from 100 DIM until the end of lactation.[3] Feeding supplemental biotin at 20 g/d during the last 16 days post partum and at 30 g/d from calving through to 70 days post partum elevated concentrations of plasma and milk com-

pared with cows unsupplemented with biotin.[4] Supplemental biotin also elevated plasma glucose and lowered non-esterified fatty acids, which indicates that supplemental biotin is involved in hepatic gluconeogenesis. The triacylglycerol concentration in liver tended to decrease at a faster rate within 2 days after parturition.

The supplementation of Holstein cows in the Atherton Tablelands in Australia, with biotin at 20 mg/head per day resulted in improved locomotion scores compared to unsupplemented cows.[5] In the wet summer period, the number of lame cows observed by the farmer, were significantly fewer during the rainy period for the biotin-supplemented herds and required fewer antibiotic treatments than unsupplemented herds. Most hoof lesions were most commonly observed in the outer claws of the hind limb.

In a randomized control field trial on five commercial dairy farms in Gloucestershire, south-west UK, the effect of parity and duration of supplementation with oral biotin at 20 mg/d on white line disease was studied over a period of 18 months.[6] The incidence of white line disease increased with increasing parity independent of biotin supplementation from two cases per 100 cow years in primiparous cows to 15.5 cases per 100 cow years in all multiparous cows, but up to 47.7 cases per 100 cow years for cows in parities =5. Supplementation with biotin reduced white line disease lameness by 45% in multiparous cows down to 8.5 cases per 100 cow years, whereas the effect of biotin supplementation in primiparous cows was not significant. A supplementation of length of at least 6 months was required to reduce the risk of white line lameness in multiparous cows. The overall incidence rate of lameness (per 100 cows per year) was 68.9 with a range of 31.6 to 111.5 per farm.[5,7] The incidence rates of the four most frequently reported causes of lameness were sole ulcer, 13.8; white line separation, 12.7; digital dermatitis, 12.0; and interdigital necrobacillosis, 7.1 per 100 cows per year. The incidence of lameness was highly variable between farms. However, when the data from all farms were pooled, the risk of lameness caused by white line separation in cattle supplemented with biotin was approximately 50%. Approximately 130 days of biotin supplementation is required before a significant difference in white line lesion lameness occurs.

A controlled 14-month field trial evaluated the effect of biotin supplementation on hoof lesions, milk production and reproductive performance of dairy cows housed in the same free-stall facility with the same environment, base diet, and management.[8] Supplemented cows received 20 mg/d by computer feeder. The feet of a select number of cows were trimmed three times at 6-month intervals and hoof health was evaluated. At the final hoof trimming, the incidence of sole hemorrhages was significantly higher in the control group (50%) compared with the supplemented group at 24%. No cases of lameness occurred. Milk production and fat yield increased in all parities and fertility was improved in first calf heifers.

It is possible that biotin improves the quality of claw horn, which encourages the replacement of defective horn, improves healing and makes it less likely for sole lesions to develop from laminitis in its early stages. The administration of biotin at 40 mg per day for 50 days to dairy cows with uncomplicated sole ulcers, resulted in significant improvement in histological horn quality of the newly formed epidermis covering the sole ulcer.[9] Biotin supplementation at 20 mg/d did not affect the tensile strength of the white line.[10]

Vertical fissures, or sandcracks, are vertical cracks of the hoof that may extend across the coronary band and continue to the bearing surface of the dorsal wall of the claw.[11] Sandcracks are common in beef cattle in western Canada. One survey, 37.5% of beef cows were affected with one or more cracks. Supplementary dietary biotin at 10 mg/head per day significantly increased serum levels of biotin and increased claw hardness compared with unsupplemented cows. After 18 months, 15% of the biotin supplemented cows had vertical fissures compared with 35% in the unsupplemented cows.

Pigs

The principal source of biotin for the pig is the feed it receives and feeds vary greatly in their biotin content and in the biological availability of that biotin. Diets based on cereals with a low available biotin content may provide insufficient dietary biotin for the maintenance of hoof horn integrity in pigs. The biotin content in basal diets fed to pigs has varied from 29 to 15 μg/kg available biotin and supplementation of these diets has resulted in improvements in litter size. Continuous feeding of sulfonamides or antibiotics may induce a deficiency. An antivitamin to biotin (avidin) occurs in egg white and biotin deficiency can be produced experimentally by feeding large quantities of uncooked egg white.[12]

In pigs, experimental biotin deficiency is manifested by alopecia, dermatitis, and painful cracking of the soles and the walls of the hooves.[13,14]

Naturally occurring outbreaks of lameness in gilts and sows associated with lesions of the soles and the walls of the hooves, which responded to biotin supplementation, have now been well-described.[13,14] The severe lameness and long course of convalescence have been responsible for a high rate of culling in breeding animals. In gilts fed a basal diet with a low level of biotin (32 μg available biotin/kg) from 25 kg live weight to 170 days of age, there were no significant differences in the number of lesions and claws affected compared with gilts fed a biotin-supplemented diet (350 μg available biotin/kg).[15] However, between 170 days of age and the first weaning, the incidence of hoof lesions increased markedly. Over the next four litters, the incidence of lesions increased with the age of the sow. The predominant lesions in the foot were cracks, which occurred mainly in two associated regions: the heel/toe junction and the heel and the sidewall and adjacent white-line region of the toe.[15] Supplementation of the diet of breeding sows with biotin at an early stage of development makes a significant contribution to the maintenance of horn integrity.

Affected animals become progressively lame after being on a biotin-deficient ration for several months. Arching of the back and a haunched stance with the hindlegs positioned forward occurs initially. This posture has been described as a 'kangaroo'-sitting posture. The foot pads become softer and the hoof horn less resilient. The feet are painful and some sows will not stand for breeding. Deep fissures at the wall-sole junction may extend upwards beneath the wall horn and gaping cracks may separate the toe and heel volar surfaces. The foot pads initially show excessive wear, later longitudinal painful cracks develop. In well-developed cases, the foot pads appear enlarged, the cracks are obvious and covered by necrotic debris. The foot pads of the hindfeet are usually more severely affected that those of the forefeet and the lateral digit is more frequently affected. The dewclaws also are affected by cracks and the accumulation of necrotic tissue.

Skin lesions also develop in affected gilts and sows. There is gradual alopecia, particularly over the back, the base of the tail, and the hindquarters. The hairs are more bristly than normal and break easily. The alopecia is accompanied by a dryness of the skin.

As the lesions of the feet and skin develop there is a marked drop in the serum biotin concentrations, which is considered as a sensitive index of biotin deficiency.[12] Adequate biotin status may be indicated by serum biotin levels (ng/L) >700; marginal, 600–700; inadequate,

400–600; and deficient below 400.[12] Compression and hardness tests made on external hoof have also been used as an indirect measure of biotin adequacy in pigs.[16] The tests indicate that significant improvements in the strength and hardness of pig hoof horn are produced by biotin. Supplementation of the diet with biotin does not affect either horn growth or wear rates.[14] Biotin supplementation does affect the structure of the coronary epidermis; there is an increase in the density of the horn tubules in the stratum medium, the horny squames in the stratum medium are more tightly packed and the tubules are more clearly defined.[17]

Reproductive performance of sows is also influenced by their biotin status.[18] Supplementation of the diet with biotin may increase litter size, increase the number of pigs weaned, decrease the mean interval in days from weaning to service and improve conception rate. Over a period of four parities, piglet production increased by 1.42 pigs/sow year.[18]

Biotin requirements

Pigs

The daily requirements of biotin for pigs have not been well-defined, but certain amounts have been associated with an absence of lameness and improved reproductive performance. Basic diets for gilts contain 35–50 μg/kg and the addition of 350–500 μg/kg is recommended. This provides a daily intake of 4.0–5.0 mg/sow per day. The response to dietary supplementation may take several months; therefore, supplementation should begin at weaning. The details of biotin studies in pigs, including experimental deficiency, the absorption and synthesis of biotin, biotin availability in feedstuffs, and the biotin requirements of the growing pig are available.[19]

Supplementation of a basal diet, calculated to contain 56 μg/kg available biotin with daily allowances of biotin at 1160 μg/sow per day in pregnancy and 2320 μg/sow per day in lactation, produced significant improvements in litter size in second and fourth parity sows. It is suggested that the requirement is in excess of 175 μg available biotin per kg of diet.[18] In a swine herd with a lameness problem, the supplementation of the sow's ration during pregnancy and lactation with daily intakes of biotin of 400 and 800 μg/sow per day, respectively and the rations of the weaners and growers to 150 and 250 was effective.

Horses

The dietary supplementation of horses with 10–30 mg biotin/d for 6–9 months is considered to be effective as an aid in the treatment of weak horn hoof in horses.[20] The hoof horn quality of more than two-thirds of the Lippizaner horses had moderate to severe changes: microcracks visible in the transition from the middle to the inner zone of the coronary horn; separation of the sole from the coronary horn in the region within the white zone. Biotin supplementation for 19 months improved horn quality.[21] Continuous dietary supplementation with biotin at a daily dose of 20 mg is necessary to improve and maintain hoof horn quality in horses with less than optimum quality hoof.[22]

FOLIC ACID DEFICIENCY (HYPOFOLICOSIS)

Folic acid (pteroylglutamic acid) is necessary for nucleic acid metabolism and its deficiency in humans leads to the development of pernicious anemia. A dietary source is necessary to all species and an adequate intake is provided by pasture. Although naturally occurring deficiencies have not been diagnosed positively in domestic animals, folic acid has numerous and complex interrelationships with other nutrients and the possibility of a deficiency playing a part in inferior animal performance should not be overlooked. The vitamin has a particular interest for equine nutritionists. Permanently stabled horses and some horses in training may require additional folic acid, preferably on a daily basis by the oral route.[1] Folic acid deficiency can be induced in fetal foals and adult horses by administration of folate orally coincident with administration of inhibition of folate metabolism (pyrimethamine trimethoprim, sulfonamides).[2,3] Folic acid at a dose of 1 mg/kg BW orally daily for 2 weeks was used successfully for the treatment of acquired alopecia in a 3-week-old Charolais calf, but spontaneous recovery without treatment was a possibility.[4]

CHOLINE DEFICIENCY (HYPOCHOLINOSIS)

Choline is a dietary essential for pigs and young calves. Calves fed on a synthetic choline-deficient diet from the second day of life develop an acute syndrome in about 7 days. There is marked weakness and inability to get up, labored or rapid breathing, and anorexia. Recovery follows treatment with choline. Older calves are not affected. On some rations, the addition of choline increases daily gain in feedlot steers, particularly during the early part of the feeding period.

Supplementation of 20 g/day of rumen protected choline to dairy cows 14 days before parturition increased milk production during the first month of lactation and the concentration of choline in milk, but did not affect fat or protein concentration in the milk, or plasma levels of glucose, β-hydroxybutyrate, cholesterol and non-esterified fatty acids (NEFA).[1] The NEFA concentrations at the time of parturition were lower in treated animals than in controls, indicating improved lipid metabolism. Choline also increased α-tocopherol plasma concentrations.

In pigs, ataxia, fatty degeneration of the liver and a high mortality rate occur. Enlarged and tender hocks have been observed in feeder pigs. For pigs, 1 kg/tonne of food is considered to supply sufficient choline.[2]

Congenital splayleg of piglets has been attributed to choline deficiency but adding choline to the ration of the sows does not always prevent the condition.

VITAMIN B_{12} DEFICIENCY (HYPOCYANOCOBALAMINOSIS)

Vitamin B_{12} deficiency is unlikely to occur under natural conditions other than because of a primary dietary deficiency of cobalt, which is an important disease in many countries of the world.

Although microbial synthesis of the vitamin occurs in the rumen in the presence of adequate cobalt and in the intestines of other herbivores such as the horse, it is probably a dietary essential in the pig and young calf. Animal protein is a good source. A deficiency syndrome has been produced in young calves on

a synthetic ration. Signs include anorexia, cessation of growth, loss of condition, and muscular weakness. The daily requirement under these conditions is 20–40 μg of vitamin B_{12}. Sows vary in their ability to absorb the vitamin and those with poor absorption ability, or on deficient diets, show poor reproductive performance. For pigs, 10–50 mg/tonne of feed is considered to be adequate.[1]

The vitamin is used empirically in racing dogs and horses to alleviate parasitic and dietetic anemias in these animals at a dose rate of 2 μg/kg BW. Cyanocobalamin zinc tannate provides effective tissue levels of vitamin B_{12} for 2–4 weeks after one injection and normal and abnormal blood levels have been established for all species. It is also used as a feed additive for fattening pigs, usually in the form of fish or meat meal or as 'animal protein factor'. It is essential as a supplement if the diet contains no animal protein and maximum results from the feeding of antibiotics to pigs are obtained only if the intake of vitamin B_{12} is adequate.

Diseases associated with physical agents 31

ENVIRONMENTAL POLLUTANTS AND NOISE

Pollution from outside the farm

Deposition of contaminants in soil and water and on plants can derive from a large number of sources including atmospheric pollution, residues from the petroleum and metalloferrous industries – both mining and smelting, persistent pesticides, and the application of sludge. Deposition in soil, but not on plants, does not preclude animal toxicity as soil can comprise a significant proportion of the dry matter (DM) intake of grazing ruminants.[1] Pollutants may exert their effect through direct toxicity, immunosuppression[2,3] or, in the case of some heavy metals, also by the competitive induction of trace element deficiencies.

Mine spills and **smelter emissions** have been associated with soil and water contamination with a number of different heavy metals. Water from mines is also potentially toxic to livestock that drink it.[4] Pastures adjacent to **major roads** and animals grazing them, are also contaminated by heavy metals from vehicle emissions.[5] Cattle will readily ingest petroleum products and the toxicology of **oil field pollutants** has been reviewed.[6] Another important group of compounds is the polychlorinated biphenyls and the **polybrominated biphenyls** and the chlorinated hydrocarbons generally. These substances are extensively used in agriculture and in industry. They have very long half-lives and although they are not in themselves dangerous, they cause a great deal of trouble if they get into the human food chain and become deposited in fatty tissues.

Pollution from farms

Pollution of the environment by animal feces and urine is now a matter of great importance especially to intensive animal farmers located near population centers. There are increasing regulations governing livestock farming, effluent disposal, nitrogen and mineral cycles, odor emission and increasing regulatory actions, or private law suits, against farms that offend. This is not a subject for a text on veterinary medicine although efforts to minimize nitrogen, phosphorus, and potassium fecal outputs by dietary manipulation and water restriction[7–9] have potential veterinary and welfare implications.

Slurry application to pastures and run off to streams and ground water introduces health problems such as salmonellosis, cryptosporidiosis, leptospirosis, and mycobacteriosis, under which headings the subject is discussed. Shallow wells near animal accommodation are also likely to contain high levels of nitrates derived from nitrogen filtering through surrounding earth. Such water is a potential source of nitrate poisoning especially in pigs.

One of the important pollutants for housed animals is **ammonia** from urine. When it is combined with dust, it can cause severe inflammation of the respiratory mucosae. **Dust** may be the carrier of pathogenic bacteria or viruses, or antigens which provoke a hypersensitivity reaction, e.g. interstitial pneumonia.[10] Carbon monoxide and hydrogen sulfide from **slurry pits** can cause mortality in both animals and humans. The highest risk is during agitation of the slurry, when they are released. Sulfur dioxide is also an environmental contaminant capable of causing respiratory tract irritation in animals.

Noise

Animals are more susceptible to high-pitched noise than are humans and the elimination of such noises in working facilities improves the **orderly handling** of cattle and sheep.[11] Pollution by noise,[12] a matter of increasing importance for veterinarians who police codes of practice for animal welfare and for those who are called upon to act as expert witnesses in cases involving excessive noise and its effects on animals, is also an important subject.

The effects of a sonic bang from **aircraft** are shortlived and are due to fear reactions but include injury due to sudden flight, killing of young by mink and rabbits, suffocation in panic-stricken chickens and reduced egg production. Cattle are unaffected and the effect on livestock and wildlife of the noise produced by low flying aircraft appears minimal.[13–15]

RADIATION INJURY

Synopsis

Etiology Ionizing radiation from radionuclides in environment or feed resulting from nuclear bombs or nuclear power plant accidents.
Epidemiology Type, severity and extent of exposure will depend on atmospheric conditions and the radionuclides released.
Clinical findings Anorexia, depression, and severe diarrhea in acute sickness. Bone marrow depression with anemia and septicemic disease.
Clinical pathology Neutropenia and thrombocytopenia, bone marrow depression.
Necropsy findings Hemorrhagic and ulcerative lesions in the alimentary tract. Pneumonia, general septicemia.
Diagnostic confirmation Radiation exposure from nuclear disaster.

Animals exposed to radioactive material may suffer radiation injury. They may also serve as reservoirs for radioactive material which could be passed to humans in meat, milk, and other animal products. This hazard to humans is a problem of public health and is primarily addressed by establishing tolerance limits for contamination in animal products for human food and by changes in agronomic practices and policy. Reviews of measures taken following the Chernobyl accident are cited in the Review Literature at the end of this section. The following discussion is restricted to the effects of irradiation on the health of animals exposed to it.

ETIOLOGY

Radiation injury can be caused in a number of ways including nuclear bombs, contamination from nuclear power plant accidents and exposure to X-rays, but the effects on the tissues are the same, differences occurring only in depth of penetration and degree of injury caused. The radiation emitted by radionuclides has a similar biological effect to external irradiation by X-rays because both sources are **ionizing** – they remove electrons from their orbits causing atoms within animal tissue and produce pairs of charged ions, which are the instruments of the biological damage.

Atomic explosions can also injure through the effects of blast and heat.

EPIDEMIOLOGY

Incidence and case fatality

There is considerable variation in the effects of an atomic explosion, or a nuclear power plant accident, depending on the distance from and the time after the blast, whether the explosion occurs in the air or on the ground surface and the types of radionuclides released.[1,2] With nuclear explosions, animals within the range of immediate irradiation are more severely affected than those exposed only to the 'fallout' of radionuclides on pasture. However, grazing animals are exposed to very great risk because of this fallout. The area where direct radiation effects occur is significantly smaller than that where 'intervention levels' for radionuclides are exceeded.[1]

Risk factors

Animal

Radio sensitivity differs between animal species when death is defined as the end point. Horses are more resistant to whole body radiation than other animal species. Sheep appear the most susceptible and die earlier than cattle at equivalent exposure doses. Pigs are the least susceptible to low radiation. Age is also a risk factor and calves are more susceptible than adult cattle and are prone to develop respiratory and enteric disease, effects that are uncommon in adult cattle which commonly show hemorrhagic disease.[2]

Nature of radiation

Of the radioactive materials produced by an atomic explosion, a number of **radionuclides**, including iodine-131, barium-140, strontium-89 and strontium-90, cesium-134 and cesium-137, are likely to enter biological systems. Of these, radioactive iodine, barium, and strontium-89 are of less importance because of their short **half-lives**. On the other hand, strontium-90, cesium-134, and cesium-137 may occur in very large quantities, have long half-lives and are therefore of greatest biological significance. If sufficient of these radionuclides is ingested and tissue levels of them reach critical points, injury similar to that produced by external irradiation will occur. Cesium-134 and cesium-137 are of particular concern because of their biological mobility. They behave metabolically like potassium and are distributed widely through the body. Both are beta and gamma emitters and effectively will administer a dose of whole-body radiation to an animal ingesting pasture contaminated with them. Iodine-131 (^{131}I) behaves like stable iodine and is concentrated in the thyroid gland.

Soil type can influence radionuclide intake by animals grazing contaminated pastures. Persisting concentrations of radiocesium in plants are associated with acid soils with high organic and low clay content.[3] In mineral soils, cesium is strongly bound to clay particles which limits its uptake by plants; clay minerals, such as bentonite, fed to ruminants will reduce the alimentary absorption of radiocesium.[4] Animal contamination is further influenced by **differences in uptake** of radionuclides by different pasture species and animal breed differences in **grazing behavior.**[5,6]

Zoonotic implications

Radionuclides are excreted in the **milk** of animals[7,8] and are present in the **meat**,[5,9,10] posing a risk for humans consuming them. Radioiodine transfer to the milk of sheep and goats is considerably greater than to that of cows.[10] The half-life of radioiodine is sufficiently short that contaminated milk could be diverted to stored dairy products, although this would not have public acceptance. The **maximum permissible concentration** of radioactive substances in meat is reached at much lower levels of pasture contamination than would be required to cause physical injury to the cattle or sheep; in most countries it is set at around 1000–2000 Becquerels (Bq) per kg fresh weight.

PATHOGENESIS

The acute radiation syndromes and from acute radiation usually occur within the first few days after exposure to whole body radiation to 30–60 days depending on the radiation dose. Based on the dose the major manifestations have been divided into three major presentations, CNS, gastrointestinal, and hemorrhagic, but there is considerable overlap in clinical signs at all but the high doses that result in the per-acute CNS syndrome.[2]

Doses greater than 80–100 Gray (Gy) induce rapid damage to blood vessels, changes in permeability and an increase in intracranial pressure with death in 2–5 days. Gastrointestinal disease results when the radiation dose ranges between 10 and 80 Gy and results from damage to the rapidly dividing undifferentiated cells in crypts of intestinal villi which are the progenitor cells to the differentiated enterocytes of the intestinal villi. Damage to bone marrow stem cells is the main cause of death at whole body doses between 2 and 10 Gy with death in large animals occurring 6–8 weeks after exposure. Clinical disease is slow in development after exposure as the effect of this damage is not evident until the death of existing circulating blood cells. The effects are the result of decreased granulocytes, platelets, and red cells and are manifest with increased susceptibility to infection, bleeding syndromes, and anemia.

Initially there is a lymphopenia followed by a depression of granulocyte and platelet counts. The leukopenia permits invasion by bacteria from the alimentary tract and **bacteremia** and septicemia develop 1–4 weeks after irradiation. The clotting mechanism and antibody production are impaired and facilitate the invasion. Progressive necrosis of the gut wall without inflammation is characteristic. Thrombocytopenic hemor-

rhage into the lymphatic system and other tissues lead to the development of a profound anemia.

The activity of **germinative epithelium** is also profoundly depressed; if the animal survives the early stages listed above, the hair commences to shed, the skin to ulcerate, and a gross reduction in fertility occurs. Degenerative changes in the lens of the eye, particularly cataract, may also occur. **Long-term effects** in animals are of less concern than in man because of the short life span of animals and any genetic damage can be removed by selective breeding. Very long-term effects of irradiation include a high rate of **mutations** and a high incidence of tumors, mostly of the hemopoietic system but also an increased risk for squamous cell carcinoma of the skin.

Thyroid damage by ^{131}I does not appear a major risk for ruminants. The thyroid gland of the sheep is more radiosensitive than that of the cow but very high and sustained doses of ^{131}I are required to produce damage and clinical signs in thyroid-damaged ruminants are minimal.

CLINICAL FINDINGS

Acute syndrome

After immediate irradiation with high doses death occurs from damage to the CNS. At lesser doses damage to the alimentary tract occurs and, particularly in young animals, there is a resulting intense, refractory diarrhea. Death occurs in a few days due to dehydration and electrolyte imbalance. Local contact of radioactive materials to skin causes changes within a few hours. Observable lesions vary from depilation and slight desquamation to extensive necrosis depending upon the irradiation dose.

Subacute syndrome

Immediately after irradiation with median doses there is an **initial phase** of 'radiation sickness' characterized by anorexia, vomiting in pigs, and profound lethargy which lasts from several hours to several days.

The **second phase** is one of apparent normality lasting until 1–4 weeks after irradiation. This is followed by a **third phase** in which most deaths occur associated with damage to stem cells in bone marrow and secondary infections. Clinical signs vary with the nature of the infection and the age of the animal. Calves commonly develop respiratory and enteric disease with fever, weakness, and diarrhea developing to melena and dysentery, sometimes with tenesmus. Anorexia is complete but there is great thirst. Weakness, recumbency and hyperirritability are present. Respiration is rapid and panting and there is a profuse nasal discharge, sometimes blood-stained. In adult cattle severe anemia and septicemia occur.

In general, if the animal survives this period, there is a **long period of convalescence** which is accompanied by failure to make normal weight gains, alopecia, sterility, and lenticular defects. The sterility may be permanent, or normal fertility may be restored by the end of 8 months in pigs and 2 years in cattle. During the ensuing years, recovered animals may produce mutant offspring. Tumors, especially of the hemopoietic system and of areas of skin which suffer radiation injury are also likely to occur.

Experimental irradiation of pregnant animals causes fetal death and resorption, defects of individual organ and limb development, decreased survival of young born alive and depressed growth rate and fertility of surviving young, the type of abnormality depending upon the stage of pregnancy at which exposure is experienced.

Chronic exposure

Chronic exposure to gamma and mixed neutron-gamma radiation for several years produces lenticular opacities.[11] At levels of irradiation which cause lesions in the human lens similar opacities occur in the lens of cattle, but not of pigs or burros.

CLINICAL PATHOLOGY

In cattle receiving median somatic doses, the **total leukocyte count** falls precipitately during the first few days after irradiation with the peak of fall at the 15th–25th post-irradiation (PI) day. In this species, the most sensitive leukocyte is the **neutrophil**, in contrast to the lymphocyte which is most seriously affected by irradiation in humans.

Platelet counts begin to decrease from a normal of 500 000/mm^3 on the 7th PI day to 40 000/mm^3 at about PI day 21.

Erythrocyte counts and hematocrit levels also fall and prothrombin times increase in parallel to the other changes mentioned. The return to pre-irradiation levels requires about a year for granulocytes and platelets, but from 4 to 5 years for agranulocytes.[12]

NECROPSY FINDINGS

Gastroenteritis, varying from hemorrhagic to ulcerative, is constant and ulceration of the pharyngeal mucosa and pulmonary edema occur commonly. Hemorrhages into tissues are also characteristic and include all degrees from petechiae and ecchymoses to hematomas and large extravasations. In experimentally produced irradiation sickness, a severe fibrinous pneumonia, pleuropneumonia, and pericarditis are common. Degeneration of many tissues,[13] but especially bone marrow, intestinal mucosa, and lymphoid tissue is evident histologically. Evidence of secondary bacterial invasion is usually seen. Confirmation of the diagnosis usually requires documentation of exposure to radiation.

Samples for confirmation of diagnosis

- **Histology: jejunum, lymph node, bone marrow.**

DIFFERENTIAL DIAGNOSIS

The subacute syndrome closely resembles poisoning by bracken fern in cattle and by trichloroethylene-extracted soybean meal, but the diagnosis will usually depend upon a knowledge of exposure to irradiation.

CONTROL

The problems of veterinary civil defence in the event of thermonuclear warfare are too extensive to discuss here and the necessary information is provided by most governments. The use of clay minerals and iron-hexacyanoferrates in the feed can bind and **restrict the uptake** of radiocesium from the alimentary tract of ruminants but is impractical for widespread use.[4,14] Long-term control of exposure rests with changes in agronomic practices.[1,10,15]

BRISKET DISEASE (MOUNTAIN SICKNESS)

Synopsis

Etiology Cor pulmonale from effects of alveolar hypoxia.
Epidemiology Sporadic disease, at high altitudes, of cattle, particularly young or newly introduced. Genetic susceptibility. Exacerbated by grazing locoweed.
Clinical findings Right-sided congestive heart failure. The name derives from the edema that occurs in the brisket region.
Clinical pathology None usually practiced because of location. Pulmonary arterial pressures. Echocardiography.
Necropsy findings Right-sided congestive heart failure.
Diagnostic confirmation Clinical and epidemiological. Recovery with movement to lower altitudes.
Treatment Move to lower altitudes.
Control Identification of susceptible cattle. Avoidance of grazing locoweed.

ETIOLOGY

Alveolar hypoxia in cattle at high altitudes results in pulmonary hypertension and the resultant increase in pressure load on the right ventricle can lead to cor pulmonale and heart failure. Any additional factor such as myocardial dystrophy, anemia, pulmonary disease, or hypoproteinemia may exacerbate the primary condition. The additional effort required to obtain feed on sparse pasture at high altitudes may also be a predisposing cause.

EPIDEMIOLOGY

Occurrence

Brisket disease occurs sporadically in high mountainous areas in North America and South America. The disease also occurs in the highlands of Ethiopia and India.[1] Cattle residing above 1500 m are predisposed and at altitudes above 2200 m an annual incidence of 0.5–2% is recorded.[2]

Risk factors

Brisket disease can occur in all ages and breeds of **cattle** that are maintained at high altitudes for some months. The incidence is highest in calves, yearlings, in late pregnant cattle, and in cattle newly introduced to these altitudes. Cattle can adapt to high altitudes and the morbidity rate in indigenous cattle seldom exceeds 1%. In affected cattle, case fatality is high unless they are moved to lower altitudes. Susceptibility is **inherited**.[2]

The ingestion of **locoweed** (*Oxytropis sericea*) intensifies the effect of high altitude on the development of congestive heart failure. The mechanism is unknown,[3,4] but when groups of cattle at high altitude graze locoweed the annual incidence may approach 100% with high case fatality.[5] An unidentified plant is also believed to potentiate the disease in mountainous areas of Brazil.

The congestive heart failure that develops at altitude is peculiar to cattle although other animal species may show an effect from altitude. **Horses** which are moved up from 300 to 2400 m above sea level show standard increases in pulse and respiratory rates and hemoglobin and erythrocyte levels. **Mules** are much less susceptible and appear to be unaffected by altitudes as high as 3200 m. **Goats, sheep**, and **donkeys** are also reputed to be affected in that order of reducing susceptibility. **Llamas** and **alpacas** are adapted to hypoxia at high altitudes, in particular by an oxygen dissociation curve in their hemoglobin which increases oxygen uptake.[6]

PATHOGENESIS

Acute alveolar hypoxia (lowered alveolar PO_2) is a potent cause of constriction of the precapillary pulmonary vessels and pulmonary hypertension in several species, but cattle are especially reactive and there is a genetic predisposition that determines the magnitude of the response. Prolonged hypoxia and persistent pulmonary vasoconstriction leads to medial muscular hypertrophy of the small pulmonary arteries and arterioles with a further increase in pulmonary vascular resistance and the development of cor pulmonale.

The disease can be produced experimentally in low-pressure chambers. The movement of cattle from an altitude of 1100 up to 3000 m has been shown to cause hypertrophy of the right ventricle, an increase in pulmonary arterial pressure from 27 mmHg (3.6 kPa) to 45 mmHg (6.0 kPa) to over 100 mmHg (13.3 kPa) and the development of right heart failure.

CLINICAL FINDINGS

Affected cattle have a dejected appearance, loose condition rapidly, have a rough, lusterless coat and stand with the elbows abducted. Jugular vein engorgement is followed by the appearance of edema of the brisket, spreading up the neck to the intermandibular space and back along the ventral aspect of the body. Abdominal enlargement due to the development of ascites is accompanied by diarrhea.

There is hyperpnea at rest and dyspnea and weakness on slight exertion. The mucosae may be cyanotic, particularly after exercise and the lung sounds vary from an increased vesicular murmur to moist crackles and an absence of breath sounds when pneumonia is present and to crepitant crackles in the presence of emphysema.

Auscultation of the heart reveals tachycardia, increased absolute intensity of the sounds, or a decrease when there is hydropericardium and an increase in the size of the heart. A systolic murmur is usually present and a '**pistol shot**' sound can often be heard with auscultation over the jugular vein. The appetite is normal until the late stages and the temperature is normal unless secondary pneumonia develops.

Horses at high altitude lose weight, fatigue easily, become weak and rough-coated and show pain; many suffer from flatulent colic but do not develop congestive heart failure.

CLINICAL PATHOLOGY

In sheep and cattle, a change to altitudes of 1800–3500 m causes rises in hemoglobin (35% in sheep, 9% in cattle) and packed cell volumes (27% in sheep but no change in cattle) and hemoglobin concentration in red cells (8–9% increase in cattle and sheep).[7] Central pulmonary arterial pressures increase significantly immediately after cattle are moved to high altitudes, but the high pressures subside as adaptation develops. Pressures rise from a normal of 22–26 mmHg (2.9–3.5 kPa) up to 37–55 mmHg (4.9–7.3 kPa) depending on whether the calf is susceptible or resistant to the effects of altitude.[8] Cattle accustomed to live at high altitudes have much less pulmonary hypertension than introduced cattle.[9]

In clinical cases, there can be a significant reduction in the packed cell volume and in hemoglobin levels.

NECROPSY FINDINGS

There is enlargement of the heart, with dilatation of the right ventricle and hypertrophy of the right ventricular wall.[8] Slight thickening of the heart valves may be present and there may be areas of calcification in the large arteries. Accumulations of edema fluid are within the pericardial sac, peritoneal and pleural cavities and in subcutaneous tissues. This edema may also involve the wall of the alimentary tract. Typical congestive changes are evident in the liver – enlargement, rounding of the edges, an enhanced zonal pattern on capsular and cut surfaces, dilatation of the hepatic veins and a marked deposition of fibrous tissue around the central veins. In the lungs, there is often severe alveolar emphysema and in some cases, bronchitis and pneumonia are also present. Histologically, the changes include thickening of the tunica media of vessels in the pulmonary arterial tree and hypertrophy of cardiac myofibers. Microscopic findings in the liver are typical of chronic passive congestion.

Samples for diagnostic confirmation

- **Histology** – lung, liver, right ventricular myocardium (LM).

DIFFERENTIAL DIAGNOSIS

Other causes of congestive heart failure. Cor pulmonale associated with chronic pneumonia

TREATMENT

The only effective treatment is to move the affected cattle to a **lower altitude**. Pending this, avoidance of excessive exercise is advisable. Temporary improvement in severely affected animals may be achieved by treatment with digoxin and this may help counteract the stress associated with the movement off altitude, but this is only a short-term expedient. Diuretics to promote fluid loss and antibiotics to combat secondary infection may be indicated in individual cases.

CONTROL

Control measures are difficult to implement as the prime predisposing factor is the grazing of cattle at high altitudes. Avoidance of grazing of locoweed is easy to state but almost impossible to implement. Restriction of grazing of cattle showing signs by hand-feeding a high-protein diet and prompt treatment of cases of pulmonary disease are recommended as worthwhile procedures although they are really more treatment methods. The testing of cattle for pulmonary artery reactivity as a method of selection is also a possible method of long-term control in view of the heritable predisposition.

LIGHTNING STROKE AND ELECTROCUTION

Synopsis

Etiology Exposure to high-voltage electric currents.
Epidemiology Single or multiple cases. Following a thunderstorm dead animals at pasture may be under trees or along fence lines. Posterior paralysis in housed pigs.
Clinical findings Bone fractures, temporary unconsciousness, or immediate death. In recovered animals residual nervous signs may persist. Posterior paralysis in pigs.
Necropsy findings Singe and burn marks with some cases. Fractures of long bones in some cases and of lumbar vertebrae in swine.
Diagnostic confirmation Difficult. History and environmental evidence of lightning or electric shock exposure and no postmortem lesions of other causes of disease.

ETIOLOGY

The three common causes are flashes of linear lightning during thunderstorms, broken overhead electrical transmission wires which usually carry very high voltages and faulty electrical wiring in cowsheds and barns.

In lightning stroke, trees, fences, barns, and pools of water may become electrified and it is not unusual for damp ground to act as a conductor for electricity passing along the roots of stricken trees. Animals electrocuted by standing on electrified earth are unlikely to show burn marks on the body. Oak trees are particularly prone to lightning stroke and because of their spreading foliage and extensive root system, are common mediators of electrocution deaths in pastured animals. Poplar, elm, walnut, beech, ash, and conifer are also mediators of electrocution to animals that shelter under them.

Electrical transmission wires are most dangerous when they fall into pools of water, as they are likely to do during the storms which bring the wires down. In such cases, the entire pool is electrified and animals passing through it may be killed instantly. Electrocution can also occur from this source without obvious evidence of line fault.[1]

In accidents caused by **faulty wiring**, voltages of 110–220 V are sufficient to kill adult cattle provided they make good contact with the source and the ground. Water pumps and milking machines are the common sources of electricity which may electrify water pipes or the milk line through the earth wire or a short circuit. The use of very heavy fuse wire (30–60 A) may cause continuance of the trouble, which could be avoided if lower capacity fuses were used. In situations of electrical fault, certain farm owners will chose to try to circumvent it by improper use of fuse breakers that can lead to substantial risk of electrocution hazard.

EPIDEMIOLOGY

The area incidence is never high but heavy mortalities may occur on individual farms when a barn or a group of animals sheltering under a tree is struck. As many as 20 head of cattle may be killed by one lightning flash. Behavioral abnormalities of housed animals may indicate the presence of faulty wiring in barns.

Most fatalities caused by lightning stroke occur during the summer months when the cattle are at pasture. Deaths due to electrocution in barns may occur at any time.

PATHOGENESIS

Tissue damage from electrical trauma is induced by the direct effects of the electric current and the development of heat and tissue ischemia. Exposure to high-voltage electrical currents causes severe **nervous shock** with complete unconsciousness and flaccid paralysis. In some instances, focal destruction of nervous tissue occurs and **residual signs of damage** to the nervous system persist after nervous shock disappears.[2] Death when it occurs is usually due to paralysis of vital medullary centers. Ventricular fibrillation may also occur and contribute to the fatal outcome.[1] **Superficial burns** may be evident at the site of contact with the current or along the path of flow from the point of contact to ground. The burn is produced by heat generated from the resistance of tissues to the passage of the electricity. **Fractures** are believed to be the result of sudden and profound muscular contraction.

CLINICAL FINDINGS

Varying degrees of shock occur. With high-voltage currents and good earth contacts such as wet concrete floors, water, and damp earth, the animal may fall dead without a struggle. Singeing and burning are likely to occur because of the severity of the shock. The burns may be localized to the muzzle or feet and be in the form of radial deposits of carbon with or without disruption of tissue, or they may appear as tree-like, branching patterns of singeing running down the trunk and limbs.

In less severe shocks, the animal falls unconscious, **sudden collapse**, or there may be some struggling, followed by a period of unconsciousness varying from several minutes to several hours. When consciousness is regained, or the animal is removed from the electric field, the animal may rise and be perfectly normal,[1]

or show depression, blindness, ataxia, posterior paralysis, monoplegia, and cutaneous hyperesthesia. In some cases there may be more local signs including nystagmus and unilateral paralysis. Sloughing of the skin at the sites of burns may occur after a few days. These signs may persist or disappear gradually over a period of 1–2 weeks. With electrocution in **pigs** caused either by lightning stroke or wiring faults, the major signs are related to spinal injury or to fracture of the ileum, ischium, and the transverse processes of the lumbar vertebrae with a large number of animals exhibiting apparent lameness and especially posterior paralysis.[3,4] Vestibular disease is described as a sequela to lightning strike in horses.[5]

The actual occurrence of electric shock often is not observed and electrocution should always be considered in the differential diagnosis of spinal or pelvic fracture or injury in pigs.

With minor shocks, especially as they occur in barns on low-voltage domestic current, the animal may be knocked down or remain standing. Consciousness is not lost and the clinical picture is one of restlessness. The animal may kick violently at the stanchion or the dividing rail. The attacks may be intermittent and occur only when the cattle supply a good ground contact such as standing in the gutter, when they are drinking, or when they are wet. Dairy farmers are often unaffected in the same environment because their boots provide effective insulation.

CLINICAL PATHOLOGY

Laboratory examinations are of no value in diagnosis.

NECROPSY FINDINGS

If electrocution is suspected it is best to ensure that possible **sources of electric power** are shut off before proceeding with a postmortem examination.

Diagnostic lesions are often minimal[3] but singe marks on or under the skin, or damage to the environment, or both, occur in about 90% of lightning deaths. Rigor mortis develops but passes off quickly.

In cattle, anthrax is often a consideration as the carcass decomposes rapidly and blood may exude from the external orifices. The pupils are usually dilated and the anus relaxed. All viscera are congested and the blood is dark and unclotted. Petechial hemorrhages may occur throughout the body, including the trachea, endocardium, meninges, and central nervous system. The superficial lymph nodes, particularly the prescapular and the interior cervical, are often hemorrhagic. Superficial singeing of the hair, burn marks on the feet or muzzle, and internal or subcutaneous extravasations of blood in arboreal patterns also occur.

In some cases of electrocution there are longitudinal **fractures** of long bones and in incidents involving pigs, local hemorrhage and extensive fractures of the bones in the pelvic area are observed.[3] Fractures of the lumbar vertebrae have also been described in electrocuted swine.

Theoretically, the passage of electric current through tissue may cause cell nuclei to elongate and assume orientations parallel to one another. Skin lesions can be examined histologically for this change and hyperconcentration of skeletal muscle fibers may also be observed.

DIFFERENTIAL DIAGNOSIS

Great care must be taken in accepting an owner's suggestion that an animal has been killed or injured by lightning stroke. Insurance against loss by lightning is commonly carried and the many other causes of sudden death or injury are seldom covered by insurance. In order to minimize the possibility of conflict and potential future legal problems it is wise to have a representative of the insurance company present at the autopsy so that all may agree on the diagnosis.

To make the diagnosis, there should be a history of exposure and evidence of sudden injury or death. In the latter case, half-chewed food may still be present in the mouth. Burns on the skin, scorching of the grass and tearing of the bark on nearby trees are also accepted as contributory evidence. The possibility of electrocution caused by faulty wiring should be considered when sudden shocks or death occur in animals confined in stanchions. Differentials include:

- Other causes of sudden death
- Pigs: Other causes of posterior paresis/paralysis.

TREATMENT

Central nervous system stimulants and artificial respiration should be provided for unconscious animals but in most instances the animals are dead or recovered before treatment can be instituted.

CONTROL

Precautions taken to avoid lightning stroke in animals are largely ineffective, but proper installation of all electric equipment in barns and milking parlors is essential to prevent losses. All motors should be earthed to a special iron spike or pipe driven at least 2.5 m into the ground, preferably in a damp spot and electrical machinery that has potential contact with animals should be shielded. Earthing to water pipes should not be permitted. Minimum amperage fuses should be used to provide protection in cases of short-circuiting.

STRAY VOLTAGE

Synopsis

Etiology Electrical shock.
Epidemiology Risk with any electrified housing system but most recognized in dairy cattle and pig housing.
Clinical findings Behavioral changes in feeding or eating patterns, reluctance to move freely in some areas of buildings. Claims for increased disease incidence and decreased production not substantiated experimentally.
Diagnostic confirmation Demonstration of stray voltage with amelioration of the problem when this is corrected.

ETIOLOGY

Stray voltage can produce minor electrical shock and discomfort to animals. The term 'stray voltage' is used to denote an electrical voltage between two points that can result in a current flow through an animal when it contacts them. The voltages are usually low and are usually not detected by humans because of the insulation provided by clothing and footwear. **Other terms** that have been used for stray voltage include 'free electricity', 'tingle voltage', and 'transient voltage'. The term 'neutral to earth voltage' or 'neutral to ground voltage' usually applies to the voltage measured between the service entrance neutral bus and a reference ground rod. **'Cow contact voltage'** refers to voltage measured between a potential cow contact, such as a drinker and the ground.

The source and cause of the problem is complex. Stray voltage can be associated with the electrical distribution network and the farmstead wiring system and the contribution from both sources can be superimposed. **Seven potential sources** have been identified, five of which originate on the farm.[1]

EPIDEMIOLOGY

The potential presence of stray voltage has been recognized for many years but the possible relation to production and disease gained particular attention in the 1980s when different surveys indicated that over 50% of dairy farms had significant cow contact voltage and more current studies indicate a continuing problem.[2–4] Deteriorating wiring, poor wire insulation, and older buildings are **risk factors.**

Heavy milking cows are believed more sensitive to electric shock; scratched, infected, and sore muzzles and hooves may increase sensitivity.

PATHOGENESIS

The reaction of the animal to stray voltage will depend upon the current flow, or shock, which is related directly to the voltage and inversely to the **impedance** to flow in the animal.[5] The impedance decreases as body weight increases owing to increase of the surface of contact and the pressure exerted by the hoofs on the floor and, with pigs, current flow at the same voltage is higher through a gilt or sow than through a piglet.[6,7] There are some differences in impedance between different pathways in animals (e.g. mouth to hooves or udder to hooves) but there can also be individual animal **variation in sensitivity** to stray voltage.[8] In general, the problem will only be suspected if the stray voltage is high enough so that a significant proportion of the herd shows signs.

The reactivity of **cows** to different voltage levels has been studied and the **lowest behavioral perception** is observed at 1–2 V for the most sensitive cows and moderate behavioral responses at 1.5–3 V.[2,3,9] With **pigs**, feeding and drinking behavior is affected at 5 V but not at 2 V, and resting time is disturbed at 8 V.[10,11]

CLINICAL FINDINGS

Behavioral changes

The behavioral responses exhibited by **cows** exposed to stray voltage depend upon the site at which the voltage occurs and the strength of the current flow.[12] Stray voltage in the **milking parlor** results in a reluctance to enter the parlor, a reluctance to cross the floor grids, extreme nervousness while in the parlor and rapid exit or stampeding from the parlor. Where stray voltage occurs at **drinkers** cows may show reluctance to drink, with lapping of water rather than full drinking and crowding at the drinker to result in one cow being the ground while others drink.[1,3] Cows that are experiencing current flow are restless, they may tremble and the back is arched and the head is elevated with the ears held back rigidly and there is frequent urination and defecation.

In **pigs**, restlessness, increased aggressiveness and changes in drinking and feeding patterns have been associated with stray voltage.[10]

Effects on production and disease

Field observations have indicated that stray voltage in the milking parlor at milking time can result in incomplete milk letdown, increased milking times, elevated somatic cell counts, an increased incidence of clinical mastitis, and poor production.[3,4] However, **controlled trials** have found no effect of stray voltage on the incidence of disease nor an effect on production in dairy cattle[12–14] or pigs.[10,11,15]

DIFFERENTIAL DIAGNOSIS

The presence of stray voltage should be suspected where animals exhibit behavioral abnormalities and for the present, it is probably wise to consider it as part of the differential of problems of production inefficiency.

Cow contact voltage can be measured with a sensitive voltmeter but the ground must be well established. The measurement of the neutral to earth voltage does not give a good prediction of cow contact voltage and is not recommended as the sole measure for the risk of stray voltage on the farm.[2] In most instances a qualified electrician is required to correct the problem. The use of a commercially available tingle voltage filter has been recorded to significantly reduce stray levels.[3]

VOLCANIC ERUPTIONS

Active and potentially active volcanic chains exist in several countries in close proximity to significant livestock production areas. Major volcanic eruptions are rare but the experiences of the eruptions of Hecla in Iceland, Mount St Helens in the USA, the Lonquimay complex in the Southern Andes, and Ruapehu in New Zealand suggest that most are inconvenient to orderly livestock production, but have minimal effects on animal health.

Blast and gas damage

Volcanic eruption can result in devastation of land areas from the effects of lateral blast and pyroclastic, laval, and mud flows. Livestock losses which occur in this way can be total, but the affected areas are restricted to the immediate vicinity of the eruption. Toxic gases from the eruption may accumulate in close low-lying areas and result in mortality.

Ash hazards

Significantly greater land areas can be affected by tephra fallout consisting of ash and rock fragments from the volcanic eruption. The size of the sector affected by ash fallout will be determined by the strength and direction of winds at the altitude reached by the ash column at the time of the eruption, but several thousand square kilometers can receive ash fallout varying from a light dusting to falls several centimeters in depth.

The hazards to livestock during the fallout period appear minimal, although in areas where the ash fall is heavy, there is virtually total darkness. Animals, particularly sheep, mill about excessively and some die of **suffocation** or **misadventure** including drowning.

The immediate effect of the fallout is to blanket pastures with ash and in heavy fallout areas, taller succulents may become lodged and unavailable for grazing. Livestock may be forced to graze more robust, but toxic, plant species if stored feeds are not provided and loss from **plant poisoning** was observed following the Mount St Helens eruption. **Hypocalcemia**, apparently resulting from food deprivation, was also observed in the immediate post-fallout period with Mount St Helens and was also recorded following the Mount Hecla eruption.[1]

Ash fallout may have a devastating effect on insect life and this may be followed soon afterwards by death from starvation of **insectivorous avian species**. This may be misinterpreted by the public as evidence for ash toxicity.

Toxic chemicals

Potential hazards to livestock health exist in the chemical composition of ash. In the fallout from Mount St Helens and from Ruapehu several potentially toxic heavy metals and trace elements were present, but none in a concentration sufficient to be a hazard to livestock health.[2,3] During the air-borne stage, wind sorting of the dust into particles of varying size, shape, and density results in area variation in the composition of the fallout. Consequently, area variations in chemical analysis over the fallout area can occur. Analyses based on acid-leachable or water-soluble analysis are more relevant to immediate animal health than those reporting total content.

Mortality resulted from acute **fluorine poisoning** in association with high fluoride levels in ash and ash-contaminated grasses and water in the period immediately following the Mount Hecla and Lonquimay eruptions.[1,4] It is therefore advisable to remove livestock from

ash-contaminated pastures until this hazard is determined. In most circumstances, this will necessitate removal to indoor housing and ***feeding of stored feed and well water if they are available.***

Physical properties

The ash particulate count in air and the respiratory exposure to livestock is highest during the fallout period, but can remain high for long periods following the fallout when ground ash is disturbed by animal movement, winds, and normal farming practices. A significant proportion of this material is of **small particulate size** and is **respirable**.[2] Chemical and/or physical irritation of the respiratory tract, with a significant increase in the prevalence of respiratory disease, might be expected in these circumstances. This did not occur following the Mount St Helens eruption, even in animals with known pre-existing respiratory disease, nor was it a reported problem following the eruption of Mount Hecla.[1] Signs of irritation such as lacrimation were observed widely, but with no untoward sequelae.

Long-term effects

Volcanic ash is composed predominantly of pumiceous volcanic glass and crystalline mineral silicates such as feldspar. These materials have no innate pulmonary toxicity. Volcanic ash may also contain variable amounts of free crystalline silica such as quartz, cristobalite and tridymite which, if present in respirable sized particles for prolonged exposure periods, can induce pulmonary fibrosis.

Silicosis is primarily a human health concern, although spontaneous silicosis is recorded in livestock.[5] While it is a concern with all eruptions, the long-term health history of animals and man following volcanic eruptions suggests this hazard is minimal.

In the vicinity of Mount St Helens there have been two appreciable effects on livestock health:

- The first has been a marked increase in the incidence of **hypomagnesemia** in cattle in the semiarid channelled scab lands of central Washington. This has possibly resulted from the reflective nature of the ash layer on the soil reducing soil temperature increase during early grass growth and thus reducing magnesium uptake. Grass magnesium concentrations are low and potassium levels are high but there are no pre-eruption values for comparison
- The second effect has been an increase in the severity of **selenium deficiency**. The association between selenium deficiency and recent volcanic origin soils is well recognized. Problems have been corrected by additional and more intensive selenium supplementation.

Animals may ingest considerable quantities of ash from grazing contaminated pastures or from hay subsequently prepared from these areas. There is little field evidence for disturbance of **digestive function** in livestock following the Mount St Helens or Ruapehu eruptions and feeding trials of ash to cattle and sheep have shown no clinical or postmortem evidence of untoward effects nor any depression of production except that associated with decreased feed palatability at high ash feed levels.[6]

BUSHFIRE (GRASSFIRE) INJURY (THERMAL BURNS)

Synopsis

Etiology Thermal or smoke inhalation injury from fire.
Epidemiology Large numbers of livestock with thermal burns in bush and prairie fires. Smoke inhalation injury more common in horses rescued from barn fires.
Clinical findings Edema and thermal injury in skin. Upper respiratory signs in short term and lower respiratory disease in the longer term, with smoke inhalation.
Treatment Palliative local therapy, fluid therapy to prevent shock with superficial thermal injury. Maintenance of airway and lower respiratory function with smoke inhalation. The major dilemma with treatment is the conflict between the welfare of the animals and the responsibility to the owner.

ETIOLOGY

Heat, carbon monoxide, and toxic gases are the cause of injury and death in fires. Most fire victims have thermal burns. The treatment of burns is, by common consent a surgical subject, but there are aspects of bushfire or forest fire injury which warrant discussion in a textbook of large animal medicine. For example, when large numbers of animals are affected the most important questions to be decided are whether to treat them and what to treat them with and, if they are not to be treated, whether they are to be summarily destroyed or salvaged for meat. When large numbers of animals are burnt there is also a major moral conflict for the veterinarian between the welfare of the animals and the responsibility to the owner.

EPIDEMIOLOGY

Forest fires

Although no written information is readily available about forest fires in **softwood forests** it is assumed that few animals would survive the suffocating effects of intense heat and high smoke concentration. The intensity of the heat arises from the fact that the entire forest from leaves to trunks is burned.

In **hardwood forests**, such as eucalyptus forests in Australia, the heat is not so severe because the tops only are destroyed. Underbrush is burned but the tree trunks are only scorched and usually survive to regrow. Depending on the density of the forest and the amount of underbrush there may be many survivors as badly burned animals. The most severe burns are on the lower surfaces and undersurfaces of the body and are caused by burning of the litter on the forest floor.

Grass fires

The most serious situation is caused by a grass or prairie fire which, because of the short period of intense heat that is generated by the wind-driven fire, burns but does not necessarily kill animals. The fires can be extensive and involve large numbers of animals. Many animals will die of suffocation, especially sheep, but the majority survive in various states of burn injury.

Barn fires

Animals may die of carbon monoxide poisoning and asphyxiation, or be burned all over, but some may be rescued without burn but with the risk of smoke-induced respiratory injury (Chapter 10).[1] Animals trapped, but subsequently rescued, in barn fires are more usually horses.

The problems for veterinarians created by large-scale burnings are several-fold:

- The first is that **national disaster services** are usually recruited to deal with the damage to property and welfare problems of humans. They are often poorly equipped to deal with animal problems yet assume authority over their fate in the temporary absence of the owners. The normal reaction of the average person is to judge that burn injuries are much more serious than in fact they are and to shoot burned animals out of hand
- The second problem is that the facilities for penning and treating burned animals have usually been destroyed in the fire so that a general feeling of helplessness prevails,

especially if several hundred animals are affected

- **Insurance** also exerts an influence on the owner's decision on the course to be followed. Most livestock are protected by fire insurance and there will be no argument with a veterinarian's decision that burned animals should be destroyed for humane reasons. This is often done unnecessarily if the interests of insurers are to be protected
- **Salvage** for slaughter is often difficult to arrange at such short notice for such large numbers and public sentiment is against the practice. However, delayed salvage must be kept in mind for animals which will have impaired functions because of burns, e.g. ewes with teat injuries, rams with preputial injuries, bulls with scrotal injury.

CLINICAL FINDINGS

Burn injury

The parts most affected by burning are the face, especially the eyelids, conjunctivae and lips, the undersurface of the body especially udder, teats, and perineum and the coronets.[2,3] Badly damaged corneas take many weeks to heal but badly swollen lips and eyelids can be almost normal within 48 h. Marked edema is always a feature of skin burns in animals, but badly burned skin will be dry and ready to slough in a week.

The teats of **dairy cows** may be damaged to the point where they will not be milkable again; wethers and rams may suffer urethral obstruction. In dairy cattle it is heifers that have the worst prognosis with respect to machine milkability.

Separation of the coronary band from the **hoof** is a common occurrence as a result of burning and there may be sufficient weeping at the separation to suggest that the hoof is about to slough, but they seldom do and hooves that appear quite loose do heal normally.

TREATMENT

Decision criteria

A major decision must be made at the outset whether to treat an affected animal or whether to destroy it on humane considerations. This decision is more easily made when an individual, rather than several hundred animals, is the consideration.

Recommended **criteria** for deciding the fate of sheep burnt by **pasture fire** depend on the presence of burns to the hooves and legs below the carpal and tarsal joints which cause local swelling and a dry leathery appearance of the skin. Such sheep are likely to be recumbent and immobile and to die. Burns which do not cause swelling of the lower limbs, or to other parts of the body are not likely to be fatal, nor to produce chronic ill-health,[3,4] unless they affect a large part, more than 15–20%, of the body surface.

Animals which are unconscious or very distressed, cannot walk, or have severe difficulty in breathing are poor prospects for recovery and are best **euthanized** forthwith. It may be necessary to monitor sheep for 10 days after a fire before deciding what to do with them. It is necessary at all times to consider the need to avoid inflicting suffering on the animals, but to also consider the farmer's need to retrieve his assets. If the animals are insured against fire it is also highly desirable to keep the insurer advised of developments.

Animals which have been trapped in a **burning building** are likely to be burned all over and to have upper and lower respiratory damage from smoke inhalation. Bronchoscopy can aid in establishing the severity of injury.

Skin burns

Extensive skin burns are accompanied by fluid shifts, vascular leakage, protein loss, and the potential for hypovolemia. The initial therapy is with crystalloid and colloid fluids as discussed in the section on shock. Tetanus prophylaxis is appropriate. Topical antibiotics, silver sulfadiazine and aloe vera are topical therapies. Non-steroidal anti-inflammatory agents can decrease the inflammatory response and help in pain management.[5] Glucocorticoids may potentiate burn sepsis. In horses, euthanasia is recommended if greater than 50% of the body surface is affected.[5]

Smoke inhalation

Tracheostomy may be required to maintain the upper airway. Bronchodilators such as aminophylline or terbutaline sulfate are used to relieve reflex bronchoconstriction and humidified oxygen and local hydration by fluid nebulization to relieve hypoxemia. Corticosteroids are used to reduce airway inflammation in animals with minimal cutaneous burns.[1]

WETNESS

Frequent exposure to wetting, sufficient to keep the skin permanently wet for long periods, predisposes to fleece rot in sheep and mycotic dermatitis in all species. In horses it leads to a superficial dermatitis along the dorsum, especially over the croup and is known as scald. Frequent immersion of the lower limbs of cattle on irrigated pasture causes dermatitis on the backs of the pasterns leading to mycotic dermatitis. Wetting also predisposes to hypothermia in the young.[1]

Standing in cold water for a period of more than 3 days causes the immersed parts to become edematous and congested and slough their skin in the form of a cuff around the limb. Recovery is slow and incomplete.[2]

DROWNING

Near drowning has been defined as survival following asphyxia and aspiration of water while submerged. Cases are rare in large animals but there is increased potential with the increasing popularity of swimming as a method of exercising and training horses.[1] Fresh water can inactivate pulmonary surfactant and lead to collapse of the alveolus with a loss of pulmonary compliance and the resultant ventilation-perfusion mismatch coupled with alveolar damage can lead to severe hypoxemia. The inhalation of water may also carry bacteria and the risk of a secondary bacterial aspiration pneumonia.[2] Affected animals present with an elevated heart rate, tachypnea, and dyspnea. There is a decrease in normal air flow sounds on auscultation, which may occur in all areas of auscultation or be more pronounced in one lung and rales or crackles may be heard in local areas.[1,2] Consolidation may be detected with thoracic radiography. The mucous membranes may be congested, cyanotic, or muddy. Arterial blood gas analysis has shown a metabolic acidosis and hypoxemia.[1,2]

Therapy has been based on experience with near drowning cases in humans[3]; horses have been successfully treated by nasal insufflation of humidified oxygen, the correction of the base deficit with sodium bicarbonate and lactated Ringer's solutions administered intravenously, treatment with bronchodilators and non-steroidal anti-inflammatory drugs and the pulmonary infusion with a surfactant transplant from a recently euthanized horse.[1] Antibacterials are given to cover the risk or the presence[2] of a bacterial pneumonia and the cover should include the possibility of infection with anaerobic organisms. Respiratory distress can be more severe when the animals are recumbent and enforced standing may be

indicated. Near drowning requires immediate and aggressive therapy and the recovery can be prolonged.

COLD INJURY (FROSTBITE, CHILBLAINS)

Synopsis

Etiology Exposure to cold temperatures, usually below freezing, without adequate protection.
Epidemiology Cooler seasons of the year, primarily in young animals, especially beef calves, debilitated from other disease. Teats of lactating dairy cows also susceptible.
Clinical findings Lesions may occur on extremities of limbs, especially hindfeet, ears, and tail. Demarcated lesions with initial swelling with edema followed by necrosis and sloughing. Teats and udder of adult cows may be affected.
Clinical pathology None specific.
Necropsy findings Subcutaneous edema and hemorrhage in affected areas.
Diagnostic confirmation Clinical findings and history of exposure to cold.
Treatment Warm, dry environment. Improve peripheral circulation.
Control Remove debilitated calves from cold environments. Adequate and dry bedding.

ETIOLOGY AND EPIDEMIOLOGY

The injury occurs during cold weather in the winter or spring months and is most common in **calves** which are weak or in which the peripheral circulation of the limbs is impaired, usually because of diarrhea and dehydration. In a retrospective study of frostbite in calves, 80% of cases were associated with a concurrent disease such as pneumonia, diarrhea, omphalitis, septicemia and ocular disease.[1] Hypothermia (<37.5°C) was present in about 50% of the calves. The disease in calves appears more common in beef breeds, possibly because of management risk factors.

In **dairy herds** with loose housing, access to outdoor exercise yards without adequate bedding can be a risk factor. There can be a high incidence of teat lesions in drylot-housed herds in temperate areas when freak cold weather fronts invade the region. Regional differences in teat chapping in winter are associated with regional differences in winter temperature.[2]

PATHOGENESIS

Physiologically, body heat is lost from the skin surface by radiation and convection and by conduction and evaporation when the skin and hair-coat are wet. **Newborn calves** are particularly susceptible to cold because of their inadequate insulation and high ratio of body surface area (through which heat is lost) to body volume (in which heat is generated). The core and trunk body temperature is preferentially conserved during cold stress at the expense of the peripheral tissues which are most susceptible to cold injury.

The **peripheral tissues** are also most susceptible because of their contact with the ambient temperature and wet environments. When cattle are in sternal recumbency, the uppermost pelvic limb is fully exposed and the distal aspect of the opposite limb from the hoof to above the fetlock joint is exposed to the environment. The distal extremities of the thoracic limbs are usually covered by the thorax. Thus, any situation which results in prolonged sternal recumbency will allow the distal extremities of the pelvic limbs to cool excessively and if there is impairment of circulation because of pre-existing dehydration, varying degrees of cold injury can occur. Field observations suggest that if a weak calf does not move from a sternally recumbent position for several hours, the cold injury can progress to the stage of severe irreversible frostbite before the clinical signs are recognized by the owner.

The **teats of dairy cows** are also exposed when standing and lying. Residual teat dip after milking predisposes to cold injury.

Cold injuries of extremities vary from mild to severe. Exposure to cold results in vasoconstriction and coolness of the affected part. Most dry-cold injury is superficial and the skin may become gangrenous resulting in a hard shell or carapace over healthier tissue. Deeper cold injury causes inflammation, redness or cyanosis, local swelling and pain or loss of sensation.

CLINICAL FINDINGS

Frostbite of the **feet** of calves is not readily obvious even to the experienced observer. The normal hair covering and pigmentation of the skin often mask the early changes of frostbite. Commonly, cases are identified during the treatment with fluids of scouring, recumbent calves, when further clinical examination reveals that the hindfeet are cool and clammy.

In the **early stages** of frostbite of the distal parts of the limbs, the tissues are swollen, edematous and may have well demarcated limits. After several hours of warming indoors, the feet remain cool and close examination reveals some moistness and dark red to bluish coloration of the skin. There may be a line of demarcation between normal and affected tissue at about the level of the fetlock joints. If the injury is not severe, complete recovery may occur in a few days.

In more **severe cases**, within 24–48 h, necrosis and sloughing of the skin may occur and the hooves may become detached several days later. Pain on palpation of affected tissues, especially at the line of demarcation, is obvious.

When there is avascular necrosis of the affected part, the skin may be hard like a shell (known as a carapace) and moderate palpation will elicit pain.

Freezing of the **ears** results in loss of pliability of the ears, gangrene, and loss of the affected parts and curling of the affected skin adjacent to the affected parts. Some sloughing of affected parts will occur and after several days the ears appear shortened.

Freezing of the **tail** occurs most commonly at the distal end resulting in stiffness and loss of flexibility because of a carapace. Varying portions of the tail may be affected but usually 5–10 cm of the distal end is involved. The distal parts of the tail of adult cattle may freeze in very cold weather.

In adult cattle, freezing of the **teats** and **base of the udder** can occur in lactating cattle which have inadequate bedding and shelter from wind and snow. Affected teats are swollen and cold and the skin begins to vesiculate and peel. Freezing of the teats of cows may result in permanent injury, chronic thelitis and the possibility of mastitis with gangrene. Less severe lesions predispose to mastitis.[3]

Freezing of the **scrotum** occurs in yearling beef bulls kept outdoors during the cold winter months but the lesions are not commonly recognized until the spring of the year.

NECROPSY FINDINGS

Necrosis of the skin of the affected area with severe diffuse hemorrhagic subcutaneous edema is typical of frostbite.

TREATMENT

Affected calves should be moved to a warm well-bedded **dry environment** and circulation should be improved by providing **fluid therapy** as necessary. In early cases, affected calves will recover in a few days and the swelling and pain will regress. Field observations suggest that superficial freezing of the skin between the fetlock and coronets will heal over a period of several weeks providing the lesion does not extend into the coronary bands and the laminae of the feet which commonly results in sloughing of the hoof.

In severe cases with extensive necrosis, the skin will begin to slough. Such open wounds should be treated with suitable antibiotic ointments and bandaged for

several days. Calves with extensive freezing of the hindlimbs extending from the feet up to hock joints are incurable and should be euthanized.

There is no specific treatment for freezing of the ears and tails of calves or the teats of cows.

CONTROL

The prevention of cold injury in newborn **calves** requires daily surveillance of calves to insure that any animal which is inactive for any reason is examined for evidence of illness and treated immediately and placed in a protected environment.

When an exceptional cold period is forecast for **dairy cows** at risk, teat dipping should be temporarily suspended during the cold period. Additional bedding should be provided for loose-housed cows and bedding with some manure can be piled in the center of drylot yards to provide composting heat upon which the cows can bed.

ELECTRIC AND MAGNETIC FIELDS

Electric and magnetic fields are generated from the transmission of electricity through high tension lines and livestock are exposed to these fields when high-voltage lines pass through rural areas. There is no apparent effect of high-voltage transmission lines on the behavioral or feeding patterns or the reproductive performance of cattle grazed under them or near them[1] but experimental studies have observed equivocal effects on melatonin production[2] dry matter intake milk yield and milk components.[3,4]

German veterinarians have expressed concern for livestock health from the effect of radiofrequency electromagnetic fields associated with the establishment of a national mobile phone network. Alterations in behavior and an increase in birth defects are reported in cows with high exposure but there is little hard data.[5,6]

Diseases associated with inorganic and farm chemicals

32

Suspicion of poisoning is aroused when illness occurs in a number of previously healthy animals; all affected at the same time and showing the same signs and necropsy findings, to the same degree of severity. These conditions, of course, may also apply to some infections, metabolic and nutritional deficiency diseases. It is only by acquaintance with the syndromes produced by the common poisons, particularly those likely to occur locally, that this primary differentiation can be made.

Poisonous plants often show a geographical limitation in distribution; particular industrial enterprises may create poison hazards in local areas; certain agricultural practices, including the spraying of orchards, the dipping or spraying of cattle for ectoparasites, and the use of prepared concentrate feed for pigs and cattle, may also lead to poisoning in groups of animals. So many chemical agents are used in agriculture today that a section of miscellaneous farm chemicals likely to be associated with the poisoning of animals has been included.

The appearance of clinical illness soon after feeding, after a change of ration, after medication or spraying, or after change to new pasture, is a common history in many outbreaks of disease associated with chemical agents. The report which accompanies material for toxicological analysis should include a full record of history, clinical signs and necropsy findings and particularly the results of a search of the environment for access to a poison. If the animal has been treated, the drugs that were used and the dates of administration should be given as they may create difficulties for the analyst. The poison or group of poisons suspected should be defined.

Specimens for analysis should include a sample of the suspected source material. Next most important is a specimen of alimentary tract contents, so that ingestion of the material can be proven, and a sample of tissue, usually liver, to prove that absorption of the poison has occurred. Kidney also provides a route for concentrating many toxicants for excretion and is an important specimen for chemical poisoning. Most toxic chemicals are ingested but percutaneous absorption and inhalation must be considered as possible portals of entry. One of the advantages of an examination of alimentary tract contents is that qualitative tests can be carried out and in many cases this determines whether or not further examination of tissues is necessary.

Additional specimens required other than liver and alimentary tract and contents, vary with the poison and the following list is suggested for the common chemicals:

- Arsenic – kidney, skin, and hair
- Lead – kidney, liver, bones, and whole blood
- Phosphorus – kidney and muscle
- Mercury – kidney, brain if organomercurials are suspected
- Copper – kidney, liver, and blood
- Sodium chloride – alimentary tract and contents, brain, and serum
- Fluorine – bones, teeth, and urine, contaminated forages
- Hydrocyanic acid – ingesta in a filled and airtight container, blood and muscle
- Nitrate and nitrite – ingesta (plus chloroform or formalin) in an airtight, filled container, blood, ocular vitreous humor
- Strychnine – blood, kidney, and urine
- Insecticides – liver, kidney, brain, fat, ingesta.

Careful packing of specimens is necessary to avoid loss of some poisons by escape as gas or conversion by bacterial fermentation, and to prevent contamination. No preservative should be added except in the case of suspected nitrite poisoning. If a preservative is necessary because of distance from the laboratory, packing in dry ice or ethyl alcohol (1 mL/g of tissue) is advisable; in the latter instance a specimen of the alcohol should also be sent. Ingesta and tissues must be kept separate as diffusion is likely to occur between the two. Specimens should be packed in glass or plastic to prevent contamination by lead in soldered joints of cans. Metal tops on jars should also be separated from the tissues by a layer of plastic or other impervious material. A suitable amount of material should be submitted for analysis: 1 kg of ingesta, 1 kg of liver, 0.5 kg of kidney, and proportionate amounts of other viscera are suggested to cover all contingencies. Urine (200 mL or whatever is available) may allow quick analysis of some toxicants.

Both blood and serum are helpful for rapid testing of some toxicants and for characterizing a potential poisoning through complete blood count and clinical chemistry. Special action is needed when plant poisoning is suspected. First examine the premises for evidence that known toxic plants actually appear to have been eaten. It is possible to ascertain the identity of the plants eaten recently by a careful examination of the ruminal contents. The freshest, least macerated material is best and whole leaves preferred. Atlases of epidermal plant fragments are available to aid in identification of ingested plant species in agricultural animals. Laboratories with sophisticated equipment can now identify most plant toxins in ruminal contents by spectrometric analysis, leaving the veterinarian with the simpler task of deciding whether any of the plants which contain the toxin are present in the environment. At such times access to a computerized data bank of plants and their toxins[1] is a great advantage.

Commonly, with plant poisonings, there are perplexing epidemiological features. For example, animals already grazing in the dangerous field are often unaffected and only those recently introduced may be poisoned. Some of the factors which affect susceptibility to plant poisonings are:

- Hungry, ravenous animals are more likely to be affected
- Animals thirsty or recently moved to a new location may sample toxic plants
- Curious, excited animals are likely to sample the plants they would not otherwise eat
- Young animals are less discerning and are less easily put off
- Plants that are different in texture, e.g. sprayed weeds, lopped foliage, often appear to be attractive
- Pica due to mineral deficiency or some other association may encourage toxic plant consumption
- Genetic selection of animals toward tolerance of a particular poison, e.g. fluoroacetate.

Poisoning is in most instances accidental, although it may occasionally be deliberate. Deliberate or criminal poisoning is often suspected but is rarely proved. If there is a strong suspicion of criminal poisoning, or if litigation appears possible in accidental poisoning, specimens should be collected in duplicate and placed in sealed containers in the presence of witnesses. A complete set of specimens should be available to both plaintiff and defending parties for independent analysis. Also, if litigation appears possible, the veterinarian should make detailed observations of the clinical, pathological, and epidemiological findings and record them in detail. The taking of photographs of affected animals and the environmental surroundings is also recommended for future reference and documentation if necessary.

MINERAL TOLERANCE OF ANIMALS

One of the very important aspects of toxicology as it applies to agricultural animals is the determination of levels of dietary constituents which the animals will tolerate for a limited period without impairing their performance and without producing unsafe residues in products destined for the human food chain. There is a great deal of information on this subject and it has been collated and published.[2] Table 32.1 is an adapted summary of the information.

PRINCIPLES OF TREATMENT IN CASES OF POISONING

There are certain principles which apply to all cases of poisoning and they are listed briefly below. The three main principles are:

- Removal of the residual poison from the alimentary tract or skin
- Provision of chemical and physiological antidotes to the poison that has been absorbed
- Effective supportive care, nursing, and convalescent care.

In farm animals, gastric lavage and emetics are of little or no practical value and the removal of residual poison from the alimentary tract depends largely upon the use of adsorbents and purgatives. The only effective adsorbent is activated charcoal. The dose rate is 1–3 g/kg BW repeated as necessary. It adsorbs chlorinated hydrocarbons, organophosphorus compounds, mycotoxins and plant alkaloids, the common feed additives, antibacterial agents and bacterial toxins. It does not adsorb cyanide, heavy metals, halogens, nitrite, alcohols, caustics, sodium chloride, or chlorate. A purgative is necessary to remove the combined adsorbent and poison; it can be administered simultaneously with the adsorbent. The use of irritant purgatives is not advisable when the poison is an irritant and has already been associated with gastroenteritis, and non-absorbable oily purgatives (e.g. mineral oil) are preferable in these cases. Saline purgatives (sodium sulfate) are of value in the treatment of non-irritant poisons such as cyanogenetic glucosides. Neutralization of residual poison in the alimentary tract includes use of oxidizing agents or tannic acid preparations for precipitating alkaloids; proteins, including milk and eggs, are effective chemical antidotes for poisons that coagulate proteins; lead is precipitated by the addition of sulfates to the alimentary tract contents.

Poison that has already been absorbed can in some instances be inactivated or its excretion facilitated by the provision of chemical antidotes. For instance, sodium nitrite and sodium thiosulfate are effective systemic antidotes to hydrocyanic acid, and calcium versenate is an effective antidote against lead.

Table 32.1 Maximum tolerance levels of dietary minerals for domestic animals

	Cattle	Sheep	Pig	Horse
Arsenic mg/kg

Treatment of the effects of a poison includes provision of physiological antidotes, e.g. the injection of a calcium salt in cases of overdosing with magnesium salts. Ancillary or supportive treatment, including the provision of fluids in dehydration due to diarrhea, demulcents in gastroenteritis, sedatives in excitement, stimulants in cases of central nervous system depression, all treat the effects of poisoning.

It is essential when undertaking the treatment of animals for poisoning, especially those which are producing milk or which are destined to become meat in a short time, to take into account the possible unsuitability of the product for human consumption because of the presence of the poison or the antidote. Carefully planned sampling in concert with regulatory authorities can avoid unwanted contamination of the human food supply.

Diseases associated with inorganic poisons

LEAD POISONING (PLUMBISM)

Synopsis

Etiology Accidental ingestion of lead or ingestion of feed or grazing pasture containing excessive lead.
Epidemiology Occurs in all age groups. One of the most common poisonings of farm livestock especially in young calves after turn out in spring. In cattle, usually sporadic and due to ingestion of single source of lead but outbreaks occur when feed is contaminated. High case fatality rate if untreated. Sources include discarded lead batteries, lead-based paints, industrial sources of lead, pastures near motor vehicle highways and smelters. Occurs in sheep and horses grazing contaminated pastures.
Signs
Cattle: Acute – convulsions, blindness, tremors, charging, rapid death unless treated. Subacute – blindness, stupor, head-pressing, rhythmic ear tics, blepharospasm, rumen stasis and eventual death.
Sheep: Lambs on pasture with posterior paresis.
Horses: On pasture. Signs highly variable. Inspiratory dysnea, roughened hair coat, weight loss most commonly. Occasionally convulsions.
Clinical pathology Lead levels in blood, feces, liver, kidney; elevated porphyrins in blood
Lesions Encephalopathy, degeneration of liver and kidney; pale musculature, brain laminar cortical necrosis, intranuclear renal inclusion bodies.
Diagnostic confirmation Toxic levels of lead in blood and tissues.
Differential diagnosis list
Cattle: See Table 32.3.
- Polioencephalomalacia
- Hypovitaminosis-A
- Ophthalmitis
- Hypomagnesemic tetany
- Nervous acetonemia
- Arsenic poisoning
- Claviceps paspali toxicity
- Meningoencephalitis
- Rabies

Horses: See Table 22.1.
- Laryngeal hemiplegia
- Viral encephalomyelitides/West Nile virus
- Rabies
- Hepatoencephalopathy due to hepatotoxic plants
- Equine degenerative myeloencephalopathy
- Protozoal encephalomyelitis
- Equine motor neuron disease
- Horsetail poisoning
- Chronic weight loss
- Chronic upper respiratory tract disease
- Botulism

Sheep:
- Enzootic ataxia
- Polyarthritis
- Muscular dystrophy

Treatment Calcium versanate and thiamin hydrochloride.
Control Prevent access of animals to sources of lead.

ETIOLOGY

Lead poisoning is associated with the accidental ingestion of sources of lead metal or compounds or the ingestion of feed, usually forage, containing lead usually from pollution of the environment.

EPIDEMIOLOGY

Occurrence

Lead is one of the most common poisonings in farm animals, especially young cattle. Sheep and horses are also affected but not as commonly. Pigs are not often exposed to lead and appear to be more tolerant to it than other species.

Cattle. Data from diagnostic toxicology laboratories illustrate that lead poisoning is the most common toxicosis in cattle.[1,2] The disease occurred most commonly in younger cattle with 52% of the cases reported in animals 6 months of age or less. Approximately 60% of the cases occurred during the summer months from May to August, when the cattle have ready access to lead-containing materials such as crankcase oil and batteries that are being changed in agricultural machinery. In many countries the incidence of the disease is highest in cattle in the spring of the year a few days after the animals have been turned out onto pasture.[3] Lead poisoning occurs most commonly in young cattle soon after spring turnout when animals gain access to discarded waste materials including batteries, dump oil, oil paint containers, and bonfire ash where painted lumber has been burned.[4] In Alberta, Canada, over a period of 22 years, lead poisoning was the most frequently diagnosed toxicosis of cattle, representing 0.68% of all bovine submissions to the provincial diagnostic laboratories.[5] Young cattle, particularly, are curious and amazingly seem to find sources of lead.

Lead poisoning in cattle is usually due to the accidental ingestion of a toxic quantity of lead over a short period of time. The natural curiosity, licking habits, and lack of oral discrimination of cattle makes any available lead-containing material a potential source of poisoning. Cattle will readily drink crankcase oil, lick machinery grease, and chew batteries. Present-day machinery grease does not commonly contain lead. Compared to earlier times, used crankcase oil may not contain lead if leaded gasoline is banned in a country or region, or if diesel engines are used where lead additive is not utilized in the fuel. In ruminants there is a tendency for metallic lead particles to settle in the reticulum and poisoning results from the gradual conversion of lead particles to soluble lead acetate. Horses, on the other hand, are much more selective than cattle in their eating habits. They usually do not lick old paint cans, lead storage batteries, and peeling paint, nor do they seem to find the taste of used motor oil attractive.[6] Several epidemics of lead poisoning in domestic animals have been recorded throughout the world where the source of the metal was contamination of pasture or crops by nearby industrial lead operation.[6] Animals eating vegetation in these areas may accumulate amounts of lead sufficient to produce clinical signs of lead poisoning.

Sheep are usually affected by eating forage contaminated by environmental sources of lead.

Horses. Lead poisoning in horses occurs most commonly when they graze lead-contaminated pastures rather than by the accidental ingestion of a toxic amount of lead. Young horses are particularly more susceptible than older horses and cattle grazing on the same pasture. Some cases in horses have been due to ingestion of paint chips from a fence on pasture.[7]

Buffalo. Lead poisoning in buffalos has been reported and provides interesting comparative data[8]; they may have a higher tolerance to lead than cattle.

Morbidity and case fatality

Where groups of animals have access to the same source of lead, outbreaks occur and the morbidity rate ranges from 10 to 30%. The case fatality rate may reach 100% but early intensive therapy can be successful and reduce the figure to less than 50%. In one recorded outbreak, in which a discarded 24-volt battery was accidentally mixed and ground up into the feed of 80 heifers, 55 of the animals died or were destroyed on humane grounds.[9]

Sources of lead

Cattle on pasture. Lead poisoning occurs most commonly in cattle at pasture, particularly if the pasture is poor and the animals are allowed to forage in unusual places, such as rubbish dumps. Phosphorus deficiency may also be a predisposing factor, in that affected animals will chew solid objects as a manifestation of osteophagia. However, cattle on lush pasture may also seek out foreign material to chew. Confined housing of calves with or without overcrowding is often followed by the appearance of pica which may be associated with boredom or mineral deficiency.

Lead paint and lead batteries. The common sources of lead are lead-bearing paints and metallic lead. Discarded lead batteries are one of the most common sources of lead poisoning in cattle. In Alberta, Canada, over a period of 22 years, discarded batteries or used crankcase oil accounted for more than 80% of cases for which the source of lead was determined: batteries, 39.5%; used crankcase oil, 31.6%.[10] The batteries are commonly placed in garbage dumps on the farm and, in temperate climate countries, the batteries freeze during the winter months and break open, exposing the plates which are attractive and palatable for cattle to lick and chew.

Lead contaminated feed. The contamination of forage supplies with shotgun lead pellets used in hunting and shooting exercises, can serve as a source of lead for cattle grazing the pasture or consuming haylage or silage made from the contaminated field. Automobile batteries have been accidentally added to feed mixers where they are ground by powerful augers and mixed into the feed supply of cattle.[9] Feed accidentally contaminated with lead affected some 15 000 cattle on 330 farms in the Netherlands within a 3-month period.[11,12] Discarded lead-based paint cans are particularly dangerous but fences, boards, and the walls of pens, painted canvas and burlap are also common sources in calves. Painted silos may cause significant contamination of the ensilage. One outbreak of lead poisoning in cattle was associated with silage containing 1200 mg/kg DM lead which had become contaminated by ash and debris left after burning an old lead-containing electrical cable in the silo before it had been filled.[13]

Industrial lead. Metallic lead in the form of lead shot, solder, or leaded windows has been associated with mortalities, although, experimentally, sheet lead is not toxic. Lead sheeting which has been exposed to the weather or subjected to acid corrosion appears to be more damaging, possibly because of the formation of a fine coating of a soluble lead salt. Lead poisoning can be a major hazard in the vicinity of oil fields, and engine sump oil may contain over 500 mg lead per 100 mL. Automotive and other mineral oils are very palatable to young beef calves. In one study, used crankcase oil was the most common source of lead poisoning in cattle, followed by paint, grease, and lead car batteries. As lead use becomes more restricted in many countries, grease and lead contaminated engine oil have become less common sources of lead. Less common but still potent sources of lead are linoleum, roofing felt, putty, automobile oil filters, and aluminum paint. Some of the latter paints contain large quantities of lead, others none at all. Only lead-free aluminum paint should be used on fixtures to which animals have access.

Lead parasiticide sprays, particularly those containing lead arsenate, was once associated with heavy losses in cattle grazing in recently sprayed orchards or vegetable crops. These are not commonly used now, except in some countries, but cattle may accidentally ingest old stores of the compound.[14]

Environmental pollution with lead

Environmental pollution with lead is a common occurrence in cities and on their edges. For farm animals, significant pollution is more likely to occur near smelters or other industrial enterprises, or near major highways where pasture is contaminated by exhaust fumes of automobiles, only if leaded gasoline is still used in the region. Much of the poisoning is subclinical because of the low level of absorption, and any program intending to use domestic animals as monitors of pollution would need to be based on tissue lead levels.

Lead in pastures near highways. The lead levels in whole blood of sheep grazing near main highways in three areas of the Nile delta region of Egypt were 0.062, 0.067, and 0.083 mg/mL (ppm).[15] Pasture adjacent to heavily used roads may carry as much as 390 mg/kg of lead, in contrast to 10 mg/kg on lightly used roads. The concentration of lead on pasture varies markedly with proximity to the traffic, falling rapidly the greater the distance, and with the time of the year. Pastures contaminated by smelters are recorded as carrying 325 mg/kg of lead (equivalent to a daily intake for an animal of 6.4 mg/kg BW). In some locations near lead smelters, lead poisoning is considered to be a predictable occurrence in horses which are allowed to graze on local pastures. As a result horses are either not raised in these areas or hay is imported from other areas. Although ingestion is the principal method of poisoning of animals, inhalation may also be a significant method of entry for cattle grazing close to smelters or highways.

Lead, cadmium, and zinc. Lead as an environmental contaminant is often combined with cadmium which has some effects similar to those of lead so that the effects may be somewhat additive. Experimental poisoning with both elements is associated with reduced weight gains in calves at dose levels up to 18 mg/kg BW of each, and clinical signs appear at levels above 18 mg/kg BW of each. Lead is also combined with chromate for industrial purposes. It is not toxic when combined with lead at lead intake levels of 100 mg/kg BW.

Environmental pollution in the vicinity of lead and zinc-ore processing factories can result in varying degrees of poisoning with lead, zinc, and cadmium. These can be monitored by the analysis of blood, hair, and tissues obtained at necropsy.[16,17]

Lead in human food chain. There is some concern that toxic levels of lead may occur in the human food chain. Canadian studies of the lead and mercury residues in kidney and liver of slaughter animals have shown that all levels were below the official tolerance level of 2 mg/kg WW for lead and 0.5 mg/kg for mercury. Levels of lead in beef randomly selected from supermarkets in the US were for muscle 0.46, liver 0.50, and kidney 0.45 mg/ kg (WW).[18] The upper range of liver levels exceeded the 1 mg/kg WW guideline which may cause for concern about the source of the lead. Moderate exposure of people to meat, including liver and kidney, from animals exposed to lead poisoning is thought not to represent a human health hazard. The biological monitoring of cadmium and lead from contaminated sandy soil into sudan-sorghum hay consumed by pregnant dairy goats over a period of 98 days revealed that only miniscule amounts of soil cadmium and

lead were retained in the selected animal tissues (liver and kidney) via the ingestion of the hay.[19] It was concluded that if these animal tissues were used as food, no deleterious effect to human health would be induced.

Lead in blood, milk, kidneys, and liver. The relationship between lead concentrations in blood of cattle with lead poisoning and those in the milk is exponential.[20] The lead level in milk is relatively constant up to a blood level of 0.2–0.3 mg/L, and increases sharply at higher blood levels. The biological half-life of lead in blood is approximately 9 weeks. Recent studies in six affected dairy herds reported a variable half-life ranging from 48 to 2507 days.[21] A probable reason for this great variance is the ability of the ruminant to retain variable amounts of metallic lead in the rumen which thus acts as a continuing reservoir. Since classical biological half-life studies do not account for variable intake and retention of a persistent reservoir of toxicant, the concept of half-life in dealing with lead-poisoned cattle is likely not accurate. Owners of such cattle should be advised of the potentially long withdrawal period. It may be advisable to test periodically and allow marketing based on actually measured levels, or to estimate the costs of such a plan and consider salvage. This recent work casts doubt on the economic utility of holding recovered animals. In acutely sick cows which were emergency slaughtered, the range of lead levels in edible muscle tissue was 0.23–0.50 mg/kg WW. The concentrations in the kidneys ranged from 70 to 330 mg/kg WW and in the livers 10–55 mg/kg WW.

Background blood lead is the concentration of lead in whole blood resulting from the daily exposure to lead which does not produce any clinical evidence of disease.[21] The background levels of blood lead which have been reported ranged from 3 to 50 µg/dL,[22] but most were less than 10 µg/dL. A recent analysis of 266 blood samples from dairy cattle submitted to the diagnostic laboratory at the New York State College of Veterinary Medicine, for reasons other than heavy metal toxicity, indicated that 259 (97%) had levels lower than minimum detectable level of 2.5 µg/dL (0.025 ppm).[22] Six had concentrations between 2.6 and 5.8 and one had 10 µg/dL. Blood lead concentrations in cows with lead poisoning ranged from 56.4 to 1390.0 µg/dL.

Toxic levels of lead

The toxic level of lead varies between species and the chemical composition of the compound containing lead may influence its toxicity. Lead acetate is very soluble and more toxic than insoluble lead oxide, or solid lead sheeting.

Acute lethal single doses. In calves, acute single lethal doses range from 400 to 600 mg/kg body weight (BW), in adult cattle 600–800 mg/kg and for goats 400 mg/kg. The acute dose for horses is less than for ruminants, one horse having survived 1000 mg/kg BW on two occasions 6 months apart. Pigs are also less susceptible but single lethal dose levels are not recorded. Buffalo calves given a single oral dose of 600 mg/kg BW of lead acetate died within 120 hours.[23]

Young animals, e.g. milk-fed calves, are more susceptible. A daily intake of 2.7 mg/kg BW of lead can be associated with the death of calves fed a milk diet in 20 days or less, while 5 mg/kg BW of lead is consistently associated with signs of poisoning or death within 7 days. The absorption rate of lead is rapid and tissue depositions are high in calves on a milk replacer diet and given lead. In toxicity studies, calves on a milk diet absorb lead much more quickly than calves fed a grain diet. The addition of lactose to a grain diet will also increase the absorption of lead.

Daily dose levels likely to lead to chronic poisoning are important because of the impact that contamination of the environment by industrial effluents has had. Daily dose levels likely to lead to chronic plumbism in cattle are 6–7 mg/kg BW (equivalent to 100–200 mg/kg DM of diet). This dose level must be close to the definitive point because dose levels of 100 mg/kg (in diet) may be without effect. A dose level of 15 mg/kg BW results in the loss of weight gain and normochromic anemia. In sheep, dose levels of more than 4.5 mg/kg BW are necessary to produce a toxic effect. Horses are more susceptible to the daily administration of lead, 100 mg/kg BW producing toxic effects in 28 days. A dose rate of 15–30 mg/kg BW of lead for up to 190 days is associated with toxicity and some deaths, and deaths are recorded on pastures carrying 100–300 mg/kg on foliage. Pigs appear to be more resistant, and daily doses of 33–66 mg/kg BW are required for periods of up to 14 weeks to produce fatal effects, a more serious end-point than for the other dose rates quoted.

PATHOGENESIS

Regardless of the chemical form of the ingested lead, only a small proportion is absorbed because of the formation in the alimentary tract of insoluble lead complexes which are excreted in the feces. For example, only 1–2% of lead ingested as lead acetate or carbonate is absorbed from the alimentary tract of sheep. Of the lead absorbed, some is excreted in the bile, milk, and urine and the blood levels of lead provide a reliable indication of the lead status of the animal. Urine levels may not be as reliable. Deposition in tissues occurs, particularly in the liver and renal cortex and medulla in acute poisoning and in the bones in chronic poisoning. The deposition of lead in the brain is not high compared to other tissues but deposited lead is gradually liberated from tissues into the bloodstream and excreted via the bile and urine. Consideration must be given to these aspects of lead metabolism when assessing the results of chemical analyses of tissues.

Although acute lead poisoning usually develops rapidly there may be a delay of several days after toxic material has been ingested before clinical signs appear.

Toxic effects of lead

The toxic effects of lead are manifested in three main ways:

- Lead encephalopathy
- Gastroenteritis
- Degeneration of peripheral nerves.

In general, acute nervous system involvement occurs following the ingestion of large doses in susceptible animals such as calves, alimentary tract irritation following moderate doses, and peripheral nerve lesions following long-term ingestion of small amounts of lead. The nervous signs of encephalopathy and the lesions of peripheral nerve degeneration are due to the degenerative changes of nervous system tissue. Lead localizes principally in the cytoplasm of capillary endothelial cells and these localizations are later associated with the development of edema. The basic lesion is likely to be vascular with a basic change in transport mechanisms between the blood and brain.[24] Gastroenteritis is associated with the caustic action of lead salts on the alimentary mucosa. Ruminal atony occurs in cattle and sheep and initially is associated with scant feces, followed later in some cases by diarrhea due to gastroenteritis. The rumen protozoa in cattle with acute lead poisoning are commonly absent or inactive. Peripheral nerve degeneration occurs principally in horses.

The lesions, including degeneration of the liver and kidney, vary in their severity with the tissue levels of lead attained. Lead does not remain in tissues for long periods except in bone where it is deposited in an inert form, but from which it can be liberated at a later date in sufficient quantities to be associated with chronic lead poisoning. This is particularly likely to occur during periods of acidosis.

The blue 'lead-line' at the gum–tooth junction, which is seen in man and the

dog, does not commonly occur in ruminants because of failure to form tartar but may be present in the horse. The 'lead-line'is a deposit of lead sulfide formed by the combination of lead with sulfide from the tartar.

Lead is transferred across the placental barrier and high liver levels occur in the lambs of ewes fed more than normal amounts of lead. Calves born from cows experimentally poisoned with lead have elevated levels of lead in bone, kidney, and liver. In a naturally occurring case of lead poisoning in a pregnant heifer, the blood and liver concentrations in the fetus were 0.425 ppm and 4.84 ppm, respectively, which was 72% and 84% of the same tissue lead concentrations of the dam.[25] Hepatic lysosomes of the fetus contained metallic electron densities which may have been lead.

The pathogenesis of the **osteoporosis in young lambs** with chronic lead poisoning has not been explained, nor has the paresis and paralysis of lambs which occur in the same circumstances. The paralysis in the former condition is caused by compression of the spinal cord by collapsed lumbar vertebrae.

Anemia may occur in chronic lead poisoning. The erythrocytes are microcytic and hypochromic, and reticulocytosis and basophilic stippling may be observed. However, basophilic stippling is non-specific and probably does not correlate well with levels of lead exposure. The basophilic stippling of erythrocytes is usually an indication of bone marrow response to anemia, although it can occur, rarely, in chronic lead poisoning. It may be related to the effects of lead on pyrimidine nucleotidase activity. The anemia in chronic lead poisoning is associated with two basic defects: a shortened erythrocyte lifespan and impairment of heme synthesis. Lead is associated with an increased concentration of protoporphyrin by inhibiting heme synthetase, the enzyme which combines protoporphyrin and iron to form heme. The measurement of free erythrocyte porphyrin is considered to be a sensitive indicator of chronic lead poisoning in calves. Lead is also associated with an inhibition of the enzyme delta-aminolevulinic acid dehydratase (ALA-D), resulting in a failure of utilization of delta-aminolevulinic acid which is excreted in increased quantities in the urine.

CLINICAL FINDINGS

Cattle

Both acute and subacute poisoning occurs in cattle. The acute form is more common in calves and the subacute form in adults.

In the acute form there is usually a sudden onset of signs and a short course of 12–24 hours so that many animals, especially those at pasture, are found dead without signs having been observed. **Staggering**, and **muscle tremors** particularly of the head and neck, with **champing of the jaws (chewing gum fits)** and frothing at the mouth are obvious. Snapping of the eyelids, rolling of the eyes and bellowing are common. Blindness and cervical, facial and auricular twitching are consistent in acute lead poisoning of cattle. The animal eventually falls and intermittent tonic–clonic convulsions occur and may continue until death. Pupillary dilatation, opisthotonos and muscle tremor are marked and persist between the convulsive episodes. There is hyperesthesia to touch and sound, and the heart and respiratory rates are increased. In some cases, particularly in adults, the animal remains standing, is blind, maniacal, charges into fences, attempts to climb or jump over walls, and head-presses strongly against walls or fences. Frenzy is common and some animals appear to attack humans but the gait is stiff and jerky and progress is impeded. Death usually occurs during a convulsion and is due to respiratory failure.

In the subacute form the animal remains alive for 3–4 days. There is dullness, total anorexia, blindness, and some abnormality of gait including incoordination and staggering, and sometimes circling. The circling is intermittent and not always in the same direction and usually occurs when the animal is confined in a small space like a box stall. Muscle tremor and hyperesthesia are common but not as pronounced as in the acute form. Grinding of the teeth is common, excessive salivation may occur, and mild abdominal pain may be seen occasionally. Alimentary tract dysfunction is one of the most common abnormalities. Ruminal atony is accompanied by constipation in the early stages. Later a fetid diarrhea occurs in most cases.

The animal presents a picture of extreme dullness, will not eat or drink, and stands immobile for very long periods. Death frequently occurs by misadventure, the animal walking blindly into a waterhole or being trapped in a fence or between trees. In other circumstances the animal becomes recumbent and dies quietly. In both the acute and subacute forms, the palpebral eye preservation reflex is absent or markedly diminished. This is a useful distinguishing feature from polioencephalomalacia in which this reflex is usually normal. Edema of the optic disc may be present but is not common.

Experimental lead poisoning in young milk-fed calves, initially is characterized by severe depression and hypoglossal paresis which interferes with sucking. Within the next 12–24 hours, the calves become unsteady, ataxic, and exhibit muscular tremors of the head and forelimbs and finally convulsions, opisthotonos; they die in respiratory failure during status epilepticus.

Sheep

Lead poisoning in sheep is usually manifested by a subacute syndrome similar to that seen in adult cattle. There is anorexia and scant feces followed by the passage of dark, foul-smelling feces. Weakness and ataxia follow, often with abdominal pain, but there is no excitement, tetany, or convulsions. Polyuria occurs when the intake of lead is small but with large amounts there is oliguria.

Although ruminants are relatively resistant to chronic lead intoxication, two syndromes of posterior paresis have been described in young lambs in old lead-mining areas and tissue levels of lead are abnormally high in both instances. In both syndromes there is impairment of the gait. Osteoporosis is present in one but in the other there is no suggestion of skeletal changes. In the osteoporotic disease the signs occur only in lambs 3–12 weeks of age and never in adults. There is stiffness of gait, lameness, and posterior paralysis. Affected lambs are unthrifty and the bones, including the frontal bones, are very fragile. The paralysis is caused by lesions of the vertebrae, usually affecting one or more of the lumbar bones, and resulting in compression of the spinal cord. In the other form, gait abnormalities occur in the same lamb age group and are manifested initially by incomplete flexion of the limb joints so that the feet drag while walking. In a later stage the fetlocks are flexed, the extensor muscles paretic, and the lamb soon becomes recumbent. Recovery is common, although many lambs die of intercurrent disease.

Chronic ingestion of metallic lead by pregnant sheep can be associated with abortion and transitory infertility.[26]

Horses

Horses are not commonly affected by lead poisoning, although the chronic form occurred occasionally in the vicinity of lead mines and processing works.[27] The clinical findings are extremely variable.[7] A roughened hair coat, pharyngeal dysfunction, and weight loss were the most common clinical findings in 10 case reports involving a total of 68 animals.[7] Some horses died without any previous clinical illness but where clinical signs are apparent they were usually distinct and dramatic rather than subtle. Inspiratory dyspnea associated with paralysis of the recurrent laryngeal nerve is the most

common finding. This may be accompanied by pharyngeal paralysis in which recurrent choke and regurgitation of food and water through the nostrils occur. Aspiration pneumonia may result after inhalation of ingesta through the paralyzed larynx. Paralysis of the lips occasionally accompanies the other signs. General muscle weakness and stiffness of the joints occur commonly and the hair coat is usually harsh and dry. When chronic poisoning with both lead and zinc occurs the signs in zinc poisoning predominate despite high lead levels in liver and kidney. In experimental chronic lead poisoning in horses, there is noisy breathing constantly, but no lesions in the pharynx or larynx. Muscle fasciculations over the triceps are prominent in some horses and recumbency and convulsions may occur[7].

When large amounts of lead are ingested by horses a syndrome similar to that of the subacute form in cattle occurs. There is complete anorexia, severe nervous depression, partial paralysis of the limbs followed in most cases by complete paralysis and recumbency. Mild-to-severe abdominal pain and clonic convulsions may also occur. The response to experimental lead poisoning in the horse is highly variable.[7] The dose–response effect is highly variable and unpredictable.

Pigs

Early signs include squealing as though in pain, mild diarrhea, grinding of the teeth, and salivation. The disease is usually a prolonged one and listlessness, anorexia, and loss of weight develop followed by muscle tremor, incoordination, partial or complete blindness, enlargement of the carpal joints, and disinclination to stand on the front feet. Convulsive seizures occur in the terminal stages.

Subclinical lead poisoning

Because of the present concern about environmental pollution, the effects of the chronic low-level intake of lead have been examined and defined. In cattle, at intake levels below those which are associated with clinical signs, there are metabolic changes and changes in blood variables accompanied by a decreased rate of growth.[28] One concern is that continuous low-level consumption by pregnant females will result in teratogenic effects in the newborn. Trials to detect this manifestation in ewes have shown no effect on their lambs.

CLINICAL PATHOLOGY

In the living animal which has ingested lead, the element can be detected in blood, feces, urine, and milk.

Blood lead

The estimation of blood levels is generally useful for determining the lead status of the animal and is used most frequently to support or refute a clinical diagnosis of lead poisoning. Bovine blood lead reference materials are available and have been certified for many years.[29] Whole blood levels of lead in normal ruminants are usually below 0.05–0.25 ppm; poisoned animals usually have levels above 0.35 ppm and deaths begin at 1.0 ppm. Interestingly, buffalo may have blood levels above 1.0 ppm and still survive, which suggests that they have a higher tolerance level than cattle. However, when used alone, blood lead concentrations do not permit evaluation of length of exposure, amount of lead deposition in the body or the effects of lead on physiological systems. Blood lead concentrations also fluctuate markedly after administration of lead and consequently the clinical importance of blood lead concentrations is often questionable and a diagnosis based on this single determinant is equivocal. Blood lead concentration also has limited value for assessing the effectiveness of therapy for lead poisoning. Blood level concentrations may change rapidly during chelation therapy, often decreasing by 50% or more within 24 hours after initiation of treatment despite certain body tissues still containing high concentrations of lead. Thus the evaluation of biochemical indicators such as ALA-D may be useful. The blood and liver levels of fetuses from pregnant cattle with lead poisoning may be higher than what are considered toxic levels in adults which suggests concentration in the fetus.[25]

Representative values of lead for normal and poisoned animals are summarized in Table 32.2. The levels found in the liver and the kidneys are presented under necropsy findings.

Milk lead

Only limited information is available on the concentrations of lead which occur in cattle affected with field cases of lead poisoning. Lead levels of 0.13 mg/L of milk have occurred in natural cases with a half-life of 4.6 days.[12] The regulatory limit for lead in bovine milk in the Netherlands is 0.05 mg/L milk. In acute lead poisoning in lactating buffalo pastured near smelters in India, the lead concentrations in milk were 1.13 ppm compared to 0.24 ppm in the milk from buffaloes in unpolluted areas.[8] The mean lead concentrations in the forage of poisoned animals were 706 ± 73.0 ppm, compared to the unpolluted area of 78 ± 12 ppm.

Fecal lead

Fecal levels of lead represent unabsorbed and excreted lead deriving from the bones, and are of limited value unless considered in conjunction with blood levels because ingested lead may have been in an insoluble form and harmless to the animal. When fecal levels are high it can be assumed that the lead has been ingested in the preceding 2–3 weeks but high blood levels may be maintained for months after ingestion. Thus high blood and low fecal levels indicate that the lead was taken in some weeks previously but high blood and high fecal levels suggest recent ingestion and significant absorption.

Urinary lead, ALA-D

Urine lead levels are variable, rarely high (0.2–0.3 mg/L), and although elevated urine levels are usually associated with high blood levels, this relationship does not necessarily hold.

Because of some of the limitations of blood lead, other indirect measurements of lead poisoning, such as the levels of **delta-aminolevulinic acid dehydratase (Delta-ALA-D)** in blood, are being used to supplement blood lead determinations.[30] For example, the best method of detecting the presence of lead poisoning in its early stages, except in the horse, is the estimation of ALA-D in the blood. At dietary intakes as low as 15 mg/kg DM of lead in cattle there are detectably lowered levels of ALA-D. At the same time, the urinary levels of **delta aminolevulinic acid (Delta-ALA)** are increased. **Delta-ALA-D** is important in the synthesis of heme and is probably the most sensitive enzyme in the heme pathway. Inhibition of the enzyme results in a block in the utilization of delta-ALA, a subsequent decline in heme synthesis and a marked increase in the urinary excretion of delta-ALA. In cattle, sheep, and pigs affected with chronic lead poisoning, the plasma levels of **delta-ALA-D** are decreased and the urinary levels of **delta-ALA** are increased before clinical signs are detectable. In sheep, erythrocyte **delta-ALA-D** is recommended as the most sensitive diagnostic test available.

Table 32.2 Lead levels in blood and feces of normal and poisoned animals

Specimen	Lead levels (ppm) Normal	Poisoned
Whole blood (ruminants and horses)	0.05–0.25	More than 0.35 (deaths commence at 1.0)
Whole blood (pigs)	0.05–0.25	1.2
Feces (dry matter) (cattle)	1.5–35	Up to 1000
Pasture		350

The disadvantages of the assay for blood delta-ALA-D include age-related variations particularly in calves; the methods used for analysis are not yet uniform and blood must be collected in polystyrene or polyethylene tubes rather than glass tubes and an anticoagulant other than EDTA must be used. The levels of delta-ALA-D increase in calves from birth to 10 weeks of age and age-matched controls should be evaluated simultaneously when conducting the test in calves of under 6 months of age.[30] In cattle under 1 year of age, delta-ALA-D values of less than 200 mmol of porphobilinogen (PBG)/mL of RBC/hour should raise suspicion of their having ingested lead. In this same age range values below 100 mmöl would confirm ingestion of lead. In cattle equal to or less than 2 years of age, values of delta-ALA-D of less than 100 mmol of PBG/mL of RBC/hour would indicate ingestion of lead. Severe inhibition of delta-ALA-D occurs rapidly in calves given 1 mg of lead/kg BW per day or 5 mg of lead/kg BW/d. Inhibition of delta-ALA-D will reach approximately 50% of pre-exposure levels when blood lead concentrations are above 0.5 mg/kg, and if the initial dose of lead increases blood lead concentration above 0.5 mg/kg the delta-ALA-D becomes maximally depressed and remains so with continued exposure. The delta-ALA-D is so sensitive to lead that it remains inhibited even after lead exposure has ceased. Following treatment with a chelating agent the blood lead levels will often decline giving a false indication of a positive treatment effect. If the delta-ALA-D levels do not decrease following therapy, it indicates that there is sufficient lead present to continue to depress the enzyme. In summary, the evaluation of delta-ALA-D and blood lead concentrations together can assist in resolving diagnostic situations in which the blood lead concentration is in the questionable range of 0.25–0.35 ppm.

Erythrocyte protoporphyrin

The levels of free erythrocyte zinc protoporphyrin increase in lead poisoning and this is indicative of the chronic metabolic effect of lead on the erythroid cells being released from bone marrow into the peripheral circulation.[5] A mean value of 21.56 µg coproporphyrin/100 mL of erythrocytes has been determined. It may be of some value along with determinations of blood lead and delta-ALA-D. The use of delta-ALA-D activity and erythrocyte protoporphyrin content as cumulative lead exposure indicators in cows environmentally exposed to lead is recommended.[31] Plasma exposed to ultraviolet light may fluoresce due to high concentrations of porphyrins, and this may be a useful early diagnostic test.

Environmental lead

Because of the frequency with which lead appears in the environment as a pollutant, there is often concern for the validity of the normal values for establishment of a diagnosis. In the average city-polluted atmosphere it seems that lead intake will be significantly elevated. The lead content of hair of cattle and horses, and of the wool of sheep, is reported to be raised significantly in poisoned animals but hair is not routinely used in diagnosis of acute poisoning. However, the lead content of hair when cattle are exposed to long-term ingestion as a result of industrial contamination can reach as high as 88 mg/kg (in a clean environment comparable figures are of the order of 0.1 mg/kg). There is likely to be a seasonal variation in deposition and intake of lead. Hair is also a valuable source of information on environmental pollution with cadmium, copper, and zinc.

Hematology

In chronic lead poisoning, hematological examination may reveal a normocytic, normochromic anemia in some and, although basophilic stippling does not occur often enough to be diagnostic, it is recorded in some experimental poisonings. It is recorded as occurring in lead-exposed pigs and a horse. In some, poikilocytosis and anisocytosis were marked.[22] The cerebrospinal fluid (CSF) is approximately normal with slightly elevated leukocyte numbers but no increase in protein or other biochemical components.

NECROPSY FINDINGS

In most acute cases there are no gross lesions at necropsy. In cases of longer standing there may be some degree of abomasitis and enteritis, diffuse congestion of the lungs and degeneration of the liver and kidney. Epicardial hemorrhages are common. Congestion of meningeal and cerebral vessels may also be observed and hemorrhages may be present in the meninges. An increase in cerebrospinal fluid is often recorded but is of minor degree in most cases. In chronic cases gross lesions are recorded in cattle.[24] These include cerebrocortical softening, cavitation and yellow discoloration with most severe lesions in the occipital lobes. Histological lesions were most severe at the tips of the gyri. Similar lesions were produced experimentally. Acid-fast inclusion bodies deep in the renal cortex have diagnostic significance. Examination of the contents of the reticulum in ruminants for particulate lead matter is essential. Flakes of paint, lumps of red lead, or sheet lead usually accumulate in this site. Their absence is not remarkable especially if animals have licked fresh paint but their presence does give weight to the provisional diagnosis.

Liver and kidney lead

The submission of alimentary tract contents and tissues for analysis forms an important part of the diagnosis of lead poisoning but results must be interpreted with caution.

Cattle: 25 mg/kg of lead WW (wet weight) in kidney cortex is diagnostic and is a more reliable tissue for assay than liver which may contain 10–20 mg/kg WW. The concentrations in kidney are always much higher than in liver.[13,23] A diagnostic laboratory found mean levels in livers of poisoned cattle of 93.3 µg/g WW weight, and 437.7 µg/g in kidneys.[1] Tissue lead levels in cattle from industrial areas are significantly higher (liver 0.23 mg/kg WW, kidney 0.42 mg/kg WW) than in cattle from clear air zones (liver and kidney less than 0.1 mg/kg WW). Tissues which have been fixed in formalin are useful when they are the only tissues available.

Horses: Levels of 4–7 mg/kg WW of lead have been found in the livers of horses dying of chronic lead poisoning but 25–250 mg/kg are more likely, and 40 mg/kg WW may occur in the livers of affected pigs. Mean levels in livers of poisoned horses are 5.5 µg/g WW.[1]

Samples for confirmation of diagnosis

- **Toxicology** – 50 g liver, kidney, and reticulum content (ASSAY (Pb))
- **Histology** – formalin-fixed cerebral cortex, kidney (LM).

DIFFERENTIAL DIAGNOSIS

In all cases, much importance must be attached to the possibility of access to lead and the environmental circumstances which may arouse suspicion of other poisonings or errors in management. Estimation of the lead content of blood and feces should be carried out at the earliest opportunity and tissues form necropsy specimens submitted for analysis.

Cattle

Lead poisoning in cattle must be differentiated from the common diseases of the nervous system of cattle and other diseases in which neurological signs occur. The differential diagnosis of brain dysfunction and lead poisoning in cattle is summarized in Table 32.3. The diseases which closely resemble bilateral blindness are as follows:

Rabies characterized by normal eyesight, incoordination, gradual ascending paralysis, inability to swallow, bellowing and death in 4–7 days.

Polioencephalomalacia characterized by sudden onset of blindness, normal palpebral reflexes to touch, head pressing, tremors of head and neck, nystagmus, normal ruminal contractions.

Hypovitaminosis-A characterized by blindness, dilated and fixed pupils, optic disc edema, convulsions followed by recovery.

Ophthalmitis characterized by blindness due to lesions of the eyes but normal mentation.
Other diseases in which blindness is not characteristic but tremors, ataxia, convulsions, and bizarre behavior occur include: hypomagnesemic tetany, nervous acteonemia, arsenic poisoning, *Claviceps paspali* toxicity, memingoencephalitis.

Horses
Lead poisoning in horses must be differentiated from diseases causing loss of body weight, muscle fasciculations, incoordination, roughened hair coat, laryngeal and pharyngeal dysfunction. The differential diagnoses of diseases of the nervous system of the horse are summarized in Table 22.1. The diseases most closely resembling lead poisoning in horses include:
Laryngeal hemiplegia
Viral encephalomyelidites, including West Nile virus
Rabies
Hepatoencephalopathy due to hepatotoxic plants
Equine degenerative myeloencephalopathy
Protozoal encephalomyelitis
Equine motor neuron disease
Horsetail poisoning
Chronic weight loss
Chronic upper respiratory tract disease
Botulism
Fumonisin toxicosis (equine leucoencephalomalacia)

Sheep
The chronic forms of lead poisoning in lambs must be differentiated from other forms of posterior paralysis, particularly:
- **Enzootic ataxia due to copper deficiency**
- **Polyarthritis** due to bacterial infection
- **Enzootic muscular dystrophy** which may be associated with lameness and paresis but may be distinguished clinically by careful examination of the joints and skeletal muscles.

TREATMENT

Sedation and care

The case fatality rate of acute lead poisoning of cattle is high because of their high susceptibility and the nature of the material ingested. Sedation by IV injection of anesthetic doses of pentobarbital sodium in calves and chloral hydrate in adults temporarily relieves the convulsions.

Calcium versenate

Calcium versenate (calcium disodium ethylenediamine tetra-acetate, CaEDTA) has been used successfully in cases of lead poisoning produced experimentally in calves and in natural cases in cattle. CaEDTA is available as a 6.6% solution for IV administration. The manufacturer's recommendations are to use 1 mL/kg BW per day given in divided doses 2–3 times daily over a period of 3–5 days. Based on the treatment of experimentally induced lead poisoning in calves, the optimum conditions for lead mobilization in calves are provided by concentrations of about 135 μmol EDTA/mL, or higher, maintained for 10–12 hours. This is attained by the IV infusion of calcium EDTA at a dose of 110–220 mg/kg BW over 12 hours, which is approached by rapid IV injections of two doses of 110 mg/kg BW weight, 6 hours apart. This can be done daily for 3–5 days.

CaEDTA removes lead directly from bone-sensitive sites and not from parenchymatous organs because cell membranes form a barrier to the therapeutic removal of intracellular lead. The lead is removed from soft tissues by equilibration with bone. The process takes time and thus necessitates multiple treatment. Thus it is recommended that calcium versenate be given on alternate days to allow redistribution of lead from soft tissues to available bone sites. An increase in the heart and respiratory rates and the development of muscle tremors during injection indicates a toxic reaction but can be avoided by slow administration. Recovery may take 5–15 days and parenteral or stomach tube alimentation may be required. Blindness may persist for several days after general recovery and may continue indefinitely. Dramatic improvement has also been reported in cases of chronic lead poisoning in horses after the use of calcium versenate.

Thiamin hydrochloride

In combination with CaEDTA, thiamin is now being used for the treatment of lead poisoning.[32] Thiamin hydrochloride reduced the deposition of lead in most tissues especially liver, kidney, and the central and peripheral nervous system of experimentally poisoned calves. However, the levels of erythrocyte delta-aminolevulinic acid dehydratase (ALA-D) activity were decreased by 70% from pretreatment levels which indicated that thiamin had no protective effect on the ability of lead to inhibit the enzyme.[33] In experimental lead poisoning in mature dairy cows, the use of thiamin was not successful in reducing blood lead concentration, but treatment with disodium CaEDTA and thiamin was effective.[33] The use of thiamin also induced a remission of clinical signs of lead poisoning in cattle. Thus thiamin increases the elimination of lead from the body and may be beneficial in chelation therapy.

In naturally occurring cases in cattle, the use of thiamine and CaEDTA increases urinary lead output nearly a thousand times the untreated urinary level.[24] The blood and urinary lead half-lives with CaEDTA and thiamine therapy were 2.08 and 1.38 days, respectively.[25]

In experimental lead poisoning in calves, thiamin at 25 mg/kg BW SC BID cured 50% of affected calves.[34] The same dose of thiamin combined with 110 mg/kg BW of calcium versanate IV BID cured 100% of affected calves which had been given lead acetate at 5 mg/kg BW orally until clinical signs occurred. CaEDTA chelates lead from blood and bone while thiamine chelates lead in soft tissues and restores lead-induced biochemical alterations.[34]

In experimental lead poisoning in laboratory rats and mice, thiamin at a dose of 25 or 50 mg/kg BW along with CaEDTA at 50 mg/kg BW was more effective than the respective individual treatments alone.[31,35] Thiamin alone decreased the blood, liver, and kidney concentrations of lead, and thiamin at 50 mg/kg BW reduced the tissue concentrations in tissues more effectively than 25 mg/kg BW.

In experimental lead poisoning in sheep, the use of thiamin at 75 mg/kg BW SC along with CaEDTA at 100 mg/kg BW IV, increased the excretion of lead via the bile and urine. Overall, thiamin, CaEDTA, and thiamin and CaEDTA increased lead excretion by 72%, 595%, and 842%, respectively over basal levels.[36] It appears that thiamin can mobilize intracellular lead into blood and increase lead excretion via bile and urine.

Rumenotomy

Rumenotomy to remove the ingested lead has been used but may be unsatisfactory because of the difficulty of removing particulate material from the recesses of the reticular mucosa. However, it may be appropriate when a valuable animal is affected and it is known that the animal ingested a certain compound of lead which may be removable from the reticulum and rumen. Oral dosing with small amounts of magnesium sulfate has been used on the basis that soluble lead salts will be precipitated as the insoluble sulfate and excreted in the feces. However, the lead is often present in large quantities and in the form of particles which are only slowly dissolved.

Public health aspects of lead in meat and milk

A major concern with the treatment of lead poisoned animals, particularly food-producing animals, is the assurance that the edible tissues of recovered animals do not contain toxic levels of lead. The length of time required after successful treatment of cattle with typical clinical lead poisoning before such animals can be sent to slaughter or before the milk can be used safely is not known. It is suggested that treated animals should be appropriately identified and blood lead levels determined once or twice monthly for several months. When the blood lead levels have dropped to background levels for three consecutive samplings at least 2 weeks apart, the animals are assumed

Table 32.3 Differential diagnosis of diseases of cattle with clinical findings referable to brain dysfunction

Disease	Epidemiology	Clinical findings	Clinical pathology and pathology	Response to treatment
Lead poisoning	All ages calves and cows on pasture with access to dumps. Discarded lead batteries, used crankcase oil, lead-based paint common sources. Case fatality rate high	Acute in calves. Blindness and 'chewing gum' champing of jaws, convulsions, charging, rapid death. Subacute in adults: blindness, stupor, head-pressing, grinding teeth, rumen static, protozoa dead	Blood and tissue for lead. Encephalomalacia	Will respond favorably to treatment in early stages if not too severe but most cases do not return to normal. Calcium versenate and thiamin hydrochloride. Must be concerned about disposition of meat and milk of treated animals
Polioencephalomalacia	Grain-fed rapidly growing feedlot cattle. May occur on pasture containing plants and water high in sulfates. Outbreaks occur	Sudden onset, blindness, tremors and shaking of head, twitching of ears, head-pressing, opisthotonos, nystagmus, strabismus, rumen contractions normal, CSF pressure increased	Blood biochemistry (see text). Brain for histopathology	Responds to thiamin in early stages.Those due to sulfate toxicity may not respond
Hypovitaminosis A	Calves 6–8 months of age most commonly but mature cows too off dry summer pasture (CSF form). Young rapidly growing cattle fed deficient ration for several months (ocular form)	CSF form: sudden on set; syncope and convulsions followed by recovery, eyesight and pupils normal. Nyctalopia. CSF pressure increased. Ocular form: blindness in daylight, pupils dilated and fixed, optic disc edema. Syncope and convulsions may also occur. Usually preceded by nyctalopia but missed by owner	Plasma and liver vitamin A. Optic nerve constriction. Squamous cell metaplasia of parotid ducts	CSF form: recover in 48 hours following treatment with vitamin A injections. Ocular form: will not recover because of optic nerve degeneration
Haemophilus meningoencephalitis (thromboembolic meningoencephalitis)	Feedlot cattle (8–12 months), outbreaks, preceded by respiratory disease in group. High case fatality if not treated early	Found down, fever common, ataxic, not usually blind, fundic lesions, irritation signs uncommon, weakness and paresis common, synovitis, laryngitis, pleuritis, May die in 8–10 hours. Myocardial abscesses may also occur	Neutrophilia CSF contains neutrophils. Typical gross lesions in brain. Pleuritis, pneumonia, synovitis, myocardial abscesses	Respond favorably to antimicrobials if treated early. Later, high case fatality rate
Listeria meningoencephalitis	Sporadic. Fed silage. Yearlings and adults	Unilateral facial paralysis, deviation of head and neck, mild fever, endophthalmitis, may be recumbent	CSF for cells. Brain for histopathology	Recovery may occur. Antimicrobials. Residual signs in survivors common
Nervous signs with coccidiosis (see text)	In 20% of young cattle affected with dysentery due to coccidiosis. Case fatality may exceed 50%	Tonic–clonic convulsions, normal eyesight, hyperesthesia, normal temp., dysentery, may live 2–4 days	Oocysts in feces	Unfavorable response to treatment. Must control coccidiosis
Rabies	Cattle exposed to wildlife, one or more affected, all ages, incubation 3 weeks to few months	Quiet and dull (dumb form) or excitable and easily annoyed (furious form). Bellowing, yawning, drooling, saliva, eyesight normal, tenesmus, ascending paralysis beginning with anesthesia over tail head, progressive course, dies in 4–6 days, usually no gross muscular tremors or convulsions, mild fever early	Hemogram normal. Brain for laboratory diagnosis	Nil
Bovine spongiform encephalopathy (BSE)	Mostly in dairy cattle; Epizootic began in Britain in 1986; long incubation period; caused by scrapie-like agent in protein concentrate made from sheep carcasses following change in processing procedures	Insidious onset, clinical course several weeks, change in behavior, hyperesthesia, ataxia, loss of body weight, stare, agnostic behavior, kick during milking, knuckling, falling, progressive weakness leading to recumbency	Nil	Nil
Pseudorabies	Disease of pigs transmitted to cattle by bites.	Intense, local pruritus at site of bite, excitement, bellowing, convulsions, paralysis, death 2–3 days	Tissues for injection into rabbit. Histopathology of brain	Nil
Hypomagnesemic tetany (lactation tetany)	Lactating dairy cows on lush pasture, late pregnant beef cows, cold, windy weather in spring. May be precipitated by long transportation or deprivation of feed and water. Outbreaks occur. Seen in yearlings too. Case mortality can be high	Acute: sudden onset of irritability, hyperesthesia; convulsions, recumbency, loud heart sounds, tachycardia, polypnea. Subacute: gradual onset (2–4 days), hyperirritable, difficult to handle, stilted gait, falling, stumbling, sudden movement may precipitate convulsion	Serum magnesium level slow	Responds to magnesium sulfate early

Table 32.3 (Cont'd) Differential diagnosis of diseases of cattle with clinical findings referable to brain dysfunction

Disease	Epidemiology	Clinical findings	Clinical pathology and pathology	Response to treatment
Nervous acetonemia	2–6 weeks postpartum. High-producing cow. Single animal	Sudden onset, bizarre mental behavior, chewing, licking, bellowing, hyperesthesia, sweating	Ketonuria, hypoglycemia	Responds to glucose parenterally and/or propylene glycol orally
Bovine bonkers (Bovine hysteria)	Mature cattle and calves consuming ammoniated feeds (lucerne hay, bromegrass hay, fescue hay, wheat hay, maize stalks or silage). May also occur when animals have access to molasses-urea-protein blocks. Toxic agent may be substituted imidazole formed by combination of soluble carbohydrates and ammonia. Usually occurs when high quality forage treated with ammonia concentrate of more than 3% dry matter by weight. Can occur in nursing cows fed ammoniated feedstuffs	Periodic episodes of hyperexcitability, bellowing, running, charging, circling, convulsions, weaving, episodes last 30 seconds and may recur every 5–10 minutes. Some die. Most recover following removal of feed	Information not available	Recover spontaneously following removal of feed source
Hepatic encephalopathy (i.e. ragwort poisoning)	Cattle with access to plants containing pyrrolizidine alkaloids Many cattle may be affected	Loss of body weight, gradual onset of aggressive behavior, ataxia, muscular tremors, recumbency, convulsions, tenesmus and bellowing	Hyperbilirubinemia, decreased excretion of BSP. Liver lesions	No treatment
Brain abscess	Sporadic, young cattle (6 months to 2 years of age) may have history of previous infections	Localizing signs, rotation or deviation of head and neck, loss of equilibrium, circling, mild fever, may be blind in one eye, nystagmus one eye	Neutrophilia, neutrophils in CSF	Unfavorable response to therapy
Enterotoxemia due to *Clostridium perfringens* type D	Calves 2–4 months of age sucking high producing cows grazing on lush pastures. Outbreaks occur. Uncommon	Peracute: found dead. Acute: bellowing, mania, convulsions, blindness, death in 1–2 hours. Subacute: dull, depressed, blind	Hyperglycemia (150–200 mg/dL), glycosuria marked. Smear intestinal contents. Recover toxin (mouse protection tests)	Hyperimmune serum. Most die. Vaccination effective
Whole milk hypomagnesemic tetany of calves	Calves 2–4 months of age on whole milk. Also in calves on milk replacers, concentrates and hay and occasionally in nursing calves on pasture	Sudden alertness, hyperesthesia, head-shaking, opisthotonos, muscular tremors, frothing at mouth, convulsions, heart rate 200–250/min	Serum magnesium levels usually below 0.8 mg/dL	Magnesium sulfate intravenously gives good response, must follow up daily because of previous depletion of bone reserves

to be safe for slaughter. Undocumented field observations suggest that at least 6 months are necessary for background levels to be achieved. Recently, a study in dairy cattle determined a blood lead half-life that ranged from 48 to 2507 days. This was presumed due in part to exposure to batteries which may have been associated with prolonged retention of large pieces of metallic lead in the rumen or reticulum.[21] Although this study did not determine milk concentrations of lead, the low ratio of milk lead to blood lead may allow marketing of the milk. Decisions about reaching acceptable residue levels will depend on national or local regulations as well as the economics of maintaining a herd for long periods without sales of milk or meat, and appropriate food safety and public health officials should be consulted in this decision. The lead concentrations in blood and milk from periparturient heifers 7 months after an episode of acute lead poisoning revealed no lead in the milk. Animals which had been severely affected by lead poisoning experienced a transient increase in whole blood lead concentration at parturition which was not high enough to be considered toxic.[6]

CONTROL

The following practices are recommended to reduce the incidence of lead poisoning:

Adequate nutrition and consistent feeding practices will minimize pica or abnormal feeding behavior in livestock

Garbage should always be dumped at a single, isolated, fenced-off location, and preferably buried and burned if appropriate. Pastures are unsuitable sites for garbage

Used lead batteries and crankcase oil should be stored and disposed of safely, without spillage, and confined to areas where animals have no access

Vehicle service and machinery storage areas should be separate from areas used by livestock

Holding of animals in farm yards should be minimized, because such yards tend to be multipurpose areas with high risk for contamination

Only lead-free paints should be used on surfaces and fixtures to which livestock have access

All pastures should be inspected before cattle are introduced to them.

ARSENIC POISONING

Synopsis

Etiology Insecticidal dipping fluids, sprays; herbicides; wood preservatives, pharmaceuticals, feed additives. Inorganic compounds most toxic; organic arsenicals least.
Epidemiology Outbreaks due to accidental access to source, or due to use of excessive amounts as a dose rate or over time. Most cases result from ingestion but percutaneous absorption also possible.
Clinical signs Enteric form a highly fatal gastroenteritis with diarrhea, dehydration. Nervous form with incoordination and blindness, or a syndrome of incoordination, restlessness, squealing, convulsions.
Clinical pathology High levels of arsenic in feces, urine, milk for 5 days (organic arsenicals), 10 days (inorganic arsenic). Chronic cases best assayed in hair or skin.
Necropsy lesions Gastroenteritis in enteric form, no lesions in nervous form.
Diagnostic confirmation Higher than normal levels of arsenic in body fluids or tissues.
Treatment
Primary: 2,3-dimercaptopropanol (BAL) or sodium thiosulfate.
Supportive: fluids, electrolytes for dehydration.

ETIOLOGY

Arsenic compounds likely to be encountered by large animals are as follows:

Inorganic compounds used as insecticidal dips or as herbicides

- Oxide, e.g. arsenic trioxide
- Trivalent, e.g. sodium arsenite
- Pentavalent, e.g. sodium arsenate.

Organic compounds

Aliphatic organic arsenicals:

- Pharmaceuticals, e.g. cacodylic and phenylarsonic acids
- Weedicides, e.g. monosodium, and disodium methanearsonates (MSMA & DSMA).

Aromatic organic arsenicals, used as pharmaceuticals:

- Trivalent phenylorganic arsenicals, e.g. thiacetarsamide and arsphencomplexamine
- Pentavalent phenylorganic arsenicals, e.g. arsanilic acid, roxarsone (4-hydroxy-3-nitrophenylarsonic acid), nitarsone (4-nitrophenylarsonic acid).

Relative toxicities

Inorganic and aliphatic organic compounds. The organic pharmaceuticals are the least toxic, while the insoluble oxides of medium toxicity and the trivalent inorganic compounds are associated with the most severe syndrome. Toxic oral doses may range from 1 to 25 mg/kg for the arsenite, 30–100 mg/kg for the arsenate, cacodylic acid 25 mg/kg daily for 8–10 days, and 10–25 mg/kg for 5–6 days for the methanearsonates.[1,2]

Aromatic organic arsenicals are toxic when the recommended cumulative dose is exceeded by 2–4 times the recommended dose, delivered by either exceeding the recommended percentage in the feed or feeding it for too long. Seven to 10 days feeding of Arsanilic acid at 500 mg/kg diet or 3-nitro,4,hydroxyphenylarsonic acid at 250 mg/kg diet will be associated with toxicosis in swine; approximately twice these concentrations will result in poisoning of poultry.[1]

EPIDEMIOLOGY

Occurrence

Arsenic is less commonly associated with the poisoning of livestock nowadays because of the displacement of arsenic from almost all phases of farming activity.

Source of toxin

Arsenic is indestructible and remains in the environment permanently so that the source may not be recorded in contemporary history.

Dips and sprays. Fluids used for dipping and spraying of animals to control ectoparasites are the commonest source. Animals may swallow the solution while in the dip or in the draining yards after dipping. Animals that are not allowed to drain completely and faulty disposal of drainage from yards and dips may contaminate the pasture. Opened containers of dipping solutions or powders may accidentally contaminate feed or be mistakenly applied as a skin dressing. Appreciable amounts of arsenic are absorbed through the skin after dipping in sodium arsenite. The absorption is increased if the animals are dipped when hot, if the fleece is long, if they are crowded too tightly in draining yards or driven too soon after dipping. However, in most outbreaks of poisoning some ingestion appears to occur and supplements the cutaneous absorption. There is some danger in dipping rams at mating time when erythema of the skin of the thighs and scrotum is present. Dipping immediately after shearing and jetting at too high pressure or with excessively strong solutions may also be associated with increased absorption.

Herbicides include sodium or potassium arsenite, arsenic pentoxide, and monosodium or disodium acid methanearsonate sprays used to kill potato haulms prior to mechanical harvesting.

Insecticidal sprays used in orchards and pasture contaminated by calcium arsenate applied to kill Colorado beetle grubs are sources. In most instances poisoning occurs when animals accidentally gain access to recently sprayed areas, although drifting of windblown spray may result in accidental contamination of pasture. Grass clippings from lawn areas treated with arsenical herbicides 6 months earlier may carry 15 000 mg/kg arsenic. With lead arsenate the major effects are usually ascribed to the effects of the lead but this does not always appear to be so.

Insect baits may contain Paris green (cupric acetoarsenite) mixed with bran and when these are laid over large areas of land in an attempt to control grasshopper plagues they constitute a major hazard to livestock.

Wood preservatives especially arsenic-copper-chromium are used to treat pine in wooden calf pens. The compound has a salty taste and is licked avidly. Ashes from burned treated pine posts are also palatable to cattle.

Some metal-bearing ore deposits including iron, arsenic pyrites in volcanic soils, gold and copper ores contain large quantities of arsenic which may be licked *in situ*, or carried off in the fumes from

smelters and contaminate surrounding pastures and drinking water supplies.

Pharmaceuticals and growth stimulants including arsanilic acid and sodium arsanilate, and phenylarsonic acid preparations such as roxarsone, nitarsone, are used both as feed additives and in the control and treatment of vibrionic dysentery in animals, and as antidotes to selenium poisoning. Overdosing with them can occur accidentally by carrying on the administration for too long or when there is an error in mixing a batch of feed. The toxicity of feed containing arsanilic acid depends to a certain extent on the intake of drinking water but moderate water restriction does not make normal dose rates dangerous.

Route of poisoning

Arsenic poisoning usually occurs after ingestion of the toxic substance but percutaneous absorption can occur especially if the skin is abraded or hyperemic and percutaneous toxic dose is much lower (probably one-tenth) of the oral toxic dose.

Poison risk factors

Soluble salts are highly poisonous; arsenic trioxide and sodium arsenate are much less soluble and thus less toxic than sodium arsenite. Organic chemicals used as weedicides are as poisonous as the arsenite but organic arsenicals used as growth stimulants are less toxic, although they are absorbed rapidly.

Host risk factors. The LD_{50} of sodium arsenite varies between species with pigs, horses, cattle, and sheep requiring increasing doses to be affected.

Importance

In cases in which gastroenteritis is the predominant lesion, the case fatality rate approximates 100%. In cases characterized by nervous system involvement the illness is incidental and losses minimal if access to the poison denied, but residues become a problem.

Meat and milk residues reduce the safety of the products for human consumption. Arsenic is excreted rapidly after absorption, chiefly in the urine, and after the ingestion of non-toxic amounts by the cow there is no detectable excretion in the milk. When much larger doses are taken arsenic may be excreted in the milk, as well as in urine and feces, but the concentration is still low. The biological half-life of arsenic taken orally in the form of arsanilate is 4.2 days in liver, 5.7 days in kidney, and 15 days in muscle. In pigs fed arsanilic acid at 200 mg/kg in the feed the level of arsenic in muscle is still more than the admissible level of 0.1 mg/kg 18 days after withdrawal. The usual recommendation is to withdraw arsanilic acid 5–7 days before slaughter. This is adequate at normal dose levels.

PATHOGENESIS

Mode of action. Arsenic is a general tissue poison. The inorganic salts and the enteric-oriented organic compounds exert their toxic effects by combining with and inactivating the sulfhydryl groups in tissue enzymes. Trivalent arsenicals are most toxic because of their greater affinity for these sulfhydryl groupings. The efficiency of sulfur-containing compounds such as BAL (dimercaptopropanol) as antidotes depends on the ability of these compounds to compete with sulfur containing compounds of enzyme systems for the available arsenic.

Tissue susceptibility. Although all tissues are affected, deposition and toxic effects are greatest in those tissues which are rich in oxidative enzyme systems. Thus alimentary tract wall, liver, kidney, spleen, and lung are most susceptible to the general depression of metabolic activity which results.

Alimentary tract lesions produce the most obvious clinical signs due to the extensive damage to capillaries causing increased permeability and exudation of serum into tissue spaces. The mucosa lifts from the underlying muscle coat and is shed with the resulting loss of large quantities of body fluids. Arsenic does not precipitate protein and there is no direct local effect on alimentary tract mucosa; this is indicated by the fact that the parenteral injection of arsenic produces lesions in the gut wall which are identical with those associated with ingestion.

Time lag. Because arsenic does not precipitate protein it does not limit its own absorption, and there is a considerable time lag after ingestion before clinical signs appear; corrosive substances produce lesions and signs immediately.

Percutaneous absorption. Arsenic absorbed from the skin may be associated with local necrosis without systemic signs if the peripheral circulation is poor or the concentration of arsenic is excessively high, but if the cutaneous circulation is good, the arsenic is quickly carried away and is associated with a systemic disease without skin necrosis.

Chronic poisoning. The chronic toxicity of arsenic at low levels of intake is due to its accumulation in particular organs, especially the liver, kidney, alimentary tract wall, epidermis, spleen, and lung.

Nervous tissue lesions. The nervous signs associated with organic arsenicals are the result of inhibition of dehydrogenase enzyme systems (e.g. pyruvate and alpha-ketoglutarate systems), causing degenerative changes in peripheral nerves. These appear as demyelination and axonal degeneration in prolonged cases. Animals recumbent longer than 7 days are unlikely to recover and will remain paralyzed until death from other associated conditions. In poisoning with the arsanilic acid compounds the lesions are mostly in the optic nerves, causing blindness. In poisoning with the phenylarsonic acid group the nerves to the limbs appear to be affected most.[2]

CLINICAL FINDINGS

Ruminant gastroenteritis syndromes

Acute cases are the commonest syndromes in ruminants; the onset of signs of illness is delayed 20–50 hours from the intake of the poison, the length of time varying with the fullness of the forestomachs. Distress develops suddenly, commencing with severe abdominal pain, restlessness, groaning, an increased respiratory rate, salivation, grinding of the teeth, complete ruminal stasis, and vomiting, even in cattle. A fluid and fetid diarrhea develops later. The heart rate is greatly increased, the pulse small in amplitude; dehydration, and oliguria are marked.

Peracute cases show little except depression and prostration and die before signs of enteritis develop. A fluid sound in the abdomen can be elicited by shaking the animal. Death occurs 3–4 hours after commencement of the illness and is usually preceded by clonic convulsions and diarrhea.

Subacute cases give the same signs as acute cases but the course may extend over 2–7 days. Nervous signs of muscle tremor, incoordination, and clonic convulsions are followed by terminal coma.

Chronic cases. Commonly observed signs include low body weight, a dry, staring coat which is easily shed, loss of vigor and spirit, capricious appetite, bouts of indigestion, conjunctival and mucosal erythema, eyelid edema and conjunctivitis. Buccal mucosal ulceration may extend to the muzzle. Milk yield is seriously reduced and abortions and stillbirths may occur. Local skin lesions include initial hyperemia followed by necrosis and sloughing leaving indolent lesions which are extremely slow to heal.

Horses

Signs include marked congestion of the mucosae and a very sudden onset of severe colic which passes off in a few hours in horses which survive. Severe diarrhea may be followed by a period of complete stasis of the alimentary tract with diarrhea recurring just before death.

Nervous syndromes in pigs and lambs

Chronic poisoning resulting from overdosing with arsanilic acid is manifested by

incoordination and blindness appearing about 7 days after the compound is first fed. Consciousness, body temperature, and appetite are unaffected. If feeding is continued the signs gradually worsen but disappear within a few days if the feed is changed. Some pigs remain permanently blind or paralyzed.

In chronic poisoning with roxarsone and nitarsone the emphasis is on restlessness, frequent urination, and defecation, incoordination due to loss of balance, frequent shrill 'screaming', tremor, and convulsions, all of which are stimulated by rousing the pig. If it is left alone in a recumbent position it may appear normal.

CLINICAL PATHOLOGY

Arsenic can be detected in the urine, feces, and milk for periods of up to about 10 days, beginning shortly after the toxic material is ingested. The rate of excretion is faster with organic compounds than with inorganic arsenic and urine levels may be back to normal in 5 days. The most satisfactory material for laboratory examination from a living animal is a large volume (about 1 L) of urine in which arsenic levels may be as high as 16 mg/kg. Levels in milk are low. Normal levels of up to 0.25 mg/kg in cows'milk may be elevated to 0.34–0.47 mg/kg in cases of acute poisoning and to 0.8–1.5 mg/kg in the milk of normal cows which graze arsenic-contaminated pasture for long periods. Deposition in the hair occurs and the arsenic persists there until the hair is shed, making possible the detection of prior arsenic ingestion in the absence of arsenic from the blood and feces. The hair of animals not exposed to arsenic should contain less than 0.5 mg/kg, but that of normal, exposed animals may contain as much as 5–10 mg/kg. Estimations of amounts of arsenic present in suspected materials are mandatory, but delay in sampling of herbage after a contaminating incident may distort results because of leaching of soluble compounds.

NECROPSY FINDINGS

In acute and subacute cases of **inorganic arsenic poisoning** there are pronounced hyperemia and patchy submucosal hemorrhage in the stomach, duodenum, and cecum. Hemorrhage and multifocal ulceration of the cecum and large colon have been observed in horses.[3] In ruminants the forestomachs are unaffected but typical lesions are present in the abomasum. The gut contents are very fluid, and contain much mucus and shreds of mucosa. Profuse subendocardial hemorrhages are common and ulceration of the gallbladder mucosa is often observed in sheep. Macroscopic lesions may be minimal in cases which die after a very short course. Histologically, most of the hemorrhages can be attributed to the necrosis of capillaries, although damage to the walls of larger vessels may sometimes be found.[3] Severe intravascular hemolysis has been observed in sheep. Degenerative changes are common in the liver and kidney of animals suffering from arsenic toxicosis and these changes become more pronounced if the disease course is prolonged. In some cases of chronic poisoning, loss of myelin may be observed in the peripheral nerves, with secondary neural degeneration in the central nervous system.

The liver is the best organ for assay of acute arsenic poisoning, while kidney may contain high levels in subacute or chronic poisoning. Levels of over 10–15 mg/kg wet matter of arsenic trioxide in the kidney or liver are considered to be diagnostic of arsenic poisoning. However, it is probable that many animals die of arsenic poisoning when their hepatic levels are much lower than this. Maximum concentrations of arsenic in tissues occur about 8 hours after ingestion and animals which survive for 2–3 days may have levels as low as 3 mg/kg. Conversely, normal animals which are dipped routinely in arsenical dips may have hepatic levels of the element as high as 8 mg/kg. Levels of 1–3 mg/kg are obtained in cattle dying from arsenic poisoning after percutaneous exposure and levels of over 10 mg/kg in cattle which ingest arsenical dip. The toxic dose in ingesta varies widely but averages about 36 mg/kg. Assay of the arsenic level in hair may be useful in chronically poisoned animals.

Animals poisoned with **organic arsenicals** show no significant gross pathological changes. Histologically, degeneration of the optic nerves, optic tracts, and peripheral nerves is apparent.[3] The animals maintain tissue levels of arsenic for as long as exposure continue, although the levels fall rapidly during the first 7 days after feeding of the arsenic ceases, and normal levels are not reached until a further 7 days. Levels of about 6 mg/kg arsenic trioxide in liver and kidney on a fresh, wet-matter basis indicated poisonous levels of intake. Arsenic levels in brain, spinal cord, and peripheral nerves are retained longer after poisoning than are liver and kidney values. Because the stomach and intestinal wall appear to attain maximum concentrations of arsenic most rapidly after poisoning, the use of these tissues for quantitative assay has been recommended. Therefore a part of the upper alimentary tract including contents should accompany the liver and kidney samples submitted for analysis. However, animals that are no longer exposed to arsenic or are recovering after exposure stops will have relatively little arsenic retained after the initial acute episode.

Samples for confirmation of diagnosis

- **Toxicology** – 50 g liver, kidney; segment of stomach/intestine including content; sample of suspected poison (ASSAY(As))
- **Histology:**
  - *inorganic As*: formalin-fixed stomach, intestine, cecum, large colon, liver, kidney, peripheral nerve;
  - *organic As*: formalin-fixed optic nerve and tract, peripheral nerve (LM).

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation in all kinds of arsenic poisoning is by detection of toxic levels of arsenic in tissues and fluids of the patient.

Acute inorganic arsenic poisoning presents a clinical syndrome of gastroenteritis with minor signs of nervous system involvement, which is common in other diseases.

Differential diagnosis list

- **Lead poisoning:** the emphasis is on nervous system signs with gastroenteritis an inconstant accompaniment
- **Bovine malignant catarrh** develops in somewhat the same manner especially in the alimentary tract form but there are diagnostic lesions in the eyes and buccal mucosa
- **Mucosal disease** is also characterized by erosions in the buccal and nasal mucosae
- **Salmonellosis** is often confused with arsenic poisoning especially when the disease is seen in the later stages and the fever has subsided
- **Poisonous plants** which are associated with nervous signs and gastroenteritis include bracken, mustards, and a miscellaneous group in which specific toxins have not been identified

Chronic inorganic arsenical poisoning is associated with a syndrome of diarrhea and weight loss in areas around mining and smelting plants. It may be confused with:

- inanition
- internal parasitism especially ostertagiasis, trichostrongylosis and oesophagostomiasis.

Organic arsenical poisoning is characterized by dramatic but mild nervous signs, but a normal appetite and no fever.

Differential diagnosis list:

- Organic mercury poisoning
- Salt poisoning
- Encephalitis.
- Tri-ortho-cresyl phosphate or other industrial organophosphates that could contaminate swine feeds
- Selenium toxicosis (chronic) in swine with focal symmetrical poliomyelomalacia.

TREATMENT

In acute cases treatment is of little value because of the large amounts ingested and the delay between ingestion and the appearance of illness, but affected animals are unsuitable for human consumption so that treatment is not usually undertaken.

Primary treatment

Compounds containing sulfur are theoretically the best antidotes and of these **BAL (2,3-dimercaptopropranol)** is an efficient antidote for poisoning by organic arsenicals, but is often disappointing in cases of poisoning by inorganic salts, unless therapy is begun before clinical signs appear. Dosing at 4-hourly intervals is necessary and the oily injection is associated with some local pain. Although BAL has a general beneficial effect and is recommended as a treatment, the drug is quite toxic itself and in the doses required may be associated with deaths in sheep. It also is associated with a reaction at the injection site sometimes serious enough to warrant the animal's destruction.

Sodium thiosulfate is a practicable and frequently used treatment. The compound is almost completely non-toxic and can be given in large amounts and without accurate measurement. Intravenous injection is desirable as an initial treatment using 15–30 g of the salt in 100–200 mL of water and this should be followed by oral dosing of 30–60 g at 6-hour intervals. Treatment should be continued until recovery occurs which may require 3–4 days.

A comparison of these treatments in experimentally poisoned cattle shows little benefit from sodium thiosulfate administration and most effect with a combination of BAL and thioctic acid.[1] Dimercaptosuccinate is a water soluble analog of dimercaprol, is less toxic than BAL, is available in the USA and should be more effective than BAL. The antioxidants zinc, methionine, and cysteine, used with chelation therapy, have been reported to enhance excretion of arsenic in experimental poisoning. Their use may be helpful as adjuncts to recommended chelation therapy.[5]

Supportive treatment

Attempts should be made to adsorb the residual arsenic in the gut by administering charcoal (1–4 g/kg BW *per os*), and then removed by the administration of an oil demulcent, or osmotic aperient like magnesium sulfate. Drastic purgatives should be avoided. Several products are used in an attempt to precipitate arsenic in the gut lumen. Ferric hydrate is most commonly used but has little apparent effect on the course of the disease.

Severe dehydration occurs and supportive treatment must include the provision of ample fluids preferably by parenteral injection. An adequate supply of drinking water containing electrolytes should be provided and the animals should be disturbed as little as possible and provided with shelter from the sun. Astringent preparations given by mouth may help to reduce the loss of body fluids. Recovering animals should receive a bland diet and high-quality protein.[1]

Withdrawal time. After the treatment of pigs with arsanilic acid the arsenic content of their livers may exceed 1 mg/kg, the statutory level of arsenic in food for human consumption. At least 10 days should be permitted between ceasing to feed the arsanilate and slaughter to avoid poisoning of humans.

Control

Arsenical preparations must be handled and stored with care and contamination of feed and pasture avoided. Therapeutic preparations containing arsenic should be labelled 'Poison' and strict instructions given on dosage, particularly the length of time for which administration should continue. Animals to be dipped in arsenical solutions should be allowed to cool off before dipping, to drain properly afterwards and to dry before being driven. They should be watered before dipping to prevent them drinking the dip. Much mortality has occurred when instructions for mixing dip solutions were not closely followed. Dipping solutions containing more arsenic than is safe usually occur when tanks which have lost water by evaporation are reconstituted by guesswork. The maximum safe concentration of arsenic trioxide in a dip for cattle is 0.20%.

SELENIUM POISONING

Synopsis

Etiology Ingestion of or injection with excessive amounts of selenium.
Epidemiology Enzootic disease where soils and pasture contain toxic amounts of selenium. Outbreaks after errors in feed supplementation or oral or injection doses.
Clinical signs
Acute: dyspnea, diarrhea, prostration, short course, death.
Chronic: emaciation, rough coat, stiff gait, lame, hoof deformity.
Clinical pathology toxic levels of selenium in body tissues and fluids.
Necropsy lesions All forms – liver necrosis.
Diagnostic confirmation High selenium levels in body fluids and tissues.
Treatment Nil. Avoid toxic pasture. Care with medication and feed additives containing selenium.

ETIOLOGY

Selenium poisoning is associated with the ingestion of organic or inorganic selenium compounds as follows:

- Organic selenocompounds (selenocysteine, selenocystine) occurring in pasture plants
- Inorganic selenium compounds administered as feed supplements
- Pharmaceutical preparations administered orally, frequently combined with vitamin E, for prophylaxis or by injection in treatment.

Toxic dose. Discrepancies exist in the toxic doses quoted in the literature and the following information is subject to that limitation. Daily intakes of 0.25 mg/kg BW are toxic for sheep and cattle; feed containing 44 mg/kg selenium for horses and 11 mg/kg for pigs is associated with poisoning. The daily intake of a diet containing 2 mg/kg of selenium can be marginally toxic for sheep. Toxic single oral doses (as mg/kg BW) are 2.2 for horses and sheep, 9 for cattle, and 15 for pigs. An oral dose of 10–15 mg of selenium has been known to kill lambs. Recommended limits for seleniumin feed are given under Control, and for injection in the section on treatment.

EPIDEMIOLOGY

Occurrence

- **Pastoral.** Selenium poisoning occurs in restricted areas in North America, Ireland, Israel, Canada, Australia, and South Africa where the soils are derived from particular rock formations containing a high content of selenium. No authoritative reason has been advanced to explain why the reported occurrence of the disease in these areas is much less now than it used to be
- **Dosing errors.** Substantial losses due to selenium poisoning also occur because of misunderstanding about the dose rates of selenium compounds used therapeutically or prophylactically.

Source of toxin

Pastoral. The effective selenium is contained in the top 60–90 cm of the soil

profile, selenium at lower levels than this not being within reach of most plants. Selenium poisoning may occur on soils containing as little selenium as 0.01 mg/kg, but some soils may contain as much as 1200 mg/kg. Most pasture plants seldom contain selenium in excess of 100 ppm, but a number of species, the so-called **converter or indicator plants**, take up the element in such large quantities that selenium levels may reach as high as 10 000 ppm. Included in this category are *Acacia cana*, *Artemisia canescens*, *Aster* spp., some of the *Astragalus*, *Atriplex* and *Castilleja* spp., *Comandra pallida*, *Descurainia pinnata*, *Grindelia* spp., *Machaeranthera ramosa*, *Morinda reticulata*, *Neptunia amplexicaulis*, *Oonopsis*, *Penstemon* and *Sideranthus* spp., *Stanleya pinnata* and *Xylorrhiza* spp.

These plants tend to grow preferentially on selenium-rich soils and are thus 'indicator' plants. They are in general unpalatable because of a strong odor so that an acute syndrome is unlikely but heavy losses have been attributed in the past to two chronic forms of the disease known as **blind staggers** and **alkali disease**. Much of these data are now discounted and losses due to chronic selenosis in cattle in the western USA in recent years have been small.

Industrial deposition, e.g. fly ash from soft coal deposited in fields has been shown to be associated with increased selenium levels in tissues from sheep grazing there.

Dietary supplement is used in the prevention of known deficiency syndromes such as white muscle disease in lambs, as a non-specific growth stimulant, and as a prophylactic for a large number of other vague syndromes. It is not surprising that the careless use of selenium compounds has induced selenium poisoning on a wider scale.

Prophylactic. It is now common practice to combine a selenium compound with an anthelmintic drench or injection and, if the mixture is not thoroughly shaken, poisoning may occur. Concurrent administration of monensin and selenium also increases the toxicity of the selenium being fed.[1] There are many case reports of unexpected illness and mortality in animals dosed with selenium preparations and it is apparent that not all of the factors affecting selenium toxicity are known. Identified factors include the cobalt and protein status of the animal, deficiencies of either causing increased susceptibility.

Risk factors

Environment factors. Selenium poisoning in animals grazing plants growing on seleniferous soils may be restricted to very distinct areas as small as individual fields. A low rainfall predisposes to selenium poisoning because soluble, available selenium compounds are not leached out of the topsoil and lack of competing forage may force animals to eat large quantities of indicator plants.

Toxin factors. Organic selenium compounds, especially those occurring naturally in plants, are generally considered to be much more toxic than inorganic compounds but this difference may not be apparent in ruminants because of alterations in ingested compounds produced by digestive processes in the rumen. Selenite is more toxic than selenate and both are more damaging than selenium dioxide.

Host factors. Cattle are more tolerant than sheep. Pigs are unlikely to be exposed but can develop the disease in the field.

PATHOGENESIS

Acute oral poisoning is associated with chemical erosion of alimentary tract mucosa. Poisoning with a single injection, e.g. in pigs, is associated with sudden death due to vasogenic circulatory failure, a vasculogenic shock.[2]

The mechanism forming the basis of chronic poisoning has not been identified. Selenium occurs in plants in analogs of the sulfur-containing amino acids, e.g. selenocysteine, and a possible mechanism of intoxication is by interference with enzyme systems which contain these amino acids. Selenium reduces the sulfur and protein content of sheep's liver and high protein diets have a protective effect against selenium poisoning. Selenium is deposited in greatest concentration in the liver, kidney, and hair. It has a marked dystrophic effect on skeletal musculature and is associated with a marked rise in SGOT levels after subcutaneous administration.

CLINICAL FINDINGS

The terms **blind staggers** and **alkali disease**, used previously in this section have been discontinued as misleading and being based on misunderstandings about the etiological agents involved.

Acute poisoning. In naturally occurring and experimental poisoning there is severe respiratory distress, restlessness, complete anorexia, salivation, watery diarrhea, fever, tachycardia, abnormal posture and gait, prostration, and death after a short illness. Mildly affected pigs show posterior ataxia, walking on tiptoe, difficulty in rising, sternal recumbency, tremor, and vomiting in some. Extreme cases assume a posture of lateral recumbency.

Chronic poisoning is manifested by dullness, emaciation, rough coat, lack of vitality, stiffness, and lameness. In cattle, horses, and mules the hair at the base of the tail and switch is lost and in pigs, goats, and horses there may be general alopecia. There are hoof abnormalities including swelling of the coronary band, and deformity or separation and sloughing of the hooves in all species. Lameness is severe. Congenital hoof deformities may occur in newborn animals. Hemorrhagic lesions on the proximal wall and soles of claws on all four feet may accompany these deformities.[3] Chronic poisoning in pigs on rations containing 20–27 mg/kg is also associated with a syndrome of reduced feed intake, paraplegia and quadriplegia[4] due to **poliomyelomalacia**. Pigs on marginal levels of intake of selenium (10 mg/kg) develop necrosis of the coronary band, low conception rates, and increased neonatal mortality.

CLINICAL PATHOLOGY

Selenium can be detected in the urine, milk, and hair of affected animals. Clinical illness is evident at blood levels of 3 mg/kg and at urine levels of more than 4 mg/kg of selenium. Normal serum levels of 140–190 ng/mL are elevated to the 1500 ng/mL level.

Critical levels of selenium in hair include the following:

- Less than 5.0 mg/kg suggests that chronic selenosis is unlikely
- From 5.0 to 10.0 mg/kg suggests that borderline problems will occur
- More than 10 mg/kg is diagnostic of chronic selenosis.

A moderate anemia occurs in acute and chronic poisoning and a depression of hemoglobin levels to about 7 g/dL is one of the early indications of selenium poisoning.

NECROPSY FINDINGS

In confirmed cases of natural or experimentally produced[5] acute selenium poisoning most of the macroscopic findings can be attributed to cardiovascular compromise. There is pulmonary edema and congestion, petechiation of the thoracic viscera, and congestion of the liver, kidneys, and gastrointestinal tract. In parenterally overdosed lambs and piglets there is usually hydrothorax, hydropericardium, and ascites[6]. Histologic lesions may be minimal if the clinical course is brief. Changes which may be observed in animals surviving more than 24 hours include a serous effusion within pulmonary alveoli, mild hyaline or granular degeneration of skeletal muscle fibers, hydropic degeneration in renal tubular epithelial cells and periacinar degeneration and necrosis of hepatocytes. Cardiac

myocytes may appear swollen and contain areas of cytoplasmic granularity and lysis.

The causal link between selenium intoxication and blind staggers is weak and the lesions described in accounts of this largely historical disease are in dispute. It is probable that this clinical entity is the result of other etiologic factors.[7] In animals suffering from subacute to chronic selenium poisoning there is a skeletal and cardiac myopathy. Deformities of the feet and skin are usually apparent, as described under Clinical findings. Atrophy and dilatation of the heart and pulmonary edema, cirrhosis and atrophy of the liver, glomerulonephritis, mild gastroenteritis, and erosion of articular surfaces have also been recorded.[2] Symmetrical poliomyelomalacia has been identified in both natural and experimental settings in pigs fed excessive selenium. The areas primarily affected are the ventral horns of the cervical and lumbar enlargements, with lesser damage in brainstem nuclei. The microscopic appearance of affected spinal cord includes vacuolation of the neuropil and sometimes of the cytoplasm of neurons. Neuronal chromatolysis, axonal swelling, and endothelial cell swelling and proliferation are consistently present.

Samples for confirmation of diagnosis

- **Toxicology** – 50 g liver, kidney; 500 g of suspect feed (ASSAY (Se))
- **Histology** – formalin-fixed skeletal muscle, heart, liver, kidney, +/- spinal cord from cervical and lumbar enlargements (LM).

Selenium levels in tissue. In chronic selenosis in sheep hepatic and renal levels of selenium are about 20–30 mg/kg and levels in wool are in the range of 0.6–2.3 mg/kg. In horses hair levels of more than 5 mg/kg are recorded.

DIFFERENTIAL DIAGNOSIS

The diagnosis of selenium poisoning rests largely on the recognition of the typical syndromes in animals in areas where the soil content of selenium is high, or when there has been administration of selenium as medication or as a feed additive. The clinical and necropsy lesions associate with the poisoning cover a wide range of signs and lesions and are not easily summarized. Diagnostic confirmation depends on an assay of toxic levels of selenium in body tissues or fluids.

Differential diagnostic list:

Acute poisoning

- Anaphylaxis
- Septicemia
- Toxemia
- Acute arsenic toxicosis.

Chronic poisoning

- Hypovitaminosis A.

TREATMENT

A number of substances have been tried in the treatment of selenium poisoning, including potassium iodide, ascorbic acid, and beet pectin but without apparent effect. BAL is contraindicated.

CONTROL

The manufacturers' advice on dose rates for pharmaceutical and feed additive preparations should be followed at all times. As a further guide to safe dose levels which avoid toxicity the following guidelines are provided:

- In general, the ratio between acute toxic and therapeutic doses is 50–100:1 and dosing accidents should not be common
- **Sheep.** The subcutaneous injection of selenium, as sodium selenite, is associated with poisoning in sheep at doses of 0.8 mg/kg BW and doses of 1.6 mg/kg are lethal. A single injection of 5 mg of selenium may kill some lambs and the toxic level for single injections in lambs has been reported as 455 µg/kg BW
- **Cattle.** Lethal doses by injections are 1.2 mg/kg BW
- **Pigs.** Lethal doses are between 1 and 2 mg/kg BW
- **Ponies.** Only relatively large doses, e.g. 6–8 mg/kg BW is associated with fatality.

Selenium in feeds should not exceed 5 mg/kg dry matter if danger is to be avoided and feeding on pasture containing 25 mg/kg dry matter for several weeks can be expected to be associated with chronic selenium poisoning. Pasture may contain as much as 2000–6000 mg/kg of selenium and is associated with the acute form of the disease when fed for a few days.

Protection against the toxic effects of selenium in amounts up to 10 mg/kg in the diet has been obtained by the inclusion in the ration fed to pigs of 0.01–0.02% of arsanilic acid or 0.005% of 3-nitro-4-hydroxyphenyl arsonic acid. In cattle 0.01% arsanilic acid in the ration or 550 mg/day to grazing steers gives only slight protection. The addition of linseed oil to the ration improves the efficiency of this protection. A high protein diet also has a general protective effect. Pretreatment with copper is also known to be an effective preventive measure in all species. The mechanism of this protection is unknown. A single oral dose of 20–40 mg/kg of copper given 24 hours before administration of selenium protects ponies.

PHOSPHORUS POISONING

Phosphorus is rarely used as a rodent poison nowadays and this is the only likely source of phosphorus for animals. Toxic effects are increased when the phosphorus is finely divided and mixed with oils or fats which facilitate its absorption. Phosphorus used for military purposes is associated with extensive contamination of pasture.

Phosphorus has a local caustic action and on ingestion is associated with severe irritation of the alimentary mucosa with signs of gastroenteritis appearing within an hour or two. Some phosphorus may be absorbed and is associated with acute hepatic necrosis but signs do not appear for several days.

CLINICAL FINDINGS

These include severe diarrhea, acute abdominal pain, salivation, and intense thirst. Pigs vomit violently and the vomitus is luminous and has a garlic odor. The patient often dies of acute shock during this stage. Survivors show jaundice, weakness and anorexia, oliguria and hematuria. Death may occur in coma or be accompanied by convulsions. Phosphorus can be detected in the vomitus and feces of affected animals.

NECROPSY FINDINGS

Macroscopically there is congestion and hemorrhage of the alimentary mucosa. The carcass is often jaundiced and the liver is swollen and pale. Histologically there is fatty degeneration of both the liver and kidney, sometimes accompanied by hepatic necrosis. The acute stages of phosphorus poisoning may appear similar to acute stages of inorganic arsenic, mercury, or selenium poisoning.

Samples for confirmation of diagnosis

- **Toxicology** – 50 g liver, kidney and a portion of alimentary tract with content (ASSAY (P))
- **Histology** – formalin-fixed liver, kidney (LM).

Diagnostic confirmation requires evidence of access to the poison and the detection of large amounts of it in the alimentary tract.

Treatment. An emetic or hydragogue purgative should be given immediately. Supportive treatment includes the administration of astringents to allay the gastroenteritis and parenteral electrolyte solutions to relieve the dehydration. Hypotension and shock as well as coagulopathy may occur and should be treated supportively as needed.

MERCURY POISONING

Synopsis

Etiology Rarely inorganic mercury, commonly organic preparations.
Epidemiology Inorganic salts in preparations used as rubifacients. Organic preparations used in seed grain fed accidentally to livestock.
Clinical signs
Inorganic salts: Acute – vomiting, diarrhea, abdominal pain; Chronic – weight loss, depression, alopecia, scabby dermatitis, long course.
Organic preparations: blindness, incoordination, paralysis.
Clinical pathology High levels of mercury in all tissues and fluids; high blood urea nitrogen, urine alkaline phosphatase in cases of nephrosis.
Necropsy lesions
- Inorganic salts: Acute – gastroenteritis; Chronic – nephrosis.
- Organic preparations: neuronal necrosis in brain and spinal nerves.
- Poisoning by mercury is associated with inflammation of the alimentary mucosa and damage to the kidneys. It is manifested clinically by gastroenteritis and terminally by signs of uremia.
- Diagnostic confirmation. High blood, urine, tissue levels of mercury.

Treatment
Primary: Sodium thiosulfate orally and parenterally; BAL by injection.
Supportive: Astringents orally, fluids parenterally.
Control Care in the handling of agricultural and pharmaceutical mercurials.

ETIOLOGY

Mercuric chloride and mercury biniodide are highly poisonous, the toxic dose for horses and cattle being about 8 g and for sheep 4 g. Organic mercury taken regularly in the diet at a level of 1 mg/kg is associated with chronic poisoning in pigs. A level of 6 mg/kg is associated with deaths in pigs within 5 days.

EPIDEMIOLOGY

Source of toxin

Mercury poisoning in farm animals occurred in the past almost exclusively as a result of accidental feeding of grain, pellets, or concentrate mixtures treated with organic mercurial antifungal agents.

Because of the availability of fungicidal agents other than mercury it is possible to limit the use of mercuric agents by legislation to those excreted rapidly by animals, the phenylmercury compounds, and prohibiting those which are retained in animal tissues, the ethyl and methyl compounds. Worldwide use of mercurial fungicides has declined and poisoning is much less common than in the past. The commonest agents, when used, are dusts of 5.25% methoxyethylmercury silicate or methylmercury dicyandiamide. These and ethylmercuric chloride are toxic when fed to pigs at the rate of 0.19–0.76 mg of mercury per kg BW per day for 60–90 days. Methylmercury dicyandiamide fed to pigs at the rate of 5–15 mg/kg is associated with illness, and 20 mg/kg is associated with some deaths with a delay of 3 weeks between dosing and illness.

Treated seed is usually not harmful if it comprises only 10% of the ration and must be fed in large amounts for long periods before clinical illness occurs. A single feeding even of large amounts of grain is thought to be incapable of causing mercury poisoning in ruminants but horses may be susceptible.

Accidental administration of medicines containing mercury, licking of skin dressings (e.g. mercuric oxide), and absorption from liberally applied skin dressings or combined with dimethyl sulfoxide may be associated with sporadic cases as occurs in horses after application of mercury containing 'blisters'.[1] Inorganic mercury salts contaminating lakes or other anaerobic ecological areas can be reduced and converted to methyl mercury and serve as a source of organic mercurial poisoning or food contamination through accumulation in fish or fish meal.[2]

Risk factors

The toxicity of mercury compounds depends on their solubility and the susceptibility of the animals. Cattle are highly susceptible, toxicosis occurring on an average daily intake of mercury, in organic mercury form, of 10 mg/kg per day, while toxic effects are only obtained in sheep with intakes of 17.4 mg/kg BW per day. In horses, feeding inorganic mercury at the rate of 0.4 mg/kg BW produces only mild signs of poisoning and feeding methylmercury chloride (10 g over 10 weeks) is associated with serious illness.

Importance

Meat from animals poisoned by mercury is unsuitable for human consumption. Milk is probably safe as little mercury is excreted in it.

The toxicity of mercury compounds depends on their solubility and the susceptibility of the animals.

PATHOGENESIS

Inorganic mercury compounds are associated with coagulation of the alimentary mucosa, leading to the rapid development of gastroenteritis. Animals that survive the alimentary tract disorder and absorb mercury may show signs of damage to peripheral capillaries especially those at the sites where mercury is excreted, in the kidney, colon, and mouth. Nephrosis, colitis, and stomatitis may result.

Organic mercurials in small doses liberate their mercury slowly into tissues and are associated with degenerative changes in brain, segmental degeneration in peripheral nerves, and degeneration in kidney. Extensive subcutaneous hemorrhages and a bleeding tendency occur in some cases of phenylmercuric acetate poisoning.

CLINICAL FINDINGS

Acute mercurialism occurs when large amounts of inorganic mercury are ingested, there is an acute gastroenteritis with vomiting of blood-stained material and severe diarrhea. Death occurs within a few hours due to shock and dehydration. In less acute cases the patient survives several days and the syndrome includes salivation, a fetid breath, anorexia, oliguria, tachycardia, hyperpnea and, in some cases, posterior paralysis and terminal convulsions.

Chronic mercurialism occurs when small amounts of inorganic mercury are ingested over long periods. The syndrome includes depression, anorexia, emaciation, a stiff, stilted gait which may progress to paresis, alopecia, scabby lesions around the anus and vulva, pruritus, petechiation and tenderness of the gums and shedding of the teeth, persistent diarrhea, weakness, incoordination, and convulsions.

Chronic organic mercurial poisoning is associated with neurological syndromes. In **pigs** blindness is accompanied by staggering, continuous walking, and inability to eat, although the appetite is good. **Cattle** poisoned in this way show a staggery gait, standing on tiptoe, and paresis, lying down most of the time; they appear normal in other respects, often eating well. Clinical signs may not develop until 30 days after feeding is commenced. Cattle poisoned experimentally show more severe nervous signs including incoordination, head-pressing, muscle tremor with twitching of the eyelids, tetanus-like spasms on stimulation, excessive salivation, recumbency, and inability to eat or drink, followed by tonic–clonic convulsions with opisthotonos.

CLINICAL PATHOLOGY

Mercury can be detected at higher levels than normal in the blood, feces, and urine of affected animals and in the toxic source material. Nephrosis can be diagnosed by examination of blood and urine; the earliest and most accurate indicators are the urinary concentrations of alkaline phosphatase and gamma-glutamyl transpeptidase. Less than 0.2% of ingested mercury is excreted in cow's milk.[3]

NECROPSY FINDINGS

In acute cases there is severe gastroenteritis with edema, hyperemia, and petechiation of the alimentary mucosa. The liver and kidneys are swollen and the lungs are congested and show multiple hemorrhages. There may be an accompanying catarrhal stomatitis. A crusting focus of dermatitis may be identified if exposure was percutaneous.

Histologically the renal tubular epithelial cells are swollen and vacuolated, and proteinuria is evident. An ulcerative colitis may also be visible. In chronic mercurialism associated with organic mercury compounds there are also degenerative changes in nerve cells in the cortex of cerebrum, brain stem, and spinal cord. The lesions include neuronal necrosis, neuronophagia, cortical vacuolation, and gliosis. Fibrinoid necrosis of leptomeningeal arterioles may be seen. Other common microscopic changes include degeneration of granular cells of the cerebellar cortex and of Purkinje cells of the myocardium.

Mercury reaches its greatest concentration in kidney and this tissue should be submitted for assay. Levels of 100 mg/kg may be present in the kidney of animals poisoned with inorganic mercury. With chronic organic mercurial poisoning in swine levels of mercury up to 2000 mg/kg may be present in the kidney.

Samples for confirmation of diagnosis

- **Toxicology** – 50 g kidney, brain – half fresh and half in formalin, 500 g of suspect feed (ASSAY (Hg)); muscle tissue for potential residues in food animal edible tissues.
- **Histology** – formalin-fixed kidney, heart, oral and/or skin lesions; half of midsagittally sectioned brain (LM).

DIFFERENTIAL DIAGNOSIS

Acute mercury poisoning is rare but should be suspected in animals which are exposed to inorganic mercury compounds and which show signs of gastroenteritis and nephritis. **Diagnostic confirmation** depends on a positive tissue assay for mercury.

Differential diagnosis list
When there are indications of gastroenteritis or nephrosis the syndrome resembles:
- Lead poisoning
- Arsenic poisoning.

Pigs poisoned by organic mercury compounds and showing nervous signs of blindness and incoordination resemble:
- Pigs poisoned by organic arsenicals.

TREATMENT

Primary. In **acute** cases large amounts of coagulable protein such as eggs should be given by mouth immediately, followed by mild purgatives to facilitate removal from the gut before digestion and absorption occur. In **acute and chronic** cases treatment with sodium thiosulfate as described in arsenic poisoning is recommended. BAL can be used but has the same limitations here as in arsenic poisoning, and delay in treatment of any sort is likely to be fatal. An injection of BAL (6.5 mg/kg BW) should be given every 4 hours. Dimercapto succinic acid (DMSA) at 10 mg/kg B.W. *t.i.d.* is reported effective in hastening the elimination of mercury in urine.[4]

Suppportive treatment includes astringents given orally to control the gastroenteritis and fluids given parenterally to correct the dehydration.

CONTROL

Seed grains dusted with mercury compounds should not be fed to animals.

FLUORINE POISONING

Synopsis

Etiology Inorganic or organic (in plants) fluorides.
Epidemiology Associated with continuous ingestion of small but toxic amounts of fluorine in the diet or drinking water.
Clinical signs Dental fluorosis – mottling and erosion of permanent teeth. Osteofluorosis – lameness and unthriftiness.
Clinical pathology High blood, urine, and tissue levels of fluorine.
Necropsy lesions Osteoporosis, widespread exostoses. Dental enamel and dentine hypoplasia. High bone content of fluorine.
Diagnostic confirmation Assay of food, water, bones, teeth for fluorine content.
Treatment
Primary: aluminum salts orally, calcium salts parenterally but little chance of improvement.
Supportive: parenteral glucose solutions.
Control Drinking water held in tanks, fluorine precipitated by aluminum salts; applicable only for small water volumes.

ETIOLOGY

The severity of the poisoning depends on the amount ingested, the solubility of the fluorine compound, and the animal's age.

Dose rate

The most satisfactory measure is the concentration in the total dry matter consumed. Levels in excess of 100 ppm of dry ration are likely to be associated with disease in cattle, sheep, and pigs when the fluorine is contained in rock phosphate or cryolite. At this or lower levels minor teeth lesions may occur but not to such a degree that they will affect the animal's well-being during a commercial life span. Fluorine in the form of calcium fluoride or sodium fluorosilicate is much less poisonous; intakes of 400 mg to 2 g/kg BW are necessary for fatal effects. Sodium fluoride is approximately twice as toxic as rock phosphate and a general level of 50 mg/kg of dry ration should not be exceeded.

In **experimentally induced** fluorosis in cattle mottling of the tooth enamel occurs at intakes of 27 mg/kg in the diet but there is no pitting until levels of 49 mg/kg are fed. Bony lesions are slight at intakes of 27 mg/kg, moderate at 49 mg/kg, and marked at 93 mg/kg, and milk production in dairy cows is supposed not to be affected by intakes of 50 mg/kg of fluorine in the diet until about the fourth lactation. A more recent view is that the existing tolerance level for dairy cows of 40 mg/kg is too high and will lead to serious loss of production and some dental fluorosis in high producing cows.

EPIDEMIOLOGY

Occurrence

Fluorine intoxication has been observed in most countries, usually in association with specific natural or industrial hazards. In Europe and Great Britain losses are greatest on summer grazing of pastures contaminated by **industrial fumes**, including dust from factories converting rock phosphate to superphosphate as well as effluent from aluminum smelters. Iceland and parts of the southern Andes mountains are extensively affected by contamination from **volcanic ash**. Drinking water from deep wells, industrial contamination of

pasture and the feeding of fluorine-bearing phosphatic supplements are the common associations in North America. **Deep wells** also are an important source in Australia and South America. In Africa the important association is the feeding of **phosphatic rock supplements**.

Sources

Fluorine occurs naturally in rock, particularly in association with phosphate, and these rocks, the soils derived from them and surface water leaching through the soils, may contain toxic quantities of fluorine. In such areas the **soil content** of fluorine may be as high as 2000–4000 mg/kg even up to 12 000 mg/kg and the levels in **water** up to 8.7 mg/kg; soil fluorine varies in its solubility from 10 to 20%. Levels of fluorine likely to be toxic to animals are not usually encountered in natural circumstances, interference by man being necessary in most instances to increase fluorine ingestion above the critical level.

Plants, with few exceptions, do not absorb appreciable quantities of fluorine. Two exceptions are *Camellia* spp., the decorative camellias, and *Thea chinensis* (tea) plant. Major outbreaks of intoxication occur as the result of the ingestion of pasture contaminated with fluorine, and drinking water and mineral supplements which contain excessive amounts of fluorine.

Contamination from **industrial factories** by smoke, vapor, or dust may produce pasture containing 20–50 mg/kg of fluorine. Factories producing aluminum by the electrolytic process, iron and steel with fluorine-containing fluxes, superphosphate, glazed bricks, copper, glass and enamels are likely to be potent sources and may be associated with toxic levels of contamination as far as 14 km downwind from the factory. Dust from factories manufacturing superphosphate from rock phosphate may contain as much as 3.3% fluorine. Industrial plants engaged in the calcining of ironstone have also been incriminated as sources of fluorine.

Contamination by **effluent** is a complex problem because of variation in the form of the contaminating compound. Grass can absorb and retain gaseous fluoride from the ambient air but physical deposit of liquids and dust is the critical form of contamination. Two of the common effluent substances are **hydrofluoric acid** and **silicon tetrafluoride**, both of which are as toxic as sodium fluoride, and dental lesions occur in 100% of young ruminants on an intake of 14–16 mg/kg dry matter of these substances. Severe cases occur on pasture or hay containing more than 25 mg/kg dry matter and similar lesions develop much more rapidly on pasture containing 98 mg/kg dry matter.

Fluoracetamide is also known to be a toxic factory effluent.

Dust and gases from **volcanic eruptions** may also be associated with acute fatal fluorine intoxication in the period immediately after the eruption, and contamination of pasture may be sufficient to be associated with subsequent chronic intoxication in animals eating the herbage, although the fluorine content of the contaminated materials decreases very rapidly if rain falls. Iceland is particularly afflicted with fluorine intoxication deriving from this source.

Top-dressing of pasture with **phosphatic limestone** is commonly associated with fluorosis. Most phosphatic limestones, particularly those from North Africa, are rich in fluorine (0.9–1.4%). Non-phosphatic limestones contain insignificant amounts.

Supplementary feeding of phosphates. The common occurrence of phosphorus deficiency in animals has led to the search for cheap phosphatic materials suitable for animal feeding. Rock phosphates are commonly used and many deposits contain dangerous amounts of fluorine (3–4%). The fluorine content of the mineral can be reduced but the cost encourages the use of marginally safe material.

Water. The major occurrence of waterborne fluorine intoxication is from water obtained from deep wells or artesian bores. The available data suggest that, although minor teeth lesions occur at 5 mg/kg of fluorine it is not until levels of 10 mg/kg are exceeded that excessive tooth wear occurs and the nutrition of the animal is impaired. More serious systemic effects do not occur until the water contains 30 mg/kg.

Miscellaneous sources of fluorine include the ingestion of superphosphate itself, but a supernatant liquid of a suspension of the fertilizer will contain no fluorine. Some wood preservatives may contain large quantities of fluoride which may be associated with acute poisoning in some circumstances.

RISK FACTORS

Host factors are age and species. Daily intakes of 0.5–1.7 mg/kg of fluorine as sodium fluoride produce dental lesions in growing animals without affecting general well-being. Intakes equal to twice these amounts are consumed by adult animals without ill-effect. In heifers a continuous intake of 1.5 mg/kg BW per day is sufficient to be associated with severe dental fluorosis without affecting growth rate or reproductive function. However, extensive osteofluorosis and periods of severe lameness will occur. The fluorine content of the bones of newborn calves depends on the dam's intake of fluorine in the last 3–4 months of pregnancy and not on her own bone composition.

Most recorded occurrences of fluorosis are in cattle. Sheep are less susceptible than cattle. A continuous intake of 1 mg/kg BW is the maximum safe limit for **ruminants**, an intake of 2 mg/kg BW produces clinical signs. In pigs an intake of 1 mg/kg BW added fluorine for long periods has no deleterious effect.

Importance

Death losses are rare and restricted largely to acute poisoning, the major losses taking the form of unthriftiness associated with chronic fluorosis. Although it is possible for animal tissues to contain amounts of fluorine in excess of permissible amounts this is not usually so in chronic fluorosis. The fluorine content of **milk** in these circumstances is below that permitted in fluoridated drinking water (1 mg/L).

PATHOGENESIS

Fluorine is a general tissue poison; its exact mode of action does not appear to have been closely examined.

Acute intoxication, due to the ingestion of large amounts of soluble **inorganic fluorides**, is characterized by the immediate development of gastrointestinal irritation due to the formation of hydrofluoric acid in the acid medium of the stomach. Nervous signs including tetany and hyperesthesia, and inhibition of blood clotting, may follow as a result of the fixation of serum calcium to form physiologically inactive calcium fluoride in the blood plasma. Death occurs quickly.

Organic fluorides, including sodium fluoracetate, also known as compound 1080, and fluoracetamide, are associated with sudden death by poisoning the enzyme aconitase, leading to the accumulation of diagnostically significant levels of citrate in tissues and permanent damage to myocardium.

Metabolic effects due to the ingestion of small amounts of **inorganic fluorides** over long periods are associated with an initial marked reduction in the activity of ruminal infusoria, a reduction in food intake, and a decreased production of fatty acids. The level of fluorine intake is critical and intakes of 150 mg/kg or less have no effect on food intake. At intakes of 150–200 mg/kg there is a depressing effect on milk production, and at 200 mg/kg the intake of grain is reduced.

Detoxication by deposition of fluorine occurs in association with phosphate in the teeth and bones. Deposition in bone

occurs throughout life but in teeth only in the formative stages. Fluorides inhibit the action of ameloblasts and odontoblasts during tooth formation, resulting in failure of the developing tooth to accept minerals.[1] In bones, fluorides alter mineralization and remodeling of bone by replacing hydroxyapatite in the bone crystalline structure.[2] The degree of deposition varies, being greatest on the periosteal surface of the long bones where exostoses commonly develop. Thus **teeth lesions** occur only if the intake is high before the teeth have erupted but bone lesions occur at any stage. When the tissue levels of fluorine are moderate, characteristic lesions due to hypoplasia of the enamel appear in the teeth. At higher levels the storage capacity of these organs is exceeded and blood and urine levels rise. General signs of toxicity thus appear in tissues at the same time as bone lesions develop. The **bone lesions** of osteomalacia, osteoporosis, and exostosis formation, with accompanying pathological fractures, are associated with excessive mobilization of calcium and phosphorus to compensate for their increased urinary excretion in conjunction with fluorine.

The other tissues particularly prone to fluorine intoxication and in which degenerative changes occur are bone marrow, kidney, liver, adrenal glands, heart muscle, and central nervous system. A severe **anemia** may rarely occur as a result of toxic depression of bone marrow activity, although this is not a constant or expected sign. The facility of storage in bone explains the long **latent period** which occurs in animals subjected to chronic intoxication.

There has been controversy about whether fluorine passes the **placental barrier** in significant amounts. Although the current view is that placental passage is infinitesimal in amount,[3] cases of neonatal dental fluorosis have been identified in cattle.[4]

Fluorine does not occur in significant quantities in the **milk** or colostrum of poisoned cows.

Detoxification by leaching of fluorine from bones and teeth occurs after a decrease in the intake of fluorine leads to lowering of blood levels and mobilization from deposits commences. This is of importance when interpreting urine and blood levels of the element.

CLINICAL FINDINGS

Acute intoxication

The syndrome includes dyspnea, complete anorexia, vomiting, and diarrhea in pigs, and ruminal stasis with constipation or diarrhea in ruminants. Vomiting acts as a protective mechanism and toxic doses in pigs may be eliminated in this way without the development of other signs. Nervous signs are characteristic and include muscle tremor and weakness, a startled expression, pupillary dilatation, hyperesthesia, and constant chewing. Tetany and collapse and death follow within a few hours.

Chronic intoxication-fluorosis

Because of the distinct clinical separation between animals with dental lesions and those which have, in addition, signs of lameness and general ill-health it is customary to refer to two forms of the disease: dental fluorosis and osteofluorosis. Lesions of the teeth and bones are characteristic and the signs are largely referable to these lesions. Teeth changes are the earliest and most diagnostic sign but may not produce clinical effects until other signs have developed. Consequently, they are often missed until other clinical findings suggest that the teeth be examined. Severe dental fluorosis results in excessive dental wear, inability to graze properly, difficulty mastication and lapping of water due to tooth pain. Continued impaired dentition leads to reduced milk production and poor weight gain or actual weight loss. Reproductive function may be reduced due to locomotor dysfunction and poor nutriton as a result of reduced feed intake.

Osteofluorosis

Lameness most marked in the loins, hip joints, and hind limbs and unthriftiness in animals of any age are the signs usually observed first. The occurrence of hip lameness or **fractures of the third phalanx** on a herd scale in cattle is thought to be diagnostic of fluorosis. Pain is evinced on pressure over limb bones and particularly over the bulbs of the heels. The bones may be palpably and visibly enlarged. This is most readily observed in the mandible, sternum, metacarpal, and metatarsal bones and the phalanges. This overall thickness may be subsequently replaced by well-defined exostoses. The bones are subject to easy fracture. These well-defined lesions occur only in advanced cases and are often accompanied by extensive tooth lesions in young animals. In addition to the cases affected by generalized lameness there are cases which show a sudden onset of very severe lameness, usually in a forelimb, associated with transverse fracture of the third phalanx.

Dental fluorosis

Temporary teeth of animals poisoned while *in utero* and permanent teeth exposed to intoxication before eruption will be affected. The earliest and mildest sign is **mottling** with the appearance of pigmented (very light yellow, green, brown, or black) spots or bands arranged horizontally across the teeth. Occasional vertical bands may be seen where pigment is deposited along enamel fissures. Mottling and staining occur on incisors and cheek teeth and are not evident when the affected tooth erupts and in fact may not appear until some months later. The cheek teeth are usually worse affected than the incisors but are very difficult to examine clinically. If the period of exposure to intoxication has been limited only some of the teeth may be affected but the defects will always be bilateral.

Mottling may not progress any further but if the intoxication has been sufficiently **severe defective calcification** of the enamel leads to accelerated attrition or erosion of the teeth, usually in the same teeth as the mottling. The mottled areas become pits and the teeth are brittle and break and wear easily and unevenly. Patterns of accelerated attrition are dependent upon the chronological occurrence of the intoxication and the eruption time of the teeth. Uneven and **rapid wear** of the cheek teeth makes proper mastication impossible. Infection of the dental alveoli and shedding of teeth commonly follow. The painful condition of the teeth and the inability to prehend and masticate seriously **reduce the food intake** and are associated with poor growth in the young and unthriftiness and acetonemia in adults. Affected cattle may lap cold drinking water to avoid the discomfort occasioned by normal drinking. Eruption of the teeth may be abnormal, resulting in irregular alignment.

A standard for the **classification of fluorosis** has been proposed based on the degree of mottling, pitting, and rate of wear of the teeth. The effects of dental mottling, pitting, and excessive wear of incisors can be used to estimate the lifetime exposure periods of cattle at risk during dentition.[5] The additional clinically apparent abnormalities include delayed eruption of permanent incisor teeth, necrosis of alveolar bone resulting in recession of bone and gingiva, oblique eruption of permanent teeth, hypoplasia of teeth, wide spaces between teeth, and rapid development of any dental lesions.

Other effects

Reproduction, milk yield, and wool growth are not usually considered to be adversely affected except indirectly by the reduced food intake. Severely lame animals may have lowered reproductive performance indirectly due to physical dysfunction that interferes with mating.

Additional signs including diarrhea and anestrus and other forms of infertility in cattle, diarrhea in sheep, and polydipsia and polyuria in pigs are recorded in the

naturally occurring disease but cannot be considered as constant or pathognomonic.

Housed animals. In animals that are grazed for only part of the year on pasture contaminated by factory effluent during the summer, there may be considerable clinical improvement during the winter and an annual recrudescence of signs when the animals are outside.

Horses with chronic fluorosis have lameness, dental lesions including excessive molar abrasion, and hyperostotic lesions of the metatarsus, metacarpus, mandible, and ribs.

CLINICAL PATHOLOGY

Normal cattle have blood levels of up to 0.2 mg fluorine per mg/dL of blood and 2–6 mg/kg in urine. Cattle on fluorine intakes sufficient to cause intoxication may have blood levels of 0.6 mg/dL, and urine levels of 16–68 mg/kg, although blood levels are often normal. Such high levels may not be an indication of high intakes immediately preceding the examination, as heavy deposits in bones may be associated with abnormally high blood and urine fluorine levels for some months after the intake has been reduced to normal. Urine levels should be corrected to a specific gravity of 1.040. Serum calcium and phosphorus levels are usually normal and there is a significant correlation between the amount of fluoride fed and the concentration of alkaline phosphatase in the serum. The increase in phosphatase activity is probably related to the abnormal formation of bone. The increased SAP activity may be three to seven times the normal level.

Radiographic changes of bones containing more than 4000 mg/kg of fluorine include increased density or abnormal porosity, periosteal feathering, and thickening, increased trabeculation, thickening of the compact bone, and narrowing of the marrow cavity. Spontaneous rib fractures show incomplete union. Good data are available for fluorine concentrations in rib bones, and estimations of fluorine content in biopsy samples of ribs have been used in the clinicopathological study of the disease. Samples of tail bone and the spongiosa of the tuber coxae have also been used for these purposes.

Organic fluorides are difficult to assay in excretions and tissues, and even in contaminated feed sources. In affected animals indirect measurement based on tissue concentrations of citrate may be necessary. An additional suggested procedure is the administration of an aqueous extract of suspected poisoned tissues or feed material to guinea-pigs and the measurement of tissue levels of citrate in them.

NECROPSY FINDINGS

Severe gastroenteritis is present in acute poisoning. In chronic fluorosis the bones have a chalky, white appearance, are brittle and have either local or disseminated exostoses, particularly along the diaphyses. Intra-articular structures are not primarily affected, although there may be some spurring and bridging of the joints. Histologically there is defective and irregular calcification of newly formed trabecular bone and active periosteal bone formation. Hypoplasia of the enamel and dentine are consistent physical and histological defects in the teeth of affected young animals. Young animals may also develop thickened growth plates and widened metaphyses that are grossly similar to rachitic changes. Degenerative changes in kidney, liver, heart muscle, adrenal glands, and central nervous system have been reported in severe cases. Degeneration of the bone marrow and consequent aplastic anemia also occur.

Chemical examination of necropsy specimens is valuable in the diagnosis as the fluorine content of bones from poisoned animals is greatly increased. Levels of up to 1200 mg/kg are observed in normal animals but may be increased up to 3000 mg/kg in animals exposed to fluorine and showing only mottling of the teeth. Animals showing severe clinical signs have levels greater than 4000 mg/kg of bone on a dry, fat-free basis and after prolonged heavy feeding levels may be as high as 1.04%. Care must be taken in selecting the bone samples because of the great variation in the concentration of fluorine which occurs between different bones. Good data are available for comparison between metacarpal, metatarsal, rib, pelvic, and mandibular bones and antlers of deer.[3] Mandibles usually show the greatest concentrations and in the long bones the distal and proximal quarters are more sensitive indicators than the center half.

Soft tissues are unreliable as a criterion for fluorosis because of their low levels of fluorine. In bone and teeth, ash levels of 0.01–0.15% fluorine are found in normal animals. Levels up to 1.5% fluorine indicate excessive intake but are not usually accompanied by anatomical changes. Where clinical signs of intoxication appear there is usually up to 2% fluorine in bone ash and 1% in teeth ash.

Samples for confirmation of diagnosis

- **Toxicology** – mandible/metacarpal/metatarsal; rib, vertebrae for evidence of osteofluoriosis. Urine from affected animals for evidence of recent exposure (ASSAY (F))
- **Histology** – formalin-fixed metacarpal/metatarsal/ mandible (LM).

Diagnostic confirmation depends on fluorine assay of food and water, of blood and urine of affected animals, and bones and teeth at necropsy.

DIFFERENTIAL DIAGNOSIS

Diseases causing lameness and stiff gait at herd level:

- Nutritional deficiency of phosphorus
- Nutritional deficiency of vitamin D
- Osteodystrophia fibrosa in horses
- Chronic selenium poisoning
- Enzootic calcinosis
- White muscle disease
- Ephemeral fever in cattle.

TREATMENT

Primary treatment, apart from removing the animals from the source of fluorine, is largely impractical. Acute cases require gastrointestinal sedatives.

Supportive treatment to neutralize residual fluorine in the alimentary tract and calcium salts intravenously is recommended. Aluminum salts act as neutralizers of the hydrofluoric acid produced in the stomach and because of their insolubility they are safe even in large quantities (30 g of aluminum sulfate daily for prevention, more for treatment). The calcium salts given intravenously should be given to effect, using the disappearance of tetany and hyperesthesia as a guide. This treatment will probably have to be repeated. The parenteral administration of glucose solutions is recommended because of the interference by fluorine with glucose metabolism. Irrespective of treatment used, no improvement in dental or osseous lesions can be anticipated but there may be amelioration of the other clinical signs.

CONTROL

Fluorine content of feed

Phosphatic feed supplements should contain not more than 0.2% fluorine for milking or breeding cattle or 0.3% for slaughter cattle, and should not comprise more than 2% of the grain ration if the fluorine content is of this order. In spite of this recommendation the feeding of rock phosphate containing 1–1.5% fluorine to cattle for long periods is maintained in some areas without major deleterious effects on health. Some deposits of rock phosphate have much higher contents of fluorine than others and commercial

defluorination makes these toxic deposits safe for animal feeding.

Bone meal in some areas may contain excessive quantities of fluorine and should be checked for its fluorine content. Access to **superphosphate** made from rock phosphate with high fluorine content should be avoided. Water from **deep wells and artesian bores** should be assayed for fluorine content before use.

Nutritional management

Where fluorine levels are marginal careful husbandry, including the watering of young, growing stock on fluorine-free supplies, and permitting only adults to be watered on the dangerous supplies, and rotating the animals between safe and dangerous waters at 3-month intervals may make it possible to utilize land areas otherwise unsuitable for stock raising. In some areas dairy herds may have to be maintained by the purchase of replacements rather than by the rearing of young stock. In areas where long-term ingestion of fluorine is likely to occur the aim should be to provide a diet of less than 50 mg/kg of the total diet of dairy cows. Adequate calcium and defluorinated phosphorus intakes should be insured as these reduce bone storage of fluorine.

Detoxication

Aluminum salts are the principal substances used to detoxicate food and water. They are relatively ineffective, reducing the accumulation of fluorine in bone by only 20–30%, and are thus referred to as 'alleviators'. The sulfate and phosphate have been used but all the salts are unpalatable and can only be administered daily to animals being hand-fed relatively large amounts of concentrates. It is presumed that highly insoluble aluminum fluoride is formed in the alimentary canal.

Extensive field trials of aluminum as an alleviator have not justified its use as a practicable control measure in average circumstances. Best results are obtained by improvement in nutrition of the animals and better grassland management. If effective control measures are introduced it will be some years before the affected teeth have erupted and become visible and affected animals culled.

Slaked lime. The fluorine content of drinking water can be reduced (from 10 to 0.95 mg/kg) by adding freshly slaked lime to the water; 500–1000 mg/kg should be added and the water must be allowed to settle for 6 days. The method requires the use of large storage tanks.

Legislation to control fluoride emission from factories is now general but the usual limitation of not more than 1 $\mu g/m^3$ does not completely avoid danger and serious losses can still occur at these emission levels. Prevailing tolerances for pasture contamination also appear to be incompletely protective.

ALUMINUM POISONING

Aluminum is one of the potentially toxic elements introduced into the diets of animals by the deposition of soluble salts in acid rain, or by powder particles in factory effluent. Absorption by plants may also be a factor. Overt effects are rare but at high levels of intake, the aluminum suppresses the absorption of phosphorus and may be assocated with the patient being in negative phosphorus balance. Retarded growth and hypophosphatemia have been produced experimentally in pigs.[1]

MOLYBDENUM POISONING

Synopsis

Etiology Ingestion of toxic amounts of molybdenum.
Epidemiology Enzootic in areas where soil, especially peat soils, contain high levels of molybdenum. Epizootics when molybdenum used in excessive amounts as an agricultural chemical.
Clinical signs Signs of secondary hypocuprosis (weight loss, hair coat depigmentation, anemia) plus persistent, debilitating diarrhea.
Clinical pathology High blood levels of molybdenum, low levels of copper.
Necropsy lesions No significant lesions.
Diagnostic confirmation High levels of molybdenum in feed and blood.
Treatment
Primary: copper salts orally.
Supportive: none necessary.
Control Dietary supplementation with copper.

ETIOLOGY

A daily intake of 120–250 mg of molybdenum has proved to be toxic for cattle, although the toxic dose varies widely with the intake of sulfate, copper, and possibly other factors.

EPIDEMIOLOGY

Occurrence

The major occurrence of molybdenum poisoning is on pasture growing on molybdenum-rich soils, usually derived from particular geological formations, e.g. the 'teart' pastures of Somerset (UK), the USA, and Canada, marine black shales in the UK and pastures containing excess molybdenum intake with or without a marginal deficiency of copper in New Zealand, Canada, Ireland, and Australia.

Source

Toxic intakes

Soil molybdenum levels in problem areas vary between 10 and 100 mg/kg. Illness may occur on **pasture** containing 3–10 mg/kg. Although levels of less than 3 mg/kg are usually considered to be safe, signs of toxicity may occur at levels as low as 1 mg/kg if the sulfate intake is high and the copper status low; the trigger level of molybdenum at which the interference with the metabolism of copper may occur is 2.4 mg/kg dry matter in the diet.

Forage containing 10 mg/kg must be considered dangerous at all times and, on pasture affected by aerial contamination levels of 10–200 mg/kg may be encountered. Such intakes can be provided by:

- **Industrial fallouts** of 5–40 ng/m^3 of air or 2 mg/m^2 per month on pasture
- Contamination of pasture by **motor oil** containing molybdenum as an additive[1]
- **Aerial contamination** by fumes from aluminum and steel alloy factories and oil refineries using molybdenum is associated with secondary copper deficiency
- The use of molybdenum in **fertilizer mixtures** to increase nitrogen fixation by legumes may lead to excessive amounts of molybdenum in soils.

Drinking water may not be as toxic as the same amount in fresh forages. For calves, the minimum toxic concentration in drinking water is between 10 and 50 mg/kg when dietary copper and sulfur intake in the diet is normal.

Risk factors

Sheep and cattle are clinically affected in field outbreaks of the disease and signs are most marked in young growing animals. Cattle are much more susceptible than sheep. Horses also appear to be susceptible.[2]

The concentration of molybdenum in forage varies with the season, being highest in the spring and autumn and with the plant species, legumes, particularly alsike clover, taking up molybdenum in much greater quantities than grasses.

Importance

The disease is not highly fatal but severe stunting and loss of production does occur.

PATHOGENESIS

Copper metabolism. An extended discussion of the role of molybdenum in copper metabolism is provided in the section on secondary deficiency. Excess molybdenum intake is associated with an increased formation of thiomolybdates, important enzyme inhibitors which interfere with the hepatic storage of copper and produce a state of copper deficiency.[3] This situation is exacerbated by a high intake of sulfur or a low intake of copper. The syndrome of molybdenum intoxication resembles that of copper deficiency and treatment and prevention by the administration of copper is effective.

Molybdenum poisoning. Some of the signs of molybdenum poisoning, particularly diarrhea, are not characteristic of copper deficiency, and may represent a specific toxic effect of molybdenum. An identified specific toxic effect is that of causing the development of exostoses and hemorrhages about the long bones, and separation of the great trochanters of the femur in some sheep fed molybdenum experimentally. The lesions appear to be due to defects in connective tissue at muscle insertion points, and to defects in the epiphyseal growth plates.

Experimental feeding of molybdenum, and its intravenous injection,[4] produce a syndrome identical with that seen in the naturally occurring disease in cattle but liver and plasma levels of copper may not be depressed as is usual in naturally occurring cases. Experimental feeding of a large dose, up to 40 g, of molybdenum may be associated with only transient diarrhea. Most of the molybdenum is rapidly absorbed and excreted, 90% in the first week.

CLINICAL FINDINGS IN CATTLE

- **Persistent scouring** commences within 8–10 days of the animals having access to affected pasture
- **Emaciation** and a dry, staring coat develop and there is profound depression of milk production
- **Depigmentation** of black hair causes a red or gray tinge to appear. This may be particularly noticeable around the eyes, giving a bespectacled appearance. Intense craving for copper supplement has been noted
- Young cattle (3 months to 2.5 years) also show abnormalities of locomotion including marked **stiffness** of the legs and back, difficulty in rising, and great reluctance to move. The gait is suggestive of laminitis but the feet appear normal. The lameness may be due to the periosteal lesions described above. The appetite remains good
- Rare cases in horses[2] show diarrhea and impaction colic and a high mortality rate.

CLINICAL PATHOLOGY

Blood copper levels are reduced from the normal of 1.0 µg/mL to 0.25 µg/mL. Seasonal variations occur depending on the intake of molybdenum.

Blood Molybdenum levels in normal animals are of the order of 0.05 mg/kg and rise to about 0.10 mg/kg when excess molybdenum is ingested. Levels as high as 0.70 and 1.4 mg/kg have been recorded in cattle and horses grazing on pasture contaminated by smelter fumes. On very large intakes of molybdenum cattle which are clinically normal may have molybdenum levels of 1000 mg/kg in feces, 45 mg/kg in urine, 10 mg/kg in blood, and 1 mg/kg in milk.

NECROPSY FINDINGS

There are no gross or histological findings which characterize the disease, enteritis being conspicuously absent. The carcass is emaciated and dehydrated and there may be anemia if there is an accompanying copper deficiency. Tissue copper levels will be below normal.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation. The most effective method is to treat affected animals orally with copper sulfate (2 g daily or 5 g weekly for adult cattle and 1.5 g for adult sheep). The diarrhea ceases in 2–3 days and improvement in the other signs is rapid.

The persistence of the diarrhea without other clinical signs, particularly in young cattle and sheep, may suggest:

- Internal parasitism, e.g. trichostrongylosis, ostertagiasis; examination of feces for worm eggs is necessary for differentiation
- Johne's disease which affects only adults; usually only one animal in a herd shows clinical signs at any one time
- Acute enteritides including salmonellosis, winter dysentery and virus diarrhea, acute diseases accompanied by other diagnostic signs.

PRIMARY TREATMENT AND CONTROL

Molybdenum toxicity can be treated by the administration of copper, and controlled by increasing the copper content of the diet by 5 mg/kg. But the administration of copper to large numbers of animals presents a number of problems. For long-term control, the recommended ratio of Cu:Mo is 4:1 to 10:1, and a Sulfur:Mo ratio of <100:1 is considered safe vs. copper accumulation.[5,6]

PRIMARY COPPER POISONING

- **Primary copper poisoning is associated with the intake of excessive amounts of copper**
- **Secondary copper poisoning, which occurs on low intakes of copper, is dealt with on p. 1823.**

Synopsis

Etiology Acute or chronic accidental intake of copper.

Epidemiology Usually occurs as major outbreaks. Sheep most susceptible, horses least. Significant differences in breed susceptibility. Copper originates from copper-rich soils, industrial contamination of pasture or copper preparations used pharmaceutically, as a feed ingredient, or as an agricultural chemical.

Pathogenesis Acute poisoning due to ingestion of a single large dose is associated with alimentary tract mucosal necrosis and fatal shock. Acute intravenous or chronic oral intake is associated with fatal hemolytic anemia.

Clinical signs

- Acute oral poisoning: abdominal pain, diarrhea, vomiting, shock, short course, death.
- Chronic oral poisoning: anemia, jaundice, hemoglobinuria.

Clinical pathology Chronic oral poisoning: very high blood and liver copper levels, low PCV, hemoglobinuria, elevated liver enzymes in serum.

Necropsy lesions Acute oral poisoning: severe gastroenteritis.
Chronic oral poisoning: high tissue levels of copper, tissue jaundice, swollen liver, kidneys, spleen, hemoglobinuria.

Diagnostic confirmation High copper levels in tissues.

Treatment Primary: edetate or molybdate parenterally. Supportive: blood transfusion if practicable.

Control Removal from source, prophylactic administration of molybdate.

ETIOLOGY

Acute oral poisoning is associated with the accidental ingestion of large amounts of copper salts at one time. **Acute systemic poisoning** and **chronic oral poisoning** are associated with the accumulation of small amounts of copper ingested over a long period.

EPIDEMIOLOGY

Occurrence

Sporadic outbreaks of primary copper poisoning occur in many circumstances.

In both acute and chronic cases the mortality rate approximates 100%.

Acute or chronic oral poisoning

- Accidental administration of large quantities of soluble copper salts, e.g. as parasiticide drench
- Contamination of plants with fungicidal sprays
- Contamination of drinking water during snail eradication
- Grazing pasture too soon after it has been top-dressed with:
  - a copper salt to correct a mineral deficiency in the soil
  - poultry manure or dried chicken waste where the birds have been fed on a copper-rich diet
  - similarly with pig manure, dried pig wastes or pig slurry when the pigs have been fed on a copper-enriched ration as a growth supplement
- Grazing pasture growing on soils rich in copper
- Grazing pasture contaminated by smelter fumes or by drippings from overhead power cables made of copper but corroded by the constituents of an industrially polluted area
- Feeding of seed grain which has been treated with antifungal agents containing copper

  Feeding mineral or salt licks or mixtures containing excessive amounts of copper
- Salt or mineral mixtures containing copper ingested accidentally by salt-hungry livestock
- Copper-enriched concentrate rations fed as growth supplements to poultry or pigs in excessive quantities or fed to ruminants. Pigs can survive rations providing up to 250 mg/kg; these levels are toxic for ruminants in which 20 mg/kg is maximum copper content. For sheep, continued ingestion of cattle diets that contain elevated copper and limited molybdenum results in copper accumulation.

  Miscellaneous other sources of copper causing poisoning are palm oil cake, treated pine lumber containing arsenic, copper, and chromium.

Acute parenteral poisoning

Prophylactic injections of copper salts, especially the more soluble, aqueous preparations, are very toxic if recommended dose rates are exceeded. This procedure is being increasingly used to prevent copper deficiency in grazing ruminants when other cheaper methods are not applicable. The paste preparations, usually copper glycinate, appear to be non-toxic but the soluble preparations, e.g. copper edetate, when given at recommended doses, can be associated with heavy mortalities in sheep and calves.[1] Copper as the diethylamine oxyquinoline sulfonate has also been associated with deaths in sheep after injection of recommended dose rates. The absorption is fast and the blood levels high with these toxic compounds but not with copper methionate which has a good safety record. Deaths commence 24 hours after injection and continue for up to 7 days. Postmortem findings include hepatic centrilobular necrosis, nephrosis, pleural and peritoneal effusions.

Toxic doses

There is a great deal of published anecdotal evidence about the amount of copper in specific feeds fed to specific species which was associated with illness or deaths but almost no evidence of MD50s or similar levels for the several animal species. **The following** toxic dose rates are provided as a rough guide:

- **Single doses** of 20–110 mg of copper per kg BW produce acute copper poisoning in sheep and young calves
- The status of goats generally is uncertain
- In cattle a dose rate of 220–880 mg/kg BW is necessary to cause death
- **Chronic poisoning** occurs in sheep and calves with daily intakes of 3.5 mg of copper/kg BW, 25 ppm being the maximum tolerated concentration in the feed. Even lower concentrations (15 ppm) may poison sheep if adequate molybdenum and sulfate are not present in the diet.

None of these data on toxic intakes come with information on competing and contributory dietary factors such as sulfate, molybdenum, and zinc and these are critical in determining the toxic effects of the copper intake.

Risk factors

Environmental factors

Both acute and chronic copper poisoning occurs under field conditions. Acute poisoning usually occurs because of the accidental administration of large quantities of soluble copper salts, but chronic poisoning occurs principally as a result of ingesting feed containing or contaminated by copper derived from the soil or by its application to the diet as an agricultural chemical or feed supplement.

The toxicity of the copper ingested in this way is governed not only by the absolute amount of copper but also by the interaction of a number of factors including the amount of **molybdenum** and of **sulfate** present in the diet and the presence or absence of specific plants and the level of protein in the diet. In fact either copper deficiency or copper poisoning can occur on soils with apparently normal copper levels, the syndrome depending on the particular conditioning factors present. High molybdenum and sulfate levels in the rumen lead to the microbiological synthesis of non-absorbable thiomolybdates, and a high sulfate diet also leads to lower retention of copper in tissues.

There is also a competitive relationship between copper and **zinc** in the internal metabolism of ruminants, a high level of zinc in the diet reducing the intake of copper.

Host factors

Species susceptibility. Horses are the least susceptible with a tolerance to levels of 800 ppm in the diet. **Cattle** will usually tolerate 100 ppm and swine 250 ppm, but lethal hemolysis has occurred in cattle fed a low copper level mineral supplement (38 mg/kg BW for lactating cows) for 2 years.[2] **Goats** are not featured in the literature on this subject and sheep criteria are recommended as guides. **Sheep** are the most susceptible species, tolerating as little as 25 mg/kg BW; they are peculiar in the way in which copper is handled metabolically. Increased absorption is not easily achieved but abnormally high excretion is more difficult still, so that there is the general tendency for copper to accumulate.

Breed susceptibility. Sheep, e.g. the Texel and the Finnish Landrace, are more resistant while others, e.g. the Ronaldsay and the Orkney, are much more susceptible. The Angora goat appears to be most susceptible and Nubian goats appear to be more resistant than sheep. Angus cattle are much more susceptible than Charolais.[3]

Importance

Many deaths due to copper poisoning are followed by deaths from general debility in sheep in poor condition. Dairy cows, especially those lactating at the time, fail to produce well, and special care is needed to bring them back to full production.[4]

PATHOGENESIS

Soluble copper salts in high concentrations are protein coagulants. The ingestion of large quantities is associated with intense irritation of the alimentary mucosa and profound shock. Severe intravascular hemolysis occurs if the animal survives long enough. When excessive amounts of copper are injected the response is rapid and animals begin to die the next day and with a peak of mortality about the third day after dosing. Early deaths appear to be due to severe hepatic insufficiency and later deaths to renal failure due to tubular necrosis. There appear to be no renal lesions in sheep affected

with chronic copper poisoning, unless a hemolytic crisis occurs, in which case there is a hemoglobinuric nephrosis.

The frequent ingestion of small amounts produces no ill-effects while copper accumulates in the liver. When maximum hepatic levels are reached after periods of exposure often as long as 6 months, the copper is released into the bloodstream and the animal dies of acute intravascular hemolysis. Thus there is really no such thing as 'chronic' copper intoxication; syndromes so called are fatal as acute hemolytic crises. One of the dangers of cumulative copper poisoning is that the animal shows normal health until the hemolytic crisis, when it becomes acutely ill and dies very quickly. Death is ascribed to acute anemia and hemoglobinuric nephrosis.

Two other abnormalities have been observed during and after the hemolytic crisis. One is the occurrence of methemoglobinemia; the other is the presence of degenerative lesions in the white matter of the brain. The accumulated copper can lead to the occurrence of a hemolytic crisis after ingestion of copper has ceased, and recurrent attacks can therefore occur in sheep that survive the attacks. There are a number of explanations for the development of hemolysis. One is that the erythrocytes in affected sheep become immunogenic as a result of the copper accumulation. It is suggested that this immunogenicity leads to the development of an autoantibody and the final result of an autoimmune hemolytic anemia. Alternatively, copper may act as an oxidant on the red cell membrane, leading to membrane damage and acute hemolysis as a result of oxidant injury. This is consistent with the formation of methemoglobin, a result of oxidant effects during the acute hemolytic crisis.

The liberation of the hepatic copper is incompletely understood, but the favored hypothesis is that the accumulation of copper ions in the liver cells is associated with the accumulation of electron-dense lysozymes in the hepatocytes and their eventual necrosis.[5] Various stresses including a fall in plane of nutrition, traveling, and lactation, are considered to precipitate the liberation. Complex mechanisms relating to disorders of cell membranes, a marked change in hemoglobin composition, including the development of methemoglobinemia and an increase in the oxidative status of the sheep, are described as occurring during the critical stages. During the prehemolytic stage of several weeks before the crisis there is hepatic necrosis and an elevation of levels of liver-specific enzymes. A much more serious necrosis of liver occurs at the time of the hemolytic crisis.

Sheep on a selenium-deficient diet and with low blood levels of glutathione peroxidase are more susceptible to chronic copper poisoning. Some sheep are also conditioned by inheritance to have low blood glutathione levels in spite of a normal dietary intake of selenium. They also have low glutathione peroxidase blood levels and may be more susceptible for this reason.

There is also a difference between breeds in their capacity to reduce copper absorption in response to the administration of zinc, Texels being much more responsive than Friesians and North Ronaldsays are also known to be highly susceptible. These sheep normally subsist on seaweed which has a very low content of copper and molybdenum. When the sheep are fed on terrestrial herbage containing normal levels of copper and molybdenum and high levels of zinc they develop copper poisoning.

CLINICAL FINDINGS

Acute intoxication

Severe gastroenteritis occurs accompanied by abdominal pain and severe diarrhea and vomiting in some species. The feces and vomitus contain much mucus and have a characteristic green to blue color. Vomiting occurs in the pig and dog and intense thirst is apparent. Severe shock with a fall in body temperature and an increase in heart rate is followed by collapse and death usually within 24 hours. If the animal survives for a longer period, dysentery and jaundice become apparent.

Acute poisoning associated with the injection of copper salts is manifested only by anorexia, depression, and dehydration. In calves that survive the illness for 3 days or more massive ascites, hydrothorax, hydropericardium, hemoglobinuria and massive hemorrhages, dyspnea, head-pressing, aimless wandering, circling, and ataxia occur. Lambs similarly poisoned and with similar postmortem lesions die within 24 hours of injection.

Chronic intoxication

In ruminants anorexia, thirst, hemoglobinuria, pallor, and jaundice appear suddenly. There is no disturbance of alimentary tract function. Depression is profound and the animal usually dies 24–48 hours after the appearance of signs. In pigs signs of illness are uncommon, most pigs being found dead without premonitory signs, although dullness, anorexia, poor weight gain, melena, weakness, pallor, hyperesthesia, and muscle tremor may be observed occasionally.

CLINICAL PATHOLOGY

Levels of copper in the blood and liver are markedly increased in chronic copper poisoning. In acute intoxications several days are required after ingestion before these levels rise appreciably. Fecal examination may show large amounts (8000–10 000 mg/kg) of copper. Liver biopsy is a satisfactory diagnostic technique and serves a most useful purpose in the detection of chronic copper poisoning as blood levels do not raise appreciably until the hemolytic crisis occurs just before death. Because of the greater concentration of copper in the caudate lobe as compared to other parts of the liver, an autopsy specimen is to be preferred.

Blood levels of copper during the hemolytic crisis are usually of the order of 78–114 μmol/L (4.9–7.2 ppm), compared with about 15.7 μmol/L (1 ppm) in normal animals. Normal liver levels of less than 5.5 mmol/kg dry matter (349 ppm) rise to above 15.7 mmol/kg (997 ppm) in the latter stages of chronic copper poisoning in sheep, to 95 mmol/kg in pigs, and to 30 mmol/kg in calves. In sheep, liver values greater than 7.85 mmol/kg and kidney values of greater than 1.25–1.57 mmol/kg dry matter are diagnostic. After a massive single dose it is important to include kidney among specimens submitted for copper assay, because levels may be high (more than 25 mg/kg dry matter) while liver copper levels have not yet risen. When comparing normal and toxic values it should be remembered whether results are expressed as dry weight basis or wet weight basis. Assuming approximately 20% dry matter in tissue, a wet weight value of 1.5 ppm copper is actually 7.5 ppm on a dry weight basis, comparable to the toxic range reported for blood above. Thus, a commonly observed toxic value of 200 ppm copper in liver (wet weight basis) would be reported as 1000 ppm copper on a dry weight basis.

The packed cell volume of the blood decreases sharply, from 40 down to 10% in 48 hours, during an acute hemolytic episode. Methemoglobinemia may be present and the urine should be checked for hemoglobin.

Serum enzyme activity is greatly increased just before the hemolytic episode, and there is a significant reduction in the rate of bromosulfalein clearance during this period in sheep and in calves poisoned experimentally. In sheep the aspartate amino transferase (AST) levels may rise as high as 880 SF units per mL up to 6 weeks before obvious clinical signs appear, and the test is regarded as a suitable monitor of copper poisoning in this species. Plasma aspartate aminotransferase and sorbitol dehydrogenase levels in blood are elevated at 60 days after the copper feeding begins, but diethyl succinate carboxylesterase levels rise within 7 days and are therefore

the better indicator. The hepatic enzymes GGT and AST were determined in one experimental study to be the best enzymes to assess copper-load in sheep during the pre-hemolytic phase. GGT increases were evident 28 days before the hemolytic crisis and AST concentrations increased from 14 days prior to onset of acute copper toxicosis.[6]

NECROPSY FINDINGS

Acute copper poisoning via oral exposure is uncommon in ruminants but gross changes include severe gastroenteritis with erosion and ulceration particularly in the abomasum. Macroscopic changes in calves poisoned by injected solutions of copper salts include hepatomegaly with an enhanced zonal pattern and massive fluid accumulations in body cavities. Characteristic microscopic findings in such acute copper toxicoses include extensive periacinar hepatic necrosis and a variable amount of renal tubular nephrosis.

In chronic copper poisoning, jaundice and hemoglobinuria are usual but not constant findings. The liver is swollen, yellow and may contain hemorrhagic foci. The spleen is enlarged with a soft pulp and the kidneys are swollen and have a dark gunmetal color. The hemolytic crisis typical of ovine copper toxicosis results in massive acute hepatocellular necrosis, which masks most of the chronic hepatic damage. These changes include hepatocellular vacuolation and degeneration, increased single cell necrosis of hepatocytes, a variable amount of periportal fibrosis, and proliferation of cholangiolar cells. These chronic lesions are more easily identified in cattle suffering from copper poisoning. Granular casts are often present in the renal tubules, especially in affected sheep. Hemosiderin deposits are increased in the liver and spleen.

Details of the critical copper levels of tissues are provided in the clinical pathology discussion. Although the lesions described above do occur in some outbreaks of the disease in pigs, they are not as pronounced as in ruminants and they are often accompanied by pulmonary edema and by severe hemorrhage from ulcers in the *pars esophagea* or large intestine.

Samples for confirmation of diagnosis

- **Toxicology** – 5 mL blood; 50 g liver, kidney; 100 g stomach content; 500 g suspect feed (ASSAY (Cu))
- **Histology** – formalin-fixed liver, kidney, abomasum, spleen (LM).

TREATMENT

Primary treatment. For chronic copper poisoning daily oral treatment of lambs with 100 mg ammonium molybdate and 1 g anhydrous sodium sulfate significantly reduces the copper content of tissues and appears to prevent deaths in lambs known to have toxic amounts of copper. The mode of action is by increasing the fecal excretion of copper. Under experimental conditions injection intravenously or subcutaneously has an ameliorating effect on copper poisoning by reducing the capacity of circulating copper to enter erythrocytes and cause their lysis. Injection of ammonium tetrathiomolybdate (three to six times intravenously at 2–3-day intervals at a dose rate of 2.7 mg/kg BW is also effective.[3] So too is the daily intravenous injections of sodium calcium edetate (70 mg/kg BW) for 2 days to calves. Different countries may have particular restrictions on the form of molybdenum approved for use, so locally available approved therapy should be determined and be a part of the veterinary pharmacy before acute hemolytic crises are encountered.

Supportive treatment should include blood transfusion.

In **acute cases** gastrointestinal sedatives and symptomatic treatment for shock are recommended.

CONTROL

When chronic intoxication is occurring or appears probable the provision of additional molybdenum in the diet as described under the control of phytogenous chronic copper poisoning should be effective as a preventive measure. Ferrous sulfide is effective but difficulty is usually encountered in getting the animals to eat it. In pigs and sheep the administration of iron and zinc reduces the risk of copper poisoning on diets supplemented by this element and a diet high in calcium encourages the development of copper poisoning, probably by creating a secondary zinc deficiency. A lick which contains dicalcium phosphate, sulfur, and zinc sulfate has been used to advantage as a prophylactic.[7]

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation is by demonstration of high blood and liver levels of copper plus histological evidence of liver damage. The history and the examination of feedstuffs and pastures are valuable aids in determining the cause.

Differential list
Acute hemolytic diseases which may be mistaken for chronic copper poisoning include:

- Leptospirosis in calves
- Postparturient hemoglobinuria
- Bacillary hemoglobinuria
- Plant poisoning including SMCO in rape, kale, etc., hepatoxins in *Pithomyces chartarum*
- Babesiosis
- Anaplasmosis
- Red maple (*Acer rubrum*) toxicosis
- Excessive intake of onions (*Allium* sp.)
- Many other associations with hemolytic anemia
- Some cases of acute pasteurellosis. The bacterial infections are usually accompanied by fever and toxemia but rape poisoning and postparturient hemoglobinuria can only be diagnosed tentatively by an examination of the environment and consideration of the history.

The **differential diagnosis list** for acute copper poisoning includes other associations with gastroenteritis. It can usually be identified by the blue-green color of the ingesta.

SECONDARY COPPER POISONING ('TOXEMIC JAUNDICE' COMPLEX)

Copper poisoning is a complex problem because of the many factors that influence the intake, metabolism, and excretion of the element. Consequently secondary copper poisoning ('toxemic jaundice') can occur on intakes of copper which are, in other dietary circumstances, non-toxic. The common syndromes include the following:

- **Phytogenous chronic copper poisoning** is a condition in which relatively small amounts of copper are ingested but excessive retention occurs because of the presence of specific plants which have no apparent association with liver damage
- **Hepatogenous chronic copper poisoning** results from excessive retention of copper from the ingestion of specific plants which are associated with liver damage

- One of the plants that commonly contribute in this way is *Heliotropium europaeum* which is also capable of causing uncomplicated toxipathic hepatitis without abnormality of copper metabolism.

The 'toxemic jaundice' group of diseases includes all of these forms of secondary copper poisoning and toxipathic hepatitis assocated with *Heliotropium europaeum*.

Phytogenous chronic copper poisoning

This occurs in sheep grazing pasture containing normal amounts of copper. Although the copper intake may be low, liver copper levels are high and a hemolytic crisis typical of chronic copper poisoning occurs. The predominant association is the domination of the pasture by subterranean clover (*Trifolium subterraneum*) which may contain lower than normal quantities of copper (15–20 mg/kg). British breeds of sheep and their crosses with Merinos are most susceptible.

Control of this disease is by encouragement of grass growth in the pastures. Outbreaks can also be avoided if sheep are prevented from grazing lush, clover-dominant pastures in the autumn. Avoidance of stress, particularly malnutrition, is also important. The daily administration of molybdenum in the feed (7 mg/kg molybdenum) has been shown to greatly reduce the uptake of copper by lambs on diets of high copper content and this has been used as a practical preventive measure. Molybdenized superphosphate (70 g/ha), and molybdenized licks or mineral mixtures (86 kg salt, 63 kg finely ground gypsum, 0.45 kg sodium molybdate) are suitable alternatives. When an outbreak occurs, the administration of ammonium molybdate (50–100 mg/head per day) together with sodium sulfate (0.3–1.0 g/head per day) will stop further deaths in sheep within 3 days. Solutions of the above salts may be sprayed onto hay and administration should be continued for several weeks.

Hepatogenous chronic copper poisoning

This form of the disease occurs most commonly following the ingestion of sufficient quantities of the plant *Heliotropium europaeum*, (*Senecio* spp. and *Echium plantagineum*) over a period of 2–5 months to produce morphological and biochemical changes in liver cells without major impairment of liver function. After ingestion of these plants the liver cells have an increased affinity for copper and abnormally high amounts accumulate in the liver with an increased risk of a hemolytic crisis. Sheep grazed on *H. europaeum* and then on subterranean clover are particularly prone to this form of the disease. Control depends upon preventing the ingestion of hepatotoxic plants and restricting copper retention by the methods described above.

Poisoning by *Heliotropium europaeum*

Heliotrope contains hepatotoxic alkaloids and continued ingestion of the plant is associated with liver damage. If a high copper storage occurs, hepatogenous chronic copper poisoning may develop. On the other hand, if the sheep's copper status remains normal liver damage proceeds until the animal suffers from simple toxipathic hepatitis. The effects of the plant are cumulative and grazing for one season may be associated with little apparent harm but further grazing in the subsequent year may be associated with heavy mortality. Control must aim at eradication of the plant.

SODIUM CHLORIDE POISONING

Synopsis

Etiology Ingestion of excessive amounts of sodium chloride OR normal intake but limited water intake.

Epidemiology Source of salt includes:
- Artesian bore water used as drinking water
- Water accumulating in pasture containers of salt mixture or lick
- Animals allowed access to salt after previous deprivation
- Excess salt in prepared feeds.

Clinical signs

***Very large doses*:** vomiting, diarrhea, dehydration.

***Average doses in cattle*:** opisthotonos, Nystagmus, blindness, convulsions, death.

***Continuous intake in pigs*:** blindness, deafness, aimless wandering, head pressing, regularly periodic convulsions.

Continuous intake in ruminants: bawling, restlessness, anorexia.

Clinical pathology High blood levels of sodium and sodium chloride. High salt content in water, feed. Eosinopenia only in pigs.

Necropsy lesions

***Very large doses*:** gastroenteritis.

***Average doses*:** eosinophilic meningitis in pigs; polioencephalomalacia in cattle. High tissue levels of sodium and chloride.

Diagnostic confirmation Elevated sodium and chloride content of tissues. Cerebrospinal fluid sodium exceeds serum sodium. Elevated aqueous or vitreous humor sodium.

Treatment

***Primary*:** remove source of salt, restrict water intake and allow acclimation to water slowly.

***Supportive*:** gastroenteric sedatives and fluid/electrolyte replacement for gastroenteritis form; sedative and cerebral decompressant in convulsive form.

Control Limit intake of salt-rich water, whey, concentrate mixes; insure adequate drinking water supply at all times.

ETIOLOGY

Feed and water containing excessive quantities of salt are unpalatable to animals but excessive quantities of salt are sometimes ingested, especially in saline drinking waters. Specific details about the degree of salinity of drinking water that is compatible with health in animals are difficult to provide, because of the variation in the kinds of salts which occur in natural saline waters.

Toxic doses quoted for acute sodium chloride poisoning are for pigs, horses, and cattle 2.2 g/kg BW and for sheep 6 g/kg. The toxicity of salt is significantly influenced by the age and body weight of the subject. For example, dose rates which kill pigs of 6.5–10 kg BW have little effect on pigs of 16–20 kg.

It is probable that the pathophysiological disturbance described here is one of water intoxication rather than salt poisoning in the absolute sense. High salt intakes are extensively used in sheep to restrict food intake during drought periods and in the control of urolithiasis in feeder wethers but salt poisoning does not occur if there is free access to water. Rations containing up to 13% of sodium chloride have been fed to ewes for long periods without apparent ill-effects, although diets containing 10–20% and water containing 1.5–2% sodium chloride do reduce food consumption. This may be of value when attempting to reduce feed intake but can be a disadvantage when sheep are watered on saline artesian water.

EPIDEMIOLOGY

Occurrence

Salt poisoning will occur wherever bore water is used for livestock drinking. It is reported principally from Australia, North America, and South Africa.

Sources of toxin

- Saline drinking water, especially after a change from fresh water, and especially if the animals are thirsty
- Water accumulating in salt troughs during drought periods
- Animals previously deprived of salt may eat excessive amounts if suddenly allowed access to unlimited quantities

- In animals kept in barns and small yards when prepared feeds contain too much salt, or salt is provided only intermittently, when trough space is limited and animals tend to gorge on swill or concentrate
- Swill fed to pigs may contain excessive amounts of salt when it contains dough residues from bakeries, brine from butchers' shops, salt whey from cheese factories, or salted fish waste
- Excessive sodium sulfate given to pigs as treatment for gut edema if the water intake is restricted
- Environmental pollution by oil wells. Cattle are attracted to oil residues of their salty flavor and may ingest toxic amounts
- Temporary restriction of the water supply to pigs of 8–12 weeks of age, lambs and calves fed prepared feeds containing the standard recommendation of 2% salt. Poisoning occurs when the animals are again allowed access to unlimited water. Similarly pigs brought into new pens where drinking water is supplied in automatic drinking cups may not be accustomed to their use and fail to drink for several days until they learn to operate the cups. Feeder lambs and calves may also be deprived of water when their troughs are frozen over.

Risk factors

Host factors

Sheep, beef cattle, and dry dairy cattle appear to be less susceptible than dairy cows in milk, which are in turn less susceptible than horses. Heavy milking cows, especially those in the early stages of lactation, are highly susceptible to salt poisoning because of their unstable fluid and electrolyte status.

Toxin factors

Saline waters often contain a mixture of salts and those containing high levels of magnesium or fluorine may be quite toxic. Water containing 0.2–0.5% magnesium chloride may be associated with reduced appetite and occasional diarrhea in sheep, especially if the sodium chloride content is also high, but water containing similar quantities of sodium sulfate does not have any harmful effect.

Variation between bore waters includes differences in the relative proportions of the acid radicals, particularly sulfates, carbonates, and chlorides.

Environment factors

Environmental temperatures have an effect on toxicity, signs occurring in the summer on water containing levels of salt which appear to be non-toxic in the winter. Australian recommendations are that the maximum concentration for sodium chloride or total salts in drinking water should not exceed 1.3% for sheep, 1% for cattle, and 0.9% for horses. South African and Canadian recommended levels are much lower but there does not appear to be any proof that such low levels of total and individual salts are necessary.

Importance

Many animals may be clinically affected and the mortality rate may be high where animals are kept under range conditions and have to depend on saline water supplies for drinking purposes. In animals kept under intensive conditions salt poisoning occurs only sporadically but most affected animals die and heavy losses may occur in groups of pigs.

PATHOGENESIS

Acute poisoning

When excessive amounts of salt are ingested gastroenteritis occurs because of the irritating effects of the high concentrations of salt. Dehydration results and is exacerbated by the increased osmotic pressure of the alimentary tract contents. Some salt is absorbed and may be associated with the involvement of the central nervous system as in chronic poisoning.

Chronic poisoning

Where the defect is one of decreased water but normal salt intake, there is an accumulation of sodium ions in tissues, including the brain, over a period of several days. An initial high sodium accumulation may inhibit anaerobic glycolosis, preventing active transport of sodium out of the cerebrospinal compartment. When water is made available in unlimited quantities, it migrates to the tissues to restore normal salt-water equilibrium. This is associated with acute cerebral edema and the appearance of signs referable to a sudden rise in intracranial pressure. The response is the same in all species but in pigs there is, in addition, an accumulation of eosinophils in nervous tissue and the meninges. The sodium ion is the one that accumulates in the tissues, identical syndromes being produced by the feeding of sodium propionate or sodium sulfate. It has also been observed that the feeding of soluble substances such as urea, which are excreted unchanged by the kidney, may be associated with anhydremia and an increase in the sodium ion concentration in brain tissue and the development of encephalomalacia.

This form of salt poisoning is chronic only in the sense that the sodium ion accumulates gradually. The clinical syndrome is acute in much the same way as the syndrome is acute in chronic copper poisoning. There is an apparent relationship between this form of salt poisoning and polioencephalomalacia in all species. Many outbreaks of this latter disease occur in circumstances which suggest chronic salt poisoning. Sheep become adapted to a continuous high salt intake (up to 1.3% sodium chloride in the drinking water) by significant changes in numbers of microflora in the rumen but this is not usually accompanied by any change in total metabolic activity. The same level of intake in sheep is associated with some mortality, chronic diarrhea and reduction in fertility, weight gain and wool growth.

CLINICAL FINDINGS

Acute salt poisoning in cattle

With very large doses the clinical signs are vomiting, diarrhea with mucus in the feces, abdominal pain, and anorexia. The more common syndrome, accompanying the dose of salt usually encountered, includes opisthotonos, nystagmus, tremor, blindness, paresis, and knuckling at the fetlocks. There may be a nasal discharge and polyuria occurs constantly. A period of recumbency with convulsions follows and affected animals die within 24 hours of first becoming ill. Sheep show similar signs. In swine the signs include weakness and prostration, muscle tremor, clonic convulsions, coma and death after a course of about 48 hours.

Chronic salt poisoning

In pigs this is ushered in by the appearance of constipation, thirst and pruritus 2–4 days after exposure. A characteristic nervous syndrome follows within 12–24 hours. Initially there is apparent blindness and deafness, the pig remaining oblivious to normal stimuli and wandering about aimlessly, bumping into objects and pressing with the head. There may be circling or pivoting on one front leg. Recovery may occur at this stage or epileptiform convulsions begin, recurring at remarkably constant time intervals, usually 7 minutes, accompanied by tremor of the snout and neck. Clonic contractions of the neck muscles may be associated with jerky opisthotonos until the head is almost vertical causing the pig to walk backwards and assume a sitting posture. This may be followed by a clonic convulsion in lateral recumbency, with jaw champing, salivation, and dyspnea. Death may occur due to respiratory failure or the pig relaxes into a state of coma for a few moments, revives and wanders about aimlessly until the next episode occurs. The pulse and temperature are normal except in convulsive pigs when both may be elevated. The course is variable and death may occur in a few hours or not for 3–4 days after the first appearance of illness.

Subacute poisoning

This syndrome in cattle and sheep on saline drinking water includes depression of

appetite, thirst, constant bawling, especially in calves, loss of body weight, dehydration, hypothermia, weakness, and occasional diarrhea. Incoordination, collapse, and tetanic convulsions with frothing from the mouth and nose may occur if the animals are forced to exercise. Acetonemia may be a complication in lactating cows.

Eosinophilic dermatitis has been observed at meat inspection in pigs transported in trucks salted to prevent slipping. The condition can be reproduced experimentally by rubbing salt in the skin.

Subclinical salt poisoning Lower levels of intake can suppress food intake and growth without overt clinical signs. This occurs in heifers drinking water containing 1.75% sodium chloride; the animals only maintain weight at a salt level of 1.5% and show suboptimal weight gains when the water contains 1.25% sodium chloride. Drinking water containing 0.25% salt significantly reduces the milk yield of high-producing dairy cows.

CLINICAL PATHOLOGY

In pigs serum sodium levels are elevated appreciably above normal levels (135–145 mmol/L), to about 170–210 mmol/L during the severe stage of chronic sodium salt poisoning.[1] Also polydipsia is recorded at blood serum levels of sodium chloride of 900 mg/dL, typical signs of salt poisoning at 1300 mg/dL, and death when levels exceed 1500 mg/dL. An eosinopenia is also evident during this stage and a return to normal levels usually indicates recovery. In cattle the same changes occur but there is no eosinopenia. Samples of feed and drinking water should be collected for salt assay.

NECROPSY FINDINGS

In acute salt poisoning of cattle there is marked congestion of the mucosae of the omasum and abomasum. The feces are fluid and dark. Animals that have survived for several days show hydropericardium and edema of the skeletal muscles. The blood appears to be thinner than normal. Gastroenteritis may be evident in some pigs poisoned with large doses of salt but in chronic poisoning there are no gross lesions. Histologically the neurologic lesions of acute poisoning are restricted to expansion of perivascular spaces in the brain. In contrast, the microscopic changes in chronic salt poisoning in pigs are quite diagnostic. The expansion of perivascular spaces typical of acute cerebral edema is accompanied by meningitis featuring large numbers of eosinophils, which extend along Virchow–Robin spaces into the brain tissue. In pigs that survive there may be residual polioencephalomalacia, especially of the cerebral cortex. Chemical estimation of the amount of sodium and chloride in tissues, especially brain, may be of diagnostic value. Levels exceeding 150 mg/kg of sodium in the brain and liver, and of chlorides in excess of 180 mg in the brain, 70 mg in muscle and 250 mg/kg in the liver are considered to indicate salt poisoning. Brain sodium concentrations from 2230 to 4250 μg/g tissue have been recorded in water deprivation/salt intoxication of cattle.[2] Aqueous humor sodium values in these circumstances have ranged from 172 to 218 meq/L.

Samples for confirmation of diagnosis

- **Toxicology** – 50 g liver, skeletal muscle, brain, serum, cerebrospinal fluid, aqueous, or vitreous humor, feed, water (ASSAY (Na)(Cl))
- **Histology** – formalin-fixed half of sagittally-sectioned brain (LM).

DIFFERENTIAL DIAGNOSIS

The appearance of typical signs in pigs which have been recently moved to new quarters, or subjected to a change of ration during the preceding week, or which have not had access to water at all times, should suggest sodium salt poisoning. Diagnostic confirmation depends on the detection of elevated levels of sodium chloride in blood or in tissues and fluids, and in pigs on the presence of aggregations of eosinophils in the brain.

Differential diagnosis list

Diseases which have a similar clinical profile to salt poisoning include:

- Encephalitis
- Pseudorabies which is restricted in its occurrence to young sucking pigs
- Viral encephalomyelitis
- Polioencephalomalacia in pigs and ruminants is almost identical with chronic salt poisoning and occurs in many instances under the same set of circumstances
- Gut edema occurs in rapidly growing pigs in the same age group as chronic salt poisoning. There are some differences in the clinical syndromes as they occur in the field, particularly the periodicity of the convulsive episodes in salt poisoning and the altered squeal in gut edema, but in many instances it will be impossible to decide on the diagnosis without reference to the history of salt and water intake
- Mulberry heart disease may be accompanied by nervous signs similar to those of salt poisoning but the disease is usually restricted to older pigs and deaths occur quite suddenly.

Gastroenteritis associated with excessive ingestion of saline drinking water has few diagnostic features and **diagnostic confirmation** from other causes of enteritis depends upon identification of a high salt intake.

TREATMENT

Primary treatment of both acute and chronic salt poisoning is the immediate removal of the toxic feed or water. Serum sodium levels should not be reduced by more than 0.5 mEq/hour.[3] If possible, serum sodium should be measured and a formula used to calculate the free water deficit as follows:

> Free water deficit (L) = 0.6 × body weight (kg) × ([current serum sodium concentration/reference range serum sodium concentration] – 1)[4]

Initially access to fresh water should be restricted to small amounts at frequent intervals; unlimited access may be associated with a sudden increase in the number of animals affected. In advanced cases animals may be unable to drink and water may have to be administered by stomach tube.

Supportive treatment includes alimentary tract sedatives when gastroenteritis is present and administration of isotonic fluids when dehydration has occurred. When there is evidence of cerebral edema it may be necessary to administer a sedative, and cerebral decompression may be attempted by the use of diuretics or hypertonic solutions injected parenterally.

CONTROL

Drinking water for all classes of livestock should not contain more than 0.5% sodium chloride or total salts, although sheep and beef cattle can survive on water containing as much as 1.7% sodium chloride or total salts. Waters containing a high concentration of fluoride or magnesium are particularly dangerous to livestock. Both salt and water should be freely available at all times. Diets fed to pigs should not contain more than 1% salt. The way in which whey is fed to pigs – with minimum water intake – makes prevention difficult unless the whey can be kept free of salt at the cheese factory.

ZINC POISONING

Synopsis

Etiology Soluble zinc salts in drinking water.
Epidemiology Rare occurrence due to contamination of water from galvanized vessels, or industrial pollution.

Clinical signs
Pigs: lameness due to degenerative arthritis.
Cattle: constipation, reduced milk yield.
Clinical pathology Elevated serum and tissue levels of zinc.
Necropsy lesions
Pigs: degenerative arthritis.
Cattle: degenerative lesions in all organs especially pancreas.
Diagnostic confirmation Elevated serum and tissue levels of zinc.
Treatment
Primary: remove zinc source.
Supportive: symptomatic treatment.
Control Rinse galvanized pipes and utensils after each carriage of milk or milk products. Supplement diet with additional calcium.

ETIOLOGY

Toxic doses are not well defined but drinking water containing 6–8 mg/kg of zinc is associated with constipation in cattle and 200 g of zinc as lactate fed over a period of 2 months as a 0.1% solution is associated with arthritis in pigs. The maximum amount tolerated by pigs is 0.1% zinc (as zinc carbonate) in the diet. Experimental zinc poisoning in sheep and cattle is associated with reduced weight gains and feed efficiency when zinc is fed at the rate of 1 g/kg BW. At 1.5–1.7 g/kg BW there is reduced feed consumption in both species and depraved appetite in cattle.

EPIDEMIOLOGY

Occurrence

Zinc poisoning in livestock is a rare occurrence and poorly documented.

Source of toxin

- Zinc released from galvanized surfaces when:
  - subjected to electrolysis when galvanized and copper pipes are joined
  - galvanized bins flake zinc when used for storage of pig swill
  - an outbreak of poisoning has occurred in pigs fed buttermilk from a dairy factory. The buttermilk was piped to the pig pens each day through a long galvanized iron pipe. The buttermilk lay in pools in the pipe after each batch was run through; souring occurred and the lactic acid produced was associated with the formation of zinc lactate which was passed to the pigs in the next batch of buttermilk. The concentration of zinc in the milk (0.066%) was slightly higher than the minimum toxic strength (0.05%)

  The addition of zinc to pig rations as a preventive against parakeratosis is unlikely to be associated with poisoning because of the unpalatability of rations containing excessive amounts
- Zinc chromate used as a paste in joining electrical cables
- Fumes from a nearby galvanizing factory
- Zinc, often associated with cadmium, is a common pollutant from industrial plants handling a variety of ores; nearby pasture may contain more than 500 mg/kg of zinc
- Zinc-based paints, with a 50–55% zinc content when cattle lick freshly painted ironwork
- Zinc added to calf-grower rations as a non-specific dietary supplement
- Accidental inclusion of zinc oxide in a prepared dairy cow ration
- Zinc dust as an industrial hazard; dose rates up to 45 mg/kg BW have no effect on cattle; 50 mg/kg is associated with anemia; daily dose rates of 110 mg/kg BW are associated with deaths
- Careless use of zinc sulfate as a prophylactic and treatment for:
  - poisoning by fungi, especially *Pithomyces chartarum*
  - ovine footrot
  - lupinosis. It is apparent that daily doses of 50–100 mg zinc/kg BW in these circumstances can be associated with severe abomasal lesions, pancreatic damage and death in sheep, provided the material is administered with a drenching gun. The same dose administered by ruminal intubation is non-toxic, because the zinc triggers a closure of the reticular groove resulting in its immediate deposition in the abomasum
- Accidental oral dosing with large doses of zinc oxide can also be associated with hypocalcemia and a syndrome comparable to milk fever.

Dietary levels of zinc associated with poisoning in different species have been summarized.[1] Pigs develop abnormal articular cartilage at 500 ppm dietary zinc, while 2000 ppm zinc in the ration is associated with copper deficiency, anorexia, and subcutaneous hematomata. For horses, appproximately 3600 ppm in the diet, or 90 mg/kg body weight reduces growth rate. Sheep and cattle generally are adversely affected by 900 ppm zinc in their diet.

Importance

Zinc is one of the least important agricultural industrial poisons but individual farms may suffer serious losses.

PATHOGENESIS

Zinc obtained orally is absorbed primarily from the proximal small intestine and approximately one-third of absorbed zinc is protein bound in the plasma.[2] Phytic acid content of plant proteins interferes with absorption of zinc in monogastric diets. Other nutrients or elements that reduce zinc absorption include calcium, cadmium, and copper.[3] Once absorbed, zinc accumulates rapidly in liver and pancreas with slower accumulation in muscle and bone. Excretion is primarily in feces contributed from bile and from secretion via intestinal mucosa and bile.[4]

The pathogenesis of zinc poisoning has not been determined, but it is likely that the arthritic lesions observed will be due to faulty calcium absorption. This lesion in equines has also been suggested related to interactions of zinc and copper with interference in collagen metabolism.[5] The development of anemia in some animals is poorly understood, but may be a result of interations of zinc, copper, and calcium.[6]

CLINICAL FINDINGS

Acute poisoning

Cattle. Large doses are associated with light green-colored diarrhea and drastic reduction in milk yield. Severe cases show additional signs including somnolence and paresis.

Pigs. Large doses are associated with decreased food intake, arthritis, hemorrhages in the axillae, gastritis, and enteritis. Death may occur within 21 days.

Chronic poisoning

Dairy cattle show chronic constipation and a fall in milk yield.

Pigs fed buttermilk containing zinc show anorexia, lethargy, unthriftiness, rough coat, subcutaneous hematomas, stiffness, lameness, progressive weakness with enlargement of the joints, particularly the shoulder joint, and finally recumbency.

Horses. Chronic poisoning is associated with a non-specific, degenerative arthritis especially at the distal end of the tibia. The lesion is accompanied by an effusion into the joint capsule and the obvious enlargement of the hock joint. There may also be a generalized osteoporosis, lameness, and illthrift.

Experimental dosing with large quantities of soluble zinc salts is associated with diarrhea, dysentery, or subcutaneous edema, jaundice, posterior weakness and death. Zinc fed experimentally to foals is associated with pharyngeal and laryngeal paralysis, stiffness and lameness resulting from swelling of the epiphyses of long bones.

CLINICAL PATHOLOGY

After experimental feeding high levels of zinc are detectable in tissues, especially liver, pancreas and kidney, and serum and liver levels of copper are reduced. Serum zinc levels in affected cattle may be as high as 500 µg/mL, in contrast with the

usual levels of about 140 µg/mL in normal cattle. Estimated as zinc protoporphyrin, the levels in poisoned donkeys and mules reach 900–1900 µg/mL.[7] Fecal levels of zinc are likely to be elevated from an average of 220 mg/kg in normal animals to 8740 mg/kg in affected ones.

NECROPSY FINDINGS

Severe, acute poisoning in sheep is associated with an abomasitis and duodenitis, in which the mucosa may appear green in color. In survivors a severe, fibrosing pancreatitis may develop. Acute poisoning in cattle has been accompanied by generalized pulmonary emphysema, a pale flabby myocardium, renal hemorrhages, and severe hepatic degeneration. Chronic poisoning in this species may result in lesions in many organs but the most consistent damage is in the pancreas. Atrophy of exocrine pancreatic acini with extensive interstitial fibrosis have also been described in piglets receiving a total parenteral nutrition diet.[8]

In chronic zinc poisoning in pigs there is a non-specific, degenerative arthritis affecting particularly the head of the humerus, the articular cartilage being separated from the underlying osteoporotic bone. In foals, similar joint lesions and nephrosclerosis may be seen.

The hepatic zinc content in normal animals is high (30–150 mg/kg wet matter in calves) and may reach levels of 400–600 mg/kg wet matter after continued ingestion of zinc chromate paste without being accompanied by signs of zinc poisoning. In acute poisoning by zinc oxide in cattle, levels of 2000 mg/kg dry matter in liver and 300–700 mg/kg dry matter in kidney may be achieved; tissue copper levels in these animals may be reduced to 10–20 mg/kg. Tissue levels in calves dying of experimental zinc poisoning are much lower: 200–400 mg/kg.[8]

Samples for confirmation of diagnosis

- **Toxicology** – 50 g liver, kidney; 500 g suspect feed or ingesta (ASSAY (Zn))
- **Histology** – formalin-fixed pancreas (LM).

Tissue assay The zinc content of liver in normal animals is high (30–150 mg/kg wet matter in calves) and may reach levels of 400–600 mg/kg wet matter after continued ingestion of zinc chromate paste without being accompanied by signs of zinc poisoning. In acute poisoning by zinc oxide in cattle levels of 2000 mg/kg dry matter in liver and 300–700 mg/kg dry matter in kidney may be achieved; tissue copper levels in these animals may be reduced to 10–20 mg/kg. Tissue levels in calves dying of experimental zinc poisoning are much lower – 200–400 mg/kg.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation of zinc poisoning depends on identification of elevated levels of zinc in fluids or tissues.

Differential diagnosis list

Diseases with similar clinical profiles include, in pigs:

- Rickets limited in occurrence to young pigs
- Erysipelas

TREATMENT

Primary: Other than removal of the source of the zinc, none are recommended. **Supportive treatment** is limited to symptomatic treatment.

CONTROL

Galvanized utensils and piping should be rinsed after each use in carrying milk. The addition of extra amounts of calcium to the diet of pigs is capable of preventing the toxic effects of zinc if the calcium supplementation is heavy and the zinc intake is not too high.

SULFUR POISONING

ETIOLOGY

Poisoning occurs due to ingestion of toxic amounts of the element or inhalation of sulfur dioxide gas. Sulfur and sulfates in the feed and drinking water play a significant role in the etiology of polioencephalomalacia. The feeding of 85–450 g per head to cattle has been fatal, as has 45 g of sulfur in feed pellets to ewes, and the minimum lethal dose of a sulfur-protein concentrate for sheep is estimated to be 10 g/kg BW. Continuous feeding of sulfur at the rate of 7 g per day can be fatal to adult sheep. Sulfur given to adult horses at a dose level of 0.2–0.4 kg per horse has been associated with poisoning.

EPIDEMIOLOGY

Accidental or uninformed use of sulfur (flowers of sulfur) occurs in the conventional uses of the element:

- Fed to livestock as a tonic and to control external parasites
- Used in feedlots to restrict the consumption of feed by lambs and thus reduce the incidence of enterotoxemia.

Sodium metabisulfite and **sulfur dioxide gas** are used in the preparation of ensilage but at the levels used are unlikely to have toxic effects in animals eating the ensilage. **Hydrogen sulfide gas** is often present in gases emanating from oil and natural gas wells, in cesspools, and in wells. However, animals are not likely to be exposed to concentrations of the gas which are sufficiently high to be associated with illness, although a slatted floor system of manure disposal, if functioning imperfectly, might present problems.

PATHOGENESIS

In small doses the substance is relatively non-toxic, but excessive doses can be associated with fatal gastroenteritis and dehydration. Conversion of the sulfur to hydrogen sulfide in the rumen, and the absorption of the gas can result in the development of polioencephalomalacia.[1] It is possible that sulfur is most toxic when fed in a ration containing a high level of protein. Sulfur can react with metalloproteins or proteins containing disulfides leading to production of H_2S which is inhaled and inhibits cytochrome oxidase and is directly cytotoxic.[2] Elevated hydrogen sulfide in blood also is associated with depression of respiratory and cardiovascular control in the CNS.

CLINICAL FINDINGS

The syndrome in **sulfur poisoning** is characterized by dullness, abdominal pain, muscle twitching, black diarrhea, and a strong odor of hydrogen sulfide on the breath. Dehydration is severe and the animals soon become recumbent and dyspneic, develop convulsions and die in a coma. Pigs exposed to an environment containing 35 mg/kg of **sulfur dioxide** for long periods show increased salivation accompanied by clinical and histological evidence of irritation of the conjunctiva and respiratory mucosa.

NECROPSY FINDINGS

The lungs are congested and edematous, the liver is pale, the kidneys congested and black in color, there is severe gastroenteritis with peritoneal effusion and petechial hemorrhages occur extensively in all organs and in musculature. Polioencephalomalacia, unresponsive to thiamin, may occur in a high proportion of cases.[1]

POISONING BY ORGANIC IRON COMPOUNDS

Fatal poisoning in piglets and in horses and calves is associated with the injection of organic iron preparations as prophylaxis against juvenile anemia.

Piglets

Within 1 or 2 hours of injection sudden deaths occur, sometimes accompanied by vomiting and diarrhea. By necropsy examination there is severe myodegeneration of skeletal but not cardiac muscle. The progeny of vitamin E deficient sows are most susceptible, and the most toxic compounds are those which contain a high proportion of their iron in ionic, and therefore readily absorbable, form. In the state of deficiency of vitamin E the muscle cell membranes are damaged and extensive biochemical changes result, including a great increase in extracellular potassium levels causing cardiac arrest and sudden death.

Age resistance. Pigs at 2 days of age are much more susceptible to the toxic effects of these iron compounds than are 8-day-old pigs. A suggested reason for this age resistance is the older pigs' better renal functional ability to excrete iron. Another possible reason is the greater mobilization of calcium by older pigs in response to iron administration. This mobilization, or calciphylaxis, can be great enough to result in deposition of calcium in damaged tissues or to cause death. This effect appears to be precipitated by simultaneous or immediately preceding (within 24 hours) injection of vitamin D_3 but the injection is not essential to it.

Much of the administered iron is taken up by the reticuloendothelial (monocyte-macrophage) system, and this blockage of the system by the iron preparation may remove the buffering action of the system against absorbed inorganic and bacterial toxins.

There is an additional possible damaging effect of iron injection in young pigs, the development of **asymmetric hindquarters**. In this condition there is asymmetry but the muscles are normal in composition and appear to have asymmetric blood supplies.

Horses

Deaths have occurred in horses within a few minutes of intramuscular injection of iron compounds. Others have shown severe shock but recovered. Death when it occurs appears to be due to acute heart failure. Newborn foals also die soon after the oral administration of a 'digestive inoculant' which contains ferrous fumarate (16 mg/kg) or the iron compound alone. Naturally occurring cases[1] and experimental cases point to acute hepatitis as the critical lesion, and the iron compound as the cause. Commencing 2 days after dosing the signs include depression, ataxia, recumbency, jaundice, and nystagmus. The mortality rate is 66% and the lesions are hepatitis and jaundice.

Cattle

Acute hepatitis and sudden deaths have occurred in 6–9-month-old bulls about 24 hours after injection of an organic iron preparation.[2]

IODINE POISONING

ETIOLOGY

Poisoning with **inorganic iodine** is not as common and is associated with illness in animals, because the toxic dose is so great. Doses of 10 mg/kg BW daily are usually required to produce fatal illness in calves. There is a special occurrence of goiter in foals when the foal and the dam are fed excessive amounts of iodine, when kelp is fed as a dietary supplement. Intakes of 35–40 mg iodine/day to a mare can be associated with the development of goiter in her foal. Toxicity has also occurred at much lower levels of intake (e.g. 160 mg/day per cow) and appears to be a practical risk when cows or calves are fed **organic iodides** such as ethylene diamine dihydroiodide constantly as a prophylactic against footrot.

CLINICAL FINDINGS

Inorganic iodine. In **cattle and sheep** signs include heavy dusting of the hair coat with large-sized dandruff scales, hair loss, dryness of the coat, lacrimation, hyperthermia, nasal discharge, hypersalivation, coughing due to bronchopneumonia, and anorexia. Exophthalmos occurs in some cases and severely affected animals may die of bronchopneumonia. In **horses** alopecia and heavy dandruff are characteristic.

Organic iodine. Toxic effects include a serious increased susceptibility to calf pneumonia and to abortion in pregnant cows.

CLINICAL PATHOLOGY/NECROPSY

Squamous metaplasia of tracheal and parotid duct epithelium is visible histologically, and serum vitamin A levels are reduced. Serum iodine levels are elevated above the normal level of 5–10 µg/100 mL up to 20–130 µg/mL.

Stowe CM. Iodine, iodides and iodism. J Am Vet Med Assoc. 1981; 179:334–335.

CADMIUM POISONING

There is much interest in cadmium as an **environmental pollutant** and the likelihood of its entering the human food chain via animals used as food. The chances of cadmium accumulating in lean meat are not very great because the levels of ingestion required to produce significant levels are so high that they would be associated with observable clinical illness. However, kidney and liver do accumulate cadmium much more readily than other tissues. Naturally occurring cases of poisoning by cadmium salts are rare in animals, most cases result from accidental administrations of farm chemicals, e.g. a cadmium-containing fungicide.

Sewage and sewage sludge may have higher than desirable levels of cadmium but have not been shown to be associated with poisoning when used as pasture top-dressing or as feed. Conversely, cattle are seen to be effective screens or filters between the high content of cadmium in the diet and the human consumer of the meat.

Ruminants

Chronic poisoning in cattle is associated with inappetence, weakness, loss of weight, poor hoof keratinization, dry brittle horns, matting of the hair, keratosis, and peeling of the skin. At necropsy there is hyperkeratosis of forestomach epithelium and degenerative changes in most organs. In sheep, levels of 60 µg/g of feed for 137 days are needed to be associated with illness. Experimental poisoning of sheep is associated with anemia, nephropathy, and bone demineralization at a dose rate of 2.5 mg/kg body weight per day. Abortion, congenital defects, and stillbirths are also listed as toxic outcomes. The cutaneous lesions can be partly offset by the administration of zinc.

Pigs

In young pigs, levels in the feed of 50 mg/kg for 6 weeks reduce growth rate and are associated with an iron-responsive anemia.

CHROMIUM POISONING

Use of protein concentrates prepared from tannery waste as an animal feed is not recommended because of the material's high chromium content. Trivalent chromium salts given orally to pigs at the rate of 0.5–1.5 and at 3 mg/kg BW is associated with transient diarrhea. With the higher dosage there is also tremor, dyspnea, and anorexia.

VANADIUM POISONING

Experimental and natural poisoning of adult cattle and calves are recorded. Signs include diarrhea, sometimes dysentery, oliguria, difficulty in standing, and incoordination. Field cases are only likely to be encountered when industrial contamination of pasture occurs. Careful ploughing-in of the pasture, especially when the vanadium is contained in a fertilizer such as basic slag, reduces the toxic risk.[1]

BROMIDE POISONING

Accidental access to sodium bromide can result in a syndrome of somnolence, lateral recumbency, drooping of the ears, eyelids, and tail and dribbling of urine.

COBALT POISONING

Overdosing with cobalt compounds is associated with weight loss, rough hair coat, listlessness, anorexia, and muscular incoordination. Toxic effects appear in calves at dose rates of about 40–55 mg of elemental cobalt per 50 kg BW per day. Sheep are much less susceptible, ingesting 15 mg/kg BW of cobalt without apparent effect. Pigs tolerate up to 200 mg cobalt/kg of diet but intakes of 400 and 600 mg/kg are associated with growth depression, anorexia, stiffness of the legs, incoordination, and muscle tremors. Supplementation of the diet with methionine, or with additional iron, manganese, and zinc alleviate the toxic effects.

BORON POISONING

Because boron is now accepted as an essential plant food, it is being added to agricultural fertilizers and adding another toxic chemical to the list of farm hazards for animals. To improve the availability of the element a solubilized form of it is used, increasing its toxicity and its palatability. Signs include depression, weakness, tremor, ataxia, and short seizures of gait spasticity, dorsiflexion of the head, flutter of the periorbicular muscles, followed by stumbling backwards and sternal recumbency, then lateral recumbency and a quiet death. The case fatality rate is 100%. There are no gross lesions on necropsy examination.

Experimental dosing with the fertilizer in goats is associated with the above syndrome plus head-shaking, ear-flicking, star-gazing (staring), phantom dodging, oral champing, restless weight shifting from foot to foot, sawhorse stance, mild diarrhea, and frequent urination. The goats do not eat or drink but paw and nuzzle the food and water as though they are hungry but unable to prehend.[1]

Diseases associated with farm chemicals

Poisoning of animals by agricultural chemicals has become a major area of study in farm-animal medicine. It is a problem area because of the multiplicity of the products used, their extraordinary potency, and the difficulty of determining their generic composition from their trade names. It is possible to arrive at a diagnosis by observing clinical signs and necropsy lesions if one of the more common compounds has been used, but in many other instances it is not possible to do so. It is necessary in the case of any suspected poisoning to inquire in great detail into the history of exposure of the affected animals to any noxious materials. Having identified possible exposure it is then necessary to identify exactly the compound used and then consult a suitable information source, usually the manufacturer, about toxicity problems.

Poisoning of animals has been the prime concern of veterinarians when dealing with agricultural chemicals, but there is now an additional involvement, the need to certify animals and their products as being free of residues of agricultural chemicals. Part of this responsibility is to adequately warn owners of the dangers when dispensing drugs which are regarded as contaminants in human food. The additional involvement for the veterinarian is to identify the source of violative residues when public health authorities advise that rules concerning food purity have been disregarded.

The subject has now become so large that it forms a complete new literature. It is not possible to review all the known toxic compounds in a few pages, and only the more common substances are dealt with here.

POISONING BY ANTHELMINTICS

Carbon tetrachloride poisoning

Synopsis

Etiology Overdosing or standard dose to susceptible animals.
Epidemiology Outbreaks occur when cold or nutritionally stressed, or when lactating sheep or animals with liver damage are drenched with a recommended dose.
Clinical signs
Inhalation dose: collapse, coma, death within a few minutes.
Ingestion dose: acute hepatic insufficiency (anorexia, depression, jaundice) 3 days after dosing.
Clinical pathology Elevated SGOT levels.
Necropsy lesions Acute hepatitis nephrosis.
Diagnostic confirmation History of dosing plus hepatic lesion.
Treatment Inhalation dose: artificial respiration. Ingestion dose: supportive treatment for hepatic insufficiency.

ETIOLOGY

Carbon tetrachloride is sometimes accidentally administered in excessive quantities but deaths more commonly occur when sheep are given standard doses or cattle are dosed by mouth, instead of by injection. Standard doses of 2 mL per sheep to kill adult *Fasciola hepatica* or 1 mL/10 kg BW to obtain efficiency against immature forms, have been widely used but in some circumstances these doses can be highly toxic. Doses as low as 0.5 mL/10 kg BW can be associated with liver damage in calves and clinical effects are apparent at 1 mL/10 kg BW in goats.

EPIDEMIOLOGY

Risk factors

Factors which increase the likelihood that carbon tetrachloride will be toxic in a particular dosing incident are:

- Lush pasture
- Concurrent administration of a hepatoxic anthelmintic, or dieldrin or phenobarbital
- Damage to the liver by plant or chemical poisons
- Ingestion of oxalate-rich plants
- Cold stress in shorn sheep
- Lactating ewes are more susceptible than dry sheep
- Accidental administration of the dose directly into the respiratory tract or inhalation of vapor due to faulty placement of the dose.

PATHOGENESIS

Inhalation of carbon tetrachloride is associated with an immediate and acute depression of the central nervous system and peripheral and circulatory collapse. Diffuse pulmonary edema occurs and sheep that survive show hepatic and renal damage.

Ingestion of toxic doses may result in death within 24 hours due to anesthetic depression and severe pulmonary edema, or may occur 3–7 days later resulting from renal and hepatic insufficiency. Deaths are associated with almost complete liver and kidney failure.

CLINICAL FINDINGS

In **gross overdosing or inhalation** there is an immediate onset of staggering, falling, progressive narcosis, collapse, convulsions, and death due to respiratory failure. Animals that survive this stage or, as in the most common form of carbon tetrachloride poisoning in which animals absorb insufficient dose to produce narcosis, additional signs may be manifested in 3–4 days. These comprise anorexia, depression, muscle weakness, diarrhea, and jaundice. After a further 2–3 days affected sheep go down and mild-to-moderate clonic convulsions may occur, but death is always preceded by a period of coma. Survivors

are emaciated and weak, and may develop photosensitization or shed their wool. They are very susceptible to environmental stresses, particularly inclement weather, and isolated deaths may occur for several months.

CLINICAL PATHOLOGY

In the first 3 days after dosing, liver dysfunction is suggested by a pronounced elevation of AST levels and renal dysfunction by an elevation of blood urea levels. After 4 days from dosing the AST levels return to normal but elevated blood urea levels remain. The BSP test is highly positive and gamma-glutamyltransferase levels are increased.

NECROPSY FINDINGS

Animals dying after inhalation of the drug show marked pulmonary, hepatic, and renal damage. Those dying of massive oral overdosing may show abomasitis and inflammation of the duodenum. In addition acute hepatic swelling, pallor, and mottling accompanied by centrilobular necrosis and fatty degeneration, and renal lesions of extensive tubular necrosis and degeneration, are observed in animals which die after the ingestion of small doses.

DIFFERENTIAL DIAGNOSIS

The history of deaths during dosing or commencing in sheep 3–4 days after drenching with carbon tetrachloride usually suggests the diagnosis. Diagnostic confirmation depends on demonstration of lesions of acute hepatitis.

Differential diagnosis list

Diseases manifested by acute hepatitis include:

- Facial eczema which requires the presence of *Pithomyces chartarum*
- Lupinosis
- Poisoning by *Senecio*, *Crotalaria*, or *Heliotropium* spp.

TREATMENT

Primary. In **inhalation poisoning**, artificial respiration and respiratory center stimulants are indicated. For the **hepatitis** there is no specific treatment.

Supportive treatment. should include the parenteral administration of calcium solutions and the provision of readily digestible carbohydrate. In valuable and seriously affected animals, the latter are probably best provided by the repeated parenteral injection of glucose and protein hydrolysate solutions.

CONTROL

Alternative, less toxic flukicides are almost universally used now. Carbon tetrachloride should not be used if sheep are stressed by cold or lack of feed, or if they have been grazing hepatotoxic plants. It should never be given simultaneously with anthelmintics that damage the liver. Sheep should be drenched into the pharynx when standing naturally so that the dose can be swallowed immediately.

Phenothiazine poisoning

Exposure to phenothiazine and potential poisoning has occurred in the past from its extensive use as an anthelmintic. Today, one of the remaining common uses may be for control of small strongyles in horses. Keratitis, the noteworthy sign of poisoning, occurs most commonly in calves, rarely in pigs and goats, and usually after a heavy single dose of phenothiazine, but it can occur in a program of daily intake in a dietary premix. Phenothiazine is absorbed from the rumen as the sulfoxide, conjugated in the liver and excreted in the urine as leucophenothiazine and leucothionol. As urine is voided, further oxidation turns the metabolic products to a red-brown dye, phenothiazine and thionol which may be confused as hematuria or hemoglobinuria.[1] Cattle are unable to detoxify all the sulfoxide and some escapes into the circulation and can enter the aqueous humor of the eye, causing photosensitization. Other photodynamic agents which cannot enter the eye may also be produced, and they, with the sulfoxide, are associated with photosensitization of light-colored parts of the body. Hyperlacrimation, with severe blepharospasm and photophobia commences 12–36 hours after treatment and is followed by the development of a white opacity on the lateral or dorsal aspects of the cornea, depending on which is exposed to sunlight. Most animals recover within a few days, particularly if kept inside or in a shaded paddock. If the animals continue to be exposed a severe conjunctivitis with keratitis may result.

Tetrachlorethylene poisoning

Tetrachlorethylene rarely produces incoordination which may be evident for 1 or 2 hours after dosing in cattle or sheep. Treatment is not usually necessary.

Hexachloroethane poisoning

Hexachloroethane is preferred to carbon tetrachloride for the treatment of fascioliasis in cattle but it is not completely without danger. Deaths are rare (1 in 20 000 cattle treated), and in sheep (1 in 40 000) but non-fatal illness is not uncommon. Susceptible groups may show narcosis, muscle tremor, and recumbency after administration of the standard dose (**cattle:** 15 g per 6 months of age up to a maximum of 60 g; **sheep:** 0.4 g/kg BW); such animals should be given half this dose on two occasions at 48-hour intervals.

CLINICAL SIGNS

In severe cases these take the form of ataxia, dullness, anorexia, dyspnea, ruminal tympany, and sometimes abdominal pain, diarrhea, and dysentery. The groups include:

- Emaciated animals
- Occasional idiosyncratic animals
- When the liver damage is associated with fluke, infestation is severe
- Animals on high protein diets, or grazing rape or kale
- Parturient or heavily lactating cows.

Necropsy lesions include acute abomasitis and enteritis, edema of the abomasal mucosa, and hepatic centrilobular necrosis.

Treatment with calcium borogluconate as in milk fever elicits a good response.

Hexachlorophene

At high dose rates (25–50 mg/kg BW) hexachlorophene is associated with atrophy of seminiferous epithelium of the testis of young adult rams. Repeated dosing is associated with periportal fatty changes in liver.

Rafoxanide and closantel

Rafoxanide and closantel, both highly regarded anthelmintics, and clioxanide, a discredited drug, are all halogenated salicylanilides, and have approximately the same low level of toxicity. They are capable of causing temporary or permanent blindness if overdosed.[2] In the latter case there is degeneration of optic nerve tracts and other optic pathways in the brain.

Nicotine poisoning

Nicotine poisoning seldom occurs in animals except in lambs and calves where nicotine sulfate is still incorporated in some vermifuges. Doses of 0.2–0.3 g nicotine sulfate have been toxic for lambs weighing 14–20 kg. Animals in poor condition are more susceptible than well-nourished animals. Animals are affected within a few minutes of dosing and show dyspnea with rapid shallow respirations, muscle tremor and weakness, recumbency, and clonic convulsions. Animals that survive the acute episode may show abdominal pain, salivation, and diarrhea. At necropsy there may be abomasitis and inflammation of the duodenum.

Treatment should include artificial respiration and the administration of respiratory center stimulants. Oral dosing with tannic acid preparations will precipitate the alkaloid and retard further absorption.

Piperazine

Piperazine compounds are relatively non-toxic but poisoning can occur in horses on normal or excessive doses. Signs follow a delay of 12–24 hours and include incoordination, pupillary dilatation, hyperesthesia, tremor, somnolence, and either swaying while at rest or lateral recumbency. Recovery follows in 48–72 hours without treatment.

Thiabendazole (2-(4'-thiazolyl)-benzimidazole)

At an oral dose rate of 800 mg/kg BW in sheep transient signs of salivation, anorexia, and depression appear. There are similar signs at larger dose rates and death is likely at a dose rate of 1200 mg/kg BW. Toxic nephrosis is the cause of death and is reflected in the clinical and pathological findings of hypokalemia, hypoproteinemia, and uremia.

Levamisole

All commercial preparations of levamisole consist of the levo isomer. Its mechanism of action is similar to nicotine by causing prolonged depolarization and neuromuscular junction blockade. In pigs, concurrent treatment with levamisole and pyrantel tartrate resulted in enhanced toxicity of the levamisole.[3] Following treatment at standard doses, some **cattle** and, more rarely, **sheep** show signs of lip-licking, increased salivation, head-shaking, skin tremors, and excitability. The excitability is more marked in calves; when released they tend to raise their tails and run around the paddock. Coughing may commence within 15–20 minutes, but this is due to the death and expulsion of lung worms and stops in 24 hours. With higher doses the signs are more pronounced, defecation is frequent and hyperesthesia in the form of a continuous twitching of the skin may be seen. Double doses in **goats** produce mild depression and ptosis, while higher doses produce, in addition, head-shaking, twitching of facial muscles, grinding of teeth, salivation, tail-twitching, increased micturition, and straining. Accidental injection of **pigs** caused vomiting, salivation, ataxia, recumbency, and a high mortality within a few minutes of injection.

Parbendazole, cambendazole, and albendazole

Parbendazole and cambendazole are teratogens and are specifically contraindicated in pregnant animals especially during the first third of pregnancy and at dose rates higher than normal. The safety margin is small and their use at any dose level is not recommended in these females. Defects produced include rotational and flexing deformities of the limbs, overflexion of the carpal joints, abnormalities of posture and gait, vertebral fusion and asymmetric cranial ossification, cerebral hypoplasia and hydrocephalus. Albendazole at 4 times the standard dose also produces some abnormalities if given early in pregnancy.

Fenbendazole

A dose of fenbendazole and the flukicide, bromsalans, to cattle either simultaneously or within a few days of each other may be accompanied by deaths. As fenbendazole and the other tertiary benzimidazoles, oxfendazole, and albendazole, are extremely valuable in removing dormant *Ostertagia ostertagi* larvae, it is suggested that fascol (bromsalans) should not be used where this is an important problem or that 2 weeks should elapse between treatments.

Ivermectin

The intravenous injection into horses of a cattle formulation of ivermectin, contrary to the recommended usage, may cause immediate collapse with coma and periodic nystagmus. Treatment intravenously with flumethasone and flunixin meglumine is effective. Intramuscular injection of the ivermectin is associated with ventral midline edema, due possibly to a reaction to dead microfilariae, edema of limbs and eyelids, fever, dyspnea, disorientation, colic, and sudden death. Transient swelling at the injection site is common.

Occasional outbreaks of severe neurological disorders occur in only Murray Grey cattle after the administration of normal dose rates. Signs include incoordination, knuckling of the fetlocks, a swaying gait, muscle fasciculations, ear droop, blindness, and drooling of saliva, all apparent within 24 hours of dosing. The tongue is paralyzed and protrudes in some. Exercise enhances the syndrome and the patients collapse. Some are dead within 24 hours, some survive for 3 weeks, but all die. There are no gross necropsy lesions but the concentration of ivermectin in the brain is 10 times normal. A genetic penetrability of the meninges is suspected.

Organophosphatic anthelmintics

These are dealt with in the next section on insecticides. Industrial organophosphates and organophosphatic defoliants are dealt with in the section on miscellaneous farm chemicals.

Sumicidin

Sumicidin (fenvalerate) is a synthetic pyrethroid anthelmintic capable of causing non-fatal restlessness, yawning, frothing at the mouth, dyspnea, ear and tail erection, pupillary dilatation, ruminal tympany, regurgitation of ruminal contents, staggering, tremor, clonic convulsions and recumbency after a single oral dose. Single oral doses of >450 mg/kg are lethal. Repeated daily dosing (113 or 225 mg/kg BW) also causes death after 5–15 days.[4]

INSECTICIDES

CHLORINATED HYDROCARBONS (ORGANOCHLORIDES)

Synopsis

Etiology Poisoning by any of the group of insecticides including aldrin, hexachloride, chlordane, DDT, dieldrin, endrin, heptachlor, isodrin, lindane, methoxychlor, toxaphene.
Epidemiology Accidental or misinformed overdosing. Usage on animals now superceded by other less toxic compounds. Stored or leftover products may accidentally be accessed by animals. Importance now due to residues in animal products used in human food chain.
Clinical signs Excitement, tremor, intermittent convulsions, hyperthermia, death.
Clinical pathology Assay of compounds in animal tissues.
Necropsy lesions No consistent significant lesions; some animals show pale musculature.
Diagnostic confirmation Chemical assay of liver or brain for acute poisoning; fat or other animal tissue for chronic poisoning.
Treatment ***Primary***: nil. ***Supportive***: by sedation, control of hyperthermia, removal of residual chemical; activated charcoal for oral detoxification.
Control Use alternative insecticides. Avoid mixed farming enterprises which include use of these insecticides for insect control in crops.

ETIOLOGY

This group of poisons includes DDT, benzene hexachloride (and its pure gamma isomer – lindane), aldrin, dieldrin, chlordane, toxaphene, methoxychlor, DDD, isodrin, endrin, and heptachlor. General toxicity data for the more common compounds are given in Table 32.4. Methoxychlor is less toxic than DDT, and isodrin and endrin are more toxic than aldrin and dieldrin. Camphor (2-bornanone) is chemically similar to toxaphene and is associated with a similar syndrome when fed accidentally.

EPIDEMIOLOGY

Occurrence

Poisoning with these compounds has been recorded in all animal species. The chlorinated hydrocarbons have come under so much criticism as environmental contaminants that they are rarely used directly on animals nowadays, so that outbreaks of clinical illness associated with them are much less common than they were.

Source of toxin

Ingestion, inhalation, aspiration, and percutaneous absorption are all possible portals of entry so that contamination of feed and application of sprays and dips can all be associated with poisoning.

Table 32.4 Toxic oral doses and maximum concentrations of insecticides[1]

Compound	Method of application	Calves to 2 weeks	Cattle	Sheep	Pig	Goat	Horse
DDT	Oral single dose (mg/kg BW)	–	450	200	200	200	200
	Maximum safe spray (%)			In general above 5%	In general above 5%		
Benzene hexachloride	Oral single dose (mg/kg BW)	–	1000	1000	1000	1000	1000
Lindane	Oral single dose (mg/kg BW)	5	25	25	–	–	–
	Maximum safe spray (%)	0.025	0.1	1	1	–	0.5
Aldrin	Oral single dose (mg/kg BW)	2.5–5.0	10–25	>10	–	–	–
	Oral daily dose (mg/kg BW)	–	2–5	2–5	–	–	–
Dieldrin	Oral single dose (mg/kg BW)	5–10	10–25	<25	25–50	–	<25
	Maximum safe spray (%)	0.1– 0.25	1–2	0.2–0.3	4	4	100
Toxaphene	Oral single dose (mg/kg BW)	5	–	25	–	50	–
	Maximum safe spray (%)	0.5	2	1.5	4	–	–
Chlordane and heptachlor	Oral single dose (mg/kg BW)	25	–	100	–	–	–
	Maximum safe spray (%)	0.5	2–3	2–3 1.0 lambs)	–	–	–

Organochlorides are closely regulated and banned in some countries but still widely used in agriculture, principally on growing plants to control insect pests, and on stored seed grain to control fungi. If the plants or grain, even milled and by products, e.g. bran, are fed to animals they can be associated with problems of tissue residues; if they are fed in sufficient quantities they can be associated with clinical illness. Many outbreaks are associated with the application to animals of products intended for crops, e.g. endosulfan, and labelled specifically 'Not For Animal Use'. These insecticides may also contaminate soil and persist there for many years. Rooting animals such as pigs are particularly susceptible to this source of poisoning. These compounds are also sometimes fed accidentally and in large amounts in lieu of feed additives, and are associated with acute poisoning. In feedlotted or shedded animals cases may continue for periods as long as a year because of repeated contamination from the environment. Insect baits, e.g. grasshopper baits containing toxaphene and chlordane, used on pasture and for leaf-eating insects on market gardens can be associated with poisoning in livestock, which may eat large quantities of them. These insecticides, especially heptachlor, are incorporated in the soil before the crop of potatoes or maize is sown to control soil pests. Subsequent grazing of the field will cause contamination of the livestock for several years.

Method of application

Dipping of animals is the most hazardous method of application because entry may occur through all portals. Spraying is safer, percutaneous absorption and inhalation being the only portals of entry. The small particle size of the compound and concentration of animals in confined spaces while spraying, increase the possibility of poisoning. Oily preparations are not used for animal treatment but are used inadvertently and are readily absorbed through the skin.

Formulation used

Concentrations of insecticide in formulations used for spraying barns are much higher than those used for animals. Amongst spray preparations simple solutions are most dangerous followed by emulsions and least of all suspensions of wettable powder. Dusting is safest and is preferred to other methods. Preparations for use on plants are often unstable emulsions, which come out of suspension quickly when they reach the plant. If these preparations are used in animal dips the first few animals through the dip can be heavily contaminated and suffer acute, lethal toxic effects. Although the treatment of pastures to control their insect pests is usually safe to animals grazing, the treated pasture or hay made from it can cause contamination of animal products. This contamination can be avoided by incorporating the insecticide into superphosphate granules ('prills') instead of applying it as sprays or dusts. The use of chlorinated hydrocarbons to protect stored seeds provides a hazard to animals if they are fed on the treated seed.

Risk factors

The compounds vary in their ability to pass the skin barrier. Benzene hexachloride, aldrin, dieldrin, and chlordane are readily absorbed. Species susceptibility to skin absorption also varies widely. Very young animals of any species are more susceptible than adults, and lactating and emaciated animals also show increased susceptibility.

When these compounds were first used in dips, skin and foot infections occurred frequently because of contamination of the dip in the absence of a bactericidal agent. Cases of otitis media have occurred for the same reason, but more rarely.

Importance

All of these compounds are capable of causing death due to acute poisoning but these are increasingly rare. Because the compounds are soluble in fat and accumulate in body stores of it they are formidable threats to the meat industry. They are also excreted in significant amounts in milk and enter the human food chain at this point. They are concentrated still further in cream and butter. They also represent a threat to sucklings, but the degree of contamination in fetuses and suckling animals is much less than in their dams.

The principal importance of organochlorine poisoning is the contamination of animal tissues at levels which are not acceptable by modern health standards. These contaminations become the subject of veterinary investigations, and are susceptible to standard techniques of epidemiological examination.

PATHOGENESIS

The mode of action of organochlorides is to induce repetitive discharge of motor and sensory neurons by interference with

axonal transmission of nerve impulses. After absorption, cyclodiene insecticides are activated by the mixed function oxidase (MFO) system and any prior chemical or environmental exposures that increase the MFO system may exacerbate the onset of poisoning. The diphenyl aliphatic (DDT) organochlorines affect sodium channels, prolonging sodium influx and inhibiting potassium efflux at the nerve membrane. The cyclodiene organochlorines competitively inhibit the binding of gamma amino butyric acid (GABA) at receptor sites, resulting in loss of GABA inhibition and resultant stimulation of the neuron. In all organochlorine poisonings recovery may occur, but with smaller animals paralysis follows and finally collapse and death ensue.

Most of the substances accumulate in the fat depots, where they are a potential source of danger in that sudden mobilization of the fat may result in liberation of the compound into the bloodstream and the appearance of signs of toxicity.

CLINICAL FINDINGS

The speed of onset of illness after exposure varies from a few minutes to a few hours, depending on the portal of entry and the compound and its formulation, but it is never very long.

The toxic effects produced by the members of this group include complete anorexia, increased excitability and irritability followed by ataxia, muscle tremor, weakness and paralysis and terminal convulsions in severe cases. Salivation and teeth grinding occur in large animals and vomiting in pigs. Variations on this clinical syndrome which is common to all organochlorine intoxications include:

- DDT and methoxychlor chronic poisoning may be associated with moderate liver damage
- Benzene hexachloride, lindane, chlordane, toxaphene, dieldrin, endrin, aldrin, heptachlor are associated with an exaggerated syndrome including teeth grinding, champing of jaws, dyspnea, tetany, snapping of the eyelids, auricular spasms, opisthotonus, frequent micturition, frenzied movements, walking backwards, climbing walls, violent somersaults, and aimless jumping. Fever of 5–7% above normal may occur, possibly a result of seizure activity. Seizures may persist for 2 or 3 days if the animal does not die.

CLINICAL PATHOLOGY

Blood, hair, and ingesta can be assayed chemically for specific toxins. The removal of a biopsy from the fat pad near the cow's tail offers a satisfactory means of providing samples for tissue analysis. Organochlorine residues in acutely poisoned animals may reach 4–7 ppm in brain or liver.

NECROPSY FINDINGS

At necropsy there are no specific major lesions in the nervous system but toxic hepatitis and tubular nephritis appear in some cases. For **assay** specimens of hair, if the portal is percutaneous, and of the ingesta, if oral intake is probable, are appropriate. Tissue levels need to be high to be good indicators of recent intoxication. If possible the specimens should be deep frozen and the suspected compound should be nominated as assay procedures are long and involved.

DIFFERENTIAL DIAGNOSIS

The predominantly nervous syndrome attracts attention to encephalitis, encephalomalacia and toxic and metabolic encephalomyelopathies in all species. Diagnostic confirmation depends on a positive assay on animal tissues.

Differential diagnosis list:

- Lead poisoning, confirmed by a positive assay for lead on tissue
- Rabies confirmed by histopathological examination
- Pseudorabies of cattle in early stages with pruritis and the accompanying frenzy
- Polioencephalomalacia confirmed by histopathological examination
- Thromboembolic meningoencephalitis in cattle confirmed by the isolation of *Histophilus somni*
- Salt poisoning in pigs identifiable by the characteristic lesions of eosinophilic meningoencephalitis.

TREATMENT

There is no specific primary treatment.

Supportive treatment includes sedation with pentobarbital sodium; repeated doses until signs disappear are preferred, with intravenous injections of glucose and calcium and the administration of a non-oily purgative. Activated charcoal (2 g/kg) given early by stomach tube will bind pesticide in rumen and reduce further absorption. Residual chemical should be removed from the coat, and this may be facilitated by judicious washing with soap and copious water rinse.

Toxic residues. Treatment to reduce the contamination of tissues is unsuccessful, and in most cases the time required for the contamination to subside naturally is long, of the order of 3–6 months, but varying between specific compounds. For example, cows fed DDT prepartum have required an average of 189 days from parturition for the level in the milk fat to decline to 125 ppm. Contamination in other species and with other chlorinated hydrocarbon compounds also tends to be persistent. After the source of contamination is removed drenching of cows with up to 2 kg of activated charcoal followed by daily incorporation in their feed for 2 weeks, or small amounts of mineral oil by mouth at short intervals, have been recommended for this purpose. Neither of these procedures is really practical in the average farm operation. The common procedure for reducing the level of contamination in animals is to put them in a feedlot without any contact with pasture and feed them on energy intensive rations. Sheep decontaminate much more quickly than cattle and animals on a high plane of nutrition eliminate the toxins more quickly.

CONTROL

Mixed enterprise farms, especially vegetable cropping and cattle farming, are the main sources for contamination incidents. Avoidance of the use of the compounds is recommended.

REVIEW LITERATURE

Raisbeck MF et al. Organochlorine insecticide problems in livestock. Vet Clin North Am Food Anim Pract, 1989; 5(2):391–410.

ORGANOPHOSPHORUS COMPOUNDS AND CARBAMATES (ORGANOPHOSPHATES)

Synopsis

Etiology Poisoning by accidental exposure or overdosing with any one of the very large number of insecticides in these two groups of organic compounds.
Epidemiology Outbreaks occur due to overdosing, use of oil-based preparations formulated for use on non-animal surfaces, dehydrated animals, drift of spray from orchards, field crops to pasture.
Clinical signs
Acute disease in **cattle**: salivation, diarrhea, tremor, pupillary constriction, dyspnea, moist rales, ataxia, weakness.
Horses: abdominal pain, diarrhea, dyspnea, ataxia; bilateral laryngeal paralysis.
Delayed neurotoxicity occurs only with some compounds, characterized by incoordination, posterior paralysis, with few or no cholinergic signs. Congenital defects in piglets.
Clinical pathology Marked depression of blood cholinesterase levels.
Necropsy lesions Acute disease: no diagnostic lesions. Delayed neurotoxicity: degenerative lesions in peripheral nerves and spinal cord.
Diagnostic confirmation Depressed cholinesterase levels in blood; organophosphate or carbamate in feed or environment.

Treatment Acute disease: primary treatment is atropine in large doses to effect or atropine plus oxime, remove residual toxin from hair coat and prevent absorption from GI tract with activated charcoal and cathartics.
Control Avoid use in stressed, especially dehydrated, animals. Special constraints with Chlorpyrifos.

ETIOLOGY

Organophosphorus compounds and carbamates act in essentially the same way therapeutically and toxicologically, but bonding of the compound to the esterase enzyme is irreversible in the organophosphorus compounds and spontaneously degradable with the carbamates, rendering the carbamates potentially less dangerous. A large number of compounds are included in the group and those used for the direct treatment of animals have been selected for their low toxicity. A vast amount of information is available on the relative toxicities of the many compounds but it is not possible to provide details here and the information does not lend itself to summarization.

EPIDEMIOLOGY

Occurrence

All animal species are affected. OP compound and carbamate poisoning is a common poisoning encountered by veterinarians in animal agriculture but the losses are still very small.

Source of toxin

- Grazing in recently sprayed areas, particularly orchards where the most toxic compounds are frequently used
- Spray used on cereal crops and in orchards carried by wind onto pasture fields
- Hay or cubes made from plants sprayed with organophosphate compounds
- Inadvertent access to granular insecticides intended for crops
- Use of old insecticide containers as feeding utensils
- Contamination of water supplies
- Too high a concentration of the insecticide in a spray
- Application to animals of products containing oily bases and designed specifically for spraying on walls or plants.

Risk factors

Host factors

These include susceptible groups such as:

- Young animals (but with some compounds adults are more so), stressed, water-deprived, and chilled animals. The increased susceptibility due to restriction of water intake is noted especially after oral treatment to control warble-fly infestations
- Pregnant females in that congenital defects occur in their offspring
- Brahman and Brahman-cross cattle appear to be more susceptible to some compounds than other cattle
- Dorset Down sheep may be especially susceptible
- Chlorpyrifos is more toxic for male animals with high blood levels of testosterone and is not recommended for use in bulls over 8 months of age.

Toxin factors

These include:

- Formulation used, especially the solvent or vehicle used and droplet size
- Method of application, e.g. the toxicity of pour-ons is delayed by 24 hours compared to sprays
- Toxicity of some compounds appears to increase with storage.

Importance

The introduction of these compounds into animal therapeutics as treatments for nematode, botfly, sheep nasal botfly, and warble-fly infestations and as insecticidal sprays on plants and soil has increased their importance as possible causes of poisoning, and as causes of pollution of milk, meat, and eggs. They also have a role in the poisoning of the native birdlife. They are now one of the most important causes of poisoning of agricultural animals.

PATHOGENESIS

Organophosphorus compounds are highly toxic and are readily absorbed by ingestion, inhalation and by percutaneous and perconjunctival absorption. Once absorbed, sulfur containing organophosphates (phosphorothioates and phosphorodithioates) are metabolized by MFOs and sulfur is exchanged for oxygen thus increasing toxicity. There are two forms of toxicity, cholinesterase inactivation and an organophosphorus-induced, delayed neurotoxicity.

Cholinesterase inactivation

The **inactivation of cholinesterase** by these organophosphorus compounds is associated with an increase in acetylcholine in tissues and increased activity of the parasympathetic nervous system and of the postganglionic cholinergic nerves of the sympathetic nervous system. The toxic effects thus reproduce the muscarinic and nicotinic responses of acetylcholine administration. Differences between the toxicities of compounds depend on the stability of this bonding between esterase and compound, and the toxicity of the substance formed by the bonding.

The muscarinic effects of acetylcholine are the visceral responses of the respiratory system and include marked respiratory distress due to a decrease in dynamic lung compliance and arterial oxygen tension and an increase in total pulmonary resistance; there is bronchial constriction and increased mucous secretion by bronchiolar glands. In the alimentary tract there is increased peristalsis and salivation. Effects in other systems include hypotension and bradycardia, pupillary constriction, sweating and abortion.

The nicotinic effects are the skeletal muscle responses of twitching, tremor and tetany, convulsions, opisthotonos, weakness and flaccid paralysis. There is a difference in the relative muscarinic and nicotinic responses between species, the visceral effects being more marked in ruminants and the muscular effects more evident in pigs in which posterior paralysis is the common manifestation.

Organophosphorus-induced delayed neurotoxicity

This form of toxicity is manifested by distal axonopathy commencing 1 or 2 weeks after the poisoning incident. There is a dieback of neurons causing regional flaccid paralysis, especially in long neurons. The pathogenesis of this lesion is the toxic end-product produced by the interaction between some OP compounds and the esterase, a phosphorylated neuropathy toxic esterase. Typical examples of this effect are:

- **Congenital defects** in young carried by poisoned pregnant females
- **Bilateral laryngeal hemiplegia** in horses
- Possibly the **paralytic ileus** is associated with by chlorpyrifos
- The most severe effects in this category are associated with **industrial organophosphorus compounds** and are discussed under that heading.

Haloxon has this neurotoxic effect in that it is associated with only a slight depression in cholinesterase levels, but a neurotoxic response in the form of hindlimb ataxia has been reported in a proportion of treated sheep and pigs. The susceptibility of sheep is determined by their ability to metabolize this class of organophosphorus compound and this is genetically controlled.

CLINICAL FINDINGS

Acute poisoning

Illness may occur within minutes of inhalation or ingestion of solutions of the more toxic compounds and deaths may commence 2–5 minutes later. After cutaneous application of dichlorvos to calves clinical signs appear within 30 minutes, peak at about 90 minutes and disappear in 12–18 hours. With less toxic compounds

in solid form signs may not appear for some hours and deaths may be delayed for 12–24 hours.

Cattle, sheep and goats

In acute cholinesterase inactivation cases in ruminants the premonitory signs, and the only signs in mild cases, are salivation, lacrimation, restlessness, nasal discharge, cough, dyspnea, diarrhea, frequent urination, and muscle stiffness with staggering. Grunting dyspnea is the most obvious, often audible from some distance because of the number affected. Additional signs include protrusion of the tongue, constriction of the pupils with resulting impairment of vision, muscle tremor commencing in the head and neck and spreading over the body, bloat, collapse, and death with or without convulsions or severe respiratory distress. In sheep and goats[1] the signs are similar and include also abdominal pain. Signs disappear at 12–18 hours.

In delayed neurotoxicity cases signs do not appear for at least 8 and up to 90 days after the poisoning. Signs include posterior incoordination and paralysis. Chlorpyrifos is a specific example of this kind of poisoning. It should neither be applied to adult dairy cattle nor to any mature bulls. The signs include anorexia, depression, recumbency, a distended abdomen, ruminal stasis and diarrhea, and fluid splashing sounds on percussion of the right flank. Severe dehydration develops and may cause death.

Pigs

Cholinesterase inactivation syndrome. Visceral effects except vomiting are less pronounced than in ruminants and salivation, muscle tremor, nystagmus, and recumbency are characteristic. In some instances, the syndrome is an indefinite one with muscle weakness and drowsiness the only apparent signs. Respiratory distress and diarrhea do not occur.

Delayed neurotoxicity syndromes. Outbreaks of posterior paralysis occur 3 weeks after dosing with an organophosphorous anthelmintic; clinical signs vary in severity from knuckling in the hindlimbs to complete flaccid paralysis. The hindlimbs may be dragged behind while the pigs walk on the front legs. Affected pigs are bright and alert and eat well.

Piglets with **congenital defects** of the nervous system manifested clinically by ataxia and tremor are produced by sows dosed with OP compounds during pregnancy. Teratogenicity may be a characteristic of only some organophosphorus compounds, e.g. trichlorfon is teratogenic, dichlorvos is not.

Horses

Cholinesterase inactivation syndrome. Signs include abdominal pain and grossly increased intestinal sounds, a very fluid diarrhea, muscle tremor, ataxia, circling, weakness, and dyspnea. Increased salivation occurs rarely.

Delayed neurotoxicity syndrome. Bilateral laryngeal paralysis develops in foals after dosing with an organophosphatic anthelmintic. It is described under laryngeal hemiplegia.

Miscellaneous OP poisoning

Syndromes include:

- A significant drop in conception rate when the administration is at the beginning of estrus
- The fluid diarrhea which is a transient sign in moderate intoxication in foals may be expanded to a severe gastroenteritis with heavier dose rates
- Most organophosphorus compounds are associated with only temporary interference with cholinesterase and are not associated with any permanent effects in recovered animals but with some compounds, especially coumaphos and ronnel, the recovery period may be quite long, up to 3 months in the case of ronnel, because of slow excretion of the compound and the combined compound-esterase complex
- Absorption of an organophosphorus compound may also be associated with significant changes in the patient's cholinesterase status without causing clinical signs
- Potentiation of the action of succinylcholine chloride for up to 1 month after the administration of the organophosphorus compound in horses. The administration of the relaxant to a sensitized horse can be followed by persistent apnea and death. This, and a number of other interactions with drugs which may themselves have toxic effects, mean that the manufacturer's instructions with organophosphorus compounds must be followed explicitly.

CLINICAL PATHOLOGY

The estimation of cholinesterase in body tissues and fluids is the most satisfactory method of diagnosing this poisoning, but it is essential that proper methods and standards of normality be used. Convincing figures are of the order of 50–100% reduction from normal controls. The degree and the duration of the depression of blood cholinesterase levels varies with the dose rate and the toxicity of the compound used. Blood cholinesterase levels are depressed for much longer than the clinical signs, e.g. after dichlorvos poisoning the depression of cholinesterase level in the blood does not reach bottom until 12 hours after application and the return to normal levels takes 7–14 days.[2] Similarly, cholinesterase levels in cattle poisoned with terbufos, an agricultural insecticide, do not commence to rise toward normal until 30 days and are not normal for 150 days after the poisoning incident. Unlike organophosphate insecticides, carbamate insecticide cholinesterase inhibitors may spontaneously reverse binding and cholinesterase depression may not be detectable in recently poisoned animals.

Suspected food material can be assayed for its content of organophosphorus compounds but assay of animal tissues or fluids is virtually valueless and may be misleading.

NECROPSY FINDINGS

There are no gross or histological lesions at necropsy in acute cholinesterase inactivation cases, but tissue specimens could be collected for toxicological analysis. Material sent for laboratory analysis for cholinesterase should be refrigerated but not deep frozen.

Distinctive degenerative lesions in peripheral nerves and spinal cord can be seen in **delayed neurotoxicity** cases, and hypoplasia is visible in the cerebrum, cerebellum, and spinal cord in congenitally affected piglets.

DIFFERENTIAL DIAGNOSIS

Outbreaks of a syndrome of dyspnea, salivation and muscle stiffness and constriction of the pupils after exposure plus a history of exposure and depressed blood levels of cholinesterase suggest intoxication with these organophosphorus compounds but **diagnostic confirmation** requires positive assay results on suspected toxic materials. In cattle the morbidity and case fatality rates approximate 100% but in pigs the recovery rate is good and all pigs may recover if the intake has been low and access is stopped. With the other poisons listed below death is much more common in pigs and residual defects, including blindness and paralysis occur in a proportion of the survivors.

Differential diagnosis list:
Diseases with a similar clinical profile include:
In cattle:

- Sporadic cases of **anaphylaxis**
- Groups of cattle affected by **acute bovine pulmonary emphysema and edema** (fog fever) may show a sudden onset of dyspnea but pulmonary edema is obvious on auscultation, and salivation and muscle stiffness are absent.
- Early stages of nicotine poisoning, with transient muscle tremors and salivation.

In pigs:

- Arsenic poisoning
- Rotenone poisoning
- Salt poisoning
- Mercury poisoning
- Avitaminosis-A.

TREATMENT

Primary treatment is urgent and critical, especially in cattle because of the usually high case fatality rate. **Atropine** in large (about double the normal) doses is the rational and approved treatment.[3] Recommended doses are 0.25 mg/kg BW in cattle and 1 mg/kg BW in sheep. In very sick animals about one-third of this dose should be given very slowly intravenously in a dilute (2%) solution and the remainder by intramuscular injection. Injections may have to be repeated at 4–5-hourly intervals as signs return, and continued over a period of 24–48 hours. Multiple continued dosing with atropine may not be effective and could result in atropine overdose. Cows that have received very large doses of the poison may not respond to treatment. Atropine does not reverse the nicotinic effects of the OP compound, i.e. the tremor, spasms, and convulsions, but it does block the muscarinic effects. Atropine appears to have low efficacy in sheep. This is not a serious drawback as sheep are much less susceptible than cattle to larger doses of atropine. It should be remembered that reactions in cattle following organophosphorus treatment for warble flies may be due either to the drug or to the damaged grub, and treatment with atropine would be contraindicated in the latter.

Oximes have some efficiency in the treatment of OP compounds, but not all carbamates some of which may have their toxicity enhanced; this is because of their ability to reactivate acetylcholinesterase (ACHE) by dephosphorylation. Also their usefulness as antidotes declines rapidly with the passage of time after the poisoning occurs, and they are of doubtful usefulness after 24 hours. For these reasons oximes are not recommended unless their specific relationship to the particular carbamate is known.[4] The oxime trimedoxime bromide is superior to 2-pyridine aldoxime methiodide (2-PAM) and diacetylmonoxime (DAM). Recommended dose rates for 2-pyridine aldoxime methiodide are 50–100 mg/kg BW given intravenously and for trimedoxime bromide 10–20 mg/kg BW. These dose rates can also be used for subcutaneous and intraperitoneal injection. Administration by any route is as a 10% solution in normal saline. In horses 2-pyridine aldoxime methiodide at doses of 20 mg/kg BW has given good results. Treatment may need to be repeated for up to 10 days to counteract slower acting compounds such as coumaphos.

Combined oxime and atropine, e.g. 2,3-butanedione monoxime and atropine, is recommended as superior to either drug alone.[5] The value of the treatment is greatest if it is carried out early, before 24 hours after poisoning, and is of little

Removal of residual toxin. Animals that have been dipped or sprayed should be washed with water to which soap, soda or a detergent is added to remove residual organophosphorus material. When oral intake has occurred activated charcoal will adsorb residual toxin in the gut.

CONTROL

Most outbreaks occur after accidental access to compounds and this cannot always be avoided. Animals to be treated orally with organophosphorous insecticides should be permitted ample fresh drinking water beforehand. Chlorpyrifos is restricted to use in beef cattle and then not in calves less than 12 weeks old nor in bulls over 8 months of age.

ROTENONE

Rotenone has commonly been used in the past to control bovine Hypoderma larvae (cattle grubs). It has a reputation for low mammalian toxicity but relatively high toxicity to aquatic life. The mammalian oral LD_{50} is 100–300 mg/kg while the LD_{50} for fish is less than 100 ug/L of water. Oral absorption in mammals is limited but enhanced by fat in the diet. Rotenone is relatively non-toxic but toxic effects appear in pigs fed a ration containing 2.5% rotenone. Pyrethrins are believed to enhance toxicity of rotenone. Ingesta at necropsy may contain as much as 2000 ppm of rotenone. Signs include salivation, muscle tremor, vomiting, ascending paralysis, incoordination, quadriplegia, respiratory depression, coma, and death. Accidental oral exposure may be treated with activated charcoal and an osmotic cathartic for decontamination followed by control of seizures are needed. Phenothiazine tranquilizers are contraindicated in

REVIEW LITERATURE

Osweiler GD. Toxicology, Williams & Wilkins, Philadelphia, 1996; pp. 243–245.

AMITRAZ

This acaricide is widely used in most species but is prohibited in horses; when it is applied to them accidentally it is associated with a syndrome characterized by somnolence, incoordination, depression, reduction of intestinal sounds; impaction of the large intestine may occur within 24–48 hours. The susceptibility of the compound for equids is probably due to its much greater persistence in the body.[1] Salivation, depression, anorexia, ataxia, tremors, and coma are signs attributed to amitraz in other species.[2] Concentration of the dipping fluid, environmental temperature and the condition of the skin may influence absorption of the compound and the susceptibility of the animal. Residual amitraz should be removed from affected animals by hosing with cold water and the animal should be treated with large volumes of lubricant by stomach tube at intervals of 12–24 hours. Oral fluids containing electrolytes should be given by stomach tube to counter dehydration and intravenous fluids may be necessary.

HERBICIDES

Herbicides vary widely in their composition and also in their toxicity.

- **Arsenicals** is associated with arsenic poisoning
- Sodium chlorate is also toxic by causing methemoglobinemia
- One hazard of the relatively safe organic compounds set out below is their contamination by highly toxic ones as a result of faults in the manufacturing process, e.g. the dioxins which have been found to be significant contaminants of the 2,4,5-T chemical. Today, restrictions on registration and changes in the manufacturing process have drastically reduced contamination by dioxins.
- Some herbicides, e.g. glyphosate, make pasture that is sprayed with them more palatable, thus creating their own toxicity hazard. The phenoxy acetic acid herbicides can increase palatability of some plants after spraying as well as induce elevated nitrate concentration in plants for several days after spraying.

Dinitrophenol compounds

Dinitrophenols. Animals can be poisoned

percutaneous absorption of these compounds which have the effect of increasing the basal metabolic rate. Poisoning is manifested by an acute onset of restlessness, sweating, deep rapid respiration, fever, and collapse. In ruminants, but not in non-ruminants, the metabolites of these compounds are associated with intravascular hemolysis, methemoglobinemia and hypoproteinemia. Death may occur 24–48 hours later.

Dinitrophenol (DNP) and Dinitro-orthocresol (DNOC) are the commonest members of this group. In all species, doses of 25–50 mg/kg BW are usually toxic but much smaller doses produce toxicity when environmental temperatures are high. There is no accumulation of the drug within the body. Dinoseb, now rarely used, is a highly toxic DNP.

Hormone weed killers

2,4-D, silvex, MCPA and 2,4,5-T are non-toxic in the concentrations used on crops and pasture but dosing with 300–1000 mg/kg as a single dose is associated with deaths in 50% of cattle. They have also been tentatively linked with the high prevalence of small intestinal carcinomas in sheep. The picolinic acid herbicides picloram and clopyralid have also been suspected of the same relationship.

Barban is toxic at doses of 25 mg/kg, for cattle.

2,4-D at oral doses between 150 and 188 mg/kg BW is fatal to adult cows and at 10 mg/kg BW for sheep. Reversible toxic effects are produced with single doses in calves with doses of 200 mg/kg and in pigs with 100 mg/kg. Repeated administration of 50 mg/kg is toxic to pigs. In adult cows signs include recumbency, ruminal stasis, salivation, and tachycardia. In calves the signs are dysphagia, tympanites, anorexia, and muscular weakness; in pigs additional signs include incoordination, vomiting, and transient diarrhea. Long-term administration to pigs (500 ppm in the diet for 12 months) is associated with moderate degenerative changes in kidney and liver. 2,4-D may cause poisoning indirectly by its effect on the metabolism of weeds and sugar beets, resulting in a significant increase in the nitrate content of the leaves.

A commonly used **mixture of 2,4-D, 2,4,5-T and a brushwood killer, monosodium methyl arsenate**, is very toxic by mouth or after application to the skin; signs include anorexia, diarrhea, weight loss, and death in most cases.

Repeated dosing of sheep with silvex for about 30 days at 150 mg/kg BW causes death.

Single doses of the herbicides diallylacetamide, carbamate, triazine, and propionanilide at 250 mg/kg BW are fatal to sheep. Repeated small doses of carbamate are associated with marked alopecia. Acute poisoning with any of these compounds is unlikely unless large amounts are ingested accidentally.

Paraquat is associated with fibrosing pneumonitis in pigs but this does not develop in sheep or cattle with fatal doses. Poisoning with it is unlikely to occur unless it is administered accidentally or maliciously. A dose rate of 100 mg/kg BW is uniformly fatal in pigs with signs of vomiting, diarrhea, and dyspnea. Renal damage may also be a part of acute poisoning by paraquat.

Accidental poisoning of sheep due to contamination of pasture by diquat has been associated with widespread illness with signs of diarrhea and a significant mortality. In cattle accidental poisoning with diquat has been associated with fatal abomasitis and enteritis, hepatic and myocardial degeneration and pulmonary emphysema.

The herbicide **triallate** is associated with severe illness and some deaths with single oral doses of 300 mg/kg BW to sheep and 800 mg/kg to pigs. Salivation, bradycardia, vomiting, muscular weakness, dyspnea, tremor and convulsions are followed by death in 2–3 days. It is also toxic when given in small amounts continuously.

The triazine herbicides atrazine and prometone appear to be non-toxic at usual levels of ingestion. Accidental poisoning of sheep with atrazine is associated with paralysis, exophthalmos, grinding of the teeth, diarrhea, dyspnea, and tachycardia, and of cattle is associated with salivation, tenesmus, stiff gait, weakness. Experimental dosing of heifers with large doses of atrazine is associated with fatal poisoning, but animals treated with activated charcoal survive.

Simazine and aminonitrazole in combination have been associated with death in sheep, and horses allowed access to pasture sprayed with the mixture. In sheep the signs are staggering, inappetence, and depression. In horses colic is the important feature.

Simazine on its own, with continuous access is associated with tremor, tetany and paraplegia, and a prancing gait with the head held against the chest. Death occurs after 2–4 days and mild-to-moderate myocardiopathy at necropsy.[1]

Triclopyr, a selective postemergence herbicide, is toxic to horses at five times the estimated maximum intake from herbage. It is associated with digestive and respiratory signs, ataxia, stiff gait, sometimes tremor and mild to moderate. renal damage.

Sodium chlorate

Animals seldom ingest sufficient sprayed plant material to produce clinical illness and the principal danger is from accidental dosing or permitting salt-hungry cattle to have access to the chemical. The lethal oral dose is 2–2.5 g/kg BW for sheep, 0.5 g/kg for cattle and 3.5 g/kg for dogs. Irritation of the alimentary tract is associated with diarrhea and deep, black erosions of the abomasal and duodenal mucosae. Hemoglobinuria, anemia and methemoglobinemia result and somnolence and dyspnea are characteristic. At necropsy the blood, muscles, and viscera are very dark. No specific treatment is available. Sodium thiosulfate and methylene blue are used in treatment but have little effect but copious blood transfusions have been recommended.

Delrad

This algicide is used to control the growth of algae on ponds and other water reservoirs. Cattle and sheep are unharmed by the ingestion of water containing 100 ppm of the compound. Dose rates of 250 g/kg BW in adult cattle, 150 mg/kg in calves and 500 mg/kg sheep are associated with toxic effects.

DEFOLIANTS

Substances used to remove the leaves from plants to facilitate harvesting of seed may represent a toxic hazard if the residual stalks are fed to livestock.

Monochloroacetate (SMCA) is commonly used for this purpose and, although it is unlikely to cause poisoning unless very large quantities of the stalks are fed, sheep and cattle which gain access to recently sprayed fields may be seriously affected. Toxic signs in cattle include diarrhea, colic, muscular tremor, stiff gait, ataxia, and dyspnea. Terminally there may be convulsions, hyperexcitability, and aggressiveness. The course is short, most animals dying within a few hours.

An organophosphorus compound, tributyl triphosphorotrithioite used as a defoliant for cotton plants, produces typical signs of organophosphorus poisoning.

Thidiazuron, a cotton defoliant, appears not to be toxic for animals, but may enter the human food chain via goat's milk and chicken eggs.

FUNGICIDES

Zinc ethylene dithiocarbonate (zineb) may be associated with thyroid hyperplasia and hypofunction, degeneration of myocardium and skeletal muscle, testicular weight reduction, and germ cell depletion[1].

Thiram (tetramethyl thiuram sulfide) is a widely used agricultural fungicide which is associated with conjunctivitis,

rhinitis and bronchitis on local contact; it is thought to be associated with abortion in ewes on ingestion, and is a known teratogen but no specific poisoning incidents have been recorded in animals.[2]

RODENTICIDES

The commonly used rodenticides in some countries are sodium fluoroacetate and alphanaphthylthiourea (ANTU), but their use is banned in other countries. Anticoagulants, include warfarin ((3-acetonylbenzyl)-4-hydroxycoumarin) and its analogs, as well as newer 'second generation' anticoagulants (brodificoum, bromodiolone, chlorphacinone). Zinc phosphide is often used as an alternative to anticoagulant rodenticides. They are all toxic to domestic animals and may cause death when ingested accidentally. 'Quintox', a rodenticide containing cholecalciferol (0.75 g/kg), has been associated with hypercalcemia, hyperphosphatemia, and death in dogs, and could cause death in farm animals.

SODIUM FLUOROACETATE

ETIOLOGY

Fluoroacetate occurs naturally in some plants, and in the form of compound 1080 is used as a rodenticide in agriculture. The toxic dose level for domestic animals is 0.3 mg/kg BW, and 0.4 mg/kg is lethal for sheep and cattle. Sublethal doses may be cumulative if given at sufficiently short intervals.

EPIDEMIOLOGY

Fluoroacetate's use in agriculture poses a hazard for grazing farm animals because it is usually spread out across fields combined with cereals, carrots, or bread as bait and is attractive to ruminants.

PATHOGENESIS

Its mode of action is by inhibition of the enzyme aconitase, thus blocking the intracellular energy cycle. Two actions are manifest: **myocardial depression** with ventricular fibrillation, and central nervous system stimulation producing convulsions. In sheep the predominant effect with acute poisoning is on myocardium; in dogs it is the nervous system.

CLINICAL FINDINGS

In herbivores generally there is sudden death in **acute** cases, the animals being found dead without evidence of a struggle; or there are tetanic convulsions and acute heart failure with the animals showing weakness and dyspnea accompanied by cardiac arrhythmia, a weak pulse and electrocardiographic evidence of ventricular fibrillation.

In sheep with **subacute** poisoning the signs are similar but are not apparent when the animal is at rest. When they are disturbed the nervous signs of tremor and convulsions appear but disappear when the sheep lies down.

Pigs manifest the nervous form of the disease, including hyperexcitability and violent tetanic convulsions. In all cases there is a period of delay of up to 2 hours after ingestion before signs appear.

CLINICAL PATHOLOGY/NECROPSY FINDINGS

There are no specific lesions but the tissues contain elevated levels of citrate.

DIFFERENTIAL DIAGNOSIS

A history of access to toxic material plus appropriate clinical signs and assay of fluoroacetate in ingesta provide good circumstantial evidence and approximate **diagnostic confirmation.**

Differential diagnosis list:

- Many poisonous plants associated with sudden death linked to acute cardiac arrest
- Lightning strike or electrocution
- Inherited cardiomyopathy
- Ionophore poisoning especially warfarin and in horses
- Other less common causes of sudden death.

TREATMENT/CONTROL

Care in the disposition of baits and highly dependable retrieval of uneaten baits before allowing livestock access to baited fields preempt most mortalities. No specific treatment is available.

ALPHA NAPHTHYLTHIO UREA (ANTU)

Horses, pigs, calves, and dogs are susceptible as well as rats. Tolerance develops after the ingestion of sublethal doses. Death occurs within 24–48 hours after ingestion due to marked pleural effusion, pulmonary edema, and pericardial effusion. The toxic dose rate is of the order of 20–40 mg/kg BW in a single dose.

WARFARIN AND OTHER ANTICOAGULANT RODENTICIDES

ETIOLOGY

Warfarin is a well known anti-vitamin K anticoagulant rodenticide available since the 1940s and is known as a 'first generation' anticoagulant. Related compounds are dicoumarol, coumatetralyl, and pindone.[1] Brodifacoum, bromodialone, diphacinone, difethialone, and chlorphacinone are known as 'second generation' anticoagulants and may be associated with poisoning from a single dose because of their quite prolonged elimination half lives. Single doses, are less likely to be associated with poisoning but repeated ingestion for some days may do so. Daily doses of warfarin of 0.2–0.5 mg/kg BW are fatal to pigs in 6–12 days. In cattle 200 mg/kg daily for 5 days is associated with 50% mortality. At 0.25 mg/kg for 10 days prothrombin times are depressed 20% and at 0.1–0.3 mg/kg abortions occur. Coumatetralyl was introduced to overcome the problem of resistance to warfarin which developed in some rodent populations. It is more hazardous for domestic animals than the original warfarin because it can be used in a concentrated form by laying it across rodent tracks; the rodents lick it from their paws. Brodifacoum[2] acts over a long period and is detectable in liver up to 128 days after intake.

EPIDEMIOLOGY

These products are used by incorporating them into baits and they are in widespread use because they cause no poison shyness. Although most deaths occur because of misuse by farmers, contamination of feedstuffs at the milling plant is not unknown. Calves and poultry are not usually affected, most outbreaks being recorded in pigs, cats, and dogs. Horses are not commonly affected, but warfarin poisoning has been produced experimentally in ponies.

PATHOGENESIS

The poisons exert their effects by interfering with reactivation of vitamin K, thus inhibiting the blood-clotting mechanism by preventing the operation of the thrombin to prothrombin complex. Sudden massive hemorrhage into body cavities or brain may cause immediate death, or death may occur slowly with accompanying lameness due to hemorrhage into subcutaneous tissues. Death due to rupture of a major blood vessel may also occur in 3–4-day-old calves born of cows given a non-fatal dose of warfarin during pregnancy.

CLINICAL FINDINGS

Most cases are of sudden death or found dead. The clinical syndrome includes mucosal pallor, weakness, recumbency, mild dyspnea. Coumatetralyl is associated with more specific signs in pigs, with lameness due to hemorrhage in and swelling of the legs.

CLINICAL PATHOLOGY

There are reduced values for packed cell volume, erythrocyte count, and hemoglobin content. Activated clotting time, prothrombin time, and PIVKA assays are prolonged. Anticoagulants or their metabolites can be detected chemically in

blood or urine, or in liver for animals that have died of toxicosis.

NECROPSY LESIONS

Pallor of tissues and massive hemorrhages are characteristic.

DIFFERENTIAL DIAGNOSIS

Assay of feed supply for the toxin, plus severe anemia evident on clinical, clinicopathological or necropsy findings provide diagnostic confirmation. The differential list includes other causes of acute hemorrhagic anemia.

TREATMENT

Primary treatment. Intravenous injection of a single dose of 50–75 mg/kg BW of vitamin K_1 is an effective antidote for a horse. The prothrombin time is returned to normal in 12–24 hours after this treatment and persists at this level for as long as 96 hours. Animals with acute blood loss must be treated for shock and provided plasma or whole blood which will immediately restore clotting factors and provide immediate coagulation factors for clotting.

Red squills

Poisoning by red squills seldom occurs because the material is extremely unpalatable and when eaten is usually vomited. In all species large doses (100–500 mg/kg BW) must be administered to produce toxic effects. Young calves are most susceptible and goats least. Experimental poisoning is associated with convulsions, gastritis and bradycardia.

Zinc phosphide

Zinc phosphide is also unpalatable to domestic animals, and requires an acid stomach to release its toxic phosgene gas. It is not therefore a likely poison for ruminants, but could be a hazard for pigs and horses. Experimental poisoning with doses of about 40 mg/kg BW is associated with death in most species. A general toxemia with depression of appetite, dullness, and some increase in respiratory rate occurs but there are no diagnostic signs. Necropsy lesions include congestion and hemorrhages in all organs, fatty degeneration of the liver and inflammation in the small intestine. Chemical assay is necessary to establish a diagnosis.[3]

MOLLUSCICIDES

Metaldehyde

Metaldehyde is in common use as a molluscicide. It is usually dispensed in a bran base and is toxic to farm livestock. Outbreaks occur in cattle, horses, and sheep. Lethal dose rates include **cattle** 0.2 g/kg BW in adults, and less in calves; **horses** 0.1 g/kg BW.

Clinical signs in ruminants include incoordination, hyperesthesia, muscle tremor, salivation, dyspnea, diarrhea, partial blindness, unconsciousness, cyanosis, and death due to respiratory failure. Hyperthermia (43.58°C or 110.8°F) occurs in sheep. All the signs are exacerbated by excitement or activity. A mortality rate of 3% may be expected.

Signs in horses are similar plus heavy perspiration, hypersalivation, muscle fasciculation, and death in 3–5 hours.

The only effective treatment in cattle is likely to be rumenotomy, supplemented by sedation with a tranquilizer, sedative or muscle relaxant. In horses, mineral oil by stomach tube is recommended to delay further absorption of the metaldehyde.

Methiocarb

This carbamate molluscicide has anticholinesterase and nicotinic and muscarinic activities. Poisoning of sheep is associated with depression, hypersalivation, diarrhea, dyspnea, aimless wandering, and ataxia. Death is due to pulmonary edema. Horses show sweating, dribbling, muscle tremor, hypersalivation, and finally recumbency and death due to pulmonary edema.

The compound is usually in pellet form and dyed blue so that affected animals can be detected by the blue staining of their mouths. Atropine is an effective antidote but may be required to be repeated if the amount of bait taken is large. For a wider discussion of carbamate poisoning see p. 1834.

WOOD PRESERVATIVES

Phenolic compounds

Lumber used in the construction of barns, stables, pens and yards is often treated with phenolic wood preservatives, chiefly pentachlorophenol, dinitro-orthophenols, dinitro-orthocresols (DNOC), dinitrophenol, and coal tar creosote, or mixtures of these, and animals that have access to freshly treated material or the neat preservative may be poisoned. The toxic cresols may be imbibed orally or absorbed percutaneously, and contact with freshly treated wood may be associated with local cutaneous necrosis.

Acute fatal doses in all species are in the range of 120–140 mg/kg BW for pentachlorophenol, and chronic fatal doses range from 30 to 50 mg/kg BW. Fatal doses for coal tar creosote are 4–6 g/kg BW as a single dose, or 0.5 g/kg BW daily. A high mortality may be encountered in newborn pigs and there may be a greater than normal incidence of stillbirths when sows are farrowed in treated crates. Weaned pigs may show depression, skin irritation and occasionally death.

Coal tar sealers for concrete floors may be associated with similar phenolic poisoning.

Creosote applied as a treatment for ringworm, has shown marked toxic effects in cattle.

Besides the known toxic effects of these chemicals there has been interest in possible **subclinical intoxications**. There is a lack of definitive evidence on the subject, but horses bedded on shavings from pentachlorophenol-treated wood, prepared wrongly by treating the rough lumber and then dressing it instead of applying the preservative to the dressed lumber, have been poisoned by **dioxin**, a common contaminant in the preservative. Clinical signs include depression of appetite, severe weight loss, ventral and limb edema, hair loss, anemia, a crusty, scaly dermatitis around the eyes, muzzle, the axilla and inguinal region, and on the neck. Exudation through cracks in the skin is a feature of the lesion. Lesions in liver biopsies include necrosis and severe vacuolar changes in the hepatocytes.[1]

Copper–chrome–arsenate

Softwood preserved against rot by the application of a patented mixture containing copper, chromate, and arsenic, has become very popular for use in yards and buildings used by livestock. The materials have been carefully tested to insure that there is virtually no risk of poisoning. It is recorded that animals would need to eat at least 28 g of the treated wood daily for a month before a chronic poisoning occurred. Horses that have the chewing habit could eat more than that and could theoretically become poisoned. Burning of treated lumber can make arsenic available and toxic to animal. This route of poisoning has occurred in cattle because of their tendency to lick ashes or soil where burning of wood has occurred.

SEED DRESSINGS

Many poisoning incidents are caused by livestock gaining access to seed which has been treated in some way. The more common ones are listed below, and each is dealt with under the heading of the toxic agent:

- Grain treated with arsenic used to poison birds

- Grain treated with highly toxic organophosphorus substances used to make baits for market garden pests
- Bran mixed with metaldehyde as a bait for snails
- Grain to be used as seed which has been treated with a mercury-based fungistatic agent.

Additional poisonous substances are bird repellants, grain fumigants, and fungistatic agents.

Bird repellants

Baits of corn or wheat are mixed with various substances and spread over areas to protect them from damage by bird droppings or to avoid damage to aircraft. One of these bird repellants, 4-aminopyridine, has caused poisoning in **horses**. Clinical signs include signs of fright, profuse sweating, severe convulsions, fluttering of the third eyelid, and death 2 hours after the onset of signs and 6–8 hours after ingesting the material.

In **cattle** signs include anorexia, frequent passage of small amounts of feces, and tenesmus, with some animals also showing tremor, ataxia, erratic behavior, especially walking backwards, and some sudden deaths.

Grain fumigants

Grain treated by the fumigant dibromoethane is associated with mortality in sheep. The principal lesions are pulmonary edema, septal fibrosis, alveolar epithelialization, and pleural effusion. Death occurs 48–120 hours after exposure. Methyl bromide, described under soil fumigants, is also used for stored grain.

Fungistatic agents

Hexachlorobenzene (HCB) is widely known because of its indestructibility and capacity to pass from grain through cattle and into humans. Legislation against chlorinated hydrocarbons being found in the human food chain is very harsh and hexachlorobenzene is a prime target for public health veterinarians. Its specific toxicity is not high, although experimental poisoning in pigs is associated with hepatic injury.

ADDITIVES IN FEEDS

Many antibiotics, fungistatics, vermicides, estrogens, arsenicals, urea, iodinated casein, and copper salts are added to prepared feed mixes to improve food utilization and hasten growth. Many of them are toxic if improperly used. Miscellaneous agents include amprolium, an antithiamine coccidiostat which is associated with polioencephalomalacia in ruminants, and iodinated casein, used experimentally at one time to stimulate milk production in cows but which is associated with cardiac irregularity, dyspnea, restlessness and diarrhea in hot weather. Toxic additives listed elsewhere in this book are arsanilic acid and copper compounds.

ESTROGENIC SUBSTANCES

ETIOLOGY

Poisoning by estrogenic substances occurs in the following circumstances:

- Natural substances in plants and as zearalenone in fungi
- Dietary supplements to fattening cattle
- Overdosage of clinical infertility cases
- Pigs fed hexestrol implants in capon necks
- Pasture contaminated by manure from cattle treated orally especially or by subcutaneous implants with estrogenic substances and which pass significant amounts in the feces. Ensilage made from the pasture may also be contaminated
- Cattle fed on chicken litter from farms where estrogens are used as supplements
- Steers implanted with an estrogen at a standard dose rate may respond in an exaggerated manner and show signs of toxicity. Estradiol implants are reputed to be associated with more such problems than zeranol.

EPIDEMIOLOGY

Estrogenic substance administration as a managemental tool is regarded unfavorably in many countries, because of the risk of intoxication occurring in humans eating contaminated meat. Their use is banned in some and strictly controlled in others. The supplementation may be by addition to the feed, but more commonly is by subcutaneous implants.

PATHOGENESIS

Signs and lesions are the direct result of amplification of the pharmacological effects of the substances.

CLINICAL SIGNS

Male estrogenism. Steers in feedlots include **excessive mounting** by other steers, sometimes to the point of causing death, head injuries are caused by **head-to-head butting**, frequent bawling, leading of mobs, pawing the ground to the point of **hole-digging**. These problems tend to pass off after a short time. **Preputial prolapse** can be a problem in *Bos indicus* cattle. Experimental feeding of zeranol to young bulls is associated with retardation of testicular and epididymal development.[1]

Urethral obstruction. Heavy mortalities have occurred in feeder lambs after the use of implants of estrogens as a result of prolapse of the rectum, vagina, and uterus, together with urethral obstruction by calculi. The calculi consist largely of desquamated epithelial and pus cells which form a nidus for the deposition of mineral, the desquamation probably being stimulated by the estrogen. Also urethral narrowing caused by the estrogen facilitates complete obstruction by the calculi.

Pig estrogenism. The clinical signs include straining, prolapse of the rectum, incontinence of urine, anuria, and death. At necropsy there is inflammation and necrosis of the rectal wall, enlargement of the kidneys, thickening of the ureters and distension of the bladder, and gross enlargement of the prostate and seminal vesicles. Estrogens such as zearalenone ingested by sows after day 11–13 of the estrus cycle can be associated with retention of corpora lutea and a syndrome of anestrus or pseudopregnancy that typically persists for 45–60 days post estrus. This effect may occur at zearalenone concentrations of 3–10 ppm in the diet. Pregnant sows given zearalenone post breeding may have failure of implantation and early fetal abortion.

Nymphomania in cows. Larger doses of stilbestrol, usually administered accidentally to cows, may be associated with prolapse of the rectum and vagina and **raising of the tail head** due to relaxation of the pelvic ligaments. Susceptibility to fracture of the pelvic bones and dislocation of the hip are common sequels. Nymphomaniac behavior in such animals invites other skeletal injury, especially fracture of the wing of the ilium.

Idiopathic female estrogenism. Besides the toxic effects associated with estrogens in specific plants, increased estrogenic activity is also encountered in mixed pasture, often only at certain times and on particular fields. Clinically the effects are those of sterility, some abortions, swelling of the udder and vulva in pregnant animals and in virgin heifers, and endometritis with a slimy, purulent vaginal discharge in some animals. Estrus cycles are irregular. In milking cows there is depression of the milk yield, reduction in appetite, and an increase in the cell count of the milk.

CLINICAL PATHOLOGY

High blood levels of estrogens are characteristic. In swine, the syndrome of anestrus associated with zearalenone, will be accompanied by elevated progesterone concentrations due the retention of corpora lutea.

NECROPSY FINDINGS

Enlargement and vascular engorgement of accessory sex organs, especially in neutered animals, are characteristic. Uterine

enlargement and keratinization of vaginal epithelium may be detected, and in mature female swine there may be persistent multiple retained corpora lutea.

DIFFERENTIAL DIAGNOSIS

The clinical profile is almost diagnostic, a search of the environment usually reveals a source of estrogen and estrogen assay on blood provides diagnostic confirmation.

Differential diagnosis list:
- Acute, especially traumatic, vaginitis
- Urethal obstruction in males
- Cantharidin poisoning.

UREA

ETIOLOGY

Urea is a common form of non-protein nitrogen (NPN) used in ruminant rations and as a fertilizer. Accidental access to the powder or liquid form of the compound can cause heavy mortalities. Poisoning occurs when cattle or sheep accidentally gain access to large quantities of urea, or are fed large quantities when they are unaccustomed to it, or when feeds are improperly mixed, or the water supply is polluted. Feed grade urea contains approximately 45% nitrogen and protein is approximately 16% nitrogen, and each gram of urea is equivalent to 2.81 g of protein. Thus, a ration containing 1% urea supplies the protein equivalent of 2.81% natural protein. Some care is required in bringing the animals onto urea gradually and an adequate proportion of carbohydrate must be included in the ration.

EPIDEMIOLOGY

Urea is used in agriculture as a feed additive for ruminants to provide a cheap protein substitute in the diet, and as a fertilizer on crop and pasture fields. Protein production from urea is dependent on rumen microorganisms assimilating the ammonia released from urea and converting it to bacterial protein useful to the animal. Natural urease in the rumen supports the hydrolysis of urea to release ammonia. The degree of toxicity of urea depends on the rapidity with which ammonia is released from the urea in the rumen, and this may be increased if soybean meal is being fed; soybeans contain urease which facilitates the breakdown of urea to ammonia. Ruminants are better able to assimilate ammonia into protein when adequate amounts of readily available carbohydrates are provided. This is usually from grain or a sugar source such as molasses. In the absence of sufficient digestible carbohydrate, as when only roughages are fed, urea is more toxic. At one time mixtures of molasses and urea were popular as feed supplements for cattle and are associated with outbreaks of poisoning with signs similar to those of urea poisoning and those associated with feeding ammoniated hay.

Toxic dose levels

In cattle which have been starved beforehand dose levels up to 0.33 g/kg BW is associated with increases in blood levels of ammonia and dose levels of 0.44 g/kg BW produce signs of poisoning within 10 minutes of dosing and dose rates of 1–1.5 g/kg BW are associated with death.

Tolerance to urea

Animals unaccustomed to urea may show clinical illness when fed 20 g/50kg BW, but by gradually increasing the quantity fed this amount can be tolerated. This tolerance is lost rapidly and animals which receive no urea for 3 days are again susceptible. Tolerance is also reduced by starvation, by lack of readily available dietary carbohydrate and by a low protein diet. **SHEEP** can eat 6% of their total ration as urea provided it is well mixed with roughage and fed throughout the day, preferably by spraying the urea mixed with molasses onto the roughage. Much more urea is tolerated if given to sheep in molasses (18 g), than if given as a drench (8 g) and prior feeding on lucerne further increases the tolerance and fasting for 24 hours reduces it. A dose rate of 1 g/kg BW to sheep appears to be non-toxic, but 2 g/kg is quickly fatal. In general, urea should not constitute more than 3% of the concentrate ration of ruminants.

Horses appear to be tolerant to relatively large doses of urea but the disease has been produced experimentally in ponies by administering 450 g by stomach tube. The clinical picture is similar to that in cattle, being largely related to the central nervous system. There is a sharp increase in blood ammonia levels after ingestion of the urea, and it is assumed that hydrolysis of the urea occurs in the cecum.

Pigs are quite unaffected by very large doses of urea unless they are deprived of water or have developed a cecal flora which produces urease.

PATHOGENESIS

The toxic effects are due to the sudden production of large quantities of ammonia and its rapid absorption from the rumen results in the onset of signs in 10–30 minutes after feeding. The severity of signs is related to blood ammonia levels and not to levels of ammonia in the rumen. However, the alkaline conditions in the rumen created by rapid release of ammonia can be associated with more of the ammonia to be present in a non-ionized fonn which favors rapid absorption from the rumen with resultant increase in blood ammonia concentration. Excess blood ammonia is toxic to intermediary metabolism and results in systemic lactic acidosis and elevated blood potassium, which can lead to hyperkalemic heart failure.

CLINICAL SIGNS

Cattle and sheep. Signs of toxicity commence as early as 10 minutes after the urea is eaten and include severe abdominal pain, frothing at the mouth and nose, hypersensitivity to sound and movement to the point of being aggressive, muscle tremor, incoordination, weakness, dyspnea, bloat, and violent struggling and bellowing. In severe cases the course is short and death occurs sometimes in a few minutes but usually in about 4 hours after ingestion. Less severe cases are drowsy and recumbent. The case fatality rate in affected animals is high.

CLINICAL PATHOLOGY

Cattle. Signs are visible when rumen ingesta levels of ammonia are 1000 mg/L, serum levels of ammonia nitrogen (NH_3-N) are 10–13 mmol/L (10–18 mg/L)[2] and when blood ammonia nitrogen concentrations reach 0.7–0.8 mg/dL.

Sheep deaths occur at levels of ammonia nitrogen of 33 µg/mL of blood; the ruminal contents are alkaline when tested with litmus paper (pH elevated from 6.94 to 7.90) and ruminal ammonia levels rise from 6 to 50 mg/dL.

NECROPSY FINDINGS

There are no characteristic lesions at necropsy, but most cases show generalized congestion, hemorrhages, and pulmonary edema. Death is thought to result from respiratory arrest due to ammonia intoxication.

Pigs. Encephalomalacia has been produced by feeding a ration containing 15% urea. The clinical picture and histopathological findings were similar to those of salt poisoning except that no eosinophilic aggregations are present in the cerebral lesions.

DIFFERENTIAL DIAGNOSIS

Outbreaks of this poisoning are usually closely linked to known exposure to urea and achieve **diagnostic confirmation** by assay of high blood levels of ammonia.

Without the historical link to a source of urea the **differential list** is very long because of the similarity of the syndrome to other diseases in which nervous excitation is accompanied by muscle tremor, dyspnea, convulsions, and a high case fatality rate.

Differential diagnosis list:
- Acute hepatic insufficiency
- Anaphylaxis

- Poisoning by *Clavibacter toxicus*
- Acute poisoning by cyanobacteria
- Hypomagnesemia
- Acute salt poisoning
- Acute bovine pulmonary emphysema and edema
- Acute organochlorine insecticide poisoning
- Acute 4-Methylimidazole poisoning from ammoniated forages (bovine bonkers syndrome)
- Any of the many forms of encephalitis or encephalomalacia.

TREATMENT

No primary treatment is likely to be effective but the oral administration of a weak acid such as vinegar (0.5–1 L to a sheep, 4 L to a cow), or 5% acetic acid is recommended. Cold water (10–30 L for adult cattle) will dilute excess urea and temporarily lower rumen pH. This may reduce the amount of ammonia absorbed[3] but it must be administered as soon as the first clinical signs appear and repeated dosings may be necessary as clinical signs tend to recur about 30 minutes after treatment. The only really effective treatment is prompt and efficient emptying of the rumen, either via a large bore stomach tube or by rumenotomy, but the results are indifferent because the damage has usually been done already.

CONTROL

Urea is highly toxic and care is essential when handling it in the vicinity of animals. Feed manufacturers' recommendations about maximum concentration of urea in prepared rations and acclimatization to the diet with inclusion of adequate readily available carbohydrates should be adhered to.

Propylene glycol poisoning

Propylene glycol is an unlikely poison but it is used extensively as an oral treatment for acetonemia in cattle and can be associated with poisoning if it is accidentally administered to horses, usually in mistake for mineral oil. Dose rates of 3 L to horses of 500 kg BW by stomach tube is associated with an immediate but short duration episode of abdominal pain, sweating, salivation, severe ataxia and depression, and a fetid odor of the feces.[4] Much larger doses (8 L) can be fatal. Moderate-to-severe inflammation of the lining of the gut and edema of the brain are noticeable at necropsy examination.

Dried poultry wastes

Feeding dried poultry wastes to ruminants provides them with a source of nitrogen, and gets rid of the chicken farmer's disposal problem. Deleterious effects include:

- Copper poisoning when the chickens are fed on diets supplemented with copper
- Estrogen poisoning when the chickens are fed on estrogen-supplemented diets
- An unidentified problem arises of hepatic necrosis, hypoalbuminemia, and ascites in lambs fed large amounts of poultry waste from hen batteries
- Litter from broiler houses is associated with renal damage but not to the point of causing mortality
- Botulism.

Brewer's residues

Diseases associated with the feeding of by-products of brewing and distilling include:

- Carbohydrate engorgement in cattle fed wet brewer's grains
- Possibly spinal cord degeneration in adult cattle fed sorghum beer residues contaminated by *Aspergillus flavus* and containing aflatoxin
- Excess sulfur (>0.45% in the diet) from some methods of processing which can lead to polioencephalomalacia.

Chemically treated natural feeds

Formalin-treated grain

This is a special diet fed to dairy cows to produce dairy products containing an increased proportion of polyunsaturated fats for special human diets. Fats in the grain are protected against hydrogenation in the rumen by coating the grains with formalin. If the formalin and the grain are not properly mixed, the free formalin left as a residue is associated with rumenitis and severe diarrhea.

Caustic-treated grain

Grain treated with caustic to improve its digestibility is recorded as causing focal interstitial nephritis, rumenitis, and abomasal ulceration in feedlot steers. The lesions have been produced experimentally. They may not be detected until the animals are slaughtered.

Ammoniated forage

Anhydrous ammonia is added to hay to improve its digestibility and nitrogen content. Environmental risk factors enhancing the production are low dry matter content of the feed, high environmental temperature, and high concentrations of ammonia in the treatment mixture. If the forage is high quality and has a high carbohydrate content it may undergo chemical change, possibly with the formation of a substituted imidazole, 4-methylimidazole (MeI) which is associated with hysteria (bovine bonkers) in the cattle eating it. Calves sucking cows fed ammoniated hay may also be affected by this same syndrome. Experimental feeding with MeI produces the same syndrome but it is not the sole cause; other substances are also involved.[5]

Clinical signs include hyperexcitability, hyperesthesia, restlessness, rapid blinking, pupillary dilatation, ear-flicking, frequent urination and defecation, dyspnea, frothing at the mouth, bellowing, charging, circling, and convulsions. Tremor, commencing at the head and opisthotonos are obvious early signs. Between convulsions affected sheep walk in circles and have a stiff gait. Nursing calves may show signs even though their dams are unaffected. No clinicopathological abnormalities occur, blood ammonia levels are normal, and no specific necropsy lesions have been identified.

Treatment consists of sedation but many patients do not respond to agents such as acepromazine. Dilution of toxic forage with normal feed is not recommended because the toxin may be cumulative. The maximum rate of ammoniation to avoid toxicity, for poor forage is 3% and 1% for high-moisture forage.[6]

Newsprint

Newsprint is fed commercially to ruminants as an alternative roughage. Toxicological hazards of the material in sheep fed colored magazines for 6 months and comprising 23% of their ration included a significant deposition of lead in tissues and an increase in enzyme activity in liver, but there were no clinical signs and no histopathological lesions. Feeding for periods of several weeks has no detectable clinicopathological effects and there is evidence that the known toxins are not secreted in cows' milk.[7]

Sewage sludge

Urban sewage sludge is used as top-dressing for pasture and may be associated with the spread of infectious disease as well as goiter. Sewage sludge may also be fed directly to animals, but may lead to dissemination of lead, cadmium, and polybrominated and polychlorinated biphenyls to animals and the food products derived from them. Potential damage due to illness or contamination of animal-produced feed can be minimized by leaving treated pasture exposed to weather for a period of several weeks before allowing animals access to it.

IONOPHORE POISONING

Synopsis

Etiology Carboxylic ionophores used commercially as coccidiostats and growth promotants are associated with poisoning if dose rate is excessive; horses are very susceptible.

Epidemiology Mixing errors; left-over cow feed fed to horses.
Pathogenesis Muscle damage leading to acute heart failure or limb weakness and paralysis.
Clinical signs Sudden death, paralysis, red urine or a less acute syndrome of skeletal muscle weakness, paresis, and paralysis.
Clinical pathology Myoglobinuria, elevated levels of CPK. Ionophore found in ingesta.
Necropsy lesions Myocardopathy plus skeletal myopathy. Lesions may only be apparent by microscopic examination
Diagnostic confirmation Assay of stomach contents and representative feed samples for the ionophore.
Treatment No primary treatment recommended. Supportive treatment is oral charcoal or mineral oil.

ETIOLOGY

Monensin, lasalocid, maduramicin, narasin, and salinomycin are carboxylic ionophores used as polyether antibiotics for the control of coccidiosis in poultry and with a secondary role as growth promotants in ruminants. Monensin has minor additional uses in the treatment of acetonemia, lactic acidosis, bloat and atypical interstitial pneumonia. Used properly the compounds are effective in both roles but the margin of safety is small and careless use has been associated with major losses. All of the compounds are cationic agents, causing altered balance of cations (especially Ca^{2+}, Na^{+} and K^{+}) in cells and organelles. Pharmacological effects of ionophores are similar, but they differ chemically and have differing toxicities.

The recommended doses of monensin vary depending on the age and size of the livestock and the purpose for which it is administered and the manufacturer's recommendations should be adhered to strictly. Approximate recommended levels, orally and usually in the feed, are: cattle, 50–200 mg per head per day, 16.5–33 ppm; sheep 5–10 ppm in feed.

For monensin, dosage levels at which clinical signs of poisoning can be expected to occur are: cattle 10, sheep 4, pig 7.5, and horse 1 mg/kg BW. Deaths in cattle are likely to commence at intakes of 10 mg/kg BW and in horses at 2–3 mg/kg. Toxic feed concentrations for pigs are 200–220 mg/kg of feed. Comparative LD_{50} in mg/kg BW are: cattle 26.4[12] horse 2–3, sheep 12, pig 16–50, and goat 24. It is common for cattle to be poisoned with more than 10 times the recommended dose. The LD_{50} for salinomycin for the horse is 0.6 mg/kg BW. The effects of the compounds are cumulative and may not be observed for some weeks after administration is discontinued.

EPIDEMIOLOGY

Occurrence

All animal species are affected, including zoo ruminants.[8] Poisoning incidents are most often reported in countries where animal husbandry is intensive and high levels of stall feeding are practiced.

Source of toxin

The poisonous properties of the agent are well known and poisoning is usually accidental due to failure to dilute a concentrate, poor mixing or because of wrong identification of containers. Also some liquid preparations settle out and need to be constantly mixed before and during mixing with a batch of feed. Cattle carrying reticular retention boluses of monensin to control bloat by delivering accurate daily doses of the drug, may die suddenly of acute heart failure due to myocardiopathy, a condition likely to be associated with the monensin but by an unknown mechanism.[9] The compound's main use as a coccidiostat is in poultry, and deaths from congestive heart failure have occurred in cattle and sheep fed dried poultry litter from farms feeding salinomycin or maduramicin.[10]

Risk factors

These compounds are specifically prohibited for use in horses at any time because of their toxicity for that species. Concurrent administration of monensin or salinomycin and tiamulin or chloramphenicol or triacetyloleandomycin at safe doses can be associated with ionophore poisoning in pigs. Outbreaks may occur when tiamulin is introduced into the pigs' drug regimen to control swine dysentery when the pigs' ration already includes the ionophore as a growth promotant, or when the two drugs are combined as a coccidia prevention package. The dose and time relationships are complicated and are dealt with separately. The concurrent administration of monensin and selenium to lambs also enhances the toxicity of the selenium.[11]

PATHOGENESIS

The principal pathogenesis of monensin poisoning is damage to muscles. The origin of muscle damage appears due to loss of ion control and balance in cells and mitochondria leading to impaired intermediary metabolism.[12] In cattle, the cardiac and skeletal muscles are affected about equally; in sheep and pigs the skeletal muscle is most seriously affected; in horses the myocardium is the focus of the damage. In the latter case acute or congestive heart failure may result, signs often being delayed for weeks until additional stress, such as late pregnancy or parturition, precipitates cardiac insufficiency. When the damage is principally to skeletal muscle the syndrome is one of weakness, ataxia, and recumbency; myoglobinuria is a common accompaniment.

Besides these major involvements of monensin and lasolocid there are a number of less well-known ones. There is a risk that cattle fed on a nitrogen-rich diet will be likely to suffer an outbreak of nitrite poisoning if they are also fed monensin. Another undesirable outcome may be a fall in butterfat because of shift from acetate to propionate production in the rumen. Continuous feeding of monensin to male pigs (50 ppm for 52 days) reduces blood levels of testosterone, and is associated with dystrophy of seminiferous tubules and reduced sperm counts.

CLINICAL SIGNS

In cattle signs commence within 24 hours with heavy doses but may be delayed for up to 5 days when the intake is lower. Signs commence with feed refusal followed by diarrhea, tremor, weakness, tachycardia, and ruminal atony, and animals may die at this stage from acute heart failure. Those that survive for a day or two develop congestive heart failure manifested by brisket edema, engorgement of the jugular veins, ascites, fluid feces, dyspnea, and tachycardia. Deaths may occur months after the major outbreak, usually due to the exertion of calving. When smaller doses are taken over a long period the syndrome is one of congestive heart failure in all of the cases.[13]

In sheep the syndrome may be acute followed by hyperesthesia, tremor, especially of the head, disappearance of the pupillary light reflex, recumbency, and convulsions with death occurring during a convulsion.[14] More commonly the disease commences with feed refusal, diarrhea, rumen stasis and depression, followed by muscle weakness, a stilled gait, and recumbency. Chronic cases show atrophy of the muscles of the hindquarters and a stiff gait.

In pigs monensin poisoning is associated with dyspnea, anorexia, ataxia, paresis, myoglobinuria and cyanosis, diarrhea, tympany, and pruritus. Death follows in about 6 hours. Salinomycin is associated with the same general syndrome but includes also unwillingness to stand and, when forced to stand, tremor, especially in the hindlimbs, swaying, fetlock knuckling, and abrupt lying down. Exercise exacerbates the signs. Respiratory distress is in the form of irregular breathing. Feed intake is down 50% and sham drinking is characteristic. Red urine is evident for up to 5 days after the drug is discontinued.[15]

In horses cardiac and skeletal muscle are affected. In most cases it is the myocardium that creates the prominent syndrome. Horses affected by the cardiac disease may be found dead. In others there is restlessness, respiratory distress, diarrhea, mucosal congestion, profuse sweating, sometimes myoglobinuria, cardiac irregularity, and tachycardia (50–60/min). The course of the cardiac disease is short and affected horses may not show much clinical evidence of heart failure at the time of the poisoning but survivors, and survivors of an acute attack, may develop a poor performance syndrome or congestive heart failure up to several months later.[16]

Horses with skeletal muscle involvement have a syndrome including anorexia, fever, and red or dark urine, due to the extensive muscle breakdown, frequent lying down, difficulty in rising, stiff gait, especially the hindlimbs, and with knuckling of the fetlocks, followed by final recumbency after a period of as long as several months. Colic is also recorded during the acute phase but this may be the restlessness and frequent lying down and getting up of acute myositis. Euthanasia is the common outcome of these cases because of irreparable muscle damage.

CLINICAL PATHOLOGY

In all species tests show increases in serum levels of creatinine phosphokinase, lactate dehydrogenase and aspartate aminotransferase; myoglobinuria is frequent and often prolonged. However, results of clinical pathology tests may vary substantially among individual affected animals. Samples of feed and stomach contents, obtained by stomach tube, are desirable specimens for analysis. Some feeds fed to horses have contained as much as 125–250 g/tonne of feed and their stomach contents have contained 50–100 ppm.

NECROPSY FINDINGS

In cattle there is myocardiopathy, pulmonary edema, and enlargement of the liver and heart, hydropericardium, hydrothorax, and ascites. Gross lesions at necropsy are not always evident, and multiple samples of susceptible tissues should be collected and preserved in formalin for microscopic evaluation.

In sheep postmortem changes include necrosis in both skeletal and cardiac muscles but there are no lesions suggestive of heart failure. Lambs less than 1 month old show only gastrointestinal hemorrhage.

In horses necropsy lesions in acute cases include acute myocardial necrosis, pulmonary congestion, hepatic swelling, and in some cases pulmonary petechiation. Skeletal muscle necrosis may also be evident. Myoglobinuric nephrosis and myoglobinuria are secondary lesions. Chronic cases show marked cardiac myopathy, and possibly skeletal myopathy with obvious fibrosis.

Stomach contents are an obligatory sample in cases likely to go to litigation.

DIFFERENTIAL DIAGNOSIS

In all species syndromes of acute or congestive heart failure due to acute cardiac myopathy or limb paresis or recumbency due to skeletal myopathy are sufficiently common to necessitate a positive assay for one of the ionophores in the feed or stomach contents for **diagnostic confirmation.**

Differential diagnosis list:

Cattle:

- Nutritional deficiency of vitamin E or selenium
- Poisonings with such plants as *Karwinskia humboldtiana*, *Cassia occidentalis* and *Vicia villosa*.

In **pigs** additional diagnostic alternatives include:

- Gossypol poisoning
- Porcine stress syndrome.

In **horses** there are clinical similarities to:

- Colic
- Laminitis
- Rhabdomyolysis.

TREATMENT

There is no effective primary treatment and only supportive procedures are recommended. Selenium and vitamin E are ineffective after signs begin, although selenium or vitamin E given prior to appearance of clinical signs may be beneficial. Activated charcoal or mineral oil has been standard treatments aimed at removing the residue of the poison from the alimentary tract. They are of no value if the poison has already been absorbed; recovery is unlikely once the myocardium is affected.

CONTROL

Horses are very susceptible to poisoning by these antibiotics and great care is needed to insure cattle rations containing them are not left around for horses to eat. Pretreatment with vitamin E–selenium reduces the effects of monensin poisoning without completely preventing it.

MONENSIN-TIAMULIN OR SALINOMYCIN-TIAMULIN POISONING IN PIGS

The myotoxicity of monensin for pigs is enhanced by the simultaneous administration of the two antibiotics (monensin or salinomycin and tiamulin). All three of the substances are used as coccidiostats and it is not unusual for farmers to combine them. However, all of the agents use the same detoxication pathways in the liver with tiamulin having the priority. Tiamulin inhibits mitochondrial CYP3A enzymes that stimuate monensin metabolism, allowing accumulation of monensin.[17] Monensin (or salinomycin) accumulates to the point of being toxic. The clinical syndrome consists of anorexia and weight loss and at necropsy there are lesions of myonecrosis in the tongue, diaphragm, and limbs. A similar toxicological situation arises in pigs with simultaneous dosing with tiamulin and salinomycin in which the toxic interaction is dose-related.

When tiamulin is used at therapeutic levels, in feed, water, or by injection and salinomycin is used at 60 ppm, toxic reactions and some deaths occur. The interaction does not occur when the two antibiotics are used concurrently and the tiamulin is used at the recommended prophylactic (30–40 ppm) or growth promotant (11 ppm) levels, and independently of whether the administration is oral or by injection,[18] but only if a gap of 72 hours has elapsed between the last exposure to salinomycin and the first exposure to therapeutic levels of tiamulin and *vice versa*.

Pluronics poisoning

These substances are administered to adult cattle in their feed as prevention against bloat. They are unpalatable and unlikely to be consumed in dangerous amounts unless they are well masked in feed. When they are fed accidentally to calves in their milk they are associated with dyspnea, ruminal tympany, bellowing, protrusion of the tongue, nystagmus, opisthotonos, recumbency, and convulsions. Death after 24 hours is the usual outcome.

Carbadox poisoning

Carbadox, Mecadox or Fortigro – methyl 3-(2-quinoxalinylmethylene)carbazate-N^1 – is used in pig feeds as a growth promotant and in the treatment of swine dysentery and other enteric diseases at the recommended rate of 50 mg/kg of feed/head per day. Toxic effects occur at rates of 150 mg/kg. A related compound **olaquindox** is similarly toxic. Affected pigs refuse the ration, but will eat other rations, are gaunt and emaciated, pass hard fecal pellets, and have a long rough coat, pale skin, severe tachycardia, weak hindquarters, and a swaying walk, followed by knuckling of the hind fetlocks, posterior paralysis, and death in 8–9 days. In the early stages the pigs screech frequently. Sows are agalactic, and produce stillborn or weak, undersized piglets.

Necropsy lesions are diagnostic, with extensive damage to the zona glomerulosa of the adrenal gland accompanied by renal tubular necrosis. The resulting hypoaldosteronism is manifested by low serum sodium levels, elevated serum potassium (8 mmol/L) and elevated blood urea nitrogen levels. The condition is irreversible and the outcome is severe disability or death.[19]

Bronopol poisoning

Bronopol – 2 bromo-2-nitropropoane-1, 3-diol – is used as a laboratory preservative for milk, e.g. in milk samples used for butterfat estimation. This milk is usually fed to calves or pigs and may be toxic on occasional feedings. Affected calves salivate, are depressed, collapse and die within 24 hours of feeding. Necropsy lesions include severe necrotizing abomasitis and local peritonitis on the serosal surface of the abomasum.[20]

MISCELLANEOUS FARM CHEMICALS

Polybrominated biphenyls

Mixtures of polybrominated biphenyls find a great deal of use in industry, particularly as flame retardants. They are not especially poisonous, nor are they a greater risk to farm animals because of degree of exposure, than many other industrial chemicals, but they happen to have found their way into the cattle food chain in much discussed incidents in the USA.

Cattle. Experimental dosing with 67 mg/kg BW daily for long periods is associated with poisoning but levels of 10 mg/kg BW are not toxic. Clinical signs of illness are anorexia, diarrhea, lacrimation, salivation, emaciation, dehydration, depression, and abortion. Similar signs plus extensive cutaneous hyperkeratosis occur in natural cases. Necropsy lesions include mucoid enteritis, degenerative renal lesions in natural and experimental cases, hyperkeratosis in the glands, and epithelium of the eyelids.

Pigs. Experimental poisoning in pigs causes no ill-effects in sows, but high concentrations of polybrominated biphenyls (PBB) develop in the sow's milk with death of some nursing pigs resulting.

Most of the losses due to these compounds are due to destruction of animals because they are contaminated and there is fear of adverse effects on humans who consume them or their products. However, neither animals nor humans exposed to the biphenyls showed any signs of illness. PBBs pass the placenta and are found in fetuses but appear to be associated with no health problems in the offspring.

The excretion of these compounds occurs principally in feces and urine but as much as 25% of ingested substance may be present in the milk. Also these compounds are lipotrophic and accumulate in fat depots, especially in the liver. Attempts to hasten excretion have not produced a satisfactory method. Grazing wool sheep on contaminated ground may be an option for utilization of contaminated land.[1]

REFERENCE

1. Gill IJ et al. Aust Vet J 1992; 69:155.

Polychlorinated biphenyls

These substances have a number of industrial uses and are common environmental contaminants. They are lipophilic so that they accumulate in body fat, and have low rates of biotransformation and excretion so that they persist in animal tissues for long periods. Although deleterious effects of the compounds in animal tissues are not often recorded, their presence in animal tissues is likely to cause rejection of meat from the human food chain. Recorded damage refers to unidentified reproductive inefficiency and reduction in efficiency of food conversion and possibly hepatic hypertrophy and gastric erosion, but in the same species a positive growth stimulating effect has also been recorded. Experimental poisoning of gnotobiotic pigs has been associated with diarrhea, erythema of the nose and anus, distension of the abdomen, growth retardation and, at doses of more than 25 mg/kg BW, coma and death.

Soil fumigant: methyl bromide

Soil fumigants used to prepare fields for planting may be associated with toxicity hazards in animals grazing them or in feed harvested from them. Methyl bromide has been associated with poisoning in horses, cattle, and goats when used in this way. Clinical signs in horses, cattle, and goats include ataxia, stumbling, and somnolence.

Formalin

Formalin is used to preserve colostrum for calf feeding, and in the preparation of formalin-treated grain. Milk containing too much formalin is associated with severe gastroenteritis and some deaths in calves that drink it. The clinical signs include salivation, abdominal pain, diarrhea, and recumbency.

Oil- and petroleum-product poisoning

Crude oil or petroleum distillates, including diesel oil, lamp oil, kerosene, and gasoline, are all poisonous to animals. Cattle will drink all of them and appear to have a positive liking for some products, especially used sump oil and liquid paraffin (mineral oil).

Oil-well installations

Crude oil coming directly from wells is usually repellent to animals, but they can consume lethal quantities of it if they are salt-deficient and salt-hungry: a characteristic of crude oil is that it is usually mixed with salty water which is often left lying in ponds nearby. After extraction most crude oils are temporarily stored in installations where lead paint is available so that salt and lead poisoning commonly occur with oil poisoning and may be confused with it.

OIL PRODUCTS

ETIOLOGY

The toxicity of the various products varies:

- Of natural crude oils those with the highest content of sulfur ('**sour**

crude') are most unpalatable and most toxic
- Amongst the commercial oil products those with the highest content of volatile and inflammable components, especially naphtha and petrol (gasoline) fractions, are the most toxic
- **Gasoline** up to the level of 3 ppm in the drinking water does not appear to depress water intake or to interfere with growth performance of pigs
- With commercial gasoline and oily lubricants the additives used, especially lead, may also contribute significantly to the poisoning
- Other toxic agents of all kinds can be encountered when reject sludge oil is available to animals.

Accurate dose levels are difficult to determine in field outbreaks. In experimental trials crude oil at the rate of 37 mL/kg BW in a single dose or 123 mL/kg in 5 divided daily doses were poisonous to cattle. Kerosene at 20 mL/kg BW as a single dose and 62 mL/kg BW in 5 equal daily doses was poisonous. Tractor paraffin (kerosene) at a single dose rate of 13 mL/kg BW is associated with severe illness and at 21 mL/kg was fatal to cattle.

EPIDEMIOLOGY

On farms access to **tractor fuel** (paraffin, gasoline, kerosene) is the most likely hazard. When highly chlorinated naphthalenes were used as lubricants, access to oil dumps could lead to hyperkeratosis. **Kerosene** has an unwarranted reputation as a therapeutic agent for bloat and constipation, but it is unlikely to be given in amounts sufficient to be associated with more than slight illness, unless it is given repeatedly.

The common occurrence of natural cases is in cattle, but sheep and goats can also be affected.

PATHOGENESIS

The early signs are thought to be due to regurgitation of the oil, aspiration of it causing pneumonia, and absorption of the volatile components through the pulmonary mucosa causing toxemia. The later signs are thought to be associated with the direct effect of the oil on the alimentary tract.

CLINICAL FINDINGS

Natural cases. When large volumes of crude oil are consumed by cattle and goats, there are signs of toxemia and incoordination; regurgitation (vomiting) may or may not occur; death is quick. Bloating is inconstant. In the terminal stages the pupils are dilated and tachycardia, hyperpnea, and hyperthermia are evident. The animals smell of oil, and oil is often present on the skin around the mouth and anus, and in the feces. The feces vary from constipation to diarrhea. Recovered animals usually do so poorly after the incident that they are slaughtered after a history as long as 6 months. The oil persists in the alimentary tract for very long periods and may be found in the cud and feces, and at postmortem as long as 16 days after ingestion. Animals that survive the acute toxic syndrome eat poorly, lose weight and die at variable periods from 16 to 36 days later. Oil appears at the anus on about the 8th day after administration. It may also appear in the nasal discharge, reaching there via the lungs. The vomitus always contains the oil. The feces are usually oily, often soft to semifluid, and frequently black if the oil taken has been crude oil. With kerosene the feces are often dry and firm in the later stages and the regurgitus may be in the form of gelatin-like cuds, smelling strongly of kerosene.

Experimental cases. Early signs include incoordination, shivering, head-shaking, and mental confusion. Within 24 hours anorexia, vomiting, and moderate-to-severe bloating occur. Experimental kerosene inhalation is associated with persistent severe intrapulmonary physiological shunting resulting in prolonged hypoxemia and acidemia and may account for the clinical disease in survivors.

CLINICAL PATHOLOGY

There are no specific clinicopathological findings but hypoglycemia, acetonemia and transient hypomagnesemia are all recorded.

NECROPSY FINDINGS

In crude oil or kerosene poisoning aspiration pneumonia is recorded constantly in naturally occurring and experimentally produced cases. It is thought to be the result of vomiting and aspiration from the alimentary tract of already swallowed oil. In longstanding cases of kerosene poisoning in cattle the lungs are colored gray-blue and are enlarged and firm but there are no significant histopathological changes, neither are there in the kidney or liver. Oil is always still present in the alimentary tract and there may be thickening and inflammation of the alimentary mucosa. Degenerative changes in liver and kidney are recorded in some cases.

DIFFERENTIAL DIAGNOSIS

The clinical syndrome of aspiration pneumonia, bloat, regurgitation, and obvious fouling with oil or kerosene in an environment where access is permitted to the oil products provides **diagnostic confirmation.**

Differential diagnosis list:
- Aspiration pneumonia due to other causes
- Misguided owner medication with kerosene.

TREATMENT

No **primary treatment** is undertaken. **Supportive treatment** if the animal survives the initial acute phase should include the replacement of the ruminal contents with material from a normal rumen.

Tin poisoning

Dibutyltin dilaurate is a coccidiostat fed to chickens in their feed. Errors in mixing may lead to cattle receiving toxic amounts in concentrates or pellets. Calves usually die acutely with signs of tremors, convulsions, weakness, and diarrhea. Older animals usually suffer a chronic illness characterized by persistent diarrhea, severe weight loss, inappetence, polyuria, and depression, reminiscent of arsenic poisoning. Affected animals may not be suitable for human consumption because of the high content of tin in their tissues.

Sodium fluorosilicate

A white, odorless, and tasteless powder used as a poison in baits for crickets, grasshoppers, and the like. Because of the way it is prepared in pellets in a bran base it is attractive to all animal species and poisoning is recorded in cattle, sheep, and horses, usually because unused baits were not retrieved after baiting programs.

In sheep mild illness occurs after doses of 25–50 mg/kg BW and death after 200 mg/kg. Clinical signs include drowsiness, anorexia, constipation, ruminal stasis, teeth grinding, abdominal pain, and diarrhea.

Highly chlorinated naphthalenes

The naphthalenes were extensively used in industry as lubricants, insulants, and wood-preserving agents. Recognition of their toxicity resulted in their exclusion from the farm environment and virtual elimination of the disease.

Local application or ingestion of highly chlorinated naphthalenes to cattle produces hyperkeratosis characterized by thickening and scaliness of the skin, emaciation, and eventual death. The pathogenesis of the skin lesions is due to interference with the conversion of carotene to vitamin A, causing hypovitaminosis-A. When poisoning results from accidental emission

from industrial plants there are additional signs due to ocular, nasal, and tracheobronchial irritation; infertility and abortion also occur.

Coal tar pitch poisoning

Pigs may be exposed to coal tar pitch and its toxic cresols when housed in pens with tarred walls or floors, which they nibble, or when they have access at pasture to fragments of 'clay pigeons' used as targets by gun clubs. Bitumen and asphalt appear to be non-toxic. Young pigs 6–20 weeks of age are most commonly affected.

Clinical findings include an acute illness of a few days or a chronic course of some weeks. In the **acute illness** there are non-specific signs of inappetence, rough coat, tucked-up abdomen, weakness, and depression. The **chronic illness** is characterized by anorexia, depression, weakness, anemia, and jaundice. A subclinical syndrome includes a reduction in growth rate of up to 20–30%, a severe reduction in hemoglobin concentration and erythrocyte count, and reduced vitamin A storage.

Necropsy findings include jaundice, ascites, and anemia but the characteristic finding is a red and yellow mottling of the hepatic surfaces, and histologically a hepatic lesion of severe centrilobular necrosis. Cresols can be detected in the ingesta and liver of affected pigs.

Methyl alcohol

Accidental ingestion of methyl alcohol by cattle is associated with vomiting, recumbency, death, and a high concentration of methyl alcohol in the ruminal contents. Methyl alcohol is used as antifreeze in gasoline engines for pumps working continuously on oilfields in cold regions. Accidental access to the pump enclosure may result in a poisoning incident.

Ethylene glycol

Accidental poisoning with antifreeze mixture containing ethylene glycol may occur in swine, goats, and calves. The pathogenesis of the disease is dependent upon the development of acidosis and oxalate nephrosis.

In pigs this is manifested by ascites, hydrothorax and hydropericardium, depression, weakness, and posterior paralysis.

In cattle there is dyspnea, incoordination, paraparesis, recumbency, and death. There is accompanying uremia and hypocalcemia. Calcium oxalate crystals are present in large numbers in the kidney and brain and there is a fatal nephrosis. The presence of the chemical in tissue can be detected by thin-layer chromatography. The toxic dose rates determined experimentally for cattle are 5–10 mL/kg BW in adults and 2 mL/kg in non-ruminant calves. The treatment recommended for companion animals, ethanol or preferably 4-methylpyrazole, should be worth trying.

Industrial organophosphates

Principal industrial uses of organophosphates are as fire-resistant hydraulic fluids, as lubricants, and as coolants. A number of compounds including tri-*o*-tolyl phosphate, tri-*o*-cresyl phosphate (TOCP), and triaryl phosphates (TAP) have come to veterinary notice as being associated with poisoning in animals. Triaryl phosphates contain a number of isomers as well as TOCP, e.g. *m*-cresol, *p*-cresol, *o*-cresol, all of them more poisonous than TOCP. They have also been associated with serious outbreaks of poisoning in humans when they accidentally contaminate food. Poisoning may occur by ingestion or cutaneous absorption.

Clinical signs of delayed neurotoxicity do not occur until several weeks after contact and comprise irreversible neurological signs of respiratory stertor, dyspnea, dysuria, knuckling, leg weakness, and posterior paralysis.

Necropsy lesions characteristically include neuronal degeneration in the spinal cord and peripheral nerves.

Diagnostic confirmation depends on evidence of exposure to the toxicant, signs referable to the nervous system lesions, and a positive assay for the toxicant in the animal's tissues.[1]

Superphosphate

This is the usual form in which phosphorus-rich fertilizers are applied to the soil and is therefore available to animals on most farms in most countries. It is not highly palatable but sheep will eat it when it is in pill form (small granular, resembling grain in texture and particle size). The fertilizer is also used to prepare 'superjuice' which is administered to cows as a phosphorus supplement. Higher than normal intakes of the fertilizer either by dosing or by pasture application will cause poisoning, due largely to the fluorine present.[1] Calcium pyrophosphate and calcium orthophosphate also contribute to the toxicosis causing proximal renal tubular nephrosis.[2] The LD_{50} of superphosphate for sheep is 100–300 mg/kg BW.

Clinical signs of poisoning include anorexia, thirst, diarrhea, weakness, ataxia, and death in about 48 hours.

MANURE-GAS POISONING AND RELATED CONFINEMENT EFFECTS

ETIOLOGY

Confinement housing of cattle and swine is accompanied by manure storage for varying periods of time, in large holding pits, usually under slatted floors. Oxygen is excluded from the storage so that anaerobic bacteria degrade the organic and inorganic constituents of manure yielding **hydrogen sulfide, ammonia, methane, and carbon dioxide** as major gases. When diluted with water to facilitate handling, liquid manure in storage separates by gravity. The solid wastes form sediment, the lightweight particles float to the top leaving a middle layer which is relatively fluid. Thorough remixing is necessary before pits are emptied to prevent the fluid fraction from flowing out and the solids remaining. The remixing or agitation results in the release of large quantities of toxic gases from the slurry.

Besides the well-established gaseous toxicants listed, certain other agents with detrimental inhalation risks are present in confinement operations, and have been best characterized for swine confinement operations. Total dust is a major contaminant in swine barns and may range for 2–7 mg/m^3. Particuates may adsorb gases and be part of the objectionable odors released and reaching neighbors near confinement operations. Respirable dusts may be 10% or more of the total dusts generated in swine barns. Such dust is contaminated with bacteria, fungi, endotoxins, and glucans.[1] Dusts are primarily composed of feed or fecal material. Both endotoxins and glucans have been suggested as potential contributors to swine respiratory disease as well as respiratory complications for workers in swine buildings. So far, however, high mortality and acute death losses in confinement operations are most commonly due to excessive concentrations of hydrogen sulfide and carbon dioxide, while subacute or chronic irritation and disease of the upper respiratory tract may also be contributed by elevated ammonia levels. Methane is explosive and may act as an asphyxiant, but is not implicated as a toxicant.

Additional factors that must be considered in a differential diagnosis include possible power loss during electrical storms or equipment failure; this results in the cessation of the artificial ventilation required to cool the building and exhaust carbon dioxide from the respiration of animals. In these situations, CO_2 levels build rapidly and environmental temperatures increase dramatically as well, especially when weather conditions are hot and humid. Acute loses from

hyperthermia or heat stroke may be mistaken for manure gas poisoning. This is important for veterinarians, as they may be called to establish a diagnosis that affects insurance claims for many thousands of dollars. Besides overheating and CO_2 accumulation, electrocution should be considered whenever there are large numbers of acute losses in a confinement building.

PATHOGENESIS

The exposure of humans, cattle, and swine to high concentrations (above 700 ppm of H_2S) of manure gases, particularly hydrogen sulfide, can be associated with peracute deaths in cattle and swine. Hydrogen sulfide is both an irritant as well as an acute toxicant. The inhalation of H_2S causes interaction with moist mucous membranes of the upper respiratory tract and lungs. Fatal or severe exposure often is associated with respiratory distress and pulmonary edema. Exposure to low concentrations of hydrogen sulfide over long periods is thought to be associated with reduced performance in cattle and swine. At high concentrations, from 500 to 1000 ppm, carotid body receptors are stimulated causing rapid breathing. As high concentrations continue or increase the respiratory center is depressed, animals become depressed and comatose, and die. High concentrations of H_2S depress olfactory sensors and the offensive rotten egg odor is no longer detected as a warning sign.

High concentrations of **ammonia** (100–200 ppm) combine with moisture in the air and at mucous membranes with the production of ammonia, which is associated with irritation to the conjunctiva and respiratory mucosa. An increased incidence of pneumonia and reduced daily weight gains in pigs are associated with exposure to a combination of ammonia at levels of 50–100 ppm and the presence of atmospheric dust in barns.

CLINICAL FINDINGS

In acute hydrogen sulfide poisoning the animals die suddenly. Affected animals may be found dead throughout a building in various postures of lateral or sternal recumbency. There may be little or no evidence of struggle or excitement, since high concentrations can be associated with nearly immediate respiratory paralysis. In acute ammonia poisoning the syndrome includes conjunctivitis, sneezing, and coughing for a few days but pigs will soon acclimatize after which no effects may be detectable. At very high ammonia concentrations (>500 ppm) there is pharyngeal and laryngeal irritiation, laryngospasm, and coughing. Concentrations above 2000 ppm can be associated with death within 30 minutes. Carbon dioxide overexposure first is associated with mild-to-moderate excitement followed by depression, weakness, coma, and death. Concentrations above 30% in air are serious and 40% CO_2 for more than a few minutes can cause death.

NECROPSY FINDINGS

In cattle which have died from acute hydrogen sulfide poisoning, lesions include pulmonary edema, extensive hemorrhage in muscles and viscera, and bilaterally symmetrical cerebral edema and necrosis. Ammonia exposure results in lacrimation, conjunctivitis, corneal opacity, tracheal hyperemia or hemorrhages, and pulmonary edema. Secondary bacterial pneumonia may be evident in exposed animals. For carbon dioxide, the principal lesions are of cyanosis.

CONTROL

Production of hydrogen sulfide in manure can be inhibited by aeration using air as the oxidizing agent or the use of chemical oxidizing agents. The use of ferrous salts virtually eliminates hydrogen sulfide evolution. Adequate ventilation with all doors and windows wide open during remixing and agitation of the slurry will reduce the concentration of hydrogen sulfide to non-toxic levels. Animals and personnel should not enter closed barns when the pits are being emptied. In confinement buildings, ammonia usually does not accumulate to fatal levels, but much of the economic loss is from reduced feed consumption and possibly increased susceptibility to acute or chronic respiratory disease. Limiting protein supplementation to actual needs has been considered a means for reducing nitrogen losses and the resultant production of ammonia in feces and urine.

33 Diseases associated with toxins in plants, fungi, cyanobacteria, plant-associated bacteria, and venoms in ticks and vertebrate animals

Diseases associated with major phytotoxins

Plant poisonings in farm animals have particular importance in areas where extensive pastoral management is practiced; therefore, this part of the book has limited appeal to veterinarians who work in intensive farming areas except when feedstuffs are contaminated by poisonous weed seeds or dried poisonous plants in hays. Conversely the amount of information on the subject of phytotoxins is very great because of the large number of poisonous plants. In order to maintain parity with the other parts of the book, material related to the pathogenesis of these diseases has been restricted. No botanical material has been included and only a minimum of the plant chemical information available. It is the botanical and chemical material which is best founded. The clinical data are often fragmentary, much of it anecdotal, a limited number of plants having been subjected to careful experimental scrutiny. Many plants are included in lists because they have been found to contain dangerous amounts of known toxins, without cases of poisoning ever having been recorded. Because the world list of definitely poisonous plants includes about 1500 species, only a limited number of them – those considered to be common or important enough, or whose identity as poisonous plants has been well established – have been included.

METABOLIC POISONS

Poisonous substances produced in the animal, especially the rumen, from innocuous substances in the plants ingested are not dealt with in this chapter. Examples are:

- Lactic acid produced in the rumen by anaerobic fermentation of starch and the cause of acute carbohydrate engorgement
- Indole and 3-methyl-indole, metabolites of tryptophan, and of etiological significance in acute bovine pulmonary emphysema and edema

HUMAN FOOD CHAIN

Besides the damage to animals associated with plants, there is the additional passage of plant poisons into the human food chain through animal products, especially eggs, meat, milk, and honey. Plant toxicants for humans originating in this way are not subjects for this book.

PHYTOTOXINS

The material in the chapter is arranged on the basis of the toxin present in the plant. This has been prompted by developments in the diagnosis of plant poisoning in countries with advanced technologies in which the toxin is identified by physicochemical examination of clinical or necropsy samples, usually by spectrometry, the plants containing the toxin are listed, and the environment then examined for

them. The procedure avoids the difficulty of trying to identify plants botanically from fragments of plants in the alimentary tract, but requires sophisticated laboratory techniques which are not universally available. It does not and cannot replace thorough field investigation.

DIFFERENTIAL DIAGNOSIS

Establishing a diagnosis of plant poisoning depends on the completion of all or several of the following tasks:

- Matching the circumstances of the case and the clinical signs, clinical pathology, and pathological lesions with those known to be associated with poisoning by the suspected plants
- Establishing that the suspected plants have been eaten or that the affected animals had access to them
- Precisely identifying the suspected plants through professional botanists
- Demonstrating the presence of the suspected plants in the stomach contents of affected animals
- Demonstrating hazardous concentrations of particular toxins in the plants, the stomach contents, or the tissues of affected animals
- On rare occasions, conducting feeding experiments.

CONTROL

Prevention of plant poisonings by restricting grazing of, or hay-making on, land areas containing poisonous plants needs no explanation but presents the difficulty that large areas of rangeland suited to domestic animal production are then not used. Control measures under development which limit toxin intake by grazing animals or provide effective defense within the animal's body include:

- **Immunization against toxins** for a number of phyto- and mycotoxins including phytoestrogens, pyrrolizidine alkaloids, sporidesmin, and *Pimelea* spp. toxins, all of which have failed so far. Rare successes have been achieved with phomopsins and corynetoxins. Important attributes of candidate toxins for attempted commercial immunogen production include producing syndromes with little initial tissue damage, slow onset, wide (preferably international) distribution, and frequent occurrence, being readily degraded by the body's detoxification mechanisms after capture by antibodies, and having potentially large, steady and cheap supply sources.[1,2]
- **Genetic engineering** of ruminal microbes for selective catabolism of ingested toxins has been successful with bacteria which break down fluoroacetate. Obstacles to be overcome in such work include finding the required microbial gene and a suitable recipient organism, survival of the modified organism in the rumen, and obtaining permission to release it. The simpler technique of introducing ruminal bacteria, which naturally detoxify mimosine into ruminant populations that do not have them, has solved toxicity problems with *Leucaena leucocephala*.

Creating a **conditioned aversion** to specific plants is under trial in a number of centers in the USA. Groups of animals are penned and fed intensively on the plant to which an aversion is to be created, or on a chemical component of it identified as an aversion-creating chemical, e.g. ingenol in *Euphorbia* spp.[3] The method has a number of deficiencies, including the difficulty of managing hard-to-handle livestock in this sort of intensive conditioning program. Also, a conditioned aversion can be retained in the animals' memories for years but can be quickly lost if the averted cattle are grazed with non-averted ones which readily consume the target plant.[4]

Naturally acquired aversion may be the mechanism permitting cattle to graze infested pasture, and to consume small amounts of the target plant, without developing a significant intoxication.[5] An interesting side issue from this work is the observation that adversity conditioning varies between animal species, being easy to create in cattle and sheep, but much less so in goats. This may be related to the ability of the ruminal microflora of goats to digest the aversion-inducing chemical.[6] Other range plants against which aversion conditioning control methods have been attempted are *Delphinium* and *Astragalus* spp.

CYANOGENIC GLYCOSIDE POISONING (CYANIDE, HYDROCYANIC ACID)

Synopsis

Etiology Ingestion of specific plant species containing cyanogenic glucosides.
Epidemiology Seasonal and other variations in glucoside content lead to periods of enhanced toxicity of pasture.
Clinical findings Acute poisoning – soon after access to toxic material sudden onset of dyspnea, tremor, recumbency, clonic convulsions, death within a few minutes to an hour. Chronic poisoning – neonatal goiter or arthrogryposis, adult posterior ataxia, dysuria, frequent urination.
Clinical pathology Assay of hydrocyanic acid in body tissues and fluids and in feed.
Necropsy lesions Nil.
Diagnostic confirmation Positive assay on rumen contents (difficult).
Treatment Primary treatment with sodium thiosulfate with or without sodium nitrite or other antidote.
Control Test feed for cyanide content.

ETIOLOGY

Most outbreaks of hydrocyanic acid (HCN) poisoning are associated with the ingestion of plants that contain cyanogenic glucosides. The glycosides are non-toxic but HCN may be liberated from them by β-glycosidase and lyase present in the plant tissue. Ruminal microorganisms also produce β-glycosidase. Horses and pigs are much less susceptible to the glycosides because the acidity of the stomach in monogastric animals inactivates β-glycosidase and is not great enough to be associated with acid hydrolysis of the glycosides.

Plants that contain enough cyanogenic glycosides to cause poisoning number about 120. The following list contains only the genera recognized as hazardous:

Acacia (a few spp. only) – wattle trees
Adenia, e.g. *A. digitata*
Amelanchier alnifolia – Saskatoon serviceberry
Amygdalus communis – almond
Aquilegia vulgaris – columbine
Bahia oppositifolia
Brachyachne spp., e.g. *B. convergens* – Gulf star grass
Breynia oblongifolia – coffee bush
Bridelia spp., e.g. *B. leichhardtii* – scrub ironbark
Calotis scapigera – tufted burr daisy
Carex vulpina
Castalis spectabilis – Transvaal bitou
Cercocarpus, e.g. *C. breviflorus* – mountain mahogany
Chenopodium spp., e.g. *C. carinatum* – green crumbweed (see also nitrate-nitrite poisoning)
Cydonia oblonga – quince tree
Cynodon spp., e.g. *C. aethiopicus* – couch grasses
Digitaria spp., e.g. *D. sanguinalis* – summer grass
Dimorphotheca spp., e.g. *D. cuneata* – karoo bietou
Drosera spp. – Sundew
Dysphania spp., e.g. *D. rhadinostachya* – red crumbweed (see also nitrate-nitrite poisoning)
Eleusine spp., e.g. *E. indica* – crowfoot
Eremophila maculata – native fuchsia
Eriobotrya japonica – loquat
Eucalyptus (a few spp. only), e.g. *E. cladocalyx* – sugar gum tree
Euphorbia spp., e.g. *E. drummondii* – caustic creeper
Flagellaria indica
Florestina tripteris
Glishrocaryon spp., e.g. *G. aureum* – yellow pop flower
Glyceria spp., e.g. *G. maxima* – reed sweet grass
Goodia spp., e.g. *G. lotifolia* – clover-leaf poison
Heterodendron, e.g. *H. oleifolium* – boonaree
Holcus lanatus – Yorkshire fog grass
Jatropha spp., e.g. *J. multifida* – umbrella tree
Juncus spp., e.g. *J. effusus* – blue rush
Leptopus decaisnei – andrachne
Linum spp., e.g. *L. usitassimum* – linseed or flax
Lotus spp., e.g. *L. australis* – birdsfoot trefoils
Macadamia spp., e.g. *M. integrifolia* – macadamia
Malus spp., e.g. *M. sylvestris* – common apple
Manihot esculenta – cassava
Mimosa spp., e.g. *M. invisa* – giant sensitive plant
Nandina domestica – nandina, sacred bamboo
Olax benthamiana
Osteospermum spp., e.g. *O. ecklonis* – South African daisy
Papaver nudicaule – Iceland poppy
Passiflora spp., e.g. *P. aurantia* – red passion flower
Perralderia coronopifolia – tafes
Phaseolus cuneatus – Java bean
Photinia spp. – Christmas berry
Phyllanthus spp., e.g. *P. gasstroemii*
Pomax umbellata
Prunus spp., e.g. *P. laurocerasus* – cherry laurel
Sambucus spp., e.g. *S. nigra* – common elder
Sorghum spp., e.g. *S. halepense* – Johnson grass (see also nitrate–nitrite poisoning)
Stillingia treculeana – Queen's delight
Suckleya suckleyana – poison suckleya
Triglochin spp., e.g. *T. maritima* – arrowgrass
Triraphis mollis – purple plume grass
Vicia sativa – vetch
Ximenia americana – yellow plum
Xylomelum spp., e.g. *X. pyriforme* – woody pear
Zea mays – maize, corn (see also nitrate–nitrite poisoning)
Zieria laevigata.

Toxic variability

The content of cyanogenetic glucosides in these plants varies widely between seasons and between different parts of the plant, with young, growing leaf usually having the greatest concentration.

Differences between plant species

Varieties of the same species often have different toxicities, e.g. *Amelanchier alnifolia* var *cusickii* has three times the toxicity of *A. alnifolia* var *alnifolia*.[1] Of greatest importance are the cultivated and pasture plants. Sudan grass (*Sorghum sudanense*) and sorghum (*S. bicolor*) are used extensively in some countries for forage and may be associated with heavy mortalities in particular circumstances. Sugar cane contains a cyanogenetic glucoside from which HCN can be released. Release occurs through the action of an enzyme in algarrobo pods (*Prosopsis glandulosa*) when the two are fed together.

Plant products

Linseed in the form of cake or meal may also be highly toxic if eaten in large quantities.

Fodder storage

Drying, hay-making, and physical factors, such as chilling and freezing, may appear to reduce the toxicity of cyanogenic material through destruction of β-glucosidase, but the plant material remains as potentially toxic as it was originally, requiring only the enzyme from ruminal microbes to become actively poisonous. Ensiled toxic forage loses much of its cyanide content and on exposure to air may give off large quantities of free HCN.

Glycosides

A number of specific glycosides have been isolated and include linamarin from linseed and flax, lotaustralin from *Lotus australis*, dhurrin from sorghum, lotusin from *Lotus arabicus*, and amygdalin from bitter almonds. The glycosides are byproducts of the plant's metabolism and probably form part of its defense system against herbivores such as insects and molluscs. Their concentration in the different plant species is variable depending upon climatic and other conditions which influence plant growth.

The minimum lethal dose of HCN is about 2 mg/kg BW for cattle and sheep when taken in the form of a glycoside. The minimum lethal dose (MLD) of lotaustralin for sheep approximates 4 mg/kg BW. Plant material containing more than 20 mg of HCN per 100 g (200 ppm) is likely to have toxic effects, and highly poisonous samples may contain as much as 6000 ppm. The toxic doses quoted must be accepted with some reservation, as the toxicity of a particular specimen varies with a number of factors including the concentration of the hydrolyzing enzyme in the plant, the preceding diet of the animals, and particularly the speed with which the material is eaten.

EPIDEMIOLOGY

Occurrence

Hydrocyanic acid poisoning occurs in most countries because of the common occurrence of plants containing toxic quantities of cyanogenetic glycosides. When the disease occurs, most affected animals die and, although the overall economic effects are not great, the losses may be heavy on individual farms.

Risk factors

Plant factors

Poisoning is most likely to occur when the cyanide content of the material is high and it is eaten quickly. Plants with a cyanide potential of more than 200 mg HCN/kg plant dry matter are potentially toxic. Plants must be unwilted at time of testing or falsely low results may be obtained. The glucoside content is highest when:

- Plants grow rapidly after a previous period of retardation, e.g. after autumn rains on drought-stunted pasture, after a crop is eaten back by livestock or grasshoppers, or after spraying with herbicides

- Plants are wilted, frostbitten, or just young
- In drought years[2]
- Plants are growing in soil with a high nitrogen content
- Plants growing in soil with low phosphorus content.

Animal factors

The greatest danger exists in the following circumstances:

- Hungry animals allowed access to dense plant growths
- Traveling, recently introduced or other animals unaccustomed to local plants; animals accustomed to the plants and the poison can tolerate increasing doses with experience
- Cattle or sheep may break out of dry, summer pastures into fields of young, lush, immature sorghum or Sudan grass and gorge on it.

Speed of cyanogenesis

The rate of conversion of the glycoside to HCN in the rumen also affects the toxicity of the feed[3]; factors affecting the conversion rate include:

- High pH values increase the rate and the risk of poisoning
- The rate is less when the diet includes grain and long hay rather than fresh or cubed pasture or hay
- The rate of conversion, and onset of signs, may be delayed if the ingested material is relatively indigestible, such as crabapples.[4]

Linseed meal or cake

Deaths due to the ingestion of excessive amounts occur when:

- Sheep are fed large quantities of linseed meal at the end of a period of starvation
- Calves are fed on milk replacer containing linseed that has been soaked but not boiled.

Other sources

Occasional cases of HCN poisoning occur when animals are exposed to:

- Chemicals used for fumigation
- The fertilizer, calcium cyanamide.

PATHOGENESIS

Acute intoxication

This is associated with tissue anoxia by its inhibition of the cytochrome a_3 moiety of complex IV (the terminal cytochrome *c* oxidase) in the electron transport chain, thus preventing cellular aerobic respiration. Oxygen exchange is suspended and oxygen is retained in the blood. If the course is prolonged the blood may be dark red due to inhibition of respiration and restriction of oxygen intake. The major manifestation of cyanide poisoning is cerebral anoxia resulting from heart failure.

Chronic poisoning

Doses which do not produce clinical effects appear to be well-tolerated. HCN is volatile and is exhaled or converted to thiocyanate by hepatic rhodanase and then excreted in the urine. The tolerance appears to increase with experience. Cyanides ingested in small amounts, however, are known to be **goitrogenic** through the effects of thiocyanate, e.g. pregnant ewes grazing on star grass (*Cynodon nlemfuensis*) develop goiter due partly to a low iodine intake and partly to the cyanide intake. Their lambs may also be goitrous and have skeletal deformities. **Leucomyelomalacia** (cystitis-ataxia syndrome) in ruminants and horses is also attributed to chronic cyanide intake. Urinary incontinence, loss of hair due to scalding, and incoordination of the hindlimbs occur in horses, cattle, and sheep grazing *Sorghum sudanense* (Sudan or hybrid Sudan grass). In horses, the signs are most marked when the animal is backed or turned. In sheep, the syndrome includes weakness, ataxia, head shaking, fetlock knuckling, recumbency, and opisthotonos. Mares and cows grazing sorghum may rarely produce offspring with arthrogryposis, probably the result of fetal central nervous system damage by cyanide.

CLINICAL FINDINGS

Affected animals rarely survive for more than 1–2 hours. In the most acute cases, animals become affected within 10–15 minutes of eating toxic material and die within 2–3 minutes of first showing signs. Clinical signs include dyspnea, anxiety, restlessness, stumbling gait, tremor, moaning, recumbency, and terminal clonic convulsions with opisthotonos. The mucosae are bright red in color. In the more common, acute, cases the animals show depression, staggering, gross muscle tremor and dyspnea. There may be hyperesthesia and lacrimation. The muscle tremor is evident first in the head and neck, but soon spreads to involve the rest of the body; the animal becomes weak and goes down. The pulse is small, weak and rapid, and may be irregular. There is dilatation of the pupils, nystagmus, with congestion and cyanosis of the mucosae in the terminal stages, usually accompanied by clonic convulsions and in some cases by hypersalivation, vomiting, and aspiration of ingesta into the lungs. Vomition is not a typical sign in cyanide poisoning and, when it does occur, may be the result of bloating in the recumbent animal and during the final convulsions. The course in these cases may be as long as 1–2 hours.

CLINICAL PATHOLOGY

Most tests for the presence of cyanogenic glycosides are conducted in the laboratory but suspected plants or ruminal contents can be tested in the field by the Henrici (picric acid) test. The material is placed in a test tube containing a little water and a few drops of chloroform and heated very gently in the presence of sodium picrate paper. A rapid change in the color of the reagent paper from yellow to red indicates the presence of free HCN. Once started, the color change occurs rapidly, although it may require 5–10 minutes of gentle warming before the change commences. The tube should be corked while being warmed and the paper hung from the top without touching the test material. Reagent papers are easily prepared by mixing 0.5 g picric acid, 5 g sodium carbonate in 100 mL water. Filter paper is dipped in the reagent and allowed to dry in a dark place. The reagent is stable for at least 6 months if kept in a cool place, but the papers deteriorate if kept for more than 1 week. Ruminal contents may also be tested by placing a drop of ruminal fluid on a test paper. A red discoloration is a positive reaction. The test is designed to detect free HCN and may not be positive even when cyanides are present if the gas is not liberated. Commercial test papers may give superior results.[5]

NECROPSY FINDINGS

In very acute cases the blood may be bright red in color, but in most field cases it is dark red due to anoxemia. The blood clots slowly, the musculature is dark, and there is congestion and hemorrhage in the trachea and lungs. Patchy congestion and petechiation may be evident in the abomasum and small intestines. Subepicardial and subendocardial hemorrhages occur constantly. A smell of 'bitter almonds' in the rumen is described as typical of HCN poisoning. It may occur with some plants but is not apparent with others. There are no characteristic histological changes. Specimens submitted for laboratory examination should include rumen contents, liver, and muscle. Much HCN may be lost from specimens during transit unless the samples are shipped in a very tightly stoppered, air-tight bottle. Muscle is least likely to lose its HCN and is the preferred tissue if the delay between death and necropsy has been long. To be satisfactory, liver samples must be taken within 4 hours of death and muscle tissue within 20 hours. A level of HCN of 0.63 μg/mL in muscle justifies a diagnosis of poisoning. Serum and rumen fluid of poisoned cattle have been assayed using GC-MS.[6]

Chronic cases

In arthrogryposis and in cystitis-ataxia there is focal axonal degeneration and demyelination in the spinal cord, with some cases of pyelonephritis in the cystitis-ataxia patients.

Samples for confirmation of diagnosis
- Toxicology – 50 g rumen content, liver, muscle *in air-tight container* (ASSAY (cyanide)).

DIFFERENTIAL DIAGNOSIS

The development of an acute anoxic syndrome in ruminants grazing on plants, or being fed on feeds known to be cyanogenic, usually suggests the occurrence of HCN poisoning. **Diagnostic confirmation** is dependent on a positive assay for hydrogen cyanide in blood or cyanogenetic glucosides in rumen contents. The **differential list** for **acute poisoning** includes:

- Acute pulmonary edema and emphysema may resemble it but is less acute, and auscultation of the lungs usually indicates the presence of fluid and emphysema
- In nitrite poisoning the blood is dark and tends to be brown
- Poisoning by cyanobacteria associated with obvious blooms in water sources
- Occasional cases of anaphylaxis cases in cattle, particularly young calves, are manifested by acute dyspnea, but there are usually additional signs of an allergic reaction including bloat and sometimes urticaria or angioneurotic edema, and, if the case is sufficiently severe, there is a profuse discharge of blood-stained froth from the nose. Cases occur only sporadically, whereas HCN poisoning is likely to affect a number of animals at one time.

Differential diagnosis lists for goiter, myelomalacia, and arthrogryposis are listed elsewhere.

TREATMENT

The standard **primary treatment** is the IV injection of a mixture of sodium nitrite and sodium thiosulfate (5 g sodium nitrite, 15 g sodium thiosulfate in 200 mL water for cattle; 1 g sodium nitrite, 3 g sodium thiosulfate in 50 mL water for sheep), and field experience with it has been very good. However, the results in cattle can be improved by using:

- Sodium thiosulfate in a much heavier dose (660 mg/kg BW compared to the previous level of 66 mg/kg)
- Sodium thiosulfate heavy dose combined with sodium nitrite (22 mg/kg BW)
- Sodium thiosulfate heavy dose combined with *p*-aminopropriophenone (1–1.5 mg/kg)
- *p*-aminopropriophenone (1–1.5 mg/kg) used alone
- Sodium thiosulfate heavy dose plus cobaltous chloride (10.6 mg/kg BW).

Treatment, whichever product is used, may have to be repeated because of further liberation of HCN. There is an upper limit of safe methemoglobinemia beyond which anemic anoxia occurs and doses of nitrite greater than those recommended may exacerbate the tissue anoxia. The inclusion of cobalt is based on its marked antagonistic effect against cyanide, which is enhanced by combination with thiosulfate or nitrite.

In all cases and in animals exposed but showing no signs, doses of 30 g of sodium thiosulfate are given orally to cattle and are repeated at hourly intervals.

Non-specific **supportive treatment**, including respiratory stimulants and artificial respiration are unlikely to have any effect on the course of the disease.

CONTROL

Hungry cattle and sheep should not be allowed access to toxic plants, especially cultivated *Sorghum* spp. when they are chronically drought-stressed, immature, wilted, frostbitten, or growing rapidly after a stage of retarded growth. For most *Sorghum* cultivars, stock should be allowed to graze them, or be fed green chop made from them, only after the plants exceed 75 cm in height. Hay should not be made from *Sorghum* which is potentially toxic, as toxicity may persist. *Sorghum* silage is much safer than hay.

Sulfur deficiency in ruminants causing depressed feed intake and animal production may result from grazing *Sorghum* with high cyanide potential. This results from ruminal detoxification of cyanide with sulfur to form thiocyanate. Supplementation with salt licks containing 5% sulfur can counter this problem.

If there is doubt as to the toxicity of a field of these plants, a sample may be tested by the method described under clinical pathology, or the field can be test-fed to a small group of animals. Linseed meal can be fed in small quantities without soaking, but gruel containing linseed should be thoroughly boiled to drive off any free HCN.

NITRATE AND NITRITE POISONING

Synopsis

Etiology Nitrate – as sodium or potassium nitrate fertilizer, food preservative. Nitrite preformed in nitrate-rich, moldy plant material or as nitrate converted in rumen to nitrite.
Epidemiology Outbreaks due to access to abnormal materials, including species which accumulate nitrate or moldy hay, or any plant growing profusely after a long drought or on high nitrate content soil.
Clinical findings Sudden onset of severe dyspnea, brown mucosae and blood, short course, high case fatality rate.
Clinical pathology Very high blood levels of methemoglobin.
Necropsy findings Brown blood in some.
Diagnostic confirmation Positive assay for nitrate in feed, blood or aqueous humor.
Treatment Methylene blue.
Control Avoidance of nitrate-rich feeds, monensin supplementation; supplement ration with carbohydrate.

ETIOLOGY

The **toxic principle** as it occurs in growing plants is always nitrate, usually as potassium nitrate, and may be ingested in sufficient quantities to be associated with gastroenteritis. Ruminal microbes convert nitrate to nitrite. **Toxic doses** are hard to compute because of variation in susceptibility, and in the rate of production of nitrite from nitrate.

Roots and stems usually contain more nitrate than leaves, and a total plant content of 6000–10 000 ppm dry matter (DM) of nitrate is considered to be potentially toxic. Plants that accumulate more than 1.5% potassium nitrate in dry matter are potentially toxic. For animals at pasture probably 2% DM as nitrate is safe. Levels of potassium nitrate in plants may be as high as 20% of DM and 3% is not uncommon in recognized forage plants such as sorghum and Sudax, and heavy mortality has occurred on them. Dried plants retain their toxicity.

Cattle

The minimum lethal dose of nitrite is 88–110 mg/kg BW or about 0.6 g of potassium nitrate per kg BW. Daily doses of about 0.15 g potassium nitrate have been associated with abortion after 3–13 doses. Cattle can eat sufficient quantities of toxic plants to be associated with death in 1 hour.

Sheep

The lethal dose of nitrite is 40–50 mg/kg BW. Continued low-level dosing does not appear to affect sheep. Drinking water containing 1000 ppm of nitrate nitrogen is associated with appreciable methemoglobin formation but has no obvious clinical effect.

Pigs

The lethal dose of sodium nitrite is 88 mg/kg BW. Doses of 48–77 mg/kg will be associated with moderate-to-severe,

but not fatal, methemoglobinemia. Potassium nitrate in doses of 4–7 g/kg BW is associated with fatal gastritis, and the lethal dose of potassium or sodium nitrite is about 20 mg/kg. Measured as nitrate nitrogen, the LD_{50} is 19–21 mg/kg BW. At dose levels of 12–19 mg/kg BW clinical signs occur but the pigs recover.

EPIDEMIOLOGY

Source

The common sources of nitrate for farm animals include:

- Cereal crops used as pasture, e.g. immature green oats, barley, wheat, and rye or hay; or green fodder, e.g. Sudan grass, corn. Oat hay may contain 3–7% nitrate
- Very heavy growths of rye-grass (*Lolium* spp.) in pastures
- Freshly pulled mangels. Turnip tops may contain 8% nitrate, and sugar beet tops and rape have been associated with nitrite poisoning
- Water from deep wells, contaminated with fertilizer or from reservoirs created with explosives
- The plants listed below are recognized important sources of hazardous nitrate concentrations:

Alternanthera denticulata
Amaranthus spp., e.g. *A. retroflexus* – redroot, Prince of Wales feather (see also oxalate poisoning)
Aneilema accuminatum
Arctotheca calendula – capeweed
Atriplex muelleri – annual saltbush
Avena sativa – oats
Beta vulgaris – sugar beets, feed beets, beetroots
Bidens frondosa – beggar tick
Brassica spp., e.g. *B. napus* – rape, turnips, etc.
Bromus catharticus – prairie grass
Carduus spp., e.g. *C. tenuifloris*, winged, slender thistle
Chenopodium spp., e.g. *C. ambrosioides* – mexican tea, goosefoot
Chromolaena odorata – Siam weed
Cirsium arvense – Canada thistle
Claoxylon australe
Cleome serrulata – Rocky Mountain bee plant
Dactyloctenium radulans – button grass, but only when growing in high-nitrogen soil, such as in stockyards
Daucus carota – wild carrot, Queen Anne's lace
Dysphania spp. – crumbweeds (see also cyanogenic glycoside poisoning)
Echinochloa spp., e.g. *E. crus-galli* – barnyard grass, Japanese millet
Ehretia membranifolia
Eleusine spp., e.g. *E. indica* – crowfoot (see also cyanogenic glycoside poisoning)
Franseria discolor – white ragweed
Galenia pubescens
Glaucium corniculatum
Glycine max – soybean
Gnaphalium purpureum – purple cudweed
Helianthus annuus – sunflower
Lolium spp., e.g. *L. multiflorum* – rye grasses
Lygodesmia juncea – skeleton weed
Malva parviflora – small-flowered mallow
Medicago sativa – alfalfa, lucerne
Millotia greevesii – creeping millotia
Montia perfoliata – miners lettuce
Panicum capillare – witchgrass
Parsonia spp., e.g. *P. lilacina*
Pennisetum spp., e.g. *P. clandestinum* – kikuyu
Plagiobothrys spp. – popcorn flower
Polygonum aviculare – wireweed
Portulacca spp., e.g. *P. oleracea* – pigweed (see also oxalate poisoning)
Rafinesquia californica – California chicory
Raphanus sativus – radish
Salvia reflexa – mintweed
Sigesbeckia orientalis
Silybum marianum – variegated thistle
Sinapis spp., e.g. *S. alba* – white mustard
Sonchus spp. – sow thistle
Sorghum spp., e.g. *S. bicolor* – grain sorghum
Spartothamnella juncea
Stellaria media – chickweed
Thelypodium lasiophyllum – mustard
Tribulus terrestris – caltrop
Triticum aestivum – wheat
Urochloa spp., e.g. *U. panicoides* – liverseed grass
Vigna unguiculata (catjang) – cowpea
Zaleya galericulata
Zea mays – maize, corn
Zygophyllum spp., e.g. *Z. ammophilum* – twin leaf.

Risk factors

Environmental factors

Higher than normal levels of nitrate in **plants** are usually associated with:

- Application of excessive nitrogen-containing fertilizer, human sewage, animal manure from intensive accommodation units, or with high levels of nitrogen-fixing bacteria
- Soil nitrate being taken up but not used by plants because weather conditions are unsuitable for photosynthesis which would provide the energy to convert the nitrogen into protein. Conditions which retard photosynthesis include cloudy or cold weather, at night, herbicide application, disease in the plants, wilting of plants, after a prolonged drought.[1] High levels of nitrate accumulate in the soil during the drought and are not leached out by rain. Plants absorb large amounts when the drought ends
- Green chop fed indoors is more hazardous than grazing material, probably because the intake is more rapid
- Cereals and root crops are likely to contain high concentrations when heavily fertilized with nitrogenous manures, especially crude sewage, and when growth is rapid during hot, humid weather
- Ensiled material usually contains less nitrate than the fresh crop, because normal silage fermentation destroys nitrate, but juices draining from silos containing high-nitrate materials may be toxic
- Hay made from nitrate-rich material contains almost as much as when it was made, unless some of it is converted to nitrite by overheating and the activities of molds
- Heavily fertilized grass made into grass cubes
- Nitrate combined with possible iodine deficiency is statistically associated with congenital deformities and hypothyroidism in foals in western Canada where mares were fed oaten hay or green oat forage during pregnancy.[2]

Cereal hay, especially oat hay, grown under drought conditions and cut when sappy, may develop a high concentration of nitrite when the stacked material develops some heat. Dry oat hay that is damp for some time before it is eaten, either in the stack or loose in the field in the hot sun, is also likely to contain a high concentration of nitrite.

Nitrate-nitrite poisoning by drinking polluted **water** can result from:

- Industrial contamination from rubber processing plants
- Nitrogenous fertilizer contamination
- Effluent from butchers' shops and meat processors where sodium nitrate is used in meat-pickling brine
- Effluent from premises where cheese is manufactured; the whey may contain potassium nitrate
- Deep wells filled by seepage from highly fertile soils may contain levels as high as 1700–3000 ppm of nitrate
- Open surface storage tanks collecting rain runoff from roofs may also contain toxic amounts of nitrite in the plant debris which collects at the bottom
- Juices draining from silage containing high-nitrate material may be toxic
- Water of condensation in barns may trap ammonia and eventually contain 8000–10 000 ppm of nitrate

- Composition lining board in animal barns may become highly impregnated with nitrite and is associated with poisoning if chewed
- Water containing 2300 ppm of nitrate and less than 10 ppm of nitrite when mixed into a swill, stored in tins and then cooked has resulted in the production of a mixture containing 1200–1400 ppm of nitrite.

Boiling does not reduce the nitrate content of water.[3]

Accidental poisoning with **commercial nitrate compounds** occurs sporadically when:

- Sodium or potassium nitrate is used in mistake for sodium chloride or magnesium sulfate, or when ammonium nitrate solution is used instead of whey
- Nitrates used as explosives to blast out water holes used to store drinking water for cattle can be dangerous if the nitrate is left in the hole and the dam fills soon afterwards.[4]

Animal factors

Species differences

There is considerable variation between species in their susceptibility to nitrite poisoning, pigs being most susceptible, followed by cattle, sheep, and horses in that order. The susceptibility of cattle relative to sheep is due either to their ability to convert nitrate to nitrite in the rumen or because of the known greater ability of sheep to convert nitrite to ammonia. Pigs are highly susceptible to nitrite poisoning but are affected only if they ingest it preformed.

Dietary differences

Cattle reduce nitrate to nitrite in the rumen and their capacity to do this is enhanced by continued feeding of nitrate. The enhanced capacity, due to changes in microbial activity, is transferred naturally to nearby animals not receiving additional nitrate. Cases of nitrate poisoning that occur in sheep are associated with either the ingestion of preformed nitrite or ruminal conditions, which favor reduction of nitrate. A diet rich in readily fermentable carbohydrate reduces nitrite production in the rumen of the sheep. Nitrite poisoning also occurs in sheep fed an inadequate ration after dosing with nitrite at a level innocuous to sheep fed on a good ration. There is often a delay of a few days in the appearance of signs of poisoning after sheep go onto toxic forage. It seems likely that ruminal flora need to adapt to the changed nutrients. The degree of methemoglobinemia also varies with the quality of the diet.

Differences in susceptibility

- The most important factor influencing susceptibility appears to be the rate of ingestion of the nitrate-bearing plant
- Poorly fed animals, especially traveling or recently transported stock, are more susceptible to nitrite poisoning than those on good diets, probably because of the greater intake in hungry animals, and possibly their need to adapt their ruminal flora to the conversion of nitrite to ammonia
- Prior exposure to nitrate reduces susceptibility under experimental conditions, and cattle on high nitrate hay taken off the hay for a few days and then returned to it in self-feeders where they can gorge on it may be poisoned[5]
- Monensin facilitates the conversion of nitrate to nitrite in the rumen and may result in poisoning in cattle or sheep on high nitrate fodder.

PATHOGENESIS

Nitrates have a direct caustic action on alimentary mucosa and the ingestion of sufficiently large quantities is associated with gastroenteritis. Absorption of nitrites is associated with methemoglobinemia and the development of hypoxia. Nitrites are also vasodilators which may contribute to the development of tissue hypoxia by causing peripheral circulatory failure, but this effect appears to be of little significance compared to that of methemoglobin formation. When nitrite is ingested preformed, the effects may be very rapid, but when conversion of nitrate to nitrite occurs in the rumen there is a delay of some hours before clinical illness occurs. In cattle and sheep, the maximum methemoglobinemia occurs about 5 hours after ingestion of nitrate. In pigs, it is 90–150 minutes after nitrite is ingested. Death usually occurs within 12–24 hours of ingestion of the toxic material, although in acute poisoning the duration of illness may be even shorter, and clinical signs may not be observed.

Death does not occur until a certain level of methemoglobinemia is attained. In farm animals, lethal levels in cattle are about 9 g methemoglobin per 100 mL blood; in pigs death occurs when 76–88% of hemoglobin has been altered to methemoglobin.

In cattle, prolonged ingestion of sublethal amounts of nitrite is not known to have any significant effect on productivity. However, abortion is commonly recorded as a sequel to an acute outbreak of poisoning, and it is possible that severe anoxic episodes could damage the conceptus.

CLINICAL FINDINGS

In animals poisoned by **nitrate** there is salivation, abdominal pain, diarrhea, and vomiting, even in ruminants. The more typical syndrome is that associated with the anoxia of **nitrite** poisoning. Dyspnea, with a gasping, rapid respiration is the predominant sign. Muscle tremor, weakness, stumbling gait, severe cyanosis followed by blanching of the mucosae, a rapid, small, weak pulse, and a normal or subnormal temperature are other typical signs. In the most severe cases the mucosal and conjunctival vessels and the mucosae generally, are brown because of the high content of methemoglobin in the blood.

Fatally affected animals go down, show severe depression and terminal clonic convulsions, and death occurs from a few minutes to an hour after onset. Frequent urination and abortion are other recorded signs, and in some outbreaks in cattle the principal problem is abortion a few days after exposure.[6]

CLINICAL PATHOLOGY

Nitrite poisoning is difficult to diagnose unless blood samples are collected during life and their content of nitrite, or more commonly nitrate, is estimated by the diphenylamine test.[7] Blood and ocular fluid levels of nitrate are stable for 24 hours at 23°C (73.4°F), 1 week at 4°C (39.2°F), and 1 month at −20°C (−4°F).[8] Contributory information is provided by blood levels of methemoglobin, but inaccuracy creeps in because of the rapid reversion of methemoglobin to hemoglobin. Methemoglobinemia may be detected by examination of the blood in a reversion spectrometer but it is not diagnostic of nitrite poisoning, and results are not dependable unless the blood has been collected for less than 1 or 2 hours. Methemoglobin levels of 9 g/dL of blood are lethal in cattle; levels of 1.65–2.97 g/dL are recorded in association with obvious clinical signs compared to normal levels of 0.12–0.2 g/dL. An alternative method is the diphenylamine blue test, which is very sensitive to the presence of nitrite but not entirely specific. A satisfactory test can be conducted on a thick, air-dried blood smear. Laboratory tests are available for the rough estimation of the nitrite or nitrate content of fodder but they are neither sufficiently simple for field use nor accurate enough for critical assay. A modified diphenylamine reagent provides a qualitative test suitable for field use. The test solution (0.5 diphenylamine, 20 mL distilled water and concentrated sulfuric acid to make up to 100 mL) is placed on the tissues of the inside of the stem (to avoid contact with possible iron contamination on the outside surface). An intense blue color within 10 seconds indicates a concentration of greater than 1% of nitrate. Commercial test strips are

available for detection of nitrate and nitrite in the field.

The diphenylamine test does have disadvantages and can give inaccurate results. To avoid these errors it is recommended that the blood be diluted with phosphate buffer (1 part in 20). It is also worthwhile submitting a sample of urine, as nitrite appears to pass unchanged into the urine.

NECROPSY FINDINGS

In nitrate poisoning, the gastrointestinal mucosa is congested and hemorrhagic. In nitrite poisoning, the blood is dark red to coffee-brown in color, and it clots poorly. Petechial hemorrhages may be present in the heart muscle and trachea, and there is general vascular congestion. There are no characteristic microscopic changes. Specimens for laboratory examination should include blood for methemoglobin estimation, ingesta and suspected plants or water, with added chloroform or formalin to prevent conversion of nitrates by bacterial fermentation. If the animals have been dead for some time, chemical analysis should be attempted on the aqueous humor of the eye and the cerebrospinal fluid. All of these specimens are subjected to the diphenylamine test. Postmortem blood specimens for methemoglobin assay must be collected within 1–2 hours of death to be of any value.

Samples for confirmation of diagnosis

- **Toxicology** – 1 cc aqueous humor (frozen); 1 cc urine (frozen); suspect forage material (dry) or other possible source of poison; 100 g ingesta (with chloroform or formalin added) (ASSAY (nitrate/nitrite)); 2 cc blood in 4 cc phosphate buffer (ASSAY (methemoglobin)).

DIFFERENTIAL DIAGNOSIS

The acute dyspnea, short course, and nervous signs of tremor and convulsions resemble the signs of other forms of anoxia. Although the rapid response to treatment with methylene blue is a good criterion for field use, diagnostic confirmation is by a positive assay for nitrite in body fluid and tissues. The differential diagnosis list includes:

- Hydrocyanic acid poisoning
- Acute bovine pulmonary edema and emphysema
- Anaphylaxis occurs only as sporadic cases
- Cyanobacterial poisoning.

TREATMENT

Methylene blue is the specific antidote; in large amounts it is associated with methemoglobinemia, hence its use in cyanide poisoning, but in small amounts it is associated with rapid reconversion of methemoglobin to hemoglobin. The standard dose rate is traditionally 1–2 mg/kg BW, injected IV as a 1% solution, but in ruminants it has been shown that high dose rates of methylene blue are not associated with dangerous methemoglobinemia; a higher dose rate of 20 mg/kg BW can be used, but the standard dose rate appears to be adequate. Treatment may have to be repeated when large amounts of toxic material have been ingested. The half-life of methylene blue in tissues is about 2 hours, and a repetition of treatment is recommended if necessary at intervals of 6–8 hours. Methylene blue has come under a cloud because of claimed mutagenic properties, but alternative treatments for methemoglobinemia have so far proved inadequate.

CONTROL

Ruminants likely to be exposed to nitrites or nitrates should receive adequate carbohydrate in their diet, and traveling or hungry animals should not be allowed access to dangerous plants. Haylage or silage suspected of dangerous levels of nitrate should be allowed to aerate overnight before feeding.

Toxic levels

Less than 0.6% of nitrate in the total diet is recommended. Plants, to be safe for feeding, should contain less than 1.5% potassium nitrate on a dry matter basis. For safety it is recommended that cows not be grazed on feed containing more than 1% nitrate, and slightly less when zero grazing. Cattle can eat material containing up to 8% potassium nitrate in dry matter if introduced to it gradually to allow ruminal microbes to adapt.

Dietary supplements

If hazardous feed is to be fed, supplementation of the diet of sheep and cattle with chlortetracycline (30 mg/kg of feed) or sodium tungstate is partially effective for a period of about 2 weeks in suppressing the reduction of nitrate to nitrite. Cattle adapted to potentially toxic feed should not be supplemented with monensin. L-cysteine feeding has been experimentally effective in preventing nitrate-nitrite poisoning in sheep.[8]

Ration dilution

Hungry animals should be fed hay or dry pasture as a filler to reduce their rate of intake before access to potentially toxic feed. Risks of nitrate-nitrite poisoning from pasture grass is minimized if the pasture is a mixed legume/grass one.

OXALATE (SOLUBLE FORMS) POISONING

Synopsis

Etiology Ingestion of soluble oxalates in specific poisonous plants.
Epidemiology Occurrence limited to habitats of the specific plants. Sheep most susceptible. Most severe when plant profuse and lush and livestock hungry.
Clinical findings In ruminants – hypocalcemic recumbency, nephrotic syndrome, rumenitis.
Clinical pathology Low blood calcium; azotemia; proteinuria.
Necropsy findings Nephrosis associated with calcium oxalate crystals.
Diagnostic confirmation High oxalate content of ingesta, plants. Nephrosis with oxalate crystals.
Treatment Calcium borogluconate parenterally.
Control Limit access to toxic plants; dilute feed with non-toxic materials.

ETIOLOGY

Plants usually contain soluble oxalate in the form of the potassium salt, and this is much less toxic than if it is given experimentally as the pure salt. High concentrations are present in about 70 plants included in the world list, of which important examples are listed below:

Acetosella vulgaris – sheep sorrel
Amaranthus spp., e.g. *A. cruentus* – redshank (see also nitrate-nitrite poisoning)
Atriplex spp., e.g. *A. muelleri* – annual saltbush (see also nitrate-nitrite poisoning)
Bassia spp., e.g. *B. hyssopifolia* – red burr
Beta vulgaris – fodder beet, sugar beet, mangel
Cenchrus ciliaris – buffel grass
Chenopodium spp., e.g. *C. album* – fat hen (see also nitrate-nitrite poisoning)
Delosperma spp.
Drosanthemum spp.
Emex australis – spiny emex

Halogeton glomeratus – halogeton, barilla
Mesembryanthemum spp., e.g.
M. nodiflorum – slender ice plant[1]
Neobassia (Threlkeldia) proceriflora – soda bush
Oxalis spp., e.g. *O. cernua, O. pescaprae* – soursob
Portulaca spp., e.g. *P. oleracea* – pigweed
Plantago varia – plantain
Psilocaulon spp., e.g. *P. absimile* – loogbos
Rheum rhaponticum – rhubarb
Rumex spp., e.g. *R. crispus* – curly dock[2]
Salsola spp., e.g. *S. kali* – tumbleweed
Sarcobatus vermiculatus – greasewood
Sceletium spp.
Scleroblitum atriplicinum – lambs tongue
Sclerolaena spp., e.g. *S. muricata* – prickly rolypoly
Setaria sphacelata – setaria
Spinacia oleracea – spinach
Trianthema spp., e.g. *T. portulacastrum* – giant pigweed
Zaleya galericulata – hogweed.

Soluble oxalates in plants reach their greatest concentration in the young, growing leaves. Some fungi are capable of producing significant amounts of oxalate, and moldy feedstuffs may be associated with oxalate poisoning.

Toxic dose

Large quantities of a toxic plant must be ingested to be associated with poisoning because not all the oxalate is absorbed and much is broken down in the alimentary tract. Up to 450 g of sodium oxalate given by mouth is required to produce fatal effects in horses (in which natural cases are almost unknown), and 6 g/day of anhydrous oxalic acid is required to produce toxic effects in sheep. Cattle can eat as much as 685 g of oxalic acid without harmful effect; buffalo are similarly tolerant of the poison. Deaths in sheep can occur on pasture containing as little as 2% soluble oxalate.[3]

EPIDEMIOLOGY

Occurrence

Oxalate poisoning is most prevalent under extensive grazing systems where it is impossible to control the occurrence in the pasture of the specific plants which contain large amounts of oxalate.

Risk factors

Animal factors

Species susceptibility

Oxalate poisoning is commonest in sheep that are more likely to be grazed on the kind of pasture in which the toxic plants commonly occur, but occurs also in cattle and very rarely in horses. Acute oxalate poisoning and death have been observed in cattle eating *Setaria sphacelata, Halogeton glomeratus*, and *Rumex venosus* containing up to 13.9% of oxalate.

The natural disease does not appear to have been recorded in pigs, but renal damage has been produced in this species by experimental administration of oxalate.

Adaptation

Oxalate is normally metabolized by ruminal bacteria and the continued ingestion of oxalate in small quantities results in increased ability to decompose the oxalate to the point where relatively large quantities can be ingested without toxic effects. The ruminal microflora requires 3–4 days to adapt to the introduction of oxalate into the diet. Thus, sheep and cattle may be very susceptible when they are grazed for the first time on pasture containing the toxic plants. Of the factors in the rumen which will affect the amount of oxalate rendered insoluble as calcium oxalate or digested to bicarbonate, the level of calcium in the diet and the activities of bacteria in the rumen are considered to be important.

Susceptible animal groups

Plants containing oxalates in dangerous quantities grow prolifically in specific areas, and heavy mortalities occur in traveling and recently introduced animals and other very hungry animals whose intake of potentially toxic plants is likely to be higher than normal. As a group, pregnant and lactating animals are probably more susceptible than others.

Environmental factors

State of pasture

Young, rapidly growing, fresh plants may contain as much as 17% potassium oxalate whilst old, dry plants rarely contain more than 1%, but *Halogeton*, one of the most dangerous plants, becomes more toxic as the growing season progresses, and is most dangerous when frosted and dried, when it may contain as much as 16.6% of soluble oxalate. The grass *Setaria sphacelata*, much favored for tropical conditions, may contain up to 7% oxalate and be associated with acute poisoning in cattle and horses.

PATHOGENESIS

Clinical effects vary with the amount of oxalate ingested. With large quantities the major effect is the absorption of free oxalate and precipitation of blood calcium as calcium oxalate to produce a hypocalcemia. Severe nephrosis occurs with precipitation of calcium oxalate crystals in renal tubules. There may be marked damage to vascular tissues, especially in the alimentary tract and lungs. Invasion of the chemical rumenitis that results may lead to an irreversible fungal or bacterial rumenitis or hepatitis.

Continuous ingestion of smaller amounts of soluble oxalates from pastures dominated by *Oxalis pres-caprae* over 2–12 months is associated with a chronic nephrosis with precipitation of oxalate crystals in the renal tubules. Up to 25% of sheep may be affected in some flocks. Such damage is likely to be cumulative if the sheep are periodically exposed to oxalate-bearing plants.

Other syndromes

Include **urolithiasis**, and ruminal dysfunction in sheep due to changes in pH of its contents and interference with cellulose digestion.

CLINICAL FINDINGS

Clinical signs may appear within 2–4 hours of eating oxalate-containing plants if the animals are hungry and consume large quantities.

Hypocalcemia syndrome

In acutely poisoned sheep, the clinical signs include anorexia, hyposensitivity, paresis, muscle tremor, especially of facial muscles, clear mucus dripping from the nostrils, ruminal atony, dyspnea, hypersensitivity to touch, stumbling gait, and final recumbency with the head turned into the flank, pupillary dilation, and death in coma. The heart rate is rapid, and the ruminal movements are decreased. There may be slight bloating, frequent getting up and lying down, eventually recumbency, frequent attempts to urinate, frothy blood-tinged nasal discharge, and occasionally red-brown urine. In sheep, chronic cases of nephrosis show poor appetite, failure to grow, poor bodily condition, ascites, and a significant anemia. Acute nephrosis in cattle is marked by hyposensitivity leading to coma, recumbency, proteinuria, and elevated blood urea nitrogen levels.

CLINICAL PATHOLOGY

Suspected plants should be assayed for soluble oxalate content. Hypocalcemia is a key finding in the acute disease with azotemia in cases with significant kidney damage. In sheep with chronic nephrosis, albuminuria, and sometimes hematuria may be observed, the packed cell volume may be as low as 15–20%, the blood urea nitrogen is of the order of 85 mg/dL (30.3 mmol/L) and there may be an accompanying elevation of blood potassium. The proteinuria is almost diagnostic of the disease in sheep grazing *Oxalis* spp.

NECROPSY FINDINGS

There are no gross findings at necropsy which are characteristic of acute oxalate poisoning, but perirenal edema and ascites may be evident in chronic cases. Nephrosis is the standard finding at histopathological examination, and there is usually deposition of birefringent rosettes of crystals in the renal tubules and pelvis, and even in the ureters and urethra. In experimental acute poisoning in the horse

and sheep, severe gastroenteritis and dehydration have been observed.

Samples for confirmation of diagnosis

- **Toxicology** – samples of suspect feed/forage for identification of plants and assay for soluble oxalate
- **Clinical pathology** – serum or plasma for calcium, urea, and creatine assays
- **Histology** – formalin-fixed kidney (LM).

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation is provided by a positive assay of toxic levels of soluble oxalate in the pasture plus the presence of nephrotic kidneys containing calcium oxalate crystals.

Differential diagnosis lists:

For the acute syndrome:
- Parturient paresis
- Hypocalcemia due to starvation or forced exercise
- Lactation tetany
- Transport tetany
- Severe toxemia due to coliform mastitis
- Carbohydrate engorgement
- Uremia.

For the chronic syndrome:
- Pyelonephritis
- Obstructive urolithiasis
- Amyloidosis.

TREATMENT

Primary

The parenteral injection of solutions of calcium salts is a specific treatment of the acute hypocalcemic disease. Calcium borogluconate as a 25% solution given IV or SC in doses of 300–500 mL in cattle, and 50–100 mL in sheep usually effects recovery. A proportion of cases will succumb to kidney failure despite treatment.

Supportive

Treatment should include the provision of ample fluids to decrease precipitation of oxalate crystals in the urinary tract. There is no recommended treatment for chronic cases.

CONTROL

Hungry sheep and cattle should not be allowed to feed on large quantities of the toxic plants. Ample water should be available at all times to facilitate the elimination of the oxalate, but poisoning is likely to occur when hungry sheep are watered and then allowed to graze. Alternative sources of food should be provided for animals grazing pasture dominated by one of the oxalate-bearing plants. Prophylactic feeding of dicalcium phosphate is effective, other calcium salts and bone meal being ineffective, and adequate salt should be made available.

OXALATE-INDUCED EQUINE NUTRITIONAL SECONDARY HYPERPARATHYROIDISM

Synopsis

Etiology Grazing of pure or near-pure swards of some tropical pasture grasses.
Epidemiology Signs appear after 2 or more months on the pasture.
Clinical findings Lameness, swelling of maxillae and/or mandibles; body weight loss.
Clinical pathology High blood levels of parathormone, normal blood calcium levels.
Necropsy lesions Fibrous osteodystrophy of jawbones, joint surface erosion, parathyroid gland enlargement.
Diagnostic confirmation Ratio of calcium: total oxalate in feed less than 0.5 (feed total oxalate > 0.5%), plus biopsy of jaw bone swelling.

ETIOLOGY

Cases have occurred on pastures of:

Setaria sphacelata – setaria
Cenchrus ciliaris – buffel grass
Panicum maximum – guinea grass, green panic
Pennisetum spp.
Brachiaria spp.
Digitaria spp.

Other species of *Setaria*, e.g. *S. incrassata* (purple pigeon grass), and species of *Urochloa* may also be toxic. Hazardous grasses have a calcium:total oxalate ratio of less than 0.5 and they usually contain more than 0.5% total oxalate in the dry matter.[1] Ruminants grazing the same pastures are unaffected because of ruminal bacterial catabolism of most of the crystals, releasing the calcium for absorption.

EPIDEMIOLOGY

Occurrence

This syndrome has occurred in northern Australia, the Pacific, south-eastern Asia, South America, and southern Africa. It affects horses and donkeys.

Risk factors

Animal factors

Horses confined to pure or near-pure swards of hazardous grasses without other sources of feed have developed clinical disease in 2–8 months after starting grazing. All ages and both sexes are susceptible, but nursing mares and weaned foals are more at risk. Removal of affected horses to non-hazardous pasture usually leads to recovery.

PATHOGENESIS

Water-insoluble calcium oxalate crystals (prismatic or druse types) in the leaf cells of these grasses store most of their calcium. These crystals are not digested in the horse's alimentary tract until they reach the large intestine. Because the main site of calcium absorption in horses is the duodenum, the calcium is unavailable for absorption, thus producing a negative calcium balance in the horse and leading to hyperparathyroidism.

CLINICAL FINDINGS

Affected horses have a stiff, stilted action, most evident at gaits faster than walking. This progresses to reluctance to move, and recumbency in severe cases. Exercise initiates or exacerbates the lameness. Some affected horses lose weight despite an ample supply of feed. There is bilateral firm swelling of the maxilla, the mandible or both, over the roots of the cheek teeth.

CLINICAL PATHOLOGY

Concentrations of parathyroid hormone in blood will be abnormally increased. Concentrations of calcium, phosphorus, magnesium, and alkaline phosphatase in plasma do not change consistently from normal. Some horses will have increased concentrations of alkaline phosphatase. Biopsy of the jaw swellings will reveal lesions of *osteodystrophia fibrosa*.

NECROPSY FINDINGS

Swellings of the jaws, erosions or pitting of joint surfaces, and enlargement of both the upper and lower parathyroid glands are seen. Fractures of bones may occur. Histological lesions of *osteodystrophia fibrosa* are seen in the jaw swellings, osteoporosis in long bones, and hyperplasia in the parathyroid glands.

DIFFERENTIAL DIAGNOSIS

The syndrome of lameness and bony swelling of the head is distinctive and, in the presence of the plants in the pasture, confirms the diagnosis. The differential list includes:

- Nutritional secondary hyperparathyroidism is identical but is associated with excessive phosphorus intake in hand-fed horses
- Renal hyperparathyroidism is very rare in horses and will be accompanied by signs of uremia.

TREATMENT

Affected horses should be moved to non-hazardous pasture if possible. Remineralization of the bones can be effected by feeding each horse 2 kg of rock phosphate of low fluorine content, or 2 kg of a mixture of 1 part calcium carbonate and

2 parts dicalcium phosphate weekly for at least 6 months. Each dose of the mineral supplement should be mixed with 3 kg molasses to encourage the horse to eat it. Alternative supplements should contain calcium and phosphorus in the ratio of 2:1. The use of parenteral vitamin D or parenteral calcium preparations is insufficient to correct the problem.

CONTROL

Horses should not be grazed on hazardous pastures for more than 1 month. A legume component should be encouraged in the pasture to provide an oxalate-free source of calcium. Supplementation of each horse with minerals at half the rate used for treatment will protect them against the disease while grazing hazardous pastures.

OXALATE (INSOLUBLE CALCIUM OXALATE RAPHIDE CRYSTAL) POISONING

This is a rare occurrence in agricultural animals because the source of the microscopic needle-like calcium oxalate crystals is limited to a small number of usually-inaccessible horticultural plants:

Alocasia brisbanensis – cunjevoi
Arisaema spp. – jack-in-the-pulpit, indian turnip
Arum spp., e.g. *A. italicum* – arum lily
Caladium spp.
Dieffenbachia spp. – dumbcane
Monstera deliciosa – monstera
Philodendron spp. – philodendron
Schefflera actinophylla – umbrella tree
Symplocarpus foetidus – skunk cabbage
Xanthosma spp.[1]
Zantedeschia aethiopica spp. – calla lily.

Goats and horses are more likely to be affected than other livestock. Insoluble calcium oxalate crystals of the needle-shaped, **raphide** form are the probable 'toxins' in these non-grass plants. When their concentration is sufficiently high they are associated with damage to the buccal mucosa. The principal lesion is an erosive stomatitis causing salivation, swelling and protrusion of the tongue, and dysphagia. These are the only significant lesions. Most animals recover from exposure to these plants.

The physical form of the needle-like calcium oxalate crystals in the specialized cells (idioblasts) of members of the *Araceae* family of plants is the basis for their irritant effects on the buccal mucosa. Calcium oxalate crystals in grasses are structurally different and are prismatic or druses, neither of which are sharp or likely to penetrate mucosa.

CALCINOGENIC GLYCOSIDE POISONING (ENZOOTIC CALCINOSIS)

Synopsis

Etiology Calcinogenic glycosides in a few specific poisonous plants.
Epidemiology Enzootic disease in all species in regions where toxic plants occur.
Clinical findings Chronic lameness, recumbency, wasting, eventual death.
Clinical pathology Elevated blood calcium, phosphorus. Tissue calcification visible radiologically.
Necropsy findings Calcification of all tissues, degenerative arthritis in all limb joints.
Diagnostic confirmation Identification of specific plant.
Treatment Nil.
Control Avoid toxic plants.

ETIOLOGY

Calcinogenic glycosides occur in very small quantities in plant leaves. The aglycone (non-sugar) radical is a vitamin D_3 sterol, a 1,25-$(OH)_2D_3$-like compound. Hydrolysis of the glycoside releases the vitamin D_3 analog causing the development of calcification of soft tissues, reminiscent of hypervitaminosis D. The plants in which these glycosides have been identified are *Solanum malacoxylon* (i.e. *S. glaucophyllum*, *S. glaucum*, *S. glaucescens*, *S. glaucumfrutescens*), *Nierembergia veitchii*, and *Cestrum diurnum* (wild jessamine).

Other plants known to be associated with the same disease, and in which the presence of calcinogenic glycosides is suspected, are *Stenotaphrum secundatum* (crab grass) in Jamaica,[1] *S. linnaeanum* (= *S. hermannii*, *S. sodomaeum*) (apple of Sodom), *S. torvum* (devils fig), and *Trisetum flavescens* (yellow or golden oat grass) in Europe.[2]

The plants are weeds of pasture and are readily eaten by livestock. The glycosides are very stable and resist drying and storage for periods of longer than 1 year. Heating reduces the toxicity of *Solanum malacoxylon* significantly, but has little effect on that of *Trisetum flavescens*.

EPIDEMIOLOGY

Occurrence

Enzootic calcinosis and its causative plants occur in most countries. The disease associated with *Solanum* spp. occurs in tropical and subtropical regions including Africa, Argentina, Brazil, Papua New Guinea, West Indies, and Hawaii, and *Cestrum diurnum* poisoning in southern United States, especially Florida, Texas, and California. Tentative diagnoses have been made in India and Israel. In Jamaica the disease is known as 'Manchester wasting disease', in Hawaii as 'naalehu', and in South America as 'espichamento' or 'enteque seco'.

In Austria and Germany, *Trisetum flavescens* is a common component of alpine pasture and is associated with the disease about 18 months after cattle are put onto the infested pasture. Resident cattle show clinical signs at about 3 years of age. The grass is most toxic when it is young and the clinical signs are worst when the cattle are at pasture. Silage made from the grass is toxic but hay is not.

Animal risk factors

Both sexes and all ages of all animal species are affected; ruminants most commonly, horses less so. Pigs and sucking lambs are least susceptible.

PATHOGENESIS

The glycoside ingested in the plant is hydrolyzed in the rumen by microbial activity, by intestinal mucosal enzymes, and by bone cells, to form the vitamin D_3 analog. Absorption of the active substance results in a dramatic increase in the uptake of calcium from the diet. Blood levels of calcium are markedly increased and this is followed by deposition of calcium in soft tissues. The mode of action of the glycoside is consistent with it having a mode of action similar to that of 1,25-dihydroxycholecalciferol.

CLINICAL FINDINGS

The disease is chronic and may persist for several years. It is characterized by wasting, reluctance to walk, a stiff gait, constant shifting of the weight from foot to foot, and a disinclination to get up or to lie down. Forced exercise is associated with severe distress; some animals may become aggressive. Affected animals stand for long periods with the back arched and the legs stiffly extended. Calcification of blood vessels may be palpable, for example during rectal examination. Cardiac murmurs are audible. Clinical signs subside if the animals are removed from the causative feed, but resorption of calcium deposits in tissues is minimal even 5 years after removal from the affected pastures. Animals left on the toxic pasture eventually become recumbent and die. Fetuses may be affected.[3]

CLINICAL PATHOLOGY

There are 20–25% increases in serum calcium (up to 3.4 mmol/L) and serum

phosphorus (up to 4 mmol/L) concentrations. Tissue calcification should be detectable radiologically. Anemia is common in animals poisoned by *Solanum malacoxylon.*

NECROPSY FINDINGS

Non-specific emaciation, anasarca, and ascites are common. Calcification of all blood vessels, including the aorta and coronary arteries, and of the endocardium is the most readily visible, characteristic lesions. Calcification is also present in the pleura, and the lung parenchyma, which is usually emphysematous, in most other viscera, and in tendons and ligaments. Degenerative arthritis occurs in the limb joints.

DIFFERENTIAL DIAGNOSIS

The history, clinical findings, and discovery of specific toxic plants provide diagnostic confirmation. Repeated overdosing with vitamin D, by injection or administration in compounded feeds, replicates the clinical and necropsy findings.

TREATMENT AND CONTROL

No practicable treatment is available. Careful management of affected pasture in Europe has been shown to significantly reduce the losses due to the disease.

CARDIAC GLYCOSIDE POISONING

Synopsis

Etiology Poisoning associated with naturally occurring organic compounds (cardenolides and bufadienolides) found in specific plants which have specific effects on the myocardium.
Epidemiology Widespread, in most countries; all species affected. Many toxic plants unpalatable but hay and garden waste containing them are toxic; so are seeds in grains and meals contaminated by them.
Clinical findings Two syndromes – acute heart failure and krimpsiekte, comprising poor exercise tolerance, torticollis, dysphagia.
Clinical pathology Significant electrocardiographic abnormality, azotemia.
Necropsy findings Multifocal myocardial degeneration.
Diagnostic confirmation Identification of plant and toxin.
Treatment Activated charcoal and fluids by mouth, parenteral atropine and propranolol; plus spasmolytics and analgesics in horses
Control Avoid pasture or stored feed containing toxic plants.

ETIOLOGY

Cardiac glycosides consist of an aglycone, related chemically to the steroidal hormones, and one or more sugar molecules. There are two groups of the very large number of these compounds, the **cardenolides** and the **bufadienolides**, with different chemical characteristics. Bufadienolides in some plants from southern Africa are cumulative and produce chronic nervous system damage, others are found in other plants produce acute toxicity. Toxins in toads, e.g. *Bufo marinus,* have affinities with the aglycones of bufadienolides and can poison dogs but poisoning of farm animals seems unlikely.

The plant genera with species known to contain cardiac glycosides and which can be associated with an acute syndrome or a chronic cumulative disease (cotyledonosis or krimpsiekte) are listed below.

Acute poisoning:

Acokanthera (Carissa)
Adenium
Adonis[1]
Antiaris
Apocynum
Araujia
Asclepias[2]
Bersama
Bowiea
Bryophyllum[3, 4]
Calotropis
Cascabela (Thevetia)
Cerbera
Convallaria
Corchorus[5]
Cotyledon
Cryptostegia[6]
Digitalis
Diplarrhena
Euonymus
Gomphocarpus
Gynandriris
Haemanthus
Helleborus
Homeria
Hyacinthus
Iris
Kalanchoe
Lidneria
Linaria
Melampyrum
Melianthus
Moraea
Morgania
Nerium
Ornithogalum
Ornithoglossum
Parsonia
Scilla
Scrophularia
Sisyrinchium
Strophanthus
Tacazzea
Thesium
Urginea
Vinca

Chronic poisoning – *Cotyledonosis* or krimpsiekte:

Cotyledon
Kalanchoe
Ornithogallum[7]
Tylecodon[8].

EPIDEMIOLOGY

Occurrence

Poisoning occurs wherever the plants grow and local plant-lists need to be consulted for exact details. Many other related plants, and some in other species, are associated with clinical illness similar to those of cardiac glycoside poisoning. The acute poisoning syndrome is seen in several parts of the world, principally in southern Africa, northern America, and in Australia, but chronic poisoning (cotyledonosis or krimpsiekte) is confined to southern Africa.

Risk factors

Animal factors

Ruminants are most commonly affected, horses less so. Wild animals appear to avoid the plants and some are reputed not to be susceptible. Morbidity rates vary with the intake; case fatality rates are very high.

Plant factors

Some of the plants are most readily eaten when they are in the flowering stage. Many are so unpalatable that they are unlikely to be eaten unless they are cut in with other plants and fed as hay, or seed contaminates a crop of feed grain. Some of them, like *Nerium oleander* (oleander), are decorative plants, and animals get access when they break into gardens or are fed prunings. The plants do not lose their toxicity when dry. Insects and other plants that eat or parasitize plants containing cardiac glycosides may contain the substances in significant amounts.

PATHOGENESIS

Cardiac irregularity and insufficiency, leads to acute or subacute heart failure. Animals that live for several days also develop severe diarrhea. The cardiac arrhythmia is probably the result of the acute effects of cardiac glycosides on the heart, including inhibition of the sodium pump (Na^+–K^+-ATPase) of the cardiac muscle cell membrane, enhanced vagal activity and

reduced coronary artery blood flow through vasoconstriction. Prolonged intake of small amounts of toxic material from the cumulative bufadienolide-containing plants in Southern Africa, produce the paraplegic syndrome known as cotyledonosis or krimpsiekte.

CLINICAL FINDINGS

Acute poisoning

Common signs are apathy, a tendency to stand with head bowed and abdomen tucked up, teeth grinding or groaning, cardiac arrhythmia (tachycardia or bradycardia, heart block), dyspnea, ruminal atony, bloat, diarrhea with mucoid or blood-stained feces, dehydration, and posterior paresis. Sudden death may occur, particularly during exertion. Poisoning by *Homeria* spp. in some parts of southern Africa only results in constipation rather than diarrhea. Additional signs include drooling of saliva, tenesmus, dribbling of urine, muscular tremors, dilated pupils, and seizures. Pigs are likely to vomit.

Chronic poisoning

Cotyledonosis or krimpsiekte in small ruminants is characterized by animals lagging behind the flock, tiring easily, walking with the head loosely dangling and then lying down, usually with the head and neck stretched flat along the ground. Many assume a characteristic posture with the feet gathered together beneath the body, the back arched, the head down, and the neck sometimes twisted towards one side. This torticollis can persist for months or years. Signs are aggravated by exertion; hyperesthesia, trembling, and tetanic spasms may also occur. Additional signs include drooping of the lower jaw, drooling of saliva, paralysis and protrusion of the tongue, and dysphagia with accumulation of half-masticated feed at the back of the mouth. Horses have pronounced torticollis and hyperesthesia and may show signs of colic or be paralyzed. Secondary intoxication of dogs or humans who eat meat from affected livestock occurs even after cooking.

CLINICAL PATHOLOGY

Acute poisoning of sheep by *Homeria pallida* produces progressive hemoconcentration, hyperkalemia, hypochloremia, progressive hyperglycemia associated with rises in catecholamines, cortisol and lactate, and progressive increases in plasma creatinine concentration, plasma α-hydroxybutyrate, dehydrogenase, and lactate dehydrogenase activities. Acute poisoning of cattle by *Bryophyllum* spp. also produces hemoconcentration, progressive hyperglycemia, glycosuria, and progressive increases in plasma urea and creatinine concentrations.[9]

Electrocardiographs (ECGs) may show significant changes in the ECG of affected animals indicating the presence of ventricular fibrillation and ectopic foci in the myocardium. These effects of cardiac glycosides on the ECG of livestock include prolonged P-R interval, depressed or elevated ST segment and increased amplitude and inverted T wave. The QRS complex may widen from delayed AV conduction. Other effects include AV dissociation, varying degrees of heart block, evidence of ectopic foci, and runs of ventricular tachycardia.

Because of the sudden death in many cases, the toxic plant can often be identified in stomach contents by botanical characteristics. In digitalis poisoning, the digitoxin can be assayed in the ruminal contents.

NECROPSY FINDINGS

In acute poisoning, mild-to-severe multifocal myocardial degeneration and necrosis is often present if the patient survives for more than 12 hours. Subendocardial and subepicardial hemorrhages and hemorrhages into the mucosa and lumen of the large intestine are common in acute cases. Atelectasis of lung lobules is common, and pulmonary congestion and edema secondary to cardiac failure may be seen. Fragments of the plants responsible for poisoning may be recognized in stomach contents. Nephrosis has been seen occasionally. Hemorrhages of the rumen wall, and necrosis and ulceration of the omasal leaves have been seen in animals affected for several days. Evidence of hepatic insufficiency, including jaundice, is present in some poisonings, but its pathogenesis is unclear.

Toxins may be detected in rumen or stomach contents using chromatographic techniques.[10–12]

DIFFERENTIAL DIAGNOSIS

The diagnosis depends on the detection of one of the toxic plants, either in the pasture or in conserved roughage, in the environment of animals showing characteristic clinical signs, or sudden death. Diagnosis confirmation is established by identification of the plant, the cardiac glycoside in it, or both, in ingesta in association with myocardial lesions.

Differential diagnosis list

Other poisonings which are associated with cardiomyopathy and similar clinical signs include:

- *Urechites lutea*
- *Albizia tanganyicensis, A. versicolor*
- *Fadogia homblei* (*F. monticola*)
- Fluoroacetate
- *Galenia africana*
- Gossypol
- Ionophore antibiotics, e.g. monensin
- *Pachystigma* spp.
- *Pavetta* spp.
- *Ornithoglossum viride*
- *Pseudogaltonia* (*Lidneria*) *clavata*

and by nutritional deficiencies of:

- vitamin E/selenium
- copper

and other is associated with sudden death.

TREATMENT AND CONTROL

Primary treatment

Removal of animals from the suspect pasture or changing the source of conserved roughage is usually obligatory. Activated charcoal is effective. A dose of 5 g/kg is recommended for ruminants and may need to be repeated.

Supportive treatment

Oral fluid replacement therapy for rehydration (150 mL/kg in divided doses over 24 hours) and parenteral antiarrhythmic drug therapy with atropine (0.5 mg/kg) for heart block and propranolol (5 mg doses to effect) for tachycardia are also recommended.[9] The recovery rate declines sharply with the lapse of time between ingestion of the plant and treatment.

DICOUMARIN DERIVATIVES (INCLUDING SWEET CLOVER) POISONING

Synopsis

Etiology Coumarin, ferulenol and melilotin, normal constituents of some plants, are converted to dicoumarol in the process of infection by molds of the cut plant during the making or storage of hay or ensilage.
Epidemiology Outbreaks occur on exposure to toxic plants or moldy hay made from specific plants, especially *Melilotus* spp. Insignificant trauma is associated with massive hemorrhage.
Clinical findings Pallor, weakness especially newborn calves. Hemorrhage may be internal and not visible.
Clinical pathology Severe anemia, prolonged clotting, prothrombin times; dicoumarol assay on feed is positive.
Necropsy findings Massive subcutaneous, subserosal hemorrhages, hematoma.
Diagnostic confirmation High dicoumarol content of feed.
Treatment ***Primary:*** change feed, vitamin K parenterally. ***Supportive:*** Blood transfusion.
Control Avoid feeding moldy sweet clover hay or ensilage; dilute with other feed.

ETIOLOGY

Coumarin and melilotin, normal constituents in some plants, are converted to dicoumarol (dicoumarin or dihydroxycoumarin) by fungi which grow in hay or ensilage made from the plants listed below:

- *Anthoxanthum odoratum* – sweet vernal grass[1–3]
- *Lespedeza stipulacea* – lespedeza
- *Melilotus alba* – sweet or Bokhara clover,[4] is the commonest vehicle for poisoning. The toxic level of dicoumarol in moldy sweet clover feed samples is approximately 20 mg/kg of feed. Hay containing 10–20 mg/kg dicoumarol can be fed safely for at least 100 days; 30 mg/kg is associated with illness after 4 months of feeding and 60–70 mg/kg is associated with illness after only 17 days
- *M. altissima* – tall melilot
- *M. indica* – King Island melilot, Hexham Scent
- *M. officinalis* – yellow sweet clover, ribbed melilot.

The infecting fungi include *Aspergillus* spp. and other unspecified molds.

A similar disease is associated with the ingestion of *Ferula communis* var. *brevifolia*, which contains the hypothrombinemic substance ferulenol (4-oxycoumarin).[5] Deer browsing *Wikstroemia indica* have developed a similar condition.

A common introduction to the diseases is the occurrence of severe bleeding after surgery or injury, or subcutaneous swelling of the head and neck in newborn animals. A short course (24–48 hours) and a high case fatality rate are usual.

EPIDEMIOLOGY

Occurrence

Sweet clover poisoning is recorded most commonly in North America where sweet clover is grown as a fodder crop. In affected herds the morbidity rate is about 12%, with a case fatality rate of 65%. Aborted fetuses and calves less than 2 weeks of age are the common subjects in some herds. The disease occurs most commonly during the winter months when stored hay or ensilage is fed to cattle. Its occurrence has brought the plant into disfavor and the disease incidence has been greatly reduced for this reason.

Risk factors

Plant factors

Not all moldy sweet clover hay or silage contains dicoumarol and the degree of spoilage is no indication of the toxicity of the hay sample. Varieties of sweet clover differ in their content of coumarol and thus in their potential toxicity. For example, the Cumino variety has a low, and the Arctic variety a high, coumarol content.

Grazing the crop is not dangerous but making it into hay or ensilage without the development of mold is difficult because of the succulent nature of the plant.

Dicoumarol concentrations in sweet clover hay bales, hay stacks, or silage vary widely, being highest in small bales; round bales contain more than hay stacks, and the levels are low in silage. Properly cured silage contains less still because of its anaerobic conditions; dicoumarol-producing fungi require oxygen. The levels of dicoumarol are highest in the outer parts of hay bales, presumably because they are exposed to moisture.

Animal factors

The disease can occur in all species, but is most common in cattle, less so in sheep and very rare in horses. Clinical signs may appear without apparent precipitating cause, but trauma, surgery (castration, dehorning), and warble fly migration are often followed by deaths from hemorrhage. Severe losses occur in newborn calves during the first few days of life when their dams have been fed poisonous hay without the dams being clinically affected.

Importance

In most outbreaks heavy mortalities occur without warning.

PATHOGENESIS

Dicoumarol competitively inhibits vitamin K epoxide reductase. Reduced vitamin K is essential for final carboxylation and activation of clotting factors II (prothrombin), VII (proconvertin), IX (Christmas factor), and X (Stuart factor). Inadequate synthesis of these factors results in impaired fibrin stabilization of platelet plugs, and affected animals are subjected to internal and external hemorrhage and anemia. The degree of hypoprothrombinemia is directly related to the amount and duration of dicoumarol ingestion. Coagulation system activity is maintained until the natural decay of the clotting factors in place at the time that poisoning occurs (24–36 hours after the intake of toxin). Large extravasations of blood into tissues may provide signs of disease because of the pressure exerted on internal organs. Large hemorrhages in the pelvic cavity and broad ligament of postpartum cows often delay uterine involution and shedding of fetal membranes.

CLINICAL FINDINGS

Extensive hemorrhages into subcutaneous tissues, intermuscular planes, and under serous surfaces is associated with discomfort. The hemorrhages may be visible and palpable as hematoma, but are not painful or hot and do not crepitate. They may be associated with stiffness, lameness, disinclination to move, and even recumbency. One limb may be severely swollen. There are no signs of toxemia, the affected animal continues to eat well and the temperature, respiration, and heart rate are normal until the terminal stages, but the mucosae are pale and often show hemorrhages. Hematuria, epistaxis, and dysentery occur rarely. Accidental and surgical wounds are associated with severe bleeding, but frank hemorrhages from the mucosae seldom occur. Newborn calves may show extensive swelling of the head and neck and become weak from internal or external hemorrhages within a few hours of birth.

When the loss of whole blood is severe, signs of hemorrhagic anemia appear. The animal is weak, the mucosae pallid, the heart rate increases, and the absolute intensity of the heart sounds increases markedly. A short course of 24–48 hours and a high case fatality rate are usual.

CLINICAL PATHOLOGY

Severe anemia with markedly increased clotting and prothrombin times are characteristic of the disease. Extension of prothrombin times occurs before there is any increase in clotting time or clinical evidence of bleeding, and is therefore a useful prognostic test.

Dicoumarol analysis

Representative samples of suspected feed should be submitted for analysis of the content of dicoumarol. Clinicopathological

evidence of toxicity in sheep occurs on diets containing 10 mg/kg of dicoumarol. However, significant changes in clotting time do not occur on diets containing less than 20–30 mg/kg. Similar changes commence in lambs and calves when the dietary intake of dicoumarol rises to above 2 mg/kg BW.

Quantitative determination of dicoumarol levels in blood and tissues are now available, and are especially valuable in aborted fetuses and newborn calves in which there may have been inadequate opportunity for clinical examination. High levels of dicoumarol in the feed (20–30 ppm) and in the liver (1 ppm) are supportive evidence.

NECROPSY FINDINGS

Subcutaneous hemorrhages and large hematomata occur in areas where normal activity produces mild contusion, such as the flanks, carpal and tarsal joints, and the side of the body where the animal exerts pressure while lying down. Hemorrhages of the peritoneal surface of the rumen and massive retroperitoneal hemorrhage around the kidneys are frequently observed. In contrast to hemorrhages typical of septicemia, extravasation is uncommon in the lungs, kidneys, and adrenals. The carcass is pale and there is no intravascular hemolysis, jaundice, hemoglobinuria, or hemosiderosis. Histological examination is unrewarding, other than as a means of eliminating other potential causes of diathesis, such as vascular diseases. The collection of feed samples and tests required for confirmation of the diagnosis are as described for clinical pathology.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation is based on detection of dicoumarol, or similar compound, in the feed. Differential list includes those diseases characterized by blood loss anemia resulting from spontaneous hemorrhage:

- Poisoning by other specific plants, with or without their contamination by molds (see above)
- In purpura hemorrhagica, but this disease is uncommon except in horses and rarely affects more than one animal in a group; clotting and prothrombin times are not abnormal, the defect being one of vascular damage
- Angioneurotic edema cases are not usually accompanied by an anemia
- Ptaquiloside poisoning
- Trichloroethylene-extracted soybean meal poisoning, but large extravasations of blood are unusual.

TREATMENT

Primary

Feeding of the suspected hay or silage should be stopped immediately, but new cases may continue for up to about 6 days. Vitamin K_1 (naturally occurring vitamin K_1) is an effective antidote for sweet clover poisoning. A single dose of vitamin K_1 at a rate of 1.1–3.3 mg/kg BW intramuscularly is effective in restoring the prothrombin times to within normal range within 24 hours in cattle which have been fed moldy sweet clover hay containing 90 mg/kg of dicoumarol. Vitamin K_3 (synthetic vitamin K, menadione sodium bisulfite) is ineffective as treatment or prevention.

Supportive treatment

Animals with clinical evidence of severe hemorrhage should be given a whole blood transfusion at the rate of 10 mL/kg BW. This will usually return the prothrombin time to normal within several hours.

CONTROL

Sweet clover forage must be carefully prepared, and not fed if it is damaged or spoiled during curing. Moldy portions of hay or silage should be discarded and representative samples of suspected feed should be submitted for analysis of dicoumarol content.

If the disease is suspected, discontinue the feed immediately. After 3 weeks, the sweet clover forage may be fed alone, but preferably mixed with another type of unspoiled roughage at the rate of one part sweet clover to three parts unspoiled feed. This mixture should be alternated with unspoiled hay on a weekly basis, or for longer periods if experience shows this to be safe.

Suspected feed should not be fed for at least 3 weeks before surgery such as castration or dehorning. Pregnant cows should not receive sweet clover during the last 3 weeks of pregnancy.

DITERPENOID ALKALOID POISONING

Synopsis

Etiology Toxic plants in genera *Aconitum*, *Delphinium*, *Erythrophleum* spp. Toxins include aconitine, delphinine.
Epidemiology *Delphinium* spp. occur over extensive range lands in USA. Toxic *Erythrophleum* spp. occur in northern Australia, Asia, Africa. Poisoning commonest in cattle; all species susceptible.
Clinical findings Tremor, incoordination, paralysis; salivation, vomiting, ruminal tympany; death due to respiratory paralysis or heart failure.
Clinical pathology Toxic alkaloids in blood, tissues, and plants.
Necropsy Incidental aspiration pneumonia in a few.
Diagnostic confirmation Toxic alkaloids in blood and tissues (*Delphinium*).
Treatment Physostigmine (*Delphinium*).
Control Pasture only on mature *Delphinium* plants; avoid all consumption of *Erythrophleum* plants.

ETIOLOGY

Diterpenoid alkaloids occur in *Delphinium* spp. (larkspurs), *Erythrophleum* and *Aconitum* spp. and are associated with poisoning in grazing animals. There are a very large number of alkaloids (not identified here) in five types: aconitine, barbitine, lycoctinine, delphinine, and heteratisine. The number of alkaloids in a single plant species may also be large, e.g. *D. glaucescens* contains 14. All of the alkaloids exert the same effect but they vary widely in their toxicity and in their concentration in plants at different times.

There are over 100 species of these plants but a full alkaloid content profile has been completed in only a few. The commonest species known to contain toxic diterpenoid alkaloids and to be associated with disease in livestock are:

Aconitum napellus – monkshood, wolfsbane
Delphinium barbeyi
D. bicolor
D. geyeri
D. glaucescens
D. glaucum
D. nuttallianum
D. occidentale
D. tricorne
D. virescens – larkspurs
Erythrophleum spp., e.g.
E. chlorostachys - Cooktown ironwood.

Some of the species assumed to contain the alkaloids because of their known association with the disease are:

Delphinium ajacia
D. andersonii
D. consolida
D. elatum
D. hybridum
D. nelsonii
D. parryi
D. ramosum
D. robustum
D. trollifolium.

The taxonomy of *Delphinium* spp. is unsettled and the nomenclature used may vary from other sources.

EPIDEMIOLOGY

Occurrence

North America and Europe are the principal locations of *Delphinium* and *Aconitum* spp. poisonings. *Erythrophleum* spp. occur in Africa, Asia, and Northern Australia.

Risk factors

Plant factors

Aconitum spp. are found in the UK and Europe but poisoning occurs rarely. Rangeland larkspurs (*Delphinium* spp.) are important pasture plants in North America. Many of them are associated with heavy mortalities in livestock. The incidence of poisoning varies widely with season and climate, due probably to wide variations in the concentration and chemical composition of specific alkaloids in the subject plants.

Animal factors

All animal species are susceptible but most cases are seen in cattle, less often in sheep, and rarely in horses. Cattle may develop a strong aversion, up to 40%, to larkspur plants in the pasture and refuse to eat them after the first exposure. The aversion is associated with identifiable substances in the plant and these are being used experimentally to attempt to control ingestion of the plants. Continued exposure to larkspurs does not reduce either the animals' sensitivity, or their ability to metabolize the alkaloids.[1]

PATHOGENESIS

Experimentally, tall larkspur administered to cattle produces muscle tremor, ataxia, recumbency, and death from respiratory paralysis. Cattle are more susceptible than sheep. Methyllycaconitine acts as a postsynaptic cholinergic blocker in cattle. Physostigmine appears to be an effective antidote. The skeletal muscle weakness and, later, paralysis, result from the inactivation of the motor unit of the muscle fibers. Some of the alkaloids are known to be associated with malfunction of the neuromuscular junction, but interference with the other parts of the neuromuscular arc is also possible. At sublethal doses, signs peak at 5–9 hours after first appearance, but the effects can be cumulative. The signs in the herd disappear about 4 days after the plant is withdrawn from the diet.[2] The alkaloids in *Erythrophleum chlorostachys* have a cardiac glycoside-like action.

CLINICAL FINDINGS

Initially in larkspur poisoning there is an episodic weakness with muscle tremor and staggery gait, followed by paralysis of the limbs and recumbency. There is drooling of saliva, vomiting, and ruminal tympany, all probably due to paralysis of the striated muscle of the esophagus. Bloated animals can still belch. Constipation is a common sign and is thought to be due to failure to drink any water. Diarrhea is reported in *Aconitum* spp. poisoning, possibly due to the presence of additional toxins. Cases that have ingested a lethal dose usually die of paralytic respiratory failure.[3] This may happen after a very short course if the intake of toxin is high. Aspiration of ruminal contents after regurgitation also causes some deaths. In the terminal stages, the pupils are dilated and the pulse and respiration may be barely perceptible.

Erythrophleum chlorostachys (ironwood) and *E. guineense* are both poisonous to all animal species. Clinical signs include anorexia, a staring expression, partial blindness, tremor, ataxia, contraction of abdominal muscle, increased heart sounds, mucosal pallor, and terminal dyspnea. Horses poisoned by *E. chlorostachys* have loud and often irregular heart sounds, dyspnea, sporadic contraction of abdominal muscles, and die rapidly.

CLINICAL PATHOLOGY

There are no specific findings in larkspur poisoning other than identification of toxic alkaloids in plants, ingesta, blood, and tissues. Many cases will be dehydrated because of the inability to drink.

NECROPSY FINDINGS

There are no specific findings. Aspiration pneumonia may be an incidental finding in some cases.

DIFFERENTIAL DIAGNOSIS

Differentiation from other plant poisonings causing incoordination, recumbency, and death in cattle on extensive grazing is usually based on botanical identifications. Diagnostic confirmation of larkspur poisoning depends on chemical identification of the causative alkaloids in the rumen contents and the plants. The differential diagnosis list includes:

- *Phalaris* spp. (tyramine poisoning)
- *Paspalum* spp. Infested with *Claviceps paspali* (paspalitrem poisoning)
- *Lolium rigidum, Agrostis avenacea* infested with grass nematodes, and *Clavibacter toxicus* (tunicaminyluracil poisoning)
- Lead poisoning
- Organophosphorus compounds.

TREATMENT

Primary

Physostigmine and carbachol are effective antidotes for *Delphinium* spp. poisoning, but require repeated injections and will have only limited practical value.[4] No specific treatment has been identified for *Erythrophleum* spp. poisoning, but access to immature plants, suckers, and foliage of mature trees should be prevented.

CONTROL

Control of *Delphinium* spp. poisoning is only possible by careful management of pasture and denying animals' access to badly infested areas. Deferring grazing until after the flowering stage, when the concentration of toxin has declined, avoids poisonings but the quality of the forage has declined badly. Sheep are more resistant to the poisoning than cattle, but are not fond of the plant and may have to be restricted to areas where it does not occur. Weedicides are variable in their efficacy against *Delphinium* spp. and have low efficacy against the deep-rooted perennial species.[5] Attempts to create and maintain a long-standing aversion to the plants to prevent ingestion of them and allow grazing of infested pastures have encountered disabling difficulties.[6,7] Long-term administration of carbachol and supplementation of the diet with salt also have no value as control measures.[8]

GLUCOSINOLATE POISONING

Synopsis

Etiology Glucosinolates in *Brassica* spp. and related plants used as fodder.
Epidemiology Outbreaks in cattle grazing fodder crop or fed crop by-products, especially cake or meal made from residues of oil extraction from seeds.
Clinical signs Two syndromes – goiter and reduced growth rates, or diarrhea; depending on the chemical composition of the glucosinolate.
Clinical pathology Assay of blood levels of glucosinolate or metabolic end-products.
Necropsy findings Goiter.
Diagnostic confirmation Positive blood assay of glucosinolate.
Treatment ***Primary***: Nil. ***Supportive***: symptomatic.
Control Avoid toxic plants, meals.

ETIOLOGY

Glucosinolates are organic substances containing a sulfonated oxime group, combined with glucose in the form of glycosides. The metabolic by-products include isothiocyanates, nitriles, oxazolidinethiones, and carbinols. These plants also contain thioglucosidase (myrosinase), the enzyme needed to hydrolyze the glucosinolate to glucose and the toxic radical. Although the toxic substances may be excreted in cows' milk, the observed goitrogenic effect when the milk is fed may be due to the low iodine content of the milk.

A special group, mustard oil glucosinolates, occurs in the foliage of some plants and is concentrated in their seeds and the seeds of some of the others. Plant sources of glucosinolates are mostly from the family Brassicaceae (Cruciferae) as listed in Table 33.1.

EPIDEMIOLOGY

Occurrence

Outbreaks of glucosinolate poisoning are common wherever intensive animal husbandry is practiced, especially where plant wastes from the food industries are fed to livestock in feedlots.

Risk factors

Plant factors

Plants in several uncommon botanical families contain glucosinolates, but animal poisoning is largely limited to the agriculturally important members of the Brassicaceae (Cruciferae) family, all members of which contain these substances. The common fodder plants and commercial vegetables listed in Table 33.1 have all been associated with poisoning. Seed oil crops, such as seed rape and mustard seed, may be fed as roughage after the seed has been harvested, and represent a possible source of poison. Large quantities of seed also become available for animal feed, and because of the large quantity fed may be associated with the enteric form of the disease.[1,2] Glucosinolates are present in the vegetative parts of these plants but are in much higher concentration in the seeds. The glucosinolate concentration varies widely between species of plants, e.g. *Brassica napus* is much more goitrogenic than *B. campestris*, and even between cultivars of the same species at different times of the year and under different conditions of growth. Including the rapeseed in ensilage does not reduce its goitrogenicity. Plant stress, including drought and overcrowding of plants, and the feeding of high sulfate diets are known to increase the concentration of the toxin, and small young leaves may contain as much as five times more glucosinolate than large, mature leaves. The high content of sulfate and glucosinolates in cabbages makes it a damaging feed.[3] The commonest and most serious cases of poisoning occur in animals fed rapeseed or rapeseed meal. Diets containing as low as 3% of rapeseed meal may be associated with goiter and reduced weight gain in pigs. The meal is often fed in amounts up to 20% of the diet. An extensive plant-breeding program has produced varieties of seed rape that have very low concentrations of glucosinolate.

Goitrogenic effect	
Pasture and forage plants	
Rape (syn. Canola)	*Brassica napus*

Charlock	*Sinapis arvensis*
	Erysimum cheiranthoides

NB: The taxonomy of the Brassica *spp. varies between countries.*

PATHOGENESIS

Glucosinolate metabolites and the relative proportions of them, produced by enzymatic breakdown of the glucosinolates depend largely on the composition of the glucosinolate present, but factors such as pH also have an effect. There are three groups of glucosinolates, each producing a particular metabolite:

- Glucosinolates producing principally **isothiocyanates** – some of these (e.g. allyl-isothiocyanate, 3-butenyl isothiocyanate) are the irritant components of mustard oils, contained in plant seeds, and are irritant to alimentary tract mucosa causing gastroenteritis, diarrhea, and dysentery. Others, present in the leaves of the plants, are hydrolyzed further to form thiocyanate ion
- Glucosinolates producing principally **thiocyanate** ion, which, when taken in small amounts over long periods, is a goitrogen. It is likely to be associated with goiter only when the iodine status of the diet is low. This substance reduces iodine capture by the thyroid gland and the condition can be alleviated by the administration of iodine (see also cyanogenic glycoside poisoning, p. 1852)
- **Thiones** (e.g. 5-vinyloxazolidine-2-thione or goitrin), produced by the hydrolysis of glucosinolates present in the seeds of cruciferous plants, are more potent goitrogens than thiocyanate ion. They interfere with the synthesis of thyroxin, and iodine is ineffective in the treatment of the poisoning. Clinically, the effects of low level intakes of isothiocyanate and thiones include goiter and a related reduction of the growth rate in the young, and possibly an indirect, depressing effect on reproduction in adults. The reduction in growth rate may be due to the observed hypothyroidism but there is, in addition, a reduction in palatability with diets containing high levels of glucosinolates. This effect is most noticeable in young pigs but may also be evident in high-producing cows
- Polioencephalomalacia – there is a positive correlation between cruciferous plants (*Brassica* spp.) and polioencephalomalacia in ruminants, e.g. in **rape blindness**, but the brain lesion is probably associated with the high sulfur content of the plant.[4]

Tainting of milk occurs in cows fed plants, more commonly plant seed by-products, containing glucosinolates. The odor and off-flavor are due to volatile thiocyanates and not to isothiocyanates. Treatment of the feed with caustic soda prevents the tainting. Tainting of chicken and turkey meat by diets containing glucosinolates has not been matched by unequivocal evidence of similar problems in mammalian meat, but the occurrence is suspected.

Mustard oil glucosinolates are associated with violent diarrhea, sometimes dysentery, and abdominal pain in animals eating large amounts of seeds. The rape blindness is regarded as a mild form of polioencephalomalacia. No identifiable pathogenesis is advanced as being associated with acute pulmonary emphysema and interstitial pneumonia, or the ill-defined 'digestive disturbance' seen in some outbreaks of poisoning with these plants.

CLINICAL FINDINGS

Goiter

Enlargement of the thyroid may occur at any age, including the newborn of dams fed the plants during pregnancy. Deaths due to hypothyroidism, after a period of hypothermia, weakness, recumbency, and coma, are more likely in the latter age group. In older animals the accompanying syndrome will be weight loss or failure to gain weight. In bad outbreaks the thyroid is enlarged by 50% in most lambs, with more than 10% showing gross enlargement. Affected flocks have longer than usual gestation periods and lamb mortality is increased three-fold, due to poor vigor of the lambs.[5]

Enteritis

Abdominal pain, salivation, vomiting in some cases, diarrhea, dysentery, and a short course with a fatal outcome is common after animals have access to large amounts of reject seeds of these plants.

Polioencephalomalacia (rape blindness)

Frank polioencephalomalacia, characterized by blindness, head pressing, aimless walking, ataxia, and recumbency, occurs in cattle, and rape blindness is manifested by the sudden appearance of blindness in cattle and sheep grazing these crops. The eyes are normal on ophthalmoscopic examination; the pupils show some response to light and may or may not be dilated. Complete recovery usually occurs but may take several weeks.

Acute pulmonary emphysema and interstitial pneumonia

This has been observed only in cattle. Affected animals show severe dyspnea, with stertorous rapid respiration, mouth breathing, and subcutaneous emphysema. The temperature may or may not be elevated. Affected animals may survive but often remain chronically affected and do poorly.

Other unrelated diseases

Digestive disturbances in steers on rape are usually accompanied by anorexia, the passage of small amounts of feces, absence of ruminal sounds, and the presence of a solid, doughy mass in the rumen. Only a small quantity of sticky, black material is present on rectal examination. **Photosensitization** and **bloat** are also encountered in cattle grazing rape.[6]

CLINICAL PATHOLOGY

The clinical pathology of goiter, weight loss, diarrhea, and dysentery are included in the articles on those diseases. Assays of blood levels of glucosinolates and their metabolic products are available. The diet and the pastoral environment should be examined for the presence of the plants and plant by-products known to contain glucosinolates.

NECROPSY FINDINGS

The goiter, enteritis, pulmonary emphysema, and interstitial pneumonia are non-specific and dealt with at other points in the text. In *Thlaspi arvense* poisoning there may be massive edema of the forestomach walls.[7]

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation is detection of glucosinolates in the blood of animals with access to relevant plants or feedstuffs made from them.

Differential diagnosis list:

Goiter:

- Nutritional deficiency of iodine
- A low-level but continuous intake of cyanogenetic glucosides in, e.g. pasture plants such as *Cynodon aethiopicus*, *C. nlemfuensis* (couch grasses), and *Trifolium repens* (white clover)
- Inherited goiter.

Diarrhea with or without dysentery. There are many infections and toxins associated with diarrhea and dysentery. Those most commonly associated with outbreaks include:

- Arsenic poisoning
- Salmonellosis
- Other poisonous plants in which the toxin has not been identified.

TREATMENT

Primary

There are no specific treatments.

Supportive

Attention should be directed at relieving the clinical signs.

CONTROL

Avoidance of losses can be best achieved by avoiding the use of the poisonous substance or the grazing of the affected area. Some of the goiters can be relieved by the administration of iodine (see under nutritional deficiency of iodine), and avoidance of high sulfate diets reduces the level of glucosinolate production. Plant by-products containing glucosinolate derivatives can be treated with alkali solutions to destroy their toxicity.

INDOLE ALKALOID POISONING

A large number of indole alkaloids occur in fungi, especially the *Claviceps* and *Acremonium* spp. In plants there are also some groups of toxins with similar toxic effects, and similar to those of the fungi. The important two are the β-carbolines and the dimethyltryptamines; and then there are hydroxymethyltryptamines, and a miscellaneous group of alstonine and related toxins. Plants included in the latter group and which are associated with an incoordination syndrome like phalaris staggers are *Gelsemium sempervirens* (yellow jessamine), *Alstonia constricta* (bitter bark tree) and the mushroom *Psilocybe* spp. (mad or magic mushroom). *Poa hueca, Urtica* spp. (stinging nettle) are associated with a more acute syndrome of convulsions and sudden death. *Phalaris* spp. are unusual in that they contain both β-carbolines and methylated tryptamines. Related indole alkaloids of the pyrrolidinoindoline type have poisoned livestock in Australia (idiospermuline in *Idiospermum australiense*) and North America (calycanthine in *Calycanthus* spp.), producing tetanic convulsions.

β-CARBOLINE INDOLEAMINE ALKALOID POISONING

There is a long list of carbolines in plants, including harmaline, norharmane, tetrahydronorharmane, harmine, harmol, and 3-methyl harmane. Administration of synthetic forms of these compounds is associated with the appearance of clinical

signs identical with those occurring in poisonings with *Peganum harmala* (African or Turkish rue), *Peg. mexicana* (Mexican rue), *Phalaris* spp., *Tribulus* terrestris (caltrop, catshead burr), *T. micrococcus* (yellow vine), *Kallstroemia hirsutissima* (hairy caltrop, carpet weed) and *K. parviflora*.[1] The characteristic syndrome, similar to that of an upper motor neuron lesion, includes hyper- or hypomotility, sometimes sequentially in the same patient, muscle tremor, partly flexed paresis of the thoracic and/or the pelvic limb, hypermetria, a wide-based stance, crossing of the limbs, extension of the neck, swaying of the head, walking backwards, sudden jumping movements, sham eating, and terminal convulsions. The net effect, seen in all farm animal species and camels, is one of easy stimulation, by harassment, of gait incoordination and stumbling, fetlock knuckling, easy falling, and recumbency. The signs appear gradually, are similar to, but less severe than, those associated with the methylated tryptamines and are irreversible. There is axonal degeneration in peripheral nerves. Long-term cases of *T. terrestris* poisoning pivot on their front limbs while their hindlimbs trace a circle. The pivoting is related to the unilateral muscle atrophy of limbs of one or other side.[2]

DIMETHYLTRYPTAMINE AND PHENYLETHYLAMINE POISONING

Synopsis

Etiology Associated with the ingestion of the *Phalaris* spp. grasses containing dimethyltryptamine (causing an incoordination syndrome), phenylethyltryptamines (causing a cardiac arrest-sudden death syndrome), a thiamine analog (causing a polioencepalomalacia).
Epidemiology Outbreaks on lush, rapidly growing pasture; sheep most commonly affected.
Clinical findings Incoordination, later convulsions in sheep. In cattle also incoordination of tongue and pharynx. Sudden death cases have very brief course with little to observe.
Clinical pathology Isolation of tryptamines in plants and affected animals.
Necropsy lesions Green-gray discoloration of renal medulla, medulla oblongata, brain stem.
Diagnostic confirmation By detection of tryptamines in body fluids or cadaver.
Treatment Nil.
Control Limitation of access to causative plants.

ETIOLOGY

The incoordination syndrome is associated with dimethyltryptamines in:

- *Phalaris aquatica* (synonym *P. tuberosa*)
- *P. angusta*
- *P. arundinacea* – reed canary grass
- *P. caroliniana*
- *P. brachystachys*
- *P. canariensis* – commercial canary grass
- *P. minor* – wild canary grass
- *P. paradoxa* – paradoxa grass and rhompa grass (a hybrid).

Acute death due to cardiac arrest, originally ascribed to the methylated tryptamines, is now thought to be the related phenylethylamines, and the sudden death-polioencephalomalacia to thiamin analogs produced by the ruminal flora.

EPIDEMIOLOGY

Occurrence

The disease has been recorded in many parts of Australia, New Zealand, South Africa, Spain, California, and South America where the phalaris grasses are in common use as pasture plants. Heavy losses occur on individual farms due to sudden deaths, but careful management relieves the burden of the incoordination syndrome.

Risk factors

Plant factors

The individual tryptamine alkaloids associated with the disease vary significantly in their toxicity so that plants in a pasture can vary greatly in the danger they present. The concentration of tryptamines in the grass is increased by high environmental temperature and their growing in the shade, and toxicity is greatest when the plants are young and growing rapidly, especially after a break in a dry season. Provision of cobalt appears to stimulate the proliferation in the rumen of microorganisms which are capable of destroying the causative agent, but sheep affected with phalaris staggers do not usually show any signs of cobalt deficiency. Under some circumstances, plants with low tryptamine content will be associated with the syndrome.

Animal factors

Up to 30% of a flock may be affected when the *P. aquatica* dominates the pasture or is preferentially grazed. On lightly stocked pastures the **sudden death syndrome**, with signs appearing within 4 hours but usually between 12 and 72 hours after going onto the pasture, is most likely to occur. Deaths are most common in hungry sheep in the early morning or in foggy or cloudy weather. This syndrome is also recorded in cattle on irrigated *Phalaris* spp. pasture in hot humid weather.

The **incoordination syndrome** occurs in similar circumstances, but in sheep that have protracted or repeated exposure. In this case, clinical signs appear 2–3 weeks after sheep are put onto pasture showing new growth, usually in the autumn or early winter. Both forms may occur in the one flock of sheep, and also in feedlots. Sheep of all ages are affected and mild cases may occur among cattle.

PATHOGENESIS

The tryptamines, structurally similar to serotonin, are present in the grass under certain conditions and are associated with the incoordination syndrome by a direct action on serotonergic receptors in specific brain and spinal cord nuclei.[3] By interfering with the functions of serotonin, a chemical transmitter in the autonomic nervous system with functions analogous to those of acetylcholine, the alkaloids are associated with both neurological signs and the cardiac abnormalities of tachycardia and ventricular block. The nervous disturbances of the incoordination syndrome are the direct result of dimethyltryptamine, and the cardiorespiratory disorder by phenylethylamine. The nervous disturbance appears to be functional in contrast to that associated with β-carbolines, which is accompanied by axonal degeneration and an irreversible syndrome. The nervous signs are probably tremorgenic, rather than convulsive, so that the limb movements observed are the result of the patient attempting to regain its feet rather than a centrally mediated convulsion.

A characteristic of the disease is a greenish-gray discoloration of the brain stem, diencephalon and dorsal root ganglia, and kidneys. The pigmentation is due to the accumulation of indole-like pigments at the locations where the causative alkaloids act, but the pigments themselves do not have any effect on the signs.

The variability in the numbers affected and the severity of the disability in sheep flocks from day to day appear to be due to the variation in the amount of toxin absorbed, possibly affected by the degree of detoxication of the tryptamines in the rumen. The reduction in severity of an outbreak associated with dietary supplementation with cobalt is thought to be effected in this way.

CLINICAL FINDINGS

The **sudden cardiac death syndrome** is manifested by sudden collapse, especially when excited, a short period of respiratory distress with cyanosis, and then death or rapid recovery. During the stage of collapse there is arrhythmic tachycardia followed by ventricular fibrillation and cardiac arrest. Consciousness is retained.

The **sudden death-polioencephalomalacia syndrome** cases are rarely observed alive, but occur commonly after short periods of feed deprivation.

In the initial stages of the **incoordination syndrome** in sheep, signs appear only when the animals are disturbed. Hyperexcitability and generalized muscle

tremor, including nodding of the head, occur first. On moving, the limb movements are stiff and the hocks are not bent, causing dragging of the hind feet. Incoordination and swaying of the hindquarters follow. Some cases walk on their knees, others bound or hop, others knuckle at the fetlocks; some show splaying of the digits. In the most severe cases collapse into lateral recumbency is accompanied by paddling movements of the legs and irregular involuntary movements of the eyeballs. There is rapid respiration and irregular tachycardia. The sheep may die at this stage but if left undisturbed they may recover and walk away apparently unaffected. If the sheep are left on the pasture the condition worsens in individual cases, the animal becoming recumbent and manifesting repeated convulsive episodes until death supervenes.

There is a great deal of variation from day to day in the number of sheep showing signs and in the severity of the signs observed. Even after sheep are removed from the pasture the clinical state may deteriorate and, although some appear to recover, clinical signs can usually be elicited by forcing them to exercise. Deaths are reported to continue for 1 week after removal of sheep from toxic pasture and clinical signs of the nervous form of the disease may persist for as long as 2 months. The extraordinary situation is recorded where new cases continue to occur for as long as 12 weeks after sheep are moved onto pasture that contains no *Phalaris* spp.

In cattle, the signs may be restricted to stiffness of the hocks and dragging of the hind toes, but severe cases similar to the common syndrome in sheep also occur. Additional, and more common, signs observed in cattle include an extraordinary incoordination of the tongue and lips in prehension so that the hungry animal, trying desperately to eat, can only prehend a few stalks of grass at a time. The jaw movements are quite strong, but the tongue stabs and darts, and lacks the sinuous curling movements normally present. There may also be an inability to put the muzzle to the ground so that prehension can only be effected from a raised manger or hayrack. Affected cattle are often hyperexcitable and difficult to handle.

CLINICAL PATHOLOGY

Laboratory tests on antemortem material can detect the presence of the causative tryptamines in plant material but are unlikely to be generally available.

NECROPSY FINDINGS

Other than the characteristic green-gray pigmentation of tissues in the renal medulla, brain stem, midbrain and dorsal root ganglia, gross lesions are absent. Degeneration of spinal cord tracts and of the ventral portion of the cerebellum has been observed in terminal cases of the incoordination syndrome, but is not a consistent finding. In the sudden death or cardiac syndrome sheep are usually found dead on their sides with their heads strongly dorsiflexed and legs rigidly extended. Some sheep have blood-stained nasal discharges and many have been frothing at the mouth. Abdominal visceral congestion, epicardial and duodenal hemorrhages are present and indicate acute heart failure. Polioencephalomalacia is characteristic of the sudden-death-polioencephalomalacia syndrome.

DIFFERENTIAL DIAGNOSIS

The association between the nervous disease and the plants should suggest the diagnosis. The appearance of these signs only on exercise is significant, suggesting a functional rather than a physical lesion. Diagnostic confirmation rests on the identification of the causative tryptamines in the feed materials and the tissues and fluids on antemortem or postmortem examination.

Differential diagnosis lists for the incoordination syndrome:

- Paspalum staggers
- Ryegrass staggers
- Floodplain staggers (tunicaminyluracil poisoning)
- Poisoning associated with marshmallow, stagger weed, and other plants produces a very similar syndrome and the diagnosis must depend on the identification of the toxic plant.

For the sudden death syndrome:

- Annual ryegrass toxicity
- Cyanogenic glycoside poisoning
- Nitrite poisoning.

For the sudden-death-polioencephalomalacia syndrome is as for polioencephalomalacia.

TREATMENT

Flocks of affected sheep should be removed immediately from the toxic pasture. There is no specific antidotal treatment.

CONTROL

No preventive measures are available against the sudden death syndrome, but the nervous form can often be prevented by the oral administration of cobalt. Affected pastures may be grazed if sheep are dosed with cobalt (at least 28 mg per week) at intervals of not more than 1 week, or if alternative grazing is provided in rotation. Dosing at too long intervals or with inadequate amounts may account for some failures in prevention. The parenteral administration of cobalt or vitamin B_{12} is not effective. The additional cobalt can be provided by drenching the sheep individually or spreading it on the pasture mixed with fertilizer as described under cobalt deficiency. Unfortunately, the genetic selection of *P. aquatica* cultivars with low contents of methylated tryptamines favors a significant increase in toxic β-carbolines.

INDOLIZIDINE ALKALOID POISONING

The two indolizidine alkaloids of plant origin are swainsonine and castanospermine both of them affecting cellular enzymic activity. Slaframine is a mycotoxin in this group.

SWAINSONINE POISONING

Synopsis

Etiology Poisoning by *Astragalus, Oxytropis, Swainsona* spp. is associated with induced mannosidosis.
Epidemiology Grazing toxic plants for 2–6 weeks is associated with signs, reversible if pasture changed.
Clinical signs Incoordination, paresis, star-gazing posture.
Clinical pathology Urine content of mannose-containing oligosaccharides elevated.
Necropsy findings Vacuolation of neurones.
Diagnostic confirmation Swainsonine can be detected in animal tissues or fluids, but the tests are not widely available.

ETIOLOGY

Swainsonine is an indolizidine alkaloid found in *Astragalus, Oxytropis* and *Swainsona* spp., and some *Ipomoea* spp. plants.[1] Ingestion of the toxic plants over a long period is associated with an induced lysosomal storage disease in all animal species. The common plants in which the alkaloid's presence has been identified are:

Swainsona galegifolia, S. brachycarpa, S. canescens, S. grayana, S. luteola, S. procumbens, S. swainsonioides
Astragalus lentiginosus, A. emoryanus.
Plants of this genus that are associated with a similar disease, and in which the presence of swainsonine is assumed, are *A. mollisimus, A. northoxys, A. lentiginosus* var. *waheapensis, A. lusitanicus,*[2] *A. wootonii, A. thurberi*
Oxytropis sericea, O. ochrocephala.[3]
Plants of this genus that are associated

with a similar disease, and in which the presence of swainsonine is assumed, are *O. besseyi, O. condensata, O. lambertii, O. puberula.*[4]

Swainsonine is synthesized by the fungus *Rhizoctonia leguminicola,* but the disease associated with this fungus is due to its slaframine content.

EPIDEMIOLOGY

The disease is most common in North America (as locoism associated with *Astragalus* and *Oxytropis* spp.) and in Australia as Darling pea (*Swainsona* spp.) poisoning, but *Oxytropis* spp. have been associated with poisoning in China. Grazing animals must ingest the plants for at least 2 weeks, more usually 6 weeks, before clinical signs appear. Addiction to these plants, in preference to other available pasture is generally accepted but there is no initial preference for or subsequent addiction to *A. lentiginosus*.[5] All grazing animal species are affected, and experimental administration of the alkaloid to monogastric, farm, and laboratory animals is associated with the typical neuronal lesions. The death rate need not be high if access to the source plants ceases.

PATHOGENESIS

Swainsonine is a specific inhibitor of lysosomal α-mannosidase causing accumulation of mannose in lysosomes and thus widespread neurovisceral cytoplasmic vacuolation. The vacuoles are accumulations of mannose-rich oligosaccharides, including abnormal glycoproteins.[6] Vacuolation reaches its greatest intensity in the central nervous system and this is probably related to the predominance of nervous signs in the disease. Vacuolation of the chorionic epithelium may be related to the occurrence of abortion, and a transient infertility suspected in rams to be the result of a similar lesion in the epithelium of the male reproductive tract.[7] The lesion appears quickly and is reversible if the swainsonine intake ceases. There is no information available about the mechanism by which the accumulated oligosaccharide causes the nervous dysfunction which characterizes the disease. The lesions and clinical syndrome are identical with those in the inherited mannosidoses in cattle and goats except that fetal deformity and abortion occur in the poisoning. The mechanisms for those occurrences are also unknown, although there appears to be a direct link with the combined maternal and fetal mannosidosis.

CLINICAL SIGNS

After several weeks of grazing affected pasture adult animals begin to lose condition and young animals cease to grow. The appetite is diminished and the coat becomes dull and harsh. Several weeks later nervous signs of depression, gait incoordination, muscle tremor, difficulty in rising, in eating and drinking become apparent. Sheep commonly adopt a 'star-gazing' posture, and horses may show ventroflexion of the head and rearing over backwards if handled. Cases may become overexcited if harassed. Recovery is likely if the animal is removed from the source of the toxin soon after signs appear. Recovery may be complete or there may be a residual gait incoordination if the animal is excited. Advanced cases may show no improvement and others become recumbent and die. Calves at high altitudes and fed *A. lentiginosus* or *O. sericea* develop a higher incidence of congestive heart failure than calves not fed on the plants.[8]

Pregnant ewes ingesting *Astragalus* spp. plants may abort or produce abnormal offspring. The defects take the form of small, edematous or dead fetuses or skeletal deformity. There are no such abnormalities recorded with *Swainsona* spp.

CLINICAL PATHOLOGY

Vacuolation in circulating lymphocytes occurs in poisoning due to *Swainsona* spp., and may have diagnostic significance. Serum levels of α-mannosidase are significantly reduced and swainsonine levels increased.[9] Swainsonine levels reflect the amount being ingested and not the duration of exposure, and quickly return to normal when ingestion of the plants ceases. The urine content of mannose-containing oligosaccharides is greatly increased during the period of intake of swainsonine.[10]

NECROPSY FINDINGS

The characteristic microscopic lesion is fine vacuolation of the cytoplasm in neurons throughout the central nervous system. Similar vacuolation is present in cells of other organs, especially the kidney, and the fetus in animals poisoned by *Astragalus* spp. High blood and tissue levels of swainsonine are detectable, including in frozen material.[9]

In aborted calves, lambs, and foals there is extensive vacuolation of the chorionic epithelial cells. The skeletal deformities include arthrogryposis and rotation of the limbs about their long axis.

TREATMENT

Removal of the affected animals from access to source plants may result in partial or complete recovery, provided the cases are not too advanced.

CONTROL

Pregnant animals should not be exposed to sources of swainsonine, but other stock may be grazed on the plant without ill effect for short, specified periods, namely 4 weeks for sheep and cattle, and 2 weeks for horses.[10] Attempts to reduce consumption of the toxic plants by creating conditioned reflex aversion,[11] to reduce absorption of ingested swainsonine, or by supplementing the diet with bentonite,[12] have not been rewarding.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation depends on identification of the alkaloid.

Differential diagnosis list

The combination of gait incoordination and congenital skeletal deformities in *Astragalus* spp. poisoning is also a characteristic of:

- *Conium* spp. piperidine alkaloids
- *Nicotiana* spp. alkaloids
- *Lupinus* spp. quinolizidine alkaloids

The necropsy lesion of cytoplasmic vacuolation is a characteristic of:

- Inherited mannosidosis.

CASTANOSPERMINE POISONING

Found in the seeds of *Castanospermum australe* (Moreton Bay chestnut), castanospermine inhibits mononuclear cell α-glucosidase activity so that affected cattle have been misdiagnosed as heterozygotes for generalized glycogenosis type II (Pompe's disease). The seeds are also associated with hemorrhagic gastroenteritis if eaten in large quantities, causing the passage of bloody diarrhea but the cause, originally thought to be saponins, is unknown.[13]

DITERPENE ACIDS AND VASOACTIVE LIPIDS

Phytotoxic abortion, in which serum progesterone levels of the patient are reduced by the effects of the ingested agent, is associated with the ingestion of *Pinus ponderosa* (yellow pine), *P. cubensis*, *P. radiata*, *Cupressus macrocarpa* (Monterey cypress), *Cupressus sempervirens*, and *Cupressocyparis leylandii* (Leyland cypress). These plants are associated with **pine needle abortion** in cattle but the abortifacient activity, originally thought to be estrogenic in origin, remains uncertain but candidate toxins include diterpene acids, including isocupressic acid,[1–3] and vasoactive lipids.[4,5] The tips and bark, and to a lesser extent the needles, of these trees are associated with abortion in cows, but not ewes. Poisoning is most likely to occur when cattle graze amongst the trees and have access to the wilted foliage on lopped or broken branches. Denial of access to pasture by heavy snowfalls may force intense browsing of trees. The fetus in cases of poisoning by *Cupressus* spp. has a typical leukoencephalomalacia.

NITROCOMPOUND POISONING

Synopsis

Etiology Several toxins in the group; miserotoxin in certain *Astragalus* spp. the most important.
Epidemiology Disease limited to geographical distribution of the toxic plants; mostly North America.
Clinical findings Degenerative lesions in CNS are associated with dyspnea with stertor, incoordination leading to recumbency; long course and high case fatality rate.
Clinical pathology Laboratory identification of miserotoxin in blood.
Necropsy findings Degenerative lesions in peripheral nerves and spinal cord.
Diagnosis confirmation Associated with isolation of miserotoxin in patient tissues and fluids.
Treatment Nil.
Control Management of pasture to avoid grazing pasture when relevant plants are abundant.

ETIOLOGY

Nitrocompounds (nitrotoxins) poisonous to animals occur in a number of plants, especially *Astragalus* spp. They are all glycosides of 3-nitro-1-propionic acid (NPA), or of 3-nitro-1-propanol (NPOH). The only common one is miserotoxin. The best known occurrences of the nitrocompounds are:

- Miserotoxin in *Astragalus canadensis*, *A. emoryanus*, *A. miser*, *A. pterocarpus*, *A. tetrapterus*, and others
- Karakin in *Corynocarpus laevigatus* (karaka tree)
- *Oxytropis* spp., a plant genus very similar botanically to *Astragalus* spp., is associated with the same diseases as the latter but its toxic agent has not been identified
- *Coronilla varia* also contains a nitrocompound
- *Indigofera linnaei* (Birdsville indigo), also contains karakin and other nitrocompounds.[1]

EPIDEMIOLOGY

Occurrence

The occurrence of these plant poisonings is determined by the presence and ingestion of the specific plants. *Astragalus* and *Oxytropis* spp. are, for the most part, limited in distribution to North America, but poisoning of sheep by *A. lusitanicus* is recorded in Morocco,[2] and of all species by *Oxytropis puberula* in Kazakhstan.[3] *Corynocarpus* spp. occur in New Zealand and *Indigofera* spp. are widespread, occurring in North America, Australia, Africa, and Southeast Asia.

Risk factors

Plant factors

Astragalus and *Oxytropis* spp. are herbaceous legumes, most of them perennial, and they dominate the desert range over large areas of the United States. They provide excellent forage. Only some species contain miserotoxin, but this makes them very destructive and very heavy losses of sheep and cattle may occur.

Animal factors

Cattle are the more susceptible. Lactating animals are more susceptible than dries. There are reports of the disease in horses in North America,[4] and a similar disease in horses in China after grazing *Oxytropis kansuensis*.

Importance

Miserotoxin and its metabolic end-products may be excreted in the milk of cows eating these plants.

PATHOGENESIS

In ruminants the glycosides are hydrolyzed in the rumen to NPOH and NPA. Both are absorbed from the rumen. NPOH is converted in the liver to NPA. NPA may be metabolized to nitrite, and acute poisoning is characterized by signs and necropsy lesions of nitrite poisoning. Chronic poisoning is associated with the accumulation of NPA and a resulting syndrome, characterized principally by nervous signs and the development of degenerative lesions in the central nervous system. In experimental animals the dose rate and length of exposure to the toxin determine whether the acute or chronic disease occurs.

CLINICAL FINDINGS

Acute poisoning

The syndrome of dyspnea, tremor, and sudden death is characteristic of nitrite poisoning. Death may occur as soon as 3 hours after the commencement of signs but the course is more commonly about 24 hours.

Chronic poisoning

Affected animals lose weight, and develop a poor hair coat, nasal discharge, and poor exercise tolerance. Respiratory distress, with loud stertor (roaring), is more marked in sheep than in cattle and knuckling of the fetlocks and incoordination, followed in some by paraplegia, is more common in cattle. Temporary blindness and drooling of saliva may also be evident. The mortality rate is very high, the course lasting over several months. Animals that recover have a long convalescence. Death may occur suddenly if affected animals are stressed.

Indigofera linnaei poisoning in horses (synonym Birdsville horse disease) is associated with weight loss, gait incoordination, easy falling, toe dragging, dyspnea, and convulsions. The plant is equally poisonous when dry or green, although most cases occur in the spring when the plant is succulent. Horses need to graze the plant for about 10 days before signs appear. Characteristic signs include segregation and somnolence, the animal often standing out in the open in the hot sun, apparently asleep, when unaffected horses have sought the shade. There is marked incoordination, the front legs being lifted and extended in an exaggerated manner. The hocks are not flexed, causing the fronts of the hind hooves to be dragged on the ground. The head is held in an unnaturally high position and the tail is held out stiffly. There is difficulty in changing direction and incoordination increases as the horse moves. The horse commences to sway and at the canter there is complete disorientation of the hindlegs so that the animal moves its limbs frantically but stays in the one spot with the legs becoming gradually abducted until it sits down and rolls over. Terminally there is recumbency with intermittent tetanic convulsions, which may last for up to 15 minutes and during which death usually occurs.

A chronic syndrome may develop in some horses subsequent to an acute attack. Affected animals can move about but there is incoordination and dragging of the hind feet with wearing of the toe and inspiratory dyspnea (roaring) may also occur. No lesions have been described in the nervous system of affected animals. *I. linnaei* contains the toxic amino acid, indospicine, an analog of arginine, but poisoned horses do not develop the liver damage typical of intoxication by indospicine. However, supplementation of the diet with arginine-rich protein feeds prevents development of the disease. Peanut meal (0.5–1 kg/day) and gelatin provide readily available and cheap sources of arginine.

CLINICAL PATHOLOGY

Laboratory findings related to the methemoglobinemia of nitrite poisoning are discussed under nitrite poisoning. Laboratory procedures for the determination of blood levels of miserotoxin and NPOH and NPA are available.[4]

NECROPSY FINDINGS

Brown discoloration of the blood, and extensive petechiation in tissues, are common findings in the acute form of the disease. In the chronic disease there are degenerative changes in the spinal cord and peripheral nerves, especially the sciatic nerve. Gross lesions include pulmonary emphysema and pneumonia.

DIFFERENTIAL DIAGNOSIS

The differentiation of association with nitrite poisoning is discussed under that heading. The syndrome of a chronic course, dyspnea, and incoordination, with or without paraplegia, is also common. Diagnosis confirmation depends on the identification of the poisonous plants in the environment and the toxins in the plants and animal tissues.

Differential diagnosis list (chronic form)

- Phalaris staggers
- Rye-grass staggers
- Paspalum staggers
- Chronic cyanide poisoning.

TREATMENT

Primary treatment for acute poisoning is described under nitrite poisoning. There is no treatment for the chronic form of the disease, although some cases may recover spontaneously after a recovery period of several months.

CONTROL

Control of the growth of the plants by stimulating growth of competitive grasses, or the widespread use of selective herbicides, is recommended but unlikely to be a practicable procedure in many of the situations in which the plants occur. Experimentally, the use of some herbicides significantly reduces the content of miserotoxin in *A. miser* var. *oblongifolia* in pasture. Variations between species of *Astragalus* spp. in their capacity to produce miserotoxin and store selenocompounds (some of them, e.g. *A. toanus*, do both) provides opportunities to manipulate the grazing of particular fields to best advantage.[5,6]

PHYTOESTROGEN POISONING

Synopsis

Etiology Hyperestrogenism is associated with phytoestrogens, usually in pasture legumes.
Epidemiology Pastures dominated by specific strains of legumes, in lush growth mode, or hay or ensilage made from such pasture, is associated with problems if exposure is prolonged. Sheep much more susceptible than cattle.
Clinical signs Severe flock infertility; in cows, prolongation of estrus periods, interestral periods shortened.
Clinical pathology Positive estrogen assay in blood.
Necropsy findings Ewes – cystic endometrial degeneration.
Diagnosis confirmation Elevated serum estrogen levels.
Treatment Nil.
Control Grazing management, use of low-phytoestrogen cultivars.

ETIOLOGY

Important estrogenic substances found in plants and fungi include:

- Plants – coumestans (coumestrol, 4-methoxycoumestrol, repensol, trifoliol); isoflavones (daidzein, formononetin, genistein, biochanin A); isoflavan (equol)
- Fungi – resorcylic acid lactones (zearalenone).

Compared to pharmaceutical agents these substances have low estrogenic activity but they are associated with serious clinical effects because of the high concentrations they reach in some plants, and the daily intake over long periods. The coumestans occur most commonly in plants of the *Medicago* genus, isoflavones most commonly in the *Trifolium, Baptisia,* and *Cytisus* genera. Only *Medicago* and *Trifolium* spp. are of any importance to animals. Those likely to contain sufficient amounts to be associated with disease are:

Fusarium roseum; contains zearalenone
Glycine max – soybean; contains coumestans and isoflavones; affects pigs
Medicago sativa – alfalfa, lucerne; contains coumestans; affects cattle, sheep
Trifolium alexandrinum – isoflavones
T. alpestre[1] – alpestrine clover; contains isoflavones
T. pratense – red clover; contains isoflavones; affects sheep
T. repens – white clover, Ladino clover; contains coumestans
T. subterraneum – subterranean clover; contains isoflavones; affects sheep.

EPIDEMIOLOGY

Occurrence

Animals at pasture are at the greatest risk but poisoning can also occur on diets containing prepared feeds such as soybean (*Glycine max*) meal, or moldy feed containing *Fusarium roseum.*

Risk factors

Plant factors

The estrogenic activity of pastures depends on the degree of domination of the pasture by the toxic plants, the variety of the plant species, and the duration of the animal's exposure to them. Newly sown pastures are usually most toxic because of domination by the sown legume. Pastures deficient in phosphorus are also likely to be clover-dominant. High nitrogen fertilizer applications reduce phytoestrogen content. Varieties of *Trifolium subterraneum,* e.g. Yarloop, Dwalganup, Dinninup and Geraldton, are much more toxic than Bacchus Marsh and Daliak. Pastures containing more than 30% of the first four varieties are likely to be unsafe. In some clovers, e.g. red clover, the estrogen content varies with the season, being high in early spring, low in midsummer, and high again in the autumn, after the hay has been taken off. Insect damage to pasture can increase its estrogen content 10-fold, bacterial infection, e.g. by *Pseudopezzia medicaginnis,* a leaf-spotting organism on alfalfa, and fungal infection can increase it 100-fold. Plants that have matured in the field and set seed have no estrogenic potency, but

the making of potent fodder into hay causes little depression of estrogen content. Clover ensilage can contain high levels of estrogens and the ensiling process is considered to increase the estrogenic effect of clover three- to fivefold.

Trifolium repens (white clover, in contradistinction to Ladino clover), does not have a high content of estrogens. However, when heavily infested with fungi it can contain significant amounts. It is believed that the production of estrogens is a by-product of the plant's mechanism of resistance to the fungal infection. Ladino clover, a large-growing variety of white clover, may contain large quantities of a highly active estrogen (coumestrol), and when it dominates a pasture and is grazed when the pasture is lush, it may be associated with the cornification of vaginal epithelium and functional infertility in ewes. Three estrogenic compounds have been isolated from *T. pratense* (red clover), and where this plant dominates the pasture a clinical syndrome similar to that associated with subterranean clover may be observed. Ewes grazing on red clover pasture, especially a toxic cultivar of the plant, may have their conception rate at the first mating cycle reduced from 75% to as low as 25%.

Animal factors

Sheep eating a lot of estrogenic clover in the spring can become temporarily infertile, but are normally fertile again by the usual breeding season in the autumn. However, ingestion of the plant in several successive years is associated with '**permanent clover disease**' – infertility from which ewes do not recover. The disease is important only in sheep. Cattle are generally considered to be unaffected but the subject is still a controversial one with the weight of evidence against cattle being affected. For example, cows can ingest large amounts of estrogens (over 40 g/day/cow) in red clover without showing any reduction in reproductive efficiency. Horses usually graze the toxic pasture without ill-effects.

Importance

Massive reproductive wastage has been experienced in sheep on pastures dominated by such plants as *Trifolium subterraneum*, and the death rate due to dystocia and prolapse of the uterus can also be high. The most commonly observed abnormality is a failure to conceive, even with multiple matings, and the flock breeding status worsens progressively, with the lambing percentage falling from a normal 80% down to 30%. Under these conditions sheep farming becomes unprofitable and large areas of country have been made unsuitable for sheep-raising by this disease.

PATHOGENESIS

Much of the metabolism of phytoestrogens in ruminants occurs in the rumen, as well as in the liver. The differences between sheep and cattle in the ruminal metabolism of these compounds are thought to be the reason for the comparative freedom of cattle from the clinical disease.

The amount of phytoestrogen ingested by a ewe on a highly poisonous pasture may equal her daily estrogen secretion at the peak of her estrus cycle. The effect of the phytoestrogens is exerted mainly on the uterus and ovaries. Structurally, there is hyperplasia and hypertrophy of the epithelium of the uterus, vagina, and cervix, and dysplasia of the granulosa cells of the ovary, with a consequent reduction in secretion of estradiol. Increases in teat size and milk secretion are additional, secondary effects.

The functional abnormality is not one of estrus; in sheep the demonstration and duration of estrus may be normal or depressed, and the defect is one of **sperm transport** due to changes in the composition of cervical mucus, and the structure of cervical glands. The change is to more watery mucus and this is the basis of a test in affected sheep in which the watery mucus is more readily absorbed by a cottonwood plug inserted in the vagina. The increased weight of the plug is a positive test.

It is possible that a good deal of the infertility seen in ewes on improved clover pasture may be associated with its high estrogen content, in spite of the absence of the more dramatic evidence of hyperestrogenism described above. Because of the necessity to utilize this pasture, a great deal more needs to be known about the seasonal occurrence of the estrogenic substances and the management of sheep grazing the pasture so that the effects of the disease can be minimized.

Another syndrome associated with subterranean clover and unrelated to the infertility syndrome is that of **obstructive urolithiasis** in sheep, discussed under that heading. This disease occurs in outbreaks in spring in Merino wethers grazing estrogenic strains of the clover. As the isoflavone concentrations in the plants rise, the daily excretion of phenols and acid-precipitable material in the urine increases, so does the occurrence of obstruction by the characteristic soft yellow calculi containing benzocoumarins.

CLINICAL FINDINGS

Ewes

Clover disease, the severe clinical manifestation of the poisoning, and rarely seen today, includes dystocia, prolapse of the uterus or vagina, and severe infertility in ewes. Wethers show teat elongation, mammary gland and bulbourethral gland enlargement. Deaths occur in both groups. The more common, and less severe, field expression of phytoestrogen poisoning is a significant fall in fertility rate. The infertility may be temporary, normal reproductive efficiency returning soon after the ewes are moved to clover-free pasture. In ewes exposed to a low level intake of estrogens over a long period, e.g. in excess of two grazing seasons, a process of irreversible 'defeminization' may occur. This is a state of permanent subfertility. The estrus cycle is normal, the main problem being the failure of an abnormally large number of ewes to conceive.

In affected flocks there may also be a high incidence of maternal dystocia due to uterine inertia, or failure of the cervix or vagina to dilate. Affected ewes show little evidence of impending parturition and many full-term fetuses are born dead.

Because of the similarity between this form of the disease and the disease '**ringwomb**' in ewes in the UK, it has been suggested that the latter may be associated with an excessive intake of phytoestrogens. The mortality rate in lambs may be as high as 40%, and 15–20% of ewes may die of metritis and toxemia. Uterine prolapse may also occur in unbred and virgin ewes and in mature ewes some months after lambing. The incidence of prolapse is usually 1–2% but may be as high as 12%. There is marked udder development and copious milk secretion in the ewes.

Male castrates

Wethers may also secrete milk, and metaplasia of the prostate and bulbourethral glands is evident. These can be detected at an early stage of development by digital rectal palpation. Continuing hyperplasia and cystic dilatation of these glands is associated with their prolapse in a subanal position, followed by rapid weight loss and fatal rupture of the bladder. Rams usually show no clinical abnormality and their fertility is not impaired.

Neither clover disease nor permanent subfertility occurs in **cows**. Temporary infertility, discharge of cervical mucus, and swelling of the mammary gland, the vulva, and uterus, have been recorded. Obstructive urolithiasis is described in Chapter 11.

CLINICAL PATHOLOGY

Laboratory assays of endocrines are available and essential to diagnosis and monitoring of feed contents of phytoestrogens. Chemical assays are not as sensitive as biological assessments based on increased size of genitalia in subject animals.

NECROPSY FINDINGS

In the worst cases there is severe cystic degeneration of the endometrium. Similar

clinical and histopathological changes have been produced by the daily injection of 0.03 mg of diethylstilbestrol per ewe for a period of 6 months. There is also a long-term change in the cervix with an increased incidence of cervicitis and a histologically observable transformation to a uterine-like appearance. In ewes on a long-term intake of toxic pasture, the lesions include elevation of the tail head, partial fusion of the vulvar labia, and clitoral hypertrophy.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation of phytoestrogen poisoning requires laboratory assay of feed, blood, and tissue, and the appearance of genital pathology at necropsy or via peritoneoscopy or uterine biopsy. Differential diagnosis list – the only other diagnoses of the distinctive hyperestrogenism syndrome of phytoestrogen poisoning are:

- Overdosing with a pharmaceutical preparation as part of a program to improve fertility in a herd
- Overdosing by implant or feed additive with a growth stimulant which has estrogenic capability.

TREATMENT

Administration of testosterone is a logical response to poisoning but appears to be an unlikely commercial proposition.

CONTROL

Avoidance of high estrogenic activity strains of the respective plants, grazing management to avoid dangerous pasture at the most toxic part of the season, dilution of the estrogen intake by providing additional, alternative feeds, are all used. Prevention of clover disease can only be achieved by proper management of sheep and pasture to avoid ingestion of excessive amounts of estrogens. Vaccination with a phytoestrogen-immunogenic protein conjugate has produced good levels of antibodies, but has not been successful in preventing the problem. Careful management of flocks on estrogenic pasture can significantly improve reproductive output.[2]

PTAQUILOSIDE POISONING

Ptaquiloside is a carcinogen, found in the ferns *Pteridium* spp. (bracken), *Cheilanthes sieberi* and *Onychium contiguum* (fuh); the former two also contain thiaminases. In ruminants, two principal syndromes occur. Ingestion of the plants for 2–4 weeks is associated with hemorrhagic disease known widely as bracken poisoning, here referred to as osteomyelotoxic ptaquiloside poisoning to differentiate its bone marrow-damaging effects from its carcinogenic effects and to avoid the use of 'acute' ptaquiloside poisoning which is a misnomer. Ingestion of much smaller amounts of the ferns over a period of years is associated with bovine enzootic hematuria, the carcinogenic manifestation of ptaquiloside poisoning. Other less well-known diseases associated with ptaquiloside are intestinal carcinomas of sheep and cattle, and bright blindness of sheep.

OSTEOMYELOTOXIC PTAQUILOSIDE POISONING (POISONING BY BRACKEN (*PTERIDIUM* SPP.) AND MULGA OR ROCK FERN (*CHEILANTHES SIEBERI*))

Synopsis

Etiology *Pteridium* spp. (bracken), *Cheilanthes sieberi* (rock fern).
Epidemiology Most common in cattle grazing young fronds. Signs appear after 2 weeks on affected pasture.
Clinical findings High fever, severe diarrhea, dysentery. Ecchymotic hemorrhages in mucosae.
Clinical pathology Depression of bone marrow activity with pancytopenia.
Necropsy findings Multiple hemorrhages plus bacterial invasion in all tissues.
Diagnostic confirmation Laboratory identification of ptaquiloside not generally available. Clinical signs and exposure to plant plus pancytopenia, low platelet count, abnormal bone marrow.
Treatment Blood transfusion.
Control Bracken eradication.

ETIOLOGY

Ptaquiloside (PT) is a norsesquiterpene glucoside of the illudane type found in some ferns and used to reproduce depression of the bone marrow, hematuria, bladder and bowel neoplasia, and retinal degeneration in experimental animals. Ferns known to contain ptaquiloside are *Pteridium* spp. (the bracken ferns), *Cheilanthes sieberi* (mulga fern or rock fern),[1] possibly other *Cheilanthes* spp., and *Onychium contiguum* (fuh). The fern commonly called bracken is in fact several different species of *Pteridium* in various parts of the world, known toxic species of which are *P. aquilinum* in northern temperate countries, *P. esculentum* in Australia and New Zealand, and *P. revolutum* in northern Australia and Asia. All species should be regarded as toxic. Large amounts of the plants must be eaten before poisoning occurs. Other cytotoxins in bracken are quercetin, shikimate and cyclohexanecarboxylate, but no relationship between them and animal disease has been established.[2]

EPIDEMIOLOGY

Occurrence

Bracken fern poisoning occurs in most countries as a sporadic disease. Although the losses are usually small because of the high intake of the fern required to produce illness, heavy mortalities have been observed in some outbreaks. *Cheilanthes sieberi* (mulga fern or rock fern) poisoning is confined to Australia.

Risk factors

Plant factors

The toxicity of bracken varies significantly with its geographical distribution within countries, e.g. plants from southern Australia may contain twice the concentration of ptaquiloside than those from the north, suggesting genetic variation.[3] Toxicity also varies with the stage of growth and time of the year, younger plants being more toxic. The underground stems (rhizomes) and the curled new fronds (croziers) of the fern also contain the toxic principle in approximately five times the concentration of that found in mature fronds, and have been used to produce the disease experimentally in cattle. In most outbreaks, cattle have had access to the plants in their grazing for 2–4 weeks. Bracken is most prolific and most dangerous on light sandy soil where its wide climatic and soil type tolerance quickly lead to its domination of the pasture. In these circumstances it is very difficult to control or eradicate.

C. seiberi grows in close association with pasture grasses or in large numbers in mulga (*Acacia aneura*) communities in eastern Australia, and infrequently is associated with disease in livestock. They are most hazardous after drought-breaking rain.

Animal factors

The disease is most common in, and highly fatal to, cattle. Sheep are very rarely affected by bracken poisoning but natural outbreaks have been recorded[4] and it has been produced experimentally in them by feeding the fern over a very long period. Cattle allowed access to recently plowed fields of bracken eat the rhizomes avidly and may suffer heavy mortalities.

Meadow hay may contain toxic amounts of bracken, and animals at pasture may eat large quantities, especially when young, green fronds appear after drought or burning off or when other forage is sparse. Bracken used as bedding may also be ingested in dangerous amounts by animals with a poor nutritive status.

Importance

The toxin is excreted in the milk in significant quantity, and has been associated with neoplasia in the offspring of experimental animals drinking it. The toxin is thought to have health significance for humans drinking milk from their own bracken-grazing cows, or water which has percolated through fields containing bracken populations. Dilution of the toxin in metropolitan pasteurized milk supplies probably eliminates any significant human health risk from that source.

PATHOGENESIS

Bracken fern poisoning in ruminants is manifested by the depression of bone-marrow activity, prolonged bleeding time, and defective clot retraction but with normal prothrombin times.

In the bone marrow there is depression of granulopoiesis and thrombopoiesis. The myeloid cells are particularly affected, leading to a severe reduction in circulating platelets and granular leukocytes. The erythrocyte series in bone marrow is affected, but only in the terminal stages.

Bacteremia is a significant part of the pathogenesis in osteomyelotoxic ptaquiloside poisoning. The suggested pathogenesis is that hemorrhage into the alimentary mucosa or submucosa occurs as a result of the thrombocytopenia, and ulcers develop at these hemorrhage sites. Bacterial invasion is facilitated by the neutropenia, and the resulting bacteremia may be associated with infarction in the liver if small vessels are blocked by clumps of bacteria, or the organisms may be carried into the systemic circulation and be associated with infarction in other organs, including the kidneys, lungs, and heart.

The capillary fragility, intestinal ulceration, and laryngeal edema that occur in some cases are thought to be due to damage to tissue mast cells and the liberation of histamine.

CLINICAL FINDINGS

Initially, there is loss of condition and dryness and slackness of the skin. Clinical signs occur suddenly and include high fever (40.5–43°C, 105–109°F), severe diarrhea with dysentery or melena in most cases, bleeding from the nose, eyes and, vagina, and drooling of saliva. Nasolabial ulcers and hematuria may be observed. Petechial and ecchymotic hemorrhages may be visible under mucosae and skin, and in the anterior chamber of the eye. An increase in respiratory and heart rates occurs at this stage. Death usually follows in 1–3 days.

Cattle may continue to become ill for up to 6 weeks after being taken off the bracken fern. Calves 2–4 months of age show essentially the same clinical and necropsy picture as adult animals, except that marked bradycardia and death from heart failure occur, and a laryngitic form, with marked dyspnea due to laryngeal edema, is not uncommon. Although only a few animals in a group are affected, most of those showing clinical signs die.

Sheep grazing dense stands of young bracken for periods of 2 or more months may develop a less severe form of the hemorrhagic disease.[4] The sheep lose weight, are depressed, lethargic and exercise-intolerant, anorexic, and anemic. The anemia is normocytic and hypochromic, and is accompanied by a leukopenia (lymphopenia and granulocytopenia) and, at necropsy, a gross deficiency of bone marrow, and widespread petechial and ecchymotic hemorrhages.

CLINICAL PATHOLOGY

Estimations of the occurrence of platelets in blood smears appear to be the most valuable laboratory test in diagnosis and prognosis of the disease. Platelet counts fall gradually from normal levels of about 500 000/μL to about 40 000/μL just before death. Total leukocyte levels fall gradually at first and then precipitously to about 1000/μL in the terminal stages. Polymorphonuclear leukocytes are the most profoundly depressed and often none are visible in a smear.

Bone-marrow biopsy is valuable as an indication of the status of the platelet and granulocyte series. Increase in capillary fragility is detectable, and defective clot retraction is also a feature of this disease. A fall in erythrocyte count and hemoglobin content may be detectable in the late stages. Depression of erythropoiesis is more marked in sheep than in cattle. Urine examination may reveal the presence of erythrocytes and many epithelial cells.

NECROPSY FINDINGS

Death is due to the effects of multiple internal hemorrhages, combined in some cases with bacteremia. The hemorrhages, varying in size from petechiae to large extravasations, occur in all tissues. In some organs, particularly the alimentary tract mucosa, necrosis, and sloughing occur over the hemorrhages. Areas of edema are also common in the gut wall, and particularly around the pharynx in calves. The bone marrow is paler than normal. Multiple small, pale, or red areas representing infarcts and areas of necrosis are present in the liver, kidney, and lungs.

DIFFERENTIAL DIAGNOSIS

Diagnosis confirmation is by identifying the typical signs and lesions in cattle having access to bracken, plus hematological examination of thin blood smears for platelets in live animals, and bone marrow histopathology from necropsies.

Differential diagnosis list

Osteomyelotoxic ptaquiloside poisoning may be readily confused with many of the acute septicemias and other hemorrhagic diseases of cattle, including:

- Anthrax
- Septicemic pasteurellosis
- Furazolidone poisoning
- Trichlorethylene-extracted soybean meal poisoning
- Sweet clover poisoning
- Pyrexia-pruritis-hemorrhage syndrome
- Radiation injury.

However, bacteriological findings in ptaquiloside poisoning are negative for these specific infections except for the occasional occurrence of a pasteurella septicemia.

TREATMENT

Supportive treatment may include antibiotics and blood transfusions in those animals in which serious depression of erythrocyte and leukocyte counts have occurred. The transfusions should be large and 4.5 L is considered to be a minimum dose in adult cattle.

CONTROL

Fields containing large quantities of bracken fern should not be harvested for hay, and animals forced to graze affected areas should be supplied with a supplementary diet when the pasture is short.

CARCINOGENIC PTAQUILOSIDE POISONING

The diseases associated with years of ingestion of brackens, *Cheilanthes sieberi* or *Onychium contiguum*, are bovine enzootic hematuria and alimentary tract neoplasia.

BOVINE ENZOOTIC HEMATURIA

Synopsis

Etiology Long-term ingestion of bracken, *Cheilanthes sieberi* or *Onychium contiguum*.
Epidemiology Enzootic to areas with significant populations of specific ferns. Fatal, chronic disease of adult cattle.
Clinical signs Hematuria, anemia, sometimes palpable lesions in bladder.
Clinical pathology Hematuria.
Necropsy findings Hemangiomas and other neoplastic lesions in bladder mucosa.
Diagnostic confirmation Bladder lesion histopathology.
Treatment Nil.
Control Eradication of bracken.

ETIOLOGY

Chronic ptaquiloside poisoning due to the ingestion of *Pteridium* spp., *Cheilanthes*

sieberi or *Onychium contiguum*[1] is associated with enzootic hematuria in cattle. A high incidence of vesicular carcinomas, similar to the bladder lesions of enzootic hematuria in cattle, has also been recorded in sheep grazing bracken for long periods.

EPIDEMIOLOGY

Enzootic hematuria occurs as an area problem on all continents. The overall incidence is not great, but the disease may be associated with heavy losses in areas where bracken is a common plant. The disease is usually fatal. Cattle over 3 years of age are most commonly affected, and the disease has also been recorded in sheep and water buffalo exposed to infested pastures for periods exceeding 2 years. The disease occurs mainly on poor, neglected or recently opened up land, and tends to disappear as soil fertility and land management improves. It is not closely associated with a particular soil type, although it is recorded most commonly on lighter soils. The ptaquiloside content of bracken varies considerably between geographical locations and there is good correlation between its concentration and neoplasia in rats fed bracken from those areas.[3]

PATHOGENESIS

Ptaquiloside converts to an aglycone dienone intermediate at high pH and this substance is the ultimate carcinogen. It has been suggested that the dienone reacts with DNA, particularly with adenosine, to initiate carcinogenesis.[5] Hemorrhage from the bladder wall lesions occurs intermittently and results in ongoing blood loss. Deaths are due to hemorrhagic anemia.

CLINICAL FINDINGS

Severe cases are manifested by the passage of large quantities of blood, often as clots, in the urine. Hemorrhagic anemia develops and the animal becomes weak and recumbent, and may die after an illness lasting 1–2 weeks. Less severe cases are characterized by intermittent, mild clinical hematuria or persistent subclinical hematuria. In these cases there is a gradual loss of condition over several months and eventually clinical evidence of anemia. On rectal examination there may be thickening of the bladder wall. Secondary bacterial infection of the bladder may lead to the development of cystitis and pyelonephritis.

CLINICAL PATHOLOGY

In the absence of gross hematuria, a urine sample should be centrifuged and the deposit examined for erythrocytes. Repeated examinations may be necessary. Non-specific anemia is detectable by hematological examination. Granulocyte and thrombocyte numbers are typically normal.

NECROPSY FINDINGS

All tissues of the carcass are pale and the animal is usually emaciated. The urinary bladder contains blood clots or blood-stained urine. The presence of hemangiomas in the submucosa of the urinary bladder is typical of the disease. A range of other neoplasms may be present, including transitional cell carcinoma, hemangiosarcoma, adenoma, fibroma, and papilloma. The malignant types may have invaded the deeper structures of the bladder and have metastasized to regional lymph nodes or lungs. The neoplastic changes in the bladder are accompanied by inflammatory changes of the mucosa and submucosa, including proliferative changes of mucosal epithelium, lymphocytic infiltrates, congestion, edema, and hemorrhage. In some cases, lesions are seen in the ureters and renal pelvis. The severity of the blood loss is not necessarily related to the size or extent of the lesions, and animals may bleed to death when only small localized lesions are present.

DIFFERENTIAL DIAGNOSIS

Diagnosis confirmation is by signs in animals grazing fern-infested pasture and preferably by histopathology of bladder lesions. The differential list includes:

- Cystitis
- Pyelonephritis.

Both are usually accompanied by fever, frequent urination, and the presence of pus and debris in the urine. Bacteriological examination of the urine will reveal the presence of infection.

TREATMENT

Primary

No treatment should be attempted and affected animals should be disposed of at the first opportunity.

Supportive

Blood transfusion may be justified in severe cases and hematinic mixture should be provided in other cases.

CONTROL

A general improvement in nutrition is often followed by a decrease in the number of animals affected. A specific recommendation is to apply gypsum (225–335 kg/hectare) to the pasture as a fertilizer, a measure reputed to delay the onset of the disease. Bracken eradication is difficult and should not be undertaken without the advice of the local weed control officer.

Alimentary tract neoplasia

Alimentary tract neoplasia, including the jaws and liver, is recorded in sheep grazing pasture heavily infested with bracken and has been produced experimentally in sheep fed bracken or ptaquiloside.[6] Dairy cattle on farms infested with bracken may have a high prevalence of carcinoma of the intestine and tumors of the urinary bladder. Cancer of the alimentary tract, generally with lesions on the lateral dorsum of the tongue, the soft palate and oropharynx, esophagus, esophageal groove, and the rumen is also common in upland Scotland and northern England. Similar cases are recorded from South America. The epidemiological evidence suggests that papillomas associated with the papilloma virus are transformed into carcinomas by the carcinogenic effect of an environmental agent, probably bracken. Alimentary tract neoplasms in cattle grazing on bracken may be associated in the herd or in the individual with enzootic hematuria, or it may occur on its own. Depending on where the lesions are located, clinical signs may include masticatory disability, dysphagia, or chronic bloat.

'Bright blindness' of sheep

A progressive retinal degeneration associated with ptaquiloside observed in sheep kept for more than 3 years in the UK on pastures heavily infested with bracken, the disease has been produced experimentally in sheep fed bracken. Affected sheep are blind, reluctant to move, but bright and alert. The pupils are dilated and show poor light and menace reflexes, and on ophthalmoscopic examination there is retinal degeneration. This degeneration may be observable in many more sheep than the clinically blind ones. Leukopenia is a characteristic.

PYRROLIZIDINE ALKALOID POISONING

Synopsis

Etiology Pyrrolizidine alkaloids in *Crotalaria, Echium, Heliotriopium, Senecio* spp., and other plants.
Epidemiology Outbreaks are in or enzootic to very large areas where toxic plants dominate pasture, mostly in cattle and horses. Pyrrolizidine alkaloid-containing weed seeds in feed grains or dry plants in hay also lead to poisoning. Range of diseases associated with primary cumulative toxicosis and effect of metabolites.
Clinical findings Chronic wasting. Hepatic encephalopathy with blindness, head pressing, bouts of frenzy, jaundice, photosensitization, and intravascular hemolysis.
Clinical pathology Liver function tests and blood levels of hepatic enzymes indicate hepatic inefficiency. In some cases there is only hypoalbuminemia.
Necropsy lesions Hepatic megalocytosis, fibrosis, and biliary hyperplasia.
Diagnostic confirmation Histopathology of liver. Assay of whole blood or liver for pyrrolic metabolites.
Treatment Nil.
Control Avoidance of significant exposure to plants. Biological control of plants.

ETIOLOGY

Most hepatoxic pyrrolizidine alkaloids (PAs) are esters of two amino alcohols, retronecine and heliotridine, and occur in three groups – monoesters, non-cyclic (open) diesters and cyclic diesters – in ascending order of toxicity. To be hepatoxic, PAs require a 1,2 double bond in the pyrrolizidine nucleus and a branch in the ester group. Non-toxic N-oxides of PAs may be converted to the toxic free base in the alimentary tract. A complete list of known PAs would be too long to be useful; for example, *Echium plantagineum* contains at least ten of them known to be toxic to grazing animals. Most PA-containing plants are classified in the plant families Boraginaceae, Fabaceae (Leguminosae), and Asteraceae (Compositae). The recorded plant sources of hepatoxic PAs include:

Amsinckia intermedia – tarweed, ironweed; contain intermedine, lycopsamine, echiumine
Arnebia hispidissima – contains monocrotaline, echimidine[1]
Crotalaria anagyroides
C. crispata – Kimberley horse poison
C. dura – wild lucerne
C. eremaea – bluebush pea
C. globifera – wild lucerne, jaagsiektebossie
C. goreensis – Gambia pea; contains monocrotaline
C. incana – woolly rattlepod; contains fulvine
C. juncea – sunn hemp; contains retusine
C. mauensis – contains junceine
C. mesopontica
C. mitchellii
C. novae-hollandiae – New Holland rattlepod
C. ramosissima – Kimberley horse poison
C. retusa – wedge-leaved rattlepod; contains monocrotaline, retusine
C. spectabilis – showy rattlepod; contains monocrotaline, spectabiline
Cynoglossum officinale[2] – hound's tongue; contains heliotridine,[3] heliosupine, echinatine
Echium plantagineum (*E. lycopsis*) – Patterson's curse, Salvation Jane; contains echiumine, echimidine
E. sericeum – contains echiumine
E. vulgare – viper's bugloss; contains echimidine
Heliotropium europaeum – common heliotrope, potato weed; contains indicine, heliotrine, lasiocarpine, europine, supinine, heleurine
H. amplexicaule[4] – blue heliotrope; contains lasiocarpine, echinatine
H. ovalifolium
Ligularia amplexicaulis – dola
L. mortonii – bong dok pu
Lithospermum arvense (*Buglossoides arvensis*) – corn gromwell
Senecio abyssinicus
S. alpinus[5]
S. aquaticus – marsh ragwort
S. brasiliensis
S. burchellii – geelgifbossie
S. cineraria – dusty miller
S. cisplatinus
S. cunninghamii
S. erraticus[6]
S. glabellus
S. harvieanus
S. heterotrichus
S. integerrimus
S. isatideus – Dan's cabbage, inkanga
S. jacobaea – ragwort; contains seneciphylline, senecionine, jacobine, jaconine, jacoline, jacozine
S. latifolius – Dan's cabbage, dunsiektebossie
S. brigalowensis[7] – fireweed
S. linearifolius – fireweed
S. longilobus[8] – thread-leaf groundsel; contains retrorsine, riddelline, seneciphylline
S. madagascariensis – Madagascan fireweed; contains senecionine
S. magnificus – tall yellowtop; contains seneciphylline
S. moorei
S. oxyphyllus[9]
S. plattensis
S. pterophorus – African daisy
S. quadridentatus – cotton fireweed
S. retrorsus – staggers bush, dunsiektebossie
S. riddellii[8] – Riddell's groundsel
S. ruwenzoriensis
S. scleratus
S. selloi[10]
S. spartioides – broom groundsel
S. spathulatus
S. squalidus – Oxford ragwort
S. tweediei
S. vernalis
S. vulgaris – common groundsel; contains senecionine, seneciphylline, retrorsine
Symphytum officinale – comfrey; contains echimidine, lycopsamine, symphytine
Trichodesma incanum – contains trichodesmine
T. ehrenbergii – contains senkirkine
T. zeylanicum – camel bush; contains supinine.

Some pyrrolizidine alkaloids have their most significant effect on the lungs. Plants containing these include: *Crotalaria dura, C. globifera, C. juncea, C. mitchellii, C. spartioides.*

Some effect on the lungs is produced by *C. ramosissima/C. crispata.* As well as its dominant hepatoxic effect, *C. retusa* is associated with nephrosis in affected pigs.

EPIDEMIOLOGY

Occurrence

Diseases associated with PAs occur in most animal species in most countries, causing syndromes such as 'Molteno straining disease' of cattle, 'walking disease', 'Winton disease' of horses and cattle, and 'Kimberley horse disease' (Walkabout disease), 'zdard disease', 'jaagsiekte' (panting disease), and 'dunsiekte' (thin disease), or stomach staggers of horses. Poisoning of humans, causing hepatic veno-occlusive disease also occurs.

Clinical manifestations of poisoning may be delayed for up to 18 months after ingestion of a toxic dose of PAs; the reason is unknown.

Risk factors

Plant factors

The plants are not very palatable and are usually eaten in sufficient quantity to be associated with illness only when other feed is short, or when they are included accidentally in conserved fodder such as hay or when their seeds contaminate feed grains. The toxicity of plants containing PAs is not significantly reduced by conversion of the plants to hay or ensilage or by pelleting, but hot air drying of the

plants considerably reduces their toxicity. Flowers are more toxic than herbage. Mature plants are avoided, the largest intake by animals being when the plants are sending out new shoots. With *Senecio* spp. it is the foliage that is the source of the poisoning. With *Crotalaria*, *Heliotropium*, and *Amsinckia* spp. the seeds are a common source, either as contaminants of grain crops harvested for animal feed, or in the cake made from the seeds after the extraction of oils. This is usually the way in which pigs are poisoned.

Environmental stress, including drought and high temperatures and especially spraying with herbicide, appears to increase the plants' content of PAs. The differences in PA concentration in different samples of the same plant species, invalidates the evaluation of the toxicity of the plant on the basis of intake by the animal.

Animal factors

Species

Cattle and horses are very susceptible to PA poisoning, being 30–40 times as susceptible as sheep and goats. The difference appears to be related to the animal's ability to detoxify the pyrrolizidine alkaloids in the liver, probably related to the diet consumed before domestication. Small herbivores are more likely to be browsers and to develop resistance to the toxins. It is possible that detoxication of the PAs may occur in the rumen as a result of microbial activity but there are opposing opinions about this.[11]

Stored feeds

Although most field cases of poisoning occur in animals grazing pasture infested with the toxic plants, the disease may result from the feeding of contaminated, stored feeds, especially hay, or the use of the plants in bedding. The effects of the intoxication are cumulative and fatal intoxication may develop over a period of years.

Importance

PAs and their metabolites are excreted in cows' milk but are thought not to represent a health threat to humans. Experimental feeding of goats' milk containing PA metabolites has produced hepatic lesions in rats. Concentrations of these substances in the meat of animals eating the plants are similarly not thought to be dangerous to humans. Mass mortalities are possible among intensively housed livestock such as pigs, poultry,[12] and feedlot cattle.[13]

PATHOGENESIS

Hepatic injury

PAs themselves are not poisonous but their pyrrolic metabolites,[14] produced in the liver, are serious, cumulative hepatotoxins which combine with pyrrol groups to form pyrrolic thioethers that damage liver cells by inhibiting mitosis leading to loss of hepatocyte numbers and megalocytosis, and thus causing the clinical signs and death due to hepatic dysfunction.[15] The relative resistance of **sheep** to PA toxicity may be related to the relatively low capacity of the sheep's liver to produce pyrrols. In **cattle**, as well as the megalocytosis, there is damage to the centrilobular and hepatic veins leading to occlusion of the vessels.

The progress of the disease in **ponies** may be in one of two patterns. In the chronic disease there is a gradual worsening of signs until death at 6–22 weeks. In the chronic-delayed form the lesions progress, as measured by biopsy, but there are no clinical signs until a sudden onset of illness at 38–58 weeks.[16] Similarly, the signs of the disease may not occur until several months after the last ingestion of the toxic material, with death occurring soon afterwards.[17]

Hepatic encephalopathy

One of the consequences of liver insufficiency is the systemic accumulation of metabolites such as ammonia, which is associated with cerebral edema. This results in the nervous signs of depression, aimless walking, and head-pressing. The spongy degeneration (status spongiosis) produced in the CNS is characteristic of hyperammonemia. Other metabolites may also be significantly involved, but ammonia is best studied.

Toxemic jaundice

Liver damage due to ingestion of PAs, commonly *Heliotropium europaeum*, results in the accumulation of copper in the liver, but only if the copper intake in the diet is above normal,[18] and may be associated with clinical cases of chronic copper poisoning in sheep, leading to the development of one of the forms of 'toxemic jaundice'. *Echium plantagineum* has the double disadvantage of containing PAs and a high copper:molybdenum ratio so that copper accumulation occurs readily in the plant.[19] Similar accumulations of zinc and iron also occur. There is some evidence for an impairment of storage of vitamins A and E by PAs, but there are no field occurrences of resulting wastage.

The **reactive metabolites of hepatoxic pyrrolizidines** produced during their toxic attack on the liver escape into the general circulation and are associated with damage to other tissues, and are also associated with the **nephrosis** and **interstitial pneumonia** that occur in some poisonings and in some incidents are associated with poisoning by known hepatoxins. They also react with erythrocytes and the pyrrolic esters formed there are bound to hemoglobin so that they could be used as markers of past intake of the PAs.[14] The usefulness of the technique is limited by the short life span of erythrocytes. Besides the incidental escape of toxic metabolites into the circulation and the subsequent damage to pulmonary tissue, the PAs from some plants, e.g. some southern African *Crotalaria* spp., exert their major effect on lung tissue and produce pulmonary as well as hepatic signs.[20]

An unusual outcome to pyrrolizidine toxicosis of horses is the development of **gastric impaction** with the dried stalks of the plant, causing colic with nasal regurgitation and, in some cases, a fatal gastric rupture.[21]

CLINICAL SIGNS

Although the causative lesions develop slowly in most cases, the onset of clinical signs is usually sudden. The prominent signs are hyposensitivity to external stimuli, anorexia, precipitate drop in milk yield and, in cases surviving for more than 2 days, there is often jaundice and photosensitive dermatitis. The onset of illness may occur many months after the animals have been removed from the toxic pasture. Sheep may have serious liver damage but the effects may be limited to loss of body weight and reduction in wool yield.[22] Most animals poisoned with PAs develop the hepatic syndrome detailed below. However, some cases will have signs of uremia or interstitial pneumonia, described elsewhere in this book. For example, horses fed large amounts of *Crotalaria juncea* seeds in their feed develop severe dyspnea associated with massive consolidation of lungs.[23]

Cattle

In poisoning due to *Senecio* spp., there is a sudden onset of depression and poor sensitivity to external stimuli. This hyposensitivity is sometimes punctuated by short outbursts of excitability and frenzy, and often by aggressive behavior. During these episodes there is usually severe diarrhea and straining to defecate. This may result in a high incidence of rectal prolapse. Other signs include abdominal pain, staggery gait, with dragging of the hooves, walking in circles, and partial blindness. Such cases usually die within 2–3 days of the onset of signs.

Some cases may linger on for several weeks. There are no excitable episodes, the animal remains hyposensitive, loses weight and becomes anorexic, is afflicted with diarrhea and tenesmus, and usually develops jaundice, mucosal pallor and, rarely, photosensitive dermatitis.

Horses

Horses poisoned by *Senecio jacobaea*[24] or *Crotalaria crispata/C. ramosissima* lose much weight, are mildly jaundiced, and profoundly hyposensitive to external

stimuli, often standing with the head held down and stopping eating halfway through a mouthful of hay or grass. There is muscle tremor, especially of the head and neck, frequent yawning, and difficulty in swallowing. The latter may be sufficiently severe to cause aspiration of food into the lungs or its regurgitation through the nasal cavity. Affected horses appear to be blind. They walk in circles or straight ahead, bumping into objects and becoming wedged in places from which they cannot back out; they also walk into streams, houses, or outbuildings. Death due to misadventure is a frequent outcome. Head-pressing is common and there may be attacks of frenzy and violent, uncontrollable galloping. Multiple skin abrasions of the head and chest are indicators of this deranged behavior. The disease is usually fatal, the course lasting from a week to several months. Poisoning of horses by *Echium plantagineum* is associated with weight loss, severe hyposensitivity, and jaundice. **Paralysis of the pharynx and larynx** are thought to be associated with an unusual occurrence of severe inspiratory dyspnea in ponies with severe pyrrolizidine toxicosis.[25] A further unusual effect in horses may be intravascular hemolysis, manifested as hemoglobinuria. Pseudo-neoplastic proliferation of bronchiolar epithelium is the basis of jaagsiekte of horses manifest as progressive severe dyspnoea associated with pneumotoxic pyrrolizidine alkaloids such as dicrotaline, monocrotaline, fulvine, and crispatine in some *Crotalaria* spp., including *C. dura, C.globifera, C. juncea, C. spartioides* in southern Africa and *C. ramosissima, C. crispata,* and *C. mitchellii* in Australia.

Pigs

Pigs poisoned with *Crotalaria* spp. show anasarca, pale mucosae and conjunctiva, ruffled bristles, emaciation, and apathy.[26] The disease is chronic and progressive, and the mortality rate is high.

CLINICAL PATHOLOGY

Direct diagnosis of a patient's exposure to pyrrolizidines is possible by the detection of pyrrolic metabolites bound to hemoglobin in erythrocytes. Contributory evidence is the presence of hyperammonemia, hyperbilirubinemia, and hypoalbuminemia. The bromsulphalein (BSP) clearance rate is impaired and levels of serum enzymes are transiently elevated. For the prediction of early hepatic damage in cattle grazing on *Senecio* spp., measurements of serum γ-glutamyl transpeptidase and glutamyl dehydrogenase are recommended. In horses, γ-glutamyltransferase and alkaline phosphatase estimations are favored, especially the former which is recommended as a screening test to identify subclinical cases in horse herds.[27] The changes in serum liver enzymes precede the changes detectable histologically in liver biopsy specimens. For assessment of the degree of damage to the liver in chronic cases a combination of BSP clearance test and liver biopsy is regarded as most helpful in cattle and horses.

NECROPSY FINDINGS

Hepatic megalocytosis, fibrosis, which may be veno-occlusive, and biliary hyperplasia are the common histopathological findings. In cases of sufficient duration there is jaundice, general edema, and ascites. Secondary histopathological changes occur in intestinal mucosal cells and may be responsible for impaired absorption of nutrients. In some cases, and in some poisonings associated with PA-bearing plants, necropsy findings will be dominated by lesions of nephrosis, particularly in pigs, or interstitial pneumonia, particularly in horses.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation depends on positive identification of pyrrolic metabolites in blood or liver. Presumptive diagnosis is provided by hepatic histopathology detecting megalocytosis, which needs to be differentiated from that seen in aflatoxicosis. Cases in which exposure to toxic plants occurred some time ago can only be diagnosed presumptively.

Differential diagnosis lists

Cattle, hepatopathies due to:

- Phytotoxins, e.g. in *Lantana* spp., *Myoporum*
- Mycotoxins as in *Aspergillus* spp., *Phomopsis*, *Diaporthe toxica*, *Myrothecium* spp.
- Tunicaminyluracil poisoning as in *Clavibacter toxicus*
- Cyanobacterial toxins
- Zootoxins as in *Lophyrotoma*, *Arge* spp.

Encephalopathies such as:

- Rabies
- Lead poisoning
- Polioencephalomalacia.
- Other causes of jaundice also need to be taken into account. Special attention needs to be given to chronic copper poisoning in sheep because sheep poisoned by PAs are much more inclined to develop high levels of copper in the liver than are other sheep.[28]

Horses:

- Equine viral encephalomyelitis
- Nigropallidal encephalomalacia
- Leukoencephalomalacia.

TREATMENT

Primary treatment of the hepatic lesion is unlikely to be attempted. **Supportive** treatment requires provision of a high nutrient diet during the convalescent period plus symptomatic treatment for photosensitization and dehydration. Horses that have recovered clinically may never regain their former physical fitness and any exertion will lead to rapid exhaustion.

CONTROL

Populations of these plants undergo cyclic changes and the diseases associated with them tend to wax and wane. Artificial reduction of plant numbers using herbicides is attempted. Because of the comparative resistance of sheep to PA poisoning they may also be used to keep infested pasture under control by having them graze it only intermittently, for example for a 1-month period once a year, or for only one season during their lifetime. Biological control, using insects such as the cinnabar moth (*Tyria jacobea*), which feeds only on plants that contain PAs, may be an effective control procedure for their specific host plants. A concerted effort at biological control of *Heliotropium europaeum* and *Echium plantagineum* is currently underway in Australia using several insect herbivores and fungal pathogens in combination. Attempts to control *H. europaeum* poisoning by administration of cobalt or an antimethanogen have been unsuccessful.[29] Attempts at immunization against PAs, manipulation of ruminal flora, manipulation of hepatic metabolism, protection by thiol compounds, and selection for heritable resistance, have all failed to date.

S-METHYL-L-CYSTEINE-SULFOXIDE (SMCO) AND DIPROPYL/DIPROPENYL DISULFIDE POISONING

Synopsis

Etiology *Brassica* spp. contain SMCO. *Allium* spp. contain N-propyl disulfide.
Epidemiology Outbreaks when mature plants grazed. Heavy morbidity and case fatality rates.
Clinical findings Acute onset, pallor, hemoglobinuria, jaundice if the patient survives long enough.
Clinical pathology Low blood levels of hemoglobin, erythrocytes. Hemoglobinuria.
Necropsy findings Pallor, jaundice, hemoglobinuria.
Diagnosis confirmation High blood levels of dimethyl disulfide in SMCO poisoning. The test is not generally available.
Treatment No primary treatment; supportive treatment is blood transfusion.
Control Dilute toxic feed with, e.g. pasture hay.

ETIOLOGY

Plants of all the *Brassica* species are associated with several syndromes, including hemolytic anemia due to SMCO poisoning recorded here; blindness, pulmonary emphysema, and digestive disturbances, dealt with under glucosinolate poisoning; and photosensitization. These syndromes may occur separately or in combination.

S-methyl-L-cysteine sulfoxide (SMCO) is a rare sulfur-containing α amino acid which occurs in some genera of plants in the family Brassicaceae (e.g. *Brassica, Raphanus*). Its metabolic products in ruminants are associated with serious hemolysis and anemia. The plants known to contain SMCO are *Brassica campestris* (turnip rape, cole), *B. napobrassica* (swede, rutabaga), *B. napus* (rape = canola), *B. oleracea* (kale, kohlrabi, chou moellier, cabbage, cauliflower, broccoli, Brussels sprouts, calabrese), *Raphanus raphanistrum* (wild radish),[1] and possibly *Thlaspi arvense* (fanweed)[2] and *Berteroa incana* (hoary alysum).[3] The green parts of the plants are the usual material involved in outbreaks.

The anemia-producing agent in poisonings by these plants is **dimethyl disulfide**, produced by ruminal bacteria from SMCO. The SMCO content of forage brassicas increases as the plant matures. The toxic dose of SMCO is 15 g/100 kg BW daily to produce severe, fatal anemia. Intakes of 10 g/100 kg BW are associated with a subacute, low-grade anemia.

Culinary vegetables

Particular note should be taken of the occurrence of SMCO in cabbages, swedes, and stubble turnips. The level may be insufficiently high to be associated with anemia, but may be associated with failure to gain weight satisfactorily, or clinically evident ill-thrift. *Allium* spp. (family Liliaceae), e.g. *Allium canadense* (wild onion, Canada garlic), *A. cepa* (commercial onion), *A. sativum* (garlic), *A. schoenopraum* (chives), *A. triquetrum* (three cornered garlic), *A. ursinum* (ransoms), and *A. validum* (wild onions), the plants responsible for onion-induced anemia, are usually bracketed with this group of plants because the hemolytic agents, propyl disulfide, 1-propenyl and 2-propenyl disulfides,[4] are chemically similar to, and their effects are the same as, those of the SMCO-induced anemia.

Hypophosphorosis

Although there may be no etiological relationship, it is not uncommon for the hemolytic disease to occur in the presence of hypophosphorosis, and therefore at the same time as postparturient hemoglobinuria.

The seeds and leaves of these plants also contain another glucosinolate, **sinigrin**, and its breakdown products, allyl cyanide and allyl isothiocyanate, which may depress food intake but appear to exert no hemolytic activity.[5] The plants may also contain significant quantities of **cyanogenetic glycosides** but rarely are associated with cyanide poisoning. Nitrate and **nitrite poisoning** have also been recorded on kale feeding.

EPIDEMIOLOGY

Occurrence

Rape and kale poisoning are well known where these plants are grown for fodder and in some areas they are no longer used because of the danger. The overall prevalence of poisoning is probably not great but on individual farms the number affected is usually significant, and the mortality rate is high.

Risk factors

Plant factors

The plants are more toxic as they mature and when secondary growth begins; the flowers and seeds are particularly poisonous. The toxicity of the plants varies from year to year, and on rape grazing most outbreaks occur in wet years when early frosts occur and the leaves turn a purple color. The toxicity of kale also varies significantly between varieties of the plant but the important factors in most outbreaks are the maturity of the crop and the amount eaten. The toxic principle in kale is destroyed in heat-dried or ensiled material but is still present in frozen and dried material. Onions fed at greater than 25% of the ration for cattle can be associated with hemolytic disease.

Animal factors

Only ruminants are affected by the poisoning, and the hemolytic effect is produced only when the diet consists largely of the plants and when the animals are on the feed for at least 1 and usually 3 weeks. Sheep are less susceptible to onion poisoning than cattle.

PATHOGENESIS

Dimethyl disulfide and the propyl disulfides are agents that oxidize hemoglobin, lead to Heinz–Ehrlich body formation from denatured hemoglobin in erythrocytes, and ultimately to hemolysis. The resulting hemolytic anemia affects all classes of ruminants but its effects are most serious in heavily pregnant and recently parturient females. The reasons for the observed tendency for cycles of spontaneous improvement followed by recrudescence of the anemia are not explained. A previous suggestion that they were related to variations in the cellular content of reduced glutathione, which prevents the formation of Heinz–Ehrlich bodies, has been discredited.

CLINICAL FINDINGS

In the anemia syndrome, the onset in severe cases may be so sudden that no signs are observed before the animal collapses and dies. If clinical illness is apparent, hemoglobinuria is observed first and is soon followed by weakness and dejection. Pallor of the mucosae, moderate jaundice, tachycardia, and a slight increase in respiratory rate and depth are also observed. Diarrhea occurs commonly and, although body temperatures are usually normal to low, there may be fever up to 40.5°C (105°F). Death is common unless effective treatment is provided, and surviving animals require a long period of convalescence. A normal hematological status may not be regained for up to 6 weeks. In an affected herd it is common to find a number of animals that

are not seriously ill, but with a subclinical anemia.

CLINICAL PATHOLOGY

The erythrocyte count, hemoglobin concentration, hematocrit, and leukocyte count are reduced, and Heinz–Ehrlich bodies are present in up to 100% of erythrocytes. They are significantly increased in numbers before anemia appears. The anemia is macrocytic and the hemoglobin level falls from 110 g/L to 6 g or less. Hemoglobin is present in the urine. There is often a concurrent hypophosphatemia. The dimethyl disulfide content of the blood, which will be high at the time of occurrence of the poisoning, can be measured chromatographically.

NECROPSY FINDINGS

There is pallor, jaundice, hemoglobinuria, thin, watery blood, dark coloration of the kidney, accentuation of the lobular appearance of the liver and, in peracute cases, swelling of the spleen. Histologically there is moderate periacinar, hepatocyte necrosis in the liver, compatible with the effects of hypoxia.

DIFFERENTIAL DIAGNOSIS

The occurrence of the disease when cattle or sheep are grazing on plants of the family Brassicaceae or consuming *Allium* spp. suggests the presumptive diagnosis. Diagnostic confirmation is by measurement of dimethyl sulphide levels in the blood. The differential diagnosis list includes:

- Postparturient hemoglobinuria, which is limited to cows that have calved recently
- Leptospirosis in calves
- Bacillary hemoglobinuria
- Babesiosis
- Chronic copper poisoning.

TREATMENT

Primary treatment in the form of an antidote to SMCO is unavailable. **Supportive treatment** includes, in severe cases of anemia, an immediate blood transfusion. Hematinic preparations and the provision of a highly nutritious diet are also used.

CONTROL

The provision of ample hay either daily before the animals are pastured on the rape, as a stack in the rape field, or allowing access to a field of rough grass, are recommended to reduce the consumption of rape. Rape showing purple discoloration should be regarded with suspicion and only limited grazing permitted until doubts as to its safety are satisfied. Cattle and sheep grazing on these plants should be kept under close observation so that affected animals can be treated in the early stages of the disease. An adequate phosphorus intake is particularly necessary. If feeding is stopped, the hemoglobin levels return to normal in about 3 weeks. Even if feeding is continued there is a strong tendency for a spontaneous recovery and further similar cycles to occur. Some varieties of kale have lower concentrations of SMCO and a genetic approach to preventing the disease might be worth examining.

The disposal of superfluous onions is a major horticultural problem, best solved by feeding them to animals. This can be done without fear of causing anemia by feeding them mixed into a balanced ration containing less than 25% of onions. Sheep appear to tolerate the toxins in onions more than cattle and have been adapted to a 100% onion diet without ill effect.[6]

THIAMINASE POISONING

Synopsis

Etiology Thiaminases occur in the *Marsilea*, *Cheilanthes*, *Pteridium*, and *Equisetum* spp. ferns, and are generated by microbes in the rumen of animals affected by polioencephalomalacia.
Epidemiology Outbreaks in ruminants with access to ferns, horses fed hay containing bracken; pigs eating bracken, especially rhizomes.
Clinical signs Ruminants – blindness, depression; horses – muscle tremor, cardiac irregularity, crouched posture, incoordination, recumbency, death; pigs – dyspneic sudden death.
Clinical pathology Low blood levels of thiamin, transketolase, high levels of pyruvate.
Necropsy findings Polioencephalomalacia in ruminants, not in horses; cardiac lesions in pigs.
Diagnostic confirmation. Low blood levels of thiamin.
Treatment Thiamin injected gives excellent results, provided thiaminase source is withdrawn.
Control Denial of access to toxic plants.

ETIOLOGY

The identified thiaminases which are important to animals occur in ferns and catalyze the decomposition of thiamin. The most widespread occurrence of a thiaminase-induced thiamin deficiency is polioencephalomalacia in ruminants.

The ferns which are sources of thiaminase, and the animal species affected are:

- Horses – *Pteridium* spp., *Equisetum arvense*, *E. fluviatile*, *E. hyemale*, *E. palustre*, *E. ramossisimum*, *E. sylvaticum*, *Marsilea drummondii*
- Sheep – *Marsilea drummondii*, *Cheilanthes sieberi*
- Cattle – *C. sieberi*, *Dryopteris borreri*, *D. filix-mas*.[1] See also *Phalaris aquatica* sudden death syndromes.

Thiaminases are of two types, methyltransferase, and a hydrolase. The hydrolases are not found in plants but only in the rumen, presumably as metabolites produced by ruminal bacteria from specific precursors in the plants.[2] Plants containing thiaminases are usually deficient in thiamin.

EPIDEMIOLOGY

Thiaminase poisoning associated with *Pteridium* spp. and *Equisetum* spp. occurs almost always in **horses** fed on hay contaminated by the ferns, and is most toxic if the hay is cut when the fronds are very young. The standing plants are unpalatable and rarely eaten by these animals. Signs of poisoning in grazing horses do not occur until the horses have had access to the fern for 3–4 weeks, but the period is much shorter if they are fed in stables on heavily contaminated hay. The thiaminase content of the ferns varies widely, being highest at a period of rapid growth and after being grazed severely.

Grazing **pigs** may root out and eat *Pteridium* rhizomes, which contain a much higher concentration of the thiaminase than the fronds. Sheep grazed on pastures dominated by *Marsilea drummondii* (nardoo) on floodplains in inland Australia or forced to graze *Cheilanthes sieberi* are poisoned.

Grazing **cattle** may be forced to eat the ferns because of lack of other feed and when the fern is at a toxic, rapidly growing stage, but are not affected by a thiamin deficiency. They succumb to a hemorrhagic disease. Thiaminase activity occurs in the fronds of the ferns *Marsilea drummondii*, *Cheilanthes sieberi* and *Pteridium aquilinum* in descending order of magnitude.

PATHOGENESIS

A state of thiamin deficiency is created by the destruction of thiamin in the alimentary tract. The activities of enzymes that require thiamin are impaired and there is an accumulation in tissues of pyruvate and lactate. The relationship between the intake of the thiaminase and the nervous signs is not adequately explained. That there is such a relationship is suggested by the development of brain lesions of polioencephalomalacia in sheep poisoned by *Marsilea drummondii* and in those fed

experimentally on the rhizomes of *Pteridium aquilinum*.

CLINICAL SIGNS

Affected **horses** sway from side to side, show gait incoordination, including crossing the forelimbs and a wide action in the hindlimbs. Abnormal postures include a wide stance, arching of the back, and crouching. Muscle tremor, cardiac irregularity, and bradycardia are evident and the appetite and demeanor are normal. Terminally, the animal falls easily, becomes recumbent and hyposensitive to external stimuli, and makes convulsive movements. The heart rate and the temperature become elevated. Additional signs seen in horses poisoned by *Marsilea drummondii* include carrying the head close to the ground, whinnying, partial blindness, nodding of the head, twitching of the ears, and frequent yawning.

The clinical syndrome in **pigs** fed bracken rhizomes in excess of 25% of their diet includes anorexia, recumbency, dyspnea, and death after a course of about 6 hours.

Sheep poisoned by *Marsilea drummondii* may be affected by an acute or a chronic syndrome. The chronic syndrome is indistinguishable from polioencephalomalacia, and is dealt with under that heading. The acute form of the disease is characterized by the sudden onset of dyspnea, depression, and recumbency and death in 6–8 hours. Sheep affected by *Cheilanthes* spp. poisoning are hyposensitive to external stimuli, including being blind, and walk slowly and with an uncoordinated gait.

Cattle poisoned by *Dryopteris* spp. are also blind and hyposensitive. Many recover but remain blind.

CLINICAL PATHOLOGY

The characteristic findings attributable to a nutritional deficiency of thiamin are present. These include depression of blood levels of thiamine and transketolase, and elevation of levels of blood pyruvate.

NECROPSY FINDINGS

In naturally occurring cases in horses there are no lesions recorded other than the non-specific ones of acute or congestive heart failure. Polioencephalomalacia has been seen in sheep and, in pigs, an enlarged mottled heart and congestion of the lungs and liver indicate the presence of congestive heart failure.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation is based on low blood thiamin levels. The differential diagnosis list includes:

- Hepatic encephalopathy is similar but the course is usually much longer. There are also signs of hepatic insufficiency
- Infectious encephalitides
- Toxic encephalomalacias
- Staggers syndromes, e.g. rye-grass staggers, paspalum staggers, phalaris staggers.

TREATMENT

In the early stages the administration of thiamin and removal of the dietary source of thiaminase are the critical procedures, and recovery is to be expected. In large animals the IV or IM injection of 100 mg of thiamin, twice on day 1, followed by similar daily IM injections for 7 days (with double doses in severe cases) is recommended.[3] The response to treatment is dramatic.

CONTROL

Large-scale control of bracken is attempted by a combination of pasture management, application of herbicide and mechanical slashing, but is expensive and subject to error so that professional agrostological advice is desirable.

POISONING BY MISCELLANEOUS PHYTOTOXINS

AESCULIN

The hydroxycoumarin glycoside aesculin occurs in *Aesculus* spp. plants including *A. californica*, *A. glabra*, *A. hippocastanum*, *A. octandra*, *A. pavia* (buckeyes or horsechestnuts), *A. pavia*[1] being the most toxic. Ingestion of the seeds and nuts is usually reported, but toxicity also occurs after eating foliage. In monogastric animals the glycoside is associated with gastroenteritis with vomiting, but its digestion in ruminants to a soluble aglycone results in the more common syndrome of depression, straddled posture, stiff and incoordinated gait, tremor, easy falling, recumbency, and convulsions with opisthotonos. Signs are exacerbated by handling or harassment. No necropsy lesions are reported.

ALCOHOL (COMPLEX PLANT)

Included are cicutoxin, occurring in *Cicuta* spp. (water hemlock), oenanthotoxin, isomeric with cicutoxin, in *Oenanthe* spp. (water hemlock dropwort), and tremetol in *Eupatorium rugosum* (snakeroot) and *Haplopappus heterophyllus* (goldenrod).

Cicutoxin poisoning in all species is characterized by early tremor, restlessness and stumbling gait, followed by violent clonic convulsions with bellowing, opisthotonos, and frothing at the mouth. Between convulsions there is ruminal tympany, dyspnea, profuse salivation, teeth grinding and chewing movements, frequent urination and defecation, tachycardia, hyperthermia, and pupillary dilation. Most affected animals die of respiratory failure after a course of a few minutes, but more usually several hours.[2] Serum levels of muscle enzymes are elevated as a result of the muscle activity. Necropsy lesions comprise skeletal and cardiac myodegeneration. The characteristic roots may be found in the forestomachs, more commonly lodged in the esophageal groove than in the rumen proper.[3] In experimentally produced cases, IV sodium pentobarbital administered at the onset of the first convulsion prevents further convulsions and the myodegeneration,[4] but no practicable remedy is available for natural cases. Prevention depends on keeping animals away from the plant, including the roots, which may be exposed during excavation or after flooding

Oenanthotoxin poisoning is associated with an identical syndrome, most commonly in cattle. The roots of the plant are the common source of the poison[5]

Tremetol is associated with stiffness and incoordination of gait, severe tremor, salivation, depression, recumbency, and coma preceding death in ruminants. In horses there is heavy sweating, regurgitation of food through the nostrils and the passage of dark, hard feces, and there may be congestive right heart failure with electrocardiographic abnormalities and extensive myocardial damage. The alcohol is excreted in the milk of cattle which ingest the plant and may be associated with clinical illness and even death in humans drinking the milk.[6] Liver damage and nephrosis are detectable as necropsy lesions.

ALIPHATIC ACETOGENIN (MONOGLYCERIDE)

The toxin responsible for poisoning by *Persea americana* (avocado, alligator pear) is a biologically active aliphatic acetogenin, persin, with the form of a monoglyceride.[7] Only varieties of Guatemalan origin are toxic; Mexican varieties are not. All parts of the plants can be toxic. Horses, ruminants, and ostriches have been affected.[8,9] In lactating females, poisoning

produces sterile mastitis and agalactia with necrosis of secretory epithelium of mammary glands. Horses are affected by a heart failure syndrome, usually non-fatal, with severe subcutaneous edematous swelling of the head and dyspnea. In some cases, there is ischemic necrosis of masseter and tongue muscles.[10] Fatal cases have myocardial necrosis. Colic and diarrhea have been reported in foals. Poisoned ostriches have paresis of neck muscles, edema of the neck, pulmonary edema, and necrosis of cardiac muscle.[11]

AMINE TOXICITY

Two toxic amines identified in plants are the teratogen cyclopamine in *Veratrum californicum* and tyramine (*N*-methyl-phenylethyl-amine) found in *Acacia berlandieri* (guajillo), and two mistletoes *Phoradendron villosum* and *Viscosum album.*

Tyramine

Clinical signs in poisoning by the acacia include gait incoordination, limb weakness and recumbency, all exacerbated by exercise or harrassment, and all of which disappear if the patient is removed from contact with the plant. No signs are attributed to poisoning by mistletoe, the only event recorded being the patient being found dead.

Cyclopamine

Cyclopamine, the toxic amine found in *Veratrum californicum* (skunk cabbage) is associated with severe congenital cyclopean deformities of the head, absence or displacement of the pituitary gland with prolonged gestation, and giantism in lambs, calves and kids when fed to the dams in early pregnancy (between the 14th and 30th days in ewes). Many other defects, including cleft palate, harelip, syndactyly, various leg deformities, supernumerary claws, tracheal stenosis, and fetal death and resorption have been induced in neonatal lambs by feeding ewes at specific times in their pregnancies. For example, feeding ewes root material on day 29 is associated with shortening of the metatarsal, metacarpal, and tarsal bones, medial bowing of the forelimbs at the fetlock, and severe articular surface defects and arthrogryposis in some cases.[12] Dosing ewes at day 31–33 is associated with lateral flattening of the trachea and death due to asphyxia within 5 minutes of birth. Early fetal death, possibly with resorption occurs, after dosing on day 14.[13]

AMINO ACID TOXICITY

The best-known toxic amino acids are:

- Indospicine in *Indigofera spicata* (creeping indigo)
- Indospicine in *Indigofera linnaei* (*I. dominii*, *I. enneaphylla*, Birdsville indigo),
- Canavanine in *Canavalia* spp., *Indigofera linnaei*
- Mimosine in *Leucaena leucocephala* (lead tree) and *Mimosa pudica* (sensitive plant).

Indospicine

Poisoning by *Indigofera linnaei* has generally been ascribed to indospicine but is now considered to be associated with a nitro-compound. Indospicine transmitted to dogs fed on meat from poisoned horses is associated with fatal liver damage in the dogs.[14] *Canavalia* spp. and *I. spicata* in sheep and cattle are associated with a similar syndrome including anorexia, hyposensitivity, gait incoordination, and abortion in some.

Canavanine

Canavanine poisoning is also associated with a syndrome including stiff gait, stumbling, recumbency, and diarrhea, with loss of weight and reduction of feed intake. Necropsy findings include gastroenteritis, nephritis, and pulmonary emphysema.

Mimosine

The non-protein amino acid mimosine occurs in *Mimosa pudica* (sensitive plant) and *Leucaena leucocephala*, a leguminous fodder shrub. Mimosine plus an enzyme in plant tissue produces 3,4-dihydroxypyridone (3,4-DHP), a potent goitrogen, which on mastication yields 2,3-DHP through the action of rumen flora. Mimosine, 3,4-DHP and 2,3-DHP are all toxic. Both plants are associated with alopecia but *Leucaena* spp. is associated with the disease known as 'jumbey' (Bahamas) or 'lamtoro' (Indonesia). Some varieties of the tree contain more mimosine than others. Safe daily intakes of mimosine are 0.18 g/kg BW for cattle, 0.14 g/kg BW for sheep, and 0.18 g/kg BW for goats. There is a great deal of variation in the effects of poisoning with *L. leucocephala*, depending on the variety of the tree, the amount of other fodder available, and the selection of the feed by the animal. Horses, sheep, and cattle are commonly affected, goats not so commonly.

Cattle and goats in Indonesia, Hawaii and the Virgin Islands, where the tree is indigenous, eat very large amounts of the plant without ill-effect. This immunity is due to the adaptation of ruminal microflora to degrade the mimosine, the degree of degradation varying with the diet, being much greater on a concentrate diet than on a roughage one. A transfer of rumen contents from resistant to susceptible cattle is a successful preventive veterinary procedure. The bacterium capable of degrading the toxins is *Synergistes jonesii*.[15] In some areas, if ruminants are introduced to the plant gradually enough, the ruminal microflora may develop the capacity of metabolizing mimosine so that poisoning is not a problem.

Alopecia (depilation), commencing at the tail switch and the preputial orifice, and nervous signs are constant clinical findings. Inconstant signs are cataract, gingival atrophy, lingual epithelial ulceration, goiter, infertility, and low birth weight. In experimental animals, hepatic injury is one of the most marked effects, but this is not recorded in field cases.

In horses the loss of hair is most marked in the mane and tail, and around the hocks and knees. Ring formation in the hooves and emaciation also occur. In cattle and sheep shedding of hair or wool occurs soon (7–14 days) after the first exposure to the plant, when very large amounts are fed. The alopecia is not necessarily general but is symmetrical. Experimental feeding of large amounts of the plant to steers has been associated with hair loss especially on the tail, pizzle, and escutcheon. Cattle fed on the plant for long periods develop other chronic syndromes including incoordination, temporary blindness, and hyperactivity to the point of severely interfering with normal handling procedures. A secondary phase of poisoning is associated with the formation of DHP is recorded in some countries, but not others. It is characterized by enlarged thyroid glands, poor breeding performance and goitrous, weak calves. The goitrogenic effect is limited to ruminants, is associated with 3,4-DHP, and is not responsive to iodine administration. A further complication, seen in goats on low-level feeding over a long period, is fibrous osteodystrophia of the mandible, causing salivation, slow eating, and weight loss. The long bones are normal.

In pigs, the feeding of diets containing up to 15% of dried *L. leucocephala* to pregnant gilts is associated with a high proportion of fetuses being resorbed and some having limb deformities. Feeding 1% ferrous sulfate in the diet reduces these effects, and supplementation of the diet of ruminants with iron, copper, and zinc is also claimed to reduce the toxic effects.

All toxic effects are quickly reversible by removing animals from access to the plants, so the case fatality rate is usually low. Necropsy lesions are limited to alopecia, oral and esophageal ulcers, and thyroid enlargement.

Animals grazing heavily on *L. leucocephala* are likely to have low blood levels of thyroxine, and high blood and urine levels of DHPs.[16]

AMINOPROPIONITRILE

3-Aminopropionitrile is a poisonous substance found in *Lathyrus* spp. (wild peas),[17] e.g. *Lathyrus hirsutus* (wild winter pea), sometimes sown with grasses to

provide early spring grazing. Signs of toxicity in cattle grazing mature plants bearing seed pods[18] consist of salivation, sawhorse stance, head held low, continuous head and ear movements, trance-like gaze, diminished responsiveness, reluctance to move, pain in the feet causing lameness, sitting with the feet under the body, and a marked disinclination to rise. Other signs include lameness, stumbling gait, recumbency, and paddling convulsions. The signs are exacerbated by driving or other harassment. Necropsy findings are limited to non-specific lesions such as pulmonary congestion.

ANDROMEDOTOXIN

Andromedotoxin (synonym acetylandromedol, grayanotoxin) is a resinoid substance, a member of the diterpenoid group of substances, found in plants of the Ericaceae including:

Agauria salifolia
Clethra arborea
Kalmia spp. – laurels
Ledum spp. – labrador tea
Leucothoe spp. – sierra laurel, hanahiri
Lyonia ligustrina – staggerbush
Menziezia ferruginea – mock azalea
Pieris (= *Andromeda*) spp.[19]
Rhododendron spp., most of them ornamental trees and bushes [20]

They are very poisonous; deaths occurring mostly after clippings from the plants are thrown into animal grazings. Clinical signs commence a few hours after the plant is eaten and include dullness, salivation, projectile vomiting, bloat, repeated swallowing or belching, tenesmus, abdominal pain, a staggering gait, recumbency, convulsions with opisthotonos, tremor, dyspnea, groaning and bleating, and a course of 2–3 days. Tachycardia and cardiac irregularity occur in some cases. Aspiration pneumonia is a common sequel and is the only common gross necropsy finding.[21] Histopathological changes are limited to minor lesions in the gray matter of the spinal cord.[22] The toxins are transferred to the honey made from these plants and is associated with toxicity in humans.

ANTHRAQUINONE

Anthraquinones are still extracted commercially from plants for use as irritant cathartics. Plants growing wild that contain these compounds are:

Senna (= *Cassia*) *occidentalis* – coffee senna
S. obtusifolia – sicklepod[23]
C. roemierana
C. italica
Frangula alnus – alder buckthorn
Rhamnus spp. – buckthorns.

Pigs[24] and cattle[25] may be poisoned by *Senna occidentalis* seeds which contaminate prepared rations. All of these plants are associated with severe gastroenteritis manifested by diarrhea, often with transitory signs of abdominal pain, if the dose is large and taken at one time.[26] Liver damage is also a common lesion in experimental and field cases and may dominate the necropsy findings.[27] Smaller doses of *Senna* spp. over a period of a week are associated with necrosis of striated muscle fibers characterized by limb weakness, incoordination, dragging the hind toe tips, and eventually paralysis in sternal or lateral recumbency. Necropsy lesions are cardiac and skeletal muscle necrosis, but these have not been shown to be direct effects of the anthraquinones.

ARISTOLOCHINE

This alkaloid occurs in:

Aristolochia bractea
A. clematitis – birthwort
A. densivena
A. elegans.

In goats, poisoning takes the form of diarrhea, dyspnea, alopecia, and hindlimb weakness. In horses, signs include straining to urinate, passing small amounts of urine frequently, polyuria, and tachycardia.

CANNABINOID

Cannabinoids are resinoids found in the plant *Cannabis sativa* (marihuana). The toxic principle is the alkaloid tetrahydrocannabinol. Clinical signs of poisoning in horses include restlessness, hypersensitivity, tremor, sweating, salivation, dyspnea, staggering gait, and death or recovery after a few hours. No significant necropsy lesions are recorded. Toxin is detectable in stomach (rumen) contents.[28]

COLCHICINE

The alkaloid colchicine, found in *Colchicum autumnale* (autumn crocus) and *Gloriosa superba* (flame or glory lily), is associated with acute diarrhea, abdominal pain, tenesmus, vomiting, and salivation in sheep, cattle, and pigs.[29] At necropsy, subserosal hemorrhages and gastroenteritis are evident. Mortalities are likely when cattle graze dense patches of *C. autumnale* in pasture or are fed hay containing the plant.[30] The toxin is excreted in the milk.[31]

CREPENYNIC ACID

Necrosis of cardiac and skeletal muscle, manifested clinically by a staggery gait and recumbency, or sudden death during exercise, is the significant lesion in poisoning of sheep by crepenynic acid, which is found in mature seed heads of *Ixiolaena brevicompta* (button weed).[32]

CYCAD GLYCOSIDE

All cycads that have been investigated contain one or more glycosides of methylazoxymethanol (MAM) known as cycasin, macrozamin, and pakoein. These include species of:

Bowenia
Cycas
Dioon
Encephalartos
Lepidozamia
Macrozamia
Stangeria
Zamia – cycads or zamia palms.

These robust cone-bearing plants grow in greatest numbers in poor soil in hot climates, and their young leaves and seeds are eaten eagerly by ruminants when other feed is short. MAM glycosides are much more concentrated in seeds than in leaves. The MAM glycosides are hydrolyzed in the rumen. MAM is further metabolized to a highly reactive methylating agent in the liver, producing periacinal hepatocyte necrosis and damage to blood vessels leading to hepatic veno-occlusion. Long-term intake results in liver cirrhosis. The liver lesions result in anorexia, weight loss, jaundice, and photosensitization. In addition, acute poisoning is associated with hemorrhagic necrosis of the abomasum and small intestine in sheep and cattle, causing severe diarrhea. Sheep are more likely than cattle to consume seeds and develop hepatogastrointestinal MAM poisoning. Pigs and horses have been experimentally poisoned with seeds. MAM is mutagenic and carcinogenic in laboratory animals, but this effect has not been described under natural conditions.

An unidentified neurotoxin in *Bowenia*, *Cycas*, *Macrozamia*, and *Zamia* produces posterior ataxia in cattle, a syndrome recognized in Australia where it is called zamia staggers, some Japanese islands, and in the Caribbean region. This is the most likely result of cattle consuming these plants under natural conditions; however, affected cattle often have some degree of chronic liver damage. This ataxia syndrome in sheep has been produced experimentally but is rare under natural conditions. Clinically, the condition is a proprioceptive defect affecting the hindlimbs causing an irregular, stiff, overextension ('goose-stepping'), and knuckling over at the fetlocks. Atrophy of hindlimb muscles and posterior paralysis may follow. There are degenerative lesions of the fasciculus gracilis, dorsal spinocerebellar tracts, and corticospinal tracts of the spinal cord. Affected cattle do not recover.

CYNANCHOSIDE

Cynanchoside is found in *Cynanchum* spp. (monkey rope) and a very similar

toxin is found in *Marsdenia rostrata* (milk vine), *Sarcostemma brevipedicellatum* (= *S. australe*) (caustic vine), and *S. viminale* (caustic bush). It is associated with hypersensitivity, restlessness, stumbling gait, tremor, recumbency, tetanic and clonic convulsions, and opisthotonos. Additional signs include teeth grinding, dyspnea, salivation, and vomiting.

DIANTHRONE DERIVATIVES

Hypericin is a complex derivative of dianthrone, and is found in *Hypericum perforatum* (St John's wort or Klamath weed) and *H. triquetrifolium* is the prototypical primary photosensitizing agent. All parts of these plants are associated with photosensitive dermatitis when ingested by sheep and cattle, but have to be eaten in large quantities. They are not very palatable and most outbreaks occur when they are in the young stage and dominate the pasture. Narrow leaf varieties contain two or three times as much hypericin as broad leaf varieties, and the flowering tops are six to eight times as toxic as other parts.[33] Clinical signs may appear within a few days of livestock going onto affected fields and usually disappear within 1–2 weeks after removal from them. Experimental production of poisoning with *H. perforatum* has shown that the plant contains a primary photodynamic agent. There is neither liver damage nor loss of hepatic function.

Fagopyrin, a red helianthrone pigment found in *Fagopyrum sagittatum* (buckwheat), is associated with primary photosensitization in all species.

DIHYDROXYCOUMARIN GLYCOSIDE

Toxins in the dihydroxycoumarin glycoside group are daphnetin and daphnin. Plants that contain them are:

Daphne spp.
Pimelea spp. (some only)
Gnidia spp.
Wikstroemia indica – tie-bush.

In some of *Pimelea* spp. the dihydroxycoumarin glycoside has been isolated. In most others its presence is suspected because of the similarity of the signs produced.

Clinical findings include abdominal pain, diarrhea, dysentery, stomatitis and salivation, and vomiting. Some cases have a short course and terminate fatally preceded by convulsions. Necropsy lesions include stomatitis and gastroenteritis. The clinical picture can be confused by the occurrence of simplexin (see under diterpene poisoning) in the same plant, in which case the signs of congestive heart failure are added.

In *Wikstroemia* spp. the alternative signs seen in red deer are those of a hemorrhagic disease, including mucosal pallor, bounding pulse, loud heart sounds, nasal bleeding, dysentery, and low erythrocyte count and hemoglobin level; platelet numbers are normal. Necropsy lesions include widespread hemorrhages and tissue pallor.

DITERPENOID (KAURENE) GLYCOSIDES (ATRACTYLOSIDE, CARBOXYATRACTYLOSIDE, PARQUIN, CARBOXYPARQUIN, AND WEDELOSIDE)

Diterpenoid glycoside toxins have been found in species of:

Atractylis
Atractylodes
Callilepsis
Cestrum
Iphiona
Wedelia
Xanthium.

Xanthium strumarium (cockleburr, Noogoora burr) includes the taxa *X. canadense*, *X. italicum*, *X. orientale*, *X. pungens*, *X. chinense*, and is poisonous to pigs and ruminants. *X. spinosum* (Bathurst burr) is also toxic and assumed to contain diterpenoid glycosides. The two cotyledonary leaves, either within the spiny burrs or just after sprouting, contain the largest amount of toxin and are the usual source of poisoning. The cockleburrs occur on most continents. Poisonings are reported from North America, UK, Europe, and Australia. Most deaths occur on flood plains where the weed is allowed to grow in abundance. After heavy rain the seeds in the burrs sprout and are palatable to all species, especially calves and pigs. Mortalities are also recorded in adult cows and sheep. Burrs may contaminate feed grains and poison livestock fed on the compounded ration.

Cestrum spp., e.g. *C. parqui*, *C. laevigatum*,[34] are garden plants originating from South and Central America which, except for *C. diurnum*, also contain a carboxyatractyloside toxin.

Wedelia asperrima (yellow daisy), *W. biflora*, and *W. glauca* contain wedeloside. Severe hepatic necrosis is the principal necropsy finding, and the clinical syndrome and clinical pathology are characteristic of hepatic encephalopathy.

The disease in pigs and calves is an acute one, manifested by hyperexcitability, so that the entire herd appears restless, followed by severe depression, rigidity of the limbs and ears, weakness and a stumbling gait, falling easily and recumbency, and clonic convulsions with opisthotonos. Calves may be belligerent. Acute cases die during the first convulsive episode.[35] The course may be as long as 48 hours and terminate in recovery, but death is the usual outcome. The characteristic lesion is hepatic necrosis.

Treatment is not undertaken. Control depends on keeping livestock away from pasture dominated by these weeds, especially when there are large quantities of sprouted *Xanthium* spp. seeds available.

IRRITANT DITERPENOIDS

The two important irritant diterpenoids are simplexin, an irritant diterpenoid daphnane ester found in *Pimelia simplex*, *P. trichostachya* and others, and 12-deoxyphorbol found in *Euphorbia* spp. (spurges).

Poisoning by **12-deoxyphorbol** is associated with a syndrome of stomatitis and enteritis. Cattle generally avoid leafy spurge (*Euphorbia esula*), apparently because they develop a conditioned aversion to it,[36] but sheep and goats will graze it.

Simplexin is associated with a syndrome of congestive heart failure with diarrhea and anemia only in cattle in eastern Australia called St. George disease or Marree disease. Sheep and horses are resistant.

The disease in cattle associated with *Pimelea trichostachya*, *P. simplex*, *P. latifolia*, *P. elongata*, *P. neo-anglica* (desert rice flower, flaxweed, wild flax, mustard weed, broom bush) is characterized clinically by massive edema under the jaw and down the brisket, distended jugular veins, persistent diarrhea, anemia, loss of condition, and death. Ingested simplexin is associated with constriction of pulmonary venules, pulmonary venous hypertension, and right heart failure. Diarrhea is caused by direct irritation of the intestinal lining. Inhalation of the powdered plant is associated with the pulmonary-cardiac lesion only. There is also a severe anemia shown to be due to a significant hemodilution of unknown pathogenesis. The usual field picture is that cattle graze looking for feed between old, dry flaxweed plants and inhale it so that the pulmonary cardiac form is the common one and the commonest occurrence is in summer. Experimentally, it has been possible to produce two forms of the disease, the subacute with diarrhea, weakness, and anemia as the predominant signs, and the chronic form characterized by circulatory failure as evidenced by anasarca, hydrothorax, and cardiac dilatation.

Fatal necrotic gastroenteritis is produced by feeding *Pimelea* spp. to sheep and horses, but it is unlikely they would eat the plant in natural circumstances.

FLUOROACETATE

Plants containing toxic amounts of fluoroacetate include:

Acacia georginae – Georgina gidgee (Australia)

Dichapetalum spp. (Africa)
Gastrolobium spp. (Australia)
Oxylobium spp. (some only)[37]
Palicourea spp. (South America)
Mascagnia spp. (possibly) (South America)
Spondianthus preussi (Africa)

The general syndrome appears about 12 hours after the toxic plant is ingested and includes sudden death without other signs, or hypersensitivity, frenzy, dyspnea, cyanosis, tachycardia with rates up to 300/min, cardiac irregularity, ataxia, recumbency, and convulsions. Minor signs include moderate bloat, appearance of signs when animals are driven, and frequent micturition. Death may follow in a few minutes to several hours. Necropsy lesions include necrosis of myocardium, pulmonary congestion and edema, and generalized venous congestion.

In northern inland Australia, poisoning by *Acacia georginae* has been associated with heavy mortalities in cattle and sheep, and seriously reduced the productivity of large areas of grazing land. The fluoroacetate ion is concentrated in the young leaves and seed pods. At necropsy, there is congestion of the alimentary mucosa, flabbiness of the myocardium, and multiple subendocardial and subepicardial hemorrhages. There may be edema and congestion of the lungs. *Gastrolobium* spp. (42 species known or suspected to be toxic) are also sources of poisoning in Australia, mostly in the southwest, *Palicourea* and *Mascagnia* are responsible for many outbreaks in South America. Twelve *Dichapetalum* spp., e.g. *D. cymosum* (Gifblaar), *D. ruhlandii*, *D. barteri*, are poisonous shrubs in Africa but also in the tropics generally. Their fresh green leaves contain fluoroacetate. Acetamide (2 g/kg) given experimentally soon after the ingestion of *Dichapetalum* spp. appears to have helped animals against the poison.

Similar to other organic fluorides, fluoroacetate is known to exert its effect by poisoning the enzyme aconitase leading to the accumulation of significant amounts of citrate in tissues and to irreversible cardiac damage. Native herbivorous mammals in south-western Australia have evolved a high level of genetic tolerance to this toxin and this has been used as a genetic marker to trace the evolutionary history of some of the continent's indigenous marsupials.

FURANOCOUMARIN (FUROCOUMARIN)

Plants containing furanocoumarins (including psoralens) include:

Ammi majus – bishop's weed, meadow sweet
A. visnaga – visagna
Cooperia pedunculata – thunder lily
Cymopterus longipes
C. watsonii – wild or spring parsley
Heracleum mantegazzianum – giant hogweed
Petroselinum spp. – parsley
Thamnosma texana – Dutchman's breeches, blister weed.

Similar furocoumarins, identified as 4,5,8-trimethylpsoralen, 5-methoxypsoralen, and 8-methoxypsoralen, are also present in *Pastinaca sativa* (parsnip root) infested with the fungus *Ceratocystis fimbriata*, and *Apium graveolens* (celery) infested with *Sclerotinia* spp. (pink rot fungus).[38] These toxins have the particular characteristic of being photosensitizing by contact, without the need for ingestion, and are associated with serious lesions in humans. *Ammi majus* is most poisonous to livestock when there are ripe seeds in the seedheads. Its most serious occurrence is as a contaminant in hay.[39] *Cooperia pedunculata*, a perennial forb of western range country in the United States occurs at times of high humidity or after rain has wet the foliage, and the live as well as dead leaves are toxic.

The clinical syndrome is associated with plants containing furanocoumarins is one of photosensitizing dermatitis. It includes severe cutaneous dermatitis, sometimes as severe as cutaneous gangrene, on the white parts of the skin on the dorsal and lateral sides of the body, edema of the head and ears, and the lateral aspects of the teats, the unpigmented conjunctivae, muzzle and the oral mucosa inside the lower lip, and the undersurface of the tip of the tongue. Photosensitive dermatitis in pigs may be associated with distinctive vesicles on the snout and raise a false alarm of viral vesicular disease. One serious international incident arose out of a feeding of moldy parsnips.

GALEGINE

Galegine, an isoprenoid guanidine, is found in:

Galega officinalis – French honeysuckle
Schoenus asperocarpus – poison sedge (Australia)
S. rigens (Australia)
Verbesina encelioides – crown beard (North America and Australia)

It is associated with a syndrome of severe dyspnea, frothing from the nose, convulsions, and sudden death in ruminants due to pulmonary edema with large fluid accumulations in the thoracic cavity, the result of a direct effect on pulmonary vascular permeability.[40] Sheep may find access via these plants being mixed in with hay or amongst a standing crop.[41]

IFORRESTINE

Iforrestine, a heterocyclic nephrotoxin in six *Isotropis* spp. lamb poisons, e.g. *I. forrestii*, *I. atropurpurea*, and *I. cuneifolia* is associated with severe renal damage and uremia in cattle and sheep.[42] Clinical signs include anorexia, depression, diarrhea, oliguria, anuria, recumbency, and death. Proteinuria and glycosuria are constant and there is severe renal tubular necrosis.

ISOQUINOLINE ALKALOID

Berberine, a pyridine alkaloid, a subgroup of the isoquinoline alkaloids, occurs in the weeds:

Argemone mexicana – Mexican poppy
A. ochraleuca
A. subfusiformis
Berberis spp.
Mahonia spp.

The clinical syndrome in cattle and pigs includes weight loss, dyspnea, and subcutaneous edema. Diarrhea, abdominal pain, and recumbency are also recorded. At necropsy the principal lesion is cardiomyopathy accompanied by fluid in body cavities and pulmonary edema, and gastroenteritis in some cases. The toxic effect of *A. mexicana* seeds may be due to their total content of isoquinoline alkaloids rather than to their berberine content.[43]

Bulbocapnine is an isoquinoline alkaloid found in *Corydalis flavula* (fitweed, fumatory) and *Dicentra spectabilis* (bleeding heart) and is associated with a transient syndrome of tremor, tetanic convulsions, frenzy, including biting at surrounding objects, opisthotonos, drooling of saliva, and vomiting in grazing ruminants. Some patients die during the first episode.

Chelidonine, a toxic isoquinoline alkaloid found in *Chelidonium majus* (greater celandine or celandine poppy) is associated with a syndrome of gait incoordination, dribbling urine, drooling saliva, and convulsions in cattle, especially if they are harassed.

Corydaline is an isoquinoline alkaloid found in *Corydalis caseana* (fitweed) and is associated with acute diarrhea, frenzy and excitement exacerbated by harassment, clonic convulsions, and a quick death in grazing animals. The same toxin in *Dicentra cucullaria* is associated with a similar syndrome except that vomiting occurs and diarrhea is not recorded but gastroenteritis at necropsy is.

Unspecified isoquinolines found in *Eschscholtzia californica* may be associated with poisoning.

JUGLONE

A poisonous resinoid found in the shavings of *Juglans nigra* (black walnut tree) has been suspected as being associated with lameness and edema of the

lower limbs in horses bedded on the shavings, but juglone is present in the bark and leaves, not the heart wood from which the shavings are made.[44] The lesions are produced by an increase in local capillary blood pressure.[45]

A similar syndrome is associated with *Berteroa incana* (hoary alyssum).[46] Signs appear 18–36 hours after ingestion of the plant, and disappear 2–4 days after the plant is removed. Fever and red urine are additional signs seen in some cases. An alternative syndrome of severe gastroenteritis plus intravascular hemolysis is also recorded in horses fed hay contaminated by *Berteroa incana*.[47]

JUNIPERINE

An alkaloid, juniperine, occurs in *Juniperus* spp. trees and is reputed to be associated with nephrosis, cystitis, and rumenitis when eaten. Signs include abdominal pain, diarrhea, proteinuria, elevation of blood urea nitrogen (BUN) levels, and abortion.

LECTINS (TOXALBUMINS)

Lectins are very important glycoproteins in human nutrition because of their occurrence in common foods. They are associated with damage to the gut epithelium, leading to defective digestion and absorption, and to increased permeability of the intestinal mucosa. They are of minor importance in animals. The toxins are present in foliage and seeds but are concentrated in the latter. Recorded occurrences are of nephrosis and hepatitis in ruminants. The clinical syndrome includes inappetence, vomiting, diarrhea, and sometimes dysentery, dyspnea, dehydration, rapid weight loss, recumbency, and death in most cases. Serum liver enzymes and BUN and creatinine levels are elevated. Necropsy lesions include abomasal, intestinal erosions, hepatocyte and renal tubular injury, pulmonary hemorrhage, edema, and emphysema. Plants known to be associated with lectin poisoning are:

Abrus precatorius containing abrin[48]
Adenia spp.
Jatropha curcas
Phaseolus vulgaris containing PHA (*Phaseolus* hemolytic agent)
Robinia pseudoacacia
Ricinus communis containing ricin
Wisteria sinensis – wisteria.

LYCORINE

Lycorine, an alkaloid found in the bulbs or roots of many garden plants, e.g. *Amaryllis*, *Clivia*, *Lycoris*, *Narcissus*, and *Nerine* spp., is associated with salivation, vomiting, and diarrhea when eaten.

4-METHOXYPYRIDONE

4-Methoxypyridone, a pyridoxine analog found in *Albizia* spp. (*A. versicolor*, fever tree), *Albizia tanganyicensis* (paperbark albizia), especially in the dried pods[49] is a cardiotoxin. Clinical signs in cattle include hypersensitivity, hyperthermia, dyspnea, ataxia, and tetanic convulsions with rapid blinking and nystagmus. Most cases recover spontaneously. Cardiomyopathy is the diagnostic necropsy finding. Lesions also include petechiation in many tissues, pulmonary edema, degenerative changes in myocardium and other organs and in some cases in the brain. Pyridoxine is a satisfactory antidote even if signs have already appeared.[50]

IRRITANT OILS

Irritant oils in plants are associated with gastroenteritis, with salivation, oral mucosal lesions, abdominal pain, diarrhea, and sometimes dysentery. Plants known to contain these oils include:

Actaea spicata – baneberry
Artemisia filifolia
Barbarea vulgaris – yellow rocket
Bryonia dioica – white bryony
Croton spp. – croton
Cryptocarya pleurosperma – poison walnut; contains cryptopleurine and pleurospermine
Dittrichia graveolens – (stinkwort)
Inula conyza – ploughman's spikenard
Sambucus spp. – elders, elderberry.

Bryonin is an irritant oil found in the roots and seeds of *Bryonia dioica* (white bryony or British mandrake) and is associated with a syndrome of depression, dyspnea, diarrhea, polyuria, stumbling gait, tremor, recumbency, and convulsions. Sweating, agalactia, and sudden death are also recorded.

PLANT PHENOLS (POLYPHENOL, CALLED ALSO PHENOLICS)

Two groups of plant phenols (hydroxyl derivatives of benzene), of which carbolic acid is one, are **gossypol** and the **tannins**.

Gossypol

ETIOLOGY

Gossypol, a poisonous phenolic substance present in variable amounts in cottonseed cake made from the seeds of *Gossypium* spp. and hybrids (commercial cotton), and in the seeds and their hulls, is associated with damage to the myocardium and liver. Toxic meal usually contains 300–400 ppm but may contain as much as 18 000 ppm of free gossypol in a 17% protein ration.

EPIDEMIOLOGY

Preruminant calves may be most susceptible, diets containing 100–200 mg/kg BW, of gossypol mortality.[51] Most recorded outbreaks of gossypol poisoning refer to pigs. Sheep are susceptible if the toxin is injected but appear to be unaffected when it is fed. Calves die of heart failure if fed 800–1000 g cottonseed meal/day. Illness and mortality have also been produced by feeding gossypol to adult dairy cows. Goats are more susceptible, daily intakes of 350–400 mg gossypol are fatal after 3 months.[52] Adverse effects on spermatogenesis with an increase in sperm morphology abnormalities occur in bulls on low intakes and without clinical signs.[53] Cottonseed cake should not be fed to pigs at all, especially young pigs. Adults may tolerate up to 60 ppm in the feed of gossypol.[54] Horses appear to be resistant to gossypol toxicity, no natural cases being on record.

CLINICAL FINDINGS

These do not usually appear until animals have been fed on rations containing cottonseed cake for 1–3 months. Poisoned calves show anorexia, dyspnea, cough, brisket edema, ascites, distension of the jugular vein, and weakness; hematuria occurs occasionally, and death follows an illness of several days. Pigs poisoned by gossypol are thin, lack tolerance to exercise, cough, and are dyspneic. Sublethal rates of ingestion are associated with stunting of growth and reduction of fertility in bulls. Feeding cottonseed meal to young bulls and rams is not recommended becase of the risk of permanent damage to spermatogenic tissues[55] but the risk is considered to be negligible.[56] Feeding cottonseed meal to pregnant sows at the rate of 20–40% of the ration is associated with shortening of the gestation length, and at 40% some piglets are born prematurely and soon die.[57]

CLINICAL PATHOLOGY

Elevation of serum sorbitol levels is the best laboratory indicator of gossypol poisoning; levels of 18 units/L in normal calves are elevated to 34 units/L in poisoned ones. Thoracic radiographs will demonstrate the presence of fluid, which can be examined for protein content after collection via paracentesis.

NECROPSY FINDINGS

There is generalized edema, including high protein fluid in all the serous cavities, and hepatomegaly, due to congestive heart failure, and histologically there is degeneration of the myocardium and skeletal musculature. Centrilobular necrosis in the liver is also a characteristic lesion, and the liver will contain as much as 42 μg/g gossypol.[58]

CONTROL

Cottonseed cake may be fed with safety to adult cattle provided the daily intake of meal containing ≈ 1000 ppm of gossypol is less than 10–12 kg,[59] and to pigs provided it constitutes less than 10% of the ration, or in large quantities if the material is detoxified. Cooking of the cake or the addition of 1% calcium hydroxide or 0.1% ferrous sulfate to it are efficient methods

of detoxification. In experimental trials the addition of iron in equal proportions to gossypol up to 600 mg/kg of the ration will protect pigs. Significant quantities of cations (particularly calcium and iron) in water supplies or rations appear to be protective. Providing calcium carbonate at a rate of 12 g/kg of whole cotton seed (WCS) for every 0.5% of free gossypol in the WCS prevents reproductive effects in cattle.[60]

Tannins

These include the **condensed tannins** (proanthocyanidins), which are insoluble and non-toxic, except that they may be associated with oral mucosal lesions, and the **hydrolyzable tannins**, which are soluble and potentially toxic; pyrogallol, a degradation product of hydrolyzable tannins is hepatoxic and nephrotoxic. Oaks (*Quercus* spp.) and yellow-wood tree (*Terminalia oblongata* ssp. *oblongata*) are important in this group. Miscellaneous other toxic plants in this group include:

Acacia melanoxylon – black wattle
A. salacina – black sally wattle
Clidemia hirtia – harendong
Elephantorrhiza elephantina
Stryphnodendron spp.
Thiloa glaucocarpa – sipauba, vaqueta
Ventilago viminalis – supple jack.

Oak (*Quercus* spp.)

The leaves and windfall acorns[61] of many varieties of oak trees, including *Q. robur* (synonym *Q. pedunculata*, European oak) *Q. havardii* (sand shin oak), *Q. marilandica* (blackjack oak), and *Q. garryanna*, are browsed by animals and are associated with no illness when they form only a small part of the diet. The toxic principles are hydrolyzable tannins and simple phenols in the leaves, especially the young buds. All species of animals are affected, losses in sheep and cattle being reported most commonly, with occasional cases occurring in horses. Goats are thought to be capable of surviving much greater intakes of tannin than cattle because of greater concentrations of tannase enzymes in their ruminal mucosae. Experimental administration of tannic acids to goats has produced anemia, but there is no record of the natural occurrence of the disease.

If little else is eaten, oak foliage and acorns may be associated with nephrosis manifested by polyuria, ventral edema, abdominal pain, and constipation followed by the passage of feces containing mucus and blood. Blood urea nitrogen (BUN) levels are elevated, the specific gravity of the urine is low and there is proteinuria. At necropsy there is edema of the gastrointestinal wall and mesentery, a characteristic nephrosis and hepatic damage.[61] There may also be ulcerations of gut wall consistent with the presence of uremia. Survivors of an initial attack of nephrosis make compensatory weight gains and perform well in situations like feedlots.[62]

Extensive areas of oak-brush range in the United States can be utilized for cattle grazing, but require careful management if losses are to be avoided. The phenol content varies between species so that stands of *Q. alba* can be much less toxic than those of *Q. rubra* or *Q. velutina*. Calcium hydroxide (15% of the ration) is an effective preventive under experimental conditions.

Yellow-wood tree (*Terminalia oblongata* ssp.)

The foliage contains a hepatotoxic tannin punicalagin[63] and an unidentified nephrotoxin, and is associated with losses in cattle. **Acute** poisoning of cattle is manifested by a sudden onset of hepatopathy/jaundice/photosensitization with some nephrosis and signs of abdominal pain and dehydration. Necropsy reveals a swollen congested liver, swollen gray-green kidneys and gray-green pigmentation of the gastrointestinal mucosa with multiple small hemorrhagic erosions of the abomasal mucosa. **Chronic** poisoning of cattle is dominated by severe nephrosis with pigment accumulation and fibrosis in the kidney cortex, polyuria, and wasting of the body. Yellow-wood poisoning of sheep is a nervous derangement, manifested by seizures if sheep are excited by handling, and from which they recover spontaneously.

Piperidine alkaloids

ETIOLOGY

The important, identified piperidine alkaloids include coniine, cynapine, nicotine, and lobeline. The diseases they produce are set down below.

Conium

Conium maculatum (poison hemlock) contains five major acetate-based piperidine alkaloids – coniine, *N*-methylconiine, conhydrine, pseudoconhydrine, and γ-coniceine – and a number of other, lesser, alkaloids. γ-Coniceine is probably a precursor of the others, and is much more toxic. The concentration of each of the alkaloids in different parts of the plant, in different climates, and at different times of the year is very variable. For example, the concentration of the γ-coniceine is high in the fruits when they are formed, but there is no significant content in the roots. In the dormant stage the toxicity of the roots is very high.

EPIDEMIOLOGY

The weed occurs in most parts of the world. All animal species are affected, with cattle, sheep, goats, horses, and pigs showing the nervous form of the disease. Poisoned cattle, pigs, and sheep also produce deformed offspring, with ewes being much less susceptible than cows and sows. Grazing animals are poisoned by eating the standing plant, the seeds or roots at the appropriate time of their development. The plant may also be fed in hay or green feed or the seeds may contaminate harvested grain. Milking cows secrete the alkaloids in their milk.

PATHOGENESIS

The alkaloids are associated with two modes of poisoning, paralysis of skeletal muscle by blocking transmission at neuromuscular junctions and by acting as teratogens. All of the major alkaloids are associated with the acute disease. Only coniine and γ-coniceine are known to be teratogenic. Teratogenesis is effected through reduced fetal movements in utero.[64]

CLINICAL FINDINGS

In the acute, nervous form of the disease signs include tremor, staggery gait, knuckling of fetlocks, frequent belching, sometimes with vomiting, frequent urination and defecation, drooling of saliva, tachycardia, and pupillary dilation. In cows and sows there is also prolapse of the nictitating membrane, and in cows there is a characteristic mousy odor of the milk and urine of affected animals. The course in cattle, goats, and horses is a few hours only and terminates in recumbency and death by respiratory paralysis, without convulsions. Sheep are least affected and recovery is common.[65]

Serious congenital deformities, including carpal flexure, limb malalignments, scoliosis, and torticollis, occur in piglets and calves. Lambs have similar, but lesser, defects and in many cases they are temporary, disappearing in the first few weeks after birth. By ultrasound scanning the fetal movements of lambs in ewes treated with *C. maculatum* can be seen to reduce significantly for a short period. At birth some of the lambs will have limb deformities and kinked tails, all of which recover spontaneously.[66] Cleft palate, sometimes with hare lip, is also a common accompaniment in calves and piglets but not in lambs or foals. The sensitive period of the pregnancy, during which the fetus is susceptible to the teratogen, is day 55–75 for calves, day 30–53 for sows, and day 30–60 for lambs.

The piperidine alkaloids of *C. maculatum*, *Nicotiana lunare* and the quinolizidine alkaloids of *Lupinus* spp. are all teratogenic to goat does in the 30–60-day period of pregnancy. The carpal, tarsal, and fetlock joints are fixed in flexion or extension and the spinal column is deformed with scoliosis, lordosis, or torticollis, and there are deformities of the rib cage.[67]

NECROPSY LESIONS

Other than the fetal abnormalities, neither significant necropsy nor clinicopathological findings are recorded.

DIFFERENTIAL DIAGNOSIS

Poisoning by *Trachymene* spp. (wild parsnip) in ruminants is thought to be associated with a conium piperidine alkaloid. The syndrome includes sudden death, gait incoordination stimulated by harassment, acute diarrhea in some cases, and congenital limb deformity. Limb deformities also occur after birth in lambs 8–16 weeks old grazing on *T. glauca* (wild parsnip), *T. ochracea* (white parsnip), and *T. cyanantha*.[68] Heifers and calves are not affected. There is outward bowing of all four limbs, most obvious in the pectoral limbs. Ewes preferentially graze the plant when it is in flower and their fetuses will be deformed. The deformity is reversible in mild cases.

Cynapine

Cynapine, a piperidine alkaloid found in *Aethusa cynapium* (fool's parsley, lesser hemlock) is associated with dyspnea and gait incoordination in cattle, goats, and pigs.

Nicotiana

The commonly poisonous members of the tobacco family of plants are:

Nicotiana tabacum – commercial tobacco
N. attenuata – wild tobacco
N. exigua
N. glauca – tree tobacco
N. megalosiphon
N. trigonophylla – wild tobacco
N. velutina.

The principal toxins include nicotine, anabasine, and anagyrine. Other alkaloids occurring in *Nicotiana* spp., but which are not recorded as having poisoned animals, are nornicotine and anatabine. Other plants containing these alkaloids include *Duboisia hopwoodii* (pituri). Several alkaloids may be present in the one plant but most plant species have a particular alkaloid that predominates. The concentration of the alkaloid varies between parts of the plant, and between different stages of growth. There are two forms of intoxication.

Anabasine is a teratogen and the feeding of stalks of *Nicotiana tabacum* to pregnant sows, 10–48 days pregnant and *N. glauca* to cows, 40–75 days pregnant, is associated with the congenital defects of arthrogryposis of limb and intervertebral joints. There are no abnormalities of the nervous system. The leaves and bark of *N. glauca* contain more teratogen than the woody parts. The feeding of *N. glauca* to sows also is associated with cleft palate in their offspring. Fed to pregnant ewes this plant is associated with lambs being born with cleft palates, flexed limb joints, rotation of limb joints, and lordosis. The ewes show hypersalivation, ataxia, recumbency, and death. Acute poisoning of livestock ingesting *Nicotiana* spp. or *Duboisia hopwoodii* is associated with muscle tremor, weakness, incoordination, pupil dilation, recumbency, with limb paddling progressing to paralysis. There may be diarrhea.

Tobacco-specific nitrosamines, formed from *Nicotiana* spp. alkaloids, are known to be carcinogenic to laboratory animals, but there is no record of this association in agricultural animals.

Lobeline

The piperidine alkaloid lobeline is found in the plant *Lobelia berlandieri*.[69] Ingestion of the plant is associated with mouth erosions, salivation, and diarrhea. Necropsy lesions are limited to the lesions of enteritis.

PODOPHYLLIN POISONING

Podophyllin is a resin found in *Podophyllum peltatum* and is associated with enteritis with signs of excessive salivation and severe, acute diarrhea.

PROTOANEMONIN POISONING

Protoanemonin exists in the plant as a glucoside ranunculin, which releases protoanemonin when the leaves are macerated. Plants containing ranunculin include:

Anemone spp.
Caltha palustris
Clematis spp.
Pulsatilla spp.
Ranunculus spp. – buttercups
Thalictrum spp.
Trollius spp.

Ingestion of these plants may be associated with salivation, stomatitis, abdominal pain, diarrhea, dysentery, hematuria, blindness, ataxia, and convulsions.

QUINOLIZIDINE ALKALOID POISONING

Quinolizidine alkaloids occur most frequently in plants of the *Lupinus* spp. There are two groups of alkaloids, those causing nervous signs and those acting as teratogens. Liver damage in animals grazing lupins is associated with the mycotoxin, phomopsin, produced by the fungus *Diaporthe toxica*, and not by the plant itself.

Neurogenic quinolizidine alkaloids

ETIOLOGY

Alkaloids causing the nervous syndrome include sparteine, lupinine, lupanine, hydroxylupanine, spathulatine, and thermopsine. These vary widely in their toxicity and their concentration in plant species, and within the same species between years, depending largely on the climate. Species of lupin known to contain them are: *L. angustifolius*, *L. cosentini* (synonym *L. digitatus*). Species that are associated with the characteristic nervous syndrome and in which the presence of the alkaloids in the plant is assumed are:

L. argenteus
L. caudatus
L. cyaneus
L. greenei
L. laxiflorus
L. leucophyllus
L. leucopsis
L. onustus
L. pusillus.

EPIDEMIOLOGY

The alkaloids are present in all parts of the plant but are in their greatest concentration in the seeds and pods; most outbreaks of poisoning occur when livestock graze mature, standing lupins, carrying many pods. Sheep eat the plant more readily and are more commonly affected than cattle or horses. The mortality rate in sheep is high. In cattle it is usually low, but may be as high as 50%.

Other plants in which the alkaloids occur, and which are associated with the nervous disease are:

Cytisus (synonym *Laburnum*, *Sarothamnus* spp.)
Baptisia spp.
Sophora spp.
Spartium junceum – spanish broom
Thermopsis spp.

CLINICAL FINDINGS

In the nervous disease, affected animals may develop dyspnea and depression, followed by coma and death without a struggle. More acute cases have convulsive episodes in which they are dyspneic and staggery, and show frothing at the mouth, clonic convulsions, and grinding of the teeth. A more prolonged disease is reported in cattle poisoned experimentally with *T. montana*.[70] There is anorexia, depression, edematous swelling of the eyelids, tremor, a stilted gait, arching of the back and a tucked-up abdomen, rough hair coat, and prolonged recumbency.

PATHOLOGY

High blood levels of serum glutamic–oxaloacetic transaminase (SGOT), creatinine phosphokinase (CPK) and lactic acid dehydrogenase (LDH) are accompanied by a severe myopathy. The possibility of a myopathy being associated with lupins has been raised because the prevalence of enzootic muscular dystrophy appears to be much higher on lupin than on other pasture. Lupins are low in selenium and vitamin E content, and classical white muscle disease may also occur. Histological and biochemical examination of affected calves discount myopathy as the primary lesion. In poisoning by *Cytisus* spp., both

C. laburnum (laburnum) and *C. scoparius* (broom) are associated with fatalities.

Teratogenic quinolizidine alkaloids

ETIOLOGY

The best known congenital defect is crooked calf disease, recorded only in the western United States, Kodiak Island, Alaska, and Canada in cows grazing *Lupinus sericeus* or *L. caudatus* in the 40th–120th day of pregnancy. The cause is the neurogenic quinolizidine alkaloid anagyrine, which has been identified in potentially teratogenic concentrations in *L. formosus* and *L. arboreus*, and are toxic when levels in the feed exceed 1.44 g/kg dry matter. In some cases the alkaloid may be contained in an aphid, *Aphis craccivova*, infesting the plant. Teratogenesis is effected by reduction of fetal movement *in utero*.[64] Only cattle are affected.

CLINICAL SIGNS

Affected calves have arthrogryposis, with excessive flexure, malpositioning, malalignment, and rotation of limbs, principally the forelimbs at the elbows and carpal joints, or scoliosis and torticollis, or both. Cleft palate is an occasional occurrence. The flexion of the joints is severe and may be associated with difficulty at calving. Surviving calves cannot stand to suckle, do not improve after birth, and have to be killed.

DIFFERENTIAL DIAGNOSIS

The defects are similar to those recorded in calves after poisoning of cows by *Nicotiana* spp. or *Conium maculatum*, or a nutritional deficiency of manganese. Similar defects occur after poisoning with the lathyrogen, aminoacetonitrile. Although the classical deformities are associated with anagyrine are not recorded in lambs, hemimelia has been recorded in lambs from ewes fed on *L. cosentini*.

CONTROL

This can only be achieved by arranging calving to occur when the lupins are not in a heavy growth stage at the same time as the cows in the herd are in the dangerous phase of 40–120 days pregnant.

RHOEADINE

Rhoeadine is an alkaloid found in the seed capsules of *Papaver rhoeas* (field poppy), and probably *P. nudicaule* and *P. somniferum*, which is associated with restlessness, hypersensitivity, ataxia, ruminal stasis, dyspnea, and convulsions, but no significant necropsy lesions.

SAPONIN POISONING

Saponins are naturally occurring glycosides with the physical properties of soaps; that is they produce a stable froth in water. They have a bitter taste. They also lyse erythrocytes *in vitro*. There are two classes of saponins, those with a triterpene aglycone radical and those in which the non-sugar radical is a steroid.

Diterpene saponins

In plants, almost all saponins are **triterpene** saponins. The compounds are concentrated in the rapidly growing shoots, the bark and the roots, and are thought to have an insect-repellent role in these sensitive areas of the plant. They are absorbed very slowly, if at all, from the alimentary tract and it seems unlikely that they will exert any systemic effect unless there is pre-existing damage to the intestinal mucosa. Notwithstanding this, a great deal of research has been done on the systemic pharmacological effects in humans of plant pharmacologicals such as ginseng.

Knowledge of the toxicity of triterpene saponins for animals is scrappy. The principal pathogenic effect is enteritis and gastroenteritis, manifested by diarrhea and dysentery. Other less common signs include abdominal pain, vomiting, and salivation. Plants known to have this effect are:

Agrostemma githago
Aleurites fordii
Dialopsis africana
Gutierrezia microcephala
Hedera helix
Jatropha curcas
J. hyssopifolia
Phytolacca americana
P. dioica – packalacca[71]
P. dodecandra
Saponaria officinalis
Sesbania spp.

Bulnesia sarmientii (Palo santo tree) seed pods and foliage contain an unspecified toxic saponin that is associated with convulsions, licking of forelimbs, geophagia, chewing movements, ruminal atony, bradycardia and frequent urination, and defecation. The bitter taste of saponins may result in a decrease in feed intake and a reduction in growth rate in monogastric animals.

Steroidal saponins

These are associated with Scandinavian photosentization disease (aalveld) and occasionally nephrosis in ruminants[72,73]; they occur in:

Agave lecheguilla[74]
Brachiaria decumbens grass[75,76]
Kochia scoparia – summer cypress
Nartheciium ossifragum – also associated with aalveld
Panicum spp. grasses
P. schinizii[77]
P. miliaceum – French millet
P. coloratum – kleingrass[78]
P. dichotomiflorum – smooth witch grass[79]
Tribulus terrestris.

Other *Panicum* spp. grasses which should now be on the suspicious list for this kind of poisoning are:

P. decompositum
P. effusum
P. maximum
P. queenslandicum
P. whitei.

Birefringent crystals composed of the glucuronides of epismilagenin and episarsasapogenin formed from an ingested saponin accumulate in the biliary system, blocking it and causing damage to it and surrounding hepatocytes. Jaundice, photosensitization, and hepatitis result.[80] Blockage of the bile canaliculi and bile ducts, and cramming of hepatocytes, Kupffer and renal tubules cells by acicular crystals and clefts are characteristic. Necrosis of the distal renal tubules, papillary muscles of the heart, and the adrenal cortex are accompanying lesions.[81] Other steroidal saponins are present in *Tribulus terrestris*, but appear to be non-lithogenic.

SELENOCOMPOUNDS

Organic selenocompounds occur in two classes of plants which preferentially accumulate selenium, primary converter or indicator plants that grow only in soils with abnormally high selenium content, and secondary converters that grow anywhere but accumulate selenium if it is available. Primary converters are more toxic, attaining levels of greater than 1000, and up to 10 000 ppm. Secondary converters reach levels of about 1000 ppm.

Primary converters include:

Astragalus spp. – milk vetch
A. bisulcatus
A. pattersonii
A. praelongus
A. pectinatus
A. racemosus
Oonopsis condensata – goldenweed
Stanleya pinnata – prince's plume
Xylorrhiza spp. – woody aster.

Secondary selenium indicators include:

Acacia cana
Aster spp. – woody aster
Astragalus spp. – poison vetch
Atriplex canescens – saltbush
Castilleja spp.
Comandra pallidai
Grindelia squarrosai
Machaeranthera ramosa
Morinda reticulata
Neptunia amplexicaulis
Penstemon spp.
Sideranthus spp. – ironweed.

Clinical findings include the common, acute form with signs of aimless wandering, circling, apparent blindness, head-pressing, dyspnea, lameness and recumbency, teeth grinding and salivation. The chronic form is characterized by alopecia, weight loss, coronitis, hoof deformity, and hoof shedding in all species, including pigs.[82] Assay of selenium in the feed is usually necessary to confirm the diagnosis. Daily intakes of more than 30 ppm are usual in the subacute form. In chronic cases the intake is usually below this level and has been maintained for some months.

Necropsy findings are non-specific and include hepatic, myocardial and renal injury, and erosion of joint cartilages.

SESQUITERPENES

Sesquiterpenes are common plant poisons. Subgroups of them are listed elsewhere in this chapter, are:

- furanoid sesquiterpenes
- ipomeanols
- ngaiones
- sesquiterpene lactones
- sporidesmin.

Unspecified sesquiterpenes are also listed as being associated with other poisonings. For example, *Flourensia cernua* and *Vernonia* spp. is associated with heavy losses in South America and Africa due to hepatic necrosis in grazing ruminants. Affected animals show non-specific signs of anorexia, ruminal atony, hypothermia, staggering gait, recumbency, and convulsions. Serum levels of liver enzymes are elevated, accompanying a massive liver necrosis.

Furanoid sesquiterpenes (furanosesquiterpenoid) poisoning

Furanosesquiterpenoids, including ngaione and myodesmone, are essential oils in:

Lasiospermum bipinnatum – ganskweed
Myoporum spp. – boobialla, Ellangowan poison bush, etc.

Ingestion of these plants usually is associated with jaundice, photosensitization, ruminal stasis, constipation, tenesmus, and abdominal pain. Necropsy findings are limited to hepatic necrosis, jaundice, and photosensitive dermatitis. Ingestion of *L. bipinnatum* by lambs also is associated with the same hepatic insufficiency syndrome, but the same plant from a different part of a farm may be associated with pulmonary and mediastinal emphysema and interstitial pneumonia reminiscent of the ipomeanols.[83] The fungi *Ceratocystis* spp. is associated with the same problems as *L. bipinnatum*. The following are associated with acute hepatic injury and deaths in ruminants:

Myoporum laetum – ngaio tree
Eremophila deserti (= *M. deserti*) – Ellangowan poison bush
M. tetrandrum – Australian boobialla
M. tetrandrum
M. sp. aff. *insulare*.

Ipomeanol

Ipomeanols are produced in sweet potatoes in response to infection by the fungi *Fusarium solani*, *F. oxysporum*, *F. javanicum*, and *Ceratostomella fimbriata* and are associated with pulmonary emphysema and edema and interstitial pneumonia when fed to animals. Ipomeanols are also suspected of being associated with the poisoning of *Perilla frutescens* (purple mint weed)[84] and *Zieria arborescens* (stinkwood tree). *P. frutescens* is toxic only after the plant has flowered and then loses its toxicity once it has been wilted by frost. Cases appear in calves 3–12 days after they begin eating the plant. Pulmonary edema develops because of damage to endothelial cells and young pneumocytes.[85] *Zieria arborescens*, a small tree in Tasmania and eastern Australia, is associated with interstitial pneumonia in cattle, and the disease is reproducible by feeding the foliage. Clinical signs appear as tachypnea, abdominal, grunting respiration with extension of the head, mouth breathing, and a nasal discharge. In bad cases the temperature and pulse are elevated. Most cases die after an illness of 1–21 days. Necropsy lesions include massive pulmonary edema and emphysema.

Sesquiterpene lactones

There are very many plant lactones suspected of being poisonous. Plant genera known to owe their toxicity to their content of sesquiterpene lactones include *Centaurea* spp., (especially *C. repens*, *C. solstitialis*), *Chrysanthemum* spp., which are associated with contact dermatitis, *Geigeria* spp., *Helenium* spp., *Hymenoxys* spp.,[86] *Iphiona aucheri* and *Parthenium hysterophorus* (parthenium weed).

Vomiting syndrome

Geigeria, *Helenium* and *Hymenoxys* spp. poisonings in cattle are associated with a syndrome of regurgitation (spewing sickness, vermeersiekte), salivation, dysphagia, and coughing. An ELISA is available for the quantitative detection of the sesquiterpene lactone dihydrogriesenin in *Geigeria* spp. Contrast radiography of the esophagus, and biopsy of skeletal and esophageal muscle are helpful in diagnosis.[87] Dietary supplements used to prevent poisoning by sesquiterpene lactones, including a soybean meal-sodium sulfate combination, are useful provided they add thiol groups to the ration. Urea potentiates the poisoning.[88]

Encephalomalacia syndrome

Centaurea solstitialis (yellow star thistle) and *C. repens* (Russian knapweed) poisoning in horses is associated with a well-known syndrome of severe depression, constant chewing movements, salivation, tongue flicking, dysphagia, intestinal bloat, paralysis, recumbency, and death. Yawning and somnolence are evident but the horse is easily aroused. Some horses show aimless, slow walking and, in the early stages transient circling. The gait is not grossly abnormal, a slight stiffness at the walk being the only abnormality except for weakness in the terminal stages. A fixed facial expression is common, the mouth being held half-open or the lips drawn into a straight line. Wrinkling of the skin of the lips and muzzle and protrusion of the tongue are present in many cases. Signs fluctuate in severity for 2–3 days and then remain static until the animal dies or is destroyed. Nigropallidal encephalomalacia and fluid accumulations in body cavities are characteristic necropsy lesions. Areas of necrosis or softening are visible macroscopically in the brain, in the globus pallidus and substantia nigra. The lesions are bilateral in most cases.

The plants do not appear to be toxic to ruminants, rodents, or monkeys and sheep do well on sole diets of the plants.

STEROIDAL (*SOLANUM* SPP.) ALKALOIDS

Solanum spp. plants contain many poisonous glycosidic steroidal alkaloids including solanidine, soladulcidine, solasodine, tomatidine, etc. The best known plants in the group include:

Solanum bonariensis
S. dulcamara
S. elaeagnifolium[89]
S. esuriale
S. fastigiatum
S. kwebense
S. pseudocapsicum (nightshades)
S. tuberosum (potato – sprouted).

The other important member of the genus is *S. malacoxylon* the principal association in enzootic calcinosis. *Lycium halimifolium* and *Lycopersicum esculentum* (tomato) are also listed as containing these alkaloids.

Acute poisoning with steroidal alkaloids, associated with large doses, appears in experimental animals as a syndrome of gastroenteritis, with diarrhea and necropsy lesions of mucosal necrosis in the stomach and intestines.[89] Subacute poisoning with smaller doses, which are not associated with an enteric lesion but are absorbed, is associated with nervous signs of exercise induced gait incoordination, easy falling, a straddled gait, nystagmus and convulsions with opisthotonos, complemented in some

cases by cardiac irregularity, hemolysis, and sometimes diarrhea. Records of necropsy lesions include only occasional references to the presence of encephalomalacia and cerebellar agangliosidos associated with the incoordination syndromes. *Solanum esuriale* has been suggested as being associated with **humpy back**, a common disease in sheep in Australia, but the association is unproven.[90] On forced exercise affected sheep show gait stiffness in the hindlimbs with shortness of steps. This is followed by an inability to keep walking and the adoption of a peculiar hump-backed stance. The disease occurs only in summer in full-woolled sheep. At necropsy, there is degeneration of spinal cord tracts. In the United States *S. dimidiatum* is associated with a 'crazy cow syndrome' of staggering and incoordination, with a selective loss of Purkinje cells from the cerebellum. A similar syndrome is associated with *S. kwebense* in South Africa, one by *Brunsfelsia pauciflora*,[91] one by *S. cinereum* in goats in Australia,[92] and one by *S. fastigiatum* var. *fastigiatum* in Brazil.[93] The latter appears to be an acquired gangliosidosis. It is characterized by cytoplasmic membranous bodies in the Purkinje cells and a syndrome identical to that described above for subacute poisoning with steroidal (*Solanum* spp.) alkaloids. After an attack lasting up to 60 seconds, the animal returns to normal. Affected animals do not recover but do not die unless by misadventure. The animals can be provoked to have an attack by raising their heads, or by holding them in lateral recumbency and then letting go. It is probable that these are not true 'convulsive' diseases but cerebellar incoordinations in which frantic efforts by a seriously ataxic animal give a superficial resemblance to convulsive episodes. It is also probable that the lesions in this disease are not associated with steroidal alkaloids but with β-carbolines. Other plants, e.g. *S. fastigiatum* var. *acicularium* and *S. bonariensis*, also appear to be associated with this disease.

Potatoes are toxic only if they are green and sprouted and the toxic alkaloid solanine is concentrated in those parts; potatoes must constitute more than 50% of the diet before toxicity occurs. Pigs are most commonly affected but all species are susceptible. In pigs there is dullness, copious diarrhea, anorexia, hypothermia, and coma in the terminal stages. The mortality rate may be high. In horses the signs include depression and prostration but usually there are no signs of alimentary tract irritation. In cattle dermatitis, comprising vesicles and scabs on the legs, is a more common syndrome. At necropsy in all species there is a moderate hyperemia of the alimentary mucosa. Sprouted or diseased potatoes can be fed safely if they are boiled and the amount fed restricted to less than 25% of the diet.

Some of these plants also contain specific teratogenic steroidal alkaloids which contain α-piperidine moiety. The plants, in decreasing order of toxicity in terms of producing craniofacial deformities in laboratory animals[94] are:

S. elaeagnifolium
S. saccharoides
S. dulcamara
S. melongena
S. tuberosum.

STRYCHNINE

Strychnine poisoning is an uncommon occurrence in farm animals and is usually associated with accidental overdosing with strychnine preparations, or accidental access to grain treated with strychnine and to be used for rodent control. Cattle are particularly susceptible to parenteral administration (30–60 mg of strychnine hydrochloride may be fatal) but less susceptible to oral administration because of destruction of the drug in the rumen. Lethal doses by parenteral injection are 200–250 mg in horses, 300–400 mg in cattle, and 15–50 mg in pigs.

In strychnine poisoning there is greatly increased reflex excitability and, after an initial period of muscle stiffness and tremor, tetanic convulsions occur. These can be provoked by the application of minor external stimuli. In these convulsive episodes there is extension of the limbs, opisthotonos and protrusion of the eyeballs. The seizures may last for 3–4 minutes and are followed by periods of partial relaxation which become progressively shorter as the disease develops. Respiratory arrest leads to death. The diagnosis is confirmed by the detection of strychnine in the gut contents.

Strychnine is rapidly excreted and detoxicated and sedation of the animal for a sufficiently long period may result in recovery. Tannic acid preparations administered orally precipitate the alkaloid in the alimentary tract and interfere with further absorption.

STYPANDROL

Stypandrol (synonym hemerocallin), a binaphthoquinone (binaphthalene tetrol) found in *Dianella revoluta* (flax lily), *Stypandra glauca* (= *S. imbricata*, *S. grandiflora* – nodding blue lily),[95] and *Hemerocallis* spp. (day lily).[96] Field cases occur only with *S. glauca* and are characterized by blindness, incoordination, posterior weakness and, eventually, flaccid paralysis and recumbency in grazing ruminants. Dilatation and immobility of the pupil, with retinal vascular congestion, hemorrhage, and papilledema visible ophthalmoscopically,[97] are characteristic and at necropsy there is diffuse status spongiosis in the brain, general neuronal vacuolation, and axonal degeneration of optic nerve fibers and the photoreceptor cells of the retina. Only the young green shoots are poisonous, so that outbreaks occur only in the spring when the plant is flowering.

TAXINE

Taxine is a mixture of alkaloids found in the seeds and needles of *Taxus baccata* (yew tree) and other *Taxus* spp., and have a strong depressive effect on the heart. Commonly there is sudden death without obvious clinical signs. Intakes of 0.35–0.70 g/kgBW of fresh plant are sufficient to cause death.[98] Signs in horses and cattle, if they appear, include dyspnea, muscle tremor, bradycardia, severe cardiac arrhythmia, hypothermia, weakness, and collapse. There are no significant findings at necropsy, other than the consequences of acute heart failure. Mortalities may be limited to calves sucking on clinically normal dams.[99] *Taxus cuspitata*, the Japanese yew tree, is as toxic as *T. baccata* and is a more common decorative tree. Removal of the ruminal contents of goats via a rumenotomy has been followed by recovery.

TRITERPENES

Toxic triterpenes include:

- Cucurbitacins, tetracyclic triterpenes found in *Cucumis africanus* and *C. myriocarpus*,[100] *Stemodia kingii* and *S. florulenta*[101] and, in *Ecballium elaterium*
- Lantadenes A and B, and triterpene acids found in *Lantana* spp.
- Icterogenins A, B, and C in *Lippia* spp.
- Meliatoxins A and B, tetranortriterpenes, derived from the berries of *Melia azederach* var. *australasica* (white cedar)
- Colocynthin, a glucoside found in the fruit of the vine *Citrullus colocynthis* (synonym *Colocynthis vulgaris*).

Cucurbitacins are a group of tetracyclic triterpenes found in the fruits of the vines *Cucumis africanus*, *C. melo* var. *agrestis* (Ulcardo melon)[102] *C. myriocarpus* (prickly paddymelon), and *Ecballium elaterium* (squirting cucumber). The ripe fruits are most toxic, and in cattle, sheep, and horses are associated with a syndrome of lethargy, dehydration, abdominal pain, diarrhea, dyspnea, and death in a matter of a few hours. Necropsy findings include edema and necrosis of the ruminal epithelium, intense congestion and hemorrhage in the intestinal mucosa, pulmonary congestion and edema, and hepatopathy in some cases. Seeds of the plant are conspicuous in the ruminal contents.

Icterogenins and lantadenes are associated with liver damage and nephrosis, neither of which is specific,[103] but the lantadenes cause damage to bile canaliculi, gallbladder paralysis, and intrahepatic cholestasis. Jaundice, photosensitization, and ruminal stasis result. *Lantana* is a very pungent plant and cattle will eat it only if other feed is scarce. *Bos taurus* cattle are more susceptible to lantadene poisoning than *Bos indicus* cattle. Treatment with activated charcoal is effective. So is treatment with bentonite, which is recommended as a cheaper alternative to the charcoal. The dosage of either is 5 g/kg BW as a single dose.[103]

Meliatoxin administered to pigs also is associated with a syndrome of gastroenteritis manifested by diarrhea, melena, and vomiting, plus dyspnea due to pulmonary edema.

TROPANE ALKALOIDS

Tropane alkaloids include atropine, hyoscyamine, hyoscine, and scopolamine, found in:

Atropa belladonna – deadly nightshade
Datura spp. – thornapple
Duboisia leichhardtii
D. myoporoides – corkwoods
Hyoscyamus niger – henbane.

Ingestion of these plants in sufficient quantity is associated with a syndrome of restlessness, tremor, pupil dilation, blindness, frenzied actions, convulsions, and recumbency. There are no significant necropsy lesions. *Datura stramonium* grows universally but cases of poisoning are few, possibly due to its unpalatability, its high toxic dose, and because it produces ruminal atony in cattle. The seeds of the plant are likely to contaminate grain supplies and may be associated with poisoning.

TUTIN

Tutin is a poisonous constituent of the *Coriaria* spp. (tutu trees) in New Zealand. It is associated with hypersensitivity, restlessness, convulsions, a short course and death, without any lesions visible at necropsy.

VELLEIN

The toxin vellein, found in the plant *Velleia discophora*, is associated with hyposensitivity, dyspnea, tachycardia, and recumbency but no specific necropsy lesions.

VERATRINE

The mixture of alkaloids found in *Veratrum californicum* is associated with a syndrome of salivation, dyspnea, vomiting, diarrhea, frequent urination, cardiac irregularity, and convulsions. The plant also contains the teratogen cyclopamine.

ZIGADINE (ZIGADENINE)

The phytotoxin zigadine occurs in the plants *Zigadenus* spp. (death camas), especially the bulb, and is associated with a syndrome of salivation, vomiting, tremor, ataxia, and dyspnea. The toxin has been identified in the rumen of dead cattle by electron impact mass spectrometry, avoiding the necessity of identifying the plant botanically.[104]

PLANT MATERIALS CAUSING PHYSICAL DAMAGE

Ingestion of indigestible fiber is associated with colic in horses due to:

- Gastric impaction – *Senecio jacobea*
- Impaction of the ileocecal valve – *Sorghum* spp.
- Ruminal impaction in cattle – loppings of :
  Fraxinus excelsior – ash tree
  Chrysocoma tenuifolia – bitter weed
  Eriocephalus spp.
  Pinus taeda – loblolly pine
  Prosopis juliflora – mesquite
  Eremocarpus setigerus – turkey mullein
- Gastric impaction in pigs – *Nicotiana* spp. stalks.

Tough fiber in *Romulea rosea* (onion weed) is associated with an enzootic problem of bovine intestinal and abomasal impaction by phytobezoar in parts of Australia. Phytobezoars can be a problem wherever indigestible fiber is available to ruminants. Cocoon silk of *Gonometa* spp. (Molopo moth) can be associated with ruminal impaction in cattle that eat foliage of *Acacia eriloba* or *A. mellifera* trees, the preferred habitat for the moth larvae.

Other physical injuries associated with plant material include persistent corneal ulcers from the bristles of *Arctium lappa* (burdock seeds); ulcers in the mouth from the spines of *Setaria lutescens* (yellow bristle grass), and the awns of *Triticosecale* (= triticale). *S. lutescens* carries heavy bristles which are associated with mechanical stomatitis in cattle and horses. Triticale is a hybrid between wheat and rice used mainly for grain production. If it is harvested green as a crop and made into hay the dried awns are prohibitively irritating to the pharynx and mouth of cattle and horses. Affected horses are slow eaters, refuse to eat hay, and show excess salivation. The clinical signs that result in about a week include cough, mucoid nasal discharge, foul breath, hypersalivation, quidding, and loss of body weight. Some horses develop submandibular edema and there are severe ulcerations at the gum-tooth margins, with many awns embedded in the ulcers. The ulcers are very painful, up to 5 cm in diameter at the labial–gingival junction, the lingual frenulum, the base of the lingual dorsum, soft palate, and the sides of the tongue. After careful cleaning up, the lesions heal slowly over about 3 weeks.

Grass seed abscesses are frequent when there is a large population of *Stipa* and *Stipagrostis* spp. (spear grass), *Tagetes* spp., *Aristida arenaria* (silver or kerosene grasses), *Opuntia* spp. (prickly pear), and *Hordeum jubatum* (barley grass) in the pasture. The hairs on the plant *Dittrichia* (= *Inula*) *graveolens* (stinkwort) are thought to be associated with the fatal enteritis which occurs in sheep eating the plant.

PLANT POISONINGS DUE TO UNIDENTIFIED TOXINS

In many plant poisonings the identity of the toxin is unknown. The more common of these plants are listed below in categories according to the principal sign of the syndrome they produce. Because the information about most of them is meager, no attempt is made to provide a complete picture of each of them. There will be other plants in the main section of the chapter which also are associated with diseases similar to those outlined.

ABORTION

Iva angustifolia – narrow-leafed sumpweed
Salvia coccinea – red salvia
Tanacetum vulgare – tansy
Verbena bonariensis – purple top.

CONGENITAL DEFECT

Lysichiton americanus – skunk cabbage; is associated mostly with cranio-facial deformity.

CYSTITIS

Gyrostemon (= *Didymotheca*) *cupressiformis* – double-seeded emu bush.

DERMATITIS

Entandrophragma cylindricum – redwood; shavings as bedding are associated with balanoposthitis in rams
Excoecaria spp.
Heracleum mantegazzianum – cow parsnip
Vicia benghalensis – popany vetch; is associated with dermatitis, conjunctivitis, rhinitis, fever, and multiple eosinophilic granulomas in many organs[1]
V. dasycarpa – woolly pod vetch; same symptoms as *V. benghalensis*
V. villosa – hairy vetch; same signs as *V. benghalensis*.

DIARRHEA – WITHOUT GASTROENTERITIS AS A LESION

Anredera cordifolia – lamb's tail
Blechnum spp. – bungwall fern
Bulbine bulbosa – native leek
Cadaba rotundifolia
Centaurium spp.
Chaerophyllum sylvestre
Cichorium intybus – chicory
Chlorozophora spp.
Datisca glomerata – Durango root
Dichrocephalia chrysanthemifolia
Juncus inflexus – blue rush
Linum catharticum – purging flax
Mentha australis – native mint
Pipturus argenteus
Philydrum lanuginosum – woolly water lily
Polyga klotzchii
Salvia coccinea – red salvia
Synadenium arborescens – African milk bush.

DIARRHEA – WITH GASTROENTERITIS AS A LESION, OFTEN WITH ABDOMINAL PAIN AND INCOORDINATION, SOMETIMES WITH DYSENTERY AND VOMITING

Azadirachta indica – neem
Brunsfelsia australis (= *B. bonodora*) – yesterday, today, and tomorrow
Buxus sempervirens – common box bush
Centaurium beyrichii – rock centaury
Chrysocoma tenuifolia – bitter bush
Cissus quadrangularis
Cuscuta spp. – dodder
Datisca glomerata – durango root
Dichrocephalia chrysanthemifolia
Dipcadi glaucum – poison onion
Diplocyclos palmatus

Diplolophium africanum
Drymaria spp.
Ephedra viridis
Fagus sylvatica – European beech tree[2]
Galanthus nivalis – snowdrop
Gymnocladus dioica – Kentucky coffee tree
Ligustrum vulgare – privet hedge
Ludwigia peploides – water primrose
Ornithogalum longibracteatum – chincherinchee
Robinia pseudoacacia – black locust, locust tree
Rudbeckia spp.
Sapium sebiferum – Chinese tallow wood
Scrophularia aquatica – water betony
Sisyrinchium spp. – scour weed
Sium angustifolium
Tulipa spp. – tulips
Turraea robusta.

DYSPHAGIA

Buxus sempervirens – box tree
Descurainia pinnata – tansy mustard; difficulty in swallowing due to paralysis of the tongue and the masseter and pharyngeal muscles is accompanied by spasmodic contractions of neck muscles, causing head bobbing in sheep, may occur after sheep ingest *D. pinnata*; there is doubt about the relationship.[3]
Prosopis juliflora.[4]

ESOPHAGEAL ULCERATION

Crotalaria aridicola – horses only
C. medicaginea – horses only

GESTATION PROLONGED

Lysichiton americanus – skunk cabbage
Salsola tuberculatiformis – cauliflower saltwort; in ewes, is associated with atrophy of the pituitary, adrenal and thymus glands of the fetus and prolongation of pregnancy to as long as 213 days.

HEART FAILURE – WITH SUDDEN DEATH OR CONGESTIVE FAILURE AND CARDIOMYOPATHY

Atalaya hemiglauca – whitewood
Galenia africana[5]
Phalaris coerulescens (blue canary grass)[6]
Phalaris paradoxa[7]
Tanaecium exitosium
Tetrapteris spp.
Urechites lutea.

The following contribute to the African syndrome of gousiekte ('quick sickness'):

Fadogia homblei[8]
Pachystigma latifolium
P. pygmaeum
P. thamnus
Pavetta harborii
P. schumaniana.

HEMOLYTIC DISEASE – WITH SIGNS OF HEMOGLOBINURIA, ANEMIA, AND JAUNDICE

Acacia nilotica subsp. *kraussiana* – scented thorn
Acer rubrum – red maple; wilted leaves only, to horses[9]
Mercurialis spp. – mercury
Secale cereale – cereal rye.

HEPATIC INJURY – WITH DUMMY SYNDROME OF CIRCLING, HEAD PRESSING, COMPULSIVE WALKING, BLINDNESS

In many cases, an expression of hepatic encephalopathy with hepatic necrosis and status spongiosus in the brain, e.g. *Helichrysum argyrosphaerum* which is associated with blindness, paresis, and spongy degeneration of the brain in sheep and cattle, and *H. blandoskianum* (woolly daisy) has caused death and similar brain lesions in cattle. *Oxytenia acerosa* (copperweed), *Phyllanthus* spp. (spurge), and *Riedelliella graciliflora,* are associated with hepatic injury. *Trema tomentosa* (synonym *T. aspera*) is associated with acute hepatic necrosis in cattle and horses. In *Matricaria nigellifolia* poisoning, affected cattle become clumsy and docile, and head push against fixed objects, hence the common name 'pushing disease'. Sheep are not affected.

HEPATIC INJURY – WITH JAUNDICE AND/OR PHOTOSENSITIZATION

Acanthospermum hispidum – star burr
Athanasia trifurcata
Callicarpa longifolia
Capparis tomentosa
Chlorozoa plicata – terba[10]
Enterolobium spp.
Fallopia convolvulus – black bindweed
Ficus tsiela – fig tree
Galeopsis spp. – hedge nettle
Hertia pallens – springbokbush
Heterophyllaea pustulata – cegadera
Kochia scoparia – summer cypress[11]
Lythrum hyssopifolia
Nidorella foetida
Nolina texana – sacahuiste
Persicaria lapathifolia (synonym *Polygonum lapathifolium*) – pale willow weed[12]
Pongamia glabra – Indian beech
Psathyrotes annua
Pteronia pallens – Scholtz bush
Sartwellia flaveriae – sartwell
Sessea brasiliensis[13]
Stryphnodendron coriaceum[14]
Tetradymia canescens – spineless horsebrush
Trifolium hybridum – alsike clover.[15]

The *Polygonum* spp. (= *Persicaria* spp.) listed below also are associated with photosensitive dermatitis but are credited with causing a primary hepatic injury. Many of the findings about these plants are equivocal:

P. convolvulus[16]
P. orientale – smartweeds
P. sagittatum.

INCOORDINATION OF GAIT, WITH OR WITHOUT RECUMBENCY, CONVULSIONS, OR LESIONS OF NERVOUS SYSTEM

Ageratina altissima
Araujia hortorum – cruel vine
Berula erecta
Brachychiton populneus - kurrajong tree
Brachyglottis repanda - rangiora
Catharanthus spp.
Centella uniflora
Combretum platypetalum
Craspedia chrysantha
Doronicum hungaricum – wild sunflower
Echinopogon spp. – roughbearded grass
Ervum spp.
Euphorbia mauritanica
Gomphrena celosioides – soft khaki weed
Hoya spp. – wax flower
Idiospermum australiense
Melanthrium hybridum
M. virginicum – bunchflower
Melica decumbens – dronkgras
Melochia pyramidata
Modiola caroliniana – creeping mallow
Pennisetum clandestinum – kikuyu grass[17]
Rhodomyrtus macrocarpa – finger cherry; also is associated with blindness.

The following are associated with paralysis in ewes and horses, with lesions of a lysosomal storage disease and include prominent neuronal pigmentation in the brain and spinal cord:

Romulea spp. – onion weed
Solidago chinensis
Stachys arvensis – stagger weed
Stephania spp.
Trachyandra spp.
T. laxa
T. divaricata.

Romulea bulbocordium is associated with a high incidence of phytobezoars, a level of fertility in ewes as low as 20%, and a severe gait incoordination when stimulated to move. Affected sheep walk with their heads held high, fall easily, struggle momentarily, then relax and get up and walk normally. If they are left on the same pasture for 3 or 4 weeks they become permanently recumbent.

Gomphrena celosioides is associated with outbreaks of incoordination in horses in northern Australia. Spontaneous recovery follows removal from the pasture.

Echinopogon mauritanica is associated with hypersensitivity, stiffness, tremor, incoordination, recumbency, and convul-

sions in sheep. *E. ovatus* poisoning in calves and lambs is characterized by harassment-induced episodes of stiff-legged incoordination, easy falling and bellowing, followed by spontaneous recovery.

Pennisetum clandestinum poisoning was originally attributed to lactic acid indigestion, but the more recent suggestion is that it is a poisoning associated with the fungi *Myrothecium verrucaria* and *Phoma herbarum* growing on the grass, an unlikely association in some outbreaks.[18] The disease occurs in sheep and cattle in late summer and autumn. There is depression, salivation, abdominal pain, ruminal tympany and stasis, paralysis of the tongue and pharynx, sham drinking, fine muscle tremor, incoordination, recumbency, diarrhea, cyanosis of mucosae, and dehydration. In the forestomachs there is distension, mucosal reddening, and extensive microscopically visible necrosis in the rumen and abomasum.

Epidemiologically, the disease occurs concurrently with circumstances conducive to fungal growth, including warmth, moisture, and litter under the grass, often due to the depredations of heavy infestations with army caterpillars (*Pseudoletia separata, Pseudocalymma elegans, Spodoptera exempta*). Cattle that eat the flower spikes, or sometimes the young leaves, of *Xanthorrhoea* spp. (grasstrees) in Australia develop loss of condition, urinary incontinence, a high carriage of the tail, and posterior incoordination with the hindquarters lurching consistently to one side. Cattle overbalance easily and fall heavily, which has caused farmers to call the disease 'wamps' in imitation of the sound of the body hitting the ground. Onset of clinical signs may be delayed for 2–3 weeks or more after consumption of the plants has stopped. Complete recovery usually occurs in most affected cattle removed from the plants and nursed well. Degenerative changes have been seen in spinal cord white matter in some severe cases. *Lomandra longifolia* (iron grass, long-leaved mat-rush), probably is associated with a similar syndrome.

MANIA – WITH WILD RUNNING, HYPEREXCITABILITY, INCOORDINATION, CIRCLING, AIMLESS WANDERING, BLINDNESS

Burttia prunoides[19]
Pisum sativum[20]

MYOPATHY – WITH GAIT INCOORDINATION, RECUMBENCY, ELEVATED CPK

Karwinskia humboldtiana – coyotillo.

Small amounts of *Senna* (= *Cassia*) spp. ingested over a long period are associated with skeletal muscle myopathy and paralysis, or a combination of the two syndromes can occur. For example, in *Senna occidentalis* poisoning in horses and goats, the early signs are anorexia and diarrhea and these are followed by hyperpnea, tachycardia, ataxia, staggering, and recumbency. At autopsy there is a fatal cardiomyopathy. The muscle lesion is accompanied by marked elevations of SGOT and CPK levels. Similarly, in pigs, early diarrhea may be followed by lateral recumbency and skeletal muscle myopathy.

PHOTOSENSITIZATION – PRIMARY; WITHOUT HEPATIC LESION

Echinochloa utilis – Japanese millet
Erodium cicutarium – storksbill
Holocalyx glaziovii
Lachnanthes tinctoria
Mentha satureioides
Sphenosciadium capitellatum
Medicago polymorpha – burr trefoil
Verbena spp.

Dermatitis associated with *M. polymorphia* occurs in all animal species on pasture dominated by the plant, usually in the spring. Lesions on the unpigmented parts of the skin disappear quickly when animals are taken off the pasture; there is no liver damage or permanent after-effect. Aphids, which commonly infest the plant in very large numbers, contain large amounts of a photodynamic agent and may be important in some outbreaks of the disease.

POLYDIPSIA, POLYURIA

Orobanche minor – broom rape.

PULMONARY DISEASE – WITH DYSPNEA AND PULMONARY EDEMA ETC.

Glechoma hederacea (= *Nepeta hederacea* – ground ivy)
Gyrostemon spp. – camel poison.

The following are associated with pulmonary consolidation and fibrosis, characterized by dyspnea and cough, in horses:

Eupatorium (= *Ageratina*) *adenophorum* – crofton weed
E. riparium – mist flower
Lactuca scariola – prickly lettuce.

RED URINE – DUE TO A PIGMENTED SUBSTANCE FROM THE PLANT

Haloragis odontocarpa – raspwort
Swartzia madagascariensis
Trifolium pratense – red clover; in deer
Xanthorrhoea minor; in cattle; probably associated with plant resins.

SALIVATION WITH OR WITHOUT STOMATITIS

Arenaris serpyllifolia – thyme-leaved sandwort
Puccinia graminis
Scabiosa succisa – devil's bit.

SUDDEN DEATH – WITHOUT CARDIOMYOPATHY

Arrabidia bilabiata
Burttia prunoides
Eupatorium wrightii
Lamium amplexicaule – dead nettle
Laurelia novae-zealandiae – pukatea
Nicandra physalodes – apple of Peru
Viguiera annua - annual goldeneye.

Uremia, Nephrosis – with high bun

Amaranthus spp.
Anagallis arvensis
Azadirachta indica
Cassine buchanani
Catha edulis – ghat
Dimorphandra gardneriana[21]
Lythrum hyssopifolia
Petiveria alliacea – anamu
Psilostrophe spp. – paperflowers
Sapium sebiferum – Chinese tallow tree
Sarcolobus globosus
Sartwellia flaveriae.

VOMITING

Cephaelis ipecacuanha
Tamus communis – black bryony; plus colic, paralysis, and death.

POISONING BY MYCOTOXINS

Recognition of the importance of mycotoxicoses has developed only in recent

times, partly because of improved diagnostic techniques which make possible the identification of the fungi, and of their toxins and metabolites, plus a greater accuracy in differentiating between myxotoxicoses and their bacterial, viral, helminthological, and inorganic chemical look-alikes. The need for this greater accuracy came about because of the significant increase in prevalence of the mycotoxicoses, in pastured animals fed on lush, improved pasture, and in housed livestock in feedlots, and intensive pig and chicken units where a large part of the ration consists of stored grain. A high moisture content of stored feeds is conductive to fungal growth.

CAUSES OF LOSS

- Sickness and death of animals
- Production loss due to reduced feed intake or subclinical intoxication
- Costs of treating feeds known to be contaminated by mycotoxins
- Discarding of large amounts of feed on suspicion or diagnosis of mycotoxic contamination
- Risk of flow-on to humans who consume animal meat or other food product contaminated by mycotoxins passed through the animal. Besides obvious poisoning there are two potent threats, those of neoplasia and immunosuppression.

VETERINARY SERVICES REQUIRED RELATIVE TO MYCOTOXICOSES

- Diagnosis to establish rational treatment and control measures to prevent further loss. Differentiation from diseases with similar epidemiological, clinical, clinicopathological and histopathological profiles, but associated with other pathogens, presents serious difficulties for field veterinarians because the fungal agent may be invisible to the naked eye – e.g. *Pithomyces chartarum* on plant debris and causing facial eczema, and infections with the endophytes *Neotyphodium lolii* and *N. coenophialum* – diseases in which diagnostic attention is directed to the plant rather than to the toxin
- Identification of the toxin in the feed or the animal by analytical techniques including immunoassay and chromatography. The chemicals concerned are complex organic compounds and identification may be difficult and is usually expensive. Toxins need to be identified for purposes of recuperative litigation and so that toxic feeds can be identified and either discarded, detoxified, or diverted to feeding less susceptible animals
- Identification of the fungus by culture of suspect feed requires special laboratory services. It is very important to realize that isolation of a known toxigenic fungus does not provide a diagnosis of mycotoxicosis of itself. Growth conditions in the substrate may not have suited mycotoxin production. For a diagnosis to be made it is essential to identify and quantify the mycotoxin itself in the feed or the animal. Knowledge of the identity of the fungus is essential if control of its growth is contemplated, e.g. by spraying fungistatic material on pasture, or prediction of outbreaks is to be undertaken. The difficulty is compounded by the common occurrence of mixed infections, and the often fleeting period of growth of the fungus. Fungi have very exact requirements of moisture and temperature, in particular, for optimum growth, and when these are achieved the fungus can multiply very rapidly and produce large amounts of toxin in a matter of hours
- Prediction of environmental conditions conducive to outbreaks of mycotoxicosis, especially on pasture, is possible only with an exact knowledge of the growth requirements of the particular fungus, requiring expensive monitoring of pastoral microclimate. A common compromise is to monitor fungal growth by counting the yield of spores obtained from a given area or volume of the substrate. However, this does not provide information on the growth requirements of the fungus if any attempt is to be made to restrain its growth in agricultural materials.

CONTROL MEASURES

Most of the measures identified below are at a trial level and have not been used widely in a range of climatic and industrial environments:

- Spraying of pasture with a fungistat, e.g. thiabendazole for *Pithomyces chartarum* control.
- Adding adsorbents, e.g. hydrated sodium calcium aluminosiliciate,[1] activated charcoal, a range of clays (bentonite, zeolite), and synthetic ion-exchange resins.
- Immunizing animals against some mycotoxins, e.g. phomopsin.[2]

Much of the feed fed to animals is contaminated by fungi, the harvesting techniques used and the variability of the weather predicate it, and animals can tolerate even heavy contaminations.[3] To reject all feed showing contamination would result in unnecessary financial loss. Standard management procedures used widely and traditionally to deal with a flawed feed system and limit losses due to mycotoxicoses include:

- Limitation of the use of high moisture grain as feed. Any grain containing more than 20% moisture is liable to some degree of fungal spoilage
- Avoidance of grazing mature pasture or field crop in which molds grow commonly on seed heads, e.g. *Claviceps* spp. on rye and paspalum, *Diaporthe toxica* on lupins, and *Corallocytostroma ornicopreoides* on Mitchell grass
- Avoidance of very close grazing of pasture because herbivores can ingest toxic amounts of soil fungi, e.g. *Penicillium* spp.
- Feeding of obviously moldy hay to a small group of test animals because many of the molds on feeds do not produce toxic metabolites, many do but only at certain times, and many have an as yet undetermined status. This procedure has the disadvantage that certain modes of loss may go unrecognized. For example, reduction in feed consumption, and a resulting loss of productivity, is becoming increasingly recognized as a subclinical mode of loss in mycotoxicoses
- Small amounts of feed can be used as feed by diluting it to, at the most, 10% with undamaged feeds, and preferably fed to a sample, pilot group of animals. Lactating, pregnant, and growing animals are most likely to be seriously affected and should not be put at risk.

The known syndromes are summarized in Table 33.2. A list of the mycotoxicoses in which the toxin has not been identified is included at the end of the section. The invasion of tissues by fungi is dealt with in Chapter 24.

Table 31.2 Common mycotoxicoses in farm animals

Mycotoxin	Fungus	Disease	Clinical syndrome	Pathogenesis
Aflatoxins	*Aspergillus flavus* etc.	Aflatoxicosis	Blind, circle, fall, convulsions, teeth grind, mouth frothing,	Hepatic necrosis
Citrinin	*Penicillin citrinum* etc.	1. Citrinin poisoning	Uremia (depression, recumbency, high BUN)	Nephrosis. Often combined with *Aspergillus ochraceus*
		2. Pyrexia–Pruritus–Hemorrhagic syndrome	Exudative dermatitis with pruritus, fever, hemorrhages on mucosae	Unknown
Ergot alkaloids	*Claviceps purpurea*	1. Ergotism (vascular)	Lameness, gangrene of lower limbs, tail, ear tips, loss of tail switch	Arteriolar spasm causes deficient blood supply to part
		2. Hyperthermia	Hyperthermia, salivation, dyspnea	Reduced blood supply to skin reduces heat loss
Ergot alkaloids	*Neotyphodium coenophialum*	1. Fescue summer toxicosis	Low milk yield or weight gain, hyperthermia, hypersalivation, seek shade	Depression of blood levels of prolactin
		2. Fescue foot	Loss of tail switch, distal limb, ear tips, tail tip gangrene	Local vasoconstriction impairs blood supply
		3. Prolonged gestation	Long gestation, dystokia, abortion, stillbirth, agalactia	Vasoconstriction causes placental edema, reduced circulating prolactin
Paspalitrems	*Claviceps paspali*	Paspalum staggers	Cerebellar ataxia. Non-fatal	Unknown
Fumonisins	*Fusarium verticilloides*	Equine leucoencephalomalacia	Tremor, stagger, unable to swallow, depression, recumbency, fatal	Necrosis and hemorrhage in cerebral white matter
Lolitrems	*Neotyphodium lolii*	Rye-grass staggers	When disturbed gross incoordination, falling, hypersensitivity	Functional derangement of nervous tissue function. No histological lesions
Ochratoxin	*Aspergillus ochraceus*	Nephropathy	Diarrhea, polydipsia, polyuria, BUN elevated	Nephrosis, immunosuppressant. Carries over into human food chain
Phomopsin	*Diaporthe toxica*	Lupinosis	Jaundice, depression, recumbency. Survivors have photosensitive dermaitits	Hepatitis. Skeletal muscle myopathy
Slaframine	*Rhizoctonia leguminicola*	Slaframine toxicosis	Lacrimation, diarrhea, urination frequent. Hypersalivation	Unknown
Sporidesmin	*Pithomyces chartarum*	Facial eczema	Photosensitive dermatitis, conjunctivitis, stomatitis, lethargy, anorexia, jaundice	Obliterating choloangitis
Unspecified tremorgens	*Penicillium Aspergillus* spp.	Staggers	Hypersensitivity, incoordination of gait, falling, when driven or startled	Functional nervous derangement
Macrocyclic trichothecenes	*Stachybotrys chartarum* (patratoxin,verrucarin, roridin)	Stachybotrytoxicosis	Fever, diarrhea, dysentery, necrotic ulcers and hemorrhages oral, nasal mucosae, epistaxis, nasal discharge, dermatitis peroral, periorbital	Agranulocytosis, bone marrow suppression, immunosuppression
Non-macrocyclic trichothecenes (T_2 toxin, deoxynivalenol, diacetoxyscirpenol)	*Fusarium sporotrichoides, F. roseum, F. culmorum* etc.	Fusaritoxicosis	Vomiting, feed refusal, diarrhea, mucosal ulcers, and hemorrhage	Immunosuppression and hemorrhagic disease
Zearalenone	*Fusarium roseum, F. culmorum*	Vulvovaginitis	Infertility, anestrus, stillbirths, neonatal mortality, swelling vulva, mammary glands, vagina and rectum prolapse	Vulvovaginitis

Only the common mycotoxicoses are listed. Many minor ones are listed in the text.

POISONING BY AFLATOXINS (AFLATOXICOSIS)

Synopsis

Etiology Aflatoxins produced by *Aspergillus* spp. growing on stored feed.
Epidemiology All species affected; toxin excreted in milk.
Clinical signs Blindness, circling, photosensitization abortion, tenesmus, stumbling gait.
Clinical pathology Elevated levels of liver enzymes in serum. Assay of aflatoxins in feed and tissues.
Necropsy Hepatic necrosis, megalocytosis, fibrosis; jaundice.
Diagnostic confirmation Positive assay of aflatoxin in tissue, fluids.
Treatment Symptomatic only.
Control Preventive assay of large quantities of feed stock. Detoxification of contaminated feed currently being attempted.

ETIOLOGY

Aflatoxins (AF) are metabolites produced by fungi growing on spoiled feeds. They include AFB_1, B_2, G_1, G_2, and the second

generation metabolites M_1 and M_2. They are related chemically to, and probably derived from, dicoumarin compounds. Much the most important disease associated with the ingestion of *Aspergillus* spp. is aflatoxicosis, which is associated with the aflatoxins, but other important toxins produced by the fungi are ochratoxin, patulin, and sterigmatocystin.

Levels of AF attained in feed may be as high as 3500 ng/kg for all aflatoxins, 2000 ng/kg for AFB_1 and 1000 for AFB_2. In sheep, a dose rate of 4 mg/kg is associated with death at 15–18 hours due to acute hepatic insufficiency; at dose rates of 2 mg/kg there is increased respiratory rate, a rise in temperature of 1.5°C (34°F) and diarrhea with blood and mucus; at a dose rate of 0.2 mg/kg there is anorexia and diarrhea. Similar dose relationships have been established for calves and for pigs. A great deal of aflatoxin ingested in the feed by cattle is physically bound to ruminal contents, and as little as 2–5% reaches the intestine. Levels of AFB_1 in excess of 100 µg/kg of feed are considered to be poisonous for cattle.

EPIDEMIOLOGY

Aflatoxicosis has been reported in most countries and on many spoiled feeds, especially harvested peanuts, peanuts-in-shells on hay, cottonseed meal, sorghum grain, corn, moldy bread, green chop sorghum, or rarely on a standing crop, e.g. ears of sweet corn.[1] Common sources are *Aspergillus flavus, A. parasiticus, Penicillium puberulum.* All animal species are susceptible but outbreaks occur mostly in pigs, sheep, and cattle. The mycotoxin is not destroyed by milling of the grain.

Because the toxin is excreted in cows' milk the disease has public health importance. Aflatoxin is now an important consideration in the etiology of human hepatocellular carcinoma.[2] The concentration of AF in cows' milk may be as high as 0.33 µg/L and may continue to be as high for 3–4 days after ingestion of the feed. Aflatoxins can also be present in the meat from animals eating contaminated feed, but the risks to humans eating the meat are thought to be small.[3]

PATHOGENESIS

Hepatosis and hepatic insufficiency are the principal effects, but mutagenic and teratogenic effects are recorded in laboratory animals and suspected in humans on epidemiological grounds.

CLINICAL FINDINGS

Cattle

Clinical signs include blindness, walking in circles, ear twitching, teeth grinding, frothing at the mouth, photosensitive dermatitis and keratoconjunctivitis, diarrhea, severe tenesmus, abortion, and anal prolapse. Terminally recumbency is followed by convulsions. The appetite is normal. Affected animals usually die within 48 hours, calves in the 3–6 month group being most susceptible. Aflatoxicosis is also reputed to interfere with clotting of the blood in cattle, leading to the development of hematomas. Amounts of toxin insufficient to overt disease in cows may be sufficient to reduce food intake, weight gains, and milk production, and to be associated with diarrhea.

Pigs

In pigs, the period between when the toxin is ingested and when signs appear is thought to be quite long, at least 6 weeks, and varies with the toxicity of the batch of feed. The mortality rate is often 20%, but may be as high, including euthanasias, as 90%.[4] Feeder pigs are more susceptible than adults. The clinical syndrome includes rough coat, depression, anorexia, weight loss, muscle tremor, staggery gait, walking in a daze, and recumbency. Some have intermittent or hemorrhagic diarrhea, and some have seizures just before death. The course of the disease may be as short as 6–12 hours. Abortion is a commonly reported sequel, but there is doubt about the relationship. At necropsy there is icterus, ascites, swelling of the liver, and mesenteric edema.

Horses

Aflatoxicosis in horses is recorded,[5] but is unusual probably because horses are not likely to be fed damaged feeds. No clinical signs are reported but illness, lasting 5 days after a prodromal 3–4-day period of anorexia, begins a few days after access to contaminated feeds. Necropsy lesions include encephalomalacia, hepatocyte necrosis and hepatic fibrosis, bile duct hyperplasia, hemorrhagic enteritis, and myocardial degeneration. The experimental disease is characterized by depression, inappetence, tremor, and prostration, with death following in 2–6 weeks.

CLINICAL PATHOLOGY

Estimation of AFs in feed materials, urine, blood, and tissues is standard practice. Serum hepatic enzyme levels are increased during the acute phase. Laboratory assay methods include chromatography and a quicker and more accurate ELISA.[6]

NECROPSY FINDINGS

Necropsy findings in all species are those of hepatosis, including megalocytosis, multiple foci of necrosis and fibrosis, portal round cell infiltration, and bile duct hyperplasia.[7] Jaundice and serous exudates in body cavities may occur in some animals. A pronounced lower enterocolitis with diarrhea and dysentery is common, but not constant, in pigs.

DIFFERENTIAL DIAGNOSIS

Diagnosis confirmation depends on the detection of aflatoxin in the feed and blood serum, and the characteristic gross and histopathological findings in the liver and nervous tissue.

Differential diagnosis list:

There are strong similarities to:

- Pyrrolizidine alkaloid poisoning
- Cyanobacterial toxin poisoning
- Phomopsin poisoning
- Sporidesmin poisoning
- Lantadene poisoning
- Steroidal saponin poisoning
- Fascioliasis.

Therapeutic administration of *Aspergillus oryzae* to newborn foals as a digestive inoculant to promote fast development of digestion is suspected of producing mycotoxins and being associated with acute hepatic insufficiency, including encephalopathy.

TREATMENT

Symptomatic treatment of hepatic insufficiency is all that can be attempted.

CONTROL

Since the advent of reliable and accurate methods of assaying AF in feeds there has been a notable tendency for feed to be less contaminated. Supplementation of the diet with zinc, selenium, vitamin E are not effective in preventing aflatoxicosis, and those procedures which have shown promise in experimental trials have not been translated into practicable, cost-effective techniques.[8] Useful, experimental dietary procedures include hydrated sodium calcium aluminosilicate[9] (several formulations of the compound are already used as anti-caking agents in the animal feed industry) and sodium bentonite in the form of clay.[10] Agronomic methods to reduce aflatoxin contamination of peanuts have recently been successful.[11] Ammoniation of feed has been useful in reducing contamination.[12]

CITRININ

Citrinin is most widely known as a nephrotoxin produced by the fungi *Penicillium citrinum, P. viridicatum, P. palitans,* and *Aspergillus ochraceus* and *A. terreus.* It is commonly found in combination with *A. ochraceus,* and the signs and lesions associated with poisoning by the metabolites of all of the fungi are the same. Citrinin plays a different role in the disease pyrexia-pruritis-hemorrhagic diathesis.

EPIDEMIOLOGY

Serious outbreaks of this idiopathic disease have been recorded in the UK since 1977. The **epidemiology** of a variable number of cows being affected simultaneously in a number of herds in the same locality suggested a chemical intoxicant. Suggested poisons were diureidoisobutane (DUIB), the hairy vetch (*Vicia villosa*) or the additive 'sylade', a combination of formalin and sulfuric acid, used in the making of ensilage. This was unlikely given the rarity of the outbreaks when the use of the additive was widespread. The cause is still not certain, but citrinin is now thought to be at least one of the causes.[1] A fortuitous outbreak in half a dairy herd in which moldy citrus pulp cubes were being fed, while there were no cases in the other half of the herd not fed the cubes, suggested that citrinin, which was present in the cubes (30–40 ppb), was causative.

CLINICAL SIGNS

These include pruritus, hair loss, papular dermatitis, variable appetite with roughage being taken but not concentrates, fever (40–41.5°C, 104–106.7°F), petechiation on conjunctiva, and visible mucosae. The dermatitis is widespread, exudative, initially papular, and itching. It occurs principally on the head, neck, perineum, and udder. Pruritus is variable in degree, but is often so marked that rubbing is associated with the affected skin to become raw and bleeding. The dermatitis subsides but the fever persists, and over a period of 4–7 weeks the animal becomes so unthrifty that it is usually sent for slaughter. The morbidity rate is usually 10%, but may be as high as 100%. Seriously affected animals die. A similar but more severe syndrome occurs in which there is petechiation in all tissues, especially subserosally. In these cases there are multiple hemorrhages in all mucosae and free blood at the anus and other orifices.

NECROPSY

Examination shows petechiation in all organs and tissues, although they are absent altogether in some cases. Histological findings include low-grade, longstanding interstitial nephritis, and very little else of significance. Hematology, blood chemistry, and serum enzymes are similarly normal. Antibody reactivity to some components of ruminal contents may be elevated, but not apparently significantly.

CYCLOPIAZONIC ACID

An indoletetramic acid, a secondary metabolite produced by *Aspergillus* and *Penicillium* spp. growing on stored grain, including sunflower seeds, is associated with feed refusal and conception problems in sows.[1] Isolated from *A. flavus,* cyclopiazonic acid is associated with weakness, anorexia, loss of body weight, and diarrhea in pigs. Necropsy lesions include gastric ulceration and hemorrhages throughout the alimentary tract.

ERGOT ALKALOIDS

Ergot alkaloids are a subset of indole alkaloids, many of which, like the tryptamines of *Phalaris* spp., occur naturally in plants and produce similar diseases. The individual toxins, and the plants they parasitize, are only partially identified. A list of the fungi, the toxins they contain and the syndromes attributed to them is as follows:

Neotyphodium (Acremonium) spp.
Neotyphodium (Acremonium) coenophialum; contains the ergopeptine alkaloids ergovaline, ergotamine, and is associated with hyperthermia, milk yield drop, peripheral gangrene
Neotyphodium (Acremonium) lolii; contains lolitrem alkaloids and paxilline, and is associated with gait incoordination (rye-grass staggers)
Balansia epichloe; gait incoordination, peripheral gangrene
Claviceps africana – sorghum ergot; contains dihydroergosine; is associated with agalactia, hyperthermia
C. cinerea; gait incoordination
C. fusiformis; agalactia
C. paspali; gait incoordination
C. purpurea; hyperthermia, peripheral gangrene.

NEOTYPHODIUM (ACREMONIUM) SPP.

Infestation of the grasses *Achnatherum inebrians* (drunken horse grass) in China[1] and *Stipa robusta* (sleepy grass) in North America by endophytes is associated with a syndrome of incoordination in horses and sheep grazing on the grass. Identification of the fungi is not completed but they contain ergonovine and lysergic acid amide. Low levels of paxillene and lolitrem B (indo-terpenoids) are also present.

NEOTYPHODIUM (ACREMONIUM) COENOPHIALUM

There are four diseases associated with this endophytic fungus whose toxic hyphae are present, invisible without microscopy, in the tissues of the grass *Festuca arundinacea* (tall fescue), and which do not produce fruiting bodies. Spread of the endophyte is via infected seeds. There is no visible effect on the growth of the grass. The fungus produces the ergopeptine alkaloids, principally ergovaline, and many other pharmacologically active compounds including peramine and ergine (lysergic acid amine).

Two major diseases are associated in cattle and sheep, fescue summer toxicosis and fescue foot, and two minor ones, fat necrosis and agalactia in mares. All four syndromes could theoretically occur on the one pasture, but summer toxicosis occurs only in the summer, fescue foot in the winter.

Fescue summer toxicosis (summer slump, epidemic hyperthermia)

Associated with *Neotyphodium (Acremonium) coenophialum* (synonym *Sphacelia typhina*), this disease has assumed a significant place amongst the loss in dairying in the United States, New Zealand, and Australia because of the high rate of use of tall fescue as a pasture grass.

The **syndrome** is a period of poor production manifested in cattle at pasture in the summer by a fall in milk production or a failure to grow adequately in fat cattle, both in the presence of what looks like an optimum amount of nutritious pasture. The same poor weight gain is experienced by steers fed on fescue seed, and in sheep. In cattle grazing at pasture the depressing effect on production is made worse by environmental temperatures

above 31°C (87°F). Affected cattle show hyperthermia with temperatures as high as 40.5°C (104.5°F) dyspnea, hypersalivation, inappetence, rough coat, and they may compulsively seek out water or tree shade in which to stand. The hyperthermia may not recede until about 6 weeks after the cattle are moved from the pasture.

The **mycotoxin** responsible is ergovaline, an ergopeptide similar to, but more powerful than, ergotamine.[2,3] The lowered milk yield is accompanied by low blood levels of prolactin, resulting in an indifferent prolactin surge when the premilking stimuli are applied.[4] Prolactin levels can be significantly increased by the administration of metoclopramide, a dopamine antagonist,[5] or phenothiazine or cimetidine.[6] The fescue foot is associated with vasoconstriction of sensitive blood vessels, leading to inadequate blood supply to the extremities. Vasoconstriction is also thought to be associated with the hyperthermia, the diminished cutaneous blood supply reducing heat loss.[7]

The **mode of action** of the mycotoxin is unsure but it appears to be mediated via the pineal and pituitary glands, causing an alteration in the metabolism of dopamine and serotonin.[8] Thiamin is thought to be involved in the pathogenesis because of the way in which it improves feed intake during periods of hyperthermia.[9] There is a great deal of variation in the toxicity of different varieties of the grass: KY-31 is most toxic; Kenhy, Mo-96 and Kenmont are intermediate; and Fawn is least toxic. The disease also occurs in animals fed on hay made from affected pastures.

Control of the disease can be effected by growing endophyte-resistant varieties, by rotating cattle through fescue and other grass and clover varieties. Treatment of parental plants with the fungicide benomyl produces seed, which results in pasture with a reduced infection rate and lower toxicity for cattle grazing it. Oral administration of thiabendazole just before the cattle go onto the toxic pasture prevents the onset of signs. The recommended regimen is a dose rate of 5 g/45.5 kg BW repeated every 7 days. Ammoniation of the affected hay removes its toxicity so that serum prolactin levels return to normal.[10] A similar disease is recorded as occurring with poisoning by *Claviceps purpurea*.

Fescue foot

Fescue foot also occurs in cattle which are grazing pasture dominated by tall fescue, usually within 10–14 days of being turned onto the pasture during cold weather. Cattle permanently pastured on the field do not appear to be affected and horses appear to be able to graze it with impunity. The lesions and clinical signs include severe lameness followed 2 or more weeks later by gangrene and sloughing of the extremities especially the digits and to a less extent the tail. There is a close similarity to the disease associated with the ingestion of *Claviceps purpurea* and the ergotoxins are also present in fescue (*Festuca octoflora*) so that identifying the specific cause of gangrene of the extremities may not be possible. The incidence in a herd may be as high as 10%. The lesions are associated with the vasoconstrictive agent ergovaline produced by *N. coenophialum*. In freezing temperatures, frostbite may be a complicating factor. New cases may continue to appear for up to 1 week after removal from the affected pasture. The grass heads are commonly infested by *C. purpurea* but the disease occurs in its absence.

Infertility and poor weight gain in horses

Pregnant mares fed on *Neotyphodium (Acremonium) coenophialum*-infested pasture can experience a much higher incidence of dystocia, longer gestation, low foal survival, small udder development, and poor milk yield, compared with mares on unaffected pastures.[11] Prolongation of luteal function, an increase in cycles bred per pregnancy rate, and early embryonic death significantly reduce reproductive efficiency.[12]

CLAVICEPS PURPUREA (ERGOTISM)

Synopsis

Etiology Poisoning associated with the ingestion of large quantities of the naturally occurring ergots of *Claviceps purpurea*.
Epidemiology Warm, wet climate; ingestion of pasture or cereal rye or hay made from them.
Clinical signs Gangrene of the extremities of the limbs, tip of tail and ears, hyperthermia in cattle. Abortion, poor mammary development, early neonatal deaths in mares and sows.
Clinical pathology Assay of ergot toxins in feed and animal tissues.
Necropsy findings Gangrene of extremities.
Diagnosis confirmation Ergot alkaloids in assay.
Treatment Amputation of gangrenous parts.
Control Avoid exposure or dilute feed with non-toxic material.

ETIOLOGY

Claviceps purpurea is a fungus which under natural conditions infests cereal rye and, less commonly, other cereals and many grasses, including the rye-grasses, tall fescue grass, *Phleum pratense* (timothy, cocksfoot, Yorkshire fog), *Cynosurus cristatus* (crested dogstail, tall oat grasses, the brome grasses), *Brachiaria decumbens*, *B. humidicola*, and *Pennisetum typhoides* (bulrush millet).[13] Ingestion of large quantities of seed heads infested with the sclerotia (ergots) of the fungus is associated with ergotism in cattle, sheep, pigs, horses, dogs, and birds. The ergots contain a number of alkaloids and amines with pharmacological activity and these vary in concentration with the maturity of the ergot. The pharmacologically active compounds in the group, known collectively as ergotoxins, include ergotamine, ergotoxine, and ergometrine, and stimulate the smooth muscle of arterioles, intestines and the uterus.

There is some evidence that corn smut may have pharmacological activity similar to that of *C. purpurea*. An unidentified ergot *Claviceps* spp. on *Cynodon dactylon* (Bermuda or couch grass), may be related to the tremor syndrome which occurs occasionally in cattle grazing this grass.

EPIDEMIOLOGY

Ergot of rye is widespread in its distribution, but it is seldom that sufficient is ingested in its toxic stage to be associated with poisoning. Poisoning is most likely to occur during or after warm, wet seasons which favor the growth of the fungus. Ergotism occurs commonly only in cattle and usually in stall-fed animals feeding on heavily contaminated grain over a considerable period of time. Other species are not usually exposed to the infested grain.

Ergot-infested pasture may be associated with the disease, and the toxicity is preserved through the ensiling process.[14] Cows may show early signs of lameness in as short a period as 10 days after going onto an infested pasture, but most animals do not become affected until 2–4 weeks after exposure. Peripheral gangrene occurs in the cooler months, hyperthermia in hot weather.

PATHOGENESIS

The peptide alkaloids of ergot, particularly ergotamine, are associated with arteriolar spasm and capillary endothelial damage, with restriction of the circulation and gangrene of the extremities when small amounts are taken over long periods. In spite of the known abortifacient action of *Claviceps purpurea*, abortion does not usually occur in poisoned animals.

The experimental feeding of ergots (1–2% of ration) is associated with severe reduction in feed intake and growth rate in young pigs without producing overt signs of ergotism. Experimental feeding of ergot-infested *Lolium perenne* seeds to cattle can be associated with hyperthermia, without other lesions.[15]

CLINICAL FINDINGS

There are three syndromes: **classical ergotism** characterized by gangrene of

the extremities, a **hyperthermia syndrome** in cattle, and a **reproductive syndrome**.

Classical ergotism – peripheral gangrene

The extremities, particularly the lower part of the hindlimbs, the tail, and ears are affected. There are reddening, swelling, coldness, loss of hair or wool, and lack of sensation of the parts initially, followed by the development of a blue-black color, dryness of the skin, and its separation from normal tissues. The gangrene usually affects all local tissues and, after the lapse of some days, the affected part becomes obviously separated and may eventually slough. The lesions are not painful but some lameness is evident even in the early stages and the animal may remain recumbent most of the time. Severe diarrhea is often an accompanying sign. In sheep under experimental conditions there is no gangrene of the limbs, but there is ulceration and necrosis on the tongue, the mucosae of the pharynx, rumen, abomasum, and small intestine.

Hyperthermia form

Affected cows have temperatures of 41–42°C (105–107°F), dyspnea, and hypersalivation. Milk production and growth rate are depressed and morbidity is about 100%. The syndrome occurs in hot weather conditions when affected animals seek water or shade, but exposure to sunlight under normal conditions of air temperature and humidity can be enough to be associated with clincial signs.[16,17] Affected animals stressed by exercise in ambient temperatures over 30°C (86°F) commonly die. Long-term low-level feeding of ergot to fattening beef cattle can result in reduced feed intake and weight gain, increased water intake and urination, failure to shed winter coat and increased susceptibility to heat stress.

Reproductive form

This is an uncommon manifestation in cows, but there is one report of a brief exposure to a heavily ergotized pasture causing abortion in late pregnant cows. It also occurs as a single outbreak of agalactia, lack of mammary gland development, abortions, prolonged gestations, and early foal deaths in mares fed oats containing *Lolium multiflorum* seeds heavily infested with *C. purpurea*.[18] In sheep, the feeding of ergot reduces the chance of fetuses surviving, so that relative infertility occurs, and feeding pregnant ewes on ergotized grain is not recommended.

In pigs, ergotism is manifested by lack of udder development and agalactia in sows, and the birth of small pigs which suffer a heavy neonatal mortality. Some of the piglets survive and subsequently suffer gangrene of the ear edges and tail tip. In sows, the chronic feeding of *C. purpurea* may not disturb existing pregnancies, but premature births, mummified fetuses, and low litter size are recorded. Levels up to 0.2% in the diet appear to be safe. A specific ergot, *Claviceps fusiformis*, which grows on *Pennisetum typhoides* (bulrush millet), is known to be associated with agalactia in sows in Zimbabwe. *Claviceps africana*, the ergot of sorghum, has been associated with agalactia in sows and perinatal mortality of piglets in Australia.[19]

CLINICAL PATHOLOGY

Samples of fungus-infested material may be submitted for assay or test feeding. Chromatographic and mass spectrophotometrical techniques can be used to identify the presence of ergot in feed.[20]

NECROPSY FINDINGS

In cattle, gangrene of the extremities is the principal gross lesion. There may be evidence of congestion, arteriolar spasm, and capillary endothelial degeneration in the vicinity of the gross lesions and in the central nervous system. Ulceration and necrosis of the oral, pharyngeal, ruminal, and intestinal mucosae are recorded in sheep.

DIFFERENTIAL DIAGNOSIS

Diagnosis confirmation depends on a positive assay of ergot alkaloids in feed or tissues. Differential diagnosis list includes:

For classical ergotism:

- Poisoning by *Neotyphodium coenophialum*
- Arterial thrombosis and embolism
- Trauma causing obstruction of circulation to the part
- Bacteremia, e.g. in salmonellosis.

For hyperthermic ergotism:

- Heat stroke
- Water deprivation.

For **reproductive ergotism** consult other texts dealing with diseases of the reproductive tract.

TREATMENT

Treatment is not usually attempted, although vasodilator drugs may have some beneficial effect. The infested grain should be withdrawn from the ration immediately.

CONTROL

Heavily ergotized grain or pasture fields containing ergotized grasses should not be used for animal feeding. They may be grazed if they are first mowed with the mower blade set high to remove the seed heads. Feed should not contain more than 0.1% of ergot-infested heads. It is probably safest not to feed ergot-infested feed to pregnant females.

NEOTYPHODIUM LOLII (RYE-GRASS STAGGERS, MIGRAM)

Synopsis

Etiology Tremorgens (lolitrems) from *Neotyphodium (Acremonium) lolii*, an endophytic fungus growing in *Lolium perenne*.
Epidemiology All species affected; an inconvenient disease associated with almost no fatalities. Outbreaks in late summer when pasture is short. Disappears when rain stimulates pasture growth.
Clinical signs Gross incoordination when disturbed; limbs not flexed; fall easily, struggling violently attempting to rise. If left alone calm down, rise and graze normally.
Clinical pathology Lolitrem can be assayed in feed and animal tissues.
Necropsy findings No identifying lesions.
Diagnosis confirmation Positive pasture or blood assay of lolitrems; >20 endophyte hyphae/mm leaf sheath width.
Treatment Nil. Remove animals from affected pasture.
Control Limit access to affected pasture.

ETIOLOGY

Knowledge about the cause of rye-grass staggers has changed dramatically during the past decade. It is now known to be associated with tremorgenic mycotoxins produced by the endophytic fungus *Neotyphodium (Acremonium) lolii* in *Lolium perenne* (perennial ryegrass). The mycotoxins are intensely fluorescent complex indoles called lolitrems. Lolitrem B is the abundant one, and lolitrems A, C, and D are present in only small quantities. *N. lolii* produces other metabolites including paxilline, a weak tremorgen, and peramine, a pyrrolopyrazine alkaloid which is repellent to insect pests, especially the devastating Argentine stem weevil. *N. lolii* also has an ameliorating effect on the growth of the plants that it infests, causing increases in dry matter production of 30–40%. This may be due to the deterrent effect of peramine on insect pests.

EPIDEMIOLOGY

Occurrence

Rye-grass staggers occurs chiefly in New Zealand, but also to a limited extent in Australia and Great Britain. The incidence is extremely variable depending on climatic conditions. Rye-grass staggers affects a variable number of animals (5–75%) but is associated with few, if any, deaths. Sheep, cattle, horses, and wapiti deer are all affected.

Risk factors

Plant factors

The endophytes grow in the plant tissues and are also present in the seeds. They are concentrated in the outer, lower leaf sheaths so that the disease is most likely to occur at the end of the summer when the pasture is short, and in animals that graze closest to the ground.[1] Different cultivars of perennial rye-grass vary in their degree of contamination by the endophyte; some, such as Nui and Ruanui, carry only 30% infection, whereas Yatsyn and Droughtmaster are 100% infected. Lolitrems A and B are present in high concentrations in the seeds of *L. perenne*, and feeding the seed to sheep is associated with rye-grass staggers syndromes. Rye-grass staggers has also occurred in horses fed on the cleanings of perennial rye-grass seed; heavier cleanings containing more seed are more toxic than the husk-rich cleanings.

Environment factors

Rye-grass staggers occurs most commonly in the autumn, but when the grass is dry and short and making only a small amount of slow growth. A sudden fall of rain and rapid growth of the grass is followed by disappearance of the disease. For this reason facial eczema and rye-grass staggers do not occur together in the same flocks at the same time.

Importance

The disease is an inconvenience because animals cannot be easily moved. A few deaths may occur due to misadventure.

PATHOGENESIS

Because of the transient nature of the disease, the nervous signs in rye-grass staggers are presumed to be associated with a functional derangement of nervous tissue. The disease produced experimentally by the administration to sheep of material containing the tremorgenic mycotoxin penitrem A is very similar to naturally occurring rye-grass staggers. Fine tremor, manifested as muscle fasciculations, is followed by coarse tremor causing movement of the head and body. The tremor is enhanced by movement. There is incoordination with a bounding gait, and abnormal postural reflexes leading to lateral recumbency, or sternal recumbency with the hindlegs stretched out behind. Eating and drinking are unaffected. There are no diagnostic lesions except in prolonged cases and the disease is likely to be a reversible biochemical toxicosis. Bulls grazing toxic rye-grass pastures have lower than normal blood levels of testosterone, and sheep make lower weight gains than normal.

CLINICAL FINDINGS

In **sheep**, the disease occurs commonly in animals in very good bodily condition. In mild cases, signs are observed only on driving, the limbs being moved without flexion of the joints, so that the gait is bounding. In severe cases, the animal is unable to make any movement without the legs becoming extended and abducted, causing it to fall. Vigorous attempts to rise, which may be interpreted as convulsions, follow. If the sheep are left undisturbed they appear to recover, get up and move off, only to repeat the performance within a few yards or metres. In extreme cases, the sheep are permanently prostrate.

In **cattle**, the syndrome is similar to that which occurs in sheep. There is some nodding of the head at rest and occasionally head tremor, but the convulsions are more severe and flexion of the limbs is more marked than extension.

In **horses**, there is tremor, hypersensitivity, and a reeling, drunken gait which may proceed to posterior paralysis. Recovery occurs in a few days when the animals are moved to new pasture. Horses and cattle affected mildly are unable to move quickly because of limb and trunk stiffness and a tendency to fall. Turning is achieved only with difficulty. The signs are not apparent when the animals are grazing, occurring only when they are disturbed.

CLINICAL PATHOLOGY

There are no animal-based tests available to aid in the diagnosis of rye-grass staggers. Heinz-body anemia is common in cattle grazing rye-grass, but its significance in relation to rye-grass staggers is unknown. Toxic pastures are reported to have ~35 hyphal strands/mm of leaf sheath, non-toxic pastures have about 10 strands/mm. An ELISA is available for the estimation of the lolitrems.

NECROPSY FINDINGS

The necropsy findings in rye-grass staggers include macroscopic pallor of skeletal muscles and focal areas of hyaline necrosis on histological examination. Degenerative lesions of Purkinje cell neurons are described in longstanding cases. There are no specific, identifying lesions.

DIFFERENTIAL DIAGNOSIS

Diagnosis confirmation depends on positive assays for lolitrems in the feed and in animal tissues.

Differential diagnosis list:

- Rye-grass staggers resembles many other functional diseases of the nervous system, especially those associated with poisonous plants
- Nervous syndromes associated with *Claviceps paspali*, *C. cinerea*, *Balansia epichloe*, *Phalaris aquatica* and *Echinopogon ovatus* (rough-bearded grass) are very similar to rye-grass staggers.

TREATMENT

Livestock should be immediately removed from affected pasture but no treatment is required since spontaneous recovery is rapid. Tranquilizers may be useful in severe cases.

CONTROL

Sheep and cattle should not be allowed to graze potentially toxic pasture for more than 2–3 hours a day unless it is more than 30 cm high. Supplementation of the diet with vitamin E, vitamin A, and minerals has had no effect on the incidence of the disease. Replacing existing toxic *L. perenne* swards with *L. perenne* infected with a strain of *A. lollii* that produces peramine that prevents insect attack while not producing either lolitrem or ergovaline that is associated with livestock disease is an effective control.[2,3]

PASPALITREMS (*CLAVICEPS PASPALI* - PASPALUM STAGGERS)

ETIOLOGY

Claviceps paspali is an ergot-producing fungus which infects the seed heads of:

- *Paspalum dilatatum* – paspalum or dallas grass
- *P. distichum* – salt water-couch grass
- *P. notatum* – Argentine bahiagrass
- *P. paspalodes* – water couch
- *P. scrobiculatum* (= *P. commersonii*) – scrobic or ditch millet
- *P. urvillei* – Vasey grass.

It produces tremorgens called paspalitrems, which are chemically related to the tremorgen of *Penicillium cyclopium* rather than to the ergot alkaloids. The neurological effect of the *Penicillum* spp. and *Claviceps paspali* ergots is almost identical. The ergots are most toxic when they are passing from the sticky 'honeydew' (sphacelial) stage to the hard, black (sclerotial) stage. The 'honeydew' stage itself is comparatively non-toxic. Illness can occur when mature ergots are eaten but the disease is not so severe.

EPIDEMIOLOGY

The degree of infestation of pastures varies widely with climatic conditions, being heaviest after wet, humid summers. Outbreaks of the disease occur in autumn when animals at pasture graze the seed heads because of a shortage of other feed. Cattle are most commonly affected, sheep and horses less so.

CLINICAL SIGNS

Signs include manifestations of nervous system derangement. There is hypersensitivity to noise or movement, but not to touch. Muscle tremor is at first only noticeable on exercise but is later continuous, even at rest, and is sufficiently severe to be associated with shaking of the limbs and trunk and nodding or rocking of the head. Involuntary movements may prevent grazing. There is a severe ataxia with gross incoordination of movement, sideways progression and frequent falling into unusual postures. Animals which fall, paddle violently in attempts to rise. After a period of rest they can usually rise unassisted.

The appetite is always unaffected but there may be scouring, salivation, and some loss of condition. Abortion does not occur. Some deaths are associated with misadventure but recovery occurs quickly in most cases if the animals are removed from affected pastures.

NECROPSY FINDINGS

There are no gross changes, except for some increase in cerebrospinal fluid volume, and histological examinations are negative.

DIFFERENTIAL DIAGNOSIS

There are many other causes of incoordination in animals at pasture, some of them phytotoxins and mycotoxins. One of the infrequently reported ones is *Balansia epichloe*, an ergot-producing fungus found on many pasture plants, especially *Cynodon* spp. A very similar syndrome is produced by *Claviceps cinerea* on the seed heads of the grasses *Hilaria mutica* (tobosa grass) and *H. jamesii* (galeta grass).

TREATMENT

Unnecessary for paspalum staggers, but livestock should be removed from the affected pasture, which may, however, be used by permitting only intermittent grazing or after mowing and raking of the seed heads.

FUMONISINS

Fumonisins are mycotoxins produced by *Fusarium verticillioides* (synonyms *F. moniliforme, Gibberella fujikuroi*) growing on moldy corn (maize) grain. Fourteen other *Fusarium* species and *Alternaria alternata* also can produce fumonisins.[1] They block the synthesis of sphingolipids leading to the intracellular accumulation of sphingosine and sphinganine and coagulation necrosis of cells in sensitive organs, especially the brain, heart, liver, and kidney, in which lesions occur. Horses and pigs are much more susceptible to the poisoning than cattle and poultry. Of the known toxic fumonisins, FB_1 (fumonisin B_1) is the most common cause of animal disease and is a known carcinogen in humans (esophagus) and rats (liver). Sphinganine and sphingosine are excreted in the urine and serum and this is used as a biological marker of exposure to fumonisins.[2] Fumonisins are not excreted in the milk of cows[3] or sows,[4] ingesting the toxin. Horse and pig feed should contain less than 10 µg fumonisin B_1/g. Fumonisin-contaminated feed may be salvaged by feeding it to ruminants.[5]

EQUINE LEUKOENCEPHALOMALACIA

The commonest clinical entity is equine leukoencephalomalacia (ELE), a disease of horses and donkeys associated with the ingestion of fumonisins, produced by *Fusarium verticillioides* and *F. proliferatum*.[6] The disease has been produced experimentally by dosing with cultures of the fungus,[7] and the pure mycotoxin. Of the known fumonisins, B_1 and B_2 are the most important, and B_1 has been shown to be the specific cause of ELE.[8] The fungus is commonly found growing on moldy corn (maize) grain that has been affected by rain while on the stalk or stored wet. The disease also occurs in horses fed commercial, including pelleted, feeds; the disease incident is usually in the form of an outbreak, some of them large-scale. Most feeds associated with ELE have ~10 ppm of fumonisin B_1 and exposure for 7–35 days to the feed contaminated with it is necessary to produce the disease.[9]

Clinically the disease is manifested either, and more commonly, by a neurotoxic, or by a hepatotoxic syndrome. In the **neurotoxic syndrome** the signs are initial anorexia, lethargy, and absence of gastrointestinal sounds,[10] then hypersensitivity and agitation, sweating, muscle tremor and weakness, hypermetria, staggering, circling, inability to swallow, lower lip paralysis, protusion of a flaccid tongue, apparent blindness, absent menace reflex, pupillary dilation, absent pupillary light reflex, circling, head pressing, collapse, and tonic-clonic convulsions. In the **hepatotoxic syndrome** signs are edematous swelling of the lips, nose, supraorbital fossa, and lower limbs. Jaundice, cyanosis, mucosal petechiae, and dyspnea are common signs. Death occurs after a course of 48–72 hours. Many horses are found dead without signs having been observed. At necropsy there are macroscopic areas of softening accompanied by hemorrhages in the white matter of the cerebral hemisphere, and hepatic periacinar fibrosis with fatty change and abnormal nuclei in hepatocytes.

EQUINE DUODENITIS PROXIMAL-JEJUNITIS

This idiopathic disease may be confused with colic due to intestinal obstruction. Its characteristic lesions have been produced incidentally, without the clinical signs of the disease, during the experimental production of ELE by poisoning with fumonisin. A link to the mycotoxin was established by the elevated levels of sphingosine in the duodenal lumen.[11,12]

PORCINE PULMONARY EDEMA/HEPATOSIS

The fungus *F. verticillioides* and the fumonisins B_1 and B_2 are associated with fatal pulmonary edema or hepatosis, the former lesion with higher doses of the toxin.[13] This syndrome results from acute left-sided heart failure and increased pulmonary artery pressure.[14] More chronic cases of the hepatosis syndrome are accompanied by hyperkeratosis and parakeratosis of the distal esophageal mucosa.[15] A reduction in cardiac and vascular efficiency is also part of the chronic intoxication with fumonisins in pigs.[16]

Fusaric acid, a mycotoxin also produced by *F. moniliforme*, is associated with depression and vomiting in pigs.[17]

IPOMEANOLS

4-Ipomeanol is a furanoterpinoid mycotoxin produced by *Fusarium solani* (synonym *F. javanicum*) and *F. semitectum* growing on garden refuse.[1] It has the effect of causing lesions indistinguishable from those of atypical interstitial pneumonia. Other known causes of these lesions are 3-methylindole and the ketone produced by *Perilla frutescens*, *Zieria arborescens*, and one of the fungi *Fusarium solani* or *Oxysporum* spp. on *Ipomoea batatas* (sweet potatoes) tubers. Catabolism by the fungus of phytoalexins induced in the tubers by the fungus produces four closely related ipomeanols. These are not toxic until activated by pulmonary microsomal enzymes.[2] Experimental administration of infected potatoes to calves is associated with bronchiolitis and interstitial pneumonia.[3]

MUSCARINE

A mycotoxic alkaloid found in the macrofungi *Inocybe* and *Clitocybe* spp; is associated with excessive salivation, bradycardia, diarrhea, and vomiting. Atropine is an effective antidote. Muscarine is not responsible for poisoning by *Amanita* spp.

OCHRATOXIN

ETIOLOGY

Ochratoxin A is the most potent of isocoumarin derivative mycotoxins. It is a powerful renal toxin which is associated with organellar damage, especially to epithelial cells. It, and ochratoxins B and C, are produced by *Aspergillus alutaceus* (synonym *A. ochraceus*), and other *Aspergillus* and *Penicillium* spp., e.g. *P. viridicatum*. This fungus also produces viomellein and citrinin, both potent nephrotoxins and capable of enhancing the lesion. Modern radioimmunoassay makes chemical identification of the toxin so much easier that identification of the specific fungus is becoming less necessary, and many contemporary accounts of ochratoxin poisoning do not include the identity of the causative fungus.[1]

EPIDEMIOLOGY

The species most often involved is pigs. Experiments with cattle indicate that they are likely to be affected only at very high dose rates, but goats are rather more susceptible. There is some evidence that chickens and horses can also be affected. The fungus grows on stored barley or corn grain, and nephrosis results when the grain is fed. Affected pigs placed on an ochratoxin-free diet are decontaminated in about 1 month. The ochratoxin residues have been detected as a 'carryover' in pigs and poultry meats and have some significance for persons eating contaminated pig meats.

PATHOGENESIS

A nephrosis occurs naturally, has been widespread in Denmark for many years and has been produced experimentally. The principal lesion is a degenerative change of the renal tubules and there is a consequential impairment of tubular function.

CLINICAL FINDINGS

The disease is characterized by diarrhea, polyuria, and polydipsia. Blood urea nitrogen levels are elevated and proteinuria is evident.

NECROPSY FINDINGS

These include dehydration, enteritis, generalized edema, renal enlargement, fibrosis, and necrosis of renal tubular epithelium. Poisoning by ochratoxin in pigs resembles Balkan nephropathy, a naturally occurring disease of humans. Ochratoxin is also an immunosuppressant, is associated with poor sperm quality in boars, and is thought to be associated with fetal death and resorption, and thus abortion.

CLINICAL PATHOLOGY

Assessment of ochratoxin levels in tissue is now performed with radioimmunoassay techniques.

CONTROL

Animal feeds should not be used unless they have levels of ochratoxin less than 10 ppb.[2] Experimental work with antidotes, principally aspartame, which will wash out the toxins from poisoned animals, is proceeding.[3]

PATULIN

Patulin, an important toxin in human medicine, is produced by a number of fungi including *Aspergillus clavatus*, *Byssochlamys nivea*, *Penicillium urticae*, *P. claviforme* and *P. patulum*, and is most commonly associated with rotting apples or apple juice. Cattle and sheep poisoned by patulin-producing fungi develop brain hemorrhage, pulmonary edema or liver and kidney damage with abomasal hemorrhage. Fed to piglets it is associated with vomiting, salivation, anorexia, polypnea, weight loss, leukocytosis, and anemia.[1] Patulin has an antibiotic effect on ruminal bacteria.[2]

PHOMOPSIN

Synopsis

Etiology Mycotoxin produced by fungus *Diaporthe toxica* growing on dead lupin plants or seeds.
Epidemiology Cattle and sheep grazing lupin stubble or fed seeds in ration.
Clinical findings Lupinosis is associated with hepatic encephalopathy (blindness, aimless wandering) accompanied by jaundice and photosensitization. Also skeletal myopathy syndrome with stiff gait, difficulty rising.
Clinical pathology Serum levels of liver and muscle-associated enzymes elevated.
Necropsy findings Jaundice, swollen liver, diffuse hepatic fibrosis, biliary hyperplasia, myopathy.
Diagnosis confirmation Positive assay for phomopsin.
Treatment Change feed.
Control Do not feed infected lupin stubble. Plant phomopsin-resistant lupins. A vaccine is under development.

ETIOLOGY

Diaporthe toxica (anamorph *Phomopsis* spp.), a saprophytic fungus, is the source

of the toxins causing lupinosis of cattle and sheep grazing on the stubble of lupin crops infected with this fungus. Phomopsins A, B, C, D, and E, cyclic hexapeptide mycotoxins, are the specific cause. *Diamorphe woodii* (anamorph *Phomopsis leptostromiformis*) was originally, and erroneously, considered to be the source of these toxins.[1] *Phomopsis emecis*, a saprophyte of *Emex australis* produces phomopsins *in vitro*, but is not associated with natural disease incidents.

EPIDEMIOLOGY

Occurrence

The disease is common in Europe, Australia, New Zealand, and South Africa. Cattle, and especially sheep, are most commonly affected, probably because of their greater exposure. Poisoning of pigs and horses occurs, but rarely.

Risk factors

Plant factors

Most occurrences are in animals which graze lupin stubble in which there is dry foliage, seed pods, and seeds. The disease occurs rarely in sheep fed only on the seeds, and has also occurred in pigs fed ground lupin seeds.

Factors increasing the chances of poisoning associated with fungal infection of the senescent plants include summer rain, which is conducive but not essential to fungal growth; the time lapse since rain, toxic lupins remain poisonous for several months; and the provision of alternative feed or the presence of other plants, including weeds, in a crop, both of which may reduce its lupin intake and hence its toxicity. Similarly, if good quantities of lupin seed are available either still in the pods on the standing plant, or spilled onto the ground, there is less chance of poisoning. The mature stalks are the most poisonous so that a heavy stocking rate which encourages the ingestion of all parts of the plants increases its prevalence. Stubble from which lupin seeds have been harvested is the most common cause of lupinosis. Some varieties of lupins are much more susceptible to fungal infections than others.

Animal factors

Naturally occurring cases are more commonly seen in sheep, cattle appearing to be less susceptible to the toxin.

PATHOGENESIS

Phomopsins injected intra-ruminally have variable effects depending on dose and duration of administration. Subcutaneous dosing results in anorexia, weight loss, lethargy, jaundice, elevation of serum levels of liver enzymes, recumbency, and death in 90% of sheep. Clinical biochemistry findings suggest that the hepatosis is accompanied by injury to muscle, kidney, and adrenal cortex.[2] Necropsy lesions include jaundice and patchy hepatosis with arrested mitoses.[3]

Affected sheep have a higher hepatic concentration of copper and selenium and a lower concentration of zinc, due to necrosis of liver cells. The affinity for copper may lead to the development of a complicating chronic copper poisoning in affected sheep.

CLINICAL FINDINGS

In sheep, signs include anorexia, constipation, hepatoencephalopathy, stumbling gait, recumbency, and a variable degree of jaundice and photosensitization.[4] In cattle, three syndromes may be encountered. Most common is ketosis precipitated by inappetence, seen in pregnant or just-calved cows. Less common is hepatic cirrhosis, seen in cattle usually several weeks after they are removed from lupin stubble. The course of the disease is 1–3 days, and signs include anorexia, depression, staggery gait, jaundice, and bleeding from orifices. Photosensitization occurs in cases which survive for more than a few days. Death may occur within a few days of first illness or be delayed for months, affected animals standing immobile for long periods or wandering aimlessly, often dying from misadventure. More chronic cases exhibit ill-thrift and photosensitization. Recovery may occur if animals in the early stages of the disease are taken off the dangerous pasture, but severely affected animals usually die. Animals that recover appetite will completely recover.

A substantial skeletal muscle myopathy has also been observed in sheep poisoned by phomopsins or infected lupin stubble.[5] Affected animals have a stiff gait, walk reluctantly, and stand with their back humped and their feet under the body, and have difficulty getting to their feet.

Experimental phomopsin poisoning at mating time is associated with reduced reproductive efficiency in ewes.[6]

CLINICAL PATHOLOGY

In the early stages of lupinosis, serum enzyme tests are the best aids to diagnosis. The γ-glutamyl transpeptidase test is preferred in the early subacute stages, and aspartate transaminase when the disease is more severe. In the late stages of the disease liver function tests are preferred.

NECROPSY LESIONS

There are jaundice and either a swollen, mottled bright yellow or pale orange, firm, friable liver in acute cases, or a small and fibrotic one in chronic cases, plus extensive hemorrhages under the skin and serous membranes. Spongy transformation of the brain has been recorded in naturally occurring cases and has also been produced experimentally. Histological lesion mitosis figured in many hepatocytes and necrosis of individual hepatocytes, biliary hyperplasia, and diffuse hepatic fibrosis.[7]

DIFFERENTIAL DIAGNOSIS

Diagnosis confirmation depends on liver histopathology and detection of phomopsins in rumen contents and feeds by ELISA.[10] The differential diagnosis list contains many cases of illness in pregnant and recently calved cows in lupin country which are diagnosed as lupinosis but which are actually cases of pregnancy toxemia or fat cow syndrome. Other fungal or plant hepatopathies will need to be differentiated.

TREATMENT AND CONTROL

Lupin crops should be grazed after seed harvest in early summer, not late autumn. Sheep stocking rates should be less than 30 per hectare. It is an advantage to train sheep to eat lupin seed before they are exposed to crops, thus reducing the intake of stubble as the sheep will forage for seed on the ground. Lupins can be managed to reduce their intake during summer grazing by establishing crop mixtures with wheat, oats, or barley. Prevention is assisted by restricting grazing on mature, standing, dry plants during warm, humid weather which favors fungal growth, by avoiding copper supplementation near danger periods and by encouraging the administration of cobalt. Hay made from lupins appears to be free of toxicity and this may be a useful technique in the prevention of the disease. Fungistatic agents, such as benomyl, are also sprayed onto lupins to reduce fungal growth but no specific recommendations have been made. Additional protection may be gained by the oral administration of zinc which has been shown to reduce the severity of liver damage associated with lupins/fungal poisoning, but commercial application of this knowledge is not yet possible, partly because of the toxicity of the administered zinc. It is advisable to be wary at all times when grazing mature lupin crops. If they are used the crops should be inspected regularly for evidence of fungal infection. If this does occur livestock should be permitted to have access for short periods only, and alternate and supplementary feed should be available.

A satisfactory measure of prevention has been achieved by the development of a phomopsin-resistant strain of *Lupinus angustifolius*, which is capable of reducing the mortality rate from 57 to 8%.[8] A phomopsin-conjugate vaccine has been successfully tested under field conditions[9] but is not yet commercially available.

PEPTIDE POISONING

Toxic peptides occur in the macrofungi (the mushrooms and toadstools), in *Diaporthe toxica* above, cyanobacteria and in sawfly larvae.

MUSHROOM AND TOADSTOOL POISONING

Reports of poisoning associated with mushrooms and toadstools in farm animals are rare. *Amanita verna* is associated with fatal poisoning in cattle, but large quantities must be eaten before toxic effects occur. Severe pain at defecation and matting of the perianal regions with feces are associated with vesicular and necrotic eruption about the anus and vulva. At necropsy there is severe inflammation of the alimentary mucosa.

The large cauliflower-like fruiting body *Ramaria flavobrunnescens* is credited with poisoning cattle and sheep[1] and causing:

- Salivation
- Lingual and esophageal ulcers
- Anorexia
- Abortion
- Loss of hair, especially of the tail brush
- Pain in, and loss of, hooves.

Cortinarius speciocissimus has been associated with deaths in sheep in Norway with renal tubular necrosis and terminal uremia. *Scleroderma citrinum* fed to miniature Chinese pot-bellied pigs has been associated with vomiting, depression, and recumbency. The pupillary light reflex is lost but the eye preservation reflex remains. There is pain on abdominal palpation, hyperthermia, tachycardia, mucoid feces passed with some straining, and death in about 5 hours.[2]

POISONING BY RUBRATOXIN

Penicillium rubrum and *P. purpurogenum* produce rubratoxins suspected of causing hepatic and hemorrhagic diseases,[1] and rubratoxin administered experimentally to calves has produced mild liver damage. Naturally occurring cases of *P. purpurogenum* poisoning in horses fed cornmeal and cotton seed cake is associated with an acute illness with anorexia, depression, vomiting, profuse bloody diarrhea with foul-smelling feces, recumbency on the day 4 or 5, and convulsions terminally. Necropsy lesions include icterus, liver damage, and severe hemorrhagic enteritis.[1]

POISONING BY SLAFRAMINE

Slaframine is an indolizidine alkaloid of the fungus *Rhizoctonia leguminicola* found on leguminous pasture plants, especially during wet weather, and associated with the disease of pasture known as 'black patch'.[1] Swainsonine, the phytotoxin found in *Swainsona* and *Astragalus* spp., is very similar to slaframine and has also been isolated from this fungus. Ingestion of slaframine is associated with a syndrome, identified colloquially as '**slobbers**', characterized by profuse salivation in cattle, goats, and horses. Excessive lacrimation, stiff gait, tremor, frequent urination, dyspnea, bloat, anorexia, and diarrhea also occur. The salivation is at its peak at 5–6 hours after ingestion and disappears at about 24 hours. No necropsy lesions are recorded. Slaframine is metabolized in the liver to an active metabolite resembling acetylcholine.

The fungus infests standing alfalfa or red clover plants and clover hay, especially red clover hay. Infested plants carry bronze to black spots or rings, and the hay is usually dusty and discolored by black patches on the stems and leaves. Clinical signs usually subside within several days of substituting normal hay. Atropine may be used to control the salivation.

POISONING BY SPORIDESMIN

Synopsis

Etiology Toxic metabolites of fungus *Pithomyces chartarum* growing on litter from pasture plants, particularly ryegrass.
Epidemiology Outbreaks only at pasture, commonest in sheep, in warm moist climates when pasture short and grazing animals consume the dead plant litter.
Clinical findings Facial eczema – acute hepatic injury characterized by dullness, anorexia, jaundice, photosensitization. High case fatality rate, long chronic course in survivors.
Clinical pathology Elevated serum levels of liver enzymes in early stages.
Necropsy findings Liver swollen, discolored early, later tough, contracted. Obliterative cholangitis.
Diagnosis confirmation High spore count on pasture. Elevated assay of sporidesmin in serum.
Treatment Change to rough, mature pasture.
Control Destroy fungus on pasture with fungicide, restrict access to dangerous pasture; daily oral dosing with zinc preparation.

ETIOLOGY

Sporidesmins are metabolites of the fungus *Pithomyces chartarum* (*Sporidesmium bakeri*) infesting dead plant material in standing pasture. The sporidesmins A to H are pyrrolidiones and are associated with facial eczema, a major disease of sheep and cattle. The occurrence of non-toxigenic strains of *P. chartarum* probably accounts for the wide variation in disease occurrence between countries.[1]

EPIDEMIOLOGY

Occurrence

The disease has been recorded most commonly in New Zealand and occurs to a limited extent also in Europe, Australia, and South Africa. The incidence varies widely depending on climatic conditions; in some years the disease does not occur, in others the morbidity rate in affected flocks of sheep may be 70–80% and 5–50% of these may die. Of the survivors, many are unthrifty and make less than normal weight gains. In cattle, the morbidity rate is much lower and rarely exceeds 50%. In spite of the obvious weight loss associated with the non-fatal form of the disease, there is no appreciable effect on the palatability of the carcass meat.

Risk factors

Animal factors

Sheep, cattle, goats, South American camelids, and kangaroos are affected. Experimental production of the disease in Saanen goats requires 2–4 times the sheep dose, and feral goats need 4–8 times the dose.[1]

Plant factors

The environmental factors which encourage the growth of the fungus and the production of sporidesmin include the type of plants in the pasture, and the climatic conditions. Facial eczema is commonly associated with rye-grass pastures, but the causative fungus is capable of growing on all kinds of dead leaf material, including

cereal hay, and causing facial eczema. In South Africa the ingestion of *Pithomyces chartarum* is thought to enhance the toxicity of *Tribulus terrestris*.

Facial eczema occurs extensively only when pasture is short and contains abundant dead, recently killed plant material, and during warm, humid weather, which favors growth of the fungus. This is most likely to be a problem in autumn when the summer has been hot and dry, the pasture well eaten back, and good rains fall when the ground is still warm. In such circumstances the grass and the fungus grow rapidly.

PATHOGENESIS

Sporidesmin is associated with severe damage to biliary epithelium, leading to acute biliary obstruction and a resulting severe hepatic insufficiency manifested by loss of condition, obstructive jaundice, and photosensitization. Sporidesmin administered by mouth is excreted unchanged in high concentrations in urine and bile, especially the latter where it reaches 100 times the concentration in serum. The resulting inflammation of the bile ducts and progressive obliterative cholangiolitis, slow down the rate of bile flow to negligible levels over a period of about 14 days. The photodynamic agent is phylloerythrin, a normal metabolic product of chlorophyll, which is retained in tissues because of failure of its excretion through the damaged liver and bile ducts. The frequent observation that only part of the liver is involved is probably explained by the deposition of toxin in particular parts of the liver, due to portal streaming, on its first passage through hepatic sinusoids. The toxin which reaches the general circulation is probably destroyed.

CLINICAL FINDINGS

In cattle and sheep the disease starts suddenly with the appearance of lethargy, dullness, anorexia, jaundice, and photosensitive dermatitis. The skin lesion and jaundice are both variable in occurrence and sheep may die without either having been observed. Many animals die during this acute stage, but some survive and pass into a state of chronic ill-health manifested by poor bodily condition and a susceptibility to minor environmental stresses. Many others show no clinical signs but have significant changes in serum enzyme systems indicative of an acute hepatic injury, and measurable reductions in reproductive efficiency and lamb weights. Occasional animals develop the syndrome of hepatic encephalopathy manifested by dullness, depression, progressing to tremor and lateral recumbency. Spongy vacuolation of brain tissue is observable histologically in these cases. A moderate fall in the plane of nutrition, parasitic infestation, and pregnancy may be associated with further mortalities, and photosensitive dermatitis may recur if the animals are fed on lush green pasture. Cattle are not as commonly affected by the chronic form of the disease as are sheep but dermatitis of the teats may lead to the development of mastitis.

CLINICAL PATHOLOGY

Tests of hepatic function, especially the bromosulfalein clearance test, should be of value in determining the presence of liver damage. In the very early stages, serum enzyme estimations should also be of value. Serum γ-glutamyltransferase levels are regarded as the best indicator of hepatic damage in cattle and continue high for at least several months after an attack of facial eczema.

NECROPSY FINDINGS

In the acute stages of facial eczema there is jaundice and a swollen, mottled liver with thickened bile-duct walls. In the chronic phase there is extensive hepatic fibrosis, the liver is tough and contracted, and the left lobe is almost completely atrophic. Areas of regeneration are usually apparent macroscopically. Histologically there is perilobular fibrosis with obliteration of the bile ducts and pressure atrophy of hepatic cells. The changes are much more marked in the left lobe.

DIFFERENTIAL DIAGNOSIS

Diagnosis confirmation depends on a positive assay of sporidesmin in fluids and tissues of affected animals. High spore counts on pasture are circumstantial evidence. Facial eczema must be differentiated from those other diseases in which photosensitization and hepatitis occur.

Differential diagnosis list:

- Pyrrolizidine alkaloid poisoning
- Aflatoxin poisoning
- Steroidal saponin poisoning
- Lantadene poisoning
- Cyanophyte (cyanobacterial) poisoning
- Fascioliasis
- Phomopsin poisoning
- A disease of cattle in the southern United States believed to be associated with the ingestion of dead forage on which a *Periconia* spp. fungus is growing.

TREATMENT

There is no **primary** treatment, except to change animals to new pasture. **Supportive** treatment for hepatitis and photosensitization, as outlined under those headings, and the administration of antibiotics and antihistamines to control secondary infection and shock may be applicable in animals of sufficient economic value. The provision of drinking water containing 6 g zinc sulfate per 100 L for 28 days is claimed to hasten recovery of affected cattle.

CONTROL

One of the major difficulties in the control of the disease is that of predicting the occurrence of an outbreak so that the flock can be changed to non-dangerous pasture. Meteorological observation can be of value, but the counting of spores by a mobile spore catcher is now routinely used in danger areas.

In bad seasons the incidence of facial eczema can be reduced by **alternating grazing** between native and improved pastures or by reducing the intake of the fungus in any other way. Because of the proclivity of the fungus for dead grass, two acceptable management procedures for prevention are summer irrigation and hard grazing, both of which reduce the amount of foliar substrate available for fungal growth. Avoidance of sandy soils in bad seasons is also advisable because of the greater tendency for grass death on this kind of soil. Allowing pasture to flower, the sward to grow long, the pasture to be damaged by diseases and pests, and frequent mowing, encourages facial eczema.

In a comparison of **fungicides** used to control the growth of *P. chartarum*, carbendazim was best (at 0.15 and at 0.30 kg/hectare of active ingredient), while benomyl and thiophanate methyl was effective only at 0.30 kg/hectare. The original methods of applying fungistatic agents to pasture included thiabendazole or benomyl (Benlate) sprayed on at the rate of 272 g/hectare in January. The growth of *P. chartarum* was controlled and the development of facial eczema prevented.

The discovery of **non-toxic strains** of *P. chartarum* in New Zealand and South Africa which sporulate profusely but produce no sporidesmin, and compete aggressively with sporidesmin-producing strains, raises the question of controlling facial eczema by dominating the pastoral fungal population with the sporidesmin-negative strain.[2]

The daily oral administration of **zinc** (30 mg/kg zinc BW/day) to lactating dairy cows has been shown to reduce the toxic effects of sporidesmin. The zinc salt can be administered by drench as slurry of zinc oxide, by spraying zinc oxide onto pasture, and adding zinc sulfate to the drinking water. Zinc poisoning is reported as a result of overzealous applications of zinc for these purposes. Iron salts, including ferric ammonium citrate, ferric and ferrous sulfates, have the same protective effect but the volume required makes their application impractical.[3]

Attempted **vaccination** against sporidesmin has so far been unsuccessful in protecting sheep against facial eczema. Resistance to sporidesmin is strongly inherited but flocks containing increased numbers of resistant animals do not have superior productivity.[4] Finnish Landrace sheep are significantly more resistant to *P. chartarum* poisoning than Romneys, with cross-breds in an intermediate position.[5]

POISONING BY STERIGMATOCYSTIN

Sterigmatocystin is a fungal toxin capable of causing hepatic carcinoma. It has been isolated from *Bipolaris* spp. and *Aspergillus nidulans* growing on groundnuts, and from *A. versicolor*,[1] *A. flavus*, *A. parasiticus*. It is a precursor of aflatoxins. Carcinogenesis in farm animals is not reported.

REFERENCE

1. Lepom, P. & Kloss, H. (1988) *Mycopathologia, 101*, 25.

POISONING BY TREMORGENS

Tremorgens include a number of specific mycotoxins including penitrem A, B, and C, verruculogen, roquefortine from *Penicillium* spp., fumitremorgen A and B from *Aspergillus fumigatus*, and flavus tremorgen from *A. flavus*. They produce no necropsy lesions and the clinical syndrome associated with them has the general pattern of the condition known universally as staggers. It includes muscle tremor, gait incoordination, rigid stance, falling easily, recumbency, and paddling convulsions.

Small repeated doses of *P. cyclopium* cultures to sheep are associated with a disease identical with rye-grass staggers. *P. palitans* has been shown to produce ataxia and convulsions in cattle. **Penitrem A** has been isolated from *P. puberulum* and *P. crustosum*, and a more potent one, verrucologen, from *P. crustosum* and *P. simplicissimum*. Penitrem A closely resembles the tremorgen produced by *Claviceps paspali*. It produces tremor, ataxia, muscular rigidity, and convulsive episodes in calves. The tremor is very fine, and increases with excitement. It increases until calves sway rhythmically, standing with their legs wide apart and stiff. The gait is stiff and ataxic and the calves fall often. The worst affected calves are laterally recumbent, with tetanic convulsions, opisthotonos, and severe tremor. Nystagmus and profuse salivation occur sometimes.

Other soil penicillia produce tremorgens. *P. piscarium* produces **verrucologen** and **fumitremorgen B**. *P. estinogenum* also produces verrucologen. *P. nigricans* yields penitrem A. *P. jantinellum* and *P. cyclopium* also produce penitrem A. *P. rubrum* is associated with frothing at the mouth, champing of the jaws, jaundice, cutaneous erythema, and collapse in goats and pigs. In horses, the clinical signs of intoxication include incoordination, chronic spasm, jaundice, diarrhea, abdominal pain, and vomiting. These fungi are soil-borne and could be accidentally ingested by cattle and sheep while grazing. *A. fumigatus* in moldy corn silage produces tremorgens and toxins capable of causing enteritis.

The disease '**rye-grass staggers**' is now known to be associated with the endophyte *Neotyphodium lolii* but it is possible that some outbreaks of incoordination in sheep and other species may be contributed to or even associated with other tremorgens such as those listed above. A subsidiary effect of tremorgenic fungi is a depression of testosterone production in rams and bulls. To confirm a diagnosis that fungal intoxication is the cause of cases of staggers depends on the isolation of tremorgenic fungi from the feces of affected animals. The fungal elements survive passage through the ruminant gut and can be cultured from the feces.

Other fungi causing similar incoordination syndromes but in which no toxin has been identified are listed.

POISONING BY TRICHOTHECENES

Trichothecenes are the largest group of mycotoxins, and amongst the most toxic. They are divided into two groups, the macrocyclic and the non-macrocyclic trichothecenes, on the basis of their molecular structure.

MACROCYCLIC TRICHOTHECENES (SATRATOXIN, VERRUCARIN, RORIDIN, ETC.)

The standard nomenclature for the diseases associated with this group of mycotoxins is retained, stachybotrytoxicosis, and myrotheciotoxicosis.

Stachybotryotoxicosis

Toxins in the fungus *Stachybotrys chartarum (S. atra, S. alternans)*, which is associated with this disease, are the macrocyclic tricothecenes, satratoxins G and H, roridin E, and verrucarin J. Horses, cattle, sheep, and pigs may be affected and the disease is characterized by fever, ruminal atony, diarrhea, dysentery, necrotic ulceration, and hemorrhages of the nasal and oral mucosae, causing epistaxis and purulent nasal discharge, and conjunctivitis causing lacrimation. Drying and cracking of the skin are visible, especially periorbitally and on the face. At necropsy there are hemorrhages into all tissue and under all serous membranes. An important abnormality is the depression of leukocyte formation, causing agranulocytosis, and producing a disease not unlike that associated with bracken poisoning in cattle. Hemorrhages are visible in the mucosae, there is also hemorrhagic enteritis and, in sheep, *Pasteurella haemolytica* can often be isolated from tissues. The infection is thought to occur as a result of the immunosuppression associated with the toxins. In horses there is also a subacute or acute myositis. The disease resembles alimentary toxic aleukia, associated with the ingestion of toxin from *Fusarium poae* and *F. sporotrichioides*, in humans.

Myrotheciotoxicosis

Roridin, a toxin in the fungus *Myrothecium roridum* and *M. verrucaria* growing on rye-grass and white clover plants in pasture, or on stored feeds, is associated with sudden death in sheep and cattle, with necropsy lesions of abomasitis, hepatitis, and pulmonary congestion and edema. Smaller intakes are associated with similar lesions, but over a course of 7–10 days. Very small doses administered over a 30-day period are associated with loss of weight but no deaths.

A bizarre involvement in what appears to be a plant poisoning is the role that *M. verrucaria* plays in *Baccharis* spp. poisoning. *Baccharis* spp., including *B. cordifolia*, *B. dranunculifolis*, *B. pteronioides* (synonym *B. ramulosa*), and *B. glomeruliflora*, are associated with tremor, stiff gait, and convulsions and some deaths in cattle and sheep. *Roridin*, a toxin produced by *Myrothecium* spp. growing in close apposition to the roots of the plants, is absorbed and, when eaten by animals, poisons them. In other plants roridin is lethal to the plant when present in very small amounts.

NON-MACROCYCLIC TRICHOTHECENES (T_2 TOXIN, DEOXYNIVALENOL, DIACETOXYSCIRPENOL ETC.)

Fungi which produce these mycotoxins are not fully defined in terms of which toxins they produce. Many of them produce more than one. Accordingly the syndromes described below, and attributed to specific fungi and toxins, are

tentative. A partial list of fungi includes the following best known ones:

Cephalosporium spp.
Fusarium culmorum
F. graminearum
F. moniliforme
F. nivale
F. poae
F. roseum
F. semitectum
F. sporotrichioides
F. tricinctum
Trichoderma spp.
Trichothecium spp.

The standard syndrome associated with these fungi includes vomiting, feed refusal, anorexia, diarrhea, gait incoordination, mucosal hemorrhages, and ulcerative stomatitis. Necropsy lesions consist of generalized hemorrhages and hemorrhagic enteritis.

Any one or combination of them can be implicated in the production of the following diseases if they produce the specified toxin at the specified time. The specific toxins involved, and the syndromes they are associated with include those discussed below.

T_2 toxin

A sesquiterpene compound, the T_2 toxin is produced by *F. tricinctum*, *F. nivale*, and *F. sporotrichoides* growing on grain may be associated with generalized hemorrhages, but experimental administration of the purified toxin parenterally produces a quite different range of signs including emesis, posterior paresis, lethargy, hunger, and frequent defecation of normal stools. Other experimental evidence is that the oral administration of the T_2 toxin or cultures containing it to piglets and calves is associated with no hemorrhagic disease. Field evidence of the relationship between the ingestion of the fungus and the appearance of hemorrhagic disease is strong, but the identity of the specific toxic agent may be in doubt. Confusion about the effects of the toxin may be due to the refusal of pigs to eat contaminated feed, while cattle will eat it. T_2 toxin fed to pigs is associated with necrotic, contact lesions on the snout, and commissures of the mouth and the prepuce.[1] Topical application of T_2 toxin to pig skin is associated with initial swelling and purple discoloration, followed by separation and sloughing by day 14.[2] It has also been cited as the probable cause of congenital skin defects about the head and tarsus of pigs.

T_2 toxin is associated with immunosuppression when fed to laboratory animals, sheep, and pigs. This leads to leukopenia, lymphopenia, and atrophy of lymph nodes, thymus, and spleen, but the immunosuppression is minor. Blood coagulability is reduced due to toxic effects on platelets.[3]

The toxin also is associated with reproductive inefficiency when given experimentally to pigs, causing small litters, repeat breeders, and abortion.

Deoxynivalenol

Deoxynivalenol (synonym vomitoxin), is a sesquiterpene compound found in *Fusarium graminearum (roseum)*, *F. sporotrichiella*, and *F. culmorum*. It is a potent central emetic, to which pigs are very sensitive; sheep and cattle are quite resistant, and horses much less so.[4] The toxin may be associated with acute diarrhea, dysentery, ataxia, mucosal hemorrhages, and sudden death. The commonest field observation about the toxic effect of-deoxynivalenol fed to pigs is that it is associated with absolute feed refusal or reduction in weight gain and feed intake.[5] This effect is magnified when the toxic feed also contains **fusaric acid**.[6] Deoxynivalenol is not excreted in the milk.[7]

The only effective method of preventing losses due to deoxynivalenol is to dilute affected corn with uncontaminated feed. Mixing the feed with bentonite, sweeteners, or sodium-calcium aluminosilicate is ineffective as a detoxification method,[8] but rinsing and removing floating material is recommended.[9] Feed toxic to pigs may be utilized by feeding it to ruminants.

Diacetoxyscirpenol

The most important disease in those associated with the non-macrocyclic trichothecenes is the one associated with *F. tricinctum*, a fungus common on ear corn. It produces a potent toxin (diacetoxyscirpenol) which is associated with necrotic lesions and hemorrhages in the skin, mouth, intestine, liver, and kidneys. In cattle, the clinical syndrome includes mucosal hemorrhages and erosions, intermittent salivation, and depression. The stomatitis is characteristic and needs to be differentiated from similar lesions associated with viruses. Continued exposure to the fungus can be associated with heavy mortalities in cattle. In pigs, the experimental disease is manifested by hemorrhagic bowel lesions, but the toxin also produces a syndrome including emesis, lethargy, hunger, frequent defecation of normal stools, and posterior paresis.

Fusaritoxicosis syndromes without specified toxins

F. graminearum (roseum) produces toxins associated with emesis and refusal of feed and toxins lethal to pigs, as well as estrogenic substances causing infertility in pigs. *F. culmorum* also is associated with inappetence, scouring, ataxia, and a fall in milk yield when fed to cattle. The fungus *F. moniliforme* is associated with food refusal in cattle. Food refusal is also recorded with zearalenone.

POISONING BY ZEARALENONE

Fusarium graminearum, F. roseum (*Gibberella zeae*) growing on moldy maize or barley grain produces estrogenic substances, especially F_2, or zearalenone, a nonsteroidal estrogenic mycotoxin which acts by depressing serum gonadotropin levels. Swine are most commonly affected but cases occur in cattle and sheep. *F. culmorum* growing on oat herbage also produces much zearolenone but not when growing on perennial rye grass. Zearalenone has been detected in pastures in New Zealand, where it has been associated with infertility in ewes and cows.[1]

In pigs, vulvovaginitis, including swelling of the vulva to three to four times normal size, enlargement of mammary glands, a thin, catarrhal exudate from the vulva, and increased size and weight of the ovaries and uterus is the severest form of the poisoning. Prolapse of the vagina occurs commonly (up to 30% of affected pigs), and prolapse of the rectum in some (5–10%). The toxin does reduce serum progesterone levels in sows but the administration of progesterone to affected gilts does not counteract the estrogenic effects.[2] The syndrome is indistinguishable from that produced by long-term overdosing with diethyl stilbestrol. Signs appear 3–6 days after feeding of the moldy grain commences and disappear soon after the feeding stops. Pigs of all ages are affected, including sucklings feeding on sows which themselves show no signs of estrogenism.[3] Worst affected are gilts 6–7 months old. The mortality rate is high due to the secondary development of cystitis, uremia, and septicemia.

The more important manifestation of the poisoning may be infertility, including absence of estrus, high levels of stillbirth, neonatal mortality, and reduced litter size. Small fetal size, fetal malformations, splayleg and hindlimb paresis, pseudopregnancy, and constant estrus are also recorded.

Experimental feeding of zearalenone to boars has some depressing effect subsequently on libido but all structural parameters, such as testicular size, are unaffected. There is no effect on the volume or concentration of the ejaculate, or the motility of spermatozoa in rams.[4] In small pigs, zearalenone is associated with degenerative changes in seminiferous tissue, but does not delay the onset of puberty or have any subsequent effect on female reproductive efficiency, provided the toxin is withdrawn from the diet at least 2 weeks before mating.[5]

In cattle, the effect is largely on conception rate, and the rate of services per conception may rise but the overall effect is less than in sows. Behavioral estrus occurs at times unrelated to ovarian cycles and in late pregnant cows. There is idiopathic vaginitis.[6] Symmetrical enlargement of the mammary glands is recorded in prepubertal dairy heifers feeding on fungus-infected corn. Estrogenic disturbances are also suspected in sheep. Abortion is suspected to result, and mild vulvovaginitis and hypertrophy of the uterus are recorded. Experimental feeding of zearalenone to lactating cows and ewes does result in minor contamination of their milk sufficient to produce hyperestrogenism in a lamb sucking a poisoned ewe.

CLINICAL PATHOLOGY

The toxin can be identified by chromatographic analysis and confirming the presence of the specific fungus may not be necessary. The feed should not contain more than 10 ppb of zearalenone. Assay of the feed for estrogenic activity by feeding it to laboratory animals may be attempted. Complete recovery follows when the feeding of the affected grain is stopped and no treatment other than surgical repair of the prolapsed organs is attempted.

MISCELLANEOUS FUNGI LACKING IDENTIFIED TOXINS

Diseases associated with fungi without the causative toxin having been identified, are arranged in order of the predominant clinical disorder, and are outlined below.

HEPATIC DAMAGE

Helminthosporium ravenelli growing on esparto grass is credited with producing a syndrome of excitement, dyspnea, tachycardia, hypersalivation, tremor, jaundice, and some deaths in Argentinian cattle. *Drechslera campanulata* (synonym *Helminthosporium* spp.) occurs as brown-red spots on the leaves of cereal oat plant and is associated with diarrhea, milk yield reduction, and death in some cows. Similar syndromes are found in sheep and goats, except that photosensitivity is also apparent in goats. At necropsy there is ulceration of the forestomach mucosae. A fungus, *Periconia* spp., which grows on forage in the field, is also suspected of being associated with hepatic damage and photosensitization in cattle in the southern United States. There is a close resemblance in clinical signs and circumstances of occurrence to facial eczema and myrotheciotoxicosis. Sesquiterpenes found in moldy sweet potato tubers are listed under that heading.

CONGENITAL DEFECTS

Congenital spinal stenosis

In calves whose dams were fed moldy hay during pregnancy, this defect may affect 100% of the calf drop in a particular year.[1] Clinical signs include posterior paralysis or paresis, shortened limbs, varus deformity of the front limbs, brachygnathia of the upper jaw, and dome-shaped cranium.

BLACK SOIL BLINDNESS

This is a newly-identified mycotoxicosis of grazing cattle, associated with the fungus *Corallocytostroma ornicopreoides* growing on Mitchell grass (*Astrebla* spp.) in pastures on heavy basalt (black soil) soil in tropical north-west Australia.[2,3] The disease has occurred only once, in a year marked by heavy, seasonal rainfall and a longer than usual growing season. Morbidity and mortality were high at the peak of the outbreak. Clinical characteristics include blindness and death within 24 hours. Necropsy lesions include renal tubular nephrosis, rumenoreticulitis, and moderate liver cell damage.

NERVOUS SIGNS

Nervous signs of tremor, gait incoordination, recumbency, and convulsions predominate in the toxic effects ascribed to the ingestion of *Trichothecium roseum* and *Penicillium cyclopium*. *Diplodia maydis* (synonym *D. zeae*, *Stenocarpella maydis*) is associated with a serious disease of maize crops, corn cob rot. Infected cobs fed to cattle, sheep, goats, and horses are associated with diplodiosis, a neuromycotoxicosis, reported only in South Africa. If the subjects are females in the second and third trimesters of pregnancy, there may be a very high mortality, up to 87%, of stillborn or newborn lambs or calves;[4] many of the dead neonates have widespread degeneration of the central nervous system.[5] The fungus develops its toxin only after a prolonged (more than 6 weeks) period of growth. This may explain frequent reports that the fungus is not poisonous. The same applies to cultured fungus used to produce the disease experimentally; it must be a culture at least 8 weeks old. Affected animals recover if feeding of the infected grain is stopped. Clinical signs in adults include lacrimation, salivation, tremor, ataxia, paresis, and paralysis, but signs disappear when the corn is removed from the diet. A status spongiosus lesion may occur in the brain of affected animals, but in most cases there are no necropsy lesions. Fetuses are much more susceptible and spongiform lesions in the brain are present in most. Their body weights are less than normal and the gestation period is also reduced.

Aspergillus clavatus poisoning

Substrates for *A. clavatus* include distillery by-products, sprouted barley grain, sorghum beer residues and sprouted maize.[6] Muscle tremor, frequent falling, ataxia, progressive paresis, knuckling at the fetlocks, especially in the hind limbs, seizures, paralysis, and death occur in cattle and sheep. Degenerative lesions of large neurons have been recorded in the brain stem, the gray matter in the spinal cord, and spinal ganglia in cattle and sheep. Muscle necrosis occurs in some cases.[7]

REPRODUCTIVE DYSFUNCTION

Penicillium roqueforti, growing on moldy mixed grain and ensilage, is suspected of causing bovine abortion and retained placenta. *Trifolium repens* (white clover) does not normally contain estrogens but when heavily infested with fungi it may contain significant amounts. *Ustilago hordei* (barley smut) fungus is thought to be toxic to farm animals; feeding it to experimental animals has been associated with infertility and stillbirths. In southeastern Australia a common infertility syndrome, including abortion and fetal mummification, has been ascribed to an onion-like weed, *Romulea rosea*. There is a suspicion that the disease may be due to a toxin produced by a fungus, *Helminthosporium biseptatum*, growing on the weed.

UREMIA

Tilletia tritici (wheat smut) fungus should not be included in rations for pigs because it is thought to be associated with glomerulonephritis and failure to gain weight. Estimates of the maximum safe content of infected grain that can be fed in the ration vary from 5% to 30%.[8]

POISONING BY CYANOBACTERIA

CYANOBACTERIA IN FRESH WATER BLOOMS

Synopsis

Etiology Toxins from cyanobacteria in blooms on still fresh water in lakes, ponds, billabongs, lagoons.
Epidemiology Outbreaks with heavy mortality when only drinking water is polluted by water bloom in stagnant, nutrition-rich water.
Clinical findings Sudden death syndrome due to massive hepatic necrosis or to neurotoxins. Anorexia, jaundice, photosensitization syndrome due to lesser hepatic necrosis.
Clinical pathology Elevation of liver enzymes in blood (hepatoxic), or possibly cholinesterase depression (neurotoxic).
Necropsy findings Hepatic necrosis or nil; cyanobacteria in alimentary tract.
Diagnosis confirmation Positive assay (including bioassay) of toxins in water.
Treatment Nil.
Control Avoidance of contaminated water or treatment of it with algaecide or hay immersion.

ETIOLOGY

Toxic cyanobacteria, or blue-green algae, which form dense blooms in fresh water bodies, include:

Anabaena circinalis
A. spiroides
Aphanizomenon spp.
Coelosphaerium spp.
Cylindrospermopsis raciborski (containing the hepatoxin cylindrospermopsin)
Gloeotrichia spp.
Gomphosphaeria spp.
Microcystis aeruginosa (synonym *Anacystis cyanea*),
Nodularia spumigena (brackish water)
Nostoc rivulare
Oscillatoria spp.

They contain toxins which survive in water when the cells die or are damaged. Toxicity occurs from ingestion of live cyanobacterial cells or their toxins liberated from ruptured cells.

EPIDEMIOLOGY

Occurrence

Cyanobacterial toxins are associated with outbreaks of poisoning in farm animals that drink contaminated water. Lakes, dams, ponds, stagnant rivers, and waterholes are all affected, especially when the organisms are concentrated by onshore winds so that large quantities may be ingested. In small waterholes, dams, and dugouts the surface water is often completely covered with a very thick coat of gelatinous organisms (water bloom), and animals are unable to drink without ingesting some of it. The disease has been recorded in most countries, especially the United States, Canada, Scandinavia, Japan, South Africa, Australia, and New Zealand, and affects all animals and birds. The cyanobacteria occur also in brackish and marine waters and are associated with mortalities in fish. Deaths do not necessarily occur, especially if animals are able to avoid large concentrations.

Risk factors

Heavy growth commonly occurs in the late summer to autumn period. Factors promoting growth of the organisms and increasing the chances of animals being poisoned include high water temperature, especially sunny weather when the water is very shallow, high electrolyte concentration as a result of massive water loss by evaporation, and a high concentration of other nutrients such as nitrogen and phosphorus, associated with animals defecating and urinating in the water, by fertilizer run-off or human sewage inflow.

PATHOGENESIS

The toxins in a variety of cyanobacteria appear to be the same or similar and fall into two groups: neurotoxic and hepatoxic. The known neurotoxins are a combination of at least three compounds:

- Anatoxin-a, an alkaloid and a potent postsynaptic depolarizing neuromuscular blocking agent[1]
- Anatoxin-A (s), an organophosphorus compound and potent cholinesterase inhibitor
- Saxitoxin and related paralytic shellfish toxins (sodium channel blockers).

These are known to come from *Anabaena* spp. most commonly, but also from *Oscillatoria* and *Aphanizomenon* spp. The known hepatoxins are the cyclic peptides microcystin from *Microcystis aeruginosa*[2,3] and others, including other *Microcystis* spp., *Anabaena flos-aquae*, *Oscillatoria* spp., and nodularin from *Nodularia spumigenia*, which prefers brackish water, and the alkaloid cylindrospermopsin from *Cylindrospermopsis raciborskii*.

The toxic effects of cyanobacteria vary widely depending on the species present and the amounts of toxic material consumed. Many blooms are not toxic, but all should be considered potentially so.

CLINICAL FINDINGS

Affected animals are commonly found dead, particularly so with neurotoxic blooms. Clinical signs may become apparent within 15 minutes after exposure. In acute cases the affected animals have muscle tremor, stupor, increased salivation in some outbreaks in cattle, staggering, recumbency, and in some cases hyperesthesia to touch so that slight stimulation provokes a convulsion with opisthotonos. Abdominal pain, diarrhea, and dyspnea are additional signs. After experimental dosing, death may occur within a few minutes of the first appearance of clinical signs, but in field cases the course may be prolonged for several hours.

In the less acute hepatoxic cases there is severe liver damage manifested by anorexia, stupor or hypersensitivity, ruminal atony, dehydration, recumbency, jaundice, and photosensitization in cattle and sheep. Many of the apparently unaffected and recovered animals die in the ensuing 3 months.[4]

Affected pigs are anorexic and show dullness, vomiting, lethargy, tremor, frothing at the mouth, coughing, sneezing, dyspnea, and dysentery.[5]

CLINICAL PATHOLOGY

The toxins may disappear from the water within 2–3 days and samples should be taken as soon as possible after the poisonings occur.[6] Laboratory examination for the presence of high concentrations of known toxic cyanobacteria is required. Not many laboratories are equipped to carry out the examination, and a negative result should be treated with caution, especially as there may be as yet unidentified cyanobacteria. Because there is a great deal of variation in the toxicity of strains of the known toxic species, ELISA and other analytical laboratory tests for the toxins produced by the organisms have been introduced.[7] A specimen of the bloom material should be collected and be immediately preserved for identification, as degeneration of cyanophyte cells is rapid during transport to the laboratory. Add 1 mL of 10% formalin to 20 mL of bloom material. For toxicity testing submit at least 20 mL of bloom material without added preservative (1 L preferred).

Clinical pathological findings rated in order of frequency in sheep exposed to microcystin are high levels of bile acids, glutamate dehydrogenase, γ-glutamyl transferase, and serum bilirubin, and reduced levels of albumin.[8]

NECROPSY FINDINGS

Necropsy lesions are usually absent in animals that die suddenly of the neurotoxic syndrome. In cases of the hepatoxic syndrome, lesions may include massive hepatic necrosis, generalized petechiation, plasma transudates in body cavities, and congestion of most viscera. Severe gastroenteritis with intestinal hemorrhage and

severe bloody diarrhea have also been observed in some outbreaks.

DIFFERENTIAL DIAGNOSIS

Diagnosis confirmation is by positive assay for the algal toxins in water or preferably body tissues or fluids.

Differential diagnosis list:

Neurotoxic (sudden death) syndrome:

- Electrocution or lightning strike
- Cyanide poisoning
- Anthrax
- Nutritional deficiency of selenium or vitamin E
- Nutritional deficiency of copper (falling disease)
- Poisoning by *Phalaris* spp.
- Poisoning by cardiac glycosides in plants
- Poisoning by fluoroacetate as 1080 compound or in plants
- Poisoning by a number of miscellaneous plants which are associated with cardiac arrest but in which the cardiotoxin has not been identified
- Poisoning by monensin or other ionophore, especially in horses.

Hepatoxic syndrome:

- Pyrrolizidine poisoning
- Steroidal saponin poisoning
- Lantadene poisoning
- Phomopsin poisoning
- Sporidesmin poisoning
- Aflatoxin poisoning
- Fascioliasis.

TREATMENT

There are no specific **primary** antidotes. **Supportive** treatment includes activated charcoal orally intended to prevent further absorption of toxin.

CONTROL

The two principles involved are the prevention of ingestion of floating bloom material by animals and preventing the addition of nutrients that promote cyanobacterial growth to the water.

Prevent the ingestion of toxins by:

- Moving livestock to clean water sources, or drawing drinking water from a site away from the bloom
- Keeping bloom away from water intake by a floating boom
- Add precipitants, e.g. lime, ferric alum, gypsum; removes algae without release of toxin; removes phosphates (see below). Alternatively spread straw on top of water and suspend bales of straw in the water.
- Killing cyanobacteria with algicides such as copper sulphate added to the water was a common recommendeation, but is no longer advocated. The killed cyanobacteria release toxins into the water, so as it is contaminated it cannot be used for stock drinking water for at least 5 days. The algicides also damage other vegatation and may ultimately promote further cyanobacterial blooms.

Prevention of the addition of nutrients to water by:

- Fencing off water sources from direct livestock access and providing drinking water by piping it to troughs
- Precipitate phosphates with lime, gypsum, ferric alum; useful only for small reservoirs
- Mechanical aeration of bottom layers of water body; useful only for large water reservoirs
- Exert catchment control and minimize use of phosphatic fertilizer, inflow of sewage, filter the inflow by enhancing reed bed and wetland growth, and buffer afforestation and vegetation generally along the banks of watercourses
- Remove feral fish, e.g. European carp, which increase the availability of phosphate in the stream by stirring up the sediment on the bottom.

ALPINE PASTURE CATTLE DEATHS

Cattle grazing high alpine pastures in summer have access to oligotrophic drinking water in ponds and lakes containing the cyanobacteria *Oscillatoria limosa* and *O. tenuis* (synonym *Phormidium konstantinosum*) growing as dense mats on submerged rocks and sediments and producing hepatotoxic microcystin which can be in sufficient quantity to be associated with fatal hepatoxicosis.[1]

POISONING BY TUNICAMINYLURACILS (CORYNETOXINS)

RATHAYIBACTER TOXICUS IN NEMATODE GALLS OF PASTURE GRASSES (ANNUAL RYE-GRASS TOXICITY, FLOOD PLAIN STAGGERS, STEWART'S RANGE SYNDROME)

Synopsis

Etiology Bacteriophage-infected *Rathayibacter toxicus* plus grass nematode *Anguina funesta* infesting grass, e.g. *Lolium rigidum*, *Lachnagrostis filiformis*, *Polypogon monspeliensis* eaten by all species.
Epidemiology Outbreaks when grass mature and infected seed head galls ingested.
Clinical findings Fall when disturbed; paddling convulsion, hypermetric, stiff gait; death during a convulsion. High morbidity and mortality rates; up to 100% in sheep.
Clinical pathology Increased activity of hepatic enzymes in serum.
Necropsy finding Diagnostic perivascular edema in meninges and brain.
Diagnosis confirmation Tunicaminyluracil in pasture seed heads.
Treatment Cyclodextrin. Chlordiazepoxide effective but lacks practicality.
Control Close up paddocks when pasture grasses mature.

ETIOLOGY

Nematode larvae infest and are associated with galls in the seedheads of *Lolium rigidum* (Wimmera or annual rye-grass), *Festuca nigrescens* (Chewing's fescue), *Polypogon monspeliensis* (annual beard grass)[1] and *Lachnagrostis filiformis* (formerly *Agrostis avenacea*) (blowaway grass). The nematodes *Anguina funesta*, *Anguina* spp. and *Vulpia myros* carry *Rathayibacter toxicus* (formerly *Corynebacterium rathayi* or *Clavibacter toxicus*) into the grass seeds attached to their cuticles. Provided these bacteria are infected by a bacteriophage, they produce toxins in the seedhead gall, and the sheep, cattle, and horses grazing the pasture are poisoned, with the development of a characteristic clinical picture.

The **toxins** are glycolipid tunicaminyluracils (corynetoxins) which originate from galls containing the yellow-pigmented *R. toxicus*. They reach peak concentration when the grass is fully mature.

Lethal oral dose of corynetoxins for sheep is 3–5 mg/kg. The subcutaneous lethal dose is much smaller, 30–40 µg/kg as a single dose or a set of small sequential doses. The toxins are cumulative

if the intervals between doses are less than weeks [2]

EPIDEMIOLOGY

Occurrence

The disease which occurs in livestock pastured on *L. rigidum* (termed annual rye-grass toxicity, or ARGT) or in those grazing *Lachnagrostis filiformis* (*Agrostis avenacea*) (flood plain staggers) has become a very important cause of death losses on farms in western and southern Australia, and is also recorded in South Africa. Toxicity on *Polypogon monspieliensis* (termed Stewart's Range syndrome) is restricted to a small part of southern Australia. Clinical signs do not occur until the stock has been on the pasture for several days or up to weeks. Forced exercise and high ambient temperatures precipitate or exacerbate clinical signs.

Plant risk factors

Pasture improvement based on annually alternating crop-pasture rotations seem to predispose to the disease, with the worst outbreaks occurring after the end of a cropping year. This can be avoided by burning the pasture in the autumn. It is introduced onto farms by the introduction of infested grass seed or agricultural implements contaminated with it. *Lolium rigidum* has become a weed in southern Australia and herbicide-resistant strains have evolved, complicating control measures. The standing grass becomes toxic as soon as the seed head appears, and loses the toxicity as soon as heavy rain falls. Hay made from infested grass remains poisonous for 5–6 years. The disease, associated with *Agrostis avenacea*,[3] has occurred in cattle on extensive pasture recently subjected to severe flooding, hence the name flood plain staggers.

PATHOGENESIS

The causative toxin is similar structurally to the antibiotic tunicamycin, and the diseases associated with each of the two compounds are indistinguishable. The tunicamycin interferes with glycoprotein synthesis and is capable of causing cerebral vascular lesions in experimental animals.[4] Interference with cardiovascular function and vascular integrity leads to interference with oxygenation of tissues, particularly the brain.

CLINICAL SIGNS

Signs appear when the cattle or sheep are disturbed or stressed, especially by driving. The animals fall in a convulsion with paddling of limbs, nystagmus, opisthotonos, jaw champing and salivation, sometimes neck ventroflexion, head nodding, tetanic extension of limbs and, in sheep, posterior extension of the hindlimbs. Death may occur during a convulsion or, if left alone, the animal may recover to the point of being able to stand, but there may be gait incoordination, due to hypermetria, stiff gait, a broad-based stance, head swaying, rocking backwards and forwards, and loss of balance. Intermittent convulsive episodes recur and the patients soon go down again and death occurs in up to 24 hours. Further cases occur for up to 10 days after affected animals are removed from the pasture. Morbidity and mortality rates may reach as high as 100% in sheep flocks.

CLINICAL PATHOLOGY

Blood levels of liver enzymes, bilirubin and bile acids are elevated.

NECROPSY FINDINGS

Necropsy findings are inconsistent and non-specific. The liver may be enlarged and pale. There may be haemorrhages in a range of tissues. Histologically, there may be perivascular edema in the brain, particularly in cerebellar meninges. Other lesions may include significant liver damage.

DIFFERENTIAL DIAGNOSIS

Staggers/convulsion syndromes associated with a high mortality rate are not common.

Diagnosis confirmation depends on:

- combination of a convulsive syndrome with access to mature pasture carrying seed
- detection of severe inhibition of liver microsomal N-acetylglucosamine-1-phosphate transferase activity from liver biopsy or necropsy samples
- histopathology of brain and liver
- identification of bacterial galls in seedhead material
- quantitative detection of *Rathayibacter toxicus* antigens by ELISA on pasture, fodder, rumen contents, faeces
- a positive assay of corynetoxins in pasture or fodder.

The differential diagnosis list includes:

- Phalaris staggers
- Perennial rye-grass staggers
- Lead poisoning
- Poisoning by any one of a large number of plants in which the toxic agent has not been identified.

TREATMENT

Affected flocks or herds should be removed from a toxic pasture as slowly and quietly as possible to good-quality feed with shade and water in a place free of disturbance. Pharmacological measures are impractical. An antidote was developed by CSIRO in Australia for use early in outbreaks of poisoning. It is a cyclodextrin, a cyclic glucose molecule with a hydrophobic central cavity which sequesters the corynetoxin molecules. It is formulated as a gel for intraperitoneal injection. Field trials have been disappointing.

CONTROL

Pasture management in endemic areas should aim to reduce exposure of livestock to mature pastures with seedheads. This may be achieved by a variety of measures such as heavy stocking during winter and spring, harvesting pasture for silage or hay before seeding followed by heavy grazing to remove ryegrass seedlings, burning crop and pasture residues and herbicide application. Biological control measures being pursued include development of early-flowering *L. rigidum* cultivars that carry fewer bacterial galls and the pasture application of *Dilophospora alopecuri*, a fungal pathogen of *Anguina funesta*. Administration of cobalt orally may have some prophylactic effect against the poisoning.[5] Immunization against the toxin is promising and is being actively researched.

TUNICAMINYLURACIL TOXIN IN WATER-DAMAGED GRAIN

A similar tunicaminyluracil has been isolated from water-damaged wheat which when fed to pigs is associated with clinical signs and deaths similar to those associated with the tunicaminyluracil on grasses.[1]

DISEASES ASSOCIATED WITH ZOOTOXINS (ANIMAL BITES AND STINGS)

Disease associated with zootoxins in farm animals are limited to bites of snakes, stings of bees, tick bite, and ingestion of preformed toxins, including cantharidin and the octapeptide of sawfly larvae. Spiders, centipedes, scorpions, fish, and marine mammals are not listed as being associated.

SNAKEBITE

Synopsis

Etiology Venom injected into victim by a bite with specially adapted fangs.
Epidemiology Isolated attacks during summer months. A rare clinical disease in large animals.
Clinical findings Muscle weakness, stumbling gait, recumbency, pupillary dilation, swallowing paralysis, salivation, muscle tremor. May be swelling and tissue necrosis at bite site.
Clinical pathology Venom detectable in blood, urine, body tissues and fluids generally.
Necropsy findings May be local swelling and tissue necrosis.
Diagnosis confirmation Based on detection of venom in body tissues or fluids.
Treatment Injection of type-specific antivenene.

ETIOLOGY

At least four toxic actions can result from snake venoms, and different snakes have varying combinations of toxins in their venoms (Table 33.3). The toxins include necrotizing, anticoagulant, and coagulant fractions as well as neurotoxic, cardiotoxic, and hemolytic fractions. Although there is often insufficient toxin injection to cause death in large animals, a serious secondary bacterial infection may be set up in the local swelling and cause the subsequent death of the animal. The common venomous snakes include *Crotalus* spp. (rattlesnakes and pit vipers of North America), the true vipers, e.g. *Vipera berus* (northern viper, the United Kingdom's only venomous snake), and the elapid snakes including the cobra, mamba, and most of Australia's venomous snakes including *Notechis scutatus* (tiger snake) and *Pseudonaja* (*Demansia*) *textilis* (common brown snake).

EPIDEMIOLOGY

The incidence of snakebite is controlled by the geographical distribution of the snakes and their numbers. Asia, India, Africa, Central and South America, Australia, and the southern United States are areas in which snake populations are large. In general, the morbidity rate in farm animals is low, although a mortality rate of 20% has been recorded in a small group of bitten animals.

Most snakebite accidents occur during the summer months and bites are mainly about the head because of the inquisitive behavior of the bitten animal. Pigs are not highly susceptible but not, as generally believed, because of their extensive subcutaneous fat depots. Sheep may be bitten

Table 33.3 Important venomous snakes of the world (adapted from Dorland's Illustrated Medical Dictionary, 28 edition, 1994, W.B. Saunders).

Family and common name	Scientific name	Type of venom	Distribution	Commentary
Colubridae	Colubrids	Mostly mild	Warm parts of both hemispheres	Over 1000 species; a few poisonous but not dangerous
Boomslang	*Dispholidus typus*	Hemorrhagin	South Africa	Arboreal, timid
Elapidae	Elapids	Predominantly neurotoxin	Mostly in Old World	Over 150 species; very poisonous
Cobras	*Naja* spp.	Mostly neurotoxin	Africa, India, Asia, Philipines, Celebes	Spitting cobra in Africa aims at eyes
Kraits	*Bungaras* spp.	Strong neurotoxin	India, S.E. Asia, Indonesia	Sluggish; often buried in dust
Mambas	*Dendroaspis* spp.	Neurotoxin	Tropical W. Africa	Arboreal
Blacksnake	*Pseudechis* spp.	Neurotoxin	Australia	Large snake; wet terrain
Copperhead (Australian)	*Austrelaps superbus*	Neurotoxin	Australia, Solomons	Damp environment
Brown snake	*Pseudonaja* spp.	Neurotoxin	Australia, New Guinea	Slender snake
Tiger snake	*Notechis scutatus, N. ater*	Strong neurotoxin	Australia	Dry environment, aggressive, very dangerous
Taipan	*Oxyuranus* spp.	Strong neurotoxin	Australia	Dry environment; very dangerous
Death adder	*Acanthophis antarcticus*	Neurotoxin	Australia, New Guinea	Sandy terrain
Coral snakes	*Micrurus* spp., *Micruroides* spp.	Neurotoxin	United States, tropical America	About 26 species; two in southern USA
Hydrophidae	*Hydrophis* spp.,	Some mildly toxic; others	Tropical, Indian and Pacific	Gentle, rudder-like tail; over 50
Sea snakes	*Pelamus platurus, Laticauda* spp., *Aipysurus* spp., etc.	very toxic	oceans	species
Viperidae	*Vipera, Bitis* spp.	Predominantly hematoxin	Entirely in Old World	About 50 species
True vipers, viperids				
European viper	*Vipera berus*	Hematoxin	Europe (rarely), N. Africa, Near East	Dry, rock country
Russell's viper	*Vipera russelli*	Hematoxin	S.E. Asia, Java, Sumatra	Mostly in open terrain; deadly
Sand vipers	*Vipera ammodytes*	Hematoxin	N. Sahara	Buried in sand
Puff adder	*Bitis arietans*	Hematoxin	Arabia, Africa	Open terrain; sluggish
Gaboon viper	*Bitis gabonica*	Neurotoxin and hematoxin	Tropical W. Africa	Forests; deadly
Rhinoceros viper	*Bitis nasicornis*	Hematoxin	Tropical Africa	Wet forests
Crotalidae	Crotalids, Pit Vipers	Predominantly hematoxin	Old and New Worlds; none in Africa	More than 80 species; sensitive pit between eye and nostril
Habu viper	*Trimesurus flavoviridis*	Neurotoxin	Warmer parts of E. Asia, Ryuku Islands	Caves and dry, rocky country
Rattlesnakes	*Crotaus, Sistrurus* spp.	Predominantly hematoxin	N., Central and S. America	All rattlesnakes venomous; S. American form is neurotoxic
Bushmaster	*Lachesis muta*	Hematoxin	Central and S. America	Large; in wet forests
Fer-de-lance	*Bothrops lanceolatus, B. Atrox* (wrongly)	Hematoxin	Central and N. South America; few in West Indies	Common in plantations
Palm vipers	*Bothrops schlegelii, B. neuwiedi*	Hematoxin (?)	S. Mexico, Central and S. America	Arboreal, small, greenish; bites face
Copperhead	*Agkistrodon contortrix*	Hematoxin	United states	Dry, stony terrain
Water moccasin	*Agkistrodon piscivorous*	Hematoxin	S.E. USA to Texas	Swamps
Asiatic pit viper	Not listed	Hematoxin	S.E. Asia, Taiwan	Mostly arboreal

on the udder but their long wool coat is generally effective as a protective mechanism on other parts of the body. Large animals tend to be resistant because of their large size and the large dose rate required to cause death. However, horses appear to be much more susceptible to venom than any other species.

PATHOGENESIS

The effects of snakebite (envenomation) depend upon the size and species of the snake, the size of the bitten animal and the location of the bite, particularly with reference to the thickness of the hair coat and the quantity of subcutaneous fat. As a general rule the venom is injected by fangs which leave a bite mark comprising a row of small punctures with two large punctures outside them. An exception is the coral snake, which must chew to inoculate the venom. The bites may be visible on hairless and unpigmented skin but can only be seen on reflection of the skin at necropsy in many instances. Non-poisonous snakes may bite animals, but the bite mark is in the form of two rows of small punctures.

The toxins in venom include:

- Neurotoxins, causing flaccid paralysis, pupillary dilatation and paralytic respiratory failure
- Cytolisins, which are associated with tissue necrosis, including platelets, leading to intravascular coagulation
- Hemolysins, coagulant or
- Thrombase, anticoagulants leading to a hemorrhagic tendency
- Myotoxins, causing muscle necrosis and myoglobinuria.

The overall effect of a bite by a snake depends on the mix of specific venoms in the dose delivered and the actual dose which depends on the size of the snake and the period since the snake last bit. Tiger snake venom contains neurotoxins and coagulants. Death adder venoms contain only neurotoxin, brown snake has coagulant and some neurotoxin. Rattlesnake venom is associated with necrosis of arterioles and arteriolar thrombus formation, and in most species contains an anticoagulant, causing a bleeding diathesis. The Mojave rattlesnake *Crotalus scutulatus* is an exception.[1]

CLINICAL FINDINGS

Bites by adder-type snakes (crotalids) are associated with a local swelling which develops rapidly and is associated with severe pain, usually sufficient to produce signs of excitement and anxiety. Bites about the head may be followed by swellings of sufficient size to cause dyspnea. If sufficient neurotoxin has been injected a secondary stage of excitement occurs and is followed by marked dilatation of the pupils, salivation, hyperesthesia, tetany, depression, recumbency, and terminal paralysis. In small animals, death may occur due to asphyxia during convulsions in the excitement stage of the disease. In animals that recover there is usually local sloughing at the site of the swelling.

Bites by cobra-type snakes (elapids) are associated with local swelling in animals that survive the effects of the neurotoxin. These commonly develop local swellings due to bacterial infection 3–4 days later. The major effects after bites of cobra-type snakes are excitement with convulsions, and death due to asphyxia. The signs appear quickly and death occurs usually in up to 48 hours in horses. In calves, the effects of the neurotoxin are manifested by marked pupillary dilatation, excitement, incoordination, and later paralysis.

Clinical signs in horses bitten by tiger snakes (*Notechis scutatus*) in Australia include pronounced pupillary dilatation without pupillary response to light, but the menace reflex is present and the animal can see. Muscle tremor is most obvious in the standing patient and the horse is very fidgety and wants to lie down. The tremor disappears when the animal lies down, but it will not stay down and insists on rising and wandering about in a compulsive way.

Clinical signs in foals bitten by brown snakes (*Pseudonaja textilis*) in Australia are similar to those associated with tiger snake envenomation. There is drowsiness, drooping of eyelids and lips, partial tongue paralysis, muscle tremor and weakness, leading to recumbency; pupillary dilatation occurs in some. The respiration becomes labored and abdominal. Sweating and inability to suck, swallow or whinny, occur late in the course. Adults also show inability to swallow, with salivation and accumulation of food in the mouth.

Rattlesnake bite in calves is associated with restlessness, teeth grinding, vomiting, hypersalivation, dyspnea, ataxia, and convulsions.

CLINICAL PATHOLOGY

An ELISA for identification of venom in blood, urine or other body tissue or fluid is available. It is highly accurate, suitable for field or office use, immediate but expensive. It is limited to the snake species for which reagents are available.

NECROPSY FINDINGS

Local swellings at the site of the bite are due to exudation of serous fluid, which is often deeply blood-stained. Fang marks are usually visible on the undersurface of the reflected skin.

DIFFERENTIAL DIAGNOSIS

Diagnosis confirmation depends on a positive assay for venom in the patient's blood, urine, and tissues generally. In acute cases death has usually occurred by the time the animal is seen. If the actual bite is observed the diagnosis is made on the history.

Differential diagnosis list:

Nervous syndrome:

- Tick paralysis
- Organophosphate poisoning
- Fluoroacetate poisoning.

Local swelling, consider also a diagnosis of:

- Blackleg
- Anthrax in horses and pigs
- Non-specific phlegmonous infections.

TREATMENT

In human medicine the application of a tourniquet proximal to a limb bite site has been replaced; a firm pressure bandage is applied over the bite to restrict the distribution of the venom via the lymphatics and retain it in the site and prevent systemic effects. Excision of the bite site is recommended for the bites of snakes (crotalids) which are associated with a serious local reaction.

Systemic treatment should include antivenin, antibiotics, and antitoxin. Antivenin containing antibodies against the venoms of all the snakes in the area can usually be obtained locally, often in highly purified form. It is expensive to use but highly effective. Speed is essential and the IV route is preferred. A portion of the antivenin should be injected locally around the bite. The dose rate varies widely with the size of the animal, one unit often being sufficient for animals weighing 70 kg or more, but smaller animals of 9–18 kg BW require about 5 units. A broad-spectrum antibiotic should also be administered to control the local infection at the site of the bite. The occurrence of clostridial infections after snakebite suggests the administration of antitoxins against tetanus and gas gangrene. Supportive fluid treatment may be advisable when shock is severe and the administration of a sedative may be necessary to control pain and excitement.

Many other treatments have been used in snakebite, including particularly ACTH, cortisone, and antihistamines. These drugs have been found to be valuable as a protection against possible anaphylaxis after treatment with antivenin, but in cases where local tissue damage is evident they are without value and in many cases exert deleterious effects. Adrenaline or epinephrine have little or no value and calcium salts do not significantly reduce mortality.

The application of chemicals to the incised bite area is also of no value and may exacerbate tissue damage. Attention has been drawn to the need to appreciate the mode of action of one's local snakes before attempting a general program of treatment – what may be effective in one country may very well be lethal in another.

BEE STINGS

Multiple stings by bees may be associated with severe local swelling up to 6 cm diameter, similar to those in angioedema but with a stinger in the center. The lips, eyelids, tongue, and vulva are often swollen and painful. Pain may result in pronounced excitement, and in severe cases in horses there may be diarrhea, hemoglobinuria, jaundice, tachycardia, cardiac arrythmia, rapid breathing, sweating, and prostration. Animals attacked about the head may show dyspnea because of severe local swelling. Horses often show mild-to-moderate colic.[1] In rare cases the attack may be fatal, usually after a course of 4–12 hours. Necropsy lesions include hemorrhages and edema of all connective tissues and the bowel wall. Treatment includes the local application of a weak solution of ammonia or sodium bicarbonate, nervous system stimulants if prostration is severe, and tracheotomy if asphyxia threatens.

ANT BITES

Bites from the aggressive red imported fire ant (*Solenopsis invicta*) have been associated with focal necrotic ulcers of the cornea and conjunctiva of newborn calves.[1] Weak calves are most likely to be injured.

TICK PARALYSIS

Infestations with a variety of species of ticks are associated with paralysis of animals. Dogs are most commonly affected but losses can occur in lambs, calves, goats, foals, and even children. *Ixodes holocyclus* have been shown to paralyze calves of 25–50 kg BW. Between four and ten adult female ticks are required to produce this effect and paralysis occurs 6–13 days after infestation occurs. The ticks under natural conditions parasitize wild fauna, and infestations of other species occur accidentally. The disease is limited in its distribution by the ecology of the ticks and the natural host fauna. The paralysis characteristic of the disease is associated with a toxin secreted by the salivary glands of female ticks and which is present in much greater concentration in the glands of adults than in other stages. The severity of the paralysis is independent of the number of ticks involved; susceptible animals may be seriously affected by a few ticks.

The toxin of *Dermacentor andersoni* interferes with liberation or synthesis of acetylcholine at the motor end paltes of muscle fibers. The disturbance is functional and paralysis of the peripheral neurons is the basic. Continuous secretion of toxin by a large number (35–150) of partly engorged female ticks which have been attached for 5–8 days is necessary to produce paralysis, complete recovery occurring within 24 hours when the ticks are removed. The disease is confined to calves and yearlings.[1] Clinically, there is an ascending, flaccid paralysis commencing with incoordination of the hindlimbs, followed by paralysis of the forelimbs and chest muscles, causing lateral recumbency. The respiration is grossly abnormal because of its diaphragmatic form; there is a double expiratory effort and the rate is slow (12–15/min) but deep. All limb and eye touch reflexes are absent, the pupils dilate widely and death is due to respiratory paralysis. In dogs there are additional signs, including vomiting, absence of voice, and secondary aspiration pneumonia. Death, due to respiratory failure, may occur in 1–2 days but the course is usually 4–5 days. The mortality rate may be as high as 50% in dogs, but is usually much lower in farm animals. Since tick-borne diseases, such as tularemia, often coexist with tick paralysis, this possibility should always be considered in arriving at a diagnosis.

Hyperimmune serum is used in the treatment of dogs but in farm animals, removal of the ticks in the early stages is usually followed by rapid recovery. Control necessitates eradication of the ticks or host fauna. The use of appropriate insecticides is an effective preventive.

CANTHARIDIN POISONING (BLISTER BEETLE POISONING, CANTHARIDIASIS)

Poisoning of horses by the consumption of blister beetles (*Epicauta* spp.) is now a common event in the United States.[1] There are 200 named species of the beetle, the commonest being *E. occidentalis* and *E. temexa*.[2] Originally the disease was confined to the southern States, but outbreaks now occur elsewhere because of the widespread shipment of alfalfa hay, and occasionally weedy meadow hay, infested with the beetles. The beetles contain cantharidin, and administration of 1 g of ground beetles by stomach tube is fatal to a pony. Cattle are not affected. The cantharidin content of the beetles varies widely (0.77–3.31% dry weight) between species, and male beetles contain more toxin than females. Other insects containing cantharidin include Chinese blister beetle or fly (*Mylabris phalerata*).

Signs include anorexia, oral mucosal erosions, frequent urination, colic and, occasionally, synchronous diaphragmatic flutter. Severe depression, shock, and death follow in approximately 50% of cases. Clinicopathologically there may be hematuria, azotemia, hemoconcentration, and a neutrophilic leukocytosis, but these lesions are not diagnostic and the presence of beetles in the feed should be established. Unexplained hypocalcemia and hypomagnesemia are usual. Vesiculating gastropathy of the gastric squamous mucosa is highly diagnostic but no necropsy findings occur in many cases. Mass spectrometric and gas or liquid chromatographic methods facilitate detection of cantharidin in field specimens of blood, urine, gut contents, and feed.[3]

Treatment is symptomatic. Inspection of hay for the beetles can avoid the problem. Infested fields should not be harvested.

MARE REPRODUCTIVE LOSS SYNDROME (EARLY FETAL LOSS, LATE FETAL LOSS, EPIDEMIC FIBRINOUS PERICARDITIS, EPIDEMIC UNILATERAL ENDOPHTHALMITIS)

ETIOLOGY AND EPIDEMIOLOGY

A syndrome of increased incidence of **early fetal loss** (< 70 days of gestation) and **late-term abortion** was recognized in north central Kentucky and southern Ohio, Illinois, and Indiana in 2001 and,

affecting fewer horses, in 2002. At the same time there was also a marked increase in incidence of birth of weak foals, and **pericarditis** and **endophthalmitis** in adult horses in the same region.[1]

The early fetal loss in mare reproductive loss syndrome is associated with the ingestion of **Eastern Tent caterpillars** (*Malacosoma americanum*).[1–3] Abortion of mares at 40–80 days of gestation is induced by gavage with starved Eastern Tent caterpillars, feeding of whole caterpillars, or feeding of caterpillar exoskeleton, but not gavage or feeding of caterpillar frass (excreta), autoclaved homogenate of caterpillars, or filtrate of homogenized caterpillars.[1–3] Abortion is induced by feeding or intragastric administration of 50 g of caterpillars/day for 10 days.[1–3] Mares abort from 8 to 28 days after first ingestion of caterpillars.[1–3] The lag time between ingestion of caterpillars and abortion is longer for ingestion of lesser amounts of caterpillars.[2] The association between ingestion of Eastern Tent caterpillars and late term abortion, birth of weak or non-viable foals of normal gestational age, pericarditis, and endophthalmitis has not been demonstrated experimentally. However, there is strong epidemiologic and circumstantial evidence to support a role for *M. americanum* in the etiology of these diseases.

Actinobacillus spp. is often isolated from pericardial fluid of horses with pericarditis during outbreaks of epidemic pericarditis, which has a temporal relationship with early fetal loss and late-term abortion, but is likely not the inciting agent.[4]

Occurence

The documented outbreak of the syndrome occurred from April 26 through mid-June of 2001, with a lower incidence of disease during the same months in 2002. The disease has been recorded only in the Ohio river valley and north-central Kentucky. The disease caused early fetal loss in 25–63% of mares on one-third of farms, 14–24% on another third, and 2–13% on the remaining one-third.[5] Approximately 21% of mares pregnant at 42 days of gestation were not pregnant when examined at 70–90 days of gestation.[6] The expected pregnancy loss rate between 42 days and parturition is 12%.[6] Over 3000 mares aborted during the outbreak.[4]

Risk factors

Risk factors for the disease are those associated with exposure to Eastern Tent caterpillars and include the presence of large numbers of caterpillars on pasture, pasturing or feeding hay to horses at pasture, and presence of mares with pericarditis on the farm.[5,6]

For late-term abortion the risk factors include increased amount of time at pasture, less time in stall, feeding concentrate on the ground, increased proportion of feed obtained from pasture, and being fed exclusively in pasture during the final 4 weeks of gestation.[7] All of these factors favor exposure to Eastern Tent caterpillars.

Risk factors for **pericarditis** include presence of mares or foals with mare reproductive loss syndrome on the farm, grazing, and exposure to Eastern Tent caterpillars.[7] Risk factors for endophthalmitis have not been defined.

Eastern Tent caterpillars are endemic to the eastern United States including the Ohio River valley.[8] Egg masses are laid on many trees in the Rosaceae family including cherry trees, the preferred host.[8] Eggs hatch in the early spring at the time that the cherry trees bud. Local populations of the caterpillars fluctuate dramatically from year to year, but mares are likely exposed to small numbers of the caterpillars every spring.[4,8] Climatic conditions that favor survival of Eastern Tent caterpillars and synchronize their maturation result in simultaneous hatching of large numbers of eggs. The rapid emergence of large numbers of caterpillars results in abrupt and heavy exposure of horses and consequent development of mare reproductive loss syndrome.[4] Weather conditions believed to contribute to the 2001 outbreak include a period of low temperatures in March, above normal temperatures in April, and a frost and freeze in late April immediately followed by several warm days.[9]

The **economic losses** incurred because of mare reproductive loss syndrome during 2001 are estimated to be $US330 million [4]

PATHOGENESIS

The **pathogenesis** of the diseases associated with mare reproductive loss syndrome has not been defined.

CLINICAL SIGNS

Early fetal loss

This is detected by *per rectum* uterine examination, either manual or using ultrasonographic visualization of uterine contents, during early pregnancy. Fetal loss occurs after 35 days, conception not being affected, and affected mares do not come into estrus because of the presence of endometrial cups, which do not regress until 100–150 days after ovulation.[9] Mares have no clinically detectable premonitory signs of fetal loss. Ultrasonographic examination of the uterus of pregnant mares reveals that the allantoic fluid of fetuses <80 days of age has increased echogenicity on the day of fetal death.[1] Allantoic fluid increases in echogenicity with increasing fetal age and care should be taken when interpreting this observation.

Late fetal loss

This occurs as a late-term abortion (final several weeks of gestation), birth of a stillborn foal at full term, and the birth of a foal that is weak and of reduced viability.[10–11] The birth of an affected foal is associated with premature placental separation ('red bag' deliveries), foaling while standing, and explosive expulsion of the fetus and placenta.[10,11] Foals born alive are weak, have sunken eyes, progressive neurologic signs consistent with hypoxia, and have a high death rate (50%) despite intensive care.[10,11] Severe leucopenia at birth often progresses to leucocytosis at 24–48 hours of age. Serum biochemical abnormalities include elevated serum creatinine concentrations, hypoglycemia, and increased serum creatine kinase activity.[10] Bacteria isolated from stillborn foals at necropsy or on culture of blood samples from sick foals are non-specific organisms including non-hemolytic streptococci and *Actinobacillus* spp.

Fibrinous pericarditis

This manifests as signs of congestive heart failure secondary to cardiac tamponade in adult horses. Horses often have a history of fever but not other clinical abnormalities. There is accumulation of large quantities of pericardial fluid and fibrin deposition on the parietal and visceral pericardial surfaces evident on ultrasonographic examination of the chest.[12] The lungs have ultrasonographic evidence of consolidation consistent with pneumonia in approximately 50% of cases. Pericardiocentesis yields abundant fluid that is light yellow and has a low white blood cell count ($<5 \times 10^9$/L) characterized by well-preserved neutrophils.[12] Horses with a prolonged course of the disease (>2 weeks) can have elevated white cell counts in pericardial fluid secondary to opportunistic infection, usually with *Actinobacillus* spp..[4,12] Hematologic abnormalities are minimal and characterized by a slight leukocytosis in approximately 50% of cases.[12] Azotemia occurs in horses with severe cardiac tamponade.

Diagnostic confirmation is based on the presence of appropriate clinical signs with a history of exposure of affected horses to Eastern Tent caterpillars.

NECROPSY FINDINGS

Examination of placenta, stillborn foals and foals that die after birth reveals inflammation of the intra-amniotic umbilical cord (funisitis), diffuse alveolitis, and hemorrhage in a variety of organs.[10] Horses with pericarditis have impressive accumulation of hairy fibrin in the pericardial space with marked thickening of the visceral and parietal pericardium (a hoary heart).

TREATMENT

Treatment of affected foals is based upon the principles delineated in 'Principles of the care of newborns' and is primarily supportive. Horses with pericarditis should have the fluid drained to relieve or prevent cardiac tamponade and to minimize the accumulation of fibrin. Pericardial fluid might need to be drained on a number of occasions and its accumulation should be monitored ultrasonographically. Administration of broad spectrum antibiotics and dexamethasone phosphate or equivalent (30–40 mg IV or IM once daily for 3–5 days) is successful in approximately 50% of horses with disease of <5 day's duration. Horses with disease of longer duration might require more aggressive therapy including pericardial lavage and pericardiectomy. The prognosis for survival for such horses is grave to hopeless.

CONTROL

This is based on prevention of ingestion of Eastern Tent caterpillars by horses.[11,13] The control measures include: removing wild or black cherry trees, the favored host species for Eastern Tent caterpillars, from pastures, hedges, and fence rows; applying pesticides to trees to kill over wintering eggs or, after hatching, caterpillars; installation of barriers to caterpillar migration on to pasture; manual removal of egg tents; and restricting access of mares to pasture.[11,13] Application of bifenthrin or permethrin, but not 3% horticultural oil, to egg masses (tents) during the winter prevents emergence of caterpillars in the spring.[13] Insecticidal soap or oils sprayed on neonatal caterpillars is minimally effective. Bifenthrin or spinosad are effective against all instars for 7 days when sprayed on foliage.[13] Injection of trunks of cherry trees with dicrotophos or emamectin is effective against all instars but injection with milbemectin or avermectin is not effective.[13] A spray of 50 mL of 39% permethrin diluted in 4 L of water and applied to a 2-m wide band of pasture outside the fence line kills migrating caterpillars and prevents them obtaining access to pasture.[14] This solution can also be sprayed on the trunks of trees to kill caterpillars as they leave the tree.

Preventing horses ingesting caterpillars by minimizing access to pasture and feeding hay in stalls is likely to be beneficial. Farms that have aggressively implemented measures to prevent horses ingesting Eastern Tent caterpillars have prevented the disease.[11]

LOPHYROTOMIN AND PERGIDIN (SAWFLY LARVAE) POISONING

Larvae of the sawflies *Lophyrotoma interrupta* in Australia, *Arge pullata* (birch sawfly)[1] in Denmark, and *Perreyiea flavipes* in South America[2] are eaten by cattle, sheep or pigs[3] as they lie on the pasture under the infested trees. The toxins they contain, the peptides lophyrotomin[4] and pergidin,[5] are associated with severe liver necrosis and a syndrome of tremor, dyspnea, recumbency convulsions, and sudden death in acute cases. Less acute cases show hyposensitivity, jaundice, photosensitization, diarrhea, and dysentery. Necropsy lesions include periacinar or panacinar hepatic necrosis, some nephrosis, and extensive hemorrhages in the alimentary tract, and fluid transudates in serous cavities in longer surviving cases.[6]

MOTH DAMAGE

Insect-generated fiber, e.g. in the cocoons of Molopo moths can be indigestible and, if eaten in large quantities, can be associated with ruminal impaction. The body scales of the brown-tail moth and its larvae have a **nettling** effect, causing skin irritation on contact, and bronchial mucosal irritation on inhalation.

Diseases associated with allergy

ALLOIMMUNE HEMOLYTIC ANEMIA OF THE NEWBORN (NEONATAL ISOERYTHROLYSIS, ISOIMMUNE HEMOLYTIC ANEMIA OF THE NEWBORN)

Synopsis

Etiology Maternal alloantibodies to neonate's blood group antigens are transferred to the neonate in colostrum and cause lysis of the neonate's red blood cells.
Epidemiology Disease in progeny of multiparous mares or sows. The dam lacks blood group antigens possessed by the sire and inherited by the foal, calf, or piglet. The majority of cases in foals are due to the presence of Aa or Qa antigens and antibodies. Sows vaccinated with crystal violet vaccine or cows with babesia or anaplasmosis vaccines can be associated with disease in their newborns.
Clinical findings Lethargy, recumbency, tachycardia, tachypnea, icterus, and hemoglobinuria.
Clinical pathology Anemia, hyperbilirubinemia.
Diagnostic confirmation Positive antiglobulin (Coombs test) or hemolysis test using mare's serum or colostrum and foal's red blood cells.
Treatment Transfusion of blood or packed red blood cells from suitable donor, or of mare's washed red blood cells. Supportive care.
Control Identify at-risk mares by blood typing. Examine mare's serum or colostrum for presence of incompatible antibodies before allowing foal to suckle.

ETIOLOGY

Hemolytic anemia of **newborn horse and mule foals, calves, and piglets** occurs because of immune-mediated (**antibody-dependent cellular cytotoxicity or type II hypersensitivity**) destruction of the neonate's red blood cells by antibodies acquired from the dam. The specific antibodies are present in the colostrum, absorbed by the neonate, and cause lysis and/or agglutination of red blood cells.

The disease is associated with the natural occurrence of **inherited blood groups** and only occurs if the dam is exposed to red blood cell antigens that she does not possess. In response to such exposure the dam produces antibodies directed against the foreign red blood cell epitopes. If the neonate possesses a blood type against which the dam has developed antibodies and depending on the red blood cell factor involved, red blood cell destruction can occur. The newborn acquires the red blood cell types that are foreign to the dam through inheritance from the sire. Disease occurs after birth because the fetus is not exposed to the antibodies *in utero* because of the epitheliochorial placentation in mares and sows and the syndesmochorial placentation of cattle. Antibodies in serum are secreted into the colostrum in the peripartum period and are subsequently ingested and absorbed by the newborn. Mares that have anti-red blood cell factor antibodies in their serum almost invariably have the same antibody in their colostrum.[1] The serum concentration of anti-Aa and Qa antibodies is highest in the last 3 months of gestation and peaks about 1 week after parturition. For neonatal isoerythrolysis to occur:

- The fetus must have blood group antigens (factors) that the dam does not. These are inherited from the sire
- The dam must be exposed to the foreign blood group antigens that the fetus possesses
- The dam must produce antibodies against the blood group antigens of the fetus. Not all blood group antigens are highly immunogenic or are associated with disease in the neonate
- The newborn must ingest and absorb colostrum that contains antibodies directed against antigens on the newborn's red blood cells.

The disease occurs naturally in **foals** and **piglets** but is usually iatrogenic in calves. Exposure of the dam to foreign red cell epitopes may occur at **parturition or during gestation** as a result of placental lesions although most incompatible pregnancies do not result in sensitization of the mare.

Mares may also be exposed by **transfusion of incompatible blood**. While whole blood transfusions to mares or fillies are unusual, plasma transfusions are increasingly being used to treat failure or partial failure of transfer of passive immunity to foals. Because plasma usually contains some red blood cells, transfusion of plasma from donors possessing blood group antigens that the foal does not could immunize the filly against these factors with the potential for disease when the foal matures and gives birth. However, most commercial plasma products are harvested from donors that do not have the blood group antigens identified as being problematic.

32 blood group antigens are recognized in **horses**:[2]

- A, a, b, c, d, e, f, g
- C, a
- K, a
- U, a
- D, a, b, c, d, e, f, g, h, i, k, l, m, n, o, p
- P, a, b, c, d
- Q, a, b, c.

Neonatal isoerythrolysis is attributable in over 90% of cases to antibodies directed against either Aa or Qa antigens, although disease due to antibodies against Ab, Dc, Da, Db, Ka, Qb, Qc, Qrs, Pa, and Ua is reported.[2,3] The presence in the mare of antibodies against Ca decreases the probability that she will develop anti-Aa antibodies.[4]

15 blood groups have been identified in **pigs** and the disease is recorded as occurring spontaneously associated with antibodies to the E group antigens. Historically, the main occurrence of neonatal isoerythrolysis in pigs was manmade and related to repeated vaccination against hog cholera using the pooled blood, inactivated by addition of **crystal violet**, of affected pigs.

The disease has also occurred in **calves** whose dams had been vaccinated against babesiosis or anaplasmosis using a vaccine containing bovine blood.[5] As a result of vaccination the dam develops lytic antibodies against sire antigens, usually of the

A and F blood groups, and antibodies in colostrum cause acute hemolytic anemia in the calves.

EPIDEMIOLOGY

Horses and mules

From 1 to 2% of Thoroughbred and Standardbred mares have antibodies capable of causing neonatal isoerythrolysis.[1] The **incidence** is partially related to the proportion of the mare population at risk. An at-risk mare is one that lacks either the Aa or Qa blood group factor. The proportion of mares that lack one or both of these factors is breed dependent, with 19% of Thoroughbreds lacking either Aa or Qa antigens and 17% of Standardbred mares lacking Aa antigens.[1,6] All Standardbred horses lack the Qa factor; neonatal isoerythrolysis in this breed is usually due to antibodies against the Aa factor, with 10% of Standardbred mares having anti-Aa antibodies.[1] Only 2% of Thoroughbred mares lack the Aa antigen but this low proportion is important because approximately 50% of these mares will develop anti-Aa antibodies.[2] Conversely, 16% of Thoroughbred mares lack the Qa antigen, but only 3% of these mares have the anti-Qa antibody.[2] The risk of mares developing antibodies against certain red blood cell types is also related to the prevalence of the antigen in the horse population. For instance, Standardbred mares lack the Qa antigen, but because this antigen is not found in the breed any Standardbred stallion the mare is mated to will not be Qa positive, neither will the foal, and there is no risk of the mare being exposed to the antigen.

The incidence of neonatal isoerythrolysis in **mule foals** (donkey sire X horse dam) can be 10% and is attributable to the universal presence of a unique blood group antigen, 'donkey factor', in jacks and mule foals.[7,8] Mares do not possess this factor and therefore all donkey sire X horse dam pregnancies are incompatible.[7] Progeny of horse sire X donkey dam matings are not affected.

A feature of naturally occurring neonatal erythrolysis in **foals and piglets** is that it rarely if ever occurs in offspring of **primiparous dams** because the induced anti-red blood cell antibody titer is not sufficiently high to induce the disease. Subsequent exposure during later pregnancies elicits an anamnestic response that results in higher anti-RBC antibodies, and disease in the newborn. However, first pregnancy offspring are often affected after vaccination of the dam with blood products.

PATHOGENESIS

The interaction between the antibody and the red cells of the newborn is followed by hemolysis with resultant **anemia, hemoglobinuria, and jaundice**. Following ingestion and absorption into the systemic circulation, antibodies bind to red blood cell membranes. Parts of the cell membrane of the antibody coated cells are removed from the circulation, probably by the spleen and associated reticulo-endothelial tissues, and affected cells are eventually lysed and release hemoglobin into the circulation. The affected animal develops **normovolemic anemia** and, if the destruction of red blood cells is sufficient, develops anemic hypoxia and dies. The reaction between red blood cells and antibodies occurs sufficiently quickly that the bone marrow is unable to compensate immediately for the loss of red blood cells. Disseminated intravascular coagulation (DIC) occurs and may contribute to the death.

Permeability of the intestine of the newborn foal to antibody disappears by 36 hours and in most cases much less. Hourly milking of the mare rapidly reduces the antibody content of the colostrum. The duration of the alimentary permeability in piglets has not been determined.

CLINICAL FINDINGS

Horses and mules

Pregnancy and parturition are uneventful and the foal is normal for some hours after birth. Signs appear only if the foal ingests and absorbs colostrum containing anti-red blood cell factor antibody. The severity of disease ranges from clinically inapparent to fulminant with death ensuing soon after birth.

Peracute cases develop within 8–36 hours of birth, and the first indication of the disease may be collapse. Severe hemoglobinuria and pallor are evident but icterus is not apparent initially. The mortality rate is high.

In **acute cases** signs do not develop until 2–4 days after birth and jaundice is marked, with only moderate pallor and hemoglobinuria.

Subacute cases may not show signs until 4–5 days after birth. **Jaundice** is marked, but there is no hemoglobinuria and only mild pallor of mucosae. Many subacute cases recover without treatment.

The severity of the disease is related to the type and quantity of antibody ingested. Antibodies against Aa usually produce severe disease apparent within 24 hours of birth, while ingestion of anti-Qa antibodies causes a milder disease apparent at 3–4 days after birth.

General signs include lassitude, weakness, and disinclination to suck. The foal lies down in sternal recumbency for long periods and yawns frequently. There is no febrile reaction but the heart rate is increased up to 120/min. Respiration is normal until severe anemia develops when tachypnea (respiratory rate up to 80/min) and yawning are observed. Terminally, dyspnea and convulsions may develop. Peripheral edema does not occur and there are no signs of involvement of the central nervous system. **Bilirubin encephalopathy** or kernicterus is a rare complication of neonatal isoerythrolysis. It is apparent as altered mentation and seizures in foals with high serum bilirubin concentration.[9]

Isoimmune thrombocytopenia of foals and mules may be evident as ecchymotic hemorrhages and a tendency to bleed from relatively minor wounds. A syndrome in foals characterized by ulcerative dermatitis, neutropenia, and thrombocytopenia appears to be related to ingestion of colostral antibodies.[10] Affected foals have oral and lingual ulcers, and crusting and erythema around the eyes, muzzle, perineum, trunk, and neck. There are ecchymotic and petechial hemorrhages in mucus membranes. Treatment with corticosteroids and antibiotics is associated with a good prognosis.

Pigs

Piglets show essentially the same syndrome, being normal at birth but developing jaundice at 24 hours and weakness at 48 hours, with most affected pigs dying by the 5th day. Peracute cases occur and piglets may die within 12 hours of birth, showing acute anemia but no jaundice or hemoglobinuria. A proportion of subclinical cases also occurs in which hemolysis can be detected only by hematological examination. **Isoimmune thrombocytopenic purpura** of piglets may manifest as increased bleeding following routine management procedures such as tail docking.[11]

Cattle

In calves clinical signs develop within 24–48 hours after birth and the calves die during the first week of life. Surviving calves are returned to normal health in 2–3 weeks. Peracute cases die within 24 hours, and at necropsy examination are characterized by pulmonary edema and splenomegaly.

CLINICAL PATHOLOGY

Hematological examination reveals acute anemia; erythrocyte counts, packed cell volumes, and hemoglobin concentrations are low and there is greatly increased erythrocyte fragility and sedimentation rate. Depending on the severity of the disease and its duration, there can be **leukocytosis**, attributable to neutrophilia and monocytosis, and the presence of nucleated red blood cells (in piglets and calves but rarely in foals). Affected mule foals, but not horse foals, are often **thrombocytopenic**.[8] Isoimmune throm-

bocytopenia occurs rarely in foals and is not associated with neonatal isoerythrolysis, as it is in mule foals. In piglets, the erythrocyte count may be as low as 1 million/μL, the hemoglobin level below 2 g/dL, and thrombocytopenia is present. **Serum biochemical analysis reveals** an increased serum concentration of unconjugated bilirubin.

Diagnostic confirmation is achieved by demonstration of the presence of antibodies in the mare's serum or colostrum that cause hemagglutination or lysis of foal red blood cells.[11] Tests to demonstrate hemagglutination or lysis of foal red blood cells exposed to mare serum or colostrum have been developed. Of these, the standard hemolysis test appears to have the greatest utility.[12] However, for practical purposes a positive direct antiglobulin test (**direct Coombs' test**), confirming the presence of antibodies on the surface of red blood cells in a foal with anemia, provides a diagnosis of neonatal isoerythrolysis. False negative (foal has the disease but the Coombs' test is negative) results occur occasionally because of the hemolytic nature of the antibodies. The same principle is applicable to all species. Detection of antibodies on the surface of the neonate's red blood cells is possible using direct immunofluorescence flow cytometry.[13] The test identifies the presence of antibodies on red cells in some instances when the Coombs' test is negative.

The use of blood typing and other prepartum predictive tests in the prevention of the disease are discussed under control.

NECROPSY FINDINGS

In peracutely affected foals, there is marked pallor but only slight jaundice The liver may be mildly swollen and friable but the spleen is greatly enlarged and is almost black due to the accumulation of lysed and lysing erythrocytes. In less severe cases jaundice is marked but pallor is only moderate in degree. The kidneys are usually pale and the urine is dark brown. The histopathological changes may include ischemic tubular nephrosis and periacinar hepatic necrosis and degeneration. Erythrophagocytosis is prominent and depending on the clinical course and therapeutic regime, there may be widespread hemosiderin deposition.

Hemoglobinuria is an important sign in piglets, and jaundice or port wine coloration of tissues occur constantly. The presence of blood-stained peritoneal fluid and an enlarged spleen is also typical of the disease in piglets.

Samples for postmortem confirmation of diagnosis

Formalin-fixed liver, spleen, bone marrow, kidney, and lymph node for light microscopic examination.

DIFFERENTIAL DIAGNOSIS

- There are no diseases of the newborn that present the same clinical picture as that of alloimmune hemolytic anemia.

Differential diagnosis list for unexpected death and/or lethargy of neonates

Foals and calves
- Septicemia
- Neonatal maladjustment syndrome
- Uroperitoneum
- Prematurity
- Birth trauma
- Hypoglycemia
- Equine herpesvirus-1 infection

Piglets
- Septicemia
- Birth trauma
- Hypoglycemia.

TREATMENT

The aims of treatment are to:

- Prevent the deleterious effects of anemia
- Prevent or treat hemoglobinuric nephrosis
- Prevent ingestion of further colostrum
- Prevent secondary infection in severely ill animals
- Restore normal fluid, electrolyte, and acid–base status
- Provide adequate nutrition
- Minimize stress.

The treatment of choice for neonatal isoerythrolysis depends on the severity of the disease. The choice of treatment should be based first and foremost on the severity of the clinical signs and secondarily on the hematocrit and red blood cell count. Foals or piglets with **mild clinical signs** (minimal lethargy, mild tachycardia, slight exercise intolerance) need only protection from environmental and nutritional stresses in order to recover. However, such animals should be carefully monitored to insure that their clinical condition does not worsen.

Severely affected animals need a transfusion of compatible blood to alleviate the anemia and intravenous fluids to insure adequate urine flow and minimize the risk of hemoglobin-nephrosis. In general, the younger the animal at the time the disease is evident, the more severe the disease and the more likely the need for intensive treatment. See Chapter 9 for a discussion of 'transfusion triggers'.

Foals

Transfusion

Transfusion of an adequate quantity of whole blood or packed red blood cells results in dramatic resolution of clinical signs and anemia. **The decision to transfuse blood** should be based on the foal's clinical condition, and not solely on the presence of a low hematocrit or red blood cell count (see Blood transfusion, in Chapter 9). In general, foals that are tachycardic, tachypneic, unable or reluctant to suck, have severe exercise intolerance or are unable to stand should receive blood. These foals will usually have a hematocrit less than 15% (0.15 L/L). Recumbent foals usually have a hematocrit less than 10% (0.10 L/L). Foals that are mildly tachycardic and tachypneic but are able to suckle vigorously and keep up with the mare generally have hematocrits above 15% (0.15 L/L) and do not require transfusion of red blood cells. The hematocrit should be monitored and foals in which the hematocrit is declining rapidly will likely require transfusion of blood or packed red cells.

The volume of blood transfused depends on the clinical condition of the foal and the progression of the anemia. Foals often require transfusion of 1–4 L (20–100 mL/kg body weight) of whole blood or 500 mL (approximately 10 mL/kg body weight) of packed red blood cells, and might require more than one transfusion. Blood should be administered slowly, 1 L/hour, and the foal's condition monitored closely during the infusion. Packed red cells are preferred for transfusion because of the small volume administered. Transfusion of large quantities of blood should be performed slowly because of the risk of fluid overload of the circulatory system. The half-life for mare erythrocytes transfused into foals is about 5 days.[14]

The optimal donor is a horse that does not have Aa and Qa blood group factors nor anti-Aa and Qa alloantibodies. The former should not be present as the maternal antibodies against Aa or Qa in the recipient foal's plasma will destroy the transfused cells. Similarly, donor antibodies against Aa or Qa will cause further lysis of foal red blood cells. Such donors must be identified in advance, because of the time required for the blood type testing, and are only likely to be available on large breeding farms or in specialized veterinary hospitals.

An ideal source of red blood cells is the **dam** because the maternal alloantibodies in the foal's plasma will not react with the mare's red blood cells. However, whole blood transfusions from the dam are contraindicated because of the presence of alloantibodies in the dam's plasma. This problem can be avoided by transfusing only the mare's washed red blood cells. Blood is collected from the mare (up to 25 mL/kg) into acid citrate dextrose or sodium citrate (10 mL of a 3.8% solution per 90 mL of blood). The mare's red cells are then washed by removing the plasma, resuspending the cells in isotonic (0.9%)

saline, thorough mixing, and subsequent removal of the saline. Plasma and red cells can be separated by large volume centrifugation or sedimentation. Adequate separation of red cells and plasma occurs by sedimentation within 1–2 hours if the blood is undisturbed.

If an ideal blood-typed donor is not available and the mare's red cells cannot be washed in time, or are unavailable, then a donor should be chosen based on routine cross-matching. The **sire** will not be a suitable donor, since the antigens against which the mare's antibodies are directed were inherited from him. A cross-match should match the foal's (or dam's) serum against the donor's red blood cells, and the donor's plasma against the foal's red blood cells. The chance of finding a suitable donor is enhanced by selecting ponies or breeds other than Thoroughbreds, Standardbreds, and Arabians, because of the higher prevalence of Aa and Qa negative animals in these breeds.

Emergency support of severely affected foals can be achieved by administration of a solution containing **polymerized bovine hemoglobin**.[15] This compound increases the hemoglobin concentration of blood thereby increasing oxygen carrying capacity. It is not a replacement for transfusion of blood or packed red cells, but is a useful bridging procedure while a donor is identified and blood collected. The recommended dose rate is 10–30 mL/kg administered slowly (10 mL/kg/h) intravenously. However, the cost of the compound might necessitate the use of lower doses (3–5 mL/kg).

Nutritional support

The foal should not be permitted to nurse the mare until it is >36 hours old. Therefore, **nutritional support** should provide approximately 100 kcal/kg per day in the form of mare's milk (10 L per day per 50 kg foal), goat's milk, or commercial mare's milk substitutes. If the foal is more than 36 hours old, then it is highly unlikely that either the mare's milk will still contain a significant quantity of antibodies or that the foal will be able to absorb them, and the foal should be allowed to continue to suckle the mare. In younger foals, an alternative feed should be supplied until the foal is at least 36 hours old. The mare should be milked out every 3–4 hours during this time to remove the colostrum.

The fluid, electrolyte, and acid–base status of moderately to severely ill foals should be assessed and corrected with intravenous administration of balanced polyionic fluids and sodium bicarbonate. Fluid administration should be used to insure an adequate flow of urine to prevent hemoglobinuric nephrosis.

Antibiotics

Broad-spectrum antibiotics should be administered to severely ill foals to prevent secondary infection (see Principles of providing care to the critically ill neonate.

Nursing care should be provided to minimize stress and prevent the development of complications such as pressure sores in recumbent foals.

Piglets

In pigs the prevention of sucking for periods of up to 24 hours does not prevent the disease. The safest procedure is to remove piglets from the sow, feed them artificially for 48 hours, and then return them to the sow. Frozen bovine colostrum collected as soon as possible after calving is a satisfactory substitute for sow colostrum but is improved by the addition of pig serum. When transfusion is necessary the intraperitoneal route is practical and safe.

CONTROL

The principles of control are:

- Identification of incompatible matings by blood group typing
- Identification of at-risk foals by testing of mare serum or colostrum for the presence of alloantibodies directed against blood factors possessed by the foal.

Blood group typing permits the identification of mares that are at risk of developing antibodies against Aa or Qa antigens. If an Aa or Qa negative mare is mated to a stallion that has Aa or Qa factors then there is the potential for neonatal isoerythrolysis. If the stallion is Aa and Qa negative, then there is no risk of the disease caused by antibodies to these blood groups.

Measurement of alloantibodies in the serum or colostrum of at-risk mares is useful in identifying mares at increased risk of having affected foals. Serum from at-risk mares is collected during the last month (preferably 3–5 weeks before expected parturition) of pregnancy and examined for the presence of antibodies against the blood of the sire or, if a sample of the sire's blood is not available, a range of blood group factors including Aa and Qa. Mares that have such alloantibodies causing hemolysis at >1:16 are not permitted to suckle at risk newborn foals. If the titer is between 1:2 and 1:16, it is measured again 1–2 weeks before anticipated parturition to determine if the titer is rising, in which case the mare is likely carrying a foal with an incompatible blood group. Equine blood typing and detection of isoantibodies is performed by specialized laboratories in a number of countries:

- Australia – www.aegrc.uq.edu.au/services
- New Zealand – www.ivabs.massey.ac.nz/centres/centre_blood.asp
- USA – www.uky.edu/Agriculture/VetScience/textpages/epvrl.HTM

and

http://www.vgl.ucdavis.edu/service/horse/index.html

The **jaundiced foal agglutination test** (JFA) is useful in determining the compatibility of mare's colostrum and foal's red blood cells (Table 34.1).[16,17] In this test foal red blood cells are added to serial dilutions (1:2 through 1:32) of colostrum and the presence of agglutination examined. Agglutination at dilutions of 1:16 in horses and 1:64 in mules are considered significant and the foal should not be permitted to receive the mare's colostrum.[1] The foal should be fed colostrum from another, compatible,

Table 34.1 Method for performing the jaundiced foal agglutination test[18]

1. Assemble eight 5–10 mL clean glass tubes. Label one as control (saline), and the others 1:2, 1:14, 1:8, 1:16, 1:32, 1:64, 1:128
2. Place 1 mL of 0.9% isotonic sterile saline in each tube
3. Add 1 mL of colostrum to the tube labeled 1:2. Mix this tube well and then transfer 1 mL of the contents of this tube to the tube labeled 1:4. Repeat this procedure until all tubes have had colostrums added. This procedure produces serial dilution of the colostrums.
4. Add one drop of well mixed, anticoagulated blood (e.g. blood collected into a tube containing EDTA) to each tube.
5. Centrifuge the tubes at 300–500 g for 2–3 minutes
6. Pour off the supernatant and observe the red cell pellet.

Interpretation

If no agglutination is present the red cells will flow evenly down the side of the glass tube whereas with complete agglutination (4+) the cells remain tightly packed at the bottom of the glass tube. Strong agglutination (3+) causes the cells to form large clumps that are visible to the naked eye. Agglutination of grade 3 or 4 is considered a positive test.

If there is agglutination in the saline control tube, then the foal might have already ingested colostrum containing antibodies to the foal's red blood cells. Some authorities recommend running a parallel test using mare's red blood cells in place of foal's red cells. This provides a negative control (there should be no agglutination of mare red cells by her colostrum) and aids interpretation of results especially for inexperienced operators.

mare or from a colostrum bank. The mare should be milked out every 2–4 hours until the JFA titer is less than 1:16 or for 36 hours, after which the concentration of antibodies in the milk is negligible,[1] and the foal can be permitted to suckle its dam. It is critical to the successful use of this test that it is performed before the foal is permitted to suckle the mare. If an incompatibility is detected the foal should be fed colostrum from a mare that does not have a positive jaundiced foal agglutination test to the current foal's red cells.

Avoidance of vaccines based on whole blood or cellular parts of blood is recommended, and if they have to be used it should be as far away as possible from parturition and should be restricted to one injection and one booster.

PURPURA HEMORRHAGICA

Synopsis

Etiology Deposition of immune complexes in the walls of capillaries with subsequent vasculitis and extravasation of blood and plasma.
Epidemiology Sporadic disease of horses, and rarely cattle and pigs. The disease in horses is often associated with upper respiratory tract disease, especially *Strep. equi* infection.
Clinical signs Swellings of the head, limbs, and body. The swellings are usually asymmetrical, not painful on palpation and pit with gentle pressure. Tachycardia and tachypnea are characteristic. Petechial hemorrhages are present in mucosal surfaces. Skin of the limbs may slough.
Clinical pathology None specific. High anti-streptococcal in protein liter in serum thrombocytopenia is not present.
Diagnostic confirmation Clinical signs, skin biopsy.
Treatment Corticosteroids (dexamethasone) and antibiotics. Supportive care.

ETIOLOGY

The disease is acute and non-contagious. The cause of the **vasculitis** that characterizes purpura hemorrhagica is likely the deposition of complexes of antigen and immunoglobulin in the walls of capillaries and small blood vessels. The disease appears to be **immune complex-mediated** and due to a **type III hypersensitivity reaction**. The common association of the disease is with ***Strep. equi* infection** of the upper respiratory tract. The high concentrations of antibodies to *Strep. equi* M protein in affected horses, and the presence of complexes of IgA and streptococcal M protein in sera are evidence that the disease is associated with an immune reaction to streptococcal protein.[1–3] The immune complexes are not found in the serum of horses recovering from *Strep. equi* infection that do not have purpura hemorrhagica. However, in many instances there is no history of streptococcal infection.[4] There is a suggestion that the disease might be associated with an adverse reaction to therapeutic drugs. Vaccination using modified live *Strep. equi* M protein or killed *Strep. equi* vaccines is strongly suspected of inducing the disease.

EPIDEMIOLOGY

Purpura hemorrhagica is an uncommon, non-contagious, sporadic disease of horses. It has been recorded in pigs and cattle. Estimates of the incidence of the disease are uncommon and imprecise. There was an incidence of 27 cases in 1438 horses housed over a 3-year period in a Swedish Army remount facility.[5] All cases of purpura hemorrhagica followed upper respiratory infections, of which 11 were typical of strangles. Only a small proportion of horses are affected but the incidence is highest when extensive outbreaks of strangles occur, possibly because of reinfection with streptococci of horses already sensitized by previous infection.

Of 53 horses with purpura hemorrhagic treated at a referral center, 17 had been exposed to or infected with *Streptococcus equi*, 5 had been vaccinated with *Streptococcus equi* M protein, 9 had been infected with *Corynebacterium pseudotuberculosis*, and 5 had a history of apparently infectious respiratory disease of undiagnosed cause. Fifteen of 53 horses had no history of recent infectious disease.[4]

There is a strong suspicion among clinicians of an association between purpura hemorrhagica and vaccination.[6] However, vaccination against *Strep. equi* infection has not been clearly demonstrated to be a risk factor for purpura hemorrhagica. Certainly, cases of purpura do occur in horses that have been vaccinated against strangles, but presumably there was a high probability that such horses were at increased risk of developing strangles. The consensus is that vaccination with vaccines containing M protein or avirulent *Strep. equi* is associated with increased risk of purpura. Edema of the lower limbs does occur after vaccination with streptococcal M protein and may represent a mild form of the disease.[7] It is recommended by some authorities that horses with high serum antibody titers to streptococcal M protein not be vaccinated against strangles,[6] although definitive data to support this recommendation are not available.

There does not appear to be breed, age, or sex predisposition to the disease. Horses as young as 6 months of age, and possibly younger, can be affected.

The case fatality rate with appropriate treatment is approximately 10%.[4] Purpura accounted for 2 and 8% of 2028 and 1245 deaths among horses shipped from Great Britain and the United States, respectively, to South Africa during the Boer War.[8] This mortality rate was before the advent of antimicrobials or corticosteroids which have presumably decreased the case fatality rates.

PATHOGENESIS

The basis of the disease process is an **aseptic vasculitis** of capillary walls that is accompanied by extravasation of plasma and blood into the tissues. Thrombocytopenia does not occur, nor is there a defect in coagulation in most cases. Prolonged clotting times (activated clotting time, partial thrombin time, and thromboplastin time) occur in severely affected horses with infarctive purpura hemorrhagica.[3] Skin lesions predominate but other organs, including the kidney, muscles, and gastrointestinal tract, are affected.[3,9]

CLINICAL FINDINGS

Affected horses are usually depressed and have reduced or absent appetite. The temperature is elevated in approximately 60% of cases,[4] as is the heart rate. **Extensive subcutaneous edematous swellings** are the characteristic sign of the disease. They occur most commonly about the face and muzzle, but are often present on other parts of the body and are not necessarily symmetrical in distribution. The swellings may appear suddenly or develop gradually over several days. They are cold and painless, pit on pressure, and merge gradually into normal tissue without a definite line of demarcation. There is no discontinuity of the skin, although it may be tightly distended and even ooze red-tinged serum. Swellings about the head may cause pressure on the pharynx with subsequent dyspnea and dysphagia. Lesions in the lungs are usually not clinically apparent without radiographic or ultrasonographic

examination of the chest. Extensive edema of the limbs occurs in almost all cases.[4] Rare cases of the disease in horses do not have edema.[10]

Submucous hemorrhages occur in the nasal cavities and mouth, and petechiae may be present under the conjunctiva in over 80% of cases. Hemorrhage and edema of the gut wall may cause colic but in most cases there is no diarrhea or constipation. Severely affected skin, and especially that of the legs, may slough and leave granulating wounds.

Infarctive purpura hemorrhagica is an uncommon manifestation of the disease characterized by infarction of multiple tissues including the gastrointestinal tract and muscle.[3] Affected horses have signs of colic and muscle swelling. The course is usually over 3–5 days and death, which is the most common outcome, is associated with severe colic and rapidly deteriorating metabolic status.

The course of the disease is usually 1–2 weeks and many animals die from blood loss, dyspnea due to laryngeal or pharyngeal swelling, and secondary bacterial infections. Relapses are uncommon among appropriately treated horses.

CLINICAL PATHOLOGY

There are no characteristic abnormalities detected on routine hematological or biochemical examinations of affected animals. **Hematological changes** are typically a mild anemia (usually <32% but >20%, <0.32 L/L but >0.20 L/L) with a neutrophilic leukocytosis and hyperfibrinogenemia. **The platelet count is normal**. Hypergammaglobulinemia can be present. There is an elevation in serum activity of creatine kinase (CK) and aspartate aminotransferase (AST) in affected horses, likely a result of muscle lesions, in approximately 25–30% of cases.[4] Horses with infarctive purpura have marked elevations in serum activity of creatine kinase and aspartate aminotransferase, neutrophilia, and in severely affected horses, there is evidence of disseminated intravascular coagulation.[3]

Diagnostic confirmation is achieved by **skin biopsy**, especially of early lesions, and reveals leukocytoclastic vasculitis.[7] Immunofluorescence staining of sections of skin may reveal the presence of antibodies, antigens, or complement in the walls of small blood vessels.

NECROPSY FINDINGS

Ecchymotic and petechial hemorrhages are present generally throughout the body. The subcutaneous swellings contain plasma which may be blood-stained, or sometimes whole blood. The lungs are edematous and congested. Histologically, the changes are also dominated by bland hemorrhage but a leucocytoclastic vasculitis is usually observed in scattered vessels. Sample of lung, muscle, and gastrointestinal tract, in addition to skin, should be examined via light microscopy to check for the presence of vasculitis.

Horses with infarctive purpura have dark red to black, multifocal coalescing hemorrhages in skeletal muscles.[3] Hemorrhages also occur in the lungs and gastrointestinal tract. Histological examination reveals coagulative necrosis of muscle and other tissues. There is inflammation of the blood vessels.[3]

DIFFERENTIAL DIAGNOSIS

Horses

Causes of edematous swelling include:

- Equine viral arteritis and equine herpesvirus 1 or 4 infection, which do not have petechiation and are readily distinguished by their epidemiological characteristics and by serological testing
- Equine granulocytic anaplasmosis (ehrlichiosis) which can be differentiated by the presence of granular inclusions in the cytoplasm of neutrophils
- Congestive heart failure, which should be apparent on clinical examination
- Angioneurotic edema, which is not associated with petechiation
- Stachybotryotoxicosis.

Causes of petechial hemorrhages include:

- Equine infectious anemia
- Thrombocytopenic purpura
- Stachybotryotoxicosis.

Cattle

Hemorrhagic septicemia, poisoning by bracken fern and sweet clover, thrombocytopenia associated with bovine viral diarrhea, and stachybotryotoxicosis are more likely causes of a hemorrhagic syndrome than is purpura hemorrhagica.

TREATMENT

The **principles of treatment** are to reduce inflammation of the blood vessels, remove the inciting cause, and provide supportive care. Because of the possibility that the disease is due to an adverse drug reaction, administration of any drugs that the horse is receiving at the time the disease develops should be discontinued.

Reduction of inflammation of the blood vessels involves mitigation of the immune response and removal of the source of the antigenic stimulus. The immune response, and its associated inflammatory reaction in blood vessels, should be treated with corticosteroids such as **dexamethasone** (0.05–0.2 mg/kg, IV or IM every 24 hours) or **prednisolone** (0.5–1 mg/kg, IM or IV every 24 hours). Prednisolone might not be as effective as dexamethasone. The dose of corticosteroid can be gradually reduced as the clinical signs improve, and the drug can be given orally. **Non-steroidal anti-inflammatory drugs** (phenylbutazone 2.2 mg/kg orally or IV every 12 hours, or flunixin meglumine 1.1 mg/kg orally or IV every 12 hours) may reduce inflammation and provide some analgesia.

Removal of the source of the antigenic stimulus of the disease is difficult, especially in cases when an antecedent infection or disease is not readily identified. On the assumption that purpura hemorrhagica is often a sequela to *Strep. equi* infection, and the suspicion that occult *Strep. equi* infection is present and the source of antigen associated with the disease; affected horses are usually treated with **penicillin** (procaine penicillin, 20 000 IU/kg, IM every 12 hours, or potassium penicillin, 20000 IU/kg, IV every 6 hours) until the clinical signs resolve. Treatment with antibiotics might need to be continued for as long as 20 days.[4]

Supportive care includes bandaging of swollen limbs, care of wounds, hydrotherapy, and intravenous fluid administration. Swelling of the head and pharynx may necessitate placement of a nasogastric feeding tube to permit enteral feeding of dysphagic horses. Respiratory distress can develop very rapidly and emergency tracheotomy may be required to relieve respiratory distress and prevent asphyxiation.

CONTROL

There are no specific preventive measures. However, control and prevention of upper respiratory tract infections in horses should lead to a reduction in the incidence of purpura hemorrhagica. Careful consideration should be given to the use of vaccines containing streptococcal M protein or avirulent *Strep. equi* in horses at low risk of developing strangles. Although the relationship between M protein containing vaccines and purpura hemorrhagica is not definitive, circumstantial evidence and the opinion of authorities in the field support such an association. Measurement of serum antibodies to M protein might be useful in determining the need for vaccination of horses in endemic areas or at high risk.[6] Horses with antibody titers >1:3200 should not be vaccinated.[6]

EQUINE SEASONAL ALLERGIC DERMATITIS (QUEENSLAND ITCH, SWEET ITCH)

This is an intensely pruritic dermatitis of horses caused by hypersensitivity to insect bites.

ETIOLOGY

The disease is caused by type I (immediate) hypersensitivity to salivary antigens introduced into the skin by the bites of sandflies and other insects. There may be a lesser role for type IV (cell-mediated) hypersensitivity in the disease. *Culicoides brevitarsus* is the cause in Australia,[1] *C. pulicaris* in the United Kingdom and Europe,[2] and *C. obsoletus* in Canada.[3] *Stomoxys calcitrans*, the stable fly, and *Simulium* spp. cause the disease. The distribution of the skin lesions is related to the feeding habits of the inciting insect. For instance, *C. pulicaris* has a predilection for landing at the mane and tail, and this is where the lesion is most commonly seen.

EPIDEMIOLOGY

The prevalence of the disease varies depending on environmental factors, and possibly characteristics of the local horse population. Up to 60% of horses are reported affected in areas of Queensland, Australia, 22% in Israel, and 18% of Icelandic horses in Norway.[4] The prevalence in Switzerland is very low in regions above 1000 m and 1.6% in lower areas.[5]

The disease is quite common worldwide in areas where **hot and humid summer weather** favors the causative insects: Sweden, the United Kingdom, Japan, Israel, Hong Kong, North America, Australia, the Philippines, India, and France. Most cases occur during **summer** and lesions disappear during cooler weather. Lesions disappear when the horses have been stabled in insect-proof barns for several weeks or are moved outside the geographical range of the inciting insect.

The disease is characteristically sporadic and affects only a few of a group of horses. However, because the predilection to the disease is likely inherited, there may be multiple cases among related animals on a farm.[5,6] The prevalence of the disease increases with age; 3.4% of Icelandic horses 1–7 years of age compared to 32% of horses older than 14 years were affected.[4]

PATHOGENESIS

Reaginic antibodies (IgE) produced in response to exposure to proteins in insect saliva bind to mast cells in the skin and, when exposed to the antigen, are associated with degranulation of the mast cell. Horses with sweet itch have IgE antibodies that react with constituents of the salivary gland of *Culicoides* sp., whereas horses that do not have the disease have IgG, but not IgE, antibodies against *Culicoides* salivary gland antigens.[6] Horses that have not been exposed to *Culicoides* sp. do not have either antibody to the insect salivary gland antigen.[6] **Degranulating mast cells** and intradermal or subcutaneous lymphocytes release various vasoactive substances and cytokines that cause inflammation and accumulation of eosinophils in the skin of affected areas and eosinophilia.[7] The distribution of the lesions on patients reflects the insects' preferred feeding sites. Ponies with seasonal allergic dermatitis have greater numbers of circulating CD5+ and CD4+ T-lymphocytes than do normal animals.[8] Increased numbers of CD3+ T-lymphocytes, most of which are CD4+, and eosinophils are present in the skin of affected ponies after injection of *Culicoides* antigen.[8] Furthermore, eotaxin and monocyte chemoattractant protein (MCP) 1, but not MCP-2 or MCP-4, mRNA expression is upregulated in skin biopsies of sweet itch lesions, demonstrating a mechanism for accumulation of eosinophils and T-2 lymphocytes in the lesions.[9]

CLINICAL FINDINGS

Lesions are usually confined to the base of the tail, rump, along the back, withers, crest, poll, ears and, less commonly, ventral midline. In severe cases the lesions may extend down the sides of the body and neck and onto the face and legs.

Pruritis is intense, especially at night, and the horse scratches against any fixed object for hours at a time. In the early stages slight, discrete papules, with the hair standing erect, are observed. Constant scratching may cause self mutilation, severe inflammatory lesions, and loss of hair. Scaliness and loss of hair on the ears and tail-base may be the only lesions in mildly affected horses.

CLINICAL PATHOLOGY

Affected animals have **eosinophilia** and thrombocytosis.

Diagnosis is facilitated by skin biopsy, fungal culture, and parasitological examination of skin scrapings, and intradermal sensitivity testing. **Skin biopsy** of early lesions, before trauma masks the true picture, reveals edema, capillary engorgement, and eosinophilic and mononuclear perivascular infiltration. Fungal culture and parasitological examination of **skin scrapings** are useful only in that they rule out dermatophycosis, onchocerciasis, and strongyloidosis. **Intradermal skin testing** demonstrates immediate and delayed sensitivity reactions to extracts of *Culicoides* and *Stomoxys* spp.[1]

DIFFERENTIAL DIAGNOSIS

Infection with larvae of *Onchocerca* sp. or *Strongyloides* sp., or *Dermatophilus congolensis* can produce similar lesions. Alopecia of the tail head may be caused by *Oxyuris equi*.

TREATMENT

The principles of treatment are removal of the inciting cause and suppression of the hypersensitivity reaction.

Removal of the inciting cause is achieved by preventing horses from being exposed to the inciting insects. This can be achieved by relocating the horse to a geographical region where the insects do not occur, stabling of the horse in an insect-proof stable during the periods of the day (early evening) when the insects are most active, or applying agents that kill the insect or otherwise prevent them from alighting on and biting the horse.

Suppression of the immediate hypersensitivity reaction or its sequelae can be achieved by administration of corticosteroids (prednisolone, 1 mg/kg every 24 hours initially then reducing to as low a maintenance dose as possible). Theoretically, hyposensitization may be effective, but the only controlled clinical trial to date did not demonstrate a beneficial effect, although the placebo effect on the owners was impressive.[10]

CONTROL

Prevention of the disease necessitates protection against sandfly bites by stabling in insect-proof quarters. Continuous spraying of the horses with insecticides or repellents may be of some value. A 4% permethrin pour-on gives effective protection. Most horses need only one application a week; others need an application every second day.[11]

SEASONAL ALLERGIC DERMATITIS

A disease similar to sweet itch of horses occurs in sheep in the UK.[1] The lesions

are similar to those in horses and are located principally on the teats, udder, and ventral midline, but also on the tips of the ears, around the eyes, and on the nose and the lips. Because of their appearance only in summer, and in senior ewes, and at a time when midges are plentiful enough to cause signs of insect worry, a cutaneous sensitivity to *Culicoides* spp., especially *C. obsoletus*, is suspected. Histologically the lesions represent the changes characteristic of immediate hypersensitivity. Cutaneous sensitivity to ground up *Culicoides* spp. was demonstrated. A very similar disease occurs in cattle in Japan. It is thought to be due to an allergy to the bite of an external parasite.[2]

RECURRENT AIRWAY OBSTRUCTION (HEAVES)

Synopsis

Etiology Inhalation of barn and feed dust containing inciting agents which can include particles of molds, endotoxin, mites, plant debris, and inorganic material.
Epidemiology Predominantly a disease of horses stabled in poorly ventilated barns and fed poor quality hay containing molds. Occurs worldwide but more commonly in the northern hemisphere. No breed or sex predilection.
Clinical signs Chronic cough, mucopurulent nasal discharge, poor athletic performance, increased respiratory rate, increased expiratory effort, wheezes on thoracic auscultation, and abundant mucopurulent material in the trachea on endoscopic examination.
Clinical pathology Neutrophilia in tracheal aspirate and bronchoalveolar lavage fluid.
Lesions Bronchiolitis with mononuclear cell infiltration, epithelial, and goblet cell hyperplasia, neutrophil accumulation in airway lumens, and alveolar hyperinflation.
Diagnostic confirmation Clinical signs, examination of bronchoalveolar lavage fluid, and the response to treatment.
Treatment Remove the inciting cause by providing a dust-free environment, and administer corticosteroids. Bronchodilators are useful for treatment of acute bronchoconstriction.
Control Prevent exposure to inciting cause. Insure optimal air quality in stables or maintain horses at pasture.

Heaves is a recurrent or chronic disease of stabled adult horses (previously known as chronic distructive pulmonary disease) characterized by neutrophilic airway inflammation and airway obstruction manifest clinically by the presence of coughing, excess mucus accumulation in airways, tachypnea and increased respiratory effort, and exercise intolerance. It should be differentiated from the usually transient inflammatory airway disease of young adult horses in which there is no significant impairment of pulmonary function. The disease is included in this section because it is classically considered to have an allergic component, although this assumption is increasingly questioned.

ETIOLOGY

Heaves, previously referred to as chronic obstructive pulmonary disease, is caused by inhalation by susceptible horses of dust particles found in barns, bedding, and feed materials such as dusty hay. The inhaled particles include endotoxin, mites, plant debris, inorganic materials, and conidia and fragments of molds. *Faenia rectivirgula* (formerly known as *Micropolyspora faeni*), *Aspergillus fumigatus*, and *Thermoactinomyces vulgaris* are molds commonly associated with respiratory disease in susceptible horses, as evidenced by experimental studies involving inhalation of mold or mold fragments by horses.[1] Molds contain a number of inflammatory substances including various allergens, glucans, mycotoxins, and proteases and it is not clear which of these agents are the inciting cause of heaves.[2] Furthermore, dust containing mold also contains endotoxin. Endotoxin contamination of molds contributes to the airway response to inhalation of preparations of molds used in experimental studies[3] and inhalation of endotoxin alone produces airway inflammation and impaired respiratory function in horses in a dose-dependent manner, with heaves-susceptible horses having an exaggerated response at lower doses.[4] However, the response to endotoxin is less than that of susceptible horses exposed to hay dust containing endotoxin indicating that endotoxin alone is not sufficient to cause the clinical signs of heaves. Other compounds in hay dust are integral to the development of heaves.[5]

It is emphasized that there is not one causative agent acting alone but rather a range of agents that, when inhaled in sufficient concentration by susceptible horses, induce airway disease. It is likely that heaves is associated with the potentiating interactions among several agents present in barn or hay dust and is not simply a response to one agent.[3,6] The mechanisms underlying development of airway inflammation and respiratory dysfunction are provided under 'Pathogenesis'. Viral infections and 3-methylindole intoxication are not considered important causes of heaves.[7]

EPIDEMIOLOGY

Occurrence

Although heaves is one of the more common diseases of horses, and is a major cause of loss of performance and wastage in European horses,[8] there are few reports of its epidemiological characteristics. The disease is common in Europe and North America but is rare in Australia. In Germany, 83% of horses believed to be healthy at an auction were found to have clinical evidence of chronic pulmonary disease.[8] Inflammatory airway disease is very common in horses, with 96% of racehorses in Hong Kong examined at necropsy and 12% of horses examined in an abattoir in the northern U.S having histological evidence of bronchitis.[9,10] Twenty-seven per cent of healthy racehorses in training had an increased proportion (>20%) of neutrophils in tracheal aspirate, indicating inflammatory airway disease.[11] However, the airway inflammation common in young athletic horses is not generally considered to be heaves, or a prodrome of heaves. The prevalence of heaves is not well documented.

The **case-fatality rate** for moderately to severely affected horses is approximately 20% over a 2–4-year period.[12] Most mildly to moderately affected horses respond well to treatment and continue to perform at a satisfactory level.[12]

Risk factors

Animal risk factors

The disease occurs in adult horses and ponies, and animals >7 years of age are 6 to 7 times more likely to be examined because of the disease than are horses <4 years of age.[13] There is no apparent breed or sex predisposition with the exception that Thoroughbreds are 3 times more likely to be examined for the disease than are ponies,[13] although this could represent a sampling bias in that owners of Thoroughbreds might be more likely to seek veterinary attention than owners of ponies. The finding of increased likelihood of Thoroughbred horses having the disease is not consistent among studies. Horses are approximately 2 times more likely to be examined by a veterinarian because of the disease in winter or spring compared to summer, suggesting a seasonality to the occurrence of the disease[13] perhaps as a result of increased stabling during winter.

There are horses that develop the disease and other horses, maintained in an identical situation, that do not. Development of disease is dependent upon the horse being susceptible to the inflammatory effect of inhaled dust but the reasons for this individual susceptibility are poorly understood. A familial predisposition has been suggested based on the observation that

Lipizaners and German and Swiss Warmbloods are 3.2 times more likely to have heaves if one parent was affected and 4.6 times as likely if both parents had heaves.[14] There is no association between major histocompatability markers (equine leucocyte antigens) and occurrence of heaves.[14] However, genetic and environmental factors are often closely associated, in that horses of similar genetic background are often housed in similar situations, making elucidation of inherited susceptibility to heaves difficult.

Exposure to inciting agents is associated with a variety of environmental factors, including potentially outdoor concentrations of aeroallergens and climatic factors,[15] but most importantly housing and feeding practices.

Environmental risk factors

There is a clear association between housing, feeding of hay, and development of the disease.[16,17] Typically, susceptible horses are clinically normal when at pasture and develop signs of disease within hours to days of being housed in stables and fed dusty hay. Moving affected horses to pasture, or improving air quality by increasing ventilation and feeding processed feedstuffs, results in resolution of the disease.[16]

Development of disease is related to inhalation of **respirable particles** that gain access to the lower respiratory tract. Respirable particles are less than 5 μm diameter, the principal source of these particles in stalls is hay, and the majority of particles are fungal spores.[18] The concentration of particles in air of the stable is determined by the rate of release of particles from hay, which is dependent in large part on the quality of the hay, concentration of fungal spores in the hay, and the rate of clearance of dust from the stable, a function of the ventilation rate.[19,20] Concentrations of respirable dust particles in the breathing zone of stabled horses can be as high as 20 mg/m^3.[3,21] The severity of increases in neutrophil count and proportion and decreases in pulmonary function in experimental models of heaves are related in a dose-dependent fashion to the amount of dust inhaled.[4] The presence of dust particles, and not the soluble products in hay dust, is responsible for most of the airway neutrophilia induced by inhalation of hay dust.[5]

Hay is the usual original source of spores in stable air. However, **decomposing wood shavings** are also a source of spores of fungi that multiply during degradation of plant-based materials, and housing horses in poorly ventilated stalls deeply bedded with wood shavings may be detrimental to their respiratory health.[22] Spores from hay enter the bedding either directly or after dispersal through the air and multiply in the bedding if it is not removed regularly. **Diced paper** and **wood shavings**, when fresh, usually contain very few spores. Barley and wheat straw are usually free of any small spores such as *A. fumigatus* or *M. faeni*.[19] Bedding horses on fresh wood shavings, and feeding a nutritionally complete pelleted ration, results in a respirable dust burden 3% of that of horses fed hay and bedded with straw.[23] Dust burdens measured in the air of the stall underestimate the respirable particle challenge of horses because of the high concentration of particles in hay and bedding, areas from which the horse inhales while eating.[23]

Respiratory health of horses is related to **stable design and ventilation**, with horses in poorly ventilated barns having more respiratory disease than horses in well-ventilated barns.[22] See 'Control' for recommendations regarding stable design.

PATHOGENESIS

Susceptible horses, when exposed to adequate concentrations of respirable dust in the breathing zone, develop airway inflammation, excess mucus accumulation, and respiratory dysfunction within hours to days of exposure. The putative inciting agents include fungal spores and debris, endotoxin, and particulate matter; however, the exact role for each of these agents is unclear, partly because of the difficulty in obtaining uncontaminated material. For instance, fungal material is commonly contaminated with endotoxin which has a synergistic interaction with hay dust in inducing airway neutrophilia in susceptible horses.[3]

The mechanisms underlying these responses to inhalation of dust are not well defined but can be considered in the contexts of immune and inflammatory responses, mucus secretion, and pulmonary dysfunction.

Inflammatory and immune responses

Inflammation is associated with excessive mucus production, airway swelling, and abnormal lung function.[6,24] The inflammatory response in horses with heaves is neutrophilic, with lesser numbers of mast cells and rarely eosinophils. The mechanisms underlying this inflammatory response have not been fully elucidated, although it involves activation of nuclear factor kappaB and there is support for an acquired immune-mediated process.[25–28]

The presence of allergen-specific IgE antibodies in bronchoalveolar lavage fluid is supportive of a hypersensitivity reaction, although others have proposed type 3 and type 4 immune reactions as the basis of the disease.[25] One proposed explanation is that heaves-susceptible horses exhibit a Th2-like immune response to inhalation of hay or barn dust characterized by increased expression of interleukins 4 and 5 and decreased expression of interferon-γ in cells obtained by bronchoalveolar lavage.[29,30] Others have not detected a pure Th2-like cytokine profile finding instead a mixed inflammatory response including increases in expression (mRNA) in cells obtained from bronchoalveolar lavage fluid of affected horses of interferon-γ, tumor necrosis factor-α, interleukins 1β and 4, and interleukins 8 and 17 (potent attractors of neutrophils) but not interleukins 2, 5, and 10.[31–35] However, all the studies cited above were performed on crude preparations of cells obtained by bronchoaveolar lavage and the results could have been influenced by the varying proportions of types of cells in these preparations.[32] A study examining just CD4 and CD8 lymphocytes in blood and bronchoalveolar lavage fluid of heaves-affected horses demonstrated a general down regulation in expression of interferon-γ, and interleukins 4, 5, and 13 and no evidence of a cytokine profile consistent with either sole or predominate Th1 or Th2-like responses.[26] The magnitude of the inflammatory response varies depending on the challenge (i.e. nature of the inhaled material) with responses to endotoxin characteristically being less than that of hay dust.[35a] Regardless of the underlying mechanism, exposure to inciting agents results in airway inflammation and interference with normal respiratory function.

Following inhalation of inciting agents there is recruitment of neutrophils, but not eosinophils or platelets, into the lungs in most horses that develop changes in lung function.[36,37] Histologically there is peribronchiolar accumulation of lymphocytes and luminal accumulations of neutrophils in affected horses. The entry of neutrophils into the airways is mediated at least in part by IL-8 and IL-17.[31,33] The neutrophils of horses during episodes of heaves, but not when the horses are asymptomatic, have increased adherence *in vitro* to protein coated plastic suggesting a mechanism for the increased migration of neutrophils into airways of affected horses.[38] Inhibition of neutrophil phosphodisesterase-4 activity does not alleviate clinical signs of heaves or decrease neutrophil numbers in bronchoalveolar lavage fluid in affected horses suggesting that neutrophils are not primarily involved in the genesis of airway obstruction.[39,40] The extent to which neutrophils in the airways are activated has not been determined and their role in the development of respiratory dysfunction is unclear given that glucocorticoid administration attenuates the

respiratory dysfunction but not airway neutrophilia in horses with heaves (see under 'Treatment').[41]

Airway inflammation is associated with increases in concentration of inflammatory mediators including leukotriene B_4, prostanoids including thromboxane, and proteases.[42] Activity of matrix metalloproteinase-9 is higher in horses with heaves than in unaffected horses and is induced in a dose-dependent manner by inhalation of inciting substances including hay dust and endotoxin.[42–45] MMP-9 is likely important in the inflammatory process associated with heaves through excessive gelatinolytic proteolysis that can contribute to lung injury, and through a role in lung remodelling.[43] Inflammation is also associated with increased oxidative stress in lungs of horses with heaves as indicated by elevated concentrations of epi-PGF2a and redox ratio of glutathione in pulmonary lavage fluid.[24,46]

Mucus

Accumulation of excessive quantities of mucus in the large airways is characteristic of horses affected by heaves and can contribute to nonbronchospastic airway obstruction.[6,47] Accumulation of mucus is attributable to decreased clearance and increased production.[48,49] The mucus in horses with heaves differs in both composition and viscoelasticity from that of clinically normal horses[63,65] and this might contribute to its decreased clearance. The viscosity of mucus can increase threefold in heaves susceptible horses stabled and exposed to hay dust.[48] Increased production of mucus is associated with up-regulation of the equine MUC5AC gene, which is responsible for production of mucin, in particular in small airways of horses with heaves.[49]

Airway function and gas exchange

Inhalation of inciting agents causes changes in lung function characterized by an increase in pulmonary resistance, lower dynamic compliance, altered distribution of ventilation, impaired gas exchange, increased functional residual capacity, and an altered breathing strategy.[7] **Airway obstruction** is a result of bronchospasm, inflammatory thickening of airways, and accumulation of mucus and cells in the airways. Bronchospasm is largely relieved by administration of bronchodilator drugs or removal of the inciting cause, but residual effects on lung function remain and are attributable to inflammation and fibrosis and bronchoconstriction of small airways.[7] **Bronchoconstriction** in both normal and affected horses is caused by parasympathetic activity and release of acetylcholine that reacts with muscarinic receptors on airway smooth muscle. However, the response is exaggerated in horses with heaves. Stimulation of airway sensory receptors results in an exaggerated bronchoconstrictive response, possibly because of the action of inflammatory mediators and/or by-products. The exaggerated bronchoconstrictive response is not specific for allergens, and any substance that activates airway sensory receptors may incite bronchoconstriction once the sensitivity of the receptors is enhanced by inhalation of the inciting allergens. Exaggerated airway responsiveness to inhaled irritants persists for up to 3 days after a single exposure to the inciting agent and is likely important in the development of clinical signs of the disease.[50] Bronchoconstriction increases work of breathing but hypoventilation probably contributes little to the hypoxemia of affected horses, given that $PaCO_2$ is rarely increased.[51]

Hypoxemia, which can be severe (<60 mmHg, 8 kPa), is due to ventilation–perfusion mismatches and increased dead space ventilation.[51] The increased minute ventilation of affected horses, a result of maintained tidal volume and increased respiratory rate, mainly supplies dead space and regions with high V/Q ratios.[51] Pulmonary hypertension in affected horses is probably due to hypoxia and perhaps inflammatory mediators with vasoconstrictor activity.[7,51]

The **elevated functional residual capacity** and characteristic breathing strategy of affected horses is due to airway obstruction. Airway obstruction causes trapping of air in alveoli and a higher end-inspiratory volume. The high end-inspiratory volume maximizes airway diameter and facilitates the high expiratory and inspiratory flow rates necessary for affected horses to maintain a normal tidal volume while increasing their respiratory rate.

Bronchiectasis (irreversible dilation and deformation of bronchi or bronchioles) occurs in some horses affected with heaves for a prolonged duration.[52] Neutrophilic inflammation is essential for the development of bronchiectasis.

CLINICAL FINDINGS

The degree to which horses are affected varies considerably. Minimally affected horses have airway inflammation evident on endoscopic or cytological examination of the airways, but few other signs on physical examination, whereas severely affected horses have very obvious clinical signs.

The usual **history** is that of chronic cough in a stabled horse.[12] Typically, the disease is precipitated by exposure to hay and stabling, and disease remission occurs in most horses when pastured and removed from hay. There may be a history of reduced exercise tolerance.

Affected horses are usually bright and alert and have a normal appetite and rectal temperature. Severely affected horses appear anxious and have a greatly increased respiratory effort.

Coughing is common in horses with heaves, although it is neither particularly specific nor sensitive as an indicator of the disease. Coughing may consist of a single cough every few seconds to minutes or there may be a paroxysm of coughing. The cough can also be elicited by digital massage of the larynx and proximal part of the trachea because horses with airway inflammation have increased sensitivity of the cough reflex. Stimulation of the larynx or proximal trachea by digital massage does not elicit coughing in normal horses. The cough becomes more pronounced and wheezing with exercise. It also occurs more frequently when the horse is exposed to cold air, physical activity, excitement, and when placed in a dusty environment, or if dusty feed is offered. The amount of coughing, which must be counted over at least 15 minutes and preferably 1 hour for accurate determination of its severity, correlates closely with the amount of mucus in airways, maximal change in pleural pressure (a measure of bronchoconstriction), and neutrophil count in bronchoalveolar lavage fluid.[41] Coughing is more frequent in horses with heaves, and affected horses often have paroxysmal coughing especially after barn cleaning and feeding.

An intermittent, bilateral mucopurulent to serous **nasal discharge** is a common sign in affected horses.

The resting **respiratory rate** is increased from a normal of 12/min up to 24–36/min. There is a pronounced effort during expiration and markedly affected horses have an obvious abdominal component to respiration. Normal horses have a biphasic pattern of airflow during inspiration and expiration while affected horses lack the second phase of respiration.[53] Long-standing cases develop a 'heave-line' in the flank due to hypertrophy of the abdominal oblique musculature. It is evident as a trough or furrow along the costal arch. In advanced cases the nostrils may be visibly dilated during inspiration and the force of the expiratory effort causes the anus to protrude.

Heart rate is commonly within the normal range or only slightly increased. In horses with heaves, the heart rate is significantly higher during exercise than in healthy horses.

Abnormal lung sounds are one of the most frequent abnormalities detected on clinical examination and the sensitivity of this finding can be increased from 70%

to almost 90% by auscultating the thorax while the horse breathes for 60 to 120 seconds with an airtight plastic bag over its nostrils.[12] The bag should be large enough to enable the horse to breathe unhindered (10–15 L) and should not leak. Accumulation of carbon dioxide in the bag increases the horse's respiratory rate and tidal volume and accentuates lung sounds. Auscultation of the lungs in the early stages of the disease may reveal only a slight increase in the amplitude of normal breath sounds. Abnormal lung sounds become audible as the disease progresses. **Wheezing and crackling sounds** occur at the end of inspiration and the end of expiration. These abnormal sounds are audible over most of the lung but are usually easiest to detect over the upper one-half of both lung fields. **Auscultation of the trachea** usually reveals moist sounds characteristic of fluid in the trachea. Some affected horses have quieter than expected lung sounds.

Percussion of the thorax may reveal an increase in the area of resonance by as much as one to two intercostal spaces caudally. However, the area of resonance delineated by percussion is too labile and ill-defined to be of diagnostic value.

Endoscopic examination of the upper airways, trachea, and bronchi reveals an abundance of mucopurulent material in the trachea which, in severe cases, is also present in the nasopharynx. The amount of mucus can be graded on a 0–5 scale[41]:

- Grade 0 – no visible mucus
- Grade 1 – small blobs of mucus that are not confluent
- Grade 2 – multiple blobs of mucus some of which are confluent
- Grade 3 – mucus confluent in a stream in the ventral aspect of the trachea or multiple large blobs around the circumference of the lumen
- Grade 4 – large pool of mucus in the ventral aspect of the airway
- Grade 5 – Profuse amounts of mucus occupying more than 25% of the tracheal lumen.

Observation of tracheal mucus of grade 4 or 5 has a high specificity (92%) but low sensitivity (52%) for detection of heaves.[47]

Radiographic examination of the thorax usually reveals evidence of bronchial disease with some evidence of interstitial disease. Radiography is more useful in ruling out other diseases, such as granulomatous or interstitial pneumonia, than in confirming heaves.

Sophisticated techniques for measuring pulmonary function, such as determination of tidal flow–volume loops, nitrogen washout or forced expiratory flow–volume loops, may identify mildly or subclinically affected animals but have limited day-to-day clinical utility.[53–55]

Measurement of **pleural pressure changes** by insertion of an esophageal balloon is relatively simple and may be useful in monitoring response to treatment. Affected horses have pleural pressure changes during respiration greater than 6 cm H_2O.[54] Administration of atropine (0.02 mg/kg, IM or IV), isoproterenol (isoprenaline), or a β_2-adrenergic agonist such as terbutaline (0.04 mg/kg, PO) reduces the maximal change in pleural pressure of horses with heaves.

The **course of the disease** is dependent on the removal or continual presence of the precipitating cause. If the cause is removed in the early stages, complete recovery can occur. In the continual presence of the precipitating cause relapses occur commonly or the disease becomes progressive and affected horses become severely incapacitated. **Bronchiectasis**, evident on radiographic examination of the thorax, develops in horses with heaves of prolonged duration.[52] With conscientious management and adequate housing, breeding animals and hunters or show-jumpers with heaves can remain useful for many years.[56]

CLINICAL PATHOLOGY AND SPECIAL EXAMINATIONS

There are no significant changes in the hemogram or serum biochemistry of affected horses. The PaO_2 is below normal in moderately to severely affected horses and the $PaCO_2$ is usually normal although it may be increased in severely affected horses. Blood oxygen tension measurements should be corrected for the temperature of the animal and the altitude. At approximately sea level, PaO_2 values of normal horses are usually greater than 90 mmHg (12 kPa), whereas affected horses have PaO_2 less than 82 mmHg (10.9 kPa). With increases in altitude the values in both normal and affected horses decrease.[54] The normal hypoxemia that occurs in horses during intense exercise is exacerbated by heaves.

Bronchoalveolar lavage fluid from affected horses during symptomatic episodes has a relative neutrophil count greater than 5 to 10%, and usually over 50%, of the absolute nucleated cell count.[12,57,58] It is recommended that horses not be considered to have airway inflammation unless >15% of cells in bronchoalveolar lavage fluid are neutrophils. During periods of remission, the bronchoalveolar lavage fluid of previously affected horses is not different from that of normal horses. Absolute nucleated cell counts in bronchoalveolar lavage fluid of affected horses are reported[12,57,58] but the values depend on the collection technique used.[59] The relative proportions of macrophages and lymphocytes in bronchoalveolar lavage fluid of affected horses are lower than those of normal horses. Eosinophil numbers in bronchoalveolar or tracheal aspirate fluid of affected horses may be mildly elevated (up to 10%), but are usually low (<3–5%). Higher values should raise the index of suspicion for *Dictyocaulus arnfieldi* or *Parascaris equorum* infestation. Aspirates of **tracheal fluid** reveal a profound neutrophilia (>90%).[57]

Measurement or identification of **precipitins** in serum of horses is not useful in identifying horses with heaves.[60]

Intradermal testing using putative allergens has been investigated as a means of identifying horses with heaves or of identifying antigens with which to hyposensitize affected horses with variable or undetermined efficacy.[1,61,62] Retrospective examination of records of horses with a history of heaves suggests that they are more likely to react, and react to a larger number, of intra-dermally injected allergens than horses without a history of heaves.[63] However, reactions to individual allergens cannot be used to determine hypersensitivity to particular allergens, although it is suggested that overall patterns of reactivity, with a history of exposure of the horse to these allergens, might be useful in guiding management of affected horses.[63] Contrary to these results, a prospective study demonstrated that horses with heaves did not have a greater rate of reaction to intradermal skin tests than did horses not affected by heaves.[64] Intradermal testing did not distinguish clinically relevant reactions from those that were not clinically relevant.[64] Horses with heaves have greater sensitivity to intradermal injection of histamine, which is commonly used as a positive control, than horses without heaves.[65] Overall, intradermal skin testing is neither useful in detecting horses with heaves nor in determining hypersensitivity to particular allergens in individual horses. Results of such testing might be useful in management of horses, but this has not been demonstrated. The usefulness of intradermal skin testing and subsequent administration of preparations of antigens selected on the basis of intradermal testing, in an effort to hyposensitize horses with heaves, has not been determined. The apparent lack of efficacy of intradermal testing might be because the extent of reactivity to intradermal injection of mold preparations does not correlate with the severity of pulmonary dysfunction after inhalation of the same preparation in horses with heaves.[1]

Lung biopsy demonstrates peribronchiolar lymphoplasmacytic inflammation, goblet cell metaplasia, alveolar

fibrosis, and bronchial lumen exudate and neutrophils.[12] The severity of bronchiolar neutrophil and mast cell infiltration correlates well with the severity of the clinical signs.[12]

NECROPSY FINDINGS

The major findings are restricted to the lungs, which are pale, voluminous, and do not collapse when the chest cavity is opened. The tissue damage is primarily centered on airways which are less than 2 mm in diameter. Microscopically, a variable degree of alveolar emphysema is accompanied by a chronic bronchiolitis featuring diffuse epithelial hyperplasia, goblet cell metaplasia, peribronchiolar fibrosis, and cellular infiltration by lymphocytes, plasma cells, mast cells, and sometimes eosinophils. Plugs of mucus with entrapped neutrophils often occlude bronchiolar lumina.

Samples for postmortem confirmation of diagnosis

Formalin-fixed lung for light microscopic examination.

DIAGNOSTIC CONFIRMATION

Confirmation of the disease is based on the presence of a history and clinical signs consistent with the disease, in particular the response to stabling and pasturing, and demonstration of reversible airway obstruction. Objective confirmation can be achieved by measuring the response of maximal changes in pleural pressure in response to bronchodilator drug (atropine or glycopyrolate) administration.

DIFFERENTIAL DIAGNOSIS

Horses with respiratory distress may have:

- Interstitial pneumonia
- Heart failure
- Bacterial pneumonia
- Pleuritis
- Pulmonary or mediastinal neoplasia including leiomyosarcoma[66]
- Parasitic pneumonia (*D. arnfieldi*).

Nasal discharge may be caused by:

- Guttural pouch diseases including empyema
- Dysphagia of any cause
- Esophageal obstruction
- Sinusitis
- Pneumonia.

TREATMENT

The **principles of treatment** are:

- Removal of the inciting cause
- Reduction of airway inflammation
- Bronchodilation
- Correction of hypoxemia.[55]

Heaves is an inflammatory disease caused by inhalation exposure to inciting agents. Bronchoconstriction is secondary to inflammation. Control of the disease is based upon preventing inhalation of inciting agents and suppression of inflammation by administration of corticosteroids. Relief of bronchoconstriction should be necessary only during acute exacerbations of the disease, and administration of bronchodilatory drugs for more than several days is not optimal treatment in most horses. Drugs used in the treatment of heaves are summarized in Table 34.2.

It is essential that the horse is ***not exposed to the inciting agents*** *and irritant substances that could provoke or worsen the disease.* Even relatively brief exposure of susceptible horses to the inciting agents, such as can occur if a horse is brought into a poorly ventilated barn to be fed, can result in airway hypersensitivity and the development or maintenance of clinical signs. Affected horses should be moved to a clean environment, **ideally pasture**, in which the concentration of airborne allergens is reduced to an absolute minimum. If the horse cannot be kept at pasture, then it should be housed in a well ventilated barn (see 'Control' for details), bedded with clean wood shavings or shredded paper, and fed a complete pelleted ration. If affected horses are fed hay, it should be thoroughly wetted to minimize the release of spores. Remission of clinical signs can be expected in 4–21 days if the environmental changes are adequate.[67] This may be all that is necessary to control the disease in many horses.

Antiinflammatory drugs

The disease is essentially one of inflammation of the airways and therefore one of the mainstays of treatment is administration of anti-inflammatory drugs. Nonsteroidal anti-inflammatory drugs such as phenylbutazone and flunixin meglumine are not effective. Corticosteroids including dexamethasone, prednisolone, triamcinolone, and betamethasone are effective in controlling the disease. **Dexamethasone** (0.04–0.1 mg/kg, intravenously, intramuscularly or orally every 24–48 hours) can be given to control the acute signs of the disease, and then the dose reduced and eventually discontinued as environmental alterations have their effect. Similarly, **prednisolone** (1–2 mg/kg, orally once daily), but not prednisone[68,69] can be given initially, then the dose reduced by approximately one half every 5–10 days as the disease is controlled. Often prednisolone or dexamethasone sodium phosphate is effective when administered every second day when the disease has been controlled. **Dexamethasone-21-isonicotinate** (0.04 mg/kg, intramuscularly) is effective when administered every 3 days, but not when administered only once.[69,70] **Isoflupredone** (0.03 mg/kg, intramuscularly once daily) is as effective as dexamethasone in alcohol in control of exacerbations of heaves, although it does cause hypokalemia.[71] **Triamcinolone** (0.09 mg/kg, intramuscularly) administered once provides long-term (weeks) relief of signs in some horses.[72]

Inhaled corticosteriods, such as betamethasone, beclomethasone, or fluticasone, are useful in controlling the disease.[73,74] Both inhaled and parenterally administered corticosteroids suppress adrenal function of horses[75] but 500 µg of beclomethasone proprionate inhaled twice daily effectively alleviated signs of heaves and causes less adrenal suppression than doses of 1000 µg or 1500 µg.[76] It is important to reiterate that the use of glucocorticoids should only be as an adjunct to control of the horse's environment and reduction in the inhaled particle burden.

Clebuterol decreases the production of inflammatory cytokines by cells obtained from bronchoalveolar lavage fluid of horses with heaves, suggesting that clenbuterol can have anti-inflammatory effects in such horses.[35] The clinical applicability of this finding remains to be determined.

In summary, a number of different corticosteroid preparations are useful in the control of heaves. Drugs administered by inhalation appear to have a reduced potential for adverse effects including adrenal suppression, but are more difficult to administer and require more frequent administration than drugs administered orally, intravenously, or intramuscularly. Improvements in respiratory effort and clinical signs are evident in approximately 3 days and persist for the duration of treatment. Cell counts and the neutrophilia in bronchoalveolar lavage fluid are not reduced by administration of corticosteroids. Affected horses, after institution of appropriate measures to control inhalation of hay and barn dust, should be treated with the lowest dose that controls the disease and only for as long as necessary. The dose of corticosteroid can be reduced gradually and the frequency of administration decreased from once daily to once every second or third day (or greater, depending on the preparation) to achieve this end. Administration of the lowest effective dose is important because of the effects of corticosteroids in suppressing immune and adrenal function. It is suggested that dexamethasone and triamcinolone increase the likelihood of horses developing laminitis, but this relationship has not been conclusively demonstrated.

Table 34.2 Drugs used in the treatment of heaves in horses

	Drug	Dose and frequency	Route	Comments
Bronchodilators				
β_2-agonists	Clenbuterol	0.8 to 3.2 µg/kg q12 hourly	Oral or IV	Initial therapy with lowest dose. Gradual increments depending on response. For short-term therapy pending environmental control and corticosteroid administration
	Albuterol	50 µg/kg	Oral	Unknown and doubtful efficacy
	Albuterol	1–3 µg/kg q6–12 hours	Inhalation	Has short duration of action (1 hour). Can be combined with ipratropium to prolong duration of bronchodilation.
	Fenoterol	2–4 µg/kg as needed	Inhalation	Short duration of action.
	Pirbuterol	1–2 µg/kg as needed	Inhalation	Short duration of action.
	Salmeterol	0.5–1.0 µg/kg q6–12 hours	Inhalation	Longest acting β_2-agonist available for inhalation
	Terbutaline	0.2 mg/kg as needed	Inhalation	Marked adverse effects including tachycardia. Not absorbed after oral administration.
	Terbutaline	0.01 mg/kg as needed	IV	Marked adverse effects including sweating and tachycardia
Parasympatholytics	Ipratropium	0.5–2.0 µg/kg q4-6 h	Inhalation	Usually combined with albuterol for rapidity of onset of bronchodilation
	Glycopyrolate	0.7 µg/kg as needed	IV or IM	Useful for short-term or emergency relief of bronchoconstriction
	Atropine	0.1–0.02 mg/kg as needed	IV or IM	Useful for diagnosis of reversible airway obstruction and short term relief of bronchoconstriction. Can cause colic.
Miscellaneous	Theophylline	5–10 mg/kg q8–12 hours	Oral	Antiquated therapy. Moderate bronchodilation, variable absorption, narrow therapeutic index, frequent adverse CNS effects. Not recommended.
	Pentoxyfylline	36 mg/kg q12 hourly	Oral	Not used clinically. Experimental evidence of efficacy.
Antiinflammatory drugs				
Corticosteroids	Dexamethasone phosphate or in alcohol	0.02–0.1 mg/kg q24 hourly	IV, IM, or oral	Effective at reducing clinical signs within 3 days. Gradually reduce dose and frequency to lowest efficacious dose.
	Dexamethasone-21 isonicotinate	0.04–0.06 mg/kg q 3 days	IM	Effective. Infrequent dosing.
	Prednisolone	1–2 mg/kg q24 hourly	Oral or IM	Effective at reducing clinical signs within 3 days. Gradually reduce dose and frequency to lowest efficacious dose.
	Prednisone	1–2 mg/kg q24 hourly	Oral	Variable efficacy and not efficacious in most horses. Do not use.
	Triamcinolone acetonide	0.9 mg/kg q2–4 weeks	IM	Infrequent dosing and therefore lack of ability to taper dose. Should not be repeated at <3 month intervals.
	Beclomethasone	1–3 µg/kg q12 hourly	Inhalation	Relief of bronchoconstriction within 3 days. Lowest dose does not cause adrenal suppression and is effective in relief of bronchoconstriction.
	Fluticasone	2–4 µg/kg q 12 hourly	Inhalation	Potent and effective. Expensive.
Other	Cromolyn sodium	200 mg q 12 hourly	Inhalation	Undetermined efficacy. Should be used before exposure to inciting agent.
	Montelukast	0.11 mg/kg q24 hourly	Oral	Leukotriene receptor antagonist. Not efficacious at this dose.

Modified from: Robinson, N.E. (2001) Equine Vet. Educ. 13, 247 and Couetil, L.L. & Hinchcliff K.W. (2004) Equine Sports Medicine and Surgery. Elsevier Health Sciences. p 613.

Bronchodilator drugs

Bronchodilator drugs might be needed to provide acute relief of airway obstruction but should not be used as maintenance therapy. **Atropine** (0.02–0.04 mg/kg, intramuscularly) can be used to provide short-term relief of bronchoconstriction, but its use is associated with gastrointestinal side-effects, including colic, that preclude its long-term use. **Glycopyrolate** (0.1 mg/kg, intramuscularly every 8–12 hours) is a potent bronchodilator with minimal gastrointestinal effects. **Ipratropium bromide**, a parasympatholytic drug with minimal extrapulmonary effects when given by inhalation, is very effective in relieving airway obstruction in severely affected horses.[77]

β_2-adrenergic agonists are potent bronchodilators frequently used in the management of horses with heaves. They can be administered orally or by inhalation.[73,78] **Clenbuterol hydrochloride** is used as maintenance therapy at a dose of 0.8–3.2 μg/kg, orally every 12 hours, and is effective in controlling signs in 75% of affected horses.[79] The lower dose should be used initially and then increased in 0.8 μg/kg increments until the desired effect is achieved or side-effects of tachycardia, muscle fasciculation, and sweating are apparent. Gradual, incremental increases in dose lessen the frequency and severity of side-effects. **Terbutaline** is not absorbed after oral administration to horses.[80] Terbutaline and clenbuterol can also be given intravenously, at a dose one-tenth of that given orally, to severely affected horses in which the need for bronchodilation is urgent. Side-effects of β_2-agonist administration include tachycardia, sweating, and apprehension.[79] Prolonged administration of clenbuterol is associated with potentially adverse effects on cardiac structure, alterations in body composition, and an impaired response to training.[81–83] Delayed parturition may occur in mares treated in late pregnancy. β_2-adrenergic agonists may transiently exacerbate hypoxemia in severely affected horses. Intra-tracheal administration does not produce detectable bronchodilation.[84]

Bronchodilators administered by inhalation to horses include the β_2-agonists **Albuterol, salbutamol, and salmeterol**, and the parasympatholyitc ipratropium. The efficacy and duration of action of each of these drugs varies somewhat, but all are effective in producing bronchodilation in affected horses. Salmeterol produces bronchodilation in horses with heaves that persists for up to 6 hours, although onset of action requires 30–60 minutes.[85] Similarly, ipratropium reduces pleural pressure changes and attenuates clinical signs of airway obstruction in horses with heaves.[77,86]

Theophylline (aminophylline) is a non-adrenergic bronchodilator given at a dose of 10–12 mg/kg, orally every 12 hours. Signs of toxicity include tachycardia, excitement, and convulsions. Theophylline is not a drug of first choice for the treatment of heaves and is now used infrequently because of the availability of efficacious anti-inflammatory drugs and other bronchodilators.

Other drugs

Sodium cromoglycate is useful for the prophylaxis of heaves, but has no direct bronchodilatory activity.[55] Its mechanism of action is unclear, but it may act to prevent the degranulation of mast cells. It can be given at a dose of 20–30 mg per 425 kg horse by inhalation once daily for 4 days, and then repeated in 1–2 weeks.[87]

Pentoxyfylline at high doses improves respiratory function, but not bronchoalveolar lavage fluid cytology, of horses with heaves.[88] However, bioavailability after oral administration is quite variable, contributing to variations in the responses of horses to the drug.

Drugs that reduce **leukotriene** production or activity do not appear to be useful in the treatment of heaves. An experimental leukotriene D4 receptor antagonist was not effective in relieving signs of heaves.[89] Similarly, montelukast did not improve respiratory function in 5 horses with heaves.[88]

Mucolytics are often used but their efficacy is not established and is doubtful. **Cough suppressants** should not be used as they may impair clearance of mucopurulent material from the airways.

Antibiotics are often given to affected horses but are probably not necessary in the vast majority of cases.

Acupuncture is not effective in the treatment of heaves.[90]

Administration of large quantities of **isotonic electrolyte solution** intravenously is associated with a decrement in respiratory function in both normal and heavy horses and is not recommended as a treatment for heaves.[91]

Integrated therapy

Initial treatment of affected horses usually involves changes to the horse's environment and feed in combination with administration of corticosteroids. Corticosteroids and β_2-adrenergic agonists can be given as combined therapy to severely affected horses until the disease is controlled, at which time therapy should consist of environmental control and, if needed, administration of the lowest effective dose of corticosteroids. Bronchodilators are sometimes used as sole therapy, but their use without correction of the housing and feeding factors, and attempts to control inflammation, is not rational. Long-term administration of bronchodilators is not optimal therapy and, given the documented adverse effects, is not recommended. Long-term control of heaves is achieved by environmental management and administration of corticosteroids.

CONTROL

Housing horses in stalls with good air quality is essential in reducing the occurrence of the disease. **Adequate ventilation** is critical in maintaining good air quality in stalls. Few horse housing units have adequate ventilation[19,22] although a well-designed individual box stall can meet the needs of the horse both for air hygiene and thermal comfort.[19] Many horse barns have inadequate open space for ventilation in still air conditions when the doors are closed at both ends of the building. When the release rate of spores is low, ventilation rates of 4 air changes per hour are satisfactory. However, suggested minima are 8–10 air changes per hour, airspace of 44 m^3/head, and floor space of 9.2 m^2/head.[23] In practical terms, if the upper half of the stable door is open, and faces open air and not into a barn, the natural ventilation should exceed the minimum specifications.[23] Hay and dusty feed materials should not be stored above stalls or in the same airspace as horses. Bedding should be changed frequently, preferably daily. Use of cardboard as bedding material is effective as part of an overall regimen to improve air quality.[92]

A portable slit sampler is an accurate, quick, and simple semiquantitative method of assessing the mold contamination of source materials such as hay, straw, and other feeds and bedding collected from stables.[18] The health hazard posed by any moldy source material depends on the types of organisms present and their abundance. The size of the respirable challenge from heated hays and straws arises from the prolificacy of the species involved and their small spore size. The highest respirable challenges are from the presence of thermotolerant and thermophilic mold species. The most critical factors in determining the microbial development in plant-based materials are water content and thermal environment. Hay baled at 15–20% moisture heats little, it is virtually dust-free and contains few spores. Baling hay with 20–30% moisture leads to temperatures of up to 35–45°C. At these temperatures, hazardous contamination may develop with the appearance of thermotolerant fungi and actinomycetes.[18] The heaviest contamination of hay and straw occurs with baling at 35–50% moisture when spontaneous heating up to 50–60°C may occur. Microscopically, these hays show large numbers of fungal spores in the 2–5 μm size range.

PASTURE-ASSOCIATED HEAVES (PASTURE-ASSOCIATED OBSTRUCTIVE PULMONARY DISEASE OF HORSES)

Summer pasture-associated heaves occurs in horses in the southeastern region of the United States and in Great Britain.[1–3] It appears to be a disease of adult horses that are on pasture most of the time in the summer. It occurs most commonly in the warm, humid summer months of June to September. Affected horses gradually recover during the cooler months of winter and early spring, and the disease may recur in the same horse each successive summer. Most severe signs occurred during late spring and early summer during times of high airborne pollen counts. It has been suggested that pulmonary allergy to pollens is a factor but this has not been validated. Affected horses have increased expression of interleukin-4 and interferon-? in cells of bronchoalveolar lavage fluid and peripheral blood mononuclear cells[4] but not increased concentrations of IgE in bronchoaveolar lavage fluid.[5] Affected horses have clinical findings typical of heaves including nasal discharge, coughing, tachypnea, labored expiratory effort, and crackles and wheezes on auscultation.[6] There is moderate-to-severe accumulation of mucus in the large airways evident on endoscopic examination. Lung function testing is consistent with bronchoconstrictio onchoalveolar lavage fluid contains large numbers of nondegenerate neutrophils and lesser numbers of lymphocytes and mast cells.[6] Necropy reveals overinflated lungs that do not collapse when the chest is opened and that retain the impressions made by the ribs.[6] The predominant histologic finding is accumulation of mucus in small airways. Inflammation is not severe and most inflammatory cells present are neutrophils and lymphocytes in peribronchial tissues.[6] Treatment includes stabling and administration of corticosteroids and bronchodilators, as discussed for heaves and Table 34.2).[1,2,7]

MILK ALLERGY

Signs of allergy, principally urticaria, are often manifested by cows during periods of milk retention.[1,2] Most of these occur as the cow is being dried off. The Channel Island breeds of cattle are most susceptible and the disease is likely to recur in the same cow at subsequent drying off periods; it is almost certainly inherited as a familial trait.

The important clinical signs relate to the skin. There is urticaria which may be visible only on the eyelids or be distributed generally. Local or general erection of the hair may also be seen. A marked muscle tremor, respiratory distress, frequent coughing, restlessness to the point of kicking at the abdomen and violent licking of themselves, and even maniacal charging with bellowing may occur. Other cows may show dullness, recumbency, shuffling gait, ataxia, and later inability to rise. The temperature and pulse rates are usually normal or slightly elevated but the respiratory rate may be as high as 100/min.

Diagnosis of milk allergy can be made by the intradermal injection of an extract of the cow's own milk. A positive reaction occurs with milk diluted as much as 1 in 10 000, and the edematous thickening is present within minutes of the injection. Other clinicopathological observations include the development of eosinopenia, neutrophilia, and hyperphosphatemia during an attack.

Spontaneous recovery is the rule but antihistamines are effective, especially if administered early and repeated at short intervals for 24 hours. Prevention is usually a matter of avoiding milk retention in susceptible cows, but in many cases it is preferable to cull them.

ENZOOTIC NASAL GRANULOMA OF CATTLE (ENG, BOVINE ATOPIC RHINITIS)

Of the three known clinical types of chronic nasal obstruction in cattle, two have been identified etiologically and have clinical or epidemiological features that distinguish them from enzootic nasal granuloma. One is recorded predominantly in beef cattle appears to be caused by a fungus, most commonly *Rhinosporidium* spp., or *Drechslera* spp.[1,2] Another is caused by the parasite *Schistosoma nasalis*.[3] The third type, enzootic nasal granuloma, occurs commonly in southern Australia, less commonly in New Zealand and is recorded as a sporadic disease in South America and an occasional disease in North America, Britain, and Europe.[4,5]

Enzootic nasal granuloma occurs sporadically in some herds but may reach an incidence of 30%. In one area, as much as 75% of herds may have the disease. Animals aged between 6 months and 4 years are most commonly affected, and the chronic disease may or may not be preceded by an attack of acute rhinitis. Most cases commence in the summer and autumn months. It is apparent that nasal granuloma develops as a continuous and progressive response to acute episodes of hypersensitivity to an allergen present in the summer months. This accords with the gradual development of the stertorous respiration[6] and the observations, in biopsies of nasal mucosa, of the presence of mast cells in all seasons, but the regression of eosinophils in the winter months.[4]

An extensive survey of Australian dairying areas showed that 22% of cattle had lesions, and that the prevalence was greater in areas where the average annual rainfall was over 70 cm, than where it was less than 70 cm; the prevalence varied between 4% and 48%; Jerseys were more commonly affected than Friesians. In New Zealand, 40% of farms and 36% of culled cattle were affected, whereas only 3.6% of young beef cattle showed lesions.

The disease has been identified as an allergic rhinitis and has been produced experimentally.[7] Specific antigens have not been identified as the cause but cows with nasal granuloma are much more sensitive to a number of common allergens in the environment than are unaffected cows. Bovine herpesvirus 1 is often isolated from lesions of ENG and is thought by some to predispose animals to the development of the disease. Additional possible causes include infestation of the nasal cavities with pasture mites (*Tyrophagus palmarum*). An allied condition has been described in the United States as maduromycosis but there are nasal granulomas plus multiple granulomatous lesions of the skin of the ears, tail, vulva, and thigh.[8] The granulomas contain many eosinophils and fungal elements identified provisionally as *Helminthosporium* sp.

In enzootic nasal granuloma acute cases are characterized by a sudden onset of bilateral ocular and nasal discharge and swelling of the nasal mucosa causing difficult, noisy breathing. Affected animals shake their heads and snort and rub their noses in hedges. As a result they commonly block their nostrils with twigs. This form of the disease is commonest in cattle of the Channel Island breeds and their crossbreeds. The nasal discharge in these breeds is usually yellow to orange in color.

Established cases of enzootic nasal granuloma have lesions, consisting of granulomatous nodules 1–4 mm in diameter and height, in both nostrils. The lesions extend from just inside the nostril posteriorly for 5–8 cm. They may be few in number or be packed closely together. Their texture is firm and the mucosa over them is normal. They have a characteristic histopathology of epithelial metaplasia and hyperplasia, and contain large numbers of eosinophils and mast cells.[4,9]

The predominant clinical sign is respiratory stertor and dyspnea caused by obstruction to the air flow. The severity of these signs may fluctuate but in general they progress slowly over several months and then remain static. Although the respiratory distress may be sufficiently severe to cause a loss of condition and marked reduction in milk yield, affected animals do not die. A good proportion of them have to be culled as uneconomic units.

The clinical picture in **mycotic nasal granuloma** is superficially similar with respect to noisy breathing, respiratory distress, and nasal discharge, but there is no seasonal association. Also, the visible and palpable lesions in the anterior part of the nasal cavities are polyps up to 5 cm in diameter which occur singly or in confluent masses. Their cut surfaces are yellow to green and they are sometimes ulcerated.[4,10] Histologically the lesions are eosinophilic granulomas containing fungal spores and sometimes hyphae. Fungi (*Drechslera rostrata*) have been isolated from the lesions.

Equine allergic rhinitis is a clinically and epidemiologically similar condition, but without mucosal lesions, recorded in horses as a common cause of persistent head shaking.[11]

Introduction

GENERAL

Genetic disorders are a small but important cause of wastage in farmed animals. Most occur in pure-bred animals and are inherited as autosomal recessive traits because dominant disorders tend to be self limiting, or affected animals are excluded from the breeding pool. Incomplete dominants occasionally occur in which there are three potential phenotypes, i.e. normal, affected, and more severely affected. The classic example is in the original Dexter cattle where the slightly dwarfed Dexter phenotype is dominant to the normal and is selected for. Animals homozygous for the gene abort with a non-viable 'bulldog' type fetus.[1,2] Sex-linked disorders may occur but are uncommon. Some monogenic disorders may arise *de novo* due to new mutations of germ plasm. Those with a dominant mode of inheritance are present in offspring of the animal in question, usually affecting genes for structural proteins such as collagen. A new mutation should be considered with disorders such as *osteogenesis imperfecta* or skin fragility.[3] The proportion of offspring with the defect may vary depending on what stage of gametogenesis the mutation occurred.

In-breeding, knowingly or unknowingly practiced, is an important feature in the manifestation of most outbreaks of a recessive disorder. Founder effect is an aspect of this that has been important when new breeds have been introduced to a country by importation of genetic material from a small number of individuals. Artificial breeding on a large and international scale has sometimes exacerbated this, particularly in cattle.

Genetic disorders may be manifested as disease or bodily malformation. When diagnosed, an entity may reflect the tip of an iceberg only and it can be expected that many other cases go undiagnosed. Spread across an industry their economic importance may be limited, but as particular disorders tend to be concentrated in certain herds/flocks they may have considerable importance to an individual breeder, particularly those involved with pedigree breeding. Animal welfare is also a concern to be addressed, being driven by a greater awareness of ethical standards in livestock production and by potential market access requirements.

The two main problems for the clinician investigating a suspected inherited disorder are to confirm a primary genetic cause and then to institute control in a cost-effective manner.

DIAGNOSIS

For a number of inherited diseases or malformations known to occur in a breed, morphology or histopathology may be so characteristic as to be essentially pathognomonic. However, for some disorders environmental agents (teratogens) may cause similar morphological anomalies, e.g. arthrogryposis, so care should be taken. Pedigree analysis may help if there are sufficient animals of known breeding to show that the incidence of the disorder follows a Mendelian pattern. However, in many herds/flocks animals may be closely related and pedigree analysis can sometimes be misleading and produce a fictitious relationship between inheritance and disease. As the biochemical anomaly is now known for many diseases, or perhaps can be deduced from histopathological lesions, laboratory tests may confirm a presumptive diagnosis. Test mating of a sire to daughters, related females, or females that have given birth to an affected animal is the ultimate confirmation of the genetic nature of a disorder, provided the appropriate numbers of progeny are generated. Disproving a genetic cause of a disorder may be as important as proving it. Matings of a sire to produce a minimum of 24 progeny from his daughters or 12 from putative heterozygotes (females that have given birth to affected individuals) are usually considered satisfactory numbers to exclude a likely inherited cause if no affected individuals are born ($P<0.5$). The birth of a proportion of affected offspring is strong evidence of inheritance. The use of super-ovulation and embryo transfer techniques may facilitate this, particularly if insufficient daughters or putative heterozygotes are available. The time to accomplish this may be decreased by caesarian section of the surrogate dams if the defect can be detected in the fetuses.

The degree of in-breeding is an important indicator of whether a congenital disorder is inherited or not. Consistency of the defect is a characteristic of inherited disorders but there may be some variation in age of onset or expressivity of lesions. Other epidemiological factors include the occurrence of the defect over more than 1 year and occurrence or repetition of it in the same mating group, but not in others on the property.

CONTROL OF INHERITED DISEASE

Appropriate control measures may vary, depending on the importance of the disorder and may be aimed at the herd/flock level or at the breed as a whole. It may be prospective but, at the farm level, it is mainly reactive with the purpose of preventing further losses by immediate action. This should include not breeding from putative heterozygous sires or females which should preferably be culled. Replacement sires are best acquired from another breeder but, if the defect is common in the breed, then the risk may remain and cross breeding with a sire from another breed may be considered if the type of farm operation permits it. If a test is available for detecting heterozygous animals then this can be used in new sire selection.

Control of genetic disorders in pedigree herds is more complex and to be effective depends on ability to detect heterozygotes or prove animals do not carry the recessive gene in question. Test mating is time consuming, expensive, and of limited application. The explosion of knowledge concerning the biochemical and molecular genetic basis of inherited diseases across species has opened up effective means of diagnosing genotype

for many of them. Control may be at an individual herd/flock level or applied to all at risk. It is best instigated with the help of breed societies who may exert control over the fate of animals diagnosed as heterozygous through control of registrations. Apart from the accuracy of genetic tests in genotype diagnosis, there is the added advantage that particularly valuable animals may be kept within the herd/flock for breeding as their offspring can in turn be tested as normal or heterozygous.

The first generation of tests for heterozygotes was biochemical being based on knowledge of the enzyme deficiency and the gene dosage phenomenon. Heterozygous animals having one normal and one mutant gene have enzyme values midway between normal and diseased values, although there may be some overlap. Supplementary tests or knowledge of the parents' genotype may assist with clarification of equivocal results. Such tests were used to control the economically important lysosomal storage diseases α-mannosidosis in Angus and Murray Grey cattle in New Zealand and Australia[4] and Glycogen storage disease type II in Shorthorn and Brahman cattle in Australia.[5] These have now given way to more accurate second-generation technology based on DNA for these diseases as well as a number of others.[6–8] Such tests may be performed on blood samples but are increasingly being done on hair roots.

The genome for the major farm species is essentially known and, given the will and enough affected families, the technology exists to develop tests for most disorders. If the disorder in question is poorly defined biochemically, then tests are still possible by finding a closely linked polymorphic gene marker. This is usually the first step in investigating the molecular genetics of an unknown disease but it is expensive. In contrast, if a candidate gene can be deduced from the pathology of the disease, then it is much simpler to define the mutation and through polymerase chain reaction (PCR) technology develop a DNA based test.

Artificial breeding techniques have the capacity to spread undesirable genotypes widely before they are recognized. Many artificial breeding organizations involved in the dairy industry prospectively screen for genetic disorders by mating prospective sires over a proportion of their daughters. This is possible because of the time taken to prove a sire before he enters the industry on a large scale.

ONLINE MENDELIAN INHERITANCE IN ANIMALS (OMIA)

Online Mendelian Inheritance in Animals (OMIA) is a database of genes, inherited disorders and traits in animal species (other than human and mouse) authored by Professor Frank Nicholas of the University of Sydney, Australia, with help from many people over the years. The database contains textual information and references, as well as links to relevant records from OMIM, PubMed, Gene, and soon to be NCBI's phenotype database.

Diseases characterized by chromosomal anomalies

The principal advance in cytogenetics in agricultural animals has been in the field of fertility in cattle but freemartinism and structural translocations are the only groups to have been well documented. Other chromosomal abnormalities in other species are recorded but not in sufficient numbers to make a coherent account possible; details of them should be sought in the theriogenology literature. Besides the many identifications of individual infertile males and females by this means there is the probability that chromosomal aberrations characterized by aneuploidy are the cause of many stillbirths and multisystemic anomalies that make neonates non-viable.[1,2] A true hermaphrodite in a horned goat with 60 XX/60 XY chimerism has been described.[3]

Chromosomal analysis techniques are based on tissue culture using leukocytes collected in a highly aseptic manner. The blood is placed in tissue culture medium containing a stimulant to cell division. After brief incubation, cell division is arrested by the addition of a cytotoxic agent and the cells are then swollen osmotically by treatment with a hypotonic solution, then fixed and dried onto slides and stained. Microscopic examination of dividing cells allows the total number of chromosomes in each cell to be counted, and the sex chromosomes and abnormal chromosomes identified. The individual chromosomes are cut out from photographic prints, paired, and stuck onto cards to create the document used for identification – the **karyotype**. The number of cells subjected to chromosomal analysis in each case is usually 10–20, but 50 are recommended for satisfactory accuracy.

FREEMARTINISM IN CALVES

A freemartin is defined as a sterile female partner of a pair of heterosexual twins. In cattle, 92% of females born co-twins to males are freemartins.

In normal calves the chromosomal identification of females is 60 XX (60 chromosomes, both X chromosomes) and of males is 60 XY (the Y being smaller and not readily paired with its opposite X chromosome).

The freemartin is the classical example of the chimera in cytogenetics. They are the individuals which contain two or more cell types which originated in separate individuals. The only way in which chimera can develop is via the fusion of circulations or zygotes *in utero*. Sex chromosome chimerism is also reported in goats, sheep, and pigs, and, although the male partners of female twins are usually anatomically normal, they often have reduced fertility. Bulls born co-twin with freemartin females may also be chimeric and have low reproductive efficiency.

The diagnosis of freemartinism has been based on physical examination, karyotyping, or blood typing and each has its limitations. There is variation in the degree of reproductive tract abnormalities in freemartins. The external genitalia may appear normal, the vulval hair may be coarser than usual or the clitoris may be enlarged. The vagina is generally expected to be shorter than normal. The cervix, uterus, uterine tubes, and ovaries may be absent, present in underdeveloped form, or may appear normal on rectal palpation.

Special cytogenetic techniques are also available which facilitate the diagnosis of freemartinism in a female calf of a male–female twinning. In freemartins (phenotypically female, but carrying also male cells) there is a mixture of mostly 60 XX chromosomes to a cell, and a small proportion of 60 XY cells. A large number of cells need to be analyzed if only the

freemartin calf is available because the proportion of abnormal cells present may be as low as 2%. It is, however, possible to make a diagnosis on the examination of 10–20 cells, provided the male twin is also analyzed; the female may have very few XY chromosomes but the male will have a very high proportion of XX chromosomes. The technique is much more accurate than blood group analysis, or clinical observations of a short vagina, enlarged clitoris and the presence of a vulval tuft of hair. Karyotyping is a definitive method of freemartin diagnosis but it is tedious, time consuming, and expensive. Blood typing analysis may be performed on both the male and female co-twins in order to demonstrate two blood group populations, but it is expensive and requires blood samples from both co-twins.

The **polymerase chain reaction** (PCR) method of freemartin diagnosis using sex-specific DNA sequences is rapid, accurate, relatively simple, and inexpensive to perform and a blood sample is required only from the female co-twins.[4] It allows for the accurate decision of freemartinism down to a level of 0.05% of male chimeric cells present.

CHROMOSOMAL TRANSLOCATIONS IN CATTLE

When two chromosomes which have previously been broken have fused to form a morphologically distinct chromosome this is known as a translocation. It is further identified by the chromosomal series involved. Thus a 1/29 translocation represents a fusion between a chromosome of each of the pairs numbered 1 and 29.

Translocation 1/29 has been identified in many breeds of cattle and has been associated with significant reductions in the fertility of cows bred by artificial insemination (AI) services. Early embryonic death occurs in embryos produced by fertilization of affected gametes or fertilization of normal gametes by spermatozoa carrying the 1/29 translocation. There is no abnormality of serving behavior or semen quality. The translocation has been shown to be inherited in most European beef breeds including the Blonde d'Aquitaine, Swedish Red and White, Charolais,[5] Danish Limousin,[6] British Friesian[7] and Red Poll breeds and in the wild British White cattle. In Bolivian Creole cattle breeds, the Creole-like cattle, the average frequency was 10.42% with a variation from 0 to 28.2%.[8] In contrast, Yacumeno and Creole-type cattle did not show the centric fusion. The highly significant differences between Creole cattle breeds in relation to the 1/29 translocation could be the consequence of factors such as founder group, genetic drift, and selection. The low frequency observed in the Saavendreho Creole dairy cattle might be due to breeding under a more intensive system, and selection according to milk yield and fertility traits. The frequency of affected animals in a breed may vary between 1 and 20%. Karyotyping and culling of abnormal bulls in most artificial breeding centers has reduced the impact of the defect.

Translocations 1/21, 2/4, 14/20, and **13/2** have also been identified in bulls, the 1/21 in Holstein Friesian cattle,[9] and the latter two seeming to be widespread in Simmental cattle.[10] None of them has been linked with a disease but it is becoming accepted practice not to use such animals for artificial insemination, and in some countries to refuse their importation.

A cytogenetic survey of Holstein bulls at a commercial AI unit to determine the prevalence of bulls with centric fusion and chimeric anomalies found that chimeric fusion is extremely rare in Holstein blood lines available by AI in the United States.[11] However, chimeric bulls are more common and reportedly have decreased reproductive performance. Because of the possibility of de novo onset of chimeric fusion at any time, early cytogenetic screening should be encouraged for prospective bulls intended for AI programs.

Translocation 27/29 is suspected of being associated with reduced fertility in Guernsey cattle. These and other abnormalities of chromosomal structure were detected in an examination of a large number of infertile dairy heifers.

CHROMOSOMAL TRANSLOCATIONS IN SHEEP

The literature on chromosomal aberrations in sheep has been reviewed.[12] Centric-fusion (Robertsonian) translocations have been described in sheep in New Zealand. There is no evidence to suggest that these centric-fusions, in a variety of combinations, affect the overall total reproductive performance of domestic sheep, as unbalanced spermatids failed to mature and take part in fertilization.

Inherited defects of the body as a whole

Many inherited defects, other than those listed in this section, probably have a metabolic defect as their basic cause, for example the abiotrophies, but they are listed elsewhere because of lack of certainty about their exact cause. Three known inherited enzyme deficiencies – bovine citrullinemia, bovine protoporphyria – are described in system groupings where their clinical signs are most prominent. Inherited vitamin C, D, and, E deficiencies are dealt with in the chapter on nutritional deficiency diseases. Inherited immune deficiencies are listed in this section.

DEFICIENCY OF UMP SYNTHASE (DUMPS)

This is a partial deficiency of an enzyme which is involved in the conversion of orotate to uridine 5′-monophosphate (UMP) as a step in the synthesis of pyrimidine nucleotides. It is recorded at a high prevalence in Holstein Friesian cattle in the US and is characterized by an autosomal recessive form of inheritance and the secretion of high levels of orotate in the milk. Heterozygous animals have a partial deficiency of UMP synthase[1]; they have no individual or herd clinical abnormalities but can be detected biochemically by their half-normal levels of erythrocyte UMP synthase. Bovine homozygotes die at about the 40th day of pregnancy.[2] Embryonic mortality is the only form of loss.

INHERITED GOITER

This disease is recorded in Merino sheep, Afrikaner cattle, crossbred Saanen dwarf goats, Boer goats, possibly Poll Dorset sheep, and pigs,[1] and appears to be inherited as a recessive character. The essential defect is in the synthesis of abnormal thyroid hormone leading to increased production of thyrotropic factor in the pituitary gland, causing in turn a hyperplasia of the thyroid gland. In Afrikaner cattle the defect stems from an abnormality of the basic RNA, and

heterozygotes can be identified by blot hybridization analysis.[2]

Clinically in **sheep** there is a high level of mortality, enlargement of the thyroid above the normal 2.8 g, but varying greatly up to 222 g, and the appearance of 'lustrous' or 'silky' wool in the fleeces of some lambs. Other defects which occur concurrently are edema and floppiness of ears, enlargement of, and outward or inward bowing of, the front legs at the knees, and dorsoventral flattening of the nasal area. The thyroglobulin deficiency in the neonatal lamb may result in defective fetal lung development and the appearance of a neonatal respiratory distress syndrome; there is dyspnea at birth.

The clinical picture in **goats** is the same as for lambs. It includes retardation of growth, sluggish behavior, rough, sparse hair coat, which worsens as the goats get older, and a thick scaly skin.

In Afrikaner **cattle** most of the losses are from stillbirths or from early neonatal deaths. Some are caused by tracheal compression from the enlarged gland. It is the calves with the largest glands that have the greatest mortality. In these cattle there may be a concurrent inherited gray coat color, a defect in a red breed.

In **pigs** hairless and swollen piglets with enlarged thyroid glands occur, in the proportions with normal piglets consistent with an autosomal recessive mode of inheritance.

INHERITED IMMUNODEFICIENCIES

Many of these diseases have been previously characterized as diseases of other body systems but are now correctly classified by the wider acceptance of clinicopathological examinations, especially those involving immunological studies. The group is probably still in a period of transition (see Chapter 9).

BOVINE LEUKOCYTE ADHESION DEFICIENCY (BLAD)

This granulocytopathy is inherited as an autosomal recessive trait in Holstein-Friesian cattle. Homozygotes are not viable because of their low resistance to infection. Heterozygotes are unaffected. Signs are observed first between 2 weeks and 8 months, and are characterized in most cases by bouts of infectious disease, e.g. persistent fever, diarrhea, cough, dyspnea, delayed wound healing, and stunted growth.[1] Some cases exhibit a striking periodontal gingivitis with marked retraction of the gingiva, and severe resorption of mandibular bone causing premature teeth loss.[2] In a small proportion of cases the signs are limited to unthriftiness.[3] Severe ulcers on oral mucosa, severe periodontitis, loss of teeth, chronic pneumonia, and recurrent or chronic diarrhea are common.[1]

The clinical pathology is characterized by a severe and persistent neutrophilia, without a left shift, and a significantly increased cellularity of bone marrow.[4] At necropsy there are very large numbers of intravascular neutrophils in all tissues, especially the spleen, but not in infected tissues, which may include bronchopneumonia, pseudomembranous or necrotizing enteritis, and granulomatous gingivitis.[5] Intestinal ulcers are an essential part of the pathogenesis of the disease in chronically affected animals which receive intensive medical care.[6] Affected animals are stunted and unlikely to live as long as 2 years.

The gene frequency is widespread in the Holstein-Friesian breed. The genetic basis for the disease is a single point mutation in the gene coding for CD18, a subunit of the beta[3,1] integrins, surface glycoproteins which are important to cell adhesion processes, causing a deficiency of adhesion on the surface of leukocytes.[7] Neutrophils from BLAD cattle have impaired expression of β_2 integrin (CD11a, b, c/CD 18) of the leukocyte adhesion molecule. The biochemical basis for the disease is a deficiency of interaction between receptors on the leukocytes with adhesion glycoproteins in the mediation of immunological functions.[8] A polymerase chain reaction test is available for the detection of heterozygotes[9] and an eradication program is operating in Japan[10] and the US.[11] Heterozygotes have poorer feed utilization and growth rates than non-carriers of the inheritance.[12] Control of BLAD in Holstein cattle requires publishing the genotypes and avoiding the mating between BLAD carriers which is successful.[1] Heterozygote calves are not affected.[13]

INHERITED DEFICIENCY OF LYMPHOCYTE MATURATION (LETHAL TRAIT A46, PARAKERATOSIS, ADEMA DISEASE)

This defect is recorded in Black Pied Danish cattle but probably occurs in a number of European breeds of cattle, including Friesian-type cattle, and in beef Shorthorn calves in the US.[1] It is a defect of lymphocyte maturation and is inherited as an autosomal recessive character.

Calves are normal at birth and signs appear at 4–8 weeks of age; untreated animals die at about 4 months of age. There is exanthema and loss of hair, especially on the legs, parakeratosis in the form of scales or thick crusts around the mouth and eyes, under the jaw, and on the neck and legs, and a very poor growth rate. Lymphocyte numbers and function are reduced when the patient is in a zinc-deficient state,[2] and antibody responses are suppressed.

At necropsy the characteristic skin lesion is acanthosis and hyperkeratosis and there is atrophy of the thymus, spleen, lymph nodes, and gut-associated lymphoid tissue.

There is a significant response to oral treatment with zinc (0.5 g zinc oxide/day) and an apparently complete recovery can be achieved in a few weeks if treatment is continued. The disease reappears if treatment is stopped. The dose rate needs to be increased as body weight increases. It is thought that the disease is an inherited excessive requirement for zinc and that the thymic hypoplasia is due to the dietary deficiency. Absorption studies with radioactive zinc have shown that there is impaired absorption of the element.

INHERITED DEFICIENCY OF IMMUNOGLOBULIN SYNTHESIS

An inherited complete deficiency of IgG_2 occurs in Red Danish cattle at a low level of incidence. Affected animals are unusually susceptible to severe infections including gangrenous mastitis and pneumonia.

CHEDIAK–HIGASHI SYNDROME

This inherited disease occurs in humans, in mink, and in Hereford, Japanese Black, Brangus cattle,[1,2] and possibly other breeds of cattle. Clinically affected animals grow poorly; they are incomplete albinos with generalized oculocutaneous hypopigmentation, e.g. pale gray hair, ocular iridal and fundic hypopigmentation, photophobia and lacrimation, and have anemia, enlarged, edematous lymph nodes, and a defect in immune defense mechanisms so that they often die of septicemia. Their average life span is about 1 year. The immunological defect has been identified as one of insufficient bactericidal activity within abnormal leukocytes. The clinical, morphologic, and biochemical characteristics of Chediak–Higashi syndrome in Japanese cattle has been described.[2]

A mutation in the Chediak–Higashi 1/LST gene is likely responsible for the disease in Japanese Black cattle.[3] The LYST gene responsible for the mutation has been cloned.[4]

The disease is readily diagnosed by the detection of anomalous enlarged cytoplasmic granules in neutrophils, lymphocytes, monocytes, and eosinophils. The granules are swollen lysosomes, and the disease is a lysosomal storage disease. There is also a defect in blood clotting, and this has been identified as a metabolic defect within structurally abnormal platelets. The platelets have a storage pool deficiency of dense granules and produce much less serotonin, ATP, and ADP than normal platelets. The platelets also fail to aggregate normally in response to the presence of collagen.[5] The disease is conditioned by a factor inherited as a single autosomal recessive.[6]

A DNA diagnostic system using allele-specific PCR for detection of the nucleotide substitution has been developed as an effective DNA diagnostic aid.[7]

PSEUDOALBINISM AND LETHAL WHITES

There are a number of forms of pseudoalbinism in domestic animals. There is a non-lethal form in cattle and a lethal dominant in horses in which 25% of conceptions produced by mating dominant white horses die *in utero* in early gestation. The only pigment in the affected foals is in the eyes.

The disease in **cattle** occurs in Angus, Brown Swiss, Holstein, and Hereford cattle. The Angus cattle have a brown coat and two-tone irises with an outer pale brown ring and an inner blue one. There appears to be no defect in digestion or metabolism. Hereford incomplete albinos have the Chediak–Higashi syndrome. The other breeds do not appear to have defects other than in pigmentation and the defect in Angus is probably more accurately called 'oculocutaneous hypopigmentation'. They do have one problem; they are photophobic and prefer to be out of the sun.

A complete albinism in Icelandic **sheep** is manifested by white skin color, pink eyes, and impaired vision in bright light. It is an autosomal recessive. Albinism is also a problem in Karakul sheep.

True albino **horses** rarely if ever occur in nature, but white horses with pigmented eyes do. They are more accurately called pseudoalbinos. A recessive lethal white can also be produced by mating two Overo paint horses (an Overo is a horse with a coat color pattern where white is continuous over the body, but there is pigmented hair in a patch stretching from the ears to the tail). Affected foals develop colic soon after birth, fail to pass meconium, and die at 2–4 days of age. At necropsy there is an irreparable atresia or contraction of the colon associated with a congenital absence of myoenteric ganglia in the terminal portion of the ileum and the cecum and colon. The colon is patent but unable to dilate. Another variety of paint horses, the Tobiano (white markings extend from the dorsal midline ventrally with limbs usually white, and white covering a large part of the horse or very little), are expected to produce lethal whites also but there is no record of it.[1] Both of these varieties of paints have blue or heterochromic irises.

FELL PONY SYNDROME

This is a familial disease of Fell ponies characterized by immunodeficiency, anemia, opportunistic infection, and death at 2–3 months of age.

ETIOLOGY

The disease is a putative autosomal recessive genetic defect of the immune system, although the exact nature of the defect has yet to be determined.

EPIDEMIOLOGY

The disease is restricted to Fell pony foals less than 3 months of age. The disease is reported in this breed in the United Kingdom, one case is reported in the United States (which has a total population of Fell ponies of <200) and a case is reported in the Czech Republic.[1–3,7] The frequency of the disease is not reported. The case fatality rate is 100%.

PATHOGENESIS

There is immunodeficiency associated with low concentrations of immunoglobulins in serum and B lymphocytes in blood. T lymphocytes are present in normal concentration and respond appropriately to in vitro proliferation tests. Death is coincident with declines in concentrations of antibodies derived from colostrum. Immunodeficiency results in development of opportunistic infections including glossitis, adenoviral pneumonia, and cryptosporidial diarrhea. Aplastic anemia develops and can contribute to death. Anemia is associated with aplasia of red cell series in bone marrow and is not due to hemolysis or blood loss.

CLINICAL FINDINGS

Affected foals are lethargic at birth, are unable to keep up with the herd, and do not establish a strong bond with the dam. Foals develop ill-thrift, exercise intolerance, and diarrhea beginning at approximately 3 weeks of age. Clinical signs are attributable to anemia and opportunistic infections. At the time that foals develop other clinical abnormalities they are pyrexic and tachypneic. Most foals have bilateral mucopurulent nasal discharge and abnormal lung sounds consistent with pneumonia. The tongue is covered by a pseudomembranous, hyperkeratotic membrane suggestive of *Candida* sp. infection. Foals develop diarrhea and progressive illness with death occurring by 3–4 months of age even in cases treated aggressively.

CLINICAL PATHOLOGY

The underlying hematology and serum biochemistry is influenced by the opportunistic infections that develop in all foals affected with Fell pony syndrome. Abnormalities consistently associated with the syndrome and likely as a result of the underlying disease, include anemia, B cell lymphopenia, and variable to low concentrations of immunoglobulins in serum.[1,2,4]

Normocytic, normochromic anemia (6–26%, 6–26 L/L) is present in almost all affected foals. There is no evidence of regeneration in the blood and examination of bone marrow reveals an elevated myeloid:erythroid ratio (21:1 to 62:1, reference values 0.5:1 to 1.5:1).[1] There is no evidence of hemolysis.

White blood cell concentration in affected foals is usually below or in the

lower range of the reference range of normal, age-matched foals, and is attributable to a B-cell lymphopenia.[5,6] Concentrations of CD4+ and CD8+ cells in blood are normal in affected foals.[5,6] The concentration of neutrophils is often elevated in affected foals.

Concentrations of immunoglobulins (IgGa, IgGb, IgG(T), and IgM) in serum are variable and depend on the amount of immunoglobulin ingested in colostrum and the age of the foal. Affected foals are unable to produce immunoglobulins and therefore have declining concentrations of immunoglobulins with age. Serum concentrations of IgM and IgA become undetectable before does IgG – a consequence of the shorter half-life of the former immunoglobulins in foals. Measurement of low to undetectable concentrations of IgM at >4 weeks of age provides a reasonable means of diagnosing the disease.[6]

NECROPSY FINDINGS

Gross lesions include pale bone marrow, small thymus and lymph nodes, pneumonia, and pseudomembranous glossitis. The underlying disease is characterized by lesions in bone marrow and lymphoid tissue. Bone marrow has evidence of abnormal hemopoiesis with an elevated myeloid:erythroid ratio. Lymph nodes have sparse to moderate numbers of lymphocytes in cortices and paracortices. The thymus has no clear demarcation of cortex and medulla and the thymic lobules are small.[1,2] Germinal centers are not present in the spleen and the red pulp is markedly contracted and contains siderophages. Ganglionopathy reported in foals in the original report of the disease has not been found in subsequent cases.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of immunodeficiency in foals is provided in Table 35.1.

Table 35.1 Defects of acquired immunity causing disease in foals and horses

Disease	Etiology	Epidemiology and clinical signs	Diagnostic confirmation	Treatment and prevention
Failure of transfer of passive immunity	Failure of mare to produce adequate quantities of colostrum with specific gravity >1.060; prepartum loss of colostrums; failure of foal to ingest or absorb colostrum	*Epidemiology:* Most common immunodeficiency of foals. Affects 5–35% of foals. Rate is reduced by good management. *Clinical signs:* Bacterial infections including bacteremia, septicemia, pneumonia, diarrhea, or septic arthritis/osteomyelitis develop between 2 days and 4 weeks of age.	Measurement of foal blood or serum concentrations of immunoglobulin >18 hours after birth. Concentration should be >800 mg/dL (8 g/L).	*Treatment:* Administration of plasma (20–40 mL/kg) IV. *Prevention:* Check colostrum specific gravity at foaling. Ensure foal nurses mare within 3 hours of birth. Supplement with banked colostrum. Routinely measure foal serum IgG at 18–24 hours of age.
Severe combined immunodeficiency of Arabians	Failure of V(D)J recombination secondary to a defect of the catalytic subunit of DNA-protein kinase coded for by the DNA-PKcs gene.	*Epidemiology:* Restricted to Arabians. Autosomal inheritance *Clinical signs:* Adenoviral pneumonia or diarrhea develop after ~ 4 weeks of age.	Severe lymphopenia (<1 × 109 cells/L); no IgM in presuckle serum sample or sample collected at 4–5 weeks of age; histologic demonstration of lack of lymphoid tissue. Confirmation by demonstration of homozygosity for the abnormal DNA-PKcs gene.	*Treatment:* None. *Prevention:* Identification and removal of carrier animals from the breeding population.
IgM deficiency	Unknown.	*Epidemiology:* Arabian or Quarter horse foals 2–8 months of age. *Clinical signs:* Pneumonia, septic arthritis, or enteritis.	Low to undetectable serum IgM concentrations with normal to elevated concentrations of other immunoglobulins.	*Treatment:* None specific. Symptomatic treatment. Rare foal reported to recover. *Prevention:* None
Fell pony syndrome	Unknown, likely heritable genetic defect.	*Epidemiology:* Fell Pony foals <4 months of age. *Clinical signs:* Depression, fever, diarrhea, anemia, and pneumonia in foals <4 months of age.	No single confirmatory test. Presence of disease refractory to treatment in a Fell pony foal with anemia, lymphopenia and, after 4 weeks of age, low IgM concentration, is strongly suggestive. Histologic examination of bone marrow and lymphoid tissues.	*Treatment:* None effective. *Control:* Unknown pending elucidation of transmission.
Agamma-globulinemia	Unknown. Suspect sex-linked heritable defect	*Epidemiology:* Male foals. Sporadic. *Clinical signs:* Chronic infections develop at >2 months of age (corresponds with declining colostral immunity).	Low to absent concentrations of all immunoglobulin classes in serum. No B lymphocytes detectable in blood. Normal concentrations of T lymphocytes.	*Treatment:* None specific. Supportive and symptomatic but all affected foals die. *Prevention:* None.
Common variable immunodeficiency[8,9]	Unknown in horses	*Epidemiology:* Adult horses. Sporadic. Either sex. *Clinical signs:* Chronic or recurrent infections unresponsive to medical treatment. Meningitis. Liver disease can occur in combination with CVI.	Low to undetectable concentrations of IgG, IgG(T), IgM, and IgA in serum. No or few B lymphocytes in blood or lymph nodes. Elevations in serum markers of liver disease.	*Treatment:* None specific. Affected animals die because of the opportunistic infections. Prevention: Prolonged antimicrobial administration of affected horses.

CONFIRMATION OF DIAGNOSIS

The disease is confirmed by presence of characteristic lesions at necropsy. Antemortem diagnosis is confounded by the presence of opportunistic infections, but should be suspected in any Fell pony foal with anemia, ill-thrift, and declining serum concentrations of immunoglobulin.

TREATMENT

There is no effective treatment. Supportive treatment of transfusions of blood or plasma, and administration of antibiotics does not affect the eventual outcome of the disease.

CONTROL

There are no control measures for the disease pending determination of the nature of its genetic transmission. Should the presumed autosomal recessive inheritance be demonstrated, then identification of carriers and elimination of these animals from the breeding population will permit control of the disease.

Inherited defects of the alimentary tract

INHERITED DEFECTS OF THE MOUTH AND JAW

Harelip in cattle often has a distinct familial tendency but little work appears to have been done on the mode of inheritance. An apparently inherited harelip combined with poor growth and accompanying cryptorchidism is recorded in Holstein-Friesian cattle. Bilateral cleavage of the lip which also involves the maxilla is recorded in Texel sheep as being conditioned by a single recessive autosomal gene.

Cleft palate is inherited as a simple recessive character in Hereford and Charolais cattle, concurrent with arthrogryposis in the latter, and is commonly thought to be inherited in sheep and pigs. The progeny of a commercial swine herd (Landrace x Duroc) and Large White Boar contained a number of piglets with cleft palates.[1] Chromosomal analysis of affected piglets found all had identical unbalanced karyotype with partial monosomy of chromosomes 16 and partial trisomy of chromosome 3, compared to normal piglets in the litters with balanced karyotypes.

Jaw deformity. Shortness of the maxilla is thought to be inherited in Jersey cattle and Large White pigs, sometimes in association with chondrodysplasia. Shortness of the mandible is also inherited in cattle, in Angus in combination with cerebellar hypoplasia and osteopetrosis.

Smooth tongue (epitheliogenesis imperfecta linguae bovis). A defect of Holstein-Friesian and Brown Swiss cattle, this condition is inherited as an autosomal recessive factor. The filiform papillae on the tongue are small, there is hypersalivation and poor hair coat, and the calves do not fare well. The heterozygote is normal.

Tongue aplasia. Congenital absence of the median part of the tip of the tongue occurs rarely in piglets, often in association with cleft palate and/or harelip.

Rectal prolapse may be inherited in piglets as a result of agenesis of the anal sphincter (see below).

INHERITED RECTOVAGINAL CONSTRICTION

The defect is inherited in Jersey cattle and is manifested as stenosis of the rectum in either sex and stenosis of the vaginal vestibule in females. The tone of both rectal and vaginal sphincters is increased but attempts to detect heterozygotes by electromyographic measurement of these tones have been unsuccessful.[2] The defect is regulated by an autosomal recessive gene. Affected cows are difficult to inseminate and have difficulty in calving. Their udders are small and hard and productivity is low. The condition is due to the presence of bands of non-elastic fibrous tissue. Edema of the udder is also a common complication. Some assistance in the identification of affected animals is available by the detection of collagen type II in muscle biopsies. 50% of heterozygotes also test positively, and so do a small percentage of normals.[3]

HEPATIC LIPODYSTROPHY IN GALLOWAY CALVES

Hepatic lipodystrophy has been reported occurring in Galloway calves on 5 farms in the UK over a 10-year period.[4] Calves appear normal after birth but die by 5 months of age. Clinically there is tremor, opisthotonus, and dyspnea before affected calves become recumbent and die. At necropsy the liver is enlarged, pale and mottled. Histologically there is evidence of hepatic encephalopathy. The cause is unknown, but limited evidence suggests a storage disease is possible.

INHERITED ATRESIA OF ALIMENTARY TRACT SEGMENTS

Anal sphincter atresia occurs rarely in piglets, causing rectal prolapse.

Atresia ani occurs quite commonly in pigs, sheep, and, to a less extent, in cattle. Affected animals may survive for up to 10 days and are identified by their depression, anorexia, colic, marked abdominal distension and lack of feces, feces being replaced by thick white mucus.[1] Abdominal distension in utero occasionally causes dystocia.[2] Surgical repair is possible in some cases but in others a large segment of rectum is missing and creation of a colonic fistula in the inguinal region is necessary. The condition is thought to be inherited in pigs and calves but supporting evidence is slim: the evidence is less clear still in sheep. A suggestion that the defect may be also associated with the manipulation of the fetus during pregnancy examination has not been supported.[2] A calf with atresia ani and diphallus and separate scrota has been described.

Inherited **atresia coli**, with complete closure of the ascending colon at the pelvic flexure, has been recorded in Percheron horses. A clinically similar defect in Overo horses, described in the section on pseudoalbinism, is in fact an aganglionosis. Death occurs during the first few days of life. The defect appears to be inherited as a simple recessive character.

Inherited **atresia ilei** has been recorded in Swedish Highland cattle. Affected calves manifest marked abdominal distension causing fetal dystocia. The distension is caused by accumulation of intestinal contents. Inheritance of a single recessive gene conditions the occurrence of the defect in some species and breeds but the prevalence may be higher than would be expected with that form of inheritance, especially in Jersey cattle with atresia coli.

Inherited defects of the circulatory system

BOVINE HEREDITARY DILATED CARDIOMYOPATHY

Bovine hereditary dilated cardiomyopathy is a group of progressive degenerative diseases of the myocardium causing conges-

tive heart failure.[1] At least three different types have been reported: dilatated cardiomyopathy in cattle of Canadian Holstein origin; cardiomyopathy in Japanese Black cattle; and, cardiomyopathy in Hereford cattle.

Pedigree analysis of 75 animals in three age classes and five diagnostic classes based on clinical and pathological findings using the Pedigree Analysis Package provided strong evidence for autosomal recessive inheritance of a single major gene responsible for the disease.[2] Pedigree analyses of affected animals in Canada, Japan, and Switzerland, revealed that the Holstein bull 'ABC Reflection Sovereign', the son of Canadian Holstein sire Montwick Red Apple Sovereign, as the common ancestor.[2] The disease in cattle is being used as a research model of human dilated cardiomyopathy.[3] Using proteomic analysis, the examination of tissue from younger that are genetically diseased but have not yet developed clinical disease, a number of proteins have been identified whose abundance is altered significantly to suggest a possible pathogenetic mechanism for the onset of the disease.[3]

The disease has now been reported in Denmark in the Red Danish Dairy breed, Holsteins, and Red Holsteins.[1,4] Pedigree analysis of 12 cases found both maternal and paternal relationship to the Canadian sire Monwick Red Apple Sovereign, and several sires were identified as carriers of the disease. These sires originated from breeding lines used to upgrade Danish cattle populations and pose a potential animal health problem. The introduction of the defect into the Danish cattle population is an example of how widespread a genetic disease can become in a short period of time. During their active life, two sires used for artificial insemination obtained a total of approximately 62 000 living progeny.

There can be a high incidence in certain herds, possibly associated with some unrecognized environmental precipitating factor but probably caused by autosomal recessive trait concentrated by a high coefficient of inbreeding.

There are three types recorded in cattle:

Type 1 calf – acute heart failure

Sudden death of Poll Hereford and horned Hereford[5] calves up to 3 months of age may be due to inherited cardiomyopathy. The calves are often identifiable before death by their very rapid growth rate, short curly coat, and moderate bilateral exophthalmos. Death is usually precipitated by stress or exercise and is characterized by dyspnea, the passage of bloody froth from the nose, and a course of a few minutes to a few hours. Less acute cases have a syndrome of congestive heart failure for several days before death. Life expectancy is less than 6 months. At necropsy there is an obvious patchiness of the myocardium, reminiscent of a bad case of white muscle disease. The disease appears to be conditioned by a single autosomal recessive gene.

Type 2 calf – pulmonary edema

A second form of inherited cardiomyopathy is recorded in Japanese Black cattle. Death is preceded by a brief period (a few minutes to a few hours) of agonizing dyspnea in calves aged 30 up to 120 days. At necropsy there is edema, ascites, hydrothorax, and marked dilatation of the left ventricle. This is matched by acute myocardial necrosis. A new autosomal recessive gene is credited with initiating the disease.

Type 3 – young adult congestive heart failure

This occurs in young adult cattle and has been reported in Holstein-Friesian cattle in Japan, Canada, the UK,[6,7] and Australia,[8] and in Simmental-Red Holstein crossbred[9] cattle and Black Spotted Friesian cattle in Switzerland. Similar family lines in Holstein breed have been identified in affected cattle in all three countries and it has been suggested that there is an inherited predisposition to cardiomyopathy in the Holstein breed.[8] Pedigree analysis of hereditary dilatated cardiomyopathy in Holstein-Friesian cattle in Japan suggests an association with hereditary myopathy of the diaphragmatic muscles.[10] The disease is endemic in Switzerland, occurring mainly in the Simmentaler x Red Holstein crossbreed of cattle.[3]

The disease occurs in cattle from 1.5 to 6 years of age with the peak prevalence in 3- and 4-year-old cattle. The stress of pregnancy and lactation may precipitate clinical disease and the majority of cases occur in late pregnancy or early lactation. The onset is sudden and the majority of cases have signs of congestive right heart failure. Edema of the submandibular area, brisket, ventral abdomen, and udder is prominent and there is venous engorgement, hepatomegaly, interstitial nephritis, pleural and pericardial effusion, and ascites. Muffling of the heart sounds, tachycardia, and a gallop rhythm are evident on auscultation of the heart. There is no characteristic biochemical or hematological change.[7]

Necropsy findings include congestive heart failure and histological findings compatible with congestive cardiomyopathy. There is dilation of the chambers of the heart, thickening or thinning of the ventricular wall, subcutaneous, mesenteric and pulmonary edema, hydrothorax, hepatomegaly, and ascites. Histologically there is fibrosis, myocardial degeneration, and vacuolation of cardiomyocytes and infiltration of mononuclear cells into the myocardium. In some cases, interstitial non-suppurative nephritis is present.[7] Electron microscopically, the sarcoplasm of the hypertrophic fibers is filled with fine structures of low electron-density, together with thin filamentous material, suggesting myofibillar lysis.[10]

Following introduction of an eradication program based on culling of carriers in the sire population, the incidence in Switzerland has decreased.[1]

INHERITED LYMPHATIC OBSTRUCTION

This defect has been recorded in Ayrshire and Hereford[1] calves. Males are more often affected than females; it has been suggested that some affected females may not be detected. The defect is inherited as a single, autosomal recessive character, with variable expressivity and incomplete penetrance.

The outstanding clinical feature is edema, the degree varying from slight to severe; severe cases causing dystocia to the point where embryotomy or cesarean sections is necessary. Some mortality occurs among the dams. Many calves are dead at birth and those born alive may be reared but the edema persists. Before parturition the cow may show evidence of hydrops amnii and have difficulty in rising. In calves the edema may be generalized or, more commonly, be localized to the head, neck, ears, legs, and tail. Drooping of the ears caused by increased weight is characteristic, and accessory lobes are commonly situated behind and at the base of the ears.

The edema is caused by a developmental abnormality of the lymphatic system. The lymph nodes are small and contain cystic dilatations and the lymphatic vessels are enlarged, tortuous, and dilated. Edema of the subcutaneous tissues and body cavities varies in degree; the skin is usually thickened and there is edema of the stomach wall.

INHERITED VENTRICULAR SEPTAL DEFECT

Ventricular septal defects are common in food animals; reports of their occurrence in lambs and Hereford cattle suggest that the condition can be inherited.

INHERITED AORTIC ANEURYSM

An inherited defect of the abdominal aorta, resulting in a high mortality from intra-abdominal hemorrhage, has been observed in an unidentified breed of cattle in Holland, and is an important feature in Marfan syndrome of humans.

BOVINE MARFAN SYNDROME

A model of human Marfan syndrome, this disease of cattle is an autosomal dominant disorder caused by mutations in the fibrillin-1-gene.[1] It is manifested primarily by cardiovascular lesions and signs, but lacks the skeletal abnormalities of the human disease.[2] Necropsy lesions include aortic and pulmonary artery aneurysm, with consequent cardiac tamponade in some cases. Fragmentation of elastic laminae in the vessels is also characteristic.[3]

INHERITED CONGENITAL PORPHYRIA

Synopsis

A congenital defect of porphyrin metabolism in cattle and swine characterized by excessive excretion of porphyrins in urine and feces and deposition of porphyrins in tissues, especially bones and teeth.
Photosensitization occurs in affected cattle.

ETIOLOGY

Congenital porphyria is similar to erythropoietic or Gunther's porphyria of humans. Most cases in cattle are due to the inheritance of a single recessive factor, heterozygotes being clinically normal. A deficiency of uroporphyrinogen III cosynthetase results in the accumulation of porphyrin type I isomers. Although there is no strict sex linkage in the mode of inheritance, the incidence is higher in females than in males. In pigs the pattern of inheritance is uncertain but may be due to one or more dominant genes.

EPIDEMIOLOGY

Porphyria is recorded only in cattle and pigs. Shorthorn, Holstein, Black and White Danish, Jamaica Red and Black cattle, and Ayrshires carry the defect.

There are no serious losses except that affected cattle suffer from incapacitating photosensitization when exposed to sunlight and must be kept indoors. In countries where sunlight hours are limited the disease may go unnoticed. Affected pigs appear to suffer little harm. Porphyria is of little economic importance because of its rarity.

PATHOGENESIS

The porphyrins are natural pigments but in these diseases they are present in larger than normal concentrations in the blood, urine, and feces. In porphyria the metabolic defect is one of abnormal synthesis of heme due to an enzymatic insufficiency at the stage of conversion of pyrrol groups to series 3 porphyrins. Excess series 1 porphyrins, physiologically inactive substances are produced as a result, and there is flooding of the tissues with these coloring and photosensitizing substances. The high tissue levels of porphyrins sensitize the skin to light and photosensitive dermatitis follows.

CLINICAL FINDINGS

In **cattle** the passage of amber to port wine colored urine, a pink to brown discoloration of the teeth and bones, and severe photosensitization are characteristic. Additional signs include pallor of the mucosae and retardation of growth.

Affected **pigs** are usually normal and photosensitivity does not occur, but the disease can be recognized by the red-brown discoloration of the bones and teeth, which is present even in the newborn.

CLINICAL PATHOLOGY

In porphyria the urine is amber to port wine in color when voided, due to the high content of porphyrins. The urine of affected cattle may contain 500–1000 µg/dL of uroporphyrins and 356–1530 µg/dL of coproporphyrins. The urine of normal cattle contains 1.84 µg/dL of coproporphyrins and no significant quantity of uroporphyrins. The color of the urine darkens to brown on exposure to light. Spectroscopic examination is necessary to identify the pigment as porphyrin. Erythrocyte survival time is reduced considerably. A macrocytic, normochromic anemia occurs and its severity appears to be related to the level of uroporphyrins in the erythrocytes, and there is evidence of a hemolytic anemia. Cattle with the highest erythrocyte uroporphyrin levels are also the most sensitive to sunlight.

NECROPSY FINDINGS

In porphyric animals the teeth and bones are stained brown or reddish purple, the pigment occurring chiefly in the dentine in teeth and often in concentric layers in the bones. Affected bones and teeth show a red fluorescence under illumination with ultraviolet light. The histological findings are unique to this disease.

DIFFERENTIAL DIAGNOSIS

Confirmation of the diagnosis depends on identification of greatly increased levels of porphyrins in the blood and urine.
Presumed affected cattle and pigs can be detected at birth by the discoloration of the teeth. Breeding trials are necessary to detect heterozygous, normal carrier animals.

Differential diagnosis list. Other causes of photosensitive dermatitis.

TREATMENT

Non-specific treatment for photosensitization may be necessary. Affected cattle should be reared indoors.

CONTROL

Elimination of affected carrier animals from the breeding program is the only measure available. Periodic examination of the urine and feces for excessive quantities of coproporphyrin is carried out on bulls used for artificial insemination in breeds in which the disease occurs.

Franco DA et al. Bovine congenital erythropoietic porphyria. Comp Cont Educ 1992; 14:822–825.

INHERITED ERYTHROCYTIC PROTOPORPHYRIA

Inherited erythrocytic protoporphyria is an autosomal recessive disease which occurs in Limousin[1] and Blonde d'Aquitaine[2] cattle. It is similar to the same disease in humans and to porphyria but is milder. There is deficient activity of the enzyme ferrochelatase, resulting in excessive photosensitizing protoporphyrin accumulation with high levels appearing in the erythrocytes and feces. The total amount of the enzyme is normal but up to 96% of it is non-functional.[3]

Protoporphyria is clinically differentiated from porphyria by the absence of anemia and discoloration of the teeth and urine. The major clinical abnormality is photosensitive dermatitis affecting particularly the tips of the ears and the edges of the nostrils. There may be intense pruritus and exudative dermatitis involving the head and upper aspect of the thorax.[4] The hematocrit values are within normal ranges, the teeth are normochromic, and there is no fluorescence of urine; however, whole blood fluoresces under ultraviolet light.[4] Protoporphyrin binds to proteins that are not excreted by the kidney and thus protoporphyrin will not be detected in the urine. In a Limousin calf, the disease was characterized by ataxia, and intermittent seizures.[5] At necropsy

there is hepatic portal fibrosis, bile ductule hyperplasia, and swelling of parenchyma cells. Phagocytic cells in the dermis contain large heterogeneous lysosomes.[6] Histologically, in some cases, the earliest lesions are moderate to severe acanthosis, hyperkeratosis, and parakeratosis with dermal angiofibroplasia. There may be intercellular edema, and intraepithelial vesicles and pustules.[4] Elimination of affected carrier animals from the breeding program is the only control measure available.

HEMOCHROMATOSIS

Hemochromatosis is rare in domestic animals.[1] This inherited defect of iron metabolism in humans has also been observed in yearling Salers cattle in circumstances in which an inherited etiology is suggested.[1,2] The pattern of inheritance is uncertain because of the small number of pedigrees available from affected cattle.[1] Hemochromatosis occurs when inappropriately large amounts of iron are absorbed from the intestine over an extended period. The excessive accumulation of iron causes iron-induced lysosomal injury and peroxidation by free radicals, which are the two major mechanisms responsible for hepatocellular necrosis and for sequelae such as fibrosis, bile duct hyperplasia, veno-occlusive disease, and hepatic neoplasia. Unlike hemosiderosis, hemochromatosis is associated with high transferrin saturation values in serum (>60%). Clinical disease develops between 9 and 22 months of age. Animals are normal until weaning but then lose weight, develop rough hair coats, and lose incisor teeth. The skeletal changes in hemochromatosis are due to abnormal bone development.[3] Bone analysis reveals iron levels in affected animals may be 30 to 50 times greater than normal and decreased percent ash in the outer cortex. Periosteal dysplasia and osteopenia are responsible for the pathologic fractures and tooth loss.[3]

At necropsy, there is emaciation, firm dark brown livers and lymph nodes, soft bones, and brown-colored small intestine.[1] The major histological changes are hepatocellular siderosis and periportal bridging, and perivenular fibrosis. Heavy deposits of iron in the liver, and deposits of hemosiderin are visible in liver tissue obtained by biopsy. Hepatic iron concentrations in clinically affected cattle range from 1500 to 10 500 wet weight (reference range for cattle = <300 g/g. Ultrastructurally, the heaviest intrahepatic deposition is in the hepatocyte. Iron in bone is associated with osteopenia.

FAMILIAL POLYCYTHEMIA

This inherited defect has been observed only in Jersey cattle. Attention is drawn to the presence of the disease by early calfhood deaths and a clinical syndrome including congestion of mucosae, dyspnea, and poor growth. Hematologically there is marked elevation of erythrocyte count, hemoglobin concentration, and packed cell volume. The disease appears to be a primary polycythemia inherited as a simple autosomal recessive.

INHERITED BLEEDING DISORDERS

Hemophilia

Hemophilia A (deficiency of factor VIII, or classic hemophilia) occurs in Thoroughbred, Standardbred, Arab, and Quarter horses,[1,2] causing uncontrollable bleeding after injury or surgery, or spontaneously. This may be manifested by the sudden appearance of swellings over joints or the upper cervical region causing dyspnea, or into joints or body cavities causing acute hemorrhagic anemia, and blood can be aspirated from them. The platelet-dependent bleeding time is normal but the fibrin-dependent bleeding time is markedly prolonged. The defect is genetically transmitted as a sex-linked recessive trait, appearing clinically only in males.

von Willebrand's disease has been identified in a Quarter horse which experienced bleeding episodes and a low blood level of vWF, after a normal platelet count and negative coagulation screening tests.[3]

Bovine factor XI deficiency

Factor XI (partial thromboplastin antecedent) is involved in coagulation but animals afflicted by a deficiency of it may be clinically normal even though their whole blood clotting time is very prolonged. Others may have a severe bleeding tendency but the frequency of hemorrhagic episodes with factor XI deficiency is very low.[4] Heterozygotes experience minor episodes, homozygotes may have serious ones, especially neonates, which may die at birth and be classified as uncomplicated neonatal mortality. Affected cows also experience an increase in repeat breeder problems, apparently associated with a slower luteolysis and the development of small graafian follicles.[5] Both males and females transmit the trait[6] which is inherited as an autosomal recessive.

Prekallikrein deficiency

Prekallikrein is necessary to activate factor XII in the coagulation process. An inherited deficiency of it is recorded in a family of Belgian horses,[7] as a cause of a bleeding tendency in the presence of the conventional coagulation factors. The deficiency is of the order of <1% of normal levels of 63–150%. The activated partial thromboplastin time is markedly prolonged.

Inherited thrombopathia

Thrombopathia causes uncontrolled bleeding in Simmental cattle.[8,9] Collected blood undergoes good clot retraction but platelet aggregation in response to adenosine diphosphate and collagen in a whole blood aggregation system is badly impaired. Clinical findings include epistaxis, hematuria, the sudden development of subcutaneous swellings, hemorrhagic anemia due to internal bleeding, or bleeding after external lacerations or surgery. Restriction of the problem to the Simmental breed suggests inheritance of a recessive trait. A study of the inheritance of the abnormality using embryo transfer technology and superovulating a donor cow which previously had a calf with platelet aggregation disorder found a very low incidence of the abnormality.[10] This suggests inheritance of the defect is not simple Mendelian recessive.

Afibrinogenemia (related diseases are hypofibrinogenemia, dysfibrinogenemia)

Afibrinogenemia is a rare cause of bleeding diathesis recorded in cattle, sheep, and goats, especially the newborn. Confirmation of the diagnosis and differentiation from the related diseases (above) requires sophisticated laboratory technology.[11]

INHERITED ANEMIAS

Inherited dyserythropoiesis and dyskeratosis (bovine congenital anemia, dyskeratosis, and progressive alopecia)

This disease occurs in 1–16-month old calves in some Poll Hereford families.[1] It is thought to be inherited as a simple autosomal recessive character.[2] Clinical signs commence at about 2 months of age and include skin lesions which commence on the face and neck, especially around the muzzle and along the edges of the ears, then extend in the midline down the back, then down the sides, and onto the limbs; the long hairs on the tail tip are shed.[3] The hyperkeratotic muzzle accumulates dust. The skin lesions comprise alopecia, with surviving hairs wiry, kinked or tightly curled, accumulations of sebum, and hyperkeratosis and marked wrinkling. The alopecia and hyperkeratotic dermatitis extend and the calves do not thrive, becoming small in stature, intolerant of exercise, susceptible to heat stress, and eventually pining away until they die or are euthanized. Histologically the skin is affected by dyskeratosis, hyperkeratosis, and orthokeratosis, and there are morphological abnormalities of the nucleus in erythroid precursors; anemia results from ineffective erythropoiesis. There is a persistent, nonregenerative anemia due to a failure of maturation of erythrocytes; the blood contains many nucleated erythrocytes, and bone marrow aspirates contain increased numbers of erythroid precursors.[1]

Inherited glucose-6-phosphate dehydrogenase enzyme deficiency

A single case of this persistent hemolytic disease has been recorded in a yearling American Saddlebred colt.[1] The disease in humans is well recognized as an inherited defect. A similar clinical disease is recorded in Murray Grey calves in Australia.[2] Signs are observed first when affected calves are 3–8 weeks old. Both sexes are affected. Signs include poor growth, exercise intolerance, progressive weakness, severe jaundice, and death. There is a severe regenerative anemia, hemoglobin levels of 25–30 g/L, and an absolute nucleated erythrocyte count of $9–18 \times 10^9$ L.

Necropsy lesions include jaundice, a grossly enlarged, in some cases misshapen, greenish liver, and brown urine. Histological lesions are suggestive of a persistent intravascular hemolysis. A series of cases of hemolytic anemia of undetermined origin, recorded in a familial pattern in horses, was characterized by high blood levels of methemoglobin.[3]

Inherited defects of the urinary tract

INHERITED NEPHROSIS (MESANGIOCAPILLARY GLOMERULONEPHRITIS)

An apparently inherited mesangiocapillary glomerulonephritis occurs in Finnish Landrace lambs less than 4 months old,[1] and in newborn Yorkshire pigs.[2] The lambs absorb an agent from the colostrum which causes an immunological response in the lamb and the deposition of immune complexes within the glomerular capillary walls. Many affected lambs are asymptomatic before being found dead. Some have tachycardia, conjunctival edema, nystagmus, walking in circles, and convulsions. Enlarged, tender kidneys are palpable, and there is severe proteinuria, low plasma albumin, hyperphosphatemia, hypocalcemia, and BUN levels greater than 100 μg/100 mL. Necropsy findings include pale swollen kidneys and severe vascular lesions in the choroid plexuses and the lateral ventricles of the brain. Uremia supervenes in 75% of lambs by 27 days of age. Cases also occur in crossbred lambs.

CHRONIC INTERSTITIAL NEPHRITIS

Chronic interstitial nephritis with diffuse zonal fibrosis (CINF) occurs in Japanese Black cattle (Wagyu) as an autosomal recessive disorder leading to death prior to puberty.[3] Clinically there is growth retardation between 3 and 5 months of age. A genome-wide scan using microsatellite markers in a Wagyu pedigree segregated for CINF, mapped the CINF locus to bovine chromosome 1.

INHERITED CYSTIC RENAL DYSPLASIA

Inherited, possibly conditioned by an autosomal dominant gene, this disease occurs in lambs sired by carrier Suffolk rams out of mixed ewes. Signs include recumbency and coma by days 2–3. Abortions and stillbirths occur in the same flocks at the same time. The kidneys are enlarged and cystic.[4]

INHERITED BILATERAL RENAL HYPOPLASIA

This usually lethal condition is inherited as an autosomal recessive character in Large White pigs.

INHERITED RENAL TUBULAR DYSPLASIA

This occurs in Japanese Black cattle.[5] Affected calves have intermittent diarrhea at 2 months of age, are unthrifty, behave sluggishly, have a rough hair coat, and overgrown hooves from 2 to 5 months of age. There is progressive renal failure, and a high level blood urea nitrogen and serum creatinine. However, appetites are almost normal or only slightly depressed. All affected calves have been sired by the same bull and the defect is due to an autosomal recessive trait.

At necropsy there are no gross lesions of the kidneys. Histologically, there are streaky masses of renal tubules without lumens. In calves over 3 months of age, there is interstitial fibrosis surrounding the abnormal tubules. It is suggested that the genes associated with the adhesion of epithelial cells, such as adhesion molecules, extracellular matrix components, and growth factors are abnormal in animals with renal tubular dysplasia. The causative gene (*rtd*) has been mapped to chromosome 1 by linkage analysis. A part of the *paracellin-1* gene, which encodes the renal epithelial tight junction protein is contained in the deletion and this deletion can be considered to be the cause of renal tubular dysplasia.[6,7] A DNA specific test for this mutation has been developed.[8]

INHERITED RENAL LIPOFUSCINOSIS IN DANISH SLAUGHTER CATTLE

Dark brown or black discolored kidneys ('black kidneys') have been reported as incidental findings in slaughter cattle for more than 100 years.[9] A pigment with characteristics similar to those lipofuscin is present in secondary liposomes in epithelial cells of the proximal tubules. Cases occurred only in Holstein cattle or the Red Danish Dairy Breed and mainly in animals aged 3 years or older. The prevalences of the abnormality were 0.44% and 2.51%, respectively. Epidemiological and genealogical analyses strongly indicate an autosomal recessive inheritance.

Inherited defects of the nervous system

INHERITED LYSOSOMAL STORAGE DISEASES

These are diseases in which there is a genetically determined deficiency of a specific lysosomal hydrolase enzyme causing a defective glycoprotein metabolism. As a result of the deficiency, metabolic substrates accumulate in the lysosomes. The lysosomes themselves are concerned with hydrolyzing polymeric material, which enters the vacuolar system, and converting it to monomeric units, such as amino acids, monosaccharides, and nucleotides, which can be dealt with by the better known metabolic processes.

There are other lysosomal storage diseases caused by poisonings and these are dealt with elsewhere. The best known ones are caused by poisoning with *Swainsona*, *Astragalus*, *Oxytropis*, and *Phalaris* spp. (the chronic form of that disease).

The diseases included in this section are not strictly diseases of the nervous system because the lysosomes in both **neuronal** and **visceral** sites are affected, but the effects of the disease are most obvious in terms of nervous system function.

MANNOSIDOSIS

Mannosidosis is the best known group of the inherited lysosomal storage diseases in agricultural animals.

α-Mannosidosis

This is a lysosomal storage disease in which a deficiency of the enzyme α-mannosidase results in the accumulation of a metabolite rich in mannose and glucosamine in secondary lysosomes in neurons, macrophages, and reticuloendothelial cells of lymph nodes, causing apparent vacuolations in them. Similar vacuoles are found in exocrine cells in pancreas, abomasum, and lacrimal and salivary glands. Storage appears to be cumulative in the fetus, but after birth stored material is lost from the kidney into the urine via desquamated tubular epithelium. On the other hand, postnatal storage continues in the brain, pancreas, and lymph nodes. The disease occurs in Angus, Murray Grey, and Galloway cattle, is inherited as a simple recessive, and is recorded as occurring in the United States, Australia, and New Zealand.

Clinically it is characterized by ataxia, fine lateral head tremor, slow vertical nodding of the head, intention tremor, an aggressive tendency, failure to thrive, and death or the necessity of euthanasia at about 6 months of age. These signs appear almost immediately after birth up to several months later and worsen over a period of up to 3–4 months. The signs are bad enough to require euthanasia during the first week of life in many cases.[1] The first sign observed is a swaying of the hindquarters, especially after exercise or with excitement. The stance becomes wide based and the gait jerky, stilted and high stepping, with slight overflexion of the hindquarters so that the animal appears to be squatting as it moves.

The nervous signs are exacerbated by excitement, diarrhea is common, and the calves are usually stunted and unthrifty. They are also aggressive and attempt to charge but are usually impeded by their incoordination. Many calves die after having shown general ill thrift and with minimal nervous signs. Death may occur due to paralysis and starvation, or to misadventure, and some calves appear to die during a 'fit' following a period of excitement. Many others are euthanized because of persistent recumbency. The nervous syndrome of mannosidosis is well known; affected calves will die. An α-mannosidosis is recorded in Galloway cattle and is manifested by stillbirth, moderate hydrocephalus, enlargement of the liver and kidneys, and arthrogryposis.

CLINICAL PATHOLOGY

Normal heterozygotes carrying genes for mannosidosis are identifiable because of their reduced tissue or plasma levels of α-mannosidase. The mannosidase test for α-mannosidase in goats is specific and does not cross-react with α-mannosidase.

Advances in molecular biology have now led to the development of a more accurate test based on DNA technology.[2] DNA tests based on the PCR have been developed for the detection of two breed-specific mutations responsible α-mannosidosis.[3] One of the mutations is responsible for α-mannosidosis in Galloway cattle. The other mutation is uniquely associated with α-mannosidosis in Angus, Murray Grey, and Brangus cattle from Australia. The latter mutation was also detected in ion Red Angus cattle exported from Canada to Australia as embryos. The two breed-specific mutations may have arisen in Scotland and by the export of animals and germplasm disseminated to North America, New Zealand, and Australia.[3]

CONTROL

A control program can be based on the identification of heterozygotes using the PCR based assays for detection of breed-specific mutations.[3] A program of screening cattle in herds which produce bulls for sale to commercial herds should stop the spread of the disease very quickly because the number of heterozygous females in the population will be irrelevant to the continuation of the disease in the absence of affected sires.

The α-mannosidosis gene prevalence is now insignificant and disease incidence has been reduced from an estimated 3000 cases/year to neglibile levels.[2]

β-Mannosidosis

β-mannosidosis occurs in Salers cattle[4] and Anglo-Nubian goats[5] and has been recorded in a sheep. In the **cattle** some affected calves are stillborn. The remainder is euthanized forthwith because of the severity of the congenital defects.

CLINICAL FINDINGS

All cases are affected at birth with craniofacial deformity and inability to stand. The cranium is domed and there is mild prognathism, narrow palpebral fissures, and a tough, hidebound skin. When in sternal recumbency the head is moved in a combined motion of circling and bobbing, eventually converting the calf to lateral recumbency, in which it remains until passively returned to the sternal position, where nystagmus and tremor become evident. There is no suck reflex at any time. In lateral recumbency there is opisthotonos and paddling convulsions.

CLINICAL PATHOLOGY

The diagnosis is confirmed by a reduced level of β-mannosidase in the blood.

NECROPSY FINDINGS

Include a deficiency of cerebral cortical and cerebellar substance, distended lateral ventricles, and bilateral renomegaly. The biochemical defect is one of acidic β-mannosidase,[6] and is conditioned by an autosomal recessive character. The carrier rate of the causative gene is very high in the Saler breed.[7]

DIFFERENTIAL DIAGNOSIS

By the biochemical examination of ultrasound-guided fetal fluid aspiration at between 59 and 65 days of pregnancy in ewes and goat does is accurate but not without the risk of causing abortion.[8]

In the goats the condition is present at birth and characterized clinically by tetraplegia, tremor, deafness, and nystagmus, and an inexorably fatal termination. Additional signs include bilateral Horner's syndrome, carpal contractures, pastern joint hyperextension, thickened skin, and a dome-shaped skull. Although retinal ganglion cells are obviously badly affected, there appears to be no defect of vision.[5] It is an autosomal recessive defect, very similar to α-mannosidosis.

GANGLIOSIDOSES

At least five types of gangliosidosis are known to occur in humans and animals. Two have so far been identified in agricultural animals.

GM_1 gangliosidosis

GM_1 gangliosidosis occurs in cattle and sheep. In Friesian cattle it is inherited as an lysosomal storage disease in which the activity of an enzyme, β-galactosidase, in nervous tissue is greatly reduced. As a result there is an accumulation of the ganglioside (GM_1) in the tissue. Clinical signs of progressive neuromotor dysfunction and a reduction in growth rate appear at about 3 months of age. The growth rate is reduced, and the animal is in poor condition, blind, and has a staring coat. The neuromotor signs include lack of response to external stimuli, sluggish mastication and swallowing, hindquarter sway while walking, a wide stance, a tendency to fall, reluctance to move, stiff high-stepping gait, aimless walking, head-pressing, and convulsions. Abnormal ECG tracings are common. The blindness results from lesions in the retina and the optic nerve. Ophthalmoscopic examination of the retina is recommended as an aid to diagnosis. A positive diagnosis is made on the grounds of intraneuronal lipid storage plus reduced β-galactosidase activity plus identification of the stored lipid. The stored ganglioside is visible under the electron microscope as stacks and concentric whorls of lamellae. In the live animal enzyme assays are carried out on leukocytes. The enzymatic defect is also detectable in liver, skin, and leukocytes.

The disease is also present in Suffolk and Suffolk-cross sheep. Visceral and neuronal lysosomal storage are both evident but the neuronal lesion is more severe. Deficiencies of β-galactosidase and α-neuraminidase are evident. Affected sheep become ataxic at 4–6 months old and worsen to recumbency and death in up to 2 months.

GM_1 gangliosidosis has been reported from England in 'Coopworth Romney' lambs closely related to a ram imported from New Zealand.[1]

GM_2 gangliosidosis

This has been identified in Yorkshire pigs and also causes decreased growth rate, incoordination appearing after 3 months of age, gray-white spots in the retina and dark blue granules in neutrophils, and azurophilic granules in lymphocytes. A serum enzyme assay is a suitable method of detecting 'carrier' heterozygous pigs. The test is based on the amount of *N*-acetyl-β-D-hexosaminidase in tissues.

CEROID LIPOFUSCINOSIS

The ceroid-lipofuscinoses are a group of inherited storage diseases, inherited as autosomal recessive traits. They are grouped together because of common clinical and pathological phenomena related to brain and retinal atrophy, premature death, and accumulation of a fluorescent lipopigment in neurons and many other cell types within the body.

The disease is recorded in South Hampshire sheep,[1] Rambouillet sheep,[2,3] Borderdale sheep,[4] Merino sheep,[5] Nubian goats, and Devon cattle.[6] It resembles neuronal ceroid lipofuscinosis of humans and is not strictly a primary lysosomal disorder; it is classified as a proteolipid proteinosis, and provides a good animal model for discussing the similar disease (Batten's disease) of humans. It is inherited as an autosomal recessive trait.[7] Secondary lysosomes fill with subunit C of mitochondrial ATP synthase because of excessive peroxidation of polyunsaturated fatty acids.[8] The mechanism of the accumulation is that protein is formed which is normal for mitochondria but is misdirected so that it accumulates in the lysosome.[9] The brains of affected lambs grow till they are 4 months old, then they commence to atrophy.[10] The disease in Merino sheep is a subunit c-storing abnormality, clinically and pathologically similar to ceroid-lipofuscinosis in South Hampshire sheep.[5] The South Hampshire form of the disease maps to chromosome 7q13-15, which is synthetic with human chromosome 15q21-23, the site of human CLN6.[1]

The occurrence of a neuronal ceroid-lipofuscinosis in Borderdale sheep in New Zealand has been described.[4] The severity of neurodegeneration and minor differences in the ultrastructure of storage material suggests this is a different disease from other forms of ovine ceroid-lipofuscinosis which accumulate subunit-c of mitochondrial ATP synthase.[4] An autosomal recessive mode of inheritance is considered probable.

Clinical findings include slowly progressive ataxia of the hindlimbs, commencing usually at about 4 months but possibly as late as 18 months of age, and lasting for 6 months leading to euthanasia at up to 4 years. Inability to keep up with the flock is noticed first, followed by a sawhorse stance, obvious ataxia, severe depression, and an increasing failure of the menace and pupillary light reflexes. Terminal blindness is a constant sign. Positional nystagmus, circling, and head pressing occur in some. Eating, drinking, and defecation are normal, but there is slight weight loss.[11]

The lesion in lambs and calves[12] is atrophy of the cerebrum, especially the optic cortex, with eosinophilic granulation of neurons and macrophages in the central nervous system followed by progressive retinal atrophy. There is a progressive storage of lipopigment in nervous tissue, especially retinal photoreceptors; its presence can be demonstrated by quantitative autofluorescence using a modified slit lamp microscope.[11] Other clinicopathological aids include lysosomal enzyme assay, organ biopsy, and computed tomography, which reveals the enlargement of the lateral ventricles of the brain resulting from cerebral atrophy.[12]

Neuronal ceroid lipofuscinosis has been described in three horses.[13] Clinically, there was developmental retardation, slow movements and loss of appetite at 6 months of age. Torticollis, ataxia, head tilt, and loss of eyesight were present at 1 year of age. There were abnormalities in posture and movements, decreased spinal reflexes, and some cranial nerve dysfunction, dorsal strabismus, and absence of the menace reflex. At necropsy, there was flattening of the gyri and discoloration of the brain. Histologically, eosinophilic, autofluorescent material in the perikarya of neurons were present throughout the brain, spinal cord, neurons of the retina, submucosa, and myenteric ganglia and in glial cells.

GLOBOID CELL LEUKODYSTROPHY (GALACTOCEREBROSIDOSIS)

Globoid cell leukodystrophy has been identified in Poll Dorset sheep in Australia[1]. Incoordination in the hindlimbs progresses until the animals are tetraplegic. Only histological changes are evident at necropsy. These include myelin destruction and the accumulation of characteristic globoid cells in nervous tissue. There is greatly decreased galactocerebrosidase activity in affected tissue.

INHERITED NERVOUS SYSTEM ABIOTROPHIES

These diseases are characterized by premature, progressive loss of nervous function due to spontaneous, late degeneration of nervous tissue. As a result most affected animals are born normal but develop signs of a progressive neurological disease that is either fatal or leads to such a serious neurological deficit that euthanasia is the only reasonable solution. In a few rare diseases the patient is abnormal at birth but worsens, and usually dies, during the neonatal period. Again there are exceptions and rare cases in calves recover completely. The genetic nature of some of the cases included may not be certain; they are included here if the evidence that they are inherited can be reasonably presumed. The lysosomal storage diseases, listed in the preceding section, are a specific group of abiotrophic diseases.

REVIEW LITERATURE

de Lahunta A. Abiotrophy in animals, a review. Am J Vet Res 1990; 54:65–76.

CEREBELLAR ABIOTROPHY

This disease occurs in Holstein and Poll Hereford cross[1] calves, pigs, and Merino sheep.

Cattle

In the calves ataxia appears for the first time when they are 3–8 months old. The calves are not blind but they often fail to exhibit a menace reflex. The onset of clinical signs is sudden but progression is slow or inapparent. Some become recumbent. Those that remain standing have a spastic, dysmetric ataxia, and a broad-based stance; they fall easily and have a fine head tremor. All are strong and have good appetites. Abiotrophy, or premature aging, is evident only microscopically and consists of axonal swellings and segmental degeneration and loss of cerebellar Purkinje cells. The disease appears to be inherited, but recovery of some late cases is recorded.

Sheep

The disease in sheep does not appear until about 3 years of age. There is incoordination and dysmetria so that the gait is awkward and disorganized and there is frequent falling. There are also a reduced menace response, an apprehensive manner, and a wide-based stance in the hindlimbs. At necropsy there is diffuse cerebellar degeneration and severe loss of Purkinje cells.

Pigs

A congenital progressive cerebellar abiotrophy is also reported in piglets of the offspring of Saddleback sows and an unrelated Large White boar. The disorder behaves epidemiologically like an inherited disease conditioned by a simple autosomal recessive trait. Clinical signs include dysmetria, ataxia, and tremor at standing but not at rest. There is gradual adjustment so that the piglets can walk and stand at 5 weeks of age but by 15 weeks they are no longer able to do so. Affected pigs also have a coarse matted hair coat caused by a disproportionate number of coarse hairs to fine hairs. Histopathological lesions are confined to the cerebellum where there is a significant loss of Purkinje cells.

Horses

The disease is recorded principally in Arabs but occurs also in the Australian pony, which was developed from the Arab, and in the Gotland breed from Sweden. A similar clinical syndrome occurs in the Oldenberg breed but the pathological picture is quite different.

The disease may be present at birth but is often not observed until the foal is 6–9 months old. The characteristic signs are vertical head-nodding (some cases show horizontal head tremors), especially when excited, and ataxia which is most noticeable at a fast gait. It may not be evident while the foal is walking. Very badly affected foals are unable to stand or suckle at birth, less severe ones are normal until about 4 months of age when head-nodding becomes obvious. The degree of ataxia varies from slight incoordination to inability to stand. A 'goose-stepping' gait which slams the front feet into the ground occurs in some. All foals can see but there is an absence of the menace reflex in many. Nystagmus is not recorded as occurring in this disease.

Necropsy findings are limited to histopathological lesions in the cerebellum. These include widespread loss of Purkinje cells and the presence of a gliosis. There are no degenerative lesions in the spinal cord. In the similar disease in Oldenberg horses the cerebellum is often reduced in size. The disease is an abiotrophy, a premature aging of tissues.

There have been doubts about the heritability of the disease but analysis of European data confirms that it can be inherited as an autosomal recessive.[2]

Familial convulsions and ataxia, especially of Angus cattle, is an abiotrophy and on histopathological criteria belongs in this group, but because it is usually present at birth it is included, for ease of diagnosis, in the section on congenital cerebellar defects.

CAPRINE PROGRESSIVE SPASTICITY

A possibly inherited progressive paresis of Angora goats is recorded in Australia.[1] Signs first appear at about 2 months of age, commencing with lethargy, followed by ataxia, then paresis progressing to sternal recumbency and eventual euthanasia. Tendon reflexes are normal but the kids have difficulty getting to their feet, especially in the hindlimbs. The gait is ataxic with frequent stumbles, and the kids are unwilling to run. At necropsy there are many large, clear vacuoles in many neurons of the spinal cord, posterior brainstem and midbrain, and degeneration of nerve fibers in the same areas and peripheral nerves.

INHERITED NEURODEGENERATION (SHAKER CALF SYNDROME)

This is an inherited, degenerative disorder of horned **Hereford** calves. Newborn calves show severe tremor, difficulty in rising, spastic gait, and aphonia. Terminally there is spastic paraplegia. Histologically there are accumulations of neurofilaments within neurons. A similar disease in **Holstein-Friesians** occurs only in males. There are severe degenerative changes in the spinal cord with spongiform lesions and some cavitation. It has the epidemiological distribution of a sex-linked recessive mutation.[1]

INHERITED PROGRESSIVE DEGENERATIVE MYELOENCEPHALOPATHY (WEAVER SYNDROME)

The defect is inherited in Brown Swiss cattle. It appears first in calves when they are 6 months to 2 years old with a small number more than 2 years, and is manifested by progressive bilateral hindlimb weakness and proprioceptive deficits causing difficulty in rising and a weaving, hypermetric gait, goose stepping with the forelimbs, and dragging the hindlimbs. The limb reflexes are normal. The calves are bright and alert throughout. There is a broad-based stance and finally recumbency[1] and, after a course of 12–18 months, inevitable euthanasia. Necropsy lesions include axonal degeneration, including spheroid formation, and vacuolation of white matter in the cerebellum and at all levels of the spinal cord[2] but especially in the thoracic segment.[3] There is some neurogenic atrophy of muscles but there is no muscular dystrophy.[4] The defect can be identified by examination of chromosomes.[5] The defect appears to be linked chromosomally with high milk yield traits.[6]

INHERITED SPINAL DYSMYELINATION

Bovine spinal dymyelination is a congenital neurological disease occurring in several national cattle breeds upgraded with American Brown Swiss cattle.[1] The disease was first described in Red Danish Dairy breed. In Denmark, all cases are genetically related to the ABS bull White Cloud Jason's Elegant. It is inherited as an autosomal recessive trait. Genetic mapping of the gene in cross-bred American Brown Swiss cattle to the bovine Chromosome II has been done.[1]

Clinically, in calves there is lateral recumbency, opisthotonos, limb extension, normal to increased reflexes and mental alertness and by dysmyelination, including axonal degeneration and astrogliosis, in spinal tracts, especially the ascending gracile funiculus and dorsolateral spinocerebellar tracts and the descending sulcomarginal tract.[2,3] This is probably the same defect as spinal muscular atrophy.

INHERITED PROGRESSIVE ATAXIA

This well-recognized disease occurs in Charolais cattle.[1] The first onset of signs is at about 12 months of age when the gait is seen to be stiff and stumbling, especially in the hindlimbs, and the hind toes are dragged. The ataxia may be asymmetric, and the animal cannot back up. The ataxia progresses over a period of 1–2 years. Affected animals tend to be down a lot and have difficulty in rising and posturing for urination. Urination is abnormal, being a squirting but continuous flow which soils the tail. Some affected animals nod their heads from side to side when excited. Both males and females are affected. It has been described occurring in 2-year-old Charolais steer in New Zealand.[1] Characteristic necropsy lesions are confined to the central nervous system and are histopathological. The white matter of the cerebellum and internal capsule contains multiple foci of oligodendroglial dysplasia. The somatic lymph nodes contain nodules of hyperplastic lymphoid follicles, some catarrh of the medullae of the nodes, and an accumulation of eosinophils.

INHERITED SPINAL DYSRAPHISM

This is found as a congenital defect in Charolais calves, and is associated with arthrogryposis and cleft palate.

INHERITED SPINAL MYELINOPATHY

There is a progressive spinal myelinopathy of Murray Grey cattle, similar to that seen in Charolais cattle. It is possibly genetic in origin. Some calves are affected at birth; others do not become affected until 1 year old. The syndrome is one of a progressing paresis, without significant ataxia leading to paresis and permanent recumbency. There are degenerative lesions in spinal cord, midbrain, and cerebellum. The disease is conditioned by an autosomal recessive gene.[1,2]

INHERITED MULTIFOCAL SYMMETRICAL ENCEPHALOPATHY

Two forms of the disease are recorded, in **Simmentals**[1] and in **Limousin** and Limousin-cross cattle.[2] The Limousin calves are normal at birth but from about 1 month of age develop a progressive forelimb hypermetria, hyperesthesia, blindness, nystagmus, weight loss, and behavioral abnormalities, especially aggression. The signs gradually worsen for up to 4 months when euthanasia is necessary. Necropsy lesions include brain swelling, optic chiasma necrosis, and multifocal, symmetrical areas of pallor, up to 0.5 cm diameter in the brain. These lesions show partial cavitation and multiple, pathological abnormalities especially myelin lysis and vacuolation and demyelination.[3] The distribution of cases suggests an inherited defect.

The disease in Simmental and Simmental-cross cattle recorded in Australia and New Zealand[4] also has a distribution suggesting an inherited defect. The disease is clinically similar to that in Limousin cattle except that affected animals are not blind and it develops later, 5–8 months; calves may survive longer, up to 12 months and, although the characteristic abnormality of gait is hypermetria, the hindlimbs are affected, not the forelimbs. Other signs observed are dullness, a swaying gait and, terminally, gradually developing opisthotonos and forelimb hypertonia in extension. Necropsy lesions are also similar to those in the Limousins but the distribution is in the midbrain and the entire brainstem.[5]

A multifocal symmetrical necrotizing encephalomyelopathy in Angus calves has been described.[6] Clinically calves exhibited ataxia, nystagmus, strabismus, muscular tremors, opisthotonus, bruxism, hyperaesthesis, tetanic spasms, and episodic convulsions at 2–6 weeks of age. Death occurred 4–7 days after the onset of clinical signs. Lesions consisted of symmetrical degenerative foci affecting the dorsal vagal motor, lateral cuneate and olivary nuclei in the medulla oblongata and occasionally in the spinal cord, substantia nigra and cerebellar peduncles. While an inherited basis for the disease is suspected, the etiology is unknown.

INHERITED BOVINE DEGENERATIVE AXONOPATHY

Reported in Holstein-Friesian calves in Australia,[1] most affected calves are affected at birth by recumbency, hyperesthesia or depression, rigidity of limbs, tremor, especially of the head, nystagmus, apparent blindness, and the development

of opisthotonos and tetanic spasms when stimulated. At necropsy the consistent lesion is a severe, diffuse, axonal swelling and loss in the spinal cord and brainstem. The cause is unknown but the indicators point to heredity.

INHERITED OVINE DEGENERATIVE AXONOPATHY (NEURAXONAL DYSTROPHY)

A heterogeneous group of diseases of genetic or acquired etiology is characterized by spheroidal swellings of axons, the result of accumulation of axoplasmic organelles including neurofilaments.[1]

This is reported in Suffolk, Merino, and Coopworth[2] sheep. An inherited defect is suspected in all three diseases.

In **Coopworths** the lambs are affected at birth but have a progressive syndrome in which cerebellar and proprioceptive signs predominate. Most die by 6 weeks of age. Large axonal spheroids are present in the spinal cord and midbrain, and there is a severe depletion of Purkinje cells in the cerebellum.

In **Suffolks** the disease does not appear until 1–6 months; signs are a gradual onset of ataxia, followed by recumbency, leading to death or euthanasia. Spheroids in central nervous system axons are characteristic, mostly in the spinal cord and cerebellum.

The disease in **Merinos** is in fine-wool sheep, is probably the same disease as that previously called **Murrurrundi disease**, and does not appear until 4–6 years of age. Most cases require to be euthanized after about 2 months but some mild cases survive for up to 3 years. The clinical signs include a wide-based stance, dysmetria of all limb movements with a pronounced hypermetria of the forelimbs resulting in frequent falling, a fine intention tremor of the head, and a diminished menace reflex. A similar disease of medium-wool Merinos, characterized by progressive posterior ataxia and degeneration of sensory tracts in thoracic segments of spinal cord, commencing after 5 months of age and terminating fatally before 2 years of age, is also recorded in Australia.[3] The probability is that it is also an inherited defect.

INHERITED SPONTANEOUS LOWER MOTOR NEURON DISEASE

This progressive disease of Yorkshire piglets 5–10 weeks of age is presumed to be inherited.[1] Clinical signs include hindlimb tremor, weakness, and ataxia appearing at 2–5 weeks of age. The gait includes fetlock knuckling, short choppy steps, and a tendency to collapse after a few steps. Segmental and postural reflexes are normal. By 10 weeks there is complete hindlimb paralysis, the pig is in sternal recumbency and front limb paralysis has begun. The appetite is good and the pig is bright and alert. On necropsy there is symmetrical degeneration and loss of motor neurons in the spinal cord, in some ventral spinal nerve roots.

A lower motor neuron disease in newborn Romney lambs has been described.[2] Lambs are normal at birth but within 1 week they developed weakness and ataxia, which progressed until they were unable to stand. The principal histological lesions were degeneration and loss of neurons in the ventral horns of the spinal cord and brain stem, Wallerian degeneration of ventral rootlets and motor nerves, and associated denervation atrophy of skeletal muscle fibers. Large fibrillar spheroids were found in white and gray matter including nuclei in the brain stem. A similar, though not identical, disease of newborn lambs has been recorded in a Dorset Down flock affecting about 20% of lambs. They lay with hindlimbs tucked under the body and forelimbs splayed sideways.

INHERITED MAPLE SYRUP URINE DISEASE (BRANCHED CHAIN KETOACID DECARBOXYLASE DEFICIENCY – BCKAD)

Calves affected by this disease may be stillborn. Live calves are normal at birth and develop signs only at 1–3 days of age. It is inherited as an autosomal recessive and occurs principally in Poll Hereford, Hereford, and Poll Shorthorn[1] cattle but probably occurs also in other breeds.[2] There is molecular heterogeneity between the breeds, and tests based on detection of the mutation could be prone to error.[3] Hair roots are good sources of target DNA for genotyping cattle for the mutation. This avoids the errors created by hemopoietic chimerism when blood is used for the test.[4] The disease is caused by an accumulation of branched chain amino acids – including valine, leucine, and isoleucine – due to an absence of branched chain ketoacid decarboxylase.[5] The mutation responsible for maple syrup urine disease in Poll Shorthorns and genotyping Poll Shorthorns and Poll Herefords for the maple syrup urine disease alleles has been determined.[6] The mutations responsible for maple syrup urine disease and inherited congenital myoclonus are present in the Australian Poll Hereford population.[7]

Clinical signs include dullness, recumbency, tremor, tetanic spasms and opisthotonos, a scruffy coat, blindness, and severe hyperthermia. When held in a standing position some calves have tetanic paralysis, others have flaccid paralysis. Terminal coma is followed by death after a course of 48–72 hours. The urine smells of burnt sugar.

At necropsy there is a characteristic severe spongiform encephalopathy similar to that found in comparable hereditary aminoacidurias in humans. Final identification can be made based on the elevated ratios of branched:straight chain amino acids in nervous tissue.[8]

INHERITED CITRULLINEMIA

This autosomal recessive disease is inherited in Australian Holstein-Friesians, USA Holsteins,[1] and Red Holsteins in Europe.[2] A previous report of a high incidence of the disease in a German Holstein herd has been refuted by a negative result in the breed in a wide-ranging survey.[3]

Affected calves are normal at birth but develop signs in the first week of life and die 6–12 hours after the onset of illness. The signs are depression, compulsive walking, blindness, head-pressing, tremor, hyperthermia, recumbency, opisthotonos, and convulsions. Arginosuccinate synthetase deficiency is the likely cause. Blood citrulline levels are of the order of 40–1200 times normal and the assay can be used to detect heterozygotes.[4] The alternative method of detecting heterozygotes is to use a polymerase chain reaction, a restriction endonuclease test designed to identify the mutation that causes the disease.[5] Prenatal diagnosis has been achieved by examination of cell cultures derived from amniotic fluid.[6]

EQUINE DEGENERATIVE MYELOENCEPHALOPATHY

Equine degenerative myeloencephalopathy is characterized by **symmetrical, slowly progressive spasticity and ataxia** in foals and horses less than 2 years of age. The disease occurs in most breeds in North America and Europe and is reported in captive zebra and Mongolian Wild Horses in North America.[1,2] Neuronal dystrophy of the cuneate and gracilus nuclei is considered a form of equine degenerative myeloencephalopathy.[3]

The prevalence of the disease varies widely, with up to 40% of susceptible animals on a farm being affected, although the disease is usually sporadic. There is a familial predisposition to the disease apparently involving an increased requirement for vitamin E, although other factors, including housing, are contributory.[4–7]

The pathogenesis of the disease is unknown. Abnormal expression of integral synaptic vesicle, synaptic vesicle-associated presynaptic plasma membrane and cytosolic proteins was observed in two Arabian horses with equine degenerative myeloencephalopathy.[8] These proteins have a role in trafficking, docking, and fusion of neuronal synaptic vesicles, and this finding suggests that there is disruption of axonal transport in equine degenerative myeloencephalopathy.[8] Loss of axons leads to defects in neurological function and consequent gait abnormalities.

The clinical signs are those of a slowing progressive spinal ataxia that stabilizes when the animal is 2–3 years of age. Affected foals and yearlings have symmetrical signs that are most severe in the hind limbs, of ataxia characterized by pivoting, circumduction, truncal sway, and difficulty performing complex movements such as backing or walking with the head elevated. At rest, severely affected horses may have an abnormal posture. The cutaneous trunci reflex may be absent. Spontaneous recovery does not occur, but progression to death is unusual. Radiography and myelography of the cervical spine does not reveal evidence of compression of the spinal cord.

Serum vitamin E concentrations may be normal or low. The hemogram, serum biochemical profile, and cerebrospinal fluid analysis are normal. There are no gross lesions on necropsy. Histological lesions include neuronal atrophy, accumulation of lipofuscin-like pigment, and glial cell proliferation.

Differential diagnoses are listed in Table 36.1. Diagnosis is achieved by exclusion of other causes, of abnormal gait without fever or disease in other body systems in horses, such as compressive myelopathy and equine protozoal myeloencephalopathy.

No treatment is curative, but vitamin E (6000 IU orally once daily) may prevent progression of signs. Supplementation of at-risk foals and yearlings with vitamin E can prevent the disease.[2]

INHERITED CONGENITAL HYDROCEPHALUS

Cattle

Congenital hydrocephalus without abnormality of the frontal bones occurs sporadically but is also known to be an inherited defect in Holstein and Hereford and possibly in Ayrshire and Charolais cattle. Two specific inherited entities have been described. In one there is obstruction to drainage of the cerebrospinal fluid from the lateral ventricles which become distended with fluid and may cause bulging of the forehead, often sufficient to cause fetal dystocia. Hereford calves with this defect have partial occlusion of the supraorbital foramen, a domed skull, and poorly developed teeth; at necropsy the cerebellum is found to be small and there may be microphthalmia and skeletal muscle myopathy. They are usually born a few days prematurely, are small in size and unable to stand or suck. In some cows the amniotic fluid is increased in volume.

Another form of inherited hydrocephalus due to malformation of the cranium and with no enlargement of the cranium has also been observed in Hereford cattle. The ventricular dilatation is not marked, and microphthalmia and cerebellar hypoplasia are not features. Affected calves may be alive at birth but are blind and unable to stand. Some bawl continuously and some are dumb. They do not usually survive for more than a few days. At necropsy there is internal hydrocephalus of the lateral ventricles with marked thinning of the overlying cerebrum. Other lesions include constriction of the optic nerve, detachment of the retina, cataract, coagulation of the vitreous humor, and a progressive muscular dystrophy. The condition is inherited as a recessive character.

Internal hydrocephalus inherited in combination with multiple eye defects in White Shorthorns is dealt with elsewhere, as are non-inherited forms of the disease.

Sheep

A defect comparable to the Dandy–Walker syndrome in humans and characterized by internal hydrocephalus caused by obstruction of the foramina of Magendie and Lushka occurs in several breeds of sheep, especially Suffolks,[1] and in cattle. Affected lambs are stillborn or die within a few hours of birth; because of the grossly enlarged cranium many cause dystocia which can only be relieved by a fetotomy.

Pigs

Congenital hydrocephalus in Yorkshire and European pigs has been recorded. The abnormality varies from a small protrusion of dura (meningocele) to an extensive brain hernia in which the cerebral hemispheres protrude through the frontal suture, apparently forced there by increased fluid pressure in the lateral and third ventricles. The condition is thought to be inherited in a recessive manner, but exacerbated in its manifestation by a coexisting hypovitaminosis-A. An outbreak of congenital meningoencephalocele in Landrace pigs is recorded in circumstances suggesting that it was inherited.

Horses

A Standardbred stallion sired a number of hydrocephalic foals in a pattern that suggested the inheritance of a dominant mutation in the germ line and in the form of a single locus defect.[2] Affected foals caused dystocia and were all stillborn.

INHERITED PROSENCEPHALY

Recorded in Border Leicester sheep, this defect takes the form of fusion of the cerebral hemispheres and a single lateral ventricle. It is widespread in the breed in Australia[1] and is inherited as an autosomal recessive character. Most affected lambs are stillborn. Live ones have dyspnea due to gross shortening of the nasomaxillary region creating a severely overshot mandible and interference with sucking. Blindness, nystagmus, and recumbency are constant signs. The cerebrum and the cranial cavity are much smaller than normal.

REFERENCE

1. Roth IJ et al. Aust Vet J 1987; 64:271.

INHERITED HYDRANENCEPHALY AND ARTHROGRYPOSIS

The defect is recorded in Corriedale sheep, and breeding trials indicate that it is inherited as an autosomal recessive character.[1] Most affected lambs are found dead but facial deformity, including shortening of the mandible and distortion of the facial bones will be evident. At necropsy the predominant finding is the fixation and deformity of the joints of the limbs and vertebral column, and the almost complete absence of a cerebral cortex.

INHERITED CONGENITAL CEREBELLAR DEFECTS

Several inherited cerebellar defects occur congenitally in calves, lambs, and foals. Lesions of the cerebellum may or may not be obvious. They all need to be differentiated from similar defects known to be caused by intrauterine viral infections such as swine fever, bovine mucosal disease, and bluetongue.

Cerebellar hypoplasia

This occurs in Herefords, Guernseys, Holsteins, Shorthorns, and Ayrshires and appears to be conditioned by a factor inherited in a recessive manner. Most calves are obviously affected at birth. While lying down there is no marked abnormality, although a moderate lateral tremor of the neck occurs, causing a gentle side-to-side swaying of the head. Severely affected calves are blind; they have widely dilated pupils and their pupils do not react to light. Such calves are unable to stand, even when assisted, because of flaccidity of limb muscles. When less severely affected animals attempt to rise the head is thrown back excessively, the limb movements are exaggerated in force and range and are grossly incoordinated, and many calves are unable to rise without assistance. If they are placed on their feet the calves adopt a straddle-legged stance with the feet wide apart and the legs and neck extended excessively. On attempting to move, limb movements are incoordinated and the calf falls, sometimes backwards because of overextension of the forelimbs. Affected animals drink well but have great difficulty in getting to the teat or pail, attempts usually being wide of the mark. There are no defects of consciousness and no convulsions. Tremor may be evident while standing and there may be postrotational nystagmus after rapid lateral head movements. Sight and hearing are unimpaired and, although complete recovery does not occur, the calf may be able to compensate sufficiently to enable it to be reared to a vealing weight. Diagnosis can be confirmed by magnetic resonance imaging.[1]

At necropsy the most severe defect comprises complete absence of the cerebellum, hypoplasia of the olivary nuclei, the pons and optic nerves and partial or complete absence of the occipital cortex. Less severe defects include a reduction in size of the cerebellum and absence of some neuronal elements in a cerebellum of normal size.

Although the disease is dealt with generally as an inherited one there is no firm evidence to substantiate this view, and there are sporadic, non-inherited cases in other breeds.

Cerebellar atrophy of lambs (daft lamb disease 1)

This has been recorded in many sheep breeds in Britain, Corriedales in Canada and New Zealand, and in Drysdales.[2] Affected lambs are normal at birth but are weak and unable to rise without assistance. At 3 days of age it is obvious that there is severe incoordination of limb movement, opisthotonos, tremor, and a straddle-legged stance. At necropsy the cerebellum may be of normal size but on histological examination there is gross atrophy of cerebellar neurons. The disease appears to be conditioned by a recessive gene but not as a simple homozygous recessive. A clinically similar disease has been observed in Border Leicester lambs. There is no histopathological lesion in the cerebellum, but there are significant lesions in the cervical muscles and the nerve supply to them. The disease is inherited, most likely as an autosomal recessive trait.

Star-gazing lambs (daft lamb disease 2)

An hereditary disease clinically similar to cerebral cortical atrophy has been described in newborn Leicester lambs in the UK but without histological evidence of Purkinje cell loss or reactive changes, considered the hallmark of 'cerebellar cortical atrophy'. Affected lambs exhibit 'dorsal arching of the neck with the head being pressed backwards', which has is also described as 'star-gazing'. Histological lesions are present in neck muscles and nerves but it is uncertain if these are primary or secondary.

Inherited ataxia of calves

This is a true cerebellar ataxia inherited as a recessive character in Jerseys, Shorthorns, and Holsteins. Clinically the condition resembles cerebellar hypoplasia except that signs may not occur until the calves are a few days to several weeks old. At necropsy the cerebellum is normal in size but histologically aplasia of neurons is evident in the cerebellum and also in the thalamus and cerebral cortex. An inherited condition, manifested by cerebellar ataxia which does not develop until calves are 6 weeks to 5 months old, has also been recorded but the cerebellum is small and macroscopically abnormal. Conspicuous degeneration of cerebellar Purkinje cells is evident on histological examination.

Cerebellar abiotrophy

This fourth disease in this group is described under the heading of abiotrophies.

Familial convulsions and ataxia in cattle

A neurological disease is recorded as being inherited in Aberdeen Angus cattle and their crossbreds and Charolais. In young calves there are intermittent attacks of convulsions, and in older animals these are replaced by a residual ataxia. The first signs appear within a few hours of birth; up to several months later there are single or multiple tetanic convulsions lasting for 3–12 hours. As these episodes disappear a spastic goose-stepping gait becomes apparent in the forelimbs and there is difficulty placing the hindlimbs. The characteristic necropsy lesion is a very selective cerebellar cortical degeneration. A proportion of cases make a complete recovery.[3] The epidemiology of the disease is consistent with the operation of an autosomal dominant gene with incomplete penetrance.

Inherited congenital spasms of cattle

This condition has been recorded only in Jersey cattle and appears to be conditioned by a factor inherited in a recessive manner. Affected calves show intermittent, vertical tremor of the head and neck, and there is a similar tremor of all four limbs which prevents walking and interferes with standing. Although the calves are normal in all other respects, they usually die within the first few weeks of life. No histological examinations have been reported but a cerebellar lesion seems probable.

INHERITED SPASTIC PARESIS (ELSO HEEL)

This disease occurs in the Holstein, Aberdeen Angus, Red Danish, Ayrshire, Beef Shorthorn, Poll Hereford, Murray Grey, and many other breeds of cattle. It has been observed in crossbred Brahman

cattle[1] and in an Ayrshire x Beef Shorthorn crossbred steer. The disease occurs principally in calves, with signs appearing from several weeks to 6 months or more after birth. Occasional cases are reported as developing in adult European cattle and there is one report of the occurrence of the disease in adult Indian cattle.

It has been held for a long time that the disease is inherited, and the principal argument has centered on the mode of inheritance. Attempts to determine this have shown that the rate of occurrence in planned test matings is so low that, if inheritance is involved, it can only be the inheritance of a susceptibility to the disease. It is suggested that different time appearances represent a single disease entity with varying expressivity, the late forms being affected by cumulative environmental factors. A hypothesis proposed is of a gene with increased penetrance in the homozygote, with weak penetrance in the heterozygote, acting on a polygenic basis dependent on external factors.[2,3] Infectious agents causing transmissible sub-acute spongiform encephalopathies interacting with trace elements such as lithium have been suggested as etiological agents but there is no evidence to support the hypothesis.[3]

In all forms of the disease there is excessive tone of the gastrocnemius muscle and straightness of the hock, usually more marked in one hindleg. If only one leg is affected it may be thrust out behind while the calf is walking and advanced with a restricted, swinging motion often without touching the ground. There is no resistance to passive flexion of the limb. The gastrocnemius and perforatus muscles are rigid and in a state of spastic contraction. There is a characteristic elevation of the tail. The lameness becomes progressively worse and affected animals spend much time lying down. Much body weight is lost and the animal is usually destroyed between 1 and 2 years of age.

Minor lesions described as regressive changes in the neurons of the red nucleus, in the reticular substance and the lateral vestibular nucleus are of doubtful significance, as are the observed reduction in inorganic phosphate and ascorbic acid levels in the blood and cerebrospinal fluid of affected calves. A lower CSF concentration than normal of a central neurotransmitter, dopamine, could also be an effect rather than a cause.

There are demonstrable lesions on radiologic examination of the tarsus but exhaustive examinations of muscles and tendons fail to reveal histological abnormalities. The absence of any structural lesion and the variation in intensity of the abnormality suggests that it is a functional one. The hypersensitivity of the myotic reflex which has been observed could be such a defect.

In Europe affected animals are kept for breeding purposes, especially if they are double-muscled. They are kept for this reason because of the efficacy of the curative surgical operation of partial tibial neurectomy and in view of the high incidence of double muscling in such calves. In the Holstein breed, and several German breeds, bulls which sire affected calves have been observed to have very straight hocks and to suffer from various forms of stifle and hock lameness early in life.

Several surgical techniques including tenectomy, partial tibial neurectomy, and triple tenectomy have been described.[2] Partial tibial neurectomy under caudal epidural anaesthesia was done on 113 Belgian blue calves with spastic paresis.[2] A telephone follow-up of the owners 3 months later revealed good results in 83%; a considerable improvement in 4.4%; and severe hyperflexion of the hock necessitated early culling for slaughter; and in 8% there was little or no improvement.[2]

INHERITED PERIODIC SPASTICITY OF CATTLE

This disease has been observed in Holstein and Guernsey cattle and usually does not appear until the animals are adults. A recent report described it in a Canadian Hereford bull with an early onset between 1 and 2 years of age.[1] It is a particular problem in mature bulls maintained in artificial insemination centers. In the early stages the signs are apparent only on rising, the hindlimbs being stretched out behind and the back depressed. Marked tremor of the hindquarters may be noted. Initially the attacks persist only for a few seconds but are of longer duration as the disease progresses and may eventually last for up to 30 minutes. Movement is usually impossible during the attacks. The tetanic episodes fluctuate in their severity from time to time but there is never any abnormality of consciousness. Lesions of the vertebrae have been recorded but no lesions have been found in the nervous system. Idiopathic muscle cramps have been suggested as a cause. The disease is familial and the mode of inheritance appears to be by inheritance of a single recessive factor with incomplete penetrance.

Administration of the spinal cord depressant, mephenesin (3–4 g/100 kg body weight given orally in 3 divided doses and repeated for 2–3 days) controls the more severe signs. A single course of treatment may be effective for some weeks.

INHERITED NEONATAL SPASTICITY

The defect is recorded in Jersey and Hereford cattle. Affected calves are normal at birth but develop signs 2–5 days later. The signs commence with incoordination and bulging of the eyes and a tendency to deviation of the neck causing the head to be held on one side. Subsequently, the calves are unable to stand and on stimulation develop a tetanic convulsion in which the neck, trunk, and limbs are rigidly extended and show marked tremor. Each convulsion is of several minutes' duration. Affected calves may survive for as long as a month if nursed carefully. There are no gross or histological lesions at necropsy. Inheritance of the defect is conditioned by a single, recessive character.

INHERITED CONGENITAL MYOCLONUS (HEREDITARY NEURAXIAL EDEMA)

This congenital defect of the nervous system has been reported only in Poll Hereford cattle or their crossbreds and appears to be transmitted by inheritance in an autosomal recessive pattern. A similar disease has been tentatively recorded in Peruvian Pasos horses.[2] At birth affected calves are unable to sit up or rise and are very sensitive to external stimuli, manifested by extreme extensor spasm, including fixation of thoracic muscles and apnea, especially if lifted and held upright. The response is one of hyperesthesia with myoclonic jerks of skeletal muscles in response to external stimuli or spontaneously.[3] The intellect of the calves seems unaffected, vision is normal, they drink well, and can be reared but at a great cost in time. Intercurrent disease is common and calves usually die of pneumonia or enteritis before they are 1 month old.

All affected calves have subluxations of the hip joints or epiphyseal fractures of the femoral head caused by muscle spasms in the fetus. Their gestation length is shorter than that of normal calves by 9 days.

There are no microscopic lesions in the central nervous system, but there is a biochemical defect, severe alterations in spinal cord glycine-mediated neurotransmission.[4] The specific and marked defect in glycine receptors and the increase in neuronal

uptake of glycine are accompanied by a change in the major inhibitory system in the cerebral cortex. It has also been shown that there is a specific and marked deficit of [^{3}H] strychnine-binding sites in the spinal cord. The disease needs to be differentiated from two other congenital, presumed hereditary, diseases of newborn Herefords – maple syrup urine disease and 'congenital brain edema' – in which spongy degeneration of the CNS is accompanied by severe edema of the gray and white matter. These two diseases are assumed to represent those cases of congenital disease, originally bracketed with inherited congenital myoclonus, in which there was vacuolation of nervous tissue in the central nervous system.

INHERITED CONGENITAL POSTERIOR PARALYSIS

Two inherited forms of congenital posterior paralysis are recorded in cattle. In Norwegian Red Poll cattle posterior paralysis is apparent in affected calves at birth. Opisthotonos and muscle tremor are also present. No histological lesions have been found. The disease is conditioned by an inherited recessive factor. In Red Danish and Bulgarian Red cattle a similar condition occurs but there is spastic extension of the limbs, particularly the hindlimbs, and tendon reflexes are exaggerated. Histological examination has revealed degenerative changes in midbrain motor nuclei. Both defects are lethal because of prolonged recumbency.

An inherited posterior paralysis has been recorded in several breeds of swine in Europe. Affected pigs are able to move their hindlimbs but are unable to stand on them. They are normal in other respects. Degeneration of neurons is evident in cerebral cortex, midbrain, cerebellum, medulla, and spinal cord. The disease is conditioned by the inheritance of a recessive character. An inherited progressive ataxia is also recorded in Yorkshire pigs.

INHERITED CONGENITAL MYOTONIA

This disease has been observed in goats and possibly in a horse. Because of its great similarity to Thomsen's disease (myotonia congenita) of humans, affected goats have been used in experimental studies to determine the nature of the disease. There is no apparent defect of the nervous system and the condition is thought to be due to abnormality of the muscle fibers. The specific defect is thought to be one of generalized cell membrane abnormality including muscle fibers. Affected animals run when startled but quickly develop extreme rigidity of all four limbs and are unable to move. Relaxation occurs in a few seconds and the animal can then move again. Signs are not usually present until some time after birth and may vary from day to day for no apparent reason. They tend to diminish immediately before and after parturition. Clinical signs disappear when water is withheld from affected goats for 2–3 days but reappear when drinking is permitted. The disease is inherited but the mode of inheritance is unknown.

INHERITED HYPOMYELINOGENESIS (CONGENITAL TREMOR OF PIGS)

Congenital tremor of pigs has a multiple etiology and some of the causes are not yet identified. For this reason the disease as a whole is dealt with in Chapter 36. The inherited diseases are noted here. There are two of them, congenital tremor type A-IV of British Saddleback pigs, and congenital tremor type A-III, a sex-linked inherited form of cerebrospinal hypomyelinogenesis of Landrace pigs. The A-IV disease is characterized by the presence of poorly myelinated axons in all parts of the central nervous system. The specific defect in A-IV is one of fatty acid metabolism. The structural abnormalities in the A-III disease have been identified; splayleg is a common accompaniment.

Both diseases are characterized by muscle tremor, incoordination, difficulty in standing, and some squealing. The A-III disease occurs only in males. Both are inherited as recessive characters.

EXOPHTHALMOS WITH STRABISMUS

This disease has been recorded in Shorthorn, in which it is not manifested until the first pregnancy or lactation, in Jerseys, in which it may appear at 6–12 months of age, and in German Brown Swiss.[1] Defective vision is the first sign and is followed by severe protrusion and anteromedial deviation of both eyeballs. The defects may get worse over a long period and appear to be inherited in a recessive manner, with relative absence of neurons in the abducens nerve.

REFERENCE

FAMILIAL UNDULATORY NYSTAGMUS

This is an inherited defect of Finnish Ayrshire cattle characterized by a tremor-like, synchronous movement of the eyeballs. The tremor has small amplitude (1–2 mm) and fast (200/min) rate and is usually vertical. It is present at all times, there is no sign of impaired vision, and the eye reflexes are normal. The condition is a blemish rather than a disease because there is no functional deficiency.

INHERITED IDIOPATHIC EPILEPSY OF CATTLE

Idiopathic epilepsy has been reported as an inherited condition in Brown Swiss cattle and appears to be inherited as a dominant character. Typical epileptiform convulsions occur, especially when the animals become excited or are exercised. Attacks do not usually commence until the calves are several months old and disappear entirely between the ages of 1 and 2 years.

FAMILIAL NARCOLEPSY

Affected horses, including Shetlands, Miniature Horses,[1] and Suffolks, suffer recurrent episodes of several minutes duration during which they fall and lie motionless, without voluntary or involuntary movements except respiratory and eye movements. Between episodes there is no clinical abnormality. Handling or the excitement of feeding may precipitate an attack, and a sharp blow may terminate one.

DODDLER CALVES

This is an inherited congenital defect in Hereford cattle produced by intensive breeding of half-siblings. It is no longer recorded. It was characterized by continuous clonic convulsions, nystagmus, and pupillary dilatation. Stimulation by touch or sound exacerbated the convulsions.

Inherited defects of the musculoskeletal system

INHERITED DISEASES OF BONES

INHERITED OSTEOARTHRITIS

There are strong indications from field evidence that both **degenerative arthropathy**, in which the hip joint is principally involved, and **degenerative osteoarthritis**, affecting particularly the stifle joint, are inherited in cattle. In both diseases other factors, particularly nutritional deficiency and the stress of lactation, exert an

important influence on the appearance of the clinical disease, and in **degenerative arthropathy**, described in the chapter on nutritional deficiency diseases, there is no clear evidence that it is in fact inherited. On the other hand there is good evidence that osteoarthritis can be inherited, at least in Holstein-Friesian and in Jersey cattle.

In inherited degenerative osteoarthritis, in which the stifle joints are most severely affected, there is usually a gradual onset of lameness in both hindlimbs in aged animals of both sexes. Occasionally only one limb appears to be involved. Progression of the disease takes place over a period of 1–2 years and is evidenced by failure to flex the limb, resulting in the foot not being lifted high from the ground. Crepitation in the stifle joint can be heard and felt, the muscles of the limb atrophy, and the joints are enlarged. Movement is slow, the hindlimbs at rest are placed further forward than normal, the stifles are abducted and the feet held together. Joint fluid can be aspirated and is clear and straw-colored. Appetite and milk yield remain normal until the late stages, except in cattle running at pasture.

At necropsy there is severe osteoarthritis involving particularly the stifle, with extensive erosion of the articular cartilages, great increase in synovial fluid, and the development of many osteophytes around the edges of the articular surfaces. Less severe changes are evident in other joints. It is suggested that the disease is conditioned by the inheritance of a single autosomal recessive character.

INHERITED OSTEOGENESIS IMPERFECTA

The term osteogenesis imperfecta covers a heterogeneous group of connective tissue diseases caused by quantitative or qualitative defects in Type 1 collagen.[2]

The disease is recorded as being inherited in Holstein-Friesian cattle and New Zealand Romney sheep.[1]

Cattle

It is transmitted as an autosomal dominant trait. Calves are clinically abnormal at birth with the main presenting signs being bright pink teeth and slackness of the flexor tendons on all four feet so that they are unable to stand. The calves become progressively worse to the point where they cannot walk. The full list of abnormalities in this syndrome includes smaller than normal body size at birth, a dome-shaped cranial vault, and fragility of bones, manifested by multiple fractures occurring during birth. The defect is one of connective tissue cells so that there is a faulty production of collagen and intercellular cement. Radiological examination demonstrates growth-arrest lines and multiple fractures in the long bones, and thin dentine and enamel layers on the teeth which are pink because of the exposed condition of the enlarged pulp. The excessive mobility of the joints results from the small bulk of the ligaments and tendons.

A syndrome of simple bone fragility occurs in Charolais cattle and is called osteogenesis imperfecta.

Sheep

The disease in New Zealand Romney sheep[2] is similar to that in Holstein-Friesian cattle with additional lesions of thickness of the diaphyses and reduction in size of the medullary cavity, moderate brachygnathia inferior, subcutaneous edema, skin fragility, and a dark blue color of the sclera. It is inherited as an autosomal dominant trait, and was thought to have developed as a new mutation in the testicular cell line of the parent ram.[2]

INHERITED DWARFISM

Most inherited food animal dwarfs are chondrodysplastic; they occur commonly only in cattle and are of two kinds, snorter dwarfs and Dexter bulldog calves.

Snorter dwarfs

Snorter dwarfs are no longer important because of successful efforts in eliminating carriers of the gene. These calves are short-legged with short, wide heads and protruding lower jaws. The mandibular teeth may protrude 2–4 cm beyond the dental pad, preventing effective grazing and necessitating hand-feeding if the animal is to survive. There is protrusion of the forehead and distortion of the maxillae, and obstruction of the respiratory passages results in stertorous respiration and dyspnea. The tip of the tongue usually protrudes from the mouth and the eyes bulge. There is some variation between affected animals in their appearance at birth. In most cases the defects are as described above but they become more exaggerated as the calf grows. In addition abdominal enlargement and persistent bloat develop. The head is disproportionately large. The calves fail to grow normally and are about half the weight of normal calves of the same age.

The predominant form of the condition appears to be inherited as a simple recessive character, although the relationship of the 'comprest' types to the total syndrome is more complex. Heterozygotes vary widely in conformation but some of them show minor defects which may be attractive to cattle breeders who were seeking a chunkier, short-legged type of animal. For this reason, indiscriminate selection towards the heterozygote undoubtedly occurred, resulting in widespread dissemination of the character. Herefords and Aberdeen Angus are the breeds most commonly affected but similar dwarfs occur also in Holstein and Shorthorn cattle, and typical dwarf animals have been produced by mating heterozygous Aberdeen Angus and Herefords. Besides the shortness of limbs there is also a looseness of attachment of limbs and abnormal mobility of joints.

Bovine chondrodysplastic dwarfism in Japanese brown cattle is an autosomal recessive defect with the phenotype of short limbs, joint abnormality, and ateliosis.[1] Long bones of affected animals have insufficient endochondrial ossification with irregularly arranged chondrocyte, abnormal formation of cartilaginous matrix, and partial disappearance of the epiphyseal growth plates. The gene *LBN* is the causative gene for bovine chondrodysplastic dwarfism.[1] The bovine fibroblast growth factor receptor 3 (*FGFR3*) gene is not the locus responsible for the defect.[2]

Inherited congenital achondroplasia with hydrocephalus

First recorded as **bulldog calves** in Dexter cattle, this inherited defect has since been observed in a variety of forms in other breeds, including Jerseys, Guernseys, Holsteins, and Japanese Brown cattle.[3] Chondrodysplasia in the Holstein-Friesian breed sharing morphological features with the Dexter bulldog calves have been reported from the United States, the Netherlands, Great Britain, and recently in Denmark.[4] Dexter bulldog type calves have occurred in French and Danish Holstein calves in a familial pattern related to the sire Igale Masc, and it is likely that the genetic disorder is present in the Holstein breed worldwide.[4]

Characteristic features of lethal chondrodysplasia (Dexter bulldog) calves in Australian Dexter cattle include abortion, disproportionate dwarfism, a short vertebral column, marked micromelia, a relatively large head with retruded muzzle, cleft palate and protruding tongue and a large abdominal hernia.[5] Histological changes in limb bones are consistent with failure of endochondral ossification. Dexter chondrodysplasia is considered to be inherited in an incompletely dominant manner with the homozygous form producing the congenital lethal condition. Based on analysis of the contribution of

three obligate heterozygotes whose semen has been widely used in artificial insemination in Australia, it is estimated that the heterozygote frequency is 19% within the registered Australian Dexter herd.[5]

Affected calves are often aborted but some reach full term and cause fetal dystocia because of the extreme hydrocephalus. The forehead bulges over a foreshortened face with a depressed, short nose. The tongue protrudes, the palate is cleft or absent, the neck is short and thick, and the limbs are shortened. Accompanying defects are fetal anasarca and hydrops amnii in the dam.

The defect is primarily chondrodystrophy rather than achondroplasia; the nasal bones and maxillae do not grow. Hydrocephalus develops because of the deformed cranium. In most breeds the condition is inherited as a simple recessive character but a dominant form has occurred in Jerseys. The heterozygous form in Dexters is easily recognized by the shortness of the limbs. The heterozygote in other breeds is normal in appearance.

Miscellaneous dwarfs

Other types of dwarfs have been described and include **'comprest'** and **'compact'** cattle in Herefords and Shorthorns and various other forms of **proportional dwarfs**. For example, in Charolais, miniature calves that are exact replicas of normal calves but weigh only 5–16 kg at birth and are born 2 or more weeks prematurely, have been recorded. Most are dead at birth or die soon after so that the condition is effectively lethal. Proportional dwarfs occur also in Simmentals.

Other forms of chondrodystrophy, including 'bulldog calves' and one which causes fatal nasal obstruction in the German Black Spotted breed of cattle, have also been recorded. In the latter there are multiple deformities of limb bones and the condition appears to be inherited due to the influence of a single recessive gene.

Dwarf lambs occur sporadically. The best known is the mutant **Ancon** which has appeared and disappeared three times, with one incidence in New Zealand and one in the United Kingdom. The defect is chondrodysplasia and the lambs are not viable.

CONGENITAL OSTEOPETROSIS

This inherited defect is recorded in Aberdeen Angus calves which are stillborn and undersized. The major manifestations are shortening of the mandible with protrusion of the tongue, impaction of the lower molars, a patent fontanelle, and the characteristic lesion of shortness of the long bones and absence of a marrow cavity in them. The absence of the marrow cavity, caused by defective remodeling of the bone, gives it a homogeneous shaft leading to the colloquial name of 'marble bone'. Radiographic examination makes antemortem diagnosis simple. It is considered to be an autosomal recessive trait. It is reported also in foals but there is doubt about its genetic origin in that species.

INHERITED PROBATOCEPHALY (SHEEPSHEAD)

This defect is inherited in Limousin cattle. The cranial bones are deformed so that the head resembles that of a sheep. The accompanying defects in heart, buccal cavity, tongue, and abomasum increase the chances of an early death.

INHERITED ATLANTO-OCCIPITAL DEFORMITY

(See Congenital defects of the nervous system).

INHERITED AGNATHIA

Partial or complete absence of the mandibles with ventral displacement of the ears is common in sheep and is categorized as a lethal recessive because the sheep are unable to graze properly.

INHERITED DISPLACED MOLAR TEETH

Inherited as a simple recessive character this defect usually results in the death of affected calves within the first week of life. The six premolars of the lower jaw are impacted or erupted in abnormal positions, often at grotesque angles. The mandible is shorter and narrower than normal. There is no abnormality of the incisors or upper jaw.

INHERITED JAW MALAPPOSITION

Defective apposition of upper and lower incisors, or lower incisors and dental pad in ruminants may result in inefficient grazing and malnutrition. Abnormal protrusion of the mandible (mandibular **prognathism**) is of most importance in ruminants and there is good evidence that abnormal length of the mandible is inherited. Amongst British breeds of **cattle** the defect is more common in beef than in dairy breeds. In Herefords and Angus the inheritance is thought to be conditioned by a single recessive gene.

Brachygnathia, underdevelopment of the mandible, has also been recorded in Dairy Shorthorn, Jersey, Holstein, Ayrshire, and Simmental cattle, with the defect so severe in some cases that the animals are unable to suck. In Angus brachygnathia can occur linked to a generalized degenerative joint disease, in which all joint surfaces are involved. Affected animals, detected at a few days to 4 months of age, are not viable.[1] Inheritance of the defect is probably conditioned by a recessive gene.

A less severe degree of **brachygnathia** has been recorded in Merino and Rambouillet **sheep**. The mode of inheritance is suggested to be by the interaction of several pairs of genes.

Mandibular prognathism occurs as a part of other more general defects including achondroplastic dwarfism and inherited displaced molar teeth.

Brachygnathia is also seen in **horses**.[2] The defect is present at birth but is often not apparent until much later.

INHERITED CRANIOSCHISIS (CRANIUM BIFIDUM)

The disease occurs in a number of pig breeds, but has been shown to be inherited only in Poland China pigs and their crossbreds. There is a deficit in the cranial bones and meningoceles or encephaloceles may result. The pigs are not viable. Genetic experiments have shown the inheritance to be of a recessive character with varying penetrance.

Many single cases of cranial and spinal deformity in farm animals have been likened to the human Arnold–Chiari malformation but a specific syndrome of protrusion of the medulla oblongata and the cerebellum through the foramen magnum into the spinal canal has not been identified in a hereditary context in these species.

INHERITED CRANIOFACIAL DEFORMITY

The defect is incompatible with life. One form in Border Leicester lambs is characterized by a variable degree of nasomaxillary hypoplasia, often associated with incomplete cerebral development with less pronounced sulci and gyri than normal. It appears to be inherited in a simple autosomal recessive mode. A similar lethal defect is recorded in Angus cattle (as brachygnathia superior) in association with generalized degenerative joint disease.[1]

Cyclops anomaly occurs sporadically without known cause, but attracts attention when it is part of an inherited, prolonged gestation syndrome when it is often the cause of the investigation being mounted.

INHERITED ARACHNOMELIA (INHERITED CHONDRODYSPLASIA)

Cattle

This suspected inherited disease of Simmental, Brown Swiss, Italian Brown calves,[1] and other European breeds of cattle is manifested by excessively long, thin, distal extremities which give the calves a spidery look, hence arachnomelia. The bones are very fragile, there is curvature of the spine, foreshortening of the mandible, and associated cardiac and vascular defects. In Swiss Braunvieh cattle it is combined with arthrogryposis.[2] It is thought to be inherited as a simple recessive.

Sheep

Spider lamb syndrome

A hereditary chondrodysplasia is recorded in Suffolk and Hampshire lambs[3] in which the limbs are thin, disproportionately long, and have abnormal positions of the bones about the joints causing abnormalities of posture. There is also less muscle than normal. In severe cases the deformities are obvious at birth and may be lethal. In less severe cases the deformities do not become apparent until the lambs are several weeks old. The defects are readily visible in X-rays before clinical signs develop, and affected lambs can be detected in this way. The diagnostic lesion is multiple irregular islands of ossification in the upper limb joints.[4] Spinal deformities, especially kyphoscoliosis, and cranial deformities including a roman nose, deviation of the nose poll axis, and shortening of the mandible are observed in some lambs. Inheritance by an autosomal recessive gene with complete penetrance and variable expressivity has been established as the cause in Suffolks.[5] The defect is thought to be one of deficiency of an insulin-like growth factor (IGF) and IGF-binding proteins.[6] Differentiation from arthrogryposis-hydranencephaly is important because of the superficial similarity of the two diseases.

Inherited chondrodysplasia in Texel sheep

A chondrodysplasia resulting in a dwarfing phenotype has occurred in a Texel sheep flock as a newly recognized recessively inherited genetic disease of the Texel breed.[7] Affected lambs appear normal at birth but show evidence of dwarfism, wide-based stance and exercise intolerance as early as 1 week of age. Death usually occurs within 3 months, often after developing bilateral varus deformity of the forelimbs. Some severely affected lambs die with respiratory distress, probably due to tracheal collapse. Gross and microscopic lesions of variable severity were present in the tracheal, articular, epiphyseal, and physeal cartilage. In severe cases, articular cartilage in major joints was eroded from weight-bearing surfaces. The trachea was flaccid, abnormally kinked, and had thickened cartilaginous rings and a narrow lumen. Affected sheep which survived to breeding age commonly developed severe degenerative joint disease. Histologically, chondrocyte were disorganized, surrounded by concentric rings of abnormal fibrillar material and the matrix often contained focal to coalescing areas of chondrolysis. The disease has considerable potential as a suitable model for studying various forms of therapy for human chondrodysplasia.

COMPLEX VERTEBRAL MALFORMATION IN HOLSTEIN CALVES

A lethal congenital defect of the axial skeleton of purebred Holstein calves has been reported in Denmark,[1] the United States,[2] and in the UK which are not carriers of the CVM gene.[3,4] It is caused by a mutation in the gene *SLC35A3* coding an uridine-diphosphate-*N*-acetylglucosamine transporter. A single-base transversion of guanine to thymine has been located in the abnormal allele at postion 559.[5] It is present in both copies of the allele and the mutation is lethal. It is a simple recessive genetic defect which requires that both the sire and the dam of an affected calf are carriers.

Most affected calves are born between day 250 and 285 of gestation. Approximately 80% of homozygous affected fetuses are aborted before gestation day 260.[6] Birth weights are reduced. Most affected calves are stillborn, but affected calves occasionally are born alive. Euthanasia must be performed for humanitarian reasons.

In premature, stillborn, and neonatal affected calves, the defect is characterized by congenital growth retardation, malformed vertebrae, and tetramelic arthrogryposis.[1,5,7] There is shortening of the cervical and thoracic parts of the vertebral column due to multiple hemivertebrae, fused and misshaped vertebrae, and scoliosis. Growth retardation and vertebral malformation are typical lesions. Malformation of the head, primarily in the form of dysplasia or palatoschisis, also occurs.

Symmetrical flexures of the carpal and joints and the metacarpophalangeal joint in combination with a slight lateral rotation of the phalanges are also present. Similar low-grade arthrogryposis are present in the pelvic limbs. Heart defects were present in 50% of affected calves (interventricular septal defects, dextroposition of the aorta, and eccentric hypertrophy of the right ventricle).[1]

Retrospective genotyping of affected calves according to the mutation in the *SLC35A3* gene, and there were homozygous affected, heterozygotes, and homozygous normal.[5] The morphological expression of the malformation is wide but certain aspects such as growth retardation, vertebral malformation, and symmetrical arthrogryposis are almost constant findings. A presumptive diagnosis of the malformation can be made in most cases based on necropsy findings combined with pedigree analysis and genotyping.[5] Breeding studies were carried out in Denmark using selected cows that were progeny of sires with a heterozygous genotype for the malformation, and were pregnant after insemination with semen from another sire with heterozygous malformation genotype. The number of calves born with the malformation was less than expected suggesting increased intrauterine mortality.[7] Fertility traits in Holsteins are severely affected by the malformation phenotype of the fetus.[6] If the fetus is homozygous for the malformation, 29% of the cows will abort before gestation day 100 increasing to 45% at day 150, and 77% at day 260. Non-return to service rates, frequency of calvings after the first insemination, and interval from insemination to next calving were significantly reduced by a fetal malformation phenotype.

Pedigree analysis and DNA analyses of semen from sires used for insemination have found a widely branched familial occurrence of the malformation in the Holstein breed.[5] The mutation in the *SCL35A3* gene has been traced to the US sire Penstate Ivanhoe Star born in 1963 and his widely used son Carlin-M Invanhoe Bell born in 1974. The malformation mutation is not restricted to

descendants of the American Holstein Friesian bull-Carlin-M Ivanhoe Bell. Through these sires and elite sires genetically related to them, the defect has been disseminated in the Holstein breed worldwide. Using a hair root sample from the dam of the calf, a DNA test is available. Testing is available on registered or registerable Holstein animals only through the Holstein Association (Holstein USA) or through one of the National Association of Animal Breeders' member AI organizations or at the Van Haeringen Laboratorium, Wageningen, The Netherlands. A PCR test is being developed.[8]

INHERITED ACROTERIASIS (AMPUTATES)

Patients affected by this deformity, e.g. 'mole' calves of the Danish Black and White breed, are characterized by shortened and malformed limbs, especially the extremities which are sometimes missing altogether. In male calves there is also hydrocephalus, hypoplasia of the mandible, and absence of part of the face. The body is edematous. Many are aborted during the latter part of pregnancy. The deformity is conditioned by a single recessive gene.

INHERITED REDUCED PHALANGES (AMPUTATES, ACROTERIASIS, ECTROMELIA)

This defect has been recorded in cattle and appears to be inherited as a single recessive character. The limbs are normal down to the metacarpal and metatarsal bones, which are shorter than usual, but the first two phalanges are missing and the normal hooves and third phalanges are connected to the rest of the limb by soft tissues only. The calves are unable to stand but can crawl about on their knees and hocks.

Hereditary hemimelia. Bilateral absence of the distal half of the limb, e.g. the patella, and shortening or absence of the tibia, often accompanied by hydrocephalus, meningoceles, ventral abdominal hernia, and cryptorchidism, comprise the syndrome known as **tibial hemimelia**. It is inherited in the Galloway breed of cattle. An autosomal recessive mode of inheritance is assumed. A concerted program of eradicating the defect has been undertaken, based on test matings and examination for defects of 90-days fetuses obtained by terminating pregnancy with prostaglandin.

Hereditary peromelia of mohair goats. This syndrome includes agenesis of the phalanges and parts of the metacarpus and metatarsus affecting one or more limbs, and an autosomal recessive mode of inheritance.[1,2]

Amputates. An even more serious defect, in which the mandible and all the bones below the humerus and stifle are vestigial or absent, has been reported in British, French, and German Friesians. It appears to be conditioned by the inheritance of a single recessive gene. Similar **'amputates'** have been shown not to be inherited.

INHERITED CLAW DEFORMITY

Extra claws (**polydactylism**) and fusion of the claws (**syndactylism**) are known hereditary defects of cattle, the former in the Normandy breed and the latter in Holsteins,[1] Angus, Hereford, and Chianina.

Dactylomegaly (enlarged dew claws), often associated with syndactyly or deviation of the adjacent major digit and creating a clubfooted appearance, may be inherited in Shorthorn cattle. In most cases they cause no more than inconvenience but an association of syndactyly with susceptibility to hyperthermia is recorded, and some of these animals die of hyperthermia when subjected to high environmental temperatures.

Adactyly is a recorded but less well defined defect in cattle and sheep in which the hooves are absent at birth.

There is good field evidence that **corkscrew claw** or **curled toe** is an inherited defect in cattle, especially in beef breeds, but also in Holstein-Friesians. It is almost always the lateral claw which is affected; in some breeds it is more common in the hind feet, and in others it is more common in the front feet. In the affected digit the third phalanx is much smaller than normal and is narrower and longer. The soft tissue and the horn are correspondingly deformed so that the horn grows much longer and narrower and tends to curl over the sole so that the cow walks on the wall of the hoof. The claw also curls over the front of the other digit of the limb. There are often cracks in the front of the claw, originating at the coronet and causing serious lameness. All affected animals suffer gait abnormalities as they get older and heavier. Much of this is due to distortion and wear of the articular surfaces in the companion claw which has to carry much more weight than is usual. Marked changes in the affected digit are detectable by anteroposterior radiography.[2]

INHERITED MULTIPLE EXOSTOSIS

Multiple exostosis affecting both cortical and medullary bone of the limbs and ribs has been described in Quarter horses and Thoroughbreds in the US. The lesions are visible externally but cause little apparent inconvenience. It is inherited as a single dominant autosomal gene. Restriction nuclease analysis is used to diagnose the disease.[1]

INHERITED CONGENITAL HYPEROSTOSIS (THICK FORELIMBS OF PIGS)

This defect is thought to be caused by the inheritance of a simple recessive character. Affected piglets show obvious lesions at birth and, although many of them die or are destroyed immediately, a proportion of them may survive. The forelimbs are markedly enlarged below the elbows and the skin is tense and may be discolored. There is difficulty in standing and moving about, and starvation and crushing contribute to the mortality rate. There is extensive edema of the subcutaneous tissues, thickening of the bones, and roughness of the periosteum. It is thought that the primary lesion is a separation of the periosteum from the bone.

INHERITED RICKETS

This disease of pigs is indistinguishable from rickets due to nutritional inadequacy. The pigs are healthy at birth. Subsequently there is hypocalcemia, hyperphosphatemia, and increased serum alkaline phosphatase. The defect is a failure of active transport of calcium through the wall of the small intestine.

INHERITED TAILLESSNESS AND TAIL DEFORMITY

Complete absence of the tail or deformity of the appendage occur relatively commonly as a congenital defect. The condition is thought to be inherited in Holstein cattle and in Landrace and Large White pigs. It is often seen in combination with other deformities of the hindquarters such as atresia ani and urogenital tract abnormalities.

INHERITED DISEASES OF JOINTS

INHERITED ARTHROGRYPOSIS (INHERITED MULTIPLE TENDON CONTRACTURE)

Inherited fixation of limb joints present at birth is recorded in many breeds of cattle especially in the Shorthorn, Charolais, Piedmont, and Swedish Dole. It is thought to be inherited as a single recessive character. There are many environmental causes of the disease, the most common of which is Akabane virus infection of early pregnancy and discussed under that heading.

Simple arthrogryposis

The limbs of affected calves are fixed in flexion or extension and cause dystocia due to abnormal positioning and lack of flexibility. There is no involvement of joint surfaces and the joints can be freed by cutting the surrounding tendons or muscles. There is atrophy of limb muscles and those calves which are born alive are unable to stand and usually die or are destroyed within a few days.

Arthrogryposis with dental dysplasia

This defect in cattle appears to be inherited in a dominant manner. The teeth are soft, fleshy, and easy to bend. There is no defect of bones or joints other than marked softness and the presence of excess cartilage at the epiphyses. There is abnormal ossification of the cartilage. The calves are of normal size, do not cause dystocia, and, although they are unable to stand because of the excessive flexibility of the limbs, they can suck. Hypostatic pneumonia usually develops and causes death of the calf.

Arthrogryposis with palatoschisis (SAP)

This is inherited as a simple recessive with low penetrance in pure French Charolais in France and high penetrance in 7/8 Charolais cattle in Canada, where the gene frequency is high in purebred and crossbred Charolais. Among crossbred Charolais cattle the homozygous condition is almost always markedly expressed and lethal, but a high percentage of purebred homozygous cattle show slight to no visible effect of the gene and survive. Because of the low rate of prevalence in France, attempted eradication does not appear to be economical.

In this syndrome all limbs are usually affected but the front limbs more than the hindlimbs, and the more distal joints are more rigidly fixed than proximal ones. The muscles of affected limbs are atrophic and pale in color. Histological changes in the spinal cord suggest that the muscle atrophy is neurogenic. In affected calves the gestation period may be longer than normal by an average of 2 weeks.

Arthrogryposis with multiple defects

In Simmentals a combined set of defects includes arthrogryposis, often with the limbs in a wraparound position around the body, underdevelopment of the mandible, curvature of the spine, and defects of the heart and main vessels.

Arthrogryposis in other species than cattle

Inherited arthrogryposis has also been recorded in Merino and Corriedale **sheep**, and in Norwegian Landrace **pigs** in which it is thought to be inherited as a simple recessive. The Corriedale defect is associated with other lesions including brachygnathia inferior, hydranencephaly, and thoracic scoliosis. Inherited arthrogryposis in pedigree Suffolk lambs has been described.[1] Breeding studies using superovulation and embryo transfer were used to increase the numbers of offspring from females which were carrying the gene or genes responsible for the defect which was inherited as an autosomal recessive trait.

An inherited arthrogryposis also occurs in Norwegian Fjord **horses**. The arthrogryposis affects the hindlimbs and there are accompanying defects of polydactyly, palatoschisis, and brachygnathia in some. Most foals are unable to stand and the defect must be considered to be a lethal one.

INHERITED MULTIPLE ANKYLOSIS

Multiple ankylosis affecting all limb joints has been recorded as an inherited congenital defect of Holstein calves. The abdomen of the dam shows marked enlargement at the 6th to 7th month of pregnancy and this may occasion some respiratory distress. Excessive fetal fluids are present and insertion of the hand per rectum is impeded by the distended uterus. Abortion during the last month of pregnancy is a common occurrence. Affected fetuses have a very short neck, ankylosed intervertebral joints, and varying degrees of ankylosis of all limb joints. The limbs are fixed in flexion and there is some curvature of the spine. Fetal dystocia always occurs and embryotomy or cesarean section is necessary to deliver the calf.

Ankylosis of limb joints combined with **cleft palate** occurs occasionally in Charolais cattle and is suspected of being inherited. **Ankylosis of the coffin joint**, developing at several weeks of age, has been reported in Simmental calves. The etiology of the condition is not clear.

INHERITED PATELLAR SUBLUXATION

Unilateral or bilateral subluxation occurs as an inherited defect in *Bos indicus* cattle and in water buffalo (*Bubalus bubalis*). Shetland ponies also have a predisposition and a monogenic autosomal recessive transmission is suspected.[1,2] There is periodic lameness with the affected limb held in rigid extension; the patella is displaced medially. If the animal shakes the limb the patella may go back into its normal position and the problem is relieved.

INHERITED HYPERMOBILITY (LAXITY) OF JOINTS

This inherited disease is recorded only in Jersey cattle. It has assumed great importance because of the great popularity of a sire which carried the gene. There is abnormal flexure and extension of all joints but especially the hock, stifle, hip, knee, elbow, and shoulder joints. The muscles are much atrophied and the joints look very enlarged as a result. It is impossible for the calves to stand but they are bright, alert, and eat well. The limbs are so flexible that they can be bent into extraordinary positions, and almost tied in knots. A drawer sign, a displacement of the articular surfaces laterally, and produced by manual pressure, can be elicited easily and with a displacement of up to 2 cm. There are no detectable lesions in the nervous or musculoskeletal systems. Although the disease is known to be inherited as a simple autosomal recessive, it has also been seen in circumstances which preclude inheritance being the cause.

INHERITED HIP DYSPLASIA

An inherited defective development of the acetabulum occurs in Dole horses. There is no clinical evidence of the disease at birth but osteoarthritis of the joint and disruption of the round ligament develop subsequently. For this disease in cattle see 'Degenerative joint disease'.

INHERITED DISEASES OF MUSCLES

GENERALIZED GLYCOGENOSIS (GLYCOGEN STORAGE DISEASE TYPE II)

Generalized glycogenosis is a glycogen storage disease of Corriedale sheep,[1] Shorthorn, and Brahman beef cattle which resembles Pompe's disease in humans.[2,3] Glycogenosis type II in Shorthorn and Brahman cattle is a lysosomal storage disease in which acidic

α-glucosidase is the defective enzyme. In Shorthorn cattle, glycogenosis type II is caused by a single mutation, but the initial DNA/PCR restriction enzyme test of amplicons, was occasionally compromised by inhibition of the restriction enzyme by undefined factors. This was overcome by introduction of wild and mutant allele-specific amplifications and the use of two restriction enzymes, which clarified the anomalies and provided a more accurate testing system.[2]

In Brahman cattle, glycogenosis type II is associated with loss-of-function alleles affecting the α-glucosidase gene that differ from that in Shorthorns. There is a common mutation affecting many Australian Brahmans and a less common one affecting descendants of one imported bull. In addition, a third mutation was associated with significantly reduced α-glucosidase activity, but not sufficient to cause clinical disease in the homozygous state.[3]

Clinical signs include poor growth, muscle weakness, incoordination of gait, and difficulty in rising. The animals become permanently recumbent. The disease is identified as a lysosomal storage disease with lesions present in skeletal and cardiac muscle, and central nervous tissue. During the course of the disease there is progressive muscular damage and acute degeneration of muscle fibers in the terminal stage. Affected Brahman calves die at 8–9 months of age and British breed cattle at over 1 year. Only histopathological lesions are evident and include extensive vacuolation and accumulations of granular material in affected tissues. Amongst the biochemical lesions are greatly diminished α-glucosidase activity in liver and muscle, and a correspondingly high level of glycogen. Animals in affected herds are divisible into normal heterozygotes and homozygotes on the basis of α-1,4-glucosidase activity in lymphocytes or in muscle, especially the semitendinosus muscle.

Genotyping methods using hair root and blood samples to test Shorthorn cattle for generalized glycogenosis are available,[2] and PCR assays have been developed to genotype Brahman cattle for loss-of-function alleles within the acidic α-glucosidase gene.[3]

GLYCOGEN STORAGE DISEASE TYPE V (MUSCLE GLYCOGEN PHOSPHORYLASE DEFICIENCY)

Glycogen storage disease Type V is one of a number of inherited diseases affecting glycogen metabolism and resulting in abnormal accumulation of glycogen in cells. Glycogen storage disease Type V has been recorded in Charolais cattle in North America.[1] As in Type II glycogenosis, Type V is inherited as an autosomal recessive trait α-glucosidase. There is a deficiency of myophosphorylase, mildly elevated muscle glycogen and elevated serum creatine and aspartate aminotransferase. Severely affected animals may develop rhabdomyolysis which may be accompanied by myoglobinuria.[2]

In Charolais cattle, glycogen storage disease Type V is usually seen in calves at several weeks or months of age and is associated with exercise. Calves lag behind their dam or herd and may become temporarily recumbent for several minutes; with continuous exercise there are further periods of collapse and recumbency which may become prolonged. Not all homozygous animals are clinically affected if they are allowed to 'pace their exercise' and some animals have been known to breed despite muscle weakness.

A polymerase chain reaction-restriction fragment length polymorphism test has been used to identify heterozygous individuals in a Charolais herd in New Zealand that were otherwise normal.[2] Using a similar test, a Blonde d'Acquitaine cross-bred calf with a double-muscled phenotype and suspected of having myophosphorylase deficiency based on clinical findings of brown-colored transparent urine after exercise, pain, and an elevated creatine kinase was considered negative.[3]

FAMILIAL POLYSACCHARIDE STORAGE MYOPATHY (EQUINE RHABDOMYOLYSIS SYNDROME)

This myopathy is associated with exertional rhabdomyolysis and occurs with a high incidence in some Quarter Horse, American Paint, Appaloosa, and Quarter Horse cross-bred families. An autosomal recessive pattern of inheritance is proposed.[4] Recurrent episodes occur at intervals of about 2 weeks. Clinical signs include exercise intolerance with prolonged recumbency in some. Discomfort varies between stiffness and pain suggestive of colic. Myoglobinuria is common during episodes of clinical illness. Serum activity of creatine kinase are elevated. Biopsy of gluteal or semitendinosus muscles reveals polysaccharide inclusion bodies in some muscle fibers and widespread sarcolemmal vacuoles. The defect is basically an error of glycolysis.

INHERITED DIAPHRAGMATIC MUSCLE DYSTROPHY

This is an inherited defect in diaphragmatic muscle of Meuse-Rhine-Yssel and Holstein-Friesian cattle[1] appearing in adults and characterized by anorexia, decreased rumination, and eructation leading to recurrent bloat, dyspnea, abdominal respiration, nostril dilation, and death from asphyxia after a course of several weeks. Necropsy lesions comprise degenerative changes in diaphragmatic and thoracic muscles. The immunochemical evaluation of some cytoskeletal proteins of affected muscles found an increase in the amount of desmin and vinmentin immunoreactivities and similar amounts of actin and α-actin compared with controls.[2]

CONGENITAL MYASTHENIA GRAVIS

Congenital myasthenic syndrome has been reported in Brahman cattle in South Africa.[1] Affected calves develop progressive muscular weakness, beginning at birth and up to 3–4 weeks of age. Within 1 week they are unable to stand without assistance. Some calves are able to stand and walk for 30 to 45 minutes before collapsing, but are still able to suck their dams. The calves remain alert and continue sucking but may collapse after 20 to 60 seconds. The weakness becomes progressively worse and affected calves are usually euthanized. Hematology and serum biochemistry are normal, and muscle biopsies do not reveal any abnormalities.

The underlying defect is a homozygous 20-base pair (bp) deletion in the gene, muscular acetylcholine receptor (bov*CHRNE*), coding for the -subunit of the nAChR at the neuromuscular junction.[2] A PCR-based DNA test, using blood or semen has been developed and validated.[3] The test makes it possible to differentiate rapidly and accurately between homozygous wild-type, heterozygous and homozygous affected animals. Preliminary testing of Brahman cattle in South Africa revealed several carrier animals, some of them influential in the breeding population.

BOVINE FAMILIAL DEGENERATIVE NEUROMUSCULAR DISEASE

This disease has been reported occurring in Gelbveih cattle in several separate beef herds in the United States.[1] Affected animals are 4 to 20 months of age, and the mortality rate is 100%. Clinical findings include ataxia, weakness, and terminal recumbency. Gross and histological muscle lesions were indicative of nutritional muscular dystrophy with no myocardial lesions. Acute to chronic lesions in most large skeletal muscle groups consist of degeneration, necrosis, regeneration, fibrosis, and atrophy. Fibrinoid necrosis of arterioles is a common feature in multiple tissues. Lesions in the spinal cord white matter and peripheral nerves consisted of degeneration of the dorsal columns and axons, respectively. Chronic interstitial nephritis with fibrosis, hyaline droplet change, and tubular epithelial vacuolar change were most severe in older calves. Vitamin E levels were deficient in most affected calves. Pedigree analysis found a common ancestry for all but one of the affected calves. It is hypothesized that a hereditary metabolic defect, possibly involving anti-oxidant metabolism may be the causative factor.

INHERITED UMBILICAL AND SCROTAL HERNIAS, CRYPTORCHIDISM, AND HERMAPHRODITISM

Umbilical hernias in cattle and scrotal hernias and cryptorchidism in pigs have been considered to be inherited defects for many years but the evidence is uncertain.

Umbilical hernias

Umbilical hernias are commonly identified in dairy heifers. In 18 commercial dairy herds in New York, 15% of heifer calves had umbilical hernias during the first 3 months of age.[1] The economic costs of umbilical hernias include the cost of medical and surgical treatment and the loss in value for breeding animals.

It has been generally accepted that umbilical hernias may be inherited in a dominant or recessive mode. Some studies have found the risk of hernias was higher in some breeds: the incidence being much higher in Holstein cattle than other breeds such as Angus, Ayrshire, Brown Swiss, Charolais, Guernsey, Hereford, Jersey, and Shorthorn. However, factors other than genetic may be important. For example, many veterinarians have observed that umbilical infections commonly lead to umbilical hernia by slowing closure of the umbilicus. It is unlikely that the responsible genes are sex-linked, in spite of the apparent greater incidence in females. Umbilical hernias in Holstein-Friesian cattle can also be conditioned by a dominant character with incomplete penetrance, or be due to environmental factors. In a case control study to determine risk factors associated with identification of an umbilical hernia during the first 2 months after birth in Holstein heifers, the sire and umbilical infection were associated with risk of a hernia.[2] Heifers born to sires with = 3 progeny with an umbilical hernia were 2.31 times as likely to develop a hernia as were heifers born to sires with = 2 progeny with an umbilical hernia. Heifers with umbilical infection were 5.65 times as likely to develop a hernia as were heifers without umbilical infection. Attributable proportion analysis found that the frequency of umbilical hernias in Holstein heifers with umbilical infection would have been reduced by 82% if umbilical infection had been prevented.[3]

The risk factors for congenital umbilical hernias in German Fleckvieh calves offered for sale at livestock markets were examined.[4,5] An umbilical hernia was defined as a palpable opening in the abdominal wall of the umbilical region >1.5 cm, even if no hernia had developed. Inflammation, abscesses or fistulae were excluded. Data from 53 105 calves were collected from 77 livestock markets over a 2-year period. The overall incidence of congenital hernia was 1.8%. The analyses found significant effects for sex of calf, birth type, age of calf at examination, market place and date, sire line, sire, and frequency of affected herdmate calves in male calves, the incidence was 2.2%, in females 1.5%. The calves varied from 3 to 8 weeks of age. The diameter of hernial openings was between 1.5 and 9 cm with 47% of affected calves with a hernia measuring greater than 3 cm. A significantly higher incidence occurred in twin or triplet calves. Shorter gestation periods increased the risk of hernias linearly by a factor of 1.3% for 10 days. There were differences in the incidence of hernias according to sire lines but the heritabilty estimates were low varying from $h^2 = 0.04$ (>100 progeny) or $h^2 = 0.05$ (>25 or 50 progeny). However, analysis of the data found no evidence for an autosomal monogenic recessive inheritance. The analyses indicated that the incidence of congenital umbilical hernia observed could not be explained by one autosomal recessive gene locus, but it seemed much more likely that more than one gene locus is involved or a mixed multifactorial monogenic mode of inheritance may be the underlying genetic mechanism. It is suggested that the incidence of congenital umbilical hernias could be reduced if all breeding bulls are examined as calves and a veterinary certificate confirms a closed umbilical ring.

Breeders should be aware of the implications of congenital hernias and thus, congenital hernia should get more attention in the selection process of young sires.

Breeding studies and genotyping using the Canadian Holstein bull 'Glenhapton Enhancer', have provided evidence that Enhancer is the carrier of major dominant or codominant gene with partial penetrance for umbilical hernia.[3] Five sons of Enhancer produced progeny with >10% frequency of umbilical hernia, whereas the progeny of 3 sons had <3% umbilical hernia. Genotyping of grand-progeny found significant differences in paternal allele frequencies between the affected and unaffected progeny groups for a marker BMS1591 on bovine chromosome 8(BTA8). The umbilical hernia-associated paternal allele originated from Enhancer.

Scrotal hernias

Scrotal hernias of pigs have also been shown to be inherited in some breeds, e.g. Duroc and Landrace, but not in others, e.g. Yorkshires.[6]

Cryptorchidism

Evidence suggesting the inheritance of cryptorchidism in swine, sheep, horses, and Hereford cattle and hermaphroditism in swine is also available. Cryptorchidism in horses appears to be inherited with a polygenic pattern of transmission.

MYOFIBER HYPERPLASIA (DOUBLE MUSCLING, DOPPELLENDER, CULARD)

EPIDEMIOLOGY

This is an inherited condition, characterized by an increased bulk of skeletal muscles due to the presence of a greater than normal number of muscle fibers; it is well known in many breeds of cattle but appears to be most common in the Charolais, Belgian Blue, Piedmont, and South Devon breeds. The condition is recorded only rarely in sheep. The mode of inheritance has not been established but heterozygotes usually show some degree of muscle hypertrophy. Many of

the muscle changes are in the direction of the current demand for lean, meaty carcasses, and there is interest, especially in Europe, in the exploitation of this anomaly for meat production. Pietrain pigs (see below) exhibit many of the characteristics of double-muscled cattle, including large muscle mass and susceptibility to stress.

CLINICAL FINDINGS

Severely affected cattle show a marked increase in muscle mass most readily observed in the hindquarters, loin, and shoulder, an increase in the muscle:bone ratio and a decrease in body fat. Affected calves demonstrate above-average weight gains during the first year of life if well fed and managed, although mature size is somewhat reduced. Well-marked grooves along the intramuscular septa in the hindquarters are a distinguishing feature as is an apparent forward positioning of the tail head. Macroglossia, prognathism, and a tendency toward muscular dystrophy and rickets have been observed in affected calves. Electrocardiographic abnormalities have been reported.[1] The condition often gives rise to dystocia, possibly due to increased gestation length, and affected females are said to be less fertile than normal.[2] There is also a very high incidence of Elso heel in affected cattle and this interferes greatly with their economic value. Other associated defects are brachygnathia and deviation of the incisor arch and, in Belgian Blue and White cattle, greater susceptibility than normal to laryngitis and bronchopneumonia.[3]

CLINICAL PATHOLOGY

Blood lactate is increased, as is susceptibility to stress. These findings are interpreted as being indicators of cell membrane fragility, which is also manifested by fragility of the erythrocytes.

NECROPSY FINDINGS

The skin is thinner than normal, and the muscle mass is characterized by a disproportionate number of glycolytic, anaerobic fibers.

PIETRAIN CREEPER PIGS

A progressive muscular weakness is found in stress-susceptible Pietrain pigs. The syndrome commences with muscle tremor at 2–4 weeks of age, leading to complete recumbency by 12 weeks of age. At this stage the pigs move with a creeping gait with the limbs flexed. There are no neuropathological lesions but there are myopathic changes, especially in the forelimbs.

INHERITED PROGRESSIVE MUSCULAR DYSTROPHY

This is a primary skeletal muscle disease of sheep with a strong probability of having a genetic mode of transmission.[1] It is recorded in Merino flocks in Australia and is characterized by a gradually progressive failure to flex the joints of the hindlimbs commencing at 3–4 weeks of age. Eventually the limbs are rigid at all times, and running becomes impossible. The forelimbs and the head and neck are normal. Affected sheep are easily detected when they are 1 year old and will have mobility problems by the time they are 2–3 years old. At necropsy there are pale areas in skeletal muscle and sometimes the muscles of the diaphragm in those sheep which have a tendency to bloat. The histopathology and histochemistry of the muscle lesions is comparable with that of inherited muscle atrophies in humans.[1,2]

INHERITED SPINAL MUSCULAR ATROPHY

A progressive ataxia, weakness, muscle atrophy, and recumbency develops in young calves, mostly during the first 2 weeks of life. Sensory functions are unimpaired. Some are already affected at birth and some may be stillborn. No new cases occur after 3 months of age. Conditioned by an autosomal recessive gene the defect occurs in Red Danish cattle which originated from Brown Swiss, and from German Braunvieh and American Brown Swiss. The primary lesion is degeneration of ventral horn cells of the spinal cord, without involvement of the brainstem or cerebellum. The visible lesion is the secondary atrophy of the denervated muscles.[1,2]

2. Dahme VB. Neuropathol Appl Neurobiol 1991; 17:517.

INHERITED SPLAYED DIGITS

Recorded only in Jersey cattle, this defect appears to be conditioned by an inherited gene; probably a monogenic autosomal recessive. Lameness becomes apparent at 2–4 months of age, the toes becoming increasingly widely spread and the toes themselves misshapen. Walking and standing are painful, especially on the front feet so that some animals graze and walk on their knees. Affected animals either lie down increasingly or stay standing for very long periods. The apparent abnormality is a defect of the muscles and ligaments holding the phalanges together.

EQUINE HYPERKALEMIC PERIODIC PARALYSIS

Synopsis

Etiology Defect in sodium channel of skeletal muscle.
Epidemiology Disease of Quarter Horses and crossbreds. Inherited as an autosomal dominant trait with variable penetrance.
Clinical signs Episodes of muscle fasciculation, stridor, muscle weakness, and flaccid paralysis.
Clinical pathology Hyperkalemia during episodes. Gene probe to detect mutated gene.
Lesions None.
Treatment Palliative. Potassium-free intravenous fluids. Acetazolamide.
Control Selective breeding. Low potassium diet.

ETIOLOGY

The disease is caused by a heritable defect in the sodium channel of skeletal muscle.[1] The mutation, of which only one form has been identified, results in substitution of a cytosine for guanine, with consequent replacement of phenylalanine by leucine in a transmembrane protein regulating sodium flux across the cell membrane and T-tubule. The disease is transmitted as an autosomal codominant with the result that homozygotes are more severely afected than heterozygotes, and phenotypic expression (disease severity) differs among heterozygotes.

EPIDEMIOLOGY

The disease is familial and affects Quarter Horse and crossbred descendants of a single Quarter Horse sire, Impressive.[2,3] More than 50 000 registered Quarter Horses are related to known carriers of the disease.[4] Quarter Horses with the disease are presumably selected because they outperform unaffected animals in the halter classes in which they compete at horse shows,[5] although recent rule changes have changed this practice. The disease is occurs in breeds derived from or crossed with Quarter horses including Appaloosas, American Paint horses, and crossbreds.

The disease is inherited in an **autosomal codominant** manner.[1] Therefore, 50% of the offspring of the breeding of a heterozygote and a normal animal will carry the trait, as will 75% of the offspring of the breeding of two heterozygotes. Of the breeding of 2 heterozygotes, 50% of progeny will be heterozygotes, 25% homozygotes for the mutated gene, and 25% homozygotes for the normal gene.

Animals homozygous for the abnormal gene are uncommon, representing only 0.9% of animals tested for the disease.[6] The low prevalence of the homozygote genotype is likely a reflection of severity of disease and the reduced likelihood that homozygotic animals will reach sexual maturity.

The risk of a **heterozygous** animal being affected with periodic paralysis is variable. Most heterozygous horses appear normal and never experience an attack, while others have severe episodes starting at a young age. **Homozygous** horses are much more likely to have severe manifestations of the disease at a young age.

PATHOGENESIS

The abnormality in the sodium channel coded for by the mutated gene predisposes the horse to episodes of complete depolarization of the muscle membrane and flaccid paralysis. The mutation in the sodium channel increases the probability that any one channel is open, with the result that the resting membrane potential in affected horses is higher (less negative and closer to the depolarization threshold) than that of normal horses.[7] This results in frequent depolarizations of individual muscle fibers causing muscle fasciculations. The weakness associated with severe episodes of the disease results from failure of sodium channels to close after depolarizations. Opening of potassium channels when the muscle is depolarized results in movement of potassium out of the muscle cell, and the development of hyperkalemia.

CLINICAL SIGNS

The disease in **heterozygous** animals is characterized by periods of muscle fasciculation and tremor that progress to weakness, paralysis, and recumbency. Such episodes may last minutes to hours, and most resolve spontaneously. Horses often sweat, have prolapse of the third eyelid, and contraction of facial and locomotor muscles during episodes. Episodes may be mistaken for colic. Inspiratory stertor commonly noted during episodes is probably due to laryngeal and pharyngeal dysfunction.

Episodes are more frequent and severe in **homozygous** animals and signs of **laryngeal and pharyngeal dysfunction**, such as stridor and dysphagia, occur in almost all of these animals.[6,8] Endoscopic examination of homozygotes reveals pharyngeal collapse, laryngopalatal dislocation, and laryngeal paralysis.[6,8] The disease can manifest in foals as young as 7 days of age. The severity of signs in some homozygotes diminishes with age.

Electromyographic demonstration of myotonic discharges, prolonged insertional activity, and doublets and triplets is a sensitive and specific indicator of the disease.[9]

Horses with HYPP have reduced exercise tolerance compared to normal horses.[10] Homozygotic horses have laryngospasm, airway obstruction, hypoxia, hypercapnia, and ventricular depolarizations during intense exercise, which is not recommended for these horses.[11]

CLINICAL PATHOLOGY

Hyperkalemia (>5.5 mEq/L, 5.5 mmol/L) during or immediately after episodes is characteristic of the disease, although the existence of a normokalemic variant has been suggested.[12]

Diagnostic confirmation has in the past been achieved by provocative testing by administering potassium chloride (88–166 mg/kg, orally) to suspect horses.[13] However, the development of genotyping has rendered provocative testing obsolete and, for humane reasons and because of the risk of death, its use is not recommended. The **test of choice** for demonstrating the presence of the mutated gene is a specific **gene probe**.[4] The probe can be applied to various tissues, but blood or hair, with attached root (a plucked hair), are preferred for diagnostic testing of live animals. This test classifies horses as normal, heterozygous, or homozygous but does not indicate the propensity of heterozygotes to exhibit the disease. Samples can be analyzed in the United States at the Veterinary Genetics Laboratory, University of California (*www.vgl.ucdavis.edu*).

DIFFERENTIAL DIAGNOSIS

- Colic
- Laminitis
- Hypocalcemia
- Botulism
- Exertional rhabdomyolysis
- Upper airway obstruction.

NECROPSY FINDINGS

There are no characteristic findings on necropsy examination.

TREATMENT

Acute episodes

Most acute episodes resolve spontaneously or with only minor treatment. The aim in treating more severe or prolonged episodes is to **reduce the plasma potassium concentration** by intravenous infusion of isotonic, potassium free fluids such as sodium chloride, sodium bicarbonate, or dextrose. Some authors recommend infusion of calcium gluconate but others caution against its use. A practical approach is the slow intravenous administration of 0.25 to 0.5 mL of 23% calcium gluconate per kg of body weight (125–250 mL for a 500 kg horse) diluted in isotonic sodium chloride or, preferably, 5% dextrose. Administration of $NaHCO_3$ at 1 mL/kg intravenously has been suggested.

Prevention of episodes

Maintaining affected horses on a **low potassium diet** reduces the frequency with which episodes occur. Alfalfa (lucerne), some oils including soyabean, molasses, lite salt (a mixture of KCl and NaCl), and many sweet feeds are potassium rich and should be avoided. Grass hay (timothy) and straw and oats, corn, and barley are low in potassium. There are commercial feeds that have a guarranteed low concentration of potassium. Alternatively, diets can be formulated using feed of known potassium concentration, as determined by feed analysis. Care should be taken that diets are nutritious and contain appropriate concentrations and ratios of calcium and phosphorus.

Acetazolamide (2–4 g/kg, every 12 hours) reduces the severity and frequency of episodes and is widely used to control the disease. The drug is poorly absorbed in horses but the concentration required in plasma of horses to achieve a pharmacodynamic effect is lower than that of humans.[14]

CONTROL

The disease is heritable and carriers are readily identified so a breeding program to eliminate the disease is feasible.

RECURRENT EXERTIONAL RHABDOMYOLYSIS IN THOROUGHBRED HORSES (AZOTURIA, TYING UP, CHRONIC INTERMITTENT RHABDOMYOLYSIS)

Recurrent exertional rhabdomyolysis of Thoroughbred horses is a common dis-

ease characterized by repeated episodes of muscle disease. A similar disease occurs in Standardbred horses but its etiology and epidemiology are not well documented.

ETIOLOGY

Recurrent exertional rhabdomyolysis in Thoroughbred race horses is inherited as an autosomal dominant trait with variable expression influenced by temperament, diet, and sex.[1,2] Horses with recurrent exertional rhabdomyolysis have abnormal muscle contraction and a defect in myoplasmic calcium regulation.[3,4] These abnormalities are evident after caffeine or halothane challenge of muscle fibers from affected horses examined in vitro.[2–4] Myotubules from affected horses have higher concentrations of calcium after caffeine stimulation and muscle fibers from affected horses are more likely to contract when exposed to low concentrations of caffeine.[3] The defect does not resemble that found in the ryanodine receptor in animals with malignant hyperthermia, and there is no defect in calcium-ATPase activity or its affinity for calcium in the sarcoplasmic reticulum of Thoroughbred horses with recurrent exertional rhabdomyolysis.[5]

A genetic basis to a similar disease in Standardbreds is suspected, based on analysis of pedigree information of trotters in Sweden.[6]

EPIDEMIOLOGY

Interpretation of reports of prevalence and risk factors for exertional rhabdomyolysis is difficult because studies to date have mostly not differentiated between the recurrent exertional rhabdomyolysis of Thoroughbreds, polysaccharide storage myopathy of Quarterhorses and related breeds, and the sporadic disease in other breeds.

The **incidence** or 1-year-period prevalence of exertional rhabdomyolysis in Thoroughbreds is 4.9–6.7% in Thoroughbred racehorses in the United States, Australia, and Great Britain, and 6.1% in National Hunt Thoroughbreds in Great Britain.[7–10] The disease occurs repeatedly in 74% of affected Thoroughbred race horses in Great Britain.[10]

Risk factors for exertional rhabdomyolysis in Thoroughbred horses, not all of which have the familial disease, include exercise, diet, use, and sex. Horses used for racing are more likely to have episodes of the disease than are horses used for pleasure riding or 'other' uses,[7] although racing and breed (Thoroughbred or Standardbred) are confounding factors. Female race horses are three times more likely to have episodes of exertional rhabdomyolysis than are male (intact or castrated) race horses,[7–10] and young, female Thoroughbreds are at greatest risk.[7–10] Among National Hunt horses in Great Britain, females are 24 times as likely to have an episode of the disease as are males.[9] Female polo ponies are not more likely to develop the disease.[11] Thoroughbred racehorses and polo ponies, but not National Hunt horses, with a nervous or 'flighty' temperament are more likely to experience episodes of the disease.[8,12,13] Other apparent risk factors include a rest day before hard exercise,[8] feeding >4.5 kg of grain per day,[8] lameness,[8] and training gallops of shorter distance.[9] Susceptible horses consuming a high calorie diet (>30 mCal/day) with a large proportion of the calories provided by readily digestible carbohydrate, such as starch, are at increased risk of the disease.[14,15]

The disease is of considerable **economic impact** because of its frequent occurrence in athletic horses, recurrent nature, and need to rest affected horses. On average, affected Thoroughbred race horses cannot train for 6 days after an episode, and approximately two-thirds of affected horses are unable to race because of the disease.[9,10] The effect of the loss of training days for each episode is magnified because of the recurrent nature of the disease in a large proportion of affected horses. Approximately 6% of the wastage of Thoroughbred race horses in Australia is attributable to exertional rhabdomyolysis,[16] though it is not known if all of these horses are affected by recurrent exertional rhabdomyolysis.

PATHOGENESIS

The underlying cause is described above under 'Etiology'. The disease is due to dysfunction and death of myocytes with subsequent release of cellular constituents, including the enzymes creatine kinase, aspartate aminotransferase and carbonic annhydrase, and myoglobin. Cell death is likely linked to abnormal accumulation of calcium in intracellular fluids secondary to deranged energy and/or membrane function.[17] Necrosis of myocytes caused pain and inflammation in the muscle, with infiltration of inflammatory cells. Healing and regeneration of myocytes occurs over a period of weeks in the absence of further episodes of myonecrosis.

The release of cellular constituents results in electrolyte abnormalities, primarily hypochloremic metabolic alkalosis, systemic inflammatory response, and pigmenturia. Severely affected horses can have a metabolic acidosis. Myoglobin and, possibly, other cell constituents are nephrotoxic and acute renal failure can develop as a result of myoglobinuric nephrosis. Pain and loss of muscle function are associated with stilted, short stepping gait.

CLINICAL FINDINGS

The cardinal feature of the disease is the occurrence of multiple episodes of rhabdomyolysis following exercise of Thoroughbred horses. Clinical findings are **variable** and range from poor performance to recumbency and death. Signs are usually mild and resolve spontaneously within 1–6 days.

The **usual presentation** is a young (2–5-year-old) female racehorse with recurrent episodes of stiff gait after exercise. The horse does not perform to expectation and displays a **short stepping gait** that may be mistaken for lower leg lameness. The horse may be reluctant to move when placed in its stall, be apprehensive and anorexic, and frequently shift their weight. More severely affected horses may be unable to continue to exercise, have **hard and painful muscles** (usually gluteal muscles), sweat excessively, be apprehensive, refuse to walk, and be tachycardic and tachypneic. Affected horses may be hyperthermic. Signs consistent with abdominal pain are present in many severely affected horses. Deep red urine (myoglobinuria) occurs but is not a consistent finding. Severely affected horses may be recumbent.

CLINICAL PATHOLOGY

Mildly or inapparently affected horses have moderate increases in **serum creatine kinase** (CK) (20 000–50 000 iu/L), **aspartate aminotransferase** (AST) and **lactate dehydrogenase** (LDH) activity. Severely affected horses have large increases in CK (>100 000 iu/L) and other muscle-derived enzymes. Serum CK and AST activities peak approximately 5–6 and 24 hours after exercise, respectively[11,18] and in the absence of further muscle damage serum AST might not return to normal levels for 7–10 days. The half-life of CK activity in serum is approximately 12 hours and in the absence of continuing muscle damage serum CK declines rapidly.[11] The persistence of increased AST activity, compared to CK, is useful in identifying affected horses days or weeks after the episode.[18]

Serum myoglobin concentrations increase markedly during exercise in affected horses, and decline within 24–48 hours.[18] Serum carbonic anhydrase III activity is increased in horses with exertional rhabdomyolysis.[12]

Severely affected horses are often **hyponatremic** (<130 mEq/L), **hyperkalemic** (>5.5 mEq/L), **hypochloremic** (<90 mEq/L), azotemic (increased serum urea nitrogen and creatinine concentrations) and **acidotic** or **alkalotic**. Hemoconcentration (hematocrit >50%, 0.5 L/L) and increased serum total protein concentration (>80 g/L) indicative of dehydration

are common. Serum bicarbonate concentration can be falsely markedly elevated in animals with severe rhabdomyolysis because of cellular constituents released from damaged muscle that interfere with the analytical method when automated clinical chemistry analyzers are used.[13] Measurement of urinary excretion or fractional excretion of electrolytes is not useful in detecting horses susceptible to recurrent exertional rhabdomyolysis.[19]

Myoglobinuria is detectable either grossly or on chemical analysis and should be differentiated from hemoglobinuria or hematuria. Measurement of urinary excretion of electrolytes, although popular in the past, is of no use in diagnosing, treating, or preventing exertional rhabdomyolysis.

Muscle biopsy during the acute or convalescent stages reveals myonecrosis of Type II (fast twitch, oxidative) fibers, mild myositis, and fibrosis.

NECROPSY FINDINGS

Horses dying of exertional rhabdomyolysis have widespread degeneration of striated muscle; principally, the muscles of exertion, but often involving the diaphragm and heart. Affected muscles tend to be dark and swollen, but may have a pale, streaked appearance. The kidneys are swollen and have dark brown medullary streaks. Dark brown urine is present in the bladder. Histologic examination reveals widespread necrosis and hyaline degeneration of predominantly Type II (fast twitch, oxidative) fibers. In horses with recurrent disease there may be evidence of myofiber regeneration. Myoglobinuric nephrosis is present in severely affected horses.

Samples for postmortem diagnostic confirmation

Formalin-fixed kidney and affected muscle for light microscopic examination.

DIAGNOSTIC CONFIRMATION

Biochemical confirmation of muscle damage by demonstration of increased serum CK or AST activity, in conjunction with appropriate clinical signs, provides the diagnosis.

DIFFERENTIAL DIAGNOSIS

- Ear tick (*Otobius megnini*) induced muscle cramping[20]
- Polysaccharide storage myopathy of Quarter horses
- *Casia occidentalis* toxicosis
- Hyperkalemic periodic paralysis
- Laminitis
- Colic
- Pleuritis
- Aorto-iliac thrombosis.

TREATMENT

The treatment chosen depends on the severity of the disease. The **general principles** are rest, correction of dehydration and electrolyte abnormalities, prevention of complications including nephrosis and laminitis, and provision of analgesia.[21]

Mildly affected horses (heart rate <60 bpm, normal rectal temperature and respiratory rate, no dehydration) may be treated with rest and phenylbutazone (2.2 mg/kg, orally or IV every 12 hours for 2–4 days). Horses should be given mild exercise with incremental increases in workload as soon as they no longer have signs of muscle pain. Access to water should be unrestricted.

Severely affected horses (heart rate >60 bpm, rectal temperature >39°C (102°F), 8–10% dehydrated, reluctant or unable to walk) should not be exercised, including walking back to their stable, unless it is unavoidable. Isotonic, polyionic **fluids**, such as lactated Ringer's solution, should be administered IV to severely affected horses to correct any dehydration and to insure a mild diuresis to prevent myoglobinuric nephropathy. Less severely affected horses can be treated by administration of fluids by nasogastric intubation (4–6 L every 2–3 hours). Affected horses should not be given diuretics.

Analgesia can be achieved by administration of phenylbutazone (2.2–4.4 mg/kg, IV or orally, every 12–24 hours), flunixin meglumine (1 mg/kg IV every 8 hours) or ketoprofen (2.2 mg/kg IV every 12 hours). **Mild sedation** (acepromazine or acetylpromazine 0.02–0.04 mg/kg IM, or xylazine, 0.1 mg/kg IM, both with butorphanol, 0.01–0.02 mg/kg) may decrease muscle pain and anxiety. Tranquillizers with vasodilatory activity, such as acetylpromazine, should only be given to horses that are well hydrated. Muscle relaxants, such as methocarbamol, are often used but have no demonstrated efficacy.

Recumbent horses should be deeply bedded and repositioned by rolling every 2–4 hours. Severely affected horses should not be forced to stand.

CONTROL

Prevention centers on insuring that horses are fed a balanced ration with adequate levels of vitamin E, selenium and electrolytes, and have a regular and consistent program of exercise.

Thoroughbred race horses in training consume diets providing over 30 Mcal/day. The high energy intake is associated with increased risk of exertional rhabdomyolysis, especially if the diet provides a large (40%) of calories as readily digested carbohydrate (starch). **Diets** in which fat provides 20% of digestible energy calories and 7% as starch are associated with lower serum creatine kinase activities after exercise on a treadmill.[14] These finding have been extrapolated to provide the recommendation that race horses in training receive no more than 20% of daily digestible energy from hydrolysable carbohydrate (starch) and at least 20% of DE from fat.[22] Fat can be incorporated into the diet as rice bran, soy bean hulls, and vegetable (but not animal) fats and oils. High fat, high fiber commercial diets that are formulated for treatment of horses with polysaccharide storage myopathy or recurrent exertional myopathy are available.

Despite lack of clear evidence for a widespread role for **vitamin E or selenium** deficiency in exertional rhabdomyolysis, horses are often supplemented with 1 iu/kg of vitamin E and 2.5 µg/kg of selenium daily in the feed. Care should be taken not to induce selenium toxicosis. **Sodium bicarbonate** and other electrolytes are often added to the feed of affected horses, but their efficacy is not documented and is suspect.[14]

Phenytoin has proven useful in the treatment of recurrent rhabdomyolysis. It is administered at a dose rate of 6–8 mg/kg, orally, every 12 hours, and the dose adjusted depending on the degree of sedation produced (a reduced dose should be used if the horse becomes sedated) or lack of effect on serum CK or AST activity. Phenytoin can be administered to horses for months. Dantrolene (800 mg, approximately 2 mg/kg, orally 60 minutes before exercise) was demonstrated in a controlled, cross-over field trial of 77 horses, to be effective in reducing exercise-induced increases in CK and incidence of episodes of recurrent exertional rhabdomyolysis in Thoroughbred race horses.[23] Similar results were obtained in 4 horses with recurrent exertional rhabdomyolysis administered 4 mg/kg orally 90 minutes before exercise on a treadmill.[24]

Dimethylglycine, dantrolene, altrenogest and progesterone are all used on occasion in horses with recurrent rhabdomyolysis, but again without demonstrated efficacy.

PORCINE STRESS SYNDROME (PSS; MALIGNANT HYPERTHERMIA)

Synopsis

Etiology Inherited defect caused by an autosomal recessive gene at a single locus with incomplete penetrance. Also known as the halothane sensitivity gene, or PSS mutation, which is a single point mutation of nucleotide 1843 in the skeletal muscle gene for the calcium-release channel of the sarcoplasmic reticulum.
Epidemiology Worldwide in major breeds of swine: Landrace, Yorkshire, Duroc, Pietrain, and Poland China. Market weight pigs, and adult sows and boars. Prevalence of defective gene varies between breeds and countries. Syndromes precipitated by stress of transportation, high environmental temperatures and humidity, exhaustive exercise, and by halothane anesthesia. Major economic importance because of deaths and poor quality pork.

Signs
- *Porcine stress syndrome:* death during transportation
- *Malignant hyperthermia:* induced by halothane anesthesia resulting in muscular rigidity and death
- *Pale, soft, exudative pork:* rapid rigor mortis after slaughter followed by excessive dripping of carcass and pale watery pork. Dark, firm, and dry pork is variation
- *Back muscle necrosis:* reluctance to move, acute swelling and pain over back and some may die; subacute form too.

Clinical pathology Halothane test. Blood creatine kinase test. Blood typing. DNA-based test for PSS mutation gene.
Lesions Pale skeletal muscles in PSS deaths. Pale muscles in back muscle necrosis.
Diagnostic confirmation Necropsy findings. Identification of homozygous animals with tests.

Differential diagnosis list
- Mulberry heart disease
- Acute septicemias due to salmonellosis, erysipelas, pasteurellosis, and anthrax
- Intestinal volvulus
- Heat exhaustion
- Suffocation during transportation.

Treatment None.
Control Genetic selection. Reduction of environmental and management stressors.

ETIOLOGY

Three closely related stress syndromes occur in pigs. The **porcine stress syndrome (PSS)** is characterized by acute death induced by stressors such as transport, high ambient temperature, exercise and fighting, which results in progressive dyspnea, hyperthermia, disseminated vasoconstriction and the rapid onset of rigor mortis. **Pale, soft and exudative pork (PSE)** occurs post mortem in some pigs slaughtered by conventional methods. **Malignant hyperthermia (MH)** is a drug-induced stress syndrome characterized by muscle rigidity and hyperthermia occurring in susceptible pigs following the use of halothane or the muscle-relaxant suxamethonium. **Back muscle necrosis** of pigs is a special manifestation of the PSS.

Malignant hyperthermia also occurs in humans.[1]

PSS is caused by an inherited defect due to an autosomal recessive gene at a single locus with incomplete penetrance. It is also known as the halothane sensitivity gene, or PSS mutation, which is single point mutation of nucleotide 1843 in the skeletal muscle gene for the calcium-release channel of the sarcoplasmic reticulum. The PSS defect renders muscle hypersensitive to stimulation by various stressors. In stress-susceptible pigs there is a rapid onset of anaerobic glycolysis and loss of control of skeletal muscle metabolism in response to stress and anoxia.

The gene is commonly known as the *halothane-sensitivity gene* (HAL gene) because pigs with the homozygous genotype can be identified with the halothane test which results in malignant hyperthermia. The halothane gene is located within a group of blood type genes on the same chromosome allowing identification of affected pigs by blood typing. A single point mutation in the porcine gene for the skeletal muscle ryanodine receptor is associated with malignant hyperthermia in five major breeds of heavily muscled swine.[2,3] Comparison of the sequences of the HAL genes of porcine stress syndrome and normal pigs revealed a single mutation at nucleotide 1843 in the cDNA derived from the HAL gene.[2] The literature on the causative mutation for the porcine stress syndrome has been reviewed.[4]

EPIDEMIOLOGY

Prevalence and occurrence

This subject needs to be kept in perspective. It has recently been suggested that only 4% of inferior quality meat is due to genetics (halothane positive) with the remainder being due to pre-slaughter and post-slaughter treatment.[5]

PSS occurs worldwide, but there is considerable breed and area variation in its prevalence. In some European countries the prevalence is a major problem in pig production because of the inadvertent selection for this trait in genetic improvement programs. This underlies the problems of selection based purely on performance and production characteristics.

The prevalence of PSS in the swine population can be determined by the use of screening tests applied on the farm or when pigs enter swine performance test stations. The halothane test and the creatine kinase (CK) test are useful for this purpose. A DNA-based test with 99% accuracy is also available.[6] Surveys in the UK found that the prevalence in the British Landrace varies from 0 to 23% of herds with an average of 11%. In European breeds, the prevalence varies from 0 to 88% with up to 100% in the Pietrain breed. None is present in the Large White breed although one isolated report describes malignant hyperthermia in a single Large White pig. The prevalence of halothane susceptibility is low in the Danish Landrace breed in Denmark.[7] Based on the halothane test, 1.5% of young boars entering a Record of Performance Test Station in Canada were positive reactors. The reactors originated from 7.5% of 107 herds. The halothane succinylcholine test was a more sensitive test because 18% of the same pigs were identified as reactors.

Using a DNA-based test, in a survey of 10 245 breeding swine of various breeds from 129 farms in the US, Canada, and England, approximately 1 of 5 pigs was a heterozygous carrier of the PSS mutation, and 1% were homozygous.[6] The prevalence of the PSS mutation was 97% for 58 Pietrain, 35% for 1962 Landrace, 15% for 718 Duroc, 19% for 720 Large White, 14% for 496 Hampshire, 19% for 1727 Yorkshire, and 16% for 3446 crossbred swine. The PSS gene frequencies for these breeds were 0.72, 0.19, 0.08, 0.10, 0.07, 0.10, and 0.09, respectively. The PSS mutation has also been identified in Poland China and Berkshire breeds. These gene frequencies were 30–75% lower in Canadian swine than in US swine, with the exception of Yorkshires, for which the

gene frequency is threefold in Canadian swine.[6]

Risk factors

Animal risk factors

Susceptibility to the PSS is inherited and the biochemical events leading to PSE, transport death, or malignant hyperthermia are triggered by several external influences or stressors in the living animal. PSS probably occurs in all breeds of pigs, but the incidence is highest in pigs selected for heavy muscling, and stress-susceptible pigs are leaner and more meaty. These include the Pietrain and Poland China breeds and also some European strains of Landrace where a score for muscling as well as growth rate, feed conversion, and back fat has been included in the selection index. A recent study has shown that there are considerable breed differences in that halothane stress susceptible pigs and Hampshires suffer more severely from heat stress than Yorkshires, Danish Landrace, and Duroc boars.[8]

There is a **correlation between halothane susceptibility and carcass traits**. Halothane status is the most important factor influencing pork quality, although pre-slaughter handling and stunning method also influence the carcass quality.[9,10]

Halothane-positive animals usually score higher for visual conformation of the loin and ham than pigs which are halothane-negative. The progeny of reactor boars are also more susceptible than the progeny of non-reactors. Until recently it was thought that the major limitation of the halothane test was that it identified only those pigs which are stress-susceptible to the syndrome. It is now known that the halothane-sensitivity gene is expressed in heterozygous pigs where it is likely to cause poor carcass quality.

The **gene for the porcine calcium channel** has been sequenced and the site of the causative mutation located.[2] The mutation was found in 5 major breeds of swine: Landrace, Yorkshire, Duroc, Pietrain, and Poland China. The prevalence of the gene in certain breeds in North America and England is given above.

Landrace pigs can be divided into those which are sensitive to halothane and develop pale, soft, exudative pork post mortem, those which are resistant to halothane but develop pale, soft, exudative pork, and those resistant to halothane and pale, soft, exudative pork (the normal pig). Muscle from pigs susceptible to malignant hyperthermia and pale, soft, exudative pork has significantly higher glucose-6-phosphate levels and lower phosphocreatine under thiopentone anesthesia than muscle from pigs susceptible to PSE and normal pigs. Altered muscle fiber type is not the primary basis of the disease complex.

Environmental and management risk factors

The most important precipitating factors are **transportation at high environmental temperatures and humidity, exhaustive exercise**, and under experimental conditions, the more specific reaction towards the **anesthetic halothane**. Response of pigs to transport is dependent on genotype particularly at high temperatures such as **36°C**.[11] Experimentally, psychological mechanisms can precipitate the PSS. The effects of mixing, transportation, and duration of lairage can have profound effects on carcass characteristics of susceptible pigs. Death during transportation and PSE are associated with fear, defensive or aggressive reactions in unfamiliar social environments, or conflict with other strange pigs or man. Other activities which may trigger malignant hyperthermia include restraint, mating, farrowing, fighting, and vigorous exercising.

Economic importance

The economic losses associated with the PSS are due to mortality from transport death and inferior meat quality due to pale, soft, exudative pork. As a result of the excessive rates of production of lactic acid and heat, sarcoplasmic proteins denature, thereby causing a deterioration of the water-binding capacity of muscle. The increased osmotic activity due to end-products of hypermetabolism causes an influx of water from the extracellular space resulting in hemoconcentration and increased intramyofiber water content. The muscle becomes pale, soft, and exudative, sour-smelling and loose-textured. The shrinkage due to water loss during storage, transport and processing of the carcass is the major cause of wholesale losses at pork packing plants. PSE carcasses yield less bacon and the drip loss from fresh PSE meat is more than doubled compared to normal carcasses. Another cause of lost revenue with malignant hyperthermia susceptible swine is their decreased average daily weight gains, conception rates, litter sizes, and boar breeding performance.

Pathogenesis

The molecular basis for susceptibility to the PSS is a hypersensitive triggering mechanism of the calcium-release channel of skeletal muscle sarcoplasmic reticulum.[6] The calcium channel, also known as the ryanodine receptor, plays a critical role in the initiation of muscle contraction. The PSS defect renders muscle hypersensitive to stimulation by various stressors. Stress-susceptible pigs cannot tolerate stress and lose control of skeletal muscle metabolism. The stress may be from external influences such as transportation, fear and excitement, or halothane anesthesia. There is excessive catecholamine release and the sudden onset of anaerobic glycolysis of skeletal muscle, excessive production of lactate and excessive heat production which, in conjunction with peripheral vasoconstriction, leads to hyperthermia. Following exertional or thermal stress, susceptible pigs undergo more extensive physiological change than do resistant pigs. Halothane sensitive pigs are more susceptible to becoming non-ambulatory and when subjected to multiple stressors and may be more prone to producing inferior pork products.[10] The blood glucose concentrations are dependent on the malignant hyperthermia genotype; the homozygous positive animals having the highest levels and the homozygous negative animals having the lowest.[12] The changes in carbohydrate metabolism at rest in malignant hyperthermia positive animals are caused by latent increases of intracellular Ca^{2+} concentrations. Under physical load conditions there is higher lipolysis which may be the result of an indirect activation of the lipolytic system via catecholamine induced cAMP turn-over.

Depending upon the nature, severity, and duration of the stress, the syndrome may manifest in different ways:

- The **porcine stress syndrome** causes rapid death following severe stress.
- The **pale, soft, and exudative (PSE) pork** and **dark, firm, dry (DFD) pork** are seen after slaughter which may have been preceded by mild stressors during lairage
- The **malignant hyperthermia** is drug-induced.

Pale, soft, exudative pork is attributed to increased glycolysis after slaughter. In muscles which develop **dark, firm, dry pork**, the muscle glycogen is already depleted before slaughter.[13] When PSE develops in a muscle, pH drops to values lower than 5.8 at 45 minutes after death. In normal muscles, the pH decreases from approximately 7 in living muscles to 5.3 to 5.8 at 24 hours after death. The lower pH in PSE muscles, combined with a high carcass temperature within the first hour after death, causes the proteins in the muscles to denature. This contributes to the pale color of PSE meat and to its reduced water-holding capacity. Development of muscles with PSE characteristics seems to be initiated by a combination of lower muscle pH already at exsanguination and a faster pH decrease.[13]

Malignant hyperthermia is the drug-induced, often fatal, stress syndrome occurring in susceptible pigs within 3 minutes following the inhalation of a

mixture of halothane and oxygen.[14] Susceptible pigs develop limb rigidity and a hyperthermia which are not easily reversed and may result in death. There is an increased rate of intracellular ATP hydrolysis leading to a progressive failure of ATP-dependent Ca^{2+} accumulation by sarcoplasmic reticulum and/or the mitochondria with a rise in myoplasmic concentration of Ca^{2+} and consequent contraction of muscle. The same molecular defect occurs in lymphocytes from affected susceptible pigs. There is no histomorphometric evidence of cardiac abnormalities in malignant hyperthermia susceptible pigs.[15] The mitochondria from predominantly red muscle fibers have a greater calcium binding capacity than those from predominantly white muscle fiber areas. There is extreme rigidity of skeletal muscles, hyperthermia, tachycardia, cardiac arrhythmia, an increase in oxygen consumption, lactate formation and high-energy phosphate hydrolysis in muscle, respiratory and metabolic acidosis and a rise in the creatine kinase activity and concentration of potassium, lactate, glucose, free fatty acids and catecholamines in blood. There is a large release of glucose and potassium from the liver which contributes to the hyperglycemia and hyperkalemia. There is a marked α-adrenergic stimulation which is responsible for the heat production in malignant hyperthermia susceptible pigs. However, the β-adrenergic response in stress-sensitive and stress-resistant pigs is inconsistent.[16] The lactic acidemia is severe due to the overproduction of lactate peripherally and failure of normal lactate uptake.

Malignant hyperthermia can also be induced using methoxyflurane, isoflurane and enflurane, and succinylcholine.

Exposing stress-susceptible pigs to halothane or exercise induces glycolysis but the mechanisms are different. There are no histochemical differences between muscles of susceptible and normal swine. There is some indication that halothane causes a transient but significant vasoconstrictive action which could be a contributing factor in initiating the severe reactions in malignant hyperthermia. Electron microscopy of platelets from stress-susceptible pigs reveals a defect characterized by dilatation of the open canalicular system.

CLINICAL FINDINGS

Porcine stress syndrome (transport death)

Death during or following transport to market may be significant and is more prevalent when overcrowding occurs and during the hot summer period.[17] If seen alive, affected pigs initially show a rapid tremor of the tail, general stiffness associated with increased muscular rigidity, and dyspnea to the extent of mouth-breathing. The body temperature is elevated, often beyond the limits of the clinical thermometer, and there are irregularly shaped areas of skin blanching and erythema. At this stage the affected pig is frequently attacked by other pigs within the group. The pig collapses and dies shortly afterwards and the total time course of the syndrome is generally of the order of 4–6 minutes.

Malignant hyperthermia

Malignant hyperthermia is also a manifestation of the PSS. It may be induced in stress-susceptible pigs by anesthesia with potent volatile anesthetics such as halothane or by the administration of succinylcholine. It is characterized by the development during anesthesia of increased muscle metabolism with muscular rigidity, lactic acidosis, and a marked increase in basal metabolic rate, increased oxygen consumption, carbon dioxide production and severe hyperthermia and tachycardia, tachyarrhythmia and death. Once fully developed the syndrome is irreversible. The syndrome poses a hazard in swine anesthesia which can be averted by prior medication with dantrolene and has received considerable study as a model for an analogous syndrome in man. It has also been used as a method for determining stress susceptibility for genetic selection programs.

Pale, soft, and exudative pork (PSE)

In stress-susceptible pigs, after slaughter, the inferior quality of the meat with its pale, soft, exudative characteristics is obvious. This is due to excessive postmortem glycolysis with lactic acid production and a rapid fall in muscle pH with depigmentation and reduced water binding as a consequence. In affected muscle, rigor mortis occurs rapidly after slaughter, but then decreases so that affected carcasses have been 'set' and postmortem drip is excessive. Affected pork has a pH of less than 6 and generally a temperature of 41°C (106°F) or greater 45 minutes after slaughter, compared to the normal pork with a pH above 6 and a temperature less than 40°C (104°F). This causes denaturation of muscle proteins leading to affected meat which has inferior taste, cooking and processing qualities, and does not accept curing as readily. The occurrence of this syndrome is considerably influenced by the stress of transport and handling prior to and during slaughter, and this aspect of the syndrome is of major economic importance.[9,18,19] Rapid chilling helps prevent PSE but chill type has no effect.[20]

Dark, firm, and dry pork (DFD)

Dark, firm, dry pork has darker color and higher ultimate pH than normal meat. In muscles which develop DFD the muscle glycogen is already depleted before slaughter, which may be related to prolonged transport with fasting.

Back muscle necrosis

Acute necrosis of the longissimus dorsi occurs in German Landrace pigs and other breeds. The acute syndrome lasts approximately 2 weeks and is characterized by swelling and pain over the back muscles with arching or lateral flexion of the spine and reluctance to move. The swelling and pain then subside, but there is atrophy of the affected muscle and development of a prominent spinal ridge. Some regeneration may occur after several months. Acute cases may die. The syndrome occurs in young adults weighing from 75 to 100 kg. The mild form may be undetectable except for pigs lying down near the feed trough. In the severe form, affected pigs may assume the dog-sitting position with a hunched-up back.

CLINICAL PATHOLOGY

Several testing methods are available for predicting susceptibility.

Halothane test

The halothane test is highly reliable for the identification of pigs which are homozygous for the single recessive gene responsible for susceptibility to the PSS. However, the test is not 100% accurate because of the incomplete penetrance of the halothane sensitivity trait (not all homozygous malignant hyperthermic susceptible pigs react by developing limb rigidity). Penetrance of the halothane sensitivity trait is estimated to vary from 50 to 100% depending on the breed, herd, and investigators. The test detects the worst clinical outcomes, and will not identify all the pigs which will develop PSE. There is now evidence that it will detect the heterozygote.[21] Stress-susceptible pigs are sensitive to halothane at 8 weeks of age and if the anesthetic challenge is removed immediately after obvious signs of limb rigidity develop and before the development of fulminant hyperthermia, the mortality from the procedure is negligible. Pigs that remain unreactive for a challenge period of 5 minutes are considered normal.

A halothane-sensitive muscle defect can be present in certain individuals which do not develop rigid malignant hyperthermic episodes on brief exposure to halothane. A longer halothane exposure combined with succinylcholine is required if these false negatives are to be identified. The halothane test has good predictive value for the occurrence of PSE.

However, there may be breed variations as mentioned above.

A decrease in the amplitude of the phosphocreatine (PCr) signal in the in vivo ^{31}P nuclear magnetic resonance spectrum of skeletal pigs is an early and 100% predictive measurement for the detection of malignant hyperthermia in anesthetized piglets.[22] Nuclear magnetic resonance techniques such as magnetic resonance imaging and magnetic resonance spectroscopy are sensitive diagnostic aids for detecting the onset of PSS in young animals and for following the metabolic changes in muscle tissue during the syndrome.[7]

Halothane concentration markedly affects the outcome of halothane testing, and either higher halothane concentrations or longer exposure might be required to identify positive reactors in a heterogeneous population. The ionophore A23187, a lipophilic carboxylic antibiotic which binds and transports divalent cations across both natural and artificial membrane bilayers, allows clear differentiation between the muscles of normal and pathological animals and may be a useful adjunct to the halothane test.

Blood creatine kinase levels

The blood creatine kinase (CK) levels are higher in stress-susceptible pigs. Pigs are subjected to a standard exertion test and blood samples taken 8–24 hours later and analyzed for CK. The original work indicated a good correlation between the CK levels and the halothane test. There is also an increase in CK levels in pigs as they are transported from the farm to the abattoir. However, not all pigs which develop PSE have increased serum levels of CK. Increased CK activity is highest in stress-susceptible pigs of a certain phenotype Phi-B, and their total plasma CK levels are higher than non-reactors.[23] The initial test was modified so that blood could be collected as drops on a filter paper and sent to a laboratory for identification by a bioluminescent technique. A recent evaluation of a commercial CK screening test using the method of bioluminescence compared with the halothane challenge test on young boars entering a Record of Performance Test Station revealed that it was an inadequate indicator of susceptibility to the PSS or MH. In a different study the CK levels of piglets 8–10 weeks of age predicted halothane-induced stress syndrome with an accuracy of 87–91%.

Plasma pyruvate kinase activity has been compared with CK activity as indicators of the PSS. Both enzymes are increased significantly in homozygous halothane-reacting pigs compared to non-reacting pigs. Pyruvate kinase activity was less variable within groups than CK activity which may allow more effective discrimination between the two different genotypes. However, age-related effects and the failure to identify heterozygotes may restrict the use of plasma pyruvate activity as a diagnostic test.

Blood typing

Blood typing is also used as a method for the identification of susceptible pigs. On one of the chromosomes of the pig, a region with four known loci has been identified. These loci contain the genes responsible for variants of the enzymes 6-phosphogluconate dehydrogenase and phosphoferose isomerase (PHI). The H-blood group system is determined by one of the loci, and halothane sensitivity is also determined by genes at a locus in this region. This region is of special interest because a close connection has been found between this and important carcass traits such as the PSE condition. Thus, blood grouping may be used to detect halothane-sensitive pigs as well as heterozygote carriers.

A DNA-based blood test can now be used to detect the HAL gene status.[2,3] It can be adapted for rapid batch analysis of many samples simultaneously, is less invasive, and can be applied to as little as 50 µL of blood. The test is more than 99% accurate, is cost-effective, and can be used to determine the prevalence of the PSS mutation in various breeds of swine in various countries.[6] A recent study showed that 23% of pigs classified as Hal-1843 free based on a DNA test responded abnormally to halothane anesthesia.[24]

Pale, soft, and exudative pork

This is evaluated by a meat quality index which combines meat color, pH at 24 hours postmortem, and water-binding capacity. Susceptible lines can be identified by carcass inspection and the results applied to sibling or progeny selection. A recent approach is the measurement of mitochondrial calcium efflux. Mitochondria isolated from Mm longissimus dorsi muscle exhibit a rate of Ca^{2+} efflux twice that of normal pigs. Most of the tests readily predict the worst examples of the syndrome but are not sufficiently precise to be able to identify tendencies towards it, which restricts their value in breeding programs.

Erythrocyte osmotic fragility

Erythrocyte osmotic fragility may be correlated with malignant hyperthermia and is being examined as a possible aid in the determination of susceptibility.[21]

Other tests

Any reliable test which can identify stress-susceptible pigs without using halothane testing is attractive. Increased peroxidation of the erythrocytes may be an improved diagnostic test for PSS.[25] Differences in the levels of cortisol, creatinine, aspartate aminotransferase, and lactate dehydrogenase are highly significant between halothane-sensitive and halothane-negative lines of pigs.[26]

An allele specific PCR (AS-PCR) technique has been developed.[27] A PCR followed by reduction endonuclease assay has been developed and used[28] on plucked hair as a source of genomic DNA. In a test with this method 9 of 12 Pietrains were tested homozygous or heterozygous. A one-step procedure has been developed called mutagenically separated PCR (MS-PCR).[29]

NECROPSY FINDINGS

In the PSS, rigor mortis is present immediately following death, and carcass putrefaction occurs more rapidly than normal. The viscera are congested and there is usually an increased quantity of pericardial fluid as well as pulmonary congestion and edema. The muscles – especially the gluteus medius, biceps femoris, and longissimus dorsi – are pale, wet, and soft. In back muscle necrosis, these changes appear grossly to be confined to the epaxial musculature. Histologically, the lesions in skeletal muscle may be minimal, and are easily obscured by autolysis. In some instances only interstitial edema is visible while in animals which have survived repeated episodes there is obvious phagocytosis of degenerate myofibers, with ongoing regeneration and fibrosis. The most typical microscopic finding is hypercontraction of myofibers, characterized by division of the cell into irregularly-sized segments by transverse and sometimes branching bands. Degenerate sarcoplasm of a floccular or sometimes hyaline character may be present. Degenerative changes may also be detected in myocardial cells.

Samples for confirmation of diagnosis

- **Genetic analysis** – 50 g frozen muscle (DNA ANALYSIS) and hair for PCR tests.
- **Histology** – formalin-fixed skeletal muscle (several sections, including longissimus dorsi), heart (LM).
- **Biochemistry** – it has been reported that pigs with PSS develop metabolic acidosis in association with respiratory acidosis[30] which is manifested as lower values of acid–base excess and HCO_3 – with higher H^+ concentrations and pCO_2 than resistant pigs.

DIFFERENTIAL DIAGNOSIS

The acute nature of the PSS and its relation to stress serve to differentiate it from most other syndromes causing sudden death in market and adult sized pigs. The sudden death syndrome must be differentiated from:

- Mulberry heart disease
- Acute septicemias due to salmonellosis, erysipelas, pasteurellosis, and anthrax
- Other causes of sudden death including intestinal volvulus, heat exhaustion, suffocation during transportation
- Hypocalcemic tetany resulting from severe vitamin D deficiency can produce a similar clinical syndrome
- Porcine viral encephalomyelitis may also result in a similar clinical syndrome in postweaned pigs. Pathological and biochemical examinations differentiate these from the PSS.

TREATMENT

The acute syndromes are usually not treated. Several drugs are available for the protection of pigs against drug-induced malignant hyperthermia. A combination of acepromazine and droperidol will delay the onset or prevent the occurrence of halothane-induced malignant hyperthermia. Dantrolene is also effective for treatment and prevention.[9] The therapeutic dose is 7.5 mg/kg BW. Carazolol is effective for the prevention of transport death when given 3–8 hours before transportation and improves meat quality compared to untreated susceptible animals. Acute back necrosis has been treated successfully with isopyrin and phenylbutazone. Experimentally, the supplementation of the diets of stress-susceptible pigs with vitamin E and C will provide some protective effect on cell membrane integrity.

CONTROL

The control of this syndrome depends on genetic selection and possible eradication of the PSS mutation and reduction of the severity of stress imposed on pigs.

Genetic selection

The best strategy for control of this complex is not clear.[6] Several factors must be considered. Swine homozygous for the PSS mutation are at very high risk for developing PSS and severe PSE to make them useful for market pigs. They are used primarily as a source of the PSS mutation for breeding programs and research purposes. Using swine which are heterozygous for the PSS mutation as market pigs may be advantageous. They benefit from the positive effects of the mutation, have minimal risk of developing PSS, and may have acceptable prevalence and severity of PSE, if during marketing and slaughter the environmental and management risk factors which precipitate PSE are minimized. The mutation is not a prerequisite for leanness and muscularity and it is possible for breeders to eradicate the gene from their breeding stock. The negative effects of the halothane gene on fresh pork quality are well known.[31] However, such a policy may result in the loss of an easily accessible and cost-effective selection criterion for favorable carcass characteristics. The PSS mutation has been used successfully in most swine breeds for increasing leanness and muscling. With the development of the DNA-based test for the PSS mutation, the mutation can be selected for with high precision and accuracy, and its expression finely controlled in a breeding program.

The various testing methods described under clinical pathology are used to identify pigs with the halothane gene. The tests can be applied to breeding stock entering swine performance test stations or on a herd basis. A reliable diagnostic test such as a DNA-based blood test to identify it will provide the basis for elimination of the gene or its controlled inclusion in swine breeding programs.[2]

Management of stressors

Control through reduction of stress is not easily applied because frequently the syndrome is induced by routine minor procedures within the piggery. The incidence of transport deaths or the necessity for immediate slaughter salvage of severely stressed pigs on arrival at the abattoir and the occurrence of pale, soft, exudative meat characteristics are a significant economic problem in some countries. The necessity to climb an upper deck in the transport poses a significant stress, and the use of single-deck transports or mechanical lifts for multiple-deck transports, and the shipment of pigs in containers has resulted in a decreased incidence. The provision of spacious, well-ventilated transport vehicles and spray-cooling of pigs on arrival at the holding pens is also beneficial. Pigs should not be slaughtered directly after arrival at the abattoir but should be rested for at least 1–2 hours if they have been stressed only by transportation. In cases of severe physical exertion even more time should be allowed for recovery. Where possible transport distance should be kept to a minimum and transport should be avoided on excessively hot days.

Inherited defects of the skin

INHERITED SYMMETRICAL ALOPECIA

This is an inherited skin defect of cattle in which animals born with a normal hair coat lose hair from areas distributed symmetrically over the body. It has been observed in Holstein cattle as a rare disease but its appearance among valuable purebred cattle has economic importance. It appears to be inherited as a single autosomal recessive character. Loss of hair commences at 6 weeks to 6 months of age. The alopecia is symmetrical and commences on the head, neck, back, and hindquarters, and progresses to the root of the tail, down the legs, and over the forelimbs. Affected skin areas become completely bald. Pigmented and unpigmented skin is equally affected; there is no irritation and the animals are normal in other respects. Failure of hair fibers to develop in apparently normal follicles can be detected by skin biopsy.

INHERITED CONGENITAL HYPOTRICHOSIS

In this congenital disease there is partial or complete absence of the hair coat with or without other defects of development. The main importance of the disease is in cattle, in which there are six syndromes, but it is also inherited in **pigs**, in which it is associated with low birth weights, weakness, and high mortality, and in Poll Dorset **sheep**, in which the face, ears, and lower legs are bald, there are no eyelashes, and the patient lacrimates excessively. The skin is thick, wrinkled, greasy, scaly, and erythematous. Hair fibers are completely absent from the follicles, but wool fibers and follicles are normal.[1]

Viable hypotrichosis

The condition is recorded in North America in Guernsey and Jersey cattle. Calves are viable provided they are sheltered. They grow normally but are unable to withstand exposure to cold weather or hot sun. In most instances hair is completely absent from most of the body at birth but eyelashes and tactile hair are present about the feet and head. Occasionally hair may be present in varying amounts at birth but is lost soon afterwards. There is no defect of horn or hoof growth. The skin is normal but has a shiny, tanned appearance and on section no hair follicles are present in the skin. The condition is inherited as a single, recessive character.

Congenital hypotrichosis has been reported in a Perheron draught horse.[2] At birth there were circumscribed patchy areas alopecia which was progressive becoming almost complete by 1 year of age. Skin biopsy at 7 months of age revealed severe follicular hypoplasia and the animal was still alive at 6 years of age.

Non-viable hypotrichosis

This is a complete hypotrichosis in which the thyroid is abnormally small and hypofunctional and the calves die shortly after birth.

Hypotrichosis with anodontia

Congenital X-linked hypotrichosis with missing teeth in cattle is characterized by abnormal morphogenesis to teeth, hair follicles, and eccrine sweat glands.[3] Two different forms can be distinguished according to the severity of the tooth defects: (1) congenital hypotrichosis with complete or almost complete anodontia; (2) congenital hypotrichosis with completely missing incisors or defective incisors. Impaired body condition and growth of the affected animals result from missing teeth. In addition, animals with sparse hair are more susceptible to cold and more prone to skin lesions.

The phenotype and inheritance of hypotrichosis with nearly complete anodontia has been recorded in pedigreed German Holstein calves.[3] The phenotype is inherited as a monogenic X-linked recessive trait. A reverse transcription-PCR assay was used to identify the causative large genomic deletion in the bovine *EDI* gene. The *EDI* gene for the hypotrichosis and anodontia phenotype appears to have pleotropic effects on hair follicles, eccrine nasolabial glands, apocrine sweat glands, individually expressed contours of the muzzle, and on development of incisor and premolar/molar teeth. A molecular genetic test for the pathological mutation allows the unequivocal classification of animals with congenital hypotrichosis and anodontia and identification of heterozygous carriers and their exclusion from further breeding.[3]

Streaked hairlessness

A sex-linked semidominant gene causes development of a streaked hairlessness in which irregular narrow streaks of hypotrichosis occur in female Holsteins.

Partial hypotrichosis

Recorded in polled and horned Hereford cattle. At birth there is a fine coat of short, curly hair which later is added to by the appearance of some very coarse, wiry hair. The calves survive but do not grow well. The character is inherited as a simple recessive. The disease in Poll Herefords has the same short curly coat but there is also a deficiency of hair in the switch, and over the poll, brisket, neck, and legs in some cattle. Some have a much lighter hair coat color. Histologically there is a characteristic accumulation of large trichohyaline granules in the hair follicles.

Rat tail syndrome in calves

The 'rat tail' occurred following the importation of continental European breeds of cattle into the United States when those breeds were crossed with Angus or Holsteins.[4] The abnormality is characterized by short, curly, malformed, sometimes sparse hair and lack of normal tail switch development. Histologically, there are enlarged, irregularly distribute, and clumped melanin granules in the hair shafts, which are asymmetrical, short, curled, and small. The scale surface is rough and pitted, and scale fails to form in some areas. A study of the inheritance of the abnormality found that all rat-tail calves were sired by Simmental bulls and were from cows with various percentages of Angus breeding.[4] The abnormality had no effect on birth weight, weaning weight, or gain from birth to weaning. However, rat-tail calves had significantly lower rates of gain during the winter months from weaning to yearling than non-rat-tail calves. The syndrome is controlled by interacting genes at 2 loci. Cattle which express the syndrome must have at least one dominant gene for black color and be heterozygous at the other locus I

INHERITED HAIR COAT-COLOR-LINKED FOLLICLE DYSPLASIA

Some **'buckskin'-colored follicular dysplasia** occurs in so-called 'Portugese' Holstein cattle, a grade variant of Red Holsteins with a tan color instead of the red. This defect consists of a coat-color-linked hair follicle dysplasia, in which the colored hairs are shorter and less lustrous than the white hair, making the coat much finer and smoother. Test matings seem to confirm an autosomal dominant inheritance.[1]

A **black hair colored follicular dysplasia** is also recorded in Holstein cattle.[2] Patches of hair loss varying from hypotrichosis to complete alopecia occur in a random fashion but only on black areas. Follicular dysplasia is evident in biopsy samples. The abnormality persists for the life of the animal and is of cosmetic importance only. An inherited etiology is assumed.

A follicular dysplasia in a mature Brangus-cross cow and a mature Angus cow has been described.[3] Adult onset alopecia occurred and skin biopsy revealed follicular distortion and atrophy, with melanin clumping in follicular epithelium, hair bulb matrix cells, hair shafts, and infundibular keratin.

INHERITED BIRTHCOAT RETENTION

This is recorded in Merino and Welsh mountain sheep and characterized by a coat of hairy medullated fibers in contrast with the non-medullated wool fibers of the normal sheep fleece.

INHERITED LEUKODERMA

The **Arab fading syndrome** commences in young horses in particular families of Arab horses as round, unpigmented patches of skin around the lips, eyes, perineum, preputial orifice. Some cases recover spontaneously but the blemish is usually permanent.

INHERITED ALBINISM AND LETHAL WHITE FOAL SYNDROMES

Albinism is a congenital lack of melanin pigment in the skin, hair, and other normally pigmented structures such as the uveal tract. Albinism is classified as generalized or localized and as complete or partial or incomplete. The affected skin in albinism is characterized microscopically as melanopenic rather than melanocytopenic, which distinguishes partial albinism from piebaldism. Most of the normal, inherited white markings which occur on horses are localized forms of piebaldism. Generalized and complete albino animals (oculocutaneous albinism) have white hair, white skin, pink irides and usually exhibit photophobia.[2] Generalized albinism in the horse is inherited as autosomal dominant trait which is only viable in the heterozygous states. These horses have incomplete albinism as there is some coloration to the iris. Matings of heterozygous albino horses produce a nonviable embryo 25% of the time which is resorbed in gestation. This is one form of lethal white foal syndrome. A second form of lethal white foal syndrome is an autosomal recessive defect which occurs by mating of overo paint horses. Lethal white foals from such breedings are characterized by albinism and congenital defects of the intestinal tract.

INHERITED EPIDERMAL DYSPLASIA (BALDY CALVES)

This is a lethal defect of Holstein-Friesian calves inherited as an autosomal recessive character. The calves, most commonly heifers, are normal at birth but at 1–2 months of age begin to lose condition in spite of good appetites. The skin over most of the body is slightly thickened, scaly, and relatively hairless. There are also patches of scaly, thickened, and folded skin especially over the neck and shoulders, and hairless, scaly, and often raw areas in the axillae and flanks and over the knees, hocks, and elbow joints. The skin over the joints is immovable. There is usually alopecia about the base of the ears and eyes. The tips of the ears are curled backwards. The horns fail to develop and there is persistent slobbering, although there are no mouth lesions. The hooves are long, narrow, and pointed because of gross overgrowth of the walls; these and stiffness of joints cause a shuffling, restricted gait. Calves assume a recumbent posture for most of the time. Severe emaciation leads to destruction at about 6 months of age.

Histological changes in the skin include acanthosis, hyperkeratosis, and patchy neutrophil invasion. The similarity of this condition to inherited parakeratosis and to experimental zinc deficiency suggests an error in zinc metabolism, but treatment with zinc had no effect on the course of the disease.[1]

INHERITED CONGENITAL ABSENCE OF THE SKIN

Classical epitheliogenesis imperfecta

Absence of mucous membrane, or more commonly, absence of skin over an area of the body surface has been recorded at birth in pigs, calves, lambs,[1] and foals. There is complete absence of all layers of the skin in patches of varying size and distribution. In **cattle** the defect is usually on the lower parts of the limbs and sometimes on the muzzle and extending onto the buccal mucosa. The disease is best known in Holstein-Friesians, but is also recorded in Japanese Black, Shorthorn, Sahiwal,[2] and Angus cattle. In **pigs** the skinless areas are seen on the flanks, sides, back, and other parts of the body. The defect is usually incompatible with life and most affected animals die within a few days. Inheritance of the defect in cattle is conditioned by a single recessive gene. Tissue-cultured fibroblasts from affected animals produce subnormal amounts of collagen and lipids.[3]

Familial acantholysis

Suspected of being inherited, this defect in Angus calves is characterized by defective collagen bridges in the basal and prickle layers of the epidermis so that skin, normal at birth, is subsequently shed at carpal and metacarpophalangeal joints and coronet, and there is separation of horn at the coronet.

Epidermolysis bullosa

This congenital disease of Suffolk and South Dorset Down sheep[4] and Simmental[5] and Brangus calves is characterized by the formation of epidermal bullae in the mouth and on exposed areas of skin, such as the extremities of the limbs, the muzzles and ears, leading to shedding of the covering surface and separation of the horn from the coronet. Lesions may be present at birth. Simmental calves grow poorly, have hypotrichosis, and suffer repeated breaks in the skin, apparently due to an abnormal susceptibility to trauma. Most calves die but some survive and the lesions subside. In Simmentals the disease is inherited as an autosomal dominant trait. The disease in Brangus calves is very similar to familial acantholysis in Angus cattle.

The severe form of Herlitz junctional epidermolysis bullosa, which occurs in humans has been recorded in foals of the French draft horse breeds.[6] A mutation in the *LAMC2* gene is responsible for the defect. Affected foals were born with skin blistering, skin and buccal ulceration followed by loss of hooves. In the affected skin there was disjunction of the epidermis from the underlying dermis at the dermal-epidermal junction. Genomic DNA testing is used to determine the presence of the mutation in carrier animals.

Hereditary junctional mechanobullous disease

This defect is inherited in Belgian foals, Angus and Simmental calves, and Suffolk and South Dorset Down lambs.[7,8] It is usually recorded under the heading of epidermolysis bullosa. There may be no shedding of skin but the initial bullous lesions at the coronet, considered to be initiated by abrasions, lead to sloughing of the hooves.

Red foot disease of sheep

This is similar to both of the above diseases. It is recorded in Scottish Blackface and Welsh mountain[9] sheep. The lesions are not present at birth but become apparent at 2–4 days of age when there is sloughing of skin of the limbs, the accessory digits, the ear pinna, and of the epidermal layers of the cornea and buccal mucosa, especially the dorsum of the tongue. There is also an absence of head horn and a separation of hoof horn from the coronet. Pieces of horn become completely detached exposing the red corium below, hence 'red foot'. The cutaneous and mucosal lesions often commence as blood-filled or fluid-filled blisters. The corneal lesions are similarly the result of sloughing of epidermal layers. Although the cause is unknown there are indications that it is inherited.

INHERITED CROP EARS

Inherited as a single autosomal, incomplete dominant character in Bavarian Highland cattle, this anomaly affects both ears, appears at birth, and varies from a minor trimming up to a complete deformity and reduction in size.[1]

INHERITED HYPERBILIRUBINEMIA AND PHOTOSENSITIZATION

An inherited photosensitization with hyperbilirubinemia has been observed in Southdown sheep in New Zealand and the United States, and in Corriedales in California.[1] It is inherited as an autosomal recessive trait.

Liver insufficiency is present but the liver is histologically normal. Phylloerythrin and bilirubin excretion by the liver is impeded and the accumulation of phylloerythrin in the bloodstream causes the photosensitization. There is also a significant deficiency in renal function. Symptomatic treatment of photosensitization and confining the animals indoors may enable the lambs to fatten to market weight. The persistent hyperbilirubinemia is accompanied by an inability of the kidneys of these sheep to concentrate urine and the eventual death of the sheep from renal insufficiency.

Affected sheep live for several years if they are protected from sunlight and tend to die from renal failure associated with progressive fibrosis of the kidney.

A similar disease in Corriedale sheep in California is inherited as an autosomal recessive trait.[1] The functional defect is not in the uptake of unconjugated bilirubin and phylloerythrin, but rather its excretion from liver into bile. It affects lambs as they begin to eat pasture. Lambs live until 6 months of age if provided with some shade. There is also marked melanin-like pigmentation of the liver.

These two diseases are examples of the involvement of external environmental disease factors with a genetic disease: a diet of green forage (chlorophyll) and sunlight, working in concert with the inborn error of metabolism to induce photosensitization.[1]

INHERITED CONGENITAL ICHTHYOSIS (FISH-SCALE DISEASE)

Congenital ichthyosis is a disease characterized by alopecia and the presence of plates of horny epidermis covering the entire skin surface. It has been recorded only in Holstein and Norwegian Red Poll and probably in Brown Swiss calves among the domestic animals, although it occurs also in humans.

The newborn calf appears to be either partly or completely hairless and the skin is covered with thick, horny scales separated by fissures which follow the wrinkle lines of the skin.[2] These may penetrate deeply and become ulcerated. There are plenty of normal hair follicles and normal hairs but these are lost in the areas covered by the growth of scales. A skin biopsy section will show a thick, tightly adherent layer of keratinized cells. The disease is incurable and, although it may be compatible with life, most affected animals are disposed of for esthetic reasons. The defect has been shown to be hereditary and to result form the influence of a single recessive gene.

INHERITED DERMATOSIS VEGETANS

This disease appears to be conditioned by the inheritance of a recessive, semilethal factor. Affected pigs may show defects at birth but in most instances lesions appear after birth and up to 3 weeks of age. The lesions occur at the coronets and on the skin.[3] Those on the coronets consist of erythema and edema with a thickened, brittle, uneven hoof wall. Lesions on the belly and inner surface of the thigh commence as areas of erythema and become wart-like and covered with gray-brown crusts.

Many affected pigs die but some appear to recover completely. Many of the deaths appear to be due to the giant-cell pneumonitis which is an essential part of the disease. The pathology of the disease indicates that it is the result of a genetic defect which selectively affects mesodermal tissue. It is known to have originated in the Danish Landrace breed.

DERMATOSPARAXIS (HYPERELASTOSIS CUTIS)

This is an extraordinary fragility of skin and connective tissue in general, with or without edema. It is probably inherited as a recessive character. It occurs in cattle, horses, in Finnish and White Dorper[1] sheep, and a mild form is seen in Merino sheep. The latter is inherited as a simple autosomal recessive. The skin is hyperelastic, as are the articular ligaments; marked cutaneous fragility, delayed healing of skin wounds, and the development of papyraceous scars are also characteristic. Pieces of skin may be ripped off when affected sheep are being handled. In horses the skin in some parts of the body is thinner than elsewhere, e.g. the skin of the ventral abdomen and the collagen bundles in the area are more loosely packed and are curved rather than straight. The proportion of acid-soluble collagen is also much higher in this abnormal skin. The disease involves a molecular defect of a collagen-binding protein,[2] and is related to a recognized problem in dogs and cats identified as 'dominant collagen packing defect'.[3]

Hereditary equine regional dermal asthenia has been recorded in related Quarter horses in Brazil similar to that reported in the United States.[4] Reported cases of horses with hyperextensible skin have involved Quarter Horses.[5] Clinically there were bilateral asymmetrical lesions of the trunk and lumbar regions, where the skin was hyperextensible. Handling of the skin elicited a painful response and superficial trauma led to skin wounds. The skin was thinner than normal in affected areas, with thickened borders and harder fibrotic masses. Histologically, the collagen fibrils were thinner and smaller, which created a loose arrangement of collagen fibers within the deep dermis. The deep dermis contains a distinctive horizontal linear zone in which separation of collagen bundles results in formation of large empty cleft-like spaces between the upper and lower regions of the deep dermis: 'zonal dermal separation'.[5] Pedigree analysis indicates an autosomal recessive type of inheritance.

The Ehlers–Danlos syndrome, recorded in Charolais and Simmental cattle, and Rippolesa sheep,[6] is also characterized by extreme fragility of skin and laxness of joints in the newborn. There is a defect in collagen synthesis, and histopathological findings include fragmentation and disorganization of collagen fibers.

The syndrome has also been recorded in lambs.[7] The skin was loose and present in excessive amounts, with folds over the carpal joints and lower regions of the legs. In some lambs, there may be separation of epidermis from dermis with blood-filled cavitations and intact skin which can be easily torn.

INHERITED MELANOMA

Inherited cutaneous malignant melanoma are found in National Institute for Health (NIH miniature) and Sinclair miniature swine. Its expression is associated with two genetic loci, one of them associated with the swine major histocompatibility complex.[1] Familial melanoma have also been recorded in members of successive litters from an individual Duroc x Slovak White sow.[2]

INHERITED HYPERHIDROSIS

A condition characterized by excessive sweating, and thought to be inherited, is recorded in beef Shorthorn calves. The syndrome includes conjunctivitis, some cases progressing to complete opacity of the cornea, heavy dandruff, and persistent wetness of the hair coat.

Miscellaneous inherited defects

INHERITED EYE DEFECTS

An inherited, congenital **corneal opacity** occurs in Holstein cattle. The cornea is a cloudy blue color at birth and both eyes are equally affected. Although the sight of affected animals is restricted they are not completely blind, and there are no other abnormalities of the orbit or the eyelids. Histologically there is edema and disruption of the corneal lamellae.

With **lens dystrophy** Brown Swiss cattle are affected by an inherited congenital blindness with a cloudy shrunken lens as the cause. Japanese Black cattle also suffer from an inherited blindness caused by defects in the pupil, retina, and optic disk.

Bilateral **cataract** has been observed to be an inherited defect in Romney sheep. It is inherited as an autosomal dominant and can be eradicated easily by culling.

Complete **absence of the iris** (aniridia) in both eyes is also recorded as an inherited defect in Belgian horses. Affected foals develop secondary cataract at about 2 months of age. Total **absence of the retina** in foals has also been recorded as being inherited in a recessive manner.

Microphthalmia is reported to be an inherited defect in Texel sheep, but the incidence is low. It is a well-recognized genetic defect of Texel sheep in Europe.[1,2] Following importation and 'breeding up' of the breed in New Zealand in the 1990s, animals were released from quarantine for further expansion of the breed. The abnormality has occurred in a number of flocks in New Zealand and an experimental breeding flock is maintained to study the molecular genetics.[3] It is inherited as an autosomal recessive trait. An outbreak in Texel sheep in New Zealand has been recorded.[1] The optic globes are approximately one half normal size and the optic nerves at the chiasma are approximately one half normal size. No other lesions are present in any organs. The retina is composed of an irregular mass attached to and continuous with the ciliary apparatus at one pole, and connected to the optic nerve posteriorly by a short stalk.[1] The morphology and morphogenesis of the defect has been followed in embryos at different ages from ewes known to be carriers of the microphthalmia factor.[2] The primary event was abnormal development of the lens vesicle, with disintegration of the lens and subsequent overgrowth of mesenchymal tissue. The mesenchymal tissue later differentiated in various directions, whereas the epithelial structures found in the microphthalmic eyes at days 56 and 132 of gestation and in newborn lambs appeared to be remnants of the epithelial lens vesicle.

Typical colobomata, ophthalmoscopically visible defects of one or more structures of the eye, caused by an absence of tissue, have assumed a more prominent position than previously because of their high level of occurrence in Charolais cattle. The lesions are present at birth and do not progress beyond that stage. They affect vision very little, if at all. However, because they are defects they should be named in certificates of health but they are not usually considered as being a reason for disqualification from breeding programs. In Charolais cattle the inheritance of the defect is via an autosomal dominant gene with complete penetrance in males and partial (52%) penetrance in females. The prevalence may be as high as 6% and in most cases both eyes are affected. The defect is due to incomplete closure of one of the ocular structures at or near the line of the embryonic choroidal fissure. Failure of the fissue to close represents the beginnings of the coloboma. The retina, choroid, and sclera are usually all involved.

Entropion is inherited in a number of sheep breeds including Oxfords, Hampshires, and Suffolks. Affected lambs are not observed until about 3 weeks of age when attention is drawn to the eyelids of the apparent conjunctivitis. A temporary blindness results but even without treatment there is a marked improvement in the eyelids and the lambs do not appear to suffer any permanent harm.

Ocular dermoids are recorded as genetically transmitted in Hereford cattle. They occur as multiple small masses of dystrophic skin complete with hair on the conjunctiva of both eyes of affected cattle. They can be anywhere on the cornea, on the third eyelid, or the eyelid and may completely replace the cornea; there may be a resulting marked dysplasia of the internal ocular structures.

Combined ocular defects

Although the vision appears unaffected a large number of congenital defects of the eye have been observed in cattle, including Herefords, affected by partial albinism. The defects include iridal heterochromia, tapetum fibrosum, and colobomas. Congenital blindness is also seen in cattle with white coat color, especially Shorthorns. The lesions are multiple and include retinal detachment, cataract, microphthalmia, persistent pupillary membrane, and vitreous hemorrhage. Internal hydrocephalus is present in some, and hypoplasia of optic nerves also occurs.

A combination of **iridal hypoplasia, limbic dermoids and cataracts** was recorded in the eyes of progeny of a Quarter Horse stallion, presumably as a result of a mutation in the stallion and transmission to the foals via an autosomal, dominant gene.[4] The inheritance is a simple autosomal recessive.

Iridiremia (total or partial absence of iris), **microphakia** (smallness of the lens), ectopia lentis and cataract have been reported to occur together in Jersey calves. The mode of inheritance of the characters is as a simple recessive. The calves are almost completely blind but are normal in other respects and can be reared satisfactorily if they are hand-fed. Although the condition has been recorded only in Jerseys, similar defects, possibly inherited, have also been seen in Holsteins and Shorthorns.

Inherited night blindness occurs in Appaloosa horses which have otherwise normal sight. No defect has been described in the eyes.

INHERITED PROLONGED GESTATION (ADENOHYPOPHYSEAL HYPOPLASIA)

Prolonged gestation occurs in cattle and sheep in several forms and is usually, although not always, inherited. The two recorded forms of the disease are prolonged gestation with fetal giantism and prolonged gestation with deformed or normal or small size fetuses.

Prolonged gestation with fetal giantism

The inherited disease is recorded in Holstein, Ayrshire, and Swedish cattle with prolongation of pregnancy from 3 weeks to 5 months. The cows may show marked abdominal distension but in most cases the abdomens are smaller than one would expect. Parturition, when it commences, is without preparation. Udder enlargement, relaxation of the pelvic ligaments, and loosening and swelling of the vulva do not occur and there is also poor relaxation of the cervix and a deficiency of cervical mucus.[1] Dystocia is usual and cesarean section is advisable in Holstein cattle but the Ayrshire calves have all been reported as having been born without assistance. The calves are very large (48–80 kg body weight) and show other evidence of post-term growth, with a luxuriant hair coat and large, well-erupted teeth which are loose in their alveoli, but the birth weight is not directly related to the length of the gestation period.

The calves exhibit a labored respiration with diaphragmatic movements more evident than movements of the chest wall. They invariably die within a few hours in a hypoglycemic coma. At necropsy there is adenohypophyseal hypoplasia and hypoplasia of the adrenal cortex and the thyroid gland. The progesterone level in the peripheral blood of cows bearing affected calves does not fall before term as it does in normal cows.

Prolonged gestation with craniofacial deformity

This form of the disease has been observed in Guernsey, Jersey, and Ayrshire cattle. It differs from the previous form in that the fetuses are dead on delivery, show gross deformity of the head, and are smaller than the normal calves of these breeds born at term. In Guernseys the defect has been shown to be inherited as a single recessive character and it is probable that the same is true in Jerseys. The gestation period varies widely with a mean of 401 days.

Clinical examination of the dams carrying defective calves suggests that no development of the calf or placenta occurs after the seventh month of pregnancy. Death of the fetus is followed in 1–2 weeks by parturition unaccompanied by relaxation of the pelvic ligaments or vulva or by external signs of labor. The calf can usually be removed by forced traction because of its small size. Mammary gland enlargement does not occur until after parturition.

The calves are small and suffer varying degrees of hypotrichosis. There is hydrocephalus and in some cases distension of the gut and abdomen due to atresia of the jejunum. The bones are immature and the limbs are short. Abnormalities of the face include cyclopian eyes, microphthalmia, absence of the maxilla, and the presence of only one nostril. At **necropsy** there is partial or complete aplasia of the adenohypophysis. The neural stalk is present and extends to below the diaphragm sellae. Brain abnormalities vary from fusion of the cerebral hemispheres to moderate hydrocephalus. The other endocrine glands are also small and hypoplastic.

The disease has been produced experimentally in ewes by severe ablation of the pituitary gland, or destruction of the hypothalamus, or section of the pituitary stalk in the fetus and by adrenalectomy of the lamb or kid. Infusion of ACTH into ewes with prolonged gestation due to pituitary damage produces parturition but not if the ewes have been adrenalectomized beforehand.

Prolonged gestation with arthrogryposis

A form of prolonged gestation, which occurs in Hereford cattle and is thought to be inherited, is accompanied by arthrogryposis, scoliosis, torticollis, kyphosis, and cleft palate.

INHERITED COMBINED IMMUNODEFICIENCY (CID) IN FOALS OF ARABIAN BREEDING

Synopsis

Etiology Inherited immunodeficiency in foals of Arabian parentage caused by a mutation in the gene coding for DNA-protein kinase catalytic subunit.
Epidemiology Familial pattern of occurrence with autosommal recessive inheritance. Approximately 8% of Arabian horses are heterozygous for the mutation (carriers). Random mating results in approximately 1 in 600 foals being affected, but not all matings are random and the incidence of the disease is less than this number.
Clinical findings Foals normal at birth but succumb to systemic infection soon after birth and die before 3 months of age. Death from acute septicemia, or recurrent or chronic continuous infection, usually of respiratory tract. Poor response to normally effective antibiotic therapy.
Clinical pathology Lymphopenia, hypogammaglobulinemia. PCR test detects animals heterozygous (carriers, parents of affected foals) or homozygous (affected foals) for the mutated gene.
Necropsy findings Thymic, lymph node, and splenic hypoplasia and a marked reduction in the numbers of splenic and lymph node lymphocytes.
Diagnostic confirmation. PCR detection of mutated gene (homozygouse in affected foals). Lymphopenia and agammaglobulinemia in a foal of Arabian breeding.
Treatment Nil.
Control Ideally, elimination of the mutated gene by not breeding carrier animals. The disease can be prevented by not breeding a carrier animal to another carrier.

ETIOLOGY

The fundamental defect is a 5 base-pair deletion in the specific gene that codes for DNA-dependent protein kinase.[1–3] The gene is located on chromosome ECA9.[4] This mutation causes a lack of activity of the catalytic subunit of DNA-dependent protein kinase.[1,2,3] The deficiency of protein kinase activity, which is absolute in affected foals, results in the inability to join DNA strands that have been broken as part of the normal process of creation of V (variable) regions of T cell and B cell antigen receptors on lymphocytes. Without these receptors the lymphocytes are unable to respond to antigens and thus the foal is not capable of mounting adaptive, either cellular or humoral (antibody), immune responses.[1]

EPIDEMIOLOGY

The immunodeficiency is inherited as an autosomal recessive defect. The disease occurs in purebred and part-Arabian horses. It has also occurred in an Appaloosa foal that had an Arab stallion in the fifth past generation of its mother's pedigree. In one survey of Arabian foals in the United States, the prevalence rate of affected foals was 2.3% of 257 foals of Arabian breeding, and 25.7% of the parents of affected foals were estimated to be carriers of the genetic defect.[5] However, this likely represents an overestimation of the incidence of the disease and prevalence of the mutation in the population of Arabian horses because of selective testing.[6] The frequency of carriers of the mutation for severe combined immunodeficiency is approximately 8%, with an estimated 0.2% (1 in 600) of foals of random matings between Arabian horses affected with the disease, based on

a survey of 250 horses.[6] Approximately 17% of Arabian horses are heterozygous for the mutation and 0.3% of foals are homozygous among > 6000 horses tested by a commercial laboratory.[7]

Affected foals usually appear normal at birth, but are highly susceptible to infections from 2 to 65 days after birth and usually die from one or more infections by 3 months of age. The sires and dams of affected foals are clinically normal and have normal lymphocyte counts and serum immunoglobulin concentrations.

PATHOGENESIS

Affected foals are born with a combined immunodeficiency associated with a deficiency in both B-lymphocytes (which produce immunoglobulins) and T-lymphocytes (which provide cellular immunity). There is a marked lymphopenia and failure of immunoglobulin (Ig) synthesis and absence of delayed hypersensitivity of skin responses. Foals that receive immunoglobulins from the dam's colostrum derive passive immunity and can survive for as long as 4 months. Foals that do not receive colostrum die much earlier. The cause of death is infectious disease.

Affected foals are susceptible to infections of all kinds, but mostly of the respiratory tract. Adenoviral pneumonia is considered to be the most common secondary complication, probably because adenovirus infection is so widespread in the horse population. Affected foals may also die from hepatitis, enteritis, or infection of other organs without pulmonary involvement. While adenoviral pneumonia is the most common complication, infections with bacteria and *Pneumocystis carinii* also occur. *Cryptosporidium* sp. has also been recorded in a number of foals with diarrhea, which is also a common complication.

CLINICAL FINDINGS

Affected foals usually become ill from 10 to 35 days of age. Commonly there is a history suggesting a mild disease of the respiratory tract, especially the appearance of a bilateral nasal discharge, which often becomes sufficiently thick to interfere with sucking. The foal is unthrifty, lethargic, and tires easily but still nurses and eats solid feed. A deep dry cough and a serous to mucopurulent ocular and nasal discharge are common when pneumonia is present. There is moderate fever (39.5°C, 103°F) and an increase in the heart and respiratory rates. The depth of respirations is increased and a double expiratory effort is common. On auscultation, loud bronchial tones and moist and dry crackles are common over the anterior ventral aspects of both lungs. A chronic diarrhea is present in some foals, and alopecia and dermatitis, commonly associated with an infection by *Dermatophilus congolensis*, also occur. An important clinical feature is that affected foals do not respond favorably to treatment with antimicrobial agents. The course of the illness will vary from a few days to a few weeks and probably depends on the degree of immunodeficiency and the nature of the infection. Most affected foals become progressively worse over a period of 2–4 weeks, and death by 3 months of age is the usual outcome.

CLINICAL PATHOLOGY

Lymphopenia is a constant finding with counts often less than 1000/mL and there is a concurrent hypogammaglobulinemia in foals that have not received colostrum. There is no IgM in precolostral serum of the foal. Following ingestion of colostrum, all subclasses of immunoglobulin will be present but in affected foals the level of IgM will steadily decrease weekly until at about 36 days when IgM is detectable. The lack of IgM is because of lack of synthesis and the shorter half life of this isotype of immunoglobulin in foals – serum IgG concentrations decline more slowly. Until the development of the PCR test for detection of homozygous foals and confirmation of the disease, the measurement of serum Ig concentrations was considered essential for a definitive diagnosis. Additional tests include enumeration of B-lymphocyte and T-lymphocyte responses to phytolectin stimulation and other tests of lymphocytic immunological function, but these tests are no longer required for diagnostic confirmation of the disease.

NECROPSY FINDINGS

The lymph nodes are small and splenic follicles are not visible. A viral interstitial pneumonia and a secondary bacterial bronchopneumonia are common. The thymus gland is usually hypoplastic. Histologically the lymph nodes and spleen are depleted of lymphocytes, and germinal centers are absent. In some foals there are foci of necrosis of the intestinal epithelium but with minimal infiltration of inflammatory cells. Inclusion bodies of adenovirus may be present in the cells of several different body systems. In Australian foals *Rhodococcus equi* can be commonly isolated from pulmonary abscesses. Additional histological findings include a severe adenoviral pancreatitis and adenitis of the salivary glands.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation in an apparently chronic case of pneumonia in a young foal depends on the identification of the characteristic lymphopenia.

The differential diagnosis list includes:

- Septicemia and pneumonia of foals, caused by *Rhodococcus equi*
- Agammaglobulinemia due to failure of transfer of maternal immunoglobulins from colostrum. In many foal populations as many as 20% of foals are immunodeficient for this reason
- Other immunodeficiencies (Table 35.1). Foals with these deficits are very susceptible to a variety of infectious diseases and are usually chronically ill, most often with respiratory infections. However, because they have partial protection, they survive and their life span is much longer than that of foals with CID, usually over 1 year and often 18 months. Hematologically the foal is normal unless an infection is in process, but electrophoretic examination usually reveals a marked deficiency of betaglobulins. Further tests are needed to identify the exact deficiency. A radioimmunodiffusion assay is used to quantitate serum immunoglobulins – IgA and IgM levels are usually at negligible levels, but IgG levels are discernible, although diminished. An intradermal test by injection of phytohemagglutinin determines T-lymphocyte status – a normal response is migration of mononuclear cells
- An isoimmune neonatal leukopenia can cause immune deficiency in foals; antibodies to the sire's lymphocytes are detectable in the mare's serum
- Neonatal septicemias.

TREATMENT

There is no satisfactory treatment for CID in foals. Hyperimmune serum, whole blood transfusions, and broad-spectrum antibiotics are all used without more than a temporary response. Affected foals may be kept alive by twice-weekly injections of hyperimmune serum and a constant antibiotic cover. Immunotherapy using a transplant of bone marrow and a fetal thymus transplant has been attempted without success. Corticosteroids are contraindicated.

CONTROL

Horses heterozygous for the mutation can be detected using a commercial PCR assay.[6,7] These horses have normal serum immunoglobulin concentrations and lymphocyte counts. Detection of heterozygous animals, which is required by some national breed organizations, is

useful for several reasons. Firstly, it should, ideally, permit elimination of the disease from the population by breeding of only homozygous normal animals. However, this approach has not met with success because of the financial and emotional value of some heterozygous animals. Secondly, identification of the status of an animal permits controlled breeding such that the risk of producing homozygous affected foals is eliminated. This is achieved by mating only pairs of homozygous normal animals, in which case none of the off-spring will carry the mutated gene, or by mating a heterozygous animal with a homozygous normal animal. In this instance 1 in 4 of the progeny will carry the mutated gene, but none of the progeny will be homozygous for the mutated gene and, therefore, afflicted with the disease. This second approach, if applied consistently, should almost eliminate the disease.

Specific diseases of uncertain etiology 36

Introduction

It was anticipated that, with time, this chapter would shrink in succeeding editions and, eventually, disappear. As the causes of individual diseases are demonstrated they are removed to other chapters but in the past newly identified diseases have been added at almost the same rate so that the net effect on the chapter has been small. The process could have been hastened by moving diseases when the consensus of opinion, short of proof, was that the cause had been identified. We have thought it preferable to leave those diseases here, together with those in which the combination of causes is complex, such as 'weaner illthrift'.

Synopsis

Etiology Several causes including parasitism, trace element deficiencies, pasture palatability and fungal infestations of pasture.
Epidemiology Loss of weight at weaning and failure to make satisfactory weights subsequently, in spite of the presence of ample feed and when adult sheep are faring well.
Clinical findings Poor body condition and failure to thrive.
Lesions Inanition
Diagnostic confirmation Laboratory testing for specific cause. Correction-response trial.
Treatment Correction
Control

Diseases characterized by systemic involvement

UNTHRIFTINESS IN WEANER SHEEP (WEANER ILLTHRIFT)

ETIOLOGY

A number of different diseases have been associated with this syndrome in both lambs and calves. In many cases an association has been established by a response trial but in others the association has not been established as causal. These include

intestinal parasitism, coccidiosis, infection with hemoplasma (eperythrozoonosis), deficiencies of copper, cobalt, selenium, zinc, thiamin, vitamin A, and vitamin D. A combination of these deficiencies has also been suspected.

Palatability of pasture appears a cause of illthrift in some instances, or at least associated with it, and moving the animals to a different pasture will sometimes alleviate the condition. This has been observed with perennial rye-grass (*Lolium perenne*), setaria grass (*Setaria sphacelata*), tall fescue (*Festuca arundinaceae*), and turnips (*Brassica repens*). Infestation of grass species with endophyte fungi may prove an important cause of illthrift and poor growth rates occur in calves with the 'summer syndrome' associated with the endophyte *Acremonium coenophialum* in tall fescue pastures. Infection of pasture species with toxigenic *Fusarium* spp. has been associated with ill thrift in lambs in South Africa, New Zealand, and Australia. Pasture and soil fungi have also been suspected of being associated with illthrift in sheep in eastern Canada.

EPIDEMIOLOGY

- The problem has seemed to be most severe in the **southern hemisphere** but this may be because sheep are so prevalent there
- It may also be due partly to the predominance of **Merino** and Merino-type sheep; the disease is most common in these breeds which have their own particular timorous nature which makes weaning and the need to shift for themselves more traumatic than in most other breeds
- This trait is particularly noticeable if there is **overcrowding** on pasture
- Lambs that are **weaned at light weights** are more prone to illthrift following weaning and ideally they should be 45% of mature weight when weaned
- Merino ewes have a low persistency of milk production and consequently management of the flock and the pastures is critical for effective weaning weights
- **Other management** factors likely to lead to low weaning weights and subsequent unthriftiness are multibirth lambs, small ewes, ewes with little milk, and lambs born late in the season.

Weaner illthrift does occur in breeds other than Merino and is also reported from several countries in the **northern hemisphere**. Weaner illthrift has been reported on a variety of different pastures and under a variety of different management systems.

In bad years there may be many **deaths**; in any circumstance there is a gross **delay in maturation** so that maiden lambing may be delayed to as late as 3 years of age. The economic effects can be disastrous. Illthrift syndromes are also recorded in calves although with less frequency.

CLINICAL AND NECROPSY FINDINGS

As the name indicates the disease in weaned sheep is manifest primarily by **poor body condition** and **failure to thrive**. Within an affected group not all lambs are equally affected and there will be a range of conditions. Those lambs in very poor condition are usually anemic, frequently have diarrhea, and there is a sporadic but continuing death loss amongst them. Commonly the sheep have been treated with anthelmintics with no response. There are usually no abnormal findings at postmortem other than those associated with emaciation but villous atrophy is often found on histological examination of the small intestine.

This lack of significant findings is probably the **defining factor** for placing a problem in this disease category.

DIFFERENTIAL DIAGNOSIS

When faced with this problem the initial approach should be to examine for the most likely cause which is a deficiency in energy or protein intake.

An examination of the **teeth** to insure that there is no excessive attrition of the teeth, or even breaking of the incisors if the sheep are being fed roots, is also a logical preliminary step in any investigation of an illthrift problem.

The Parasite Status of the group should be examined by techniques appropriate to their detection as outlined in previous chapters. Clinical or subclinical infestations with nematodes are common occurrences at this time in the sheep's life, before immunity is properly developed and when pasture contamination can be high.

Infections with coccidia, cryptosporidia, or *Mycoplasma* (*Eperythrozoon*) *ovis* are significant causes of illthrift and should be examined as outlined in previous chapters.

The Trace Element Status of the group should be examined if the cause cannot be found with the above examinations. Many trace element deficiencies are area deficiencies or in an area are strongly associated with certain soil types. If trace element deficiency is a cause it is likely that there will be some prior history of this problem in the area. Diagnosis by response to supplementation is a common approach and the diagnostic aspects of the trace element deficiencies are outlined under their specific headings in this text.

Examination of the above-mentioned possible causes is time-absorbing and costly and, if there is a residuum of unsolved cases, they are likely to remain undiagnosed.

Infectious Agents can produce enteric lesions and illthrift (e.g. coronavirus and yersiniosis) and the malabsorption which results may be manifested by weight loss and by chronic diarrhea. They are differentiated on the initial postmortem examinations.

BULLER STEER SYNDROME

Synopsis

Etiology Unknown. Behavioral problem of steers in feedlots
Epidemiology Prevalence varies and increases with increasing age and weight at entry.
Clinical findings and lesions Areas of denuded hair, subcutaneous hematomas, other traumatic injuries
Treatment Symtomatic
Control Removal from pen.

ETIOLOGY

The buller steer syndrome is a **behavioral** problem in cattle confined in feedlots[1] of unknown etiology. Within a pen of cattle, one or more cattle persistently ride a particular individual or individuals of the group. The ridden animals are referred to as bullers. There have been several suspect etiogies. Improper placement of hormonal growth implants has been suspected as being associated.

EPIDEMIOLOGY

Occurrence

The syndrome occurs only in cattle in feedlots. The prevalence varies, but in one study ranged from 0 to 11% with a mean of 2.7%.[1,2] The prevalence increases with increasing weight and age.[1,2] The case fatality has been estimated at 1%.[3] The incidence of occurrence is higher in the summer and the fall and during the first 30 days of the feeding period.[4]

Epidemiological studies indicate that bullers occur as a point source epidemic with the cause occurring soon after cattle arrive in the feedlot and mingle into pen groups.[1] The peak incidence of bullers occurs much sooner after arrival and declines much quicker in older cattle. Bullers occur significantly sooner after mixing in older cattle than in younger cattle. The pen prevalence also increases as cattle become older on arrival at the feedlot and are more aggressive. As the prevalence of intact bulls increases in pens of cattle, so does the prevalence of bullers, presumably due to more aggressiveness in the bulls.

Risk factors

Postulated causative and risk factors include the incorrect timing and administration of hormonal growth implants, reimplantation and double dosing, estrogenic substances in feeds, pheromones in the urine of certain cattle, improper or late castration of young cattle, daily feedlot management, weather and seasonal factors, disease, group size, and dominance behaviour. However, these factors have not been well substantiated and controlled studies have found little influence of

implant type and implant timing on buller incidence.[5]

The mixing and confinement of **unfamiliar cattle** into pen groups, with subsequent agonistic interactions as these cattle established a social hierarchy, are considered as important risk factors. Both riding behavior and antagonistic behavior cease once cattle establish a stable social hierarchy. This suggests that riding behavior and subsequent identification of bullers is associated with this dominance behavior. It is possible that when a dominant animal becomes ill in a pen, other more subordinate animals in the pen that were previously subdued in dominance contests may want to fight the sick animal to achieve higher social status

Economic importance

The syndrome has been ranked along with acute undifferentiated bovine respiratory disease and footrot as **one of the three most important disease syndromes** in beef feedlots in North America. In addition to the economic loss from decreased weight gain, injury, treatment, death, and carcase condemnation, there is economic losses associated with extra handling necessary to accommodate affected cattle, the disruption of uniform marketing of cattle, especially in custom feedlots, and the need for extra pens in which to house the bullers. The importance of the syndrome includes the animal welfare aspects.

Bullers may be at significantly greater risk of illness and mortality (from bacterial pleuropneumonia) than other steers.[2] The association between illness, mortality, and bullers among individuals was greatest among the oldest yearling steers.[2]

CLINICAL FINDINGS

Two types of bullers are identified.[3]

Type 1 or true bullers stand as if they were a heifer in estrus and do not move away or show agonistic behaviour when being mounted by rider cattlc. There can be several rider cattle in a pen and type 1 bullers are rapidly damaged.

Type 2 bullers are animals that appear low in social dominance. They use aggression to discourage riders and will lie down to avoid being ridden.

Affected animals show areas of denuded hair and have extensive subcutaneous hemorrhage. The hematomas may become infected and develop to subcutaneous pockets of pus and gas. Other traumatic injuries, such as limb fractures, also occur.

CONTROL

Management of the syndrome has usually involved identification and removal from the pen to prevent injury and even death from riding-related injuries.

The high rate of risk of illness and mortality in bullers relative to other feedlot steers suggests that bullers should always be checked for evidence of illness in addition to their removal from their designated pen to prevent severe riding-related injuries. Treating sick bullers may improve the chance of settling them back into their designated pen by allowing them to resume their original position in the social hierarchy.

STILLBIRTH/PERINATAL WEAK CALF SYNDROME

Synopsis

Etiology Multifactorial
Epidemiology Most commonly multiple cases on a farm. Several farms affected in a geographic region in a single season. Problem may not occur for several years and then occur as 'epidemic' in a region.
Clinical findings Calves may be born weak and unable to stand. More commonly are born apparently normal and stand but subsequently collapse with hypothermia and die within a few hours of birth.
Lesions Petechial hemorrhages, subcutaneous edema, and hemorrhage commonly in the subcutaneous tissue of the carpal and tarsal joints.
Diagnostic confirmation Specific to cause
Treatment Heat and supportive.
Control Correction of underlying nutritional defciciency.

HISTORICAL ASPECTS

A disease of newborn calves called the 'weak calf syndrome' was first recognized in Montana in 1964.[1] It has been recognized throughout the US and other countries since then, and is considered a major economic loss in beef cattle herds. In the earlier descriptions of the syndrome, calves were affected by 10 days of age, and approximately 20% were affected at birth.[2] Morbidity ranged from 6 to 15%. In some herds, sporadic abortions occurred before calving season of the herd began. In some cases, affected calves died within minutes after being born with varying degrees of obstetrical assistance.[3]

In calves which survived for a few days, clinical findings included lassitude, depression, weakness, variable body temperature, a reddened and crusty muzzle, lameness, and reluctance to stand, enlargement of the carpal and tarsal joint capsules along with periarticular subcutaneous swellings, and a hunched-up back if they stood. Diarrhea occurred in some calves after a few days of illness but was not a major clinical finding. Treatment was ineffective and the case fatality rates ranged from 60 to 80%.

At necropsy, the prominent lesions were hemorrhage and edema of the subcutaneous tissues over the tarsal and carpal joint regions and extending distally. Polysynovitis with hemorrhagic synovial fluid often containing fibrin was also common. Erosive and hemorrhagic lesions of the forestomachs and abomasum also occurred. Several different pathogens were isolated from these calves but no consistent relationship between the pathogens and the lesions was ever determined.[1]

In retrospect, the **case definitions** were not well described and it is possible that several different diseases of newborn calves were lumped into the enigma of the weak calf syndrome. As more detailed clinical and laboratory examinations of sick newborn calves have been done over the years, some of the causes of the original syndrome have been identified as certain diseases of newborn calves which are characterized by such non-specific signs as lack of desire to suck, weakness, and failure to respond to therapy.

A wide spectrum of clinical and pathological findings has been associated with the weak calf syndrome. In the most common situation, which is a major diagnostic challenge, calves are born weak and die within 10–20 minutes after birth; sometimes they live for up to a few days. At necropsy there are no obvious or only few lesions to account for the illness. Calves which are weak after birth due to traumatic injuries associated with dystocia or other significant lesions can be accounted for according to the nature and severity of the lesions. Reports from Northern Ireland in recent years indicate that in dairy herds the incidence of the weak calf syndrome has ranged from 10 to 20% of all calves born.[4] Field observations in problem herds found that the gestation period is of normal duration but parturition is usually prolonged with the first and second stages of labor lasting 24 hours.[5] Affected calves usually are born alive but are unable to sustain breathing following birth. Despite resuscitation efforts, they commonly die within 10 minutes often accompanied by prominent incoordinated movements of the limbs.[4] Some calves are stillborn and whether or not this is a variation of the syndrome is uncertain. In a report from the UK, the syndrome occurred in calves born from heifers and was characterized

by failure to breathe at birth, or breathing with difficulty, and/or failing to move after birth, and failure to suck.[6] The term stillbirth/perinatal weak calf syndrome has been suggested as more appropriate.

Dummy calf syndrome

A variation of the weak calf syndrome is the dummy calf syndrome reported from the southern US.[7] Affected calves appear normal at birth, are generally alert, but lack the instinct or the desire to seek the teat or suck after birth and for up to several hours later. The syndrome may occur in calves of any birth weight. The incidence has been highest in purebred Brahman females but it has also occurred in Aberdeen Angus, Hereford, Chianina, and Brown Swiss breeds of cattle. Field observations indicate that affected calves did not stand for up to 1–2 hours after birth to initiate teat-seeking.[7] Dummy calves appear to lack the sensitivity to teat-seek and if they fail to locate a teat by about 4–5 hours after birth they commonly lose the sucking reflex and then require intensive nursing care by bottle feeding to initiate sucking. In calves which fail to suck and ingest colostrum, hypothermia, hypoglycemia, and neonatal infections are common complications. Concurrently, the dam loses interest in the calf and may abandon it. The cause is unknown but is thought to be a behavioral disorder inherent in some breeds; this has not been supported with any scientific evidence.

ETIOLOGY AND EPIDEMIOLOGY

The etiology of the weak calf syndrome is unclear, but several epidemiological observations have suggested some possible causes.[8] These include:

- Fetal infection near term
- Underdevelopment because of nutritional inadequacy of the maternal diet during pregnancy
- Placental insufficiency
- Maternal dietary deficiencies of selenium and vitamin E
- Hypothyroidism
- Traumatic injuries associated with dystocia and excessive force during obstetrical assistance
- Fetal hypoxia from prolonged parturition.

Fetal infections

Fetal infections in the last few days before term can result in stillbirth or weak calves which may die within hours or days after birth. In one series of 293 weak calves in Northern Ireland, leptospiral infection was present in 25% of them.[8] Calves in which leptospiral antigen was detected in the placenta were significantly lighter by an average of 6 to 10 kg than calves with no antigen in the placenta.[9] Calves infected with *Leptospira* in the uterus were more likely to be infected by *Arcanobacterium pyogenes* or *Bacillus* species, and infection of the placenta is associated with a lower bodyweight. The adrenal gland, lung, and placenta are most useful tissues to examine for leptospiral antigen.[9]

There is some evidence that an immune inadequacy based on T lymphocyte function may be associated with the weak calf syndrome in Japanese Black calves but the data are not compelling.[10]

An unidentified type of adenovirus has been associated with the weak calf syndrome on a large dairy farm in Israel.[11] At birth the calves were reluctant to suck or drink colostrum and were force fed colostrum with a gastric tube. Affected calves were weak at birth, unable to rise without assistance and when forced to move, walked stiffly, suggestive of polyarthritis. An adenovirus was detected in the feces, synovial fluid, and aqueous humor of affected calves.

Maternal nutritional deficiency causing fetal underdevelopment

Hypothyroidism due to iodine deficiency in the pregnant dam has been considered on the basis of thyroid hyperplasia in some calves.[12] Analysis of the laboratory data from 365 calves which died from the stillbirth/perinatal weak calf syndrome in Ireland, found some differences between calves with an abnormal and normal thyroid gland.[13] Glands weighing more than 30 g were probably abnormal. Abnormal glands were heavier, consititued a greater percentage of the calfs bodyweight and had a lower iodine concentration. A higher proportion of calves with an abnormal thyroid gland had uninflated lungs and pneumonia. Abnormal thyroid glands had a lower selenium concentration in the kidneys.

However, the experimental reproduction of iodine deficiency in pregnant heifers by feeding an iodine deficient diet over the last 4 to 5 months of pregnancy resulted in clinicopathological changes and pathological changes in the thyroid glands of both the heifers and their calves, but all calves in the iodine deficient group were born clinically normal.[8]

A **maternal dietary deficiency of selenium** in pregnant cattle has also been examined but field trials have failed to show any protective effect from the parenteral administration of pregnant cattle with selenium.[4,5] The parenteral administration of both selenium and iodine to pregnant cattle did not have any effect on the incidence of the syndrome between treated and untreated herds where the incidences were 7.9% and 7.4%, respectively.[14] A general nutritional inadequacy in the maternal diet can result in underdevelopment of the fetus and the birth of smaller than normal calves but the deficiency usually must be grossly inadequate. Radiographic examination of affected calves found that intrauterine growth retardation is not a common feature in calves dying with the syndrome.[15]

Placental insufficiency

Intrauterine growth retardation associated with feto-placental dysfunction has been described in Japanese Black beef calves.[16] Affected calves were weak when born at term and were underweight compared to normal calves. Anemia due to bone marrow dysfunction was present in affected calves and presumably was associated with intrauterine growth retardation. Dams delivering weak calves had lower serum concentrations of estrone sulfate during late pregnancy than those of normal calves suggesting a feto-placental dysfunction. The dysfunction was influenced by sires and maternal families.

Fetal hypoxemia

Fetal hypoxemia due to a prolonged parturition or dystocia may be a cause of the weak calf syndrome.[17] While asphyxia is not an integral part of normal delivery, it is still an important cause of fetal death during abnormal parturitions. Various predisposing factors can cause prolonged interference with fetal blood or oxygen supply, which results in death during delivery or shortly after.[18]

In newborn mammals subjected to anoxia, initially there is a period of struggling and rapid gasping during which blood pressure rises and bradycardia becomes profound. A relatively short period of primary apnea follows, after which there is a period of more regular and deeper gasping, which may become more frequent terminally. This is followed by a period of secondary apnea, the heart rate continues to beat at a slowly declining rate, and blood pressure falls slowly. The brain lesions begin in lower brainstem nuclei and, as asphyxia becomes prolonged, progress to involve the cerebellar and thalamic nuclei and the cerebral cortex. Examination of blood gas values on newborn calves has shown that a prolonged parturition or delivery terminated by forced extraction may result in a severe acidosis due to oxygen deprivation. As blood pH drops, first vitality is reduced, subsequently vital organs like the brain are damaged and ultimately the fetus dies.[19]

The bovine fetus appears relatively susceptible to anoxia which has been studied experimentally by clamping the umbilical cords of fetuses for 4–8 minutes, at 24–48 hours before expected birth, followed by a cesarean section 30–40 minutes later. Calves born following this procedure may die in 10–15 minutes after birth or survive for only up to 2 days. Under these experimental conditions, fetuses can survive anoxia for 4 minutes

but most will die following 6 or 8 minutes of anoxia.[17] During the clamping of the umbilical cord, there is a decline in the blood pH, PO_2 and standard bicarbonate levels and an increase in the PCO_2 and lactate levels.[17] Hypoxia in neonatal calves can result in high plasma lactate concentrations, which contributes to a progressive primary metabolic acidosis.[20]

During the clamping there is also increased fetal movement and a release of meconium which stains the calf and the amniotic fluid. Those which survive for a few hours or days are dull, depressed, cannot stand, have poor sucking and swallowing reflexes, and their temperatures are usually subnormal. They respond poorly to supportive therapy.

Some calves whose umbilical cords were clamped for 4 minutes were born weak, and made repeated efforts to raise their heads and move onto their sternum but were unable to maintain an upright position for long. These calves become hypothermic, dull, and their sucking and swallowing reflexes are present but weak. These calves are usually too weak to suck the cow even when assisted, and commonly develop diarrhea and other complications.

Dystocia and traumatic injuries at birth

Dystocia is a major cause of neonatal mortality in range beef cattle and may be a cause of the weak calf syndrome because of fetal hypoxia or traumatic injuries associated with obstetrical assistance.[21,22] In a study of 13 296 calvings over a period of 15 years in two research herds in Montana, calf mortality due to dystocia accounted for the single largest loss category through the first 96 hours postpartum.[21] Dystocia accounted for 51% of calf deaths and 53% of dystocia deaths occurred in calves which were born without assistance. Calf deaths from primiparous 2- and 3-year-old dams accounted for 41% of total mortality. Necropsies done on 798 of 893 calves found that 77.7% were anatomically normal and 22.3% abnormal. At necropsy of the calves which died associated with dystocia the findings included a froth-filled trachea, non-functional lungs, bruises, contusions, hemorrhages, bone fractures, and joint dislocations. It was concluded that the provision of adequate obstetrical assistance at the right time could have reduced the mortality associated with dystocia.

Similar reports of weakness following dystocia have been reported; in some cases a collapsed trachea is present.[23] In a study of parturient calf mortality in Australia, death rates as high as 44% from heifer groups have been reported.[24] The death rate was significantly higher in male calves than female calves. Pathological changes in many of the dystocia-related deaths were minimal but a congested swollen tongue was a definitive lesion.

Traumatic injuries of calves at birth are caused primarily by the mechanical influence of traction during delivery and can result in asphyxia and a high perinatal mortality rate.[25] Excessive traction is the most important cause of rib and vertebral fractures in the calf during dystocia. A series of 235 calves which died perinatally were examined by necropsy to determine the possible causes of death related to dystocia. Most of the parturitions were protracted and needed veterinary assistance, and 58% of the calves had pathological evidence of asphyxia. Calves delivered by extraction had pathological evidence of asphyxia more often than those born unassisted or delivered by cesarean section. Intrapulmonary amniotic material may be present in the lungs[26] and represent evidence of perinatal respiratory distress.[27] The aspiration of small amounts of amniotic fluid with or without meconium is common in calves and is not associated with hypoxemia, respiratory acidosis, or failure of passive transfer.[28]

Premature expulsion of placenta

Premature expulsion of the placenta has been associated with perinatal calf mortality.[29] Field observations indicate that the majority of affected fetuses die from fetal hypoxia during stage two of calving. The most significant risk factor associated with premature expulsion of the placenta was fetal malpresentation and malposture. Prolongation of the second stage of parturition allows for sufficient detachment of the placenta for it to occupy the posterior part of the genital tract. The placenta is frequently expelled together with the calf.[30] In one series of cases, there was no significant relationship between the occurrence of premature expulsion of the placenta and parity, calving difficulty, previous calving history, or sex of the calf.[29]

NECROPSY FINDINGS

All calves which die should be examined by necropsy to identify possible causes. It is important to establish if there is one disease complex or several different diseases of newborn calves.

In the weak calf syndrome described in Northern Ireland, at necropsy, many calves had petechial hemorrhages in the thymus gland, on the ventricular epicardium and the parietal pleura and endocardium.[8] These lesions were similar to those present in animals which died of acute terminal asphyxiation.[18] The gasps made in response to asphyxia in utero result in amniotic fluid being inhaled into the respiratory tract. In one study, 84% of stillborn calves had these lesions of asphyxia. It is well established that asphyxiation during birth is a major factor in intrapartum stillbirth in piglets and contributes to early postnatal mortality.[18] Froth may be present in the caudal trachea of some calves which die within 10–20 minutes after birth.

Varying degrees of subcutaneous edema of the head and/or bruising of the rib cage are also common. Fractures of the ribs are common, accompanied by intrathoracic hemorrhage. Vertebral body fractures occur commonly at the thoracolumbar region and may be accompanied by intra-abdominal hemorrhage. The lungs may be inflated normally, partially inflated, or not inflated. Severe bruising and hemorrhage occur around the costochondral junctions, the sternal extremities of the costal cartilages, and over the sternum and shoulder regions. In some cases, the traumatic lesions are severe and may involve primarily the right side of the rib cage.[6] Severe subcutaneous hemorrhage and edema may be present over the carpal and fetlock joints due to the pressure applied by the obstetrical chains or ropes.

In the syndrome described in the US, the lesions either appeared at birth or developed in the first few weeks of life.[1] At necropsy the prominent lesions are marked edema and hemorrhages of the subcutaneous tissues over the carpal and tarsal joints and extending distally down the limbs. The synovial fluid may be blood-tinged and contain fibrinous deposits. Erosions or ulceration of the gastrointestinal tract, petechial hemorrhage of internal organs, involution of the thymus gland, and hemorrhages in skeletal muscle have also been present.

Samples for confirmation of diagnosis

- Bacteriology – fetal liver, lung, stomach content, adrenal gland; placenta (CULT). Special detection techniques for Leptospira antigens.
- Histology – fixed placenta, lung, spleen, brain, liver, kidney; maternal caruncle (LM, IHC)

DIFFERENTIAL DIAGNOSIS

Determination of the cause of the weak calf syndrome in a herd is often difficult because the limits of the case definition cannot be determined. Several risk factors may interact to contribute to the disease. The most common definition is a calf that is alive at birth, appears normal otherwise, but either fails to breathe or breathes for less than about 10 minutes and then dies. If they survive for several hours or a few days, affected calves are usually in sternal recumbency, depressed, reluctant to stand unassisted, reluctant to walk, and not interested in sucking. They may not respond favorably to supportive therapy.

Case definition

When an epidemic of the disease is encountered, an epidemiological investigation of the herd is necessary in an attempt to identify possible risk factors.

The patterns of occurrence should be determined:

- Is the problem more common in calves born to heifers than cows? In some situations, the owner may provide more surveillance for the calving heifers and less for the mature cows with a consequent greater incidence of weak calves born from the cows
- Is there any evidence that parturition is prolonged in the heifers or the cows and what are the possible reasons?
- How long are heifers and cows in the herd allowed to calve unassisted before obstetrical assistance is provided?
- Is it possible that some nutritional, management or environmental factor is interfering with normal parturition?
- Is the condition more common in male or female calves and what are the relative birth weights?
- How soon after birth are the calves affected?
- What is the course of the illness after the first clinical abnormalities are noted?
- What level of calving surveillance and assistance is being provided by the attendants?
- The veterinarian should make every effort to clinically examine a representative number of affected calves.

TREATMENT

Calves born weak, unable to stand, lacking the instinct to seek the teat or lacking a suck reflex, need intensive care including force-feeding of colostrum and the provision of warm surroundings to prevent hypothermia and other complications. Affected calves must be assisted to suck the dam normally. Bottle feeding for a few days may be necessary until the calf becomes strong enough to suck the dam on its own.

CONTROL AND PREVENTION

Control and prevention of the weak calf syndrome is based on empirical observations beginning with insuring **adequate nutrition of the dam** to avoid any possible nutritional factors affecting neonatal calf vitality. The provision of **adequate surveillance at calving time** and competent obstetrical assistance when necessary is also crucial to avoid prolonged parturition and fetal hypoxia in calves.

When epidemics of the disease are occurring, the surveillance of calving must be intensified, and it may be necessary to intervene with obstetrical assistance earlier than usual. Determination of the cause may require that the veterinarian attend several calvings, make detailed clinical examinations of the length of parturition and observe the parturition process and the health of the calves at birth.

WATERY MOUTH OF LAMBS (RATTLE BELLY, SLAVERS)

Synopsis

Etiology Non-enteropathogenic *E. coli* endotoxemia predisposed by failure of passive transfer
Epidemiology Higher risk with intensive housing with poor hygiene
Clinical findings Loss of sucking reflex, retention of meconium or feces, excessive mucoid saliva, abomasal distension.
Lesions None specific
Diagnostic confirmation Nothing pathognomonic.
Treatment Fluids and energy via stomach tube. Antimicrobials.
Control Antimicrobials at birth, pen hygiene, ensure adequate colostral transfer

ETIOLOGY

This disease is believed to be the result of **endotoxemia** in young lambs. It is postulated that the neutral pH of the abomasum in newborn lambs, coupled with low concentrations of colostral immunoglobulin in the gut, allow rapid multiplication of non-enteropathogenic strains of *Escherichia coli* in the gut, and to some extent systemically, to result in endotoxemia.[1]

EPIDEMIOLOGY

Occurrence

The syndrome is primarily reported in **lambs** in **Great Britain** but has also been reported in New Zealand and in goat kids in Spain and North America.[1,2]

Animal and environmental risk factors

Lambs 12 to 72 hours of age are affected. The disease is seen under all management systems but is rare in pastured flocks and occurs most commonly in lambs kept in **intensive housing** where there is **poor hygiene** of the lambing environment. Lambs from prolific ewes are at risk and the disease is more common in triplets than twins or singles.

Delayed or **poor colostral intake** is a major risk factor and situations that predispose this may lead to outbreaks. A high prevalence has occurred in ram lambs castrated by the use of an elastic band at a very young age and the resulting pain may have dissuaded them from feeding.

Other risk factors, all of which reduce sucking by the lamb, are inclement weather, mismothering, maternal agalactia, competition between twins or triplets, low vitality, and ewes in poor condition.

Experimental reproduction

An equivalent clinical syndrome is reproducible by administering non-enterotoxic strains of *E. coli* by mouth to colostrum-deprived lambs, all of whom died within 24 hours.[3]

Economic importance

Watery mouth disease is a major cause of mortality of housed newborn lambs in Great Britain and is reported to be the cause of approximately 25% of all deaths of lambs in indoor intensive lambing systems.[1] Where conditions allow morbidity rates may approach 24% and without early treatment case fatality rates are high.[4]

PATHOGENESIS

Gram-negative bacteria, non-enterotoxigenic and non-enteropathogenic *E. coli* in the environment, are ingested as a result of a contaminated environment, or from a contaminated fleece, and survive passage through the neutral pH of the abomasums to be absorbed into the systemic circulation by the natural pinocytosis that occurs in the intestinal epithelium of newborn ruminants, to produce an endotoxemia.

CLINICAL FINDINGS
Affected lambs are normal at birth but become sick at 24–48 hours and up to 72 hours old. The disease is characterized by dullness, a complete failure to suck, and excessive mucoid saliva around and drooling from the mouth. As the disease progresses there is hypothermia, failure to pass feces, cold extremities, depression to the point of coma, anorexia and, in the late stages, abdominal distension and recumbency, but rarely diarrhea. The alimentary tract is full of fluid and the lamb rattles when it is shaken. Some lambs are hypothermic but the temperature is normal at the onset of the condition and falls to subnormal as the disease progresses. Progress is rapid with death 6–24 hours after the first signs of illness.

CLINICAL PATHOLOGY
Total protein concentrations and base excess values are significantly elevated compared to normal lambs.[5] Blood glucose concentrations are normal but may be low in the terminal phase of the disease.

NECROPSY FINDINGS
There are no findings specific to the syndrome. The abomasal contents are fluid and mucoid, and contain small milk curds and the intestine is gas filled.

TREATMENT
Treatment with intramuscular amoxycillin and clavulanic acid, intravenous flunixin meglumine, and oral rehydration fluid, when administered early in the clinical course, has resulted in a high recovery rate in field cases.[5] Dextrose solution should also be given to those lambs that are hypoglycaemic and external warming should be provided. Other recommended treatments include emptying the alimentary tract by purgation or enema.

DIFFERENTIAL DIAGNOSIS
Most neonatal disease of lambs is manifest with diarrhea which is not present in watery mouth. The early stages of Colisepticemia and Clostridium perfringens type B or C present with similar clinical signs but are easily differentiated later in the clinical course or at post mortem examination. Hypothermia/starvation/cold stress can present with similar clinical findings but the history and environmental circumstances of occurrence differ.

CONTROL
In outbreaks the administration of antibiotics to all newborn lambs within 15 minutes to 2 hours of birth dramatically reduces the occurrence of further cases.[4–6] Fresh or frozen sheep or cow colostrum should be supplemented to lambs at risk. The provision of ewe colostrum at 50 mL/kg body weight within 6 hours of birth prevents the disease.

Lambing areas and associated pens and yards should be kept clean and fresh bedded. Contaminated fleece should be removed from around the udder of the ewe prior to lambing and every effort should be made to insure early and adequate colostral intake by newborn lambs, especially for twins and triplets.

COLD COW SYNDROME
This is a herd disease problem reported from the UK in cows freshly turned out onto lush pasture with a high (27–43%) soluble carbohydrate content.[1] There is a high morbidity (up to 80%) and a large number of outbreaks in an area. The syndrome includes hypothermia, dullness, inappetence, agalactia, and profuse diarrhea. Affected cows feel cold to the touch. Some have perineal edema, some collapse. The herd milk yield falls disastrously but there is a quick return to normal if the cows are moved to a different field. The problem may occur on the same pasture each year and recur if the cows are returned to the same pasture. There is no obvious clinicopathological abnormality. It is postulaed that the syndrome might be due to zearalenone or related metabolites produced by field micro fungi in the pasture.[2]

THIN SOW SYNDROME

Synopsis

Etiology The syndrome is the result of inadequate nutrition and unbalanced nutrition in pregnancy and lactation but can also result from parasitic or chronic infectious disease.
Epidemiology Loss of weight to the point of inanition particularly in first and second litter gilts.
Clinical findings Inanition
Control Recognition of the relation between voluntary feed intake in pregnancy and lactation, feeding based on condition scores.

ETIOLOGY
The 'thin sow syndrome' is discussed in this chapter because of its multiple etiology. Regardless of etiology the effects of this syndrome on fertility and overall farm productivity can be formidable. There are a number of causes of wasting and the occurrence of thin sows:

- The major cause of sow abnormality under this heading results from **errors in feeding** and management, which are likely to be exaggerated and multiplied on farms where intensive management is practiced. The most common errors are incorrect feeding in pregnancy and lactation. These can be exacerbated by cold or drafty housing, fluctuating temperatures, too high a temperature in the farrowing house, low-level feeding to avoid obesity, wet bedding, and lack of drinking water. Early weaning increases the risk for the thin sow syndrome, especially if nutrition is inadequate.
- **Parasitic disease**, particularly associated with infestation with *Oesophagostomum* spp. and *Hyostrongylus* spp. Is a cause of wasting in sows and the occurrence of the thin sow syndrome and is discussed under those headings (Ch. 27)
- Thin sows can be a component of the syndrome of **infectious diseases** such as cystitis and pyelonephritis .

EPIDEMIOLOGY AND PATHOGENESIS.
The syndrome is most common in first and second litter gilts but can affect all parities when nutrition is inadequate. It emerged as a problem in the 1970s as a result of poor understanding of the **inter-relation between feed intake in pregnancy and that in lactation**, combined with the move to intensive indoor housing of pregnant sows. Penning of sows exacerbated social dominance/submissive relationships. The voluntary intake of food by sows during lactation is inversely related to the intake in pregnancy. Consequently sows that are fed at high levels during pregnancy will gain excessive weight during pregnancy but will voluntarily restrict feed intake during lactation and loose excessive weight during lactation. In contrast sows that are fed what is basically a maintenance ration 2.0–2.5 kg (4.5–5.5 lbs) of a balanced sow ration during pregnancy will gain adequate weight for conceptus and body growth and during lactation will consume adequate feed for lactation requirements and loose minimal weight in this period. Knowledge of sow nutrition has improved such that major problems with this syndrome should not occur but there is still a risk of

inadequately feeding sows selected for lean genotype and high litter size and weaning weights. First and second litter gilts may require more feed to provide for body growth.

CLINICAL FINDINGS

Within a herd the thin sow syndrome develops over a period of months and often one or two pregnancy cycles, with a gradually declining of body condition of the group until 20% to 30% of sows have a low body condition score. No abnormalities are evident on clinical examination but the sow fails to regain weight after weaning, particularly sows after their first litter. The most critical period for weight loss is the first 2 weeks after weaning. Affected sows have a poor appetite but often show pica and excessive water intake and may be anemic.

CONTROL

Feeding during pregnancy

Currently the risk for the thin sow syndrome exists where it is assumed that all pregnant sows can be fed a standard amount of ration. Problems are likely to occur when sows are run in groups and fed as a group where timid sows are likely to be bullied out of their required share of food.

Individual feeders or stall feeding will prevent this.

Feeding during lactation

The critical issue is to ensure adequate feed and energy intake during lactation. This can be achieved by:

- not feeding to excess during pregnancy
- restricting the feed intake of sows in the first few days after farrowing to encourage better feed intake in later lactation
- ensuring an adequate and constant supply of water
- ad lib feeding during lactation
- a high-energy-density lactation diet
- enclosing the creep with heat for the piglets so that the farrowing house can be kept at a lower temperature 65°F (65°C) for the sow
- control of parasitic disease.

Condition scoring is a valuable guide to the feeding of individual sows and for a judgement of feeding practices in the herd as a whole. On a score of 1 to 5 it should be very rare to find sows with condition scores of 1 or 5. The optimum is to have sows entering the farrowing house between condition score 3 and 4 and not less than 2.5 at weaning. First and second parity sows in poor condition at weaning are best 'skipped' at the first heat and mated on the second heat.

Methods for condition scoring and guidelines can be found at http://www.defra.gov.uk/animalh/welfare/farmed/pigs/pb3480/pigsctoc.htm

ACUTE HEPATITIS (POSTVACCINAL HEPATITIS) OF HORSES (THEILER'S DISEASE, SERUM HEPATITIS)

An acute hepatopathy of horses often associated with administration of equine biological products such as tetanus antitoxin.

ETIOLOGY

Etiology is unknown, although an infectious agent is suspected.

EPIDEMIOLOGY

The disease occurs in horses administered equine serum or tissue products. The first reports of the disease were in horses in South Africa administered equine serum as prophylaxis for Africa Horse Sickness. Outbreaks of the disease have occurred in horses in Africa, Europe, and North America administered equine serum as prophylaxis for a variety of diseases including African horse sickness, encephalomyelitis, botulism, *Strep. equi* infection, tetanus, and influenza and in mares given pregnant mare serum.[1] Most sporadic cases of the disease appear to be associated with administration of tetanus antitoxin.

The disease is reported only from adult horses (>1 year of age) and most cases are reported in the summer and autumn.[2] There is a suspicion that pregnant mares are at increased risk.

The **morbidity rate** in outbreaks among horses administered equine serum ranges between 2 and 18%,[3] although the rate among horses administered tetanus antitoxin as prophylaxis following injuries is clearly much lower. Acute hepatitis developed in 4 (0.4%) of 1260 horses >1 year of age administered commercial equine plasma at one institution in the United States over a 6-year period.[4] The disease can occur after intrauterine infusion of equine serum to mares.

The **case fatality** rate is between 50 and 90%.

The disease occurs sporadically in horses that have not been administered equine biological products. There are reports of in-contact, non-treated horses developing the disease.

PATHOGENESIS

Destruction of hepatocytes results in hepatic dysfunction. Hepatoencephalopathy develops in severely affected horses.

CLINICAL FINDINGS

The disease usually occurs after an **incubation period** of 40–70 days (range 27–165 days). Depression, anorexia, and icterus are evident in mildly affected cases. There may be mild to moderate colic. Body temperature and heart rate are usually normal. Acutely affected, or horses observed infrequently, can die unexpectedly. Signs of **hepatoencephalopathy** include restlessness, excitement, compulsive walking and head pressing, abnormal head position, seizures, apparent blindness, muscle tremors, and ataxia. Affected horses often injure themselves by walking into fences and troughs.

CLINICAL PATHOLOGY

Leukocytosis with neutrophilia and mild lymphocytopenia is common. The hematocrit and plasma total protein concentrations may be mildly increased. Hyperbilirubinemia and an increase in direct (conjugated) bilirubin concentration are present and serum bile acid concentration is increased, as is serum activity of liver specific enzymes aspartate aminotransferase (AST), gamma-glutamyl transferase (GGT), and sorbitol dehydrogenase (SDH). Increases in serum GGT activity is often less than expected for the increases in serum AST, SDH, and bile acid concentrations, likely reflecting the primary insult to hepatocytes.

Hypoglycemia (<2 mmol/L, 40 mg/dL) and hyperammonemia (>150 μmol/L) may be severe. Clotting time, especially the one stage prothrombin time, may be prolonged.

NECROPSY FINDINGS

The liver may be enlarged, normal or shrunken and discolored slightly yellow to green. There is severe centrilobular necrosis of hepatocytes with mild infiltration of lymphocytes and plasma cells. Alzheimer type II astrocytes are present in the brains of horses with encephalopathy.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation antemortem is achieved by examination of a liver biopsy, although this should not be performed in animals with coagulation abnormalities.

Differential diagnosis list:

- Acute aflatoxicosis
- Rubratoxicosis (Penicillin rubrum)
- Pyrrolizidine alkaloid intoxication
- Dioxin intoxication
- Idiopathic hyperammonemia.[5]

TREATMENT

Treatment is essentially supportive and consists of correction of metabolic and acid–base abnormalities, reduction of plasma ammonia concentration, and preventing horses with hepatoencephalopathy from injuring themselves.

Hypoglycemia and dehydration can be corrected by intravenous administration of

5% dextrose and isotonic electrolyte solutions. Metabolic acidosis can be corrected by infusion of sodium bicarbonate. Plasma transfusions may be necessary to correct coagulation abnormalities.

Hyperammonemia can be treated by giving neomycin (20 mg/kg, orally, every 6 hours for 4 doses) or lactulose (0.25 mL/kg, orally every 8 hours) to decrease absorption of ammonia from the gastrointestinal tract.

Sedation with xylazine or similar compounds may be necessary to prevent the animal injuring itself. The affected horse should be housed in an area where it has the least opportunity to injure itself, and may need to be fitted with a padded helmet.

CONTROL

Minimal use of biologics, including plasma, of equine origin is prudent.

GRANULOCYTOPENIC DISEASE OF CALVES

A fairly widespread disease of recent origin, granulocytopenic disease of calves is commonly ascribed to poisoning with furazolidone. Affected calves are those being reared on milk replacer and sometimes, but not always, receiving prophylactic antibiotics.[1,2]

Affected calves show persistent fever, and increased salivation and nasal discharge, and there are hemorrhages and necrotic lesions in the mouth and lower alimentary tract. The disease is characterized by decreased myelopoiesis in bone marrow, neutropenia, and thrombocytopenia. The course varies from 2 to 5 days, and the mortality rate is high, apparently from bacterial invasion. Pneumonia, peritonitis, and enteritis are common accompaniments. *Fusobacterium necrophorum* can be isolated from necrotic lesions.[1] These clinical, pathological, and hematological findings resemble those of radiation sickness, and poisoning by bracken fern.

The disease has been related to long-term feeding of furazolidone (2 mg/kg BW daily), either in the milk replacer or as specific therapy, and the disease can be reproduced by this means. At higher dose rates (20–30 mg/kg BW) nervous signs, including convulsions, and death follow within a few days; both syndromes may occur at the same time in a group of calves.[3]

SWEATING SICKNESS (TICK TOXICOSIS)

Synopsis

Etiology Unknown, associated with bites of *Hyalomma truncatum*.
Epidemiology Reported in Africa, India, and Sri Lanka affecting calves 2 to 6 months of age.
Clinical findings Fever, salivation, lacrimation, hyperemia of mucosae, epistaxis, and extensive and severe dermatitis, necrosis of oral epithelium
Lesions Dermatitis and necrotic stomatitis, disseminated intravascular coagulopathy.
Treatment Symptomatic and use of hyperimmune serum
Control Tick control

ETIOLOGY

The cause has not been identified, but it behaves as though it were an epitheliotropic toxin produced by the salivary glands of certain strains of the tick *Hyalomma truncatum*. Not all strains of *H. truncatum* have the ability to produce the disease and antigens unique to sweating sickness-inducing strains are described.[1,2]

EPIDEMIOLOGY

Attempts to transmit the disease between animals by mediate or immediate contact and by injections of tissue or blood are unsuccessful. The disease occurs in Central, East and South Africa, Sri Lanka, and probably southern India. Only calves 2–6 months of age are affected as a rule but rare cases occur in adults. Sheep, pigs, and goats are susceptible, although the disease does not naturally occur in them, and the disease has been produced experimentally in dogs. Sweating sickness occurs at all times of the year but is most prevalent during the wet season when ticks are more plentiful. The morbidity rate varies with the size of the tick population but is usually 10–30%. The case fatality rate is up to 30%.

PATHOGENESIS

The clinical signs begin 4–7 days after the ticks attach, probably 3 days in experimental infestations. The effects are dose-specific; if the ticks are removed very early there is no clinical response and the animal remains susceptible; with a longer exposure before the ticks are removed the animal becomes immune but shows no clinical signs. With longer exposure of more than 5 days the subject develops the full-blown clinical disease and may die. If it recovers it has a solid and durable immunity.

CLINICAL FINDINGS

There is a sudden onset of fever up to 41°C (106°F), anorexia, hyperemia of the mucosae, and hyperesthesia. The animal is lethargic, depressed, dehydrated, and has a serous then mucopurulent oculonasal discharge, an arched back, and a rough coat. There is an extensive, moist dermatitis commencing in the axilla, groin, perineum, and at the base of the ears which extends to cover the entire body in bad cases. 'Sweating' refers to this moist dermatitis. The hair is matted together by exudate and moisture collects in the form of beads on the surface. The eyelids may be stuck together. Subsequently patches of the skin and hair are rubbed off or can be pulled off to leave raw, red areas of subcutaneous tissue exposed. The tips of the ears and tail may slough.

Affected calves seek shade and their skin is very sensitive to touch. Later it becomes dry and hard, and cracks develop. Secondary bacterial infection and infestation with blowflies or screw-worm larvae are common sequelae. The oral mucosa is hyperemic at first and then becomes necrotic with the formation of ulcers and diphtheritic membranes. The calf salivates profusely, cannot eat or drink, and becomes emaciated and rapidly dehydrated. There are similar mucosal lesions in the vagina and nasal cavities, the latter causing dyspnea. The severity of the mucosal lesions appears to vary with different 'strains' of the toxin.[3] There may be abdominal pain and diarrhea in some calves.

The course may be as short as 2 days but is usually 4 or 5 days. In recovered animals the skin may heal and the hair may regrow, but there may be permanent, patchy alopecia and the calves may remain stunted and unthrifty.

CLINICAL PATHOLOGY

There is a severe neutropenia and eosinopenia and a degenerative left shift. α-globulin and beta-globulin levels are raised. Urinalysis indicates the existence of nephrosis but serum creatinine levels are normal.[4] Dermatological examination fails to reveal the presence of any of the usual infectious causes of dermatitis.

NECROPSY FINDINGS

The lesions are essentially those seen clinically. There is also evidence of severe toxemia, dehydration, emaciation, and hyperemia of all internal organs and disseminated intravascular coagulation. The necrosis of the oral epithelium extends into the esophagus and may reach the forestomachs.

DIFFERENTIAL DIAGNOSIS

The combination of extensive dermatitis and mucosal necrosis is unusual. Mucosal disease and bovine malignant catarrh may bear some resemblance and there could be difficulty in differentiation in areas where the tick *Hyalomma truncatum* occurs.

TREATMENT

There is no specific treatment; efforts should be directed at relieving the severity of the dermatitis and mucosal loss. Non-steroidal anti-inflammatory drugs (NSAIDs) and broad-spectrum antibiotic cover is a logical regimen. Hyperimmune serum, produced in sheep and cattle by infesting them with *Hyalomma truncatum* at 6-week intervals for 2–5 occasions, is an effective treatment in pigs, sheep, and to a less extent calves.[2,5]

CONTROL

Control is limited to control of the causative tick. No vaccine is available.

Diseases characterized by alimentary tract involvement

EQUINE GRASS SICKNESS (EQUINE DYSAUTONOMIA, GRASS DISEASE, MAL SECO)

Synopsis

Etiology Unknown
Epidemiology Horses of all breeds and both sexes in the UK, Western Europe, Scandinavia, and southern South America. Greatest incidence in early summer.
Clinical signs
Acute grass sickness: Colic, nasogastric reflux, absent gut sounds, depression, dysphagia, and small intestinal distension of <2 days duration at time of death.
Subacute grass sickness: Tachycardia with or without signs of colic, reduced intestinal sounds, impaction of the colon, and clinical course of 2–7 days.
Chronic grass sickness: Insidious onset weight loss, intermittent colic, decreased appetite, rhinitis sicca, patchy sweating, and mild dysphagia.
Clinical pathology None is specific or diagnostic.
Lesions Both forms of the disease have degeneration of neurons of the autonomic nervous system, especially of the myenteric and submucosal plexuses.
Diagnostic confirmation Examination of ileal biopsy.
Treatment
Acute grass sickness/subacute grass sickness: Supportive. None effective.
Chronic grass sickness: Nursing care. Cisapride.
Control None

ETIOLOGY

The cause is unknown but is suspected to be a neurotoxin, possibly *Clostridium botulinum* toxin, based on epidemiologic data.[1,2] Evidence supporting a role for *Cl. botulinum* in the etiology of the disease included the isolation of toxin (BoNT/c) producing strains of *Cl. botulinum* type C from the ileum of 45% of horses with grass sickness and 4% of clinically normal control horses.[2] In addition to preventing the release of acetylcholine at cholinergic nerve terminals and thereby causing paralysis, a function that it shares with other botulinum toxins, BoNT/C is neurotoxic. Other studies have demonstrated increased numbers of bacterial organisms, including anaerobes, and number of species of clostridia in feces of horses with grass sickness compared with normal horses.[3] Whether these findings represent a causative role of *Cl. botulinum* in grass sickness, or an effect of the modified gastrointestinal motility and on intestinal flora remains to be determined. Further evidence to support a role for *Cl. botulinum* in the etiology of grass sickness include the observations that low serum concentrations of antibodies to *Cl. botulinum* are associated with increased risk of the disease.[1,4] However, the hypothesis of a role for toxicoinfectious botulism in grass sickness of horses does not explain the geographic distribution of the disease given that botulism occurs worldwide in horses and grass sickness does not.

EPIDEMIOLOGY

Occurrence

Grass sickness is not common and appears to be restricted in its distribution to all parts of Great Britain (including possibly Ireland), Sweden, and the northern and western coasts of Europe. A clinically and histologically indistinguishable disease, *mal seco* occurs in the Patagonia region of Argentine, southern Chile, and in the Falkland (Malvinas) Islands.[5,6]

Horses, ponies, donkeys, zebra, Prrzewalski's horses, rabbits, and hares are the predominant species affected.[7] The morbidity and mortality rates are not reported, but the **incidence** on farms with a history of the disease ranges between 0.4 and 16% per year[8] or 2.1 grass sickness cases per 100 horses per year.[9]

The **case fatality rate** for acute grass sickness is 100%, while that for the chronic form of the disease in horses treated at a referral hospital is 60–70%.[10,11] Horses that survive the chronic form of the disease are often destroyed because of weakness and emaciation, although make complete recoveries.[12] However, given the difficulty in establishing an antemortem diagnosis, it is unclear whether horses that fully recovered actually had chronic grass sickness.

Risk factors

Animal risk factors

The risk of disease is greatest in 4–5 year old horses (adjusted odds ratio of 1.9 compared with 0–3 year olds) and then declines such that the risk of disease is lowest in horses >12 years old (odds ratio 0.02 compared to that of 0–3 year olds).[1] Cases in horses 10 months to 20 years of age have been encountered. Foals born of affected mares are clinically normal.[13] There is no apparent breed predilection.[8]

Horses at pasture are at increased risk (hence the colloquial name of the disease), although the disease does occur rarely in stabled horses. A recent (<14 day) change of pasture carries an increased risk (odds ratio 24) of development of the disease.[14] Horses that have been on the farm for less than 2 months are at increased risk of developing the disease.[8] Horses on farms with previous cases of the disease are at increased risk (odds ratio 2.2–45) of the disease,[14,15] although horses that have been in contact with animals with the disease are at reduced risk (odds ratio 0.1) of developing the disease.[14]

Environmental risk factors

There is a marked seasonal distribution of cases, with the peak incidence occurring in early summer in the British Isles.[8,9,16] Outbreaks of the disease are associated with the occurrence of cooler and drier weather than normal during the 2 weeks preceding the outbreak,[9,17] although this is not consistently reported.[15]

Farm or premise risk factors

As mentioned, farms with a history of horses with the disease are at increased risk of having further cases. For premises with previous cases of grass sickness there is an increased risk of the disease developing as the number of horses on the farm increases, with the presence of young horses, on stud farms and livery/riding schools, on farms having sandy or loamy

soil, and those rearing of domestic birds and using mechanical fecal removal.[9] The risk of recurrence of disease on a farm decreased with presence of chalk soil, cograzing ruminants, grass cutting of pastures, and manual removal of feces.[9] There is no association between the disease and the type of pasture, nor with provision of supplementary feeds.[8] Feeding hay or haylage is associated with a decreased risk of the disease.[1] Any disturbance of the soil, such as by ploughing, increases the risk of disease.

Transmission

The disease is not contagious. Injection of normal horses with serum of affected horses causes lesions, but not clinical signs, consistent with the disease.

PATHOGENESIS

The clinical signs are attributable to widespread damage to the autonomic nervous system, resulting in sympathetic and parasympathetic dysautonomia that is most clinically evident in the gastrointestinal tract. Coincident with damage to the autonomic nervous system are increases in plasma concentrations of dihydroxyphenylalanine, epinephrine, norepinephrine, and dopamine,[18] possibly because of increased secretion of these compounds from affected sympathetic ganglia and neurons.[19] Lesions in the cranial nerves and brain stem are probably responsible for dysphagia and drooling evident in most cases. Rhinitis is associated with diminished nonadrenergic, noncholinergic (NANC) innervation, greatest in neurons positive for substance P or calcitonin gene-related peptide, of the nasal mucosa in subacute and chronic cases.[20]

Electrocardiographic examination of affected horses reveals evidence of loss of parasympathetic innervation of the heart, which is consistent with lesions in the terminal cardiac ganglia.[21] Splanchnic lesions are most severe in the myenteric and submucosal plexuses of the ileum, with less severe changes in the large colon and celiaco-mesenteric ganglion.[22] There is also a reduction in interstitial cells of Cajal (cells involved in pacemaker activity and autonomic transmission within the gut).[23] These neuronal changes are associated with a marked impairment of cholinergic activity in ileal tissue of affected horses.[24] Because of the altered autonomic activity, peristalsis decreases (in chronic cases) or ceases (in acute cases) with subsequent accumulation of ingesta in the small intestine, stomach, and large colon. Death is due to emaciation in chronic cases or rupture of the stomach or intestine in acute cases.

CLINICAL FINDINGS

The clinical signs of grass sickness are varied, and accurate diagnosis on clinical signs alone is very difficult. The incubation period of the disease is approximately 10–14 days[17]. **Acute, subacute, and chronic** forms of the disease are recognized,[25] although some authorities use a designation of acute and chronic.[26] In all cases, there is some dysphagia, resulting in drooling of saliva and trickling of ingesta from the nose. Dried food is impacted between the cheeks and the teeth and the animal plays at drinking. These signs are attributable to lesions in the cranial nerves. Most animals are depressed.

Acute cases the onset is sudden and the course of the disease is 1–4 days. Abdominal pain may be severe but also may be absent even in the presence of severe tachycardia. There is tachycardia (80–90/min may be >100), decreased to absent gut sounds, lack of defecation, and abdominal distension. On rectal examination, there are hard, dry pellets of feces, the large colon contains firm ingesta which has a corrugated feel that is quite distinct to the smooth surface of a primary colonic impaction. The small intestine is distended with fluid and readily palpable in the caudal abdomen. Nasogastric intubation yields a large (20 L) quantity of fluid. Urination is frequent and may be accompanied by tenesmus. Affected horses may wander about in a restless manner and a fine muscle tremor occurs constantly, especially in the upper forelimb. Periodic attacks of patchy sweating occur commonly. There is noticeable salivation. Esophageal endoscopy reveals linear ulcerations resulting from reflux esophagitis.

Subacute cases have signs of mild colic, or may not have any signs of colic, in the presence of tachycardia, depression, reduced gastrointestinal sounds, and impaction of the large colon with characteristic corrugated appearance.[25] The clinical course is 2 to 7 days and death is inevitable. Esophageal endoscopy reveals the presence of linear erosions in many affected horses.

Chronic cases the course is usually >7 days and is characterized by weight loss, patchy sweating, and intermittent colic. Horses stand with all four feet close together under them ('elephant on a tub stance') and have a tucked up abdomen. Dysphagia is evident and the gut is empty except for the colon and rectum which contain dry, hard feces. In the late stages the patient snores, the penis droops, and attempts are made to eat abnormal materials. Most cases of the chronic form have rhinitis, characterized by crusting of mucopurulent material on the turbinates and this is considered, in the presence of appropriate history and other clinical signs, almost pathognomonic for grass sickness.

Application of phenylephrine (0.5 mL of a 0.5% solution) into one eye causes a dorsal deviation of the eyelashes of the upper eyelid in horses with grass sickness, but not in normal horses.[27]

There is a radiological discernible defect in esophageal motility in horses with grass sickness.[28]

Recurrence of the disease in a horse is exceedingly rare.

CLINICAL PATHOLOGY

Serum biochemical profiles and hematological examinations do not demonstrate pathognomonic changes.[29] Signs of dehydration, electrolyte imbalances, hyperbilirubinemia, and elevations of serum activity of liver derived enzymes are all secondary to the disease.[30] Urine from horses with grass sickness has higher specific gravity, protein and creatinine concentrations, and lower pH than that from unaffected horses,[31] consistent with dehydration and electrolyte imbalances that occur with the disease. Peritoneal fluid is often abnormal, having an increased protein concentration and leukocyte count but, because of the considerable overlap with values in horses with lesions of the gastrointestinal tract requiring surgery, is of limited diagnostic value.[32]

Antemortem diagnostic confirmation can only be achieved by examination of biopsy specimens of the ileum,[33] although biopsy of nasal mucosa has been suggested as an alternative.[18] Examination of rectal biopsy is specific, but not sensitive, for the disease.

NECROPSY FINDINGS

In cases of short duration, the stomach and small intestines are distended with an excess of fluid and gas, and the colon is often impacted with corrugated ingesta coated with black material. In chronic cases, the alimentary tract is empty.

Histologically there is extensive degeneration of neurons of the autonomic nervous system without evidence of inflammation.[33] These neurons include those of the ganglia (cranial cervical, stellate, coeliaco-mesenteric, etc.) and those of the myenteric and submucosal plexi of the intestines. Degenerative neuronal changes may also be observed in the central nervous system, including the oculomotor, facial, lateral vestibular, hypoglossal and vagal nuclei, the ventral horns of spinal cord and the dorsal root ganglia. This neuropathy is difficult to confirm unless fresh, well-fixed samples are submitted for histological examination. Immunohistochemical staining for synaptophysin aids in the differentiation between autolytic tissue and tissue from horses with grass sickness.[34]

Samples for post-mortem confirmation of diagnosis
Samples for light microscopic examination: formalin-fixed sympathetic ganglia, brain stem, spinal cord with dorsal root ganglia, gastric fundus, duodenum, jejunum, distal ileum, ventral colon, and dorsal colon.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis list:
Acute grass sickness

- Small intestinal strangulation or volvulus
- Large colon torsion
- Anterior enteritis
- Peritonitis
- Terminal ileal impaction
- Ileocecal intussusception.

Subacute or chronic grass sickness

- Impaction of the large or small colon
- Helminthiasis
- Mesenteric abscessation or other chronic inflammatory disease
- Gastric squamous cell carcinoma
- Alimentary lymphosarcoma or other neoplasia
- Inadequate diet
- Poor dentition
- Equine motor neuron disease.

TREATMENT

Acute cases respond transiently to gastric decompression and intravenous fluid administration, but death is inevitable. Selected chronic cases may benefit from careful nursing care and the administration of the promotility, indirect acting cholinergic agent, cisapride (0.5–0.8 mg/kg orally every 8 hours for 7 days).[35] Administration of brotizolam (a putative appetite stimulant), acetylcysteine (antioxidant and neuroprotectant), and aloe vera gel (antioxidant, anti-inflammatory and laxative) was without beneficial effect in 29 cases.[36]

CONTROL

Successful measures have not been satisfactorily established and no definitive recommendation can be made. However, consideration should be given to the factors identified as increasing the risk of disease, such as pasturing, movement to new properties and especially those on which previous cases of this disease have occurred, and the disturbance of soil. Feeding of hay and haylage is associated with a reduced risk of developing the disease. Although administration of ivermection is associated with an increased risk of the disease, appropriate parasite control should not be ignored in horses in areas in which grass sickness is endemic.

IDIOPATHIC CHRONIC INFLAMMATORY BOWEL DISEASES OF HORSES

A syndrome of combinations of weight loss, ill thrift, diarrhea, intestinal malabsorption, and hypoproteinemia attributable to chronic inflammatory disease of the small and/or large intestine of horses is well described. The syndrome has been subdivided into granulomatous enteritis, eosinophilic enteritis, lymphocytic-plasmacytic enterocolitis, basophilic enterocolitis, and multisystemic eosinophilic epitheliotropic disease.[1] Other causes of chronic inflammatory bowel disease in horses include alimentary lymphosarcoma, tuberculosis, pithyosis, and histoplasmosis.[2]

GRANULOMATOUS ENTERITIS OF HORSES

The etiology of granulomatous enteritis is unknown. Infection with *Mycobacterium* spp. is suggested as a cause but demonstration of acid fast bacteria in tissue sections or by culture of gut or mesenteric lymph nodes of affected horses is rare and inconsistent. The disease occurs with greatest incidence in Standardbred horses between 1 and 6 years of age, although it does affect other breeds of horses. The disease is usually sporadic, although it has been recorded in siblings raised on the same farm.[1] Estimates of incidence are not available. The disease has an almost 100% case fatality rate.

Accumulation of lymphocytes and multinucleated giant cells in the lamina propria is associated with villous blunting in the small intestine. There is malabsorption of carbohydrates and fats and excessive loss of protein in feces[2] with subsequent hypoalbuminemia, edema, and weight loss. Weight loss and anorexia are the most common presenting signs. Fever is uncommon. Approximately one-third of horses have diarrhea or a history of abdominal pain. Affected horses may have a diffuse, scaling alopecia and excoriations especially of the coronary band. Rectal examination may reveal enlarged, soft mesenteric lymph nodes. Exploratory laparotomy in horses with signs of colic attributable to inflammatory bowel disease often reveals constricting circumferential bands in the large or small intestine.[3]

Hematological and serum biochemical examination reveals:

- A mild, macrocytic **anemia** (hemoglobin <100 g/L, hematocrit <30%) with a normal leukogram
- Hypoalbuminemia is a consistent finding (<25 g/L, <2.5 g/dL) while the globulin concentration may be normal, low or, more commonly, high (>50 g/L, >5.0 g/dL)
- Plasma fibrinogen concentration is usually increased (>4 g/L, 400 mg/dL)
- There are no characteristic changes on serum biochemical analysis
- Peritoneal fluid is normal.

Absorption tests using (D(+)-xylose, glucose, or starch) may indicate diminished absorption of carbohydrate by the small intestine. The **D(+)-xylose absorption test** is performed by administering D(+)-xylose at a dose of 0.5 or 1 g/kg as a 10% solution by nasogastric intubation after an overnight fast. The concentration of D(+)-xylose in blood samples collected at 0, 1, 2, 3, 4, and 5 hours after dosing is determined. An abnormal test is one in which there is not an obvious peak in the D(+)-xylose curve and in which the peak concentration is lower than expected for a normal horse on a similar diet. Administration of a 10% glucose solution orally at a dose of 1 g/kg body weight results in an increase in plasma glucose concentration of >85% the baseline values in horses with normal small intestine. An increase of <15% over baseline is found in horses with small intestinal disease that impairs

glucose absorption. Intermediate values are found in both normal and diseased horses.[4]

Diagnostic confirmation is achieved by histological examination of biopsy of rectum or small intestine. **Rectal biopsy** has a low sensitivity (less than 50%) but high specificity for diagnosis of granulomatous enteritis.[5] **Biopsy of small intestine** and mesenteric lymph nodes has a much higher sensitivity than rectal biopsy and is the recommended test.

NECROPSY FINDINGS

Necropsy examination reveals that the intestinal wall is thickened uniformly especially in the jejunum and ileum. Mesenteric lymph nodes may be enlarged. There is villous atrophy with a diffuse and patchy granulomatous infiltration of the lamina propria of the small intestine. Crypt abscesses are common. Granulomas are also present in the liver, spleen, kidney, and bone marrow of many cases. The predominant cell types are macrophages and epitheliod cells with occasional giant cells. The disease may be difficult to distinguish from alimentary lymphosarcoma.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes:

- Parasitism
- Poor nutrition or dentition
- Alimentary lymphosarcoma
- Basophilic enterocolitis
- Eosinophilic enteritis
- Intrabdominal abscessation
- Gastric squamous cell carcinoma
- Small intestinal adenomatous polyposis.[6]

TREATMENT

Attempts at treatment with a variety of anti-inflammatory and antimicrobial drugs, including prednisone and sulfasalazine, have been almost university unsuccessful.[7] Resolution of the disease occurred for up to 7 months while a horse was treated with a decreasing dose of dexamethasone, beginning at 40 mg (0.1 mg/kg) intramuscularly every 4 days for 4 weeks, and then slowly decreasing.[7] Surgical resection of defined, solitary lesions is reported but this is an unusual manifestation of the disease.

CONTROL

There are no effective control measures.

LYMPHOCYTIC-PLASMACYTIC ENTEROCOLITIS

This is an uncommon disease of horses, in contrast to dogs, affecting horses of any age and without discernible breed or sex predilection.[1,2] The etiology is unknown. Presenting signs include weight loss, diarrhea, and lethary. Clinicopathologic abnormalities include hypoproteinemia and hypoalbuminemia in approximately one-half and three-quarters of cases, respectively.[2] Results of an oral glucose tolerance test are abnormal in approximately 75% of cases. Histologic examination of a rectal mucosal biopsy reveals abnormal tissue suggestive of the disease in about one-half of cases. The diagnosis is confirmed by biopsy of ileum or necropsy examination. Differential diagnoses are similar to those for granulomatous enteritis. There is marked infiltration of the lamina propria with lymphocytes and plasma cells. Effective treatment has not been described. Control measures are not available.

CHRONIC EOSINOPHILIC GASTROENTERITIS OF HORSES

Eosinophilic enterocolitis occurs either as part of the multisystemic, eosinophilic, epitheliotropic disease complex or as a lone entity. Multisystemic, eosinophilic, epitheliotropic disease is characterized by eosinophilic infiltrates in the gastrointestinal tract and other organs, while horses with eosinophilic enterocolitis have no evidence of extraintestinal disease.

Multisystemic, eosinophilic, epitheliotropic disease occurs in adult horses of any age and without apparent breed or sex predilection. The etiology is unknown, but some cases are associated with lymphosarcoma, suggesting that the disease in these horses is due to clonal expansion of a T-lymphocyte population that secretes interleukin-5.[1] The disease is idiopathic in most horses. Clinical signs include weight loss in all cases and diarrhea or dermatitis in approximately two-thirds of cases.[2] The dermatitis occurs mainly on the face, limbs, and ventral abdomen and is exudative with alopecia, hyperkeratosis, and lichenification.[3] Lesions of the coronary band and mouth are common. Urticaria occurs in some horses. Most affected horses have low serum protein and albumin concentrations. Hypereosinophilia is not a consistent feature of the disease and blood leukocyte concentrations are usually within the reference range. There are often elevations in serum activity of gammaglutamyl transpeptidase (GGT) and alkaline phosphatase, consistent with lesions in the biliary tree. This can be useful in differentiating horses with this disease from horses with granulomatous enteritis.[2] Histologic examination of tissues reveals eosinophilic infiltration of skin, liver, and gastrointestinal tract. Rectal biopsy can reveal the presence of eosinophilic granulomas, but these must be differentiated from the more common eosinophilic infiltrate secondary to parasitism. Treatment is usually ineffective and the prognosis for recovery is very poor. Affected horses should be administered an anthelmintic in case the disease is due to nematodiasis. Administration of corticosteroids (dexamethasone, prednisolone) is the usual treatment but is only transiently effective in most cases. Hydroxyurea, which is used to treat a similar syndrome in people, was only transiently effective in one horse.[4] There are no recognized control measures.

Idiopathic eosinophilic enteritis is a sporadic disease of horses of any age. Affected horses rarely have weight loss or diarrhea.[2] The common form of the disease is one in which the infiltration is segmental and associated with acute colic due to obstruction of the small intestine or large colon by mural lesions.[5,6] The D(+)-xylose absorption curve is usually normal in affected horses.[7] Histologically, the disease is characterized by the presence of eosinophilic infiltrates in a chronic inflammatory reaction affecting the small or large intestines. The infiltrates are restricted to the intestinal tract. The cause has not been identified but the lesion suggests a continuing hypersensitivity reaction to an ingested allergen. Antemortem diagnostic confirmation is achieved by rectal or small intestinal biopsy. Successful treatment is usually surgical. Control measures are not reported.

OVINE MOUTH AND GUM OBSCURE DISEASE (OMAGOD)

During the outbreak of foot-and-mouth disease (FMD) in the UK in 2001, field investigations reported the appearance of oral lesions, initially in sheep and then in cattle which complicated the diagnostic process.[1,2] While the lesions appeared to have a common, though obscure, etiology, prior to that they had not been identified as a differential diagnosis for FMD. The lesions were usually singular, located predominantly (but not exclusively) in the gingival mucosa ventral to the incisors, often in the midline; circular to nearly circular in shape and usually ranging in

diameter from 4 to 10 m; never vesicular but always erosive with a raised edge, giving the ulcer a crater-like appearance; and were more prevalent in adult sheep than in lambs.[2]

Experienced sheep veterinarians in the UK have reported ulceration of the gums of sheep as a regular occurrence in late winter and spring.[1] It has been suggested that grazing sparse rough or short pasture, the provision of feed or salt blocks, and the use of feeding troughs with sharp edges, could be predisposing causes.

An abattoir survey of sheep in New Zealand examined the lesions of the anterior lips and gums of the animals after slaughter.[3]

Lesions of the midline of the lips and gums of traumatic or irritant etiology were common, and the prevalence was higher in adult sheep than in lambs. The lesions probably arose from the fright/flight response behaviour of sheep, resulting in the mouth impacting against wire fences or yard railings while being handled. A smaller percentage of lesions may have been due to abrasive or irritant feed or soil. The presence of plant material and bacteria in lesions delayed healing and contributed to the formation of ulcers.

ULCERATION OF THE *PARS ESOPHAGEA* OF THE STOMACH OF SWINE (GASTRIC ULCER, HYPERKERATOSIS)

Naturally occurring ulcers of the stomach in swine occur in the *pars esophagea* (non-glandular part) of the stomach. They are single or multiple bleeding ulcers often associated with hyperkeratosis. Experimental lesions in the stomach are usually produced in the glandular part of the stomach as a model for the condition in humans. The condition was first reported in Illinois in 1897.

Synopsis

Etiology Fine particle and pelleted feed. Certain bacterial species may contribute.
Epidemiology Highly variable incidence but has increased with greater intensification of swine industry, emphasis on improving digestibility and feed efficiency and use of fine particle and pelleted feed. Growing and finishing pigs, adult sows, and boars.
Signs Sudden death from peracute gastric hemorrhage. Subacute form causes anemia, pallor, unthriftiness, black tarry feces.
Clinical pathology Hemorrhagic anemia.
Lesions Hyperkeratosis, erosions, ulcers of *pars esophagea*, gastric hemorrhage, anemia.
Diagnostic confirmation Lesions at necropsy.

Differential diagnosis list
- Proliferative enteritis of swine
- Enteric salmonellosis
- Swine dysentery.

Treatment None.
Control Use of diets prepared through hammer mill screen of at least 6 mm. Incorporate S-methylmethionine-sulphonium chloride in diet.

ETIOLOGY

The etiology is multifactorial. Finely ground and pelleted feed are important causes. *Helicobacter heilmannii*[1] and *Gastrospillium suis*,[2] have been found in gastric ulcers, but not ulcers of the *pars esophagea* of pigs and are unlikely to be the primary cause of the lesion.[3] Certain environmental stressors may also be contributing factors.

EPIDEMIOLOGY

Occurrence

The disease is most common in pigs of 45–90 kg BW[4] but the disease may also occur in pigs after weaning and in adult sows and boars. All breeds are susceptible. Prevalence in groups of pigs may vary anywhere in the world from 5 to 90%. In some countries the rate is 1% and in others 87%.[5]

Most gastric ulcers of pigs are localized in the *pars esophagea* and are referred to as esophagogastric ulceration. Examination of the stomachs of pigs at abattoirs in various countries has revealed a high proportion of pigs with varying degrees of hyperkeratosis, erosions, and ulcers of the *pars esophagea*. Extensive erosions of the *pars esophagea* may be present in up to 63% of sows and 36% of finishing pigs.[6]

The incidence is variable between countries which may reflect differences in feeding or husbandry methods. In the Netherlands 11% of the pigs may be affected.[7] The incidence of ulceration may be increasing in pigs in the UK compared to earlier studies.[8] An abattoir survey of the stomachs of pigs in the UK found ulceration of the *pars esophagea* in 23% with a range from 4 to 57%.[8] The ulcers were mild in 9.5% and severe in 13.4%.

The disease has assumed increased economic importance with increased intensification of the swine industry.[9] The feed manufacturing industry is faced with the dilemma of finely ground pelleted feed providing high digestibility and feed efficiency in growing and finishing pigs but with a high incidence of lesions of the *pars esophagea* which may affect performance. Pelleting swine feed is also advantageous because it flows more easily and effectively in automated distribution systems in swine farms compared to finely ground meal which may bridge and clog in distribution systems, decrease dustiness and segregation of ingredients and increase bulk density. Meal is less damaging than pellets.

The incidence of clinical disease is low but the case fatality rate is high when severe hemorrhage occurs. The effects of the lesions on performance may vary considerably. In one study, pigs with extensive lesions gained 50–75 g/day less than pigs with no lesions[10] while in another the presence of ulcers as determined at the abattoir did not influence growth rate.[8] The disease has increased in significance with the occurrence of PMWS and PDNS associated with porcine circovirus 2. There is also an increased occurrence where there is a problem with porcine respiratory disease complex (PRDC) particularly during summer months.

Risk factors

Anything that causes an empty stomach which potentially increases the acidity in the *pars esophagea* region of the stomach is a risk factor.[7] Back in the 1960s all that was needed to produce an esophageal ulcer in a pig was to keep the pig restricted in a feeding or farrowing crate and deprive it of water for 24 hours and it would have an ulcer. This would therefore include intermittent feeding and watering, respiratory disease and hot weather.

Dietary risk factors

The disease occurs primarily in penned pigs receiving a grain diet and growing rapidly. It has also occurred in pigs fed large quantities of cheese whey or skimmed milk. Too much copper and not enough zinc may also be a factor. The incidence is highest in pigs receiving diets containing a higher proportion of corn (maize) than other grains. The incidence is even greater if the corn is finely ground or is gelatinized or expanded. Ulceration in some pigs may be associated with *Ascaris suis* infection, but in other studies there is no significant association between the parasite and ulcers.

Finely ground feed

This is the most important risk factor.[11] One of the explanations of this may be the rapid emptying of the stomach when fine particles are used.[12] There is normally a gradation of ascending pH from the cardia to the oesophagus but with rapid emptying there is the possibility of the low pH reaching the esophageal region.[11,12]

Feeding a diet based on finely ground barley to pigs beginning at 10–11 weeks results in lesions as early as 1 month later, and the incidence and severity of lesions increased progressively over the next

2 months. Diets high in wheat or corn starch may be worse than diets based on barley. The incidence and severity of hyperkeratosis may be greater in some breeds compared to others, but the effects of previous diets and environmental factors may have influenced the results.

The particle size and the physical form of the feed are important risk factors. Finely ground diets and pelleting have detrimental effects on the gastric mucosa of finishing pigs.[13] A pelleted diet uses grain that is finely ground before it is compressed into a pellet but on reaching the stomach it reverts to the fine particles. A diet finely ground through a 3 mm screen in a hammer mill and then pelleted will be associated with a 75% incidence of pigs with hyperkeratosis of the *pars esophagea* and 11% of the pigs may have severe erosions and ulceration of the *pars esophagea*.[10] The incidence of lesions decreases when the diet is ground through a 6 mm screen.[14] Finely ground barley or wheat is associated with a marked increase in gastric abnormalities compared to the use of coarsely ground grains. The size of particles in feed is significant whatever feed is used, even straw; coarsely ground barley straw at 5–10% of the ration gives almost complete protection. In growing pigs, dietary fiber rich in structural polysaccharides has been shown to be important in preventing the development of parakeratotic lesions in the *pars esophagea*.[15] But an increase in the crude fiber content of a diet which is finely ground does not affect the occurrence of severe erosions and/or ulcers of the *pars esophagea*.

Grinding barley through a 1.56 mm screen results in finely ground feed, which is associated with an increased incidence and severity of gastric ulcers in pigs. Grinding through a 4.68 mm screen approximates the screen size used most frequently for grinding barley for pigs in practice and is associated with a low incidence of ulcers.[15]

Reducing particle size and pelleting improves growth performance of finishing pigs.[16] For every 100 microns of decrease in size of the particle size there is an approximately 1.3% increase in gain efficiency but each time the level of ulcers increases.[17] The processes have additive effects on digestibilities of dry matter, nitrogen, and energy, with maximum nutrient digestibility in pelleted diets with corn milled to a particle diameter size of 400 µm. Reducing the particle size to below 400 µm causes practical problems with milling and an increased incidence of gastric lesions and it is suggested that a particle size of 600 µm, or slightly less, is optimal for corn in either meal or pelleted diets for finishing pigs.

Using endoscopic examination of the stomachs of pigs fed a fine particle diet (geometric mean size of 578 µm) it was found that as ulcer severity increases, the growth performance of individually fed pigs decreases. Feeding a coarse particle diet (geometric mean size of 937 µm) for 3 weeks resulted in a decrease in the severity of the ulcers.[18]

High levels of unsaturated dietary fat are not helpful especially if they are accompanied by low levels of vitamin E. Similarly pigs fed waste food had more severe gastric lesions.[19]

Environmental and management risk factors

It has been suggested that confinement, crowding, transportation, changes in environment, and exposure to other pigs, were important in the etiopathogenesis of gastric ulcers of pigs. All of these stresses and many others including anxiety, fear, pain, fatigue, fasting, etc., will be associated with an increase of ulcers. There is an even greater occurrence in summer when water demands are higher. Males are always more affected in prevalence and severity but that may be that they are more easily stressed. One of the most important factors is time in the lairage. Pre-mortem handling is extremely important.[20] Pigs kept overnight in the lairage have more ulcers than pigs killed on the day of arrival.[21] Similarly there is no difference in the prevalence of lesions in small and medium farms but there is a considerable increase in the prevalence in these two groups compared to the larger producer.[22] Larger herds always show more of the problem[23] and it is probably a reflection of the different diets that they use (based on wheat and pelleted). The larger farms also have more infection pressure, more selection pressure, and more feed-related factors.

Pigs that receive porcine somatotrophin may have an increased level of ulcers possibly due to the elevated circulating gastrin.[24]

There are a variety of foreign bodies reported from the pigs' stomach including stones, which outside sows chew all the time, and also sand. The majority of stones is probably passed in the feces, but may accumulate in and stretch the stomach. The stomach capacity is normally about 3–6 L. This may lead to reduced appetite and gastritis but is not believed to be a contributor to esophageal ulceration. Similarly, hairballs are a common finding, reaching 10–15 cm in size in the stomach. The occurrence of rubbish indicates pica or a depraved appetite which is often an indicator of inadequate feeding. One of the other substances found in outdoor pigs stomachs is the flakes of bitumen that remain from clay pigeon shooting, which are toxic.

Increased frequencies of any of four combinations of behavioral indicators of stress, recorded 4 weeks after weaning, were weakly associated with increased risk of acute fundic ulcers in slaughter pigs from a conventional farrow-to-finish herd.[25]

Pathogen risk factors

Gastric bacteria

The spiral-shaped *Gastrospirillium suis* has been found in 84% of the stomach of pigs with frank gastric ulcers of the *pars esophagea*. The organisms were mainly in the mucus layer and in gastric foveolas of the antral and oxyntic mucosa and only occasionally in the cardiac-*pars esophagea* region.[2] The presence of the organism has been associated with lesions of the pyloric mucosa in pigs.[26]

There is no known cause and effect relationship but the gastric environment associated with gastric ulcer may favor colonization of the organism. The oral inoculation of *Gastrillium*-like bacteria into laboratory animals is capable of inducing gastric ulceration.[27] *Helicobacter heilmannii* type 1[28] has been found more frequently in the stomachs of pigs with ulcers (100%) and in those with pre-ulcer lesions (90%) than in stomachs with macroscopically normal *pars esophagea* (35%).[1] It has been suggested that *Helicobacter heilmannii* may play a role in the pathogenesis of gastric ulcers in swine by causing increased acid secretion. *H. pylori* can colonise the pig stomach. Experimental reproduction of *Helicobacter suis* infection has recently been described.[29] The pigs had no ulcers and infection was only accompanied by a mild superficial gastritis.

PATHOGENESIS

In pigs, nearly all naturally occurring gastroduodenual ulcers are localized in the *pars esophagea* of the stomach. Excessive gastric acid production, depletion of the gastric buffering system resulting in prolonged activation of pepsinogens, and changes in mucus composition are suggested as important factors related to gastric ulceration in swine. The physical texture of the feed can influence pepsin and acid secretion, and the fluidity of the stomach contents induced by ulcerogenic diets may alter the normal pH gradient within the stomach. This allows greater pepsin and acid contact to the esophagogastric area.

The concentrations of short chain fatty acids are high in the proximal gastric contents of pigs and associated with intakes high in readily fermentable carbohydrates, like ground corn. These products of bacterial metabolism, principally acetate and lactate, reach high concentrations within 4 hours after feeding because of high pH

in the proximal gastric contents which may allow some types of bacteria to proliferate. These weak acids are lipid soluble in their undissociated form and could penetrate and acidify underlying tissue more readily than free hydrogen ions. In this way, rapid production of short chain fatty acids, followed by their absorption and tissue acidification, may be similar to ruminal acidosis and rumenitis in ruminants following the ingestion of large quantities of readily fermentable carbohydrates.[30]

The rumen epithelium, also a stratified squamous mucosa, is easily injured by short chain fatty acids at pH ≤ 5.0. The breaking of the barrier by short chain fatty acids could result in underlying inflammation and widespread tissue destruction. Experimentally, exposing undissociated short chain fatty acids to swine gastric mucosa results in rapid penetration of the outer barrier and acidification of the underlying viable tissue.[30] This results in cell swelling and vesicle formation, followed by sloughing of the outer barrier, erosion into deeper zones, and finally, ulceration.[30]

Weak organic acids, at pH ≤ 2.5 induce a greater degree of functional and histological injury in 3 stomach zones (squamous, cardiac, and oxyntic) than does hydrochloric acid. The predilection for the squamous mucosa in naturally occurring ulcers may be attributed to the lack of defense or repair mechanisms that are present in the cardiac and oxyntic mucosa, which are capable of HCO_3- and mucus secretion, which may raise the pH adjacent to these epithelial layers.[30] Thus the increased digestibility associated with decreased particle size of the diet may promote rapid fermentation following eating resulting in the production of increased concentrations of short chain fatty acids. Any increase in fluid content will also contribute to the changes in pH gradient that exist in the stomach. Excessive gastrin is then stimulated and more acid secretion follows.

Normally, the *pars esophagea* is white, smooth, and glistening and may be bile stained. The first stage in ulceration is hyperkeratosis. This is followed by erosions, ulcerations, and hemorrhage. The erosions may heal, resulting in a fibrous contraction. Chronic ulceration may occur with the development of several ulcers in combination with fibrous tissue involving all of the squamous mucosa. Advanced hyperkeratosis may cause partial stenosis of the terminal esophagus.

The erosion of a blood vessel within the ulcer will result in acute to subacute gastric hemorrhage. These cases are usually sporadic, causing deaths of individuals within a group, with cases occurring over a period of several weeks. Clinical signs are often not observed, affected pigs being found dead from acute hemorrhage into the stomach.

The regurgitation of bile into the stomach and the intensity of bile staining of esophagogastric tissue have been linked to the pathogenesis of esophagogastric ulcers in pigs. Almost all stomachs of pigs contain bile and bile staining of the *pars esophagea*; there is no evidence for the hypothesis that the regurgitation of bile into the stomach is associated with esophagogastric lesions in finishing pigs.[31] There is no evidence of an association between gastritis and ulcer.[32]

CLINICAL FINDINGS

Most cases are sub-clinical but sows will die from blood loss. Pigs frequently die from ulcers during concurrent disease such as respiratory disease[33] and in this case anorexia may disturb the gastric contents and allow material of high acidity to reach the cardia. Similarly where there is a reduced consumption of water the integrity of the mucus may be broken by the dessication that results on mucosal surfaces.

Gastric ulceration is most common in pigs over 6 weeks of age and occurs in adult sows and boars; the clinical findings are dependent on the severity of the ulcers. The effects of ulceration on production may be highly variable. Most pigs with esophagogastric ulcers are clinically normal, and growth rate and feed intake appear unaffected. Some observations suggest that there is no effect of ulceration on growth rate, while others indicate that the presence of esophagogastric ulcers results in a marked decrease in growth rate and an increase in the length of time required for the pig to reach market weight. Some affected pigs also eat slowly and regurgitate frequently. Endoscopic monitoring of the stomachs of pigs fed ulcerogenic diets found that as the severity of the ulcer increased growth performance was decreased.[18] The greatest economic losses were associated with sudden deaths due to hemorrhage and marked decreases in performance associated with fine particle size.

The erosion of a blood vessel within the ulcer will result in acute to subacute gastric hemorrhage. These cases are usually sporadic, causing deaths of individuals within a group, with cases occurring over a period of several weeks. Clinical signs are often not observed, affected pigs being found dead from acute hemorrhage into the stomach. When pigs are found dead from peracute hemorrhage, inspection of the in-contact pigs may reveal other animals with pallor and black tarry feces which represent those with subacute hemorrhage.

Cases with subacute gastric hemorrhage may survive for a few days and there is evidence of marked pallor, weakness, anorexia, and black pasty feces changing to mucus-covered pellets in small amounts. The weakness may be sufficient to cause recumbency. Vomiting frothy bile-stained fluid and grinding of the teeth may occur. Abdominal pain may be elicited by deep palpation over the xiphisternum and there may be a reluctance to walk along with a rigid back indicative of pain.[6] Animals that survive are often unthrifty, usually due to anemia from chronic blood loss with a few cases affected by chronic peritonitis. When the disease is occurring careful observation may detect early cases. Suggestive signs are a darkening of the feces and the development of pallor.

CLINICAL PATHOLOGY

Laboratory testing is not indicated. Animals with gastric ulceration generally have lower hematocrit values, haemoglobin concentrations, and erythrocyte counts than normal. The black tarry feces can be examined for the presence of blood.

NECROPSY FINDINGS

Ascarids have been found in the stomach but these are not a factor in the field.[34]

At necropsy, the ulcers are confined to the esophageal region of the stomach. Affected stomachs consistently have more fluid contents than unaffected ones. If severe blood loss from the ulcer has been the cause of death then the carcass is pale and fresh blood is usually present in the stomach (there may be large blood clots) and intestines. The colonic contents may also appear melenic. Early lesions in clinically unaffected animals include hyperkeratinization of the mucosa (usually pale raised areas without bile staining initially) which progresses to epithelial erosion without actual ulceration. Ulcers usually initially occur along the junction of the *pars esophagea* with the glandular stomach but may enlarge to efface the entire squamous portion of the stomach. These more diffuse ulcers are easily missed on cursory examination due to their uniform appearance. Chronic gastric ulcers develop thickened, raised edges due to ongoing fibrosis, occasionally resulting in a gastroesophageal stricture. The histological appearance varies with the stage of lesion development but in fatalities there is typically complete loss of the epithelial layer, with exudation of neutrophils from a bed of mature granulation tissue. Recent studies have demonstrated *Helicobacter*-like bacteria in porcine stomachs but further research is required to determine if this infection plays a significant role in ulcer formation. Small clusters of *H. hellmanii* have been seen in the gastric crypts,[35] but are not associated with histological changes.[36] A recent survey suggested no correlation between infection

in the cardiac mucosa and the severity of the lesions shown by the esophagogastric region.[37] The macroscopic findings are usually sufficient for the confirmation of a diagnosis of esophagogastric ulceration. The initial lesion of hyperkeratosis leads to parakeratosis with fissures and the lamina propria is then exposed. The epithelium sloughs off and then ulcers of the epithelium develop with haemorrhage from the vessels.

Severity and extent of esophagogastric lesions can be graded according to the following scheme[6]:

0: intact epithelium
1: small degree of hyperkeratosis (< 50% of total surface)
2: distinct hyperkeratosis (= 50% of the total surface)
3: hyperkeratosis and less than 5 erosions smaller than 2.5 cm in size
4: hyperkeratosis and more than 5 erosions or erosions larger than 2.5 cm in size
5: hyperkeratosis and more than 10 erosions or erosions larger than 5 cm in size, and/or an ulcer (with or without bleeding) or stenosis of the esophagus towards the stomach.

No difference in lesion score was found between Duroc, Landrace, and Iberian pigs.[38]

DIFFERENTIAL DIAGNOSIS

The occurrence of sudden death with a carcass that shows extreme pallor and a marble-white skin suggests the possibility of peracute hemorrhage from an esophagogastric ulcer. The disease must be differentiated at necropsy from proliferative hemorrhagic enteropathy, swine dysentery, and salmonellosis. Black tarry feces in growing and finishing pigs are characteristically due to subacute hemorrhage associated with esophagogastric ulceration.

It is possible to detect stomachs with Helicobacters by covering the stomach with urea gel containing an indicator sensitive to pH change. If there are large numbers of urease-positive bacteria then the pH changes.[39]

Severe infestation with whipworms is a differential. The clinical diagnosis can be confirmed by endoscopy[40] which requires an empty stomach (may cause ulceration in itself) and anesthesia.

TREATMENT

Vitamin K and hematinics have been tried with little success. Bovine serum concentrate given as a 1% solution is supposed to have reduced the extent and severity of signs associated with ulcers in growing pigs but in general medication does not help.[41] If a diagnosis is made euthanasia is advised.

CONTROL

Control of esophagogastric lesions of growing and finishing pigs is dependent on using diets with a particle size and physical form which will provide the most economical performance in terms of digestibility and feed efficiency and minimize the incidence of lesions.

The most desirable particle size or physical form of diet, meal, or pelleted form, has not been determined. The use of a diet ground through a 6 mm screen instead of 3 mm screen is recommended. However, screen size is not the only factor affecting particle size. Other factors include the condition of the screen and hammer, the type and variety of grain and its moisture content, the speed of the mill, the pelleting process and the flow rate in the distribution of the feed to the pigs. A particle size of 600 µm, or slightly less is suggested as optimal for corn in either meal or pelleted diets for finishing pigs.[16]

The incorporation of S-methyl-methionine-sulphonium chloride (MMSC), a nutritional component of many vegetables such as cabbage and carrots, has anti-gastric ulcer properties. Its addition to the diet, ground through a 3 mm screen, and fed to grower pigs from 45 to 107 kg liveweight, at 400 ppm decreased the incidence of severe erosions or ulcers by about 50%.[14] The addition of lucerne meal to increase the crude fiber content of one of the experimental diets did not have an effect on the incidence or severity of the lesions.

The diet should contain adequate amounts of vitamin E and selenium. Where applicable a reduction of the amount of corn in the ration and the feeding of meal rather than pellets may also be of value. The reduction of environmental and managemental stressors with attention to stocking rates may be of value.

CHRONIC INFLAMMATORY BOWEL DISEASE OF SHEEP

This syndrome of unknown etiology is manifest with wasting, ill thrift and mortality, or culling for poor production, and is reported in England and Canada.[1,2] It affects both housed and pastured sheep predominantly in their first year of life, but cases up to 3 years of age have been seen. Affected sheep are dull and anorectic with pale mucous membranes and have fecal staining of the perineum. The rumen fill is reduced and the feces are soft and malodorous. Blood examination shows hypoalbunimemia, an elevated blood urea nitrogen, and leukocytosis with neutrophilia. On post mortem there is lymphocytic enteritis with gross thickening of segments or the entire or distal part of the small intestine. There is no evidence for Johne's disease or parasitic gastroenteritis and the syndrome has similarities to the proliferative enteropathies of swine and horses.

Diseases characterized by respiratory tract involvement

INTERSTITIAL PNEUMONIA OF CATTLE

Interstitial pneumonia of cattle has been known for many years under many different terms including: atypical interstitial pneumonia, acute pulmonary emphysema and edema, bovine pulmonary emphysema, 'panters', 'lungers', bovine asthma, pneumoconiosis, and 'fog fever'.

Diffuse or patchy damage to alveolar septa is the essential feature of interstitial pneumonia which may be acute or chronic and can be caused by many forms of pulmonary injury. There is an obvious lack of lesions of the small airways which differentiates interstitial pneumonia from bronchopneumonia. Traditionally it was thought that interstitial pneumonias were characterized by chronic inflammation in which there is a predominantly proliferative response involving the alveolar walls and supporting stroma. However, acute diffuse damage of the alveolar walls accompanied by an early intra-alveolar exudative phase, which can be followed by proliferation of type 2 alveolar epithelial cells and fibroblasts, is now commonly recognized.

The recognition that interstitial pneumonia can have an acute exudative phase was the reason for the designation of acute interstitial pneumonia in cattle as 'atypical' interstitial pneumonia. The use of the word 'atypical' may create some confusion in the interpretation and diagnosis of lesions and in the conveying of information. It may be more appropriate to use the term interstitial pneumonia and specify where possible, clinically, epidemiologically, and pathologically the various forms of interstitial pulmonary disease in cattle.

The diseases in which interstitial pneumonia is the essential lesion are listed in Table 36.1. Pulmonary congestion and edema, alveolar exudation, hyaline membrane formation, interstitial emphysema, and alveolar epithelial cell hyperplasia and fibrosis of the supporting stroma without lesions of the smaller airways are the characteristic lesions, with their presence and extent varying according to the stage of the disease process.

The term atypical interstitial pneumonia as originally proposed is still useful in describing some of the diseases clinically and sets them apart from the common acute infectious diseases, especially the viral diseases of the respiratory tract of cattle. Clinically, they are atypical with regard to most clinical signs, especially when compared to the bacterial pneumonias:

> Some are acute, like fog fever, while others are chronic as in 'bovine farmer's lung'

- There is usually acute or chronic respiratory distress and a relative absence of toxemia
- Most are progressive and non-responsive to treatment
- Pathology consists of varying degrees of pulmonary emphysema, edema, hyaline membrane formation, and alveolar epithelial cell and interstitial tissue hyperplasia.

While there are obvious clinical, and particularly epidemiological, differences between the various diseases, there are fewer differences between the pathological findings which tend to merge from one to another.

Table 36.1 Diseases of the lungs of cattle in which the essential lesion is interstitial pneumonia

A. *Diseases of uncertain etiology*
1. Acute bovine pulmonary emphysema and edema (ABPEE) also known as 'fog fever', in cattle moved from dry to lush pasture (may be due to D,L-tryptophan). Usually occurs in outbreak form
2. Diffuse fibrosing alveolitis. Chronic disease which occurs sporadically in mature cows
3. Sporadic cases of acute interstitial pneumonia of young cattle (6–18 months of age). May be due to bovine respiratory syncytial virus or sequel to pneumonic pasteurellosis

B. *Hypersensitivity diseases*
1. Extrinsic allergic alveolitis (bovine farmer's lung). Epidemiologically associated with moldy feeds in housed cattle. May be sudden in onset in individual animals or develop insidiously as a chronic disease in several cows
2. Milk allergy. Occurs sporadically and is sudden in onset

C. *Plant poisoning*
1. *Ipomoea batatas* (sweet potatoes infested with the mold *Fusarium solani*)[3]
2. *Ziera aborescens* (stinkweed)
3. *Perilla frutescens* (purple mint)
4. *Brassica* spp.

D. *Parasitic diseases*
1. *Dictyocaulus viviparus* (including the hypersensitivity aspect)
2. *Ascaris suum*

E. *Exposure to irritant gases and fumes*
1. Nitrogen dioxide
2. Zinc dioxide

F. *Endotoxic or metabolic*
Shock lung due to endotoxemia such as in peracute coliform

Synopsis

Etiology D, L-tryptophan in forage. Inhalation of certain gases. Hypersensitivity to molds. Mycotoxicosis and plant poisonings. Viral and bacterial infections.
Epidemiology Primarily in adult cattle moved from dry to lush pasture. Outbreaks of acute pulmonary emphysema and edema occur primarily in adult cattle moved from dry to lush pasture in autumn in North America. In UK and Europe other interstitial pneumonias due to hypersensitivity to molds occur.
Signs Outbreaks of acute respiratory distress in pasture form of disease; severe dyspnea, mouth breathing, expiratory grunt, subcutaneous emphysema, and rapid death. Subacute form less severe and may survive but develop cor pulmonale later. Individual cases of interstitial pneumonia in UK and Europe are subacute and chronic.
Clinical pathology None clinically applicable.
Lesions Enlarged firm lungs which do not collapse, diffuse congestion and edema, interstitial and bullous emphysema, cranioventral consolidation, hyaline membrane formation, alveolar epithelial hyperplasia, fibrosis.
Diagnostic confirmation Lesions at necropsy.

Differential diagnosis list
- Pneumonic pasteurellosis
- Organophosphatic insecticide poisoning
- Nitrate poisoning
- Other interstitial pneumonias
- Bovine farmer's lung or extrinsic allergic alveolitis
- Lungworm pneumonia
- Verminous pneumonia caused by aberrant migration of *Ascaris suis* larvae
- Feedlot interstitial pneumonia
- Enzootic pneumonia of calves

Treatment None.
Control Grazing management. Use of antimicrobials to control conversion of tryptophan to 3-methylindole. Adequate housing and ventilation to control hypersensitivity pneumonias.

ETIOLOGY

There are several different possible causes.

Acute bovine pulmonary emphysema and edema (ABPEE) or fog fever

This is an acute atypical interstitial pneumonia also known as acute respiratory distress syndrome of cattle. The cause in adult cattle which have been moved from a dry to a lush pasture in the autumn season is related to the ingestion of a toxic level of D,L-tryptophan in the forage.[1] The experimental oral administration of toxic amounts of D,L-tryptophan to cattle causes clinical and pathological findings similar, if not identical, to those of the naturally occurring disease. D,L-tryptophan is converted in the rumen to 3-methylindole which, when given orally or intravenously, also produces the characteristic lesions in cattle and goats. The 3-methylindole exerts a direct effect upon cells and cell embranes of bronchioles and alveolar walls, perhaps as a result of strong lipophilic properties.

Specific forages have not been implicated, but affected cattle have often been consuming alfalfa, kale, rape, turnip tops, rapidly growing pasture grass, and several other feeds. However, pasture levels of tryptophan are not necessarily higher in those associated with the disease compared to normal pastures. In some naturally occurring cases of fog fever in beef cows changed from a dry summer range to a lush green pasture, there is a marked increase in the ruminal levels of 3-methylindole while in other cases the levels are not abnormal. Failure to detect abnormally high levels in the rumen and plasma of naturally occurring cases may be related to the rapid metabolism and elimination of 3-methylindole.

The levels of tryptophan in lush pasture are sufficient to yield toxic doses of 3-methylindole. A 450 kg cow eating grass at an equivalent DM intake of 3.5% of BW/day with a tryptophan concentration of 0.3% of DM would ingest 0.11 g tryptophan/kg BW/day. The total amount ingested over a 3-day period would approximate the single oral dose of 0.35 g/kg BW needed to reproduce the disease experimentally.

Diffuse fibrosing alveolitis

This is a chronic interstitial pneumonia of cattle which occurs sporadically and is suspected of being caused by repeated subclinical incidents of ABPEE or from recovered cases of the disease. Experimentally, repeated oral doses of 3-methylindole can result in diffuse pulmonary fibrosis and alveolitis in cattle.

Parasitic infestation

For many years it was thought that massive infestation of the lungs by large numbers of lungworm larvae in a lungworm-sensitized animal could cause an allergic reaction resulting in the development of acute bovine pulmonary emphysema. The possibility of such hypersensitivity as being associated cannot be totally ignored but at the present time there is no evidence to support such a theory. Such hypersensitivity may occur when the level of larval infestation of pasture is extremely high but it is not involved in the great majority of cases. In most cases of naturally occurring fog fever there is no laboratory evidence of lungworms in the lungs or feces of affected and in-contact animals. Reinfection of cattle with lungworm will occur 2–3 weeks following introduction to an infected pasture and cause acute respiratory distress which is indistinguishable clinically from fog fever. The migration of abnormal parasites, particularly *Ascaris suum*, has been observed to cause an acute interstitial pneumonia in cattle which were allowed access to areas previously occupied by swine.[1]

Inhalation of irritant gases

The experimental inhalation of nitrogen dioxide gas is capable of causing acute interstitial pneumonia in cattle[1] and severe alveolar edema and emphysema in pigs but it seems unlikely that animals of either species would be exposed naturally to a significant concentration of the gas for a sufficiently long period to produce such lesions.

Pigs which survived experimental exposure to silo gas did not have the lesions seen in silo-fillers' disease in man, and experimental exposure of cattle to nitrogen dioxide gas produces lesions which do not occur in naturally occurring fog fever. Acute pulmonary emphysema and deaths have occurred in cattle exposed to zinc oxide fumes produced by the welding of galvanized metal in an enclosed barn housing cattle.

Hypersensitivity to molds

The ingestion or inhalation of molds may be a cause of the disease in cattle.[1] The disease has been associated with hypersensitivity to moldy hay based on the presence of serum precipitins of the thermophilic antigens of *Thermopolyspora polyspora*, *Micropolyspora faeni*, and *Thermoactinomyces vulgaris* in cattle affected with extrinsic allergic alveolitis or bovine farmer's lung.

In Switzerland, a high incidence of serum precipitins against *Micropolyspora faeni* (60%) and moldy hay antigen (80%) was demonstrated in exposed but apparently healthy cattle from an area where 'allergic pneumonia' is common. The precipitins decreased during the pasture season and increased during winter housing.

Outbreaks of acute respiratory disease in adult cattle due to acute allergic pneumonitis can occur 15 hours after the introduction of severely moldy hay. Serological investigation and provocative challenge may reveal a hypersensitivity pneumonitis due to allergens of *Micropolyspora faeni*. A hypersensitivity pneumonitis has been produced experimentally in calves by exposure to aerosols of *Micropolyspora faeni* with or without prior sensitization by subcutaneous injection of the antigen.

In some Canadian cattle barns the disease occurred in cattle located near the hay chute from which hay and bedding are thrown down from the hay storage above the floor where the animals are kept. It has been suggested that the degree of exposure to dusty hay was greater in these cattle but that has not been substantiated. Similarly, it has been proposed that feeding finely ground feed may be associated with interstitial pneumonia in feedlot cattle but there is little evidence to support the observation.

The high incidence of ABPEE in the autumn when many legumes and other pasture plants are flowering, and the common occurrence at this time of allergic rhinitis in cattle, suggest that the inhalation of pollen may cause an allergic response of the alveolar epithelium. However, many outbreaks of the disease have occurred in cattle solely on grass pasture with no flowers; intradermal tests of sensitivity to many pasture plants and to the ruminal contents of affected animals have been negative, and blood histamine levels are within the normal range.

Mycotoxicosis and plant poisonings

In North America, the ingestion of sweet potatoes infested with the mold *Fusarium solani* has been incriminated as a cause of acute interstitial pneumonia in cattle. Growth of the mold on the potatoes produces the toxins ipomeamarone and ipomeamaronol, and a lung edema factor. The latter is a collective term for a group of substances capable of causing death associated with severe edema and a proliferative alveolitis of the lungs of laboratory animals. It produces a respiratory syndrome which is clinically and pathologically indistinguishable from ABPEE.

The fungus *Fusarium semitectum* growing on moldy garden beans, *Phaseolus vulgaris*, which were discarded on pasture, was associated with acute pulmonary emphysema in cattle that consumed the beans and their vines. The fungus produces a pulmonary toxin. The pulmonary toxin, 4-ipomeanol (ipomeanol), accumulates in mold-damaged sweet potatoes and induces pulmonary edema, bronchiolar necrosis and interstitial pneumonia in many mammalian species. Outbreaks have occurred in lactating cows following ingestion of sweet potatoes damaged by *Myzus tersicae*.[2] Other *Fursarium* spp. have been found in

peanut-vine hay, which has been associated with acute respiratory distress and atypical interstitial pneumonia in adult beef cattle.[3] The population mortality rate due to respiratory disease was about 12% and the case fatality rate 77%. Clinical signs occurred within a few days to 2 months after the animals were fed the peanut-vine hay.

A weed, *Perilla frutescens*, is considered to be a cause of the disease in cattle in the US and wherever the plant is found. High morbidity and high case fatality rates are characteristic, and the plant contains a perilla ketone which can be used to produce the disease experimentally.

Turf-quality perennial ryegrass straw (*Lolium perenne*) infected with the endophyte (*Acremonium lolii*) which yields toxic substances, including lolitrem-B has been associated with atypical pneumonia in weaned beef calves.[4] However, feeding the suspect hay resulted in typical ryegrass staggers but not atypical interstitial pneumonia.

Bacterial and *Mycoplasma* spp. infections

There is no evidence that any of the common bacterial pathogens of cattle such as *Mannheimia haemolytica, Pasteurella multocida, Histophilus (Haemophilus) somni*, or *Mycoplasma* spp. are primaily associated with acute interstitial pneumonia. In a series of feedlot cattle with clinical findings consistent with acute interstitial pneumonia, the pathogens were present in the lung tissues of some animals at necropsy but their presence was not considered as a primary cause of the pneumonia but rather secondary to the initial injury of the lung which was undetermined.[5]

Viral infections

Certain viral infections of the lung may result in interstitial pneumonia. In the interstitial pneumonias caused by the bovine respiratory syncytial virus (BRSV) there is a bronchiolitis and alveolitis and these should be termed bronchiointerstitial pneumonias. The BRSV is an important cause of outbreaks of acute interstitial pneumonia in beef calves 2–4 weeks after weaning. Pathologic evaluation of the lung tissues of feedlot cattle which had acute interstitial pneumonia found that BRSV was not a causative agent.[6] In a series of cases of interstitial pneumonia in feedlot cattle in Saskatchewan the presence of the BRSV antigen was demonstrated in only 7% of cases and there was more severe bronchiolar epithelial necrosis than in the other cases which were negative for the virus.[7]

EPIDEMIOLOGY

Acute pulmonary emphysema and edema (ABPEE) or fog fever occurs almost exclusively in adult cows and bulls, usually 4–10 days after they are moved abruptly from a dry or overgrazed summer pasture to a lush autumn pasture. The new pasture may or may not have been grazed during that summer and the species of grass or plants does not seem to make a difference, but usually there is some lush regrowth of grass, legume or other palatable plants. Merely changing pasture fields in the autumn has precipitated the disease. In the mountainous areas of North America the disease occurs commonly in cattle brought down from high altitude grasslands to the cultivated and perhaps irrigated lush pastures.

ABPEE usually occurs in outbreaks, the morbidity ranging from 10% in some herds up to 50% and higher in others, with a case fatality ranging from 25 to 50%. It is not unusual to observe a mild form of the disease in about one-third of the adults at risk but only 10% of those at risk may be severely affected. Often, a number of cows are found dead without premonitory signs; many others are severely ill and die within 24 hours and the owner believes that the entire herd will die because of the sudden onset and the large number of animals which are affected at once. Calves and young growing cattle up to 1 year of age grazing the same pasture are usually unaffected.

A retrospective analysis and random sample survey of cattle ranches in northern California found that the type of forage management has a significant effect on the occurrence of the disease. The greatest occurrence of the disease was in herds where the cattle were moved from summer ranges to second-growth hay fields or to irrigated pastures, or from one irrigated field to another. The adult morbidity rate was 2.6% and the case fatality rate about 55%. The disease did not occur on ranches with limited or no movement of cattle from summer ranges to lush autumn pastures.

Placing cattle on rape or kale forage fields or in fields where turnips have been pulled and the cattle allowed access to the tops may have the same effect. The disease has also occurred commonly in western Canada when cattle have been placed in a stubble field following harvesting of any of the cereal crops. Veterinarians have noted that the timespan over which the disease occurs during the autumn months is only 2–4 weeks and that, following the first frost in the fall, the incidence of the disease declines rapidly. The disease has also occurred in the same herd on the same pasture in successive years.

ABPEE in adult cattle in autumn has been recorded in Canada and the US, Great Britain, Holland, and New Zealand. The disease is rare in Australia. The chronic form of the disease in housed cattle appears to be the predominant form of the disease in Switzerland, but the acute form in cattle which have been changed from a dry to lush pasture is now reported. The disease has been recognized in France for many years as aftermath disease or aftermath emphysema, especially in the Normandy region. Some reports have suggested a breed incidence, Herefords being more commonly affected than the Jersey, Holstein, Shorthorn, and Angus breeds, but there are few exact epidemiological data to support the observation. One report suggested that the chronic type in housed cattle was more common in the Channel Island breeds.

Acute interstitial pneumonia in feedlot cattle. Interstitial pneumonia is recognized as important cause of economic loss in feedlot cattle in western Canada and the United States.[8] The disease occurs sporadically and the incidence is about 3.1% of all cattle placed in feedlots.[9] Cases occur most commonly during the summer and fall months and new cases occur in an even distribution across all stages of the finishing period. In southern Alberta, the disease is most common during hot, dry, dusty, spring and summer days, and typically affects animals expected to be ready for slaughter within 15 to 45 days. Some feedlot operators have observed that the disease is more common in cattle exposed to excessive dust from bedding.

In southern Alberta feedlots the disease occurred late in the finishing period, when animals had been on feed an average of 114 days and weighed 475 kg.[10] All confirmed cases were in heifers and plasma concentrations of 3-methylindole metabolites (adducts) were higher in heifers with interstitial pneumonia than in controls. Most of the heifers were receiving melengestrol (MGA) to suppress estrus. The BRSV antigen was not found in lung tissue of confirmed cases. The odds of an animal with acute interstitial pneumonia being a heifer were 3.1 times greater than the odds that an animal with the disease was a steer.[9] In some large feedlots the estimated relative risk was 4.9.

The role of 3-methylindole (3MI) has been examined as a possible cause of interstitial pneumonia in feedlot cattle.[10] Anaerobic ruminal fermentation of large amounts of tryptophan leads to a surge in 3-methylindole concentrations, which is readily absorbed across the ruminal and intestinal wall and disseminated throught the body. Bioactivation of 3MI by Clara cells leads to profound cellular injury in Clara and type-1 alveolar epithelial cells and, ultimately, acute interstitial pneumonia. It is postulated that the compound

responsible for causing the injury is the electrophilic metabolite of 3MI, 3-methylenedolenine (3MEIN) which forms stable adducts with cellular macromolecules. (Adducts are compounds formed by an addition reaction.)

Concentrations of 3-methyleneindolenine (3MEIN) in lung tissue and blood were higher in feedlot cattle that had died of acute interstitial pneumonia than in healthy feedlot cattle.[9] However, lung tissue concentrations of 3MEIN were similar in samples from cattle with interstitial pneumonia and bronchopneumonia.[9] Time-dependent patterns and magnitudes of plasma concentrations of 3MI and blood concentrations of 3MEIN-adduct in feedlot cattle during the first 8 weeks after arrival have been followed.[11] Mean concentration of 3MEIN-adduct increased to a maximum value on day 33 and then decreased to a minimum on day 54. Plasma 3MI concentrations initially decreased and remained low until after day 54. Neither 3MEIN-adduct concentrations nor plasma 3MI concentrations were associated with deleterious effects on weight gains. A single dose of acetylsalicylic acid (aspirin) to feedlot cattle on arrival did not affect serum or rumen concentrations of 3MI.[12] The combination of aspirin and vitamin E fed daily to feedlot cattle did not decrease the risk of developing respiratory tract disease.[13]

Sheep. Acute interstitial pneumonia has been recorded in sheep and there was extensive alveolar epithelialization. In Norway, an acute respiratory distress syndrome has occurred in lambs moved from mountain pastures onto lush aftermath pasture. The lesions were those of acute interstitial pneumonia and alveolar epithelial hypersensitivity to molds in the grass is being explored. The experimental oral administration of 3-methylindole to lambs will result in acute dyspnea and lesions similar to those which occur in cattle and adult sheep following dosing with 3-methylindole. However, the lesions in experimental lambs are different from those which occur in lambs affected with the naturally occurring disease.

The other types of interstitial pneumonia occur sporadically and may affect only a single animal or several over a period of time. There is not necessarily a seasonal incidence except in areas where cattle are housed and fed dusty and moldy hay during the winter months. The disease has occurred in feedlot cattle in open feedlots and in young cattle fed on fattening rations indoors.[6] Acute interstitial pneumonia occurs in weaned beef calves about 4 weeks after weaning. The interstitial pneumonia which may be the result of anaphylaxis also occurs sporadically and therefore not in outbreaks.

PATHOGENESIS

Because of the number and variety of circumstances in which acute or chronic interstitial pneumonia occurs, it is difficult to suggest a basic underlying cause, or to explain the mechanisms for the development of the lesions and the variations which occur from one circumstance to another. The reaction which occurs is a non-specific but fundamental reaction of the pulmonary parenchyma to a wide variety of insults which may be ingested, inhaled or produced endogenously. The reaction to sublethal injury is a combination of congestion, edema, an outpouring of protein-rich fluid into the alveolus, hyaline membrane formation, alveolar and interstitial emphysema which is secondary, and proliferation of alveolar septal cells and fibrosis of the interstitial spaces. Unlike the bacterial pneumonias, the emphasis is on edema and proliferation rather than on necrosis. Because mild cases of ABPEE may recover completely, it is suggested that the lesion can be reversible.

Experimental ABPEE

There has been considerable effort to experimentally induce ABPEE similar to the naturally occurring disease, by the oral administration of D,L-tryptophan or one of its metabolites, 3-methylindole, to cattle, sheep, and goats. The L-isomer of tryptophan is metabolized by ruminal microorganisms to indolacetic acid which is then converted to 3-methylindole. The conversion of L-tryptophan to 3-methylindole is maximal at a ruminal pH near neutrality. When cattle are moved from a relatively dry pasture to a lush green pasture, there is an increase in ruminal ammonia, a decrease in ruminal pH, and a decrease in ruminal buffering capacity. The 3-methylindole is absorbed from the rumen and metabolized by a mixed-function oxidase system to an active intermediate which has pneumotoxic properties.

Pulmonary edema is the first morphological change occurring in ruminants given 3-methylindole, and the severity and extent of the lesion is probably the single most important factor which determines the severity of the clinical response and the likelihood of survival. The edema is preceded by degeneration, necrosis, and exfoliation of type I alveolar septal cells. During the acute phase, there is flooding of the alveoli with serofibrinous exudate, congestion, and edema of alveolar walls, and hyaline membrane formation. Varying degrees of severity of interstitial emphysema also occur. The interstitial emphysema may spread within the lymphatics to the mediastinum and into the subcutaneous tissues over the withers, over the entire dorsum of the back and, occasionally, over the entire body including the legs. If the acute phase is severe enough there is marked respiratory distress and rapid death from hypoxemia.

In the experimental disease, the typical clinical signs of respiratory disease appear within 24–36 hours after the oral administration of L-tryptophan to adult cattle and within 4 days 50% of the dosed cows will die. The predominant pulmonary lesions include edema, interstitial emphysema, hyaline membranes, and hyperplasia of alveolar lining cells. The L-tryptophan is converted to indolacetic acid, which is decarboxylated to 3-methylindole, which is absorbed and metabolized by a mixed function oxidase system in the lung to produce pneumotoxicity.

The lesions have also been produced in cattle, sheep, and goats following oral or IV administration of 3-methylindole. Calves may be more resistant to experimental toxicity with 3-methylindole than adults, which supports the observation that the naturally occurring disease is uncommon in calves grazing the same pasture in which adults are affected. Young calves, 30–45 days of age, are susceptible to pulmonary injury induced by 3-methylindole characterized by pulmonary edema and damage to type-1 alveolar epithelial cells and non-ciliated bronchiolar epithelial cells. The 3-methylindole injury does not make the bovine lung more susceptible to the bovine respiratory syncytial virus as is the case for the parainfluenza-3 virus.

Proliferative stage. If the animal survives the acute phase, proliferation of alveolar type II cells marks the beginning of the shift from the exudative to the proliferative stages of pneumonia. There is alveolar epithelialization and interstitial fibrosis, the latter being progressive and irreversible. The central features of chronic interstitial pneumonia are intra-alveolar accumulation of mononuclear cells, proliferation and persistence of alveolar type 2 cells, and interstitial thickening by accumulation of lymphoid cells and fibrous tissue. Diffuse fibrosing alveolitis is a form of chronic interstitial pneumonia of uncertain etiology, but possibly the chronic form of ABPEE. Repeated oral administration of 3-methylindole in cattle provides a good experimental model for diffuse pulmonary fibrosis.

Effects of 3-methylindole on pulmonary function

The effects of 3-methylindole on pulmonary function and gas exchange have been examined in cattle, goats, and horses. In cattle there is impairment of sympathetic pulmonary vasconstriction, and changes in intra-acinar pulmonary arteries which may be related to a sudden elevation in arterial

and venous pressures in the pulmonary system. There are large increases in respiratory rate, minute viscous work, PCO_2 and large decreases in tidal volume dynamic lung compliance, and PO_2. All of these are compatible with the severe pulmonary edema and alveolar injury.

In goats there is a pronounced decrease in lung compliance, a moderate increase in airway resistance, a concomitant hypoxemia, a progressive decrease in tidal volume and alveolar ventilation and an increase in the dead-space-to-tidal volume ratio. These changes are characteristic of a restrictive type of respiratory tract disease in goats in which pulmonary edema and the pulmonary function changes are similar to those of adult respiratory distress syndrome in man.

CLINICAL FINDINGS

Acute bovine pulmonary emphysema and edema

This disease, also known as '**fog fever**', is usually obvious, because of its characteristic clinical presentation. The onset is sudden. Within 4–10 days after adult cattle have been moved onto a new pasture, they may be found dead without any premonitory signs. Many cattle exhibit labored breathing, often with an expiratory grunt, open-mouthed breathing, frothing at the mouth, and anxiety. Severely affected cattle do not graze, stand apart from the herd, and are reluctant to walk. If forced to walk they may fall and die within a few minutes. Often, removal of the affected herd from the pasture will result in an increased number of deaths. Moderately affected cattle continue to graze but their respirations are increased above normal. Coughing is infrequent regardless of the severity. The temperature is normal to slightly elevated (38.5–39.5°C, 102–103°F) but may be up to 41–42°C (106–108°F) during very warm weather. There is a similar variation in the heart rate (80–120/min) and those with a rate of more than 120/min are usually in the terminal stages of the disease. Bloat and ruminal atony are common in severe cases. Subcutaneous emphysema is common over the withers and may extend to the axillae and ventral aspects of the thorax. The nostrils are flared and the nasal discharge is normal. Diarrhea may occur but is mild and transient.

Loud, clear breath sounds audible over the ventral aspects of the lung, indicating consolidation without bronchial involvement, are the characteristic findings on auscultation in the early stages of the acute disease. The intensity of the breath sounds may be less than normal over the dorsal parts of the lung if involvement is severe, but in animals which survive for several days the loud crackles characteristic of interstitial emphysema are of diagnostic significance. Most severely affected cases will die within 2 days of onset but less severe cases will live for several days and then die from diffuse pulmonary involvement. Those which survive longer than 1 week will often have chronic emphysema and remain unthrifty. Of those moderately affected cattle which recover in a few days, some will develop congestive heart failure a few months later, due to chronic interstitial pneumonia (cor pulmonale). Calves running with their adult dams will usually not be affected.

Other interstitial pneumonias

These diseases usually occur sporadically, but several animals may be affected over a period of time. There may or may not be a history of a change of feed or the feeding of moldy or dusty feed. In many cases, a few days elapse after the appearance of signs before the owner is aware of the affected animals. The animal may have been treated with an antimicrobial for a bacterial pneumonia with little or no response. Dyspnea, increased respiratory effort sometimes with a grunt, deep coughing, a fall in milk production, an absence of toxemia, a variable temperature (38.5–40°C, 102–104°F) and a variable appetite are all common. On auscultation there are loud breath sounds over the ventral aspects of the lungs and crackles over both dorsal and ventral aspects. The presence of moist crackles suggests secondary bacterial bronchopneumonia. Subcutaneous emphysema is uncommon in these and most will become progressively worse.

Yearling cattle with acute interstitial pneumonia which may be viral in origin may become much worse and die in a few days in spite of therapy. Mature cattle affected with bovine farmers' lung will survive in an unthrifty state with the chronic disease for several weeks and even months.

The major clinical features of all these other interstitial pneumonias are obvious respiratory disease, lack of toxemia, poor response to treatment, progressive worsening, and abnormal lung sounds distributed over the entire lung fields.

CLINICAL PATHOLOGY

There are no abnormalities of the hemogram or serum biochemistry which have any diagnostic significance. Examination of feces and forage for lungworm larvae will aid in differentiation from verminous pneumonia if past the prepatent period. The observed high levels of 'farmer's lung hay' antibodies in serum are not of much value diagnostically because of the similar levels found in many clinically normal cows; many cases of classic fog fever have negative serum precipitin levels.

NECROPSY FINDINGS

In ABPEE, the lungs are enlarged and firm and do not collapse on cutting. In the early stages of acute cases they contain much fluid which is more viscid than usual edema fluid. The pleura is pale and opaque and appears to be thickened. In peracute cases, the entire lungs are homogeneously affected in this way. Such cases usually have edema of the larynx.

In the more common acute case, the lung has a marbled appearance. Adjacent lobes may be affected with any one of four abnormalities. Areas of normal, pink lung are restricted to the dorsal part of the caudal lobes. There are areas of pale tissue indicative of alveolar emphysema, areas of a dark pink color affected by early alveolar exudation, yellow areas in which the alveoli are filled with coagulated protein-rich fluid, and dark red areas where epithelialization has occurred. The latter two lesions are firm on palpation and resemble thymus or pancreas. They are more common in the ventral parts of the cranial lobes.

In chronic cases, as a sequel to the acute form described above, the obvious differences in the age of the lesions suggest that the disease progresses in steps by the periodic involvement of fresh areas of tissue. In all cases there is usually a frothy exudate, sometimes containing flecks of pus, in the bronchi and trachea, and the mucosa of these passages is markedly hyperemic.

Histologically, the characteristic findings are an absence of inflammation, except in the case of secondary bacterial invasion, and the presence of an eosinophilic, protein-rich fluid which coagulates in the alveoli, or may subsequently be compressed into a hyaline membrane. This is more apparent in acute cases and, if animals live for a few days, there is evidence of epithelialization of the alveolar walls. In longstanding cases, there is extensive epithelialization and fibrosis.

The pathology of bovine farmer's lung and diffuse fibrosing alveolitis has been described and consists of variations of the lesions of chronic interstitial pneumonia.

Bacteriological examination of the lungs is often negative, although in long-standing cases in which secondary bacterial pneumonia has developed *Pasteurella multocida, Mann. haemolytica, Streptococcus* spp., and *Arcanobacterium* pyogenes may be found. A careful search should be made for nematode larvae.

TREATMENT

The treatment of fog fever in cattle is empirical and symptomatic. The lesion is irreversible in severe cases and treatment is unlikely to be effective. When outbreaks of the disease occur on pasture the first reaction is to remove the entire herd from the pasture to avoid the development of new cases. However, almost all new cases will usually occur by the 4th day after the onset of the outbreak and removal from

DIFFERENTIAL DIAGNOSIS

Acute bovine pulmonary emphysema and edema

Acute bovine pulmonary emphysema and edema is usually obvious when presented with an outbreak of acute respiratory disease in adult cattle which have recently been moved onto a new pasture. The onset is sudden, many cattle are found dead and many are dyspneic. ABPEE must be differentiated from:

Pneumonic pasteurellosis

Pneumonic pasteurellosis is characterized by fever, toxemia, mucopurulent nasal discharge and less dyspnea; young cattle are more commonly affected and there is a beneficial response to therapy within 24 hours.

Organophosphatic insecticide poisoning

Organophosphatic insecticide poisoning may resemble the pasture form of pulmonary emphysema because of the dyspnea but additionally there is pupillary constriction, mucoid diarrhea, muscular tremor and stiffness of the limbs, and no abnormal lung sounds.

Nitrate poisoning

Nitrate poisoning may occur in cows moved into a new pasture with high levels of nitrate. Many cows are affected quickly, they are weak, stagger, gasp, fall down, and die rapidly. The chocolate brown coloration of the mucous membranes, the lack of abnormal lung sounds, and the response to treatment are more common in nitrate poisoning.

Other interstitial pneumonias

All of the other types of acute interstitial pneumonia in cattle not associated with a change of pasture in the autumn are difficult to diagnose clinically and pathologically, especially when they occur in a single animal. Their epidemiological characteristics summarized on p. 513 will often offer some clues.

The chronic and subacute types of interstitial pneumonia are difficult to differentiate from each other and from other pneumonias of cattle.

Bovine farmer's lung

Bovine farmer's lung or extrinsic allergic alveolitis occurs in housed cattle exposed to dusty or moldy feeds for a prolonged period and is characterized by a history of chronic coughing, weight loss, poor milk production, occasionally green-colored nasal discharge, and dry crackles over most aspects of the lungs. Not infrequently, acute cases occur and die within a week after the onset of signs.

Lungworm pneumonia

Lungworm pneumonia occurs in young cattle on pasture in the autumn months and causes subacute or acute disease which may resemble bovine farmer's lung clinically but not epidemiologically. Necropsy is necessary for the diagnosis.

Verminous pneumonia

Verminous pneumonia caused by aberrant migration of *Ascaris suis* larvae may be indistinguishable from acute interstitial pneumonia, but a history of previous occupation of the area by pigs may provide the clue to the diagnosis which can only be confirmed on histological examination of tissues. It is impossible to differentiate clinically between verminous pneumonia and some of the acute interstitial pneumonias seen in yearling cattle except by identification of the larvae in the feces or tissues of affected animals.

Feedlot interstitial pneumonia

Feedlot interstitial pneumonia occurring in recently weaned beef calves or feedlot cattle is characterized by the sudden onset of acute respiratory distress, absence of toxemia, lack of abnormal nasal discharge, and a poor response to treatment with antibiotics. It is difficult to differentiate clinically from acute viral interstitial pneumonia or pneumonic pasteurellosis. However, in acute interstitial pneumonia there is marked dyspnea and the abnormal lung sounds are usually distributed over the entire lung fields.

Enzootic pneumonia of calves

Enzootic pneumonia of calves may resemble acute or chronic interstitial pneumonia but is almost entirely restricted to housed calves less than 6 months of age. They respond to treatment gradually over a few days.

the pasture usually will not prevent new cases. Conversely, leaving the herd on pasture usually will not result in additional cases. Severely affected cattle should be removed from the pasture with extreme care, very slowly and only if necessary, and moved to shelter from the sun. Immediate slaughter for salvage may be indicated in severe cases. Mild or moderately affected cases will commonly recover spontaneously without any treatment if left alone and not stressed, a fact that has not been given due consideration when claims are made for the use of certain drugs.

Several different drugs have been advocated and used routinely for the treatment of ABPEE in cattle. However, none has been properly evaluated and definitive recommendations cannot be made.

Treatment of the chronic interstitial pneumonias is unsatisfactory because the lesion is progressive and irreversible.

CONTROL

There are no known reliable methods for the prevention of ABPEE in pastured cattle but there are some strategies which merit consideration.

Grazing management

If lush autumn pasture contains toxic levels of the substance that causes the acute disease it would seem rational to control the introduction of cattle to the new pasture. This can be done by controlling the total grazing time during the first 10 days: allow the cattle to graze for 2 hours on the first day, increasing by increments of 1 hour per day, and leave them on full time at the end of 10–12 days. Such a management procedure is laborious, requires supplementation with other feeds and daily removal of cattle from the pasture, and may not be practical depending on the size and terrain of the pasture and the holding yards which are available.

Inhibition of 3-methylindole production in rumen

Controlling the conversion of D,L-tryptophan in forage to 3-methylindole is a plausible control strategy. Experimental tryptophan-induced ABPEE can be prevented by the simultaneous oral administration of chlortetracycline or polyether antibiotics such as monensin. The daily oral administration of 2.5 g/head of chlortetracycline beginning 1 day before and for 4 days following administration of a toxin of L-tryptophan will prevent clinical signs.[14]

The daily oral administration of monensin at the rate of 200 mg/head/day beginning 1 day before and for 7 days after an abrupt change from a poor quality hay diet to a lush pasture reduced the formation of 3-methylindole during the 7 days of treatment, but the effect of the drug was dimished on day 10, 3 days after its withdrawal. Because the effects of monensin on ruminal 3-methylindole are diminished within 48 hours after withdrawal of the drug, effective prevention of acute pulmonary edema and emphysema may require continuous administration of monensin for the critical period of approximately 10 days after the mature animals are exposed to the lush pasture. The daily feeding of monensin in either an energy or protein supplement will effectively reduce ruminal 3-methylindole formation in pasture-fed cattle.

Successful prevention of the disease requires monensin supplementation with organized grazing management to reduce the intake of lush pasture by hungry cows. This may be accomplished in several ways: feed dry, mature hay ad libitum to adult cattle just before and during the transition period of a pasture change, then continue to feed hay for at least 4 days into this grazing period; cut all lush forage and allow to wilt before allowing adult cattle access to the

pasture. Alternatively, over a 7-day period, gradually increase the amount of time cattle spend grazing lush pasture. If possible, this may be accomplished by rotating cattle back and forth, either between the summer and fall pastures, or between the fall pasture and a drylot where ample supply of dry, mature hay is available. Any combination of these management practices while providing monensin at 200 mg/head per day in an energy or protein supplement may reduce 3-methylindole production to a greater extent than just providing monensin or implementing grazing management techniques.[6]

To maximize the effectiveness of monensin in reducing 3-methylindole formation, dry hay plus wilted forage should be fed to pastured cattle for at least 4 days after they are allowed access to lush pasture. Lasalocid at a dose of 200 mg per head once daily in ground grain for 12 days reduced the conversion of tryptophan to 3-methylindole and prevented pulmonary edema.[15]

The daily administration of inhibitors during the critical period immediately before and after the cattle are turned onto the lush pasture may be a practical problem.

Other interstitial pneumonias

The control of non-pasture cases of interstitial pneumonia depends on the suspected cause and removal of it from the environment of the animals. Every attempt must be made to control the concentration of dust and moldy foods to which cattle are exposed. Feed supplies must be harvested, handled, and stored with attention to minimizing dust and molds. In the preparation of mixed ground feed for cattle, the fineness of grind must be controlled to avoid dusty feed particles which may be inhaled. Because of the creation of dust, the grinding and mixing of dry feeds like hay, straw, and grains should not be done in the same enclosed area in which cattle are housed. If dusty feeds must be used they should be wetted to assist in dust control.

Lungworm control is essential in endemic areas where the disease occurs. This may necessitate careful monitoring and regular treatment to reduce the level of infestation on pasture.

Viral interstitial pneumonias. In countries where cattle are housed, especially during the winter months, the provision of adequate ventilation is necessary to minimize aerosol viral interstitial pneumonias. Vaccination is a consideration.

TRACHEAL STENOSIS OF FEEDLOT CATTLE

Tracheal stenosis, also known as 'honker cattle', occurs in feedlot cattle.[1] The etiology is unknown. It is characterized by extensive edema and hemorrhage of the dorsal wall of the trachea, resulting in coughing (honking), dyspnea, and respiratory stertor. Complete occlusion of the trachea may occur. Affected animals may be found dead without any premonitory signs.

In tracheal stenosis of feedlot cattle, there is marked submucosal hemorrhage dorsal and ventral to the tracheal is muscle resulting in ventral displacement of the mucosa and partial to complete occlusion of the tracheal lumen. Diffuse hemorrhage in the peritracheal connective tissue and surrounding muscles of the neck is common in animals dying of asphyxia. Histologically there is hyperemia and hyperplastic tracheal mucosa with focal erosions, squamous metaplasia, and loss of cilia. In acute cases the mucosa is markedly thickened because of hemorrhage and edema. Culture reveals a mixed bacterial flora.

INTERSTITIAL PNEUMONIA OF ADULT HORSES

In its most severe form, this is a disease characterized by insidious progression of pulmonary inflammation and fibrosis. Less severe forms, associated with transient viral or bacterial infections of the lungs, resolve when the infection is cleared from the lungs.

ETIOLOGY

There are many potential agents but few have been conclusively implicated as being associated with the disease. In most instances of the disease no causal association is identified.

Interstitial pneumonia is a common finding in horses associated with various infectious agents (Hendra virus infection, *Rhodococcus equi* in foals, *Aspergillus* sp., *Cryptococcus* sp. and *Hisptoplasma* sp., *Pnemoncystis carinii*,[1] *Parascaris equorum*, and *Dictyocaulus arnfiedli*). Intoxication with perilla ketone, derived from Perilla frutescens, causes acute restrictive lung disease of horses.[2,3] Similary, ingestion of *Eupratorium* sp. in Australia and Hawaii causes interstitial pneumonia in horses.[4] Inhalation of silica causes a similar disease in horses in California.[5] Inhalation or ingestion of agricultural chemical or environmental toxins (e.g. paraquat) has the potential to cause interstitial pneumonia in other species, but this has not been demonstrated in horses.

Hypersensitivity reactions may cause severe respiratory disease in horses. Incriminating allergens include fungi (unspecified) and chicken dust.[6,7]

Interstitial pneumonia has also been reported subsequent to administration of an immunostimulant containing mycobacterial cell wall extract.[8]

EPIDEMIOLOGY

The disease occurs in adult horses without apparent breed, sex, or age predisposition. In cases in which the cause is infectious, the epidemiology of the disease is characteristic of that of the causal organism.

PATHOGENESIS

The initial insult causes injury to parenchymal cells and an acute alveolitis.[9] Alveolitis results from damage to epithelial and endothelial cells by toxic, metabolic (free radicals), or infectious agents. This is followed by a phase of cellular proliferation of type 2 pneumocytes and fibroblasts with connective tissue deposition.[3] At this time there is an influx of inflammatory cells, the exact type depending to some extent on the cause of the disease. Infiltration of neutrophils, lymphocytes, and macrophages is common. Continued injury to the lung results in development of severe interstitial fibrosis and destruction of gas exchange units.

Interstitial pneumonia results in altered pulmonary function including reduced compliance, impaired pulmonary gas exchange, and a reduction in total and vital lung capacity. The work of breathing is increased.[10]

CLINICAL SIGNS

Horses with idiopathic interstitial pneumonia have various combinations of: weight loss, recurrent cough, depression,

anorexia, fever, or respiratory distress. Signs of respiratory disease are not readily apparent at initial examination in all affected horses. As the disease progresses respiratory distress develops in most, but not all, cases. The usual history of is a gradual onset of increased respiratory effort, although some horses have a sudden onset of respiratory distress.[11] Heart and respiratory rates may be elevated. Pyrexia is not a constant finding. There may be a nasal discharge. Thoracic auscultation may reveal only increased intensity of normal breath sounds or the presence of occasional crackles and wheezes. Typically, there is tachypnea with an increased respiratory effort.

Thoracic radiography reveals pulmonary disease, usually apparent as severe, diffuse interstitial disease. The interstitial opacity may be diffuse or nodular with multiple well defined opacities against an overall background of increased interstitial density. Ultrasonographic examination may reveal the presence of multiple nodules in the lung parenchyma confluent with the pleural surface. There is no excess pleural fluid.

Intradermal skin testing may be useful to identify the inciting allergen in cases of allergic interstitial pneumonia.[7]

The prognosis is poor in most cases of the idiopathic disease. Should recovery occur, it does so within approximately 2 weeks of diagnosis.

CLINICAL PATHOLOGY

Hematologic examination usually reveals a neutrophilic leukocytosis.[11,12] Mild anemia and hyperfibrinogenemia are common. Examination of a tracheal aspirate reveals neutrophil inflammation. In cases of verminous pneumonia, there may be an increased proportion of eosinophils in tracheal aspirate. Bronchoalveolar lavage fluid can reveal a similar neutrophilic leukocytosis or may be normal.[13] Serologic testing for antibodies to fungi or other inciting agents may be useful.[9]

Definitive diagnosis is provided by examination of tissue obtained by lung biopsy.

NECROPSY FINDINGS

The lungs do not deflate as anticipated and there may be indentations from the ribs on the surface of the lungs. Multiple pale, yellowish-white nodules 3–4 cm in diameter may be apparent on the surface of the lung and throughout the lung parenchyma. There is histologic evidence of severe, fibrosing alveolitis with minimal airway involvement. The acute phase of the disease is evident as extensive alveolar edema and hemorrhage.[14]

TREATMENT

Treatment should be directed toward any cause of the disease that is identified such as administration of anthelmintics. In cases of idiopathic disease, treatment is frequently unrewarding as by the time the animal is examined the disease is often advanced. Treatment includes anti-inflammatory drugs including dexamethasone or prednisolone, antimicrobials, and supportive care. Immunosuppressive drugs, such as vincristine, are not effective. Bronchodilating drugs, such as clenbuterol, may be considered, but bronchoconstriction is not a prominent component of the disease.

CONTROL

Prevention of exposure to potential infectious, toxic or environmental causes is prudent.

ACUTE BRONCHO-INTERSTITIAL PNEUMONIA IN FOALS

This is a disease of foals less than 7 months of age, and usually <2 months of age, characterized by a rapid onset of respiratory distress. The **etiology** is unclear in many cases, but suggested causes or agents associated with the disease include equine influenza virus infection,[1] *R. equi*, equine herpes virus II, equine arteritis virus,[2] or *Pneumocystis carinii*.[3–6] The disease is likely a result of severe pulmonary injury by any of a number of infectious or toxic agents. The respiratory distress results from loss of pulmonary function because of necrosis of the epithelium of alveoli and terminal bronchioles.

Foals typically present with an acute onset (<4 days) of respiratory distress, pyrexia and tachycardia. Foals are depressed and reluctant to eat. There is a pronounced respiratory effort with a marked abdominal component in most affected foals. Crackles, wheezes, and increased bronchial breath sounds are auscultable in most foals. Radiographic examination reveals a bronch-interstitial pattern which is always diffuse, although in some foals there is also a focal interstitial pattern. The prognosis is guarded, with approximately 50% of affected foals dying of the disease.

There is a neutrophilic leukocytosis and hyperfibrinogenemia in most cases. Arterial hypoxemia is present in severely affected foals. Tracheal aspirate demonstrates neutrophilic inflammation. Culture of the tracheal aspirate yields *Rhodococcus equi*, *Strep. zooepidemicus*, *Actinobacillus* sp., and other organisms of questionable significance. Serology might demonstrate evidence of infection by equine influenza virus or equine herpes virus II.[1,3,4] Viral isolation can identify equine influenza virus.[1]

NECROPSY FINDINGS

Necropsy examination reveals the presence of diffusely reddened, wet and firm lungs that fail to collapse.[3,4] The predominant histologic lesion is necrosis of the epithelium of terminal bronchioles and alveoli.

TREATMENT

Principles of **treatment** are correction of hypoxemia, reduction of inflammation and removal of inciting causes. Severely affected foals may require nasal insufflation of oxygen to ameliorate or correct hypoxemia. Administration of corticosteroids has been associated with improved survival.[3] Broad spectrum antibiotics are administered to treat concurrent bacterial infections and prevent secondary infection.

CONTROL

There are no specific control measures, but reduction of exposure of foals to infectious respiratory disease would be prudent.

CHRONIC INTERSTITIAL PNEUMONIA OF FOALS

A sporadic disease of foals less than 10 months of age characterized by respiratory distress of several weeks duration is caused by chronic interstitial pneumonia.[1] The etiology is unknown, but the disease likely represents a common final response to injury caused by any one of a number of infectious or toxic agents (see 'interstitial pneumonia of horses' and 'acute bronchointerstitial pneumonia of foals').

Affected foals are bright and alert and have markedly increased respiratory effort. The respiratory rate is elevated and there is a prominent abdominal component to respiratory effort. Fever is low grade and intermittent. Thoracic auscultation reveals increased intensity of normal breath sounds and the presence of wheezes and crackles in most affected foals. Ultrasonographic examination of the thorax reveals extensive 'comet tail' signs in most cases. Radiography demonstrates the presence of moderate to severe interstitial pneumonia which in some cases can include focal opacities suggestive of alveolar disease. The prognosis with appropriate treatment is excellent.

Affected foals have neutrophilic leukocytosis and hyperfibrinogenemia. Serological examination for antibodies to common respiratory viruses is unrewarding. Culture of tracheal aspirates does not consistently yield growth of known pathogens. Lung biopsy is not warranted because the characteristic changes on radiographic examination, combined with the clinical signs, are diagnostic for the disease. The risk of adverse events associated with lung biopsy outweighs any diagnostic utility given the good prognosis for complete recovery from the disease.

Treatment consists of administration of corticosteroids such as dexamethasone phosphate at an initial dosage of 0.1–0.25 mg/kg intravenously for 3–5 days followed by a declining dose administered orally over 2–3 weeks. Prednisolone can be substituted for dexamethasone. Broad spectrum antibiotics (combination of penicillin and aminoglycoside, trimethoprim-sulfonamide, or doxycycline) should be administered for 1–2 weeks.

There are no recognized control measures, although control of infectious respiratory disease in the herd is prudent.

Diseases characterized by nervous system involvement

POLIOENCEPHALOMALACIA (CEREBROCORTICAL NECROSIS) OF RUMINANTS

Synopsis

Etiology Several different causes including thiamin inadequacy, sulfate toxicity.
Epidemiology Sporadic disease in young well-nourished ruminants on high level grain diets and not synthesizing sufficient thiamin. Ingestion of preformed thiaminase in certain plants or production by ruminal microbes may also cause destruction of thiamin. May also occur in cattle and sheep of all ages ingesting excess amount of sulfates in feed and water.
Signs Sudden blindness, ataxia, staggering, head-pressing, tremors of head and neck, ear twitching, champing fits, clonic-tonic convulsions, recumbency, opisthotonos, rumen contractions normal initially, pupils usually normal and responsive, nystagmus, death may occur in 24–48 hours. Hydrogen sulfide odor of ruminal gas in sulfate toxicity.
Clinical pathology Erythrocyte transketolase activity decreased and thiamin pyrophosphate effect increased but both measurements difficult to interpret; blood thiamin levels decreased but not reliable.
Lesions Diffuse cerebral edema, flattened dorsal gyri, coning of cerebellum, multifocal to linear areas of fluorescence in gray and white matter borders of cortical gyri and sulci.
Diagnostic confirmation Fluorescence of gray and white matter of cortical gyri and sulci of brain.

Differential diagnosis list
Cattle:

- Lead poisoning
- Hypovitaminosis-A
- *Histophilus meningoencephalitis.*

Sheep:

- Pregnancy toxemia
- Clostridium perfringens Type D Enterotoxemia
- Focal symmetrical encephalomalacia
- Lead poisoning.

Goats:

- Caprine leukoencephalomyelitis
- Listeria meningoencephalitis
- Clostridium perfringens Type D Enterotoxemia
- Lead poisoning.

Treatment Thiamin hydrochloride parenterally.
Control Thiamin supplementation of diet. Avoid excess feeding or access to sulfate in feed and water supplies.

ETIOLOGY

Historically, PEM was considered to be caused by a thiamin inadequacy. It is now known that there are several different causes of the disease.

Thiamin inadequacy

The evidence that a thiamin inadequacy can be associated with the disease includes the following[1]:

- Affected animals respond to the parenteral administration of thiamin if given within a few hours after the onset of clinical signs
- Affected animals have biochemical findings consistent with thiamin diphosphate (TDP) inadequacy
- The clinical signs and pathological lesions can be reproduced in sheep and cattle by the administration of large daily doses of pyrimidine containing structural analogs of thiamin, principally amprolium, given orally or intraperitoneally.[1]

Excess dietary sulfur

The ingestion of excessive quantities of sulfur from the diet and water supply can cause the disease in cattle[2] and sheep[3] without any change in the thiamin status of the tissues.

EPIDEMIOLOGY

Occurrence

PEM occurs sporadically in young cattle, sheep, and goats, and other ruminants. In North America, UK, Australia, and New Zealand, the disease has been most common in cattle and sheep which are being fed concentrate rations under intensified conditions such as in feedlots. An inadequate amount of roughage can result in a net decrease in the synthesis of thiamin. The disease occurs most commonly in well-nourished thrifty cattle 6–18 months of age (peak incidence 9–12 months of age) which have been in the feedlot for several weeks. Feedlot lambs may also be affected only after being on feed for several weeks. The disease also occurs in goats and in antelope and whitetail deer.[4] The disease may affect goats from 2 months to 3 years of age and is commonly associated with milk-replacer diets in kids or concentrate feeding in older goats. The disease occurs only rarely in adult cattle which may be a reflection of the greater quantities of roughage they usually consume. However, there are recent reports of the disease occurring in adult cows on pasture with access to drinking water containing excessive concentrations of sulfates.[2]

In Cuba, the disease occurred in feedlot cattle fed primarily on molasses with a minimal quantity of roughage, and was reproduced by feeding a molasses-urea and roughage diet by gradual removal of the roughage without the use of thiamin analogs.

Morbidity and case fatality

Accurate morbidity and case fatality data are not available, but outbreaks can occur suddenly in which up to 25% of groups of feeder cattle may be affected, with case fatality rates from 25 to 50%. Case fatality rates are higher in young cattle (6–9 months) than in the older age group (12–18 months) and mortality increases if treatment with thiamin is delayed for more than a few hours after the onset of signs. In feedlot lambs, it has been suggested that approximately 19% of all deaths are due to polioencephalomalacia.

Risk factors

When PEM was first described in 1956, and for about 30 years, it was considered

to be a thiamin deficiency conditioned by dietary factors such as high-level grain feeding and inadequate roughage. PEM occurred most commonly in well nourished young cattle from 6 to 12 months of age which were being fed high-level grain rations. The scientific investigations centered on the effects of dietary factors such as grain diets, and the presence of thiaminases in certain diets on thiamin metabolism in the rumen. In recent years, it has become clear that the disease is not etiologically specific because many different dietary factors have been associated with the occurrence of the disease, and in some instances the thiamin status of the affected animals is within the normal range. Notable examples are the recent observations linking dietary sulfate with the occurrence of the disease.

Dietary risk factors

While there has been general agreement that thiamin inadequacy is associated with the cause of PEM, the possible mechanisms by which this occurs are uncertain.[5] Thiamin inadequacy in ruminants could, theoretically, occur in any of the following situations where inadequate net microbial synthesis of thiamin in the rumen may occur:

- Concentrate-fed animals receiving inadequate roughage
- Impaired absorption and/or phosphorylation of thiamin
- The presence of a thiamin inhibitor in the tissues of the host
- Lack of sufficient or appropriate apoenzyme or coenzyme-apoenzyme binding for thiamin dependent systems
- Increased metabolic demands for thiamin in the absence of increased supply
- Increased rate of excretion of thiamin resulting in its net loss from the body.

Thiamin can be destroyed by thiaminases of which significant amounts can be found in the rumen contents and feces of cattle and sheep affected with naturally occurring polioencephalomalacia.

Thiamin inadequacy

In cattle under farm conditions, using transketolase activity as a measurement of thiamin status, up to 23% of cattle under 2 years of age and 5% over 2 years may be in a thiamin-low state. Newly weaned beef calves on a hay diet are not subject to a thiamin deficiency but a low and variable proportion of young cattle on barley-based feedlot diets (1.7%) may have some evidence of thiamin deficiency based on a thiamin pyrophosphate activity effect in excess of 15%.[2] The supplementation of the diet of feedlot steers on an all-concentrate barley-based diet with thiamin at 1.9 mg/kg DM resulted in an increase in average daily gain and final carcass weights. Thus some animals may be marginally deficient in thiamin which may be associated with decreased performance in cattle fed all-concentrate diets. However, thiamin supplementation of cattle on all-concentrate diets does not consistently result in improved animal performance. The experimental disease can be produced in young lambs fed a thiamin-free milk diet and it may be unnecessary to postulate that thiamin analogs produced in the rumen are essential components of the etiology.

Thiaminases

A major factor contributing to PEM in cattle and sheep is a progressive state of thiamin deficiency caused by the destruction of thiamin by bacterial thiaminases in the rumen and intestines. Certain species of thiaminase-producing bacteria have been found in the rumen and intestines of animals with PEM. *Bacillus thiaminolyticus* and *Clostridium sporogenes* produce thiaminase type I and *Bacillus aneurinolyticus* produces thiaminase type II. While there is good circumstantial evidence that the thiaminases from these bacteria are the real source of thiaminases associated with the disease, it is not entirely certain. The experimental oral inoculation of large numbers of thiaminase type I producing *Clostridium sporogenes* into lambs did not result in the disease.

Certain species of fungi from moldy feed are also thiaminase producers but the evidence that they destroy thiamin and are associated with PEM is contradictory and uncertain.

The factors which promote the colonization and growth of thiaminase-producing bacteria in the rumen are unknown. Attempts to establish the organism in the rumen of healthy calves or lambs have been unsuccessful. Thiaminases have also been found in the rumen contents and feces of normal animals which may suggest the existence of a subclinical state of thiamin deficiency.[5] Poor growth of unweaned and weaned lambs can be associated with a thiaminase-induced subclinical thiamin deficiency. Weekly testing of young lambs over a period of 10 weeks revealed that 90% of unthrifty lambs were excreting high levels of thiaminase in their feces; low levels of thiaminase activity were present in 20% of clinically normal animals, and there were significant differences in the mean erythrocyte transketolase activity of the unthrifty animals excreting thiaminase compared to the thiaminase-free normal animals.[5]

Field and laboratory investigations have supported an association between inferior growth rate of weaner sheep in Australia and a thiaminase-induced thiamin deficiency.[5] Thiaminase activity has been detected in the feces of lambs at 2–5 days of age, with the levels increasing for 10 days and then declining over the next 3–4 weeks.[5] Decreased erythrocyte transketolase activity indicated a thiamin insufficiency in lambs with high thiaminase activity and mean growth rates were 17% less than lambs with low thiaminase activity. The oral supplementation with thiamin at 2–3 weeks of age was the most appropriate prevention and treatment for subclinical thiamin deficiency.[5]

The parenteral or oral administration of thiamin to normal calves raised under farm conditions resulted in a marked reduction in the percentage thiamin pyrophosphate effect which is an indirect measurement of thiamin inadequacy. Goats with PEM were found to have elevated ruminal and fecal thiaminase activities, low erythrocyte transketolase activity, elevated thiamin pyrophosphate effect, low liver and brain thiamin levels, and elevated plasma glucose levels compared with goats not affected with the disease. With the increased interest in goat farming, some breeders attempt to improve body condition of breeding stock for sale or show by feeding grain or concentrate, which creates a situation similar to feedlot rearing of sheep and cattle which is conducive to the establishment of thiaminases in the rumen and the occurrence of polioencephalomalacia.

High levels of thiaminase type I are present in the rhizomes of bracken fern (*Pteridium aquilinum*) and horsetail (*Equisetum arvense*). The feeding of the bracken fern rhizomes (*Pteridium esculentum*) to sheep will cause acute thiamin deficiency and lesions similar to those of polioencephalomalacia but neither of these plants is normally involved in the natural disease. The disease has occurred in sheep grazing the Nardoo fern, *Marsilea drummondii*, in flood-prone or low-lying wet areas in Australia. The fern contains a high level of thiaminase type I activity.

Amaranthus blitoides (prostrate pigweed) may contain high levels of thiaminase and be associated with polioencephalomalacia in sheep.[6]

Sulfates

Polioencephalomalacia has been associated with diets high in sulfur, particularly in the form of sulfate. A high concentrate of sulfates in the diet of cattle has been associated with episodes of the disease in 6–18-month-old cattle. **Inorganic sulfate salts in the form of gypsum (calcium sulfate)** added to feedlot rations to control the total daily intake of the diet may cause PEM.[7] Seasonal outbreaks have occurred in feedlot beef cattle between 15 and 30 days after introduction to a **high-sulfur**

diet and the risk may increase when water is an important source of dietary sulfur, and during hot weather, when the ambient temperatures exceeded 32°C.[8]

Initial outbreaks may follow the use of a **new well of water containing more sulfate** than water used previously from another well, increasing from a monthly incidence of 0.07% to 0.88%. Growing cattle consume 2.4 times more water when the temperature is 32°C than at 4°C and consequently total ingestion of sulfur by consumption of high sulfate water increases during hot weather. The feed contained 2.4 g of SO_4/kg DM with a total sulfur content of 0.20%. Samples of drinking water contained between 2.2 and 2.8 g of SO_4/L. During hot weather daily sulfur ingestion from feed and water combined was estimated to be 64 g/animal corresponding to total dietary sulfur of approximately 0.67% of DM. Daily SO_4 ingestion was approximately 160 g/animal.[8] The ruminal sulfide levels were much higher 3 weeks after entering the feedlot, when the incidence of the disease was greatest, than 2 months after entering the feedlot when the risk of the disease was low.

In western Canada, there is an association between PEM and high levels of sodium sulfate in water, and range cows are usually affected when certain waters become concentrated with this salt during the summer months.[2] Water containing high levels of magnesium sulfate, often called ***'gyp water'***, is common in the western plains and intermountain areas of the United States and Canada.[9] Ideally, water for livestock consumption should contain less than 500 ppm sulfate, and 1000 ppm is considered the maximum safe level in water for cattle exposed to moderate dietary sulfur levels or high environmental temperatures. A level of 2000 ppm of sulfate in drinking water is the taste discrimination threshold for cattle. Performance of feedlot cattle is reduced when offered water with sulfate levels of 2000 ppm or higher. The National Research Council states that the requirement of sulfur in feed to be 1500 to 2000 ppm for both growing and adult beef cattle; 4000 ppm is considered the maximum tolerated dose.[9] Ruminant diets normally contain between 1500 to 2000 ppm (0.15–0.20% sulfur).

Based on National Research Council guidelines, 30 g of sulfur is the calculated maximum tolerated dose of sulfur for a 650 lb (294 kg) steer consuming 16.25 (7.39 kg; 2.5% BW) of feed daily. If the ambient temperature reaches 32°C, a 650 lb steer can drink 14.5 gallons (53.9 L) of water daily, Consumption of 14.5 gallons of water containing 3000 ppm sulfate results in a daily intake of 55 g sulfur. A feed intake of 2.5% BW would also consume 22.2 g of sulfur from feed containing 3000 ppm sulfur for a total daily intake of 77.2 g of sulfur from both feed and water which is 2.5 times the maximum tolerated dose.

In some surveys, water supplies in western Canada contained contained 8447 ppm of total dissolved solids and 5203 ppm of sulfate. A survey of the sulfate concentrations in water on farms, found that high levels of sulfate can have a detrimental effect on the thiamin status of the cattle on those farms.[10] Cattle exposed to sulfate concentrations >1000 ppm had blood thiamin levels lower than those drinking water with low levels <200 ppm. This raises the possibility that a subpopulation of cattle under such circumstances could be marginally deficient in thiamin.

The total dietary intake of sulfur by cattle must be considered when investigating sulfur as a cause of PEM. In a study of one farm, water from a 6.1 m well containing 3875 mg/L of total dissolved solids with 3285 mg/L of sodium sulfate was associated with PEM in heifers 6 months of age.[11] However, the water contributed about 20% of the total sulfur content in the diet of the heifers, and 60% of the dietary sulfur intake was supplied by the hay and 20% by the grain supplement. The hay contained 0.4% total sulfur which is at the maximum tolerable level for cattle and at the upper limit for hay.[11] The hay consisted of variable amounts of kochia (*Kochia scorpia*) and Canada thistle (*Cirsium arvense*). *Kochia scorpia* (summer cypress or Mexican fireweed), is high in sulfur content and has been associated with the disease in range cattle.

PEM has occurred in pastured cattle usually 5–10 days after change from a poor to a good pasture, and may occur in range cattle grazing on dry, short, grama grass pasture.[12]

The levels of sulfate in water which have affected feed intake in cattle have varied from 2800 to 3340 mg sulfate per/L while other studies found no reduction in feed intake with levels up to 7000 mg/L.[11] It appears that the different effects of sulfur toxicity for similar sulfur contents in saline water are attributed to the total sulfur intake. Outbreaks of the disease may occur in adult cattle on pasture drinking water containing 7200 ppm of sodium sulfate.[2] Thus established guidelines for saline drinking water are not applicable when cattle are fed feeds grown in saline areas.

A combination of excessive intake of sulfur and a low dietary intake of trace minerals, especially copper, may affect the thiamin status of a cattle herd and contribute to PEM.[13] Sulfur adversely affects both thiamin and copper status in sheep.[14] A nutritionally related PEM has also been reproduced in calves fed a semipurified, low-roughage diet of variable copper and molybdenum concentrations and it was not related to copper deficiency.[15] The disease has occurred in cattle in New Zealand fed chou moellier (*Brassica oleracea*) which contained sulfur concentrations of 8500 mg/kg DM.[16] The morbidity was 25% and mortality 46% despite rapid conventional therapy.

Ammonium sulfate used as a urinary acidifier in the rations of cattle and sheep has been associated with outbreaks of PEM.[3] Morbidity rates ranged from 16 to 48% and mortality rates from 0 to 8%. Affected animals did not respond to treatment with thiamin.

Outbreaks have occurred in sheep exposed to an alfalfa field previously sprayed with 35% **suspension of elemental sulfur**.[17] The disease can be induced experimentally in lambs by the administration of sodium hydrosulfide into the esophagus[18] and has occurred in lambs 3–4 weeks after being fed a concentrate ration containing 0.43% sulfur.[19] Feeding experimental diets containing inorganic sulfur to young lambs was associated with PEM and supplementation of those diets with thiamin decreased the severity of the lesions.[20] Rumen microbes are able to reduce sulfate to sulfides which may be directly toxic to the nervous system. Feeding calves (115–180 kg) a semipurified diet high in readily fermentable carbohydrate, without long fiber, and with added sodium sulfate for a total sulfur content of 0.36% resulted in PEM within 21 days of the introduction of the experimental diet.[21] An odor of hydrogen sulfide was frequently detected upon passage of a stomach tube into the rumen of all calves during the experiment. The total thiamin concentrations in affected and control calves remained within normal limits.

The dietary content of copper, zinc, iron, and molybdenum may also have important modifying influences on sulfur toxicosis. Molybdenum and copper can combine with sulfur to form insoluble copper-thiomolybdate. Copper, zinc, and iron form insoluble salts with sulfide, and their expected effect would be to decrease the bioavailability of sulfide in the rumen. Conversely, low, but not necessarily deficient, dietary contents of these divalent metals could be prerequisites for excess absorption of sulfide to occur. PEM is not associated with copper deficiency but copper and sulfur metabolism are interdependent. An excess of dietary sulfur may result in depression of serum copper, or alternatively, low serum copper may potentiate the actions of toxic levels of sulfur. Chronic copper poisoning in a lamb has been associated with PEM.[22] It is suggested that the copper toxicity may have caused decreased hepatic function resulting in

increased plasma concentration of sulfur containing amino acids which may have predisposed to sulfur toxicity encephalomalacia.

Molasses toxicity occurs in Cuba in cattle fed on a liquid molasses-urea feeding system with limited forage. The clinical and necropsy findings are identical to polioencephalomalacia. However, molasses toxicity is not thiamin responsive and can be reversed by feeding forage. Molasses has high inorganic sulfur content and the thiamin concentrations in the brain and liver with PEM which were fed molasses and urea did not differ from those in normal cattle.

Other dietary circumstances

Deprivation of feed and water. In some outbreaks there is a history of deprivation of feed and water for 24–28 hours, because of either a managerial error or frozen water supplies. In other cases, a rapid change in diet appears to precipitate an outbreak. Some outbreaks are associated with a temporary deprivation of water for 24–36 hours, followed by sudden access to water and an excessive supply of salt, a situation analogous to salt poisoning in pigs, but these require more documentation to insure that they indeed are not salt poisoning.

In sheep flocks, a drastic change in management, such as occurs at shearing time, will precipitate outbreaks in which only the yearlings are affected. Changing the diet of sheep from hay to corn silage resulted in a decrease in thiamin concentrations in ruminal fluid to about 25% of control values on hay. The cause of the drop in thiamin concentrations is unknown.

Phalaris aquatica 'polioencephalomalacia-like' sudden death in sheep and cattle. The Mediterranean perennial grass, *Phalaris aquatica* (formerly *Phalaris tuberosa*) can cause sudden death in sheep and cattle throughout southern Australia.[23] The nervous form of disease is similar clinically to polioencephalomalacia but atypical because of the very rapid onset and the absence of either neuronal necrosis or malacia in cerebral cortical sections from affected animals. The available evidence suggests that this form of phalaris sudden death is more likely to involve a peracute form of ammonia toxicity than a peracute form of polioencephalomalacia.

PATHOGENESIS

Thiamin inadequacy polioencephalomalacia

High levels of thiaminases are formed in the rumen, which destroy thiamin that is naturally synthesized.[1] The circumstances in the diet or in the rumen which allow for the development of high levels of thiaminases are unknown but may be related to the nature of the ruminal microflora in young cattle and sheep fed concentrate rations which results in the development of ruminal acidosis. These rations may also allow for the development and growth of thiaminase-producing bacteria which, combined with a smaller net synthesis of thiamin in the rumens of concentrate-fed ruminants, could explain the higher incidence in feedlot animals. Experimentally PEM has been produced in lambs by continuous intraruminal infusion of a highly fermentable diet. Animals changed very rapidly to high concentrate rations develop increased ruminal thiaminase levels.

The possibility that intraruminal thiaminases may also create thiamin analogs capable of acting as thiamin antimetabolites and accentuating the disease has been studied but the results are inconclusive. The presence of naturally occurring second substrates (cosubstrates) in the rumen could produce, by the thiaminase type I reaction, a potent thiamin antimetabolite capable of accentuating the condition. In vitro studies have shown that thiaminase only caused rapid destruction of thiamin when a second substrate was added, and a large number of drugs commonly used as anthelmintics or tranquilizers may be active as second substrates. Many compounds found in the rumen of cattle are potential cosubstrates.

Amprolium has been used extensively to produce the lesions in the brains of cattle and sheep that are indistinguishable from the naturally occurring disease.[1] However, since amprolium has been found in the brain tissue, the experimental disease should perhaps be known as 'amprolium poisoning encephalopathy'. The administration of other antagonists such as oxythiamin and pyrithiamin does not produce the disease. This suggests that polioencephalomalacia is a particular form of thiamin deficiency in which the supply of thiamin is reduced by the action of intraruminal thiaminase. Thus, the thiamin status of the animal will be dependent on dietary thiamin intake, thiamin synthesis, the presence of thiaminase in the rumen and the effects of possible antimetabolites. Subclinical states of thiamin deficiency probably exist in apparently normal cattle and sheep being fed diets which are conducive to the disease. This suggests that in outbreaks of the disease the unaffected animals of the group should be considered as potential new cases and perhaps treated prophylactically.

Thiamin is an essential component of several enzymes involved in intermediary metabolism and a state of deficiency results in increased blood concentration of pyruvate, a reduction in the lactate to pyruvate ratio and depression of erythrocyte transketolase. These abnormalities affect carbohydrate metabolism in general, but in view of the specific requirements of the cerebral cortex for oxidative metabolism of glucose, it is possible that a thiamin inadequacy could have a direct metabolic effect on neurons.[1] The brain of the calf has a greater dependence on the pentose pathway for glucose metabolism, in which pathway the transketolase enzyme is a rate-limiting enzyme. Ultrastructural examination of the brain of sheep with the natural disease reveals that the first change which occurs is an edema of the intracellular compartment, principally involving the astrocytes and satellite cells. This is followed by neuronal degeneration which is considered secondary. It has been suggested that the edema may be due to a reduction in ATP production following a defect of carbohydrate metabolism in the astrocyte. There are three basic lesions which are not uniform: compact necrosis, edema necrosis, and edema alone. This may suggest that a uniform etiology such as thiamin deficiency cannot be fully supported.

In the cerebral cortex of affected animals, autofluorescent spots are observed under ultraviolet 365 nm illumination and are a useful diagnostic aid. The distribution of autofluorescence corresponds to that of mitochondria in cerebrocortical neurocytes in affected calves, suggesting that metabolic impairment occurs and the autofluorescent substance is produced in the mitochondria.[24] Mitochondrial swelling and disorganization of cristae are also observable in brain tissue, but are not specific to polioencephalomalacia.

Sulfate-induced polioencephalomalacia

Diets high in sulfur result in hydrogen sulfide production in the rumen and anaerobic bacteria from rumen samples of cattle fed high-carbohydrate, short fiber diets with added sulfate will generate hydrogen sulfide in rumen fluid broth medium.[18,25] Rumen microflora adapt to higher dietary sulfate content over a period of 10–12 days before they are capable of generating potentially toxic concentrations of sulfide.[26] In experimental sulfate diets which induce PEM, the rumen pH decreases during the transition to the experimental diet and acidic conditions in the rumen favor increased rumen gas cap concentrations of hydrogen sulfide. With a change of pH from 6.8 to 5.2, the percent hydrogen sulfide in the rumen gas cap increased from 47 to 97%.[7]

If ruminants inhale 60% of eructated gases, inhalation of hydrogen sulfide could be a route of systemic sulfide absorption,

in addition to gastrointestinal absorption.[21] Sulfide inhibits cellular respiration leading to hypoxia which may be sufficient to create neuronal necrosis in polioencephalomalacia. The nervous system lesions of sulfur toxicosis are indistinguishable from lesions in the naturally occurring disease.

Acute cerebral edema and laminar necrosis

Acute cerebral edema and laminar necrosis occur and the clinical signs are usually referable to increased intracranial pressure from the edema, and the widespread focal necrosis. Recovery can occur with early treatment which suggests that the lesions are reversible up to a certain point. ECGs of buffalo calves with amprolium-induced PEM found decreased frequency patterns, occasional spindles and decreased voltage patterns during the onset of clinical signs. In the comatose stage, there was little evidence of electrical activity. EEGs of animals treated with thiamin hydrochloride found normal awake patterns.[27]

CLINICAL FINDINGS

Cattle

Animals may be found dead without premonitory signs especially in beef cattle on pasture.[2] The clinical findings are variable but characteristically, there is a sudden onset of **blindness, walking aimlessly, ataxia, muscle tremors**, particularly of the head with ear twitching, **champing of the jaws** and frothy salivation, **head-pressing**, and the animal is difficult to handle or move. Dysphagia may be present when one attempts to force feed hay by hand. Grinding of the teeth is common. Initially, the involuntary movements may occur in episodes, and convulsions may occur, but within several hours they become continuous. The animal usually then becomes recumbent, and there is marked opisthotonos, nystagmus, clonic-tonic convulsions, particularly when the animal is handled or moved, and tetany of the forelimbs is common. The temperature is usually normal but elevated if there has been excessive muscular activity. The heart rate may be normal, subnormal, or increased and is probably not a reliable diagnostic aid.

Rumen movements remain normal for a few days, which is an important distinguishing feature from lead poisoning in which the rumen is static.

The **menace reflex is always absent** in the acute stage and its slow return to normal following treatment is a good prognostic sign. The **palpebral eye-preservation reflex is usually normal**. The pupils are usually of normal size and responsive to light. In severe cases the pupils may be constricted. Dorsal strabismus due to stretching of the trochlear nerve is common. Nystagmus is common and may be vertical or horizontal. Optic disc edema is present in some cases but is not a constant finding.

Calves 6–9 months of age may die in 24–48 hours, while older cattle up to 18 months of age may survive for several days. Recovery is more common in the older age group.

In less severe cases, affected animals are blind, head-press into walls and fences, and remain standing for several hours or a few days. In outbreaks, some cattle will be sternally recumbent; others remain standing with obvious blindness, while others are anorexic, mildly depressed, and have only partial impairment of eyesight. Those with some eyesight will commonly return to almost normal. Some survivors are permanently blind to varying degrees but may begin to eat and drink if provided with assistance. Some cases will recover following treatment and may grow and develop normally.[3]

Evidence of recovery within a few hours following treatment with thamin indicates that the disease is associated with thiamin inadequacy. A failure of response indicates the possibility of sulfur toxicity polioencephalomalacia.

Sheep

Sheep usually begin to wander aimlessly, sometimes in circles, or stand motionless and are blind, but within a few hours they become recumbent with opisthotonos, extension of the limbs, hyperesthesia, nystagmus, and periodic tonic-clonic convulsions. Hoggets affected at shearing time may show blindness and head-pressing but, if fed and watered, usually recover within a few days. Occasional animals show unilateral localizing signs, including circling and spasmodic deviation of the head. In goats, early signs may include excitability and elevation of the head. Blindness, extreme opisthotonos, and severe extensor rigidity and nystagmus are common.

In sulfur-induced PEM in sheep introduced to a diet containing 0.43% sulfur, clinical signs occurred 15–32 days later and consisted of depression, central blindness, and head-pressing, but no hyperesthesis, nystagmus, or opisthotonos were observed.[11] In sulfur toxicity in lambs with PEM, the rumen contents may have a strong odor of hydrogen sulfide (rotten egg smell).[17]

There are some reports from Australia of unthriftiness in unweaned and weaned lambs being associated with thiamin deficiency due to the presence of thiaminases in the alimentary tract.[5] In affected flocks the incidence of illthrift in lambs is much higher than the usual incidence and other causes of unthriftiness were ruled out. Affected lambs lose weight, may have chronic diarrhea, and become emaciated and die from starvation. In some flocks, clinical signs of PEM may occur in a small percentage of animals. The disease occurs most commonly in early July which is the coldest part of the year in Australia for lambs which are born in May and June. In affected lambs the fecal thiaminase levels are high and the blood transketolase level activity is increased above normal. Treatment of affected lambs with thiamin resulted in an increase in growth rate.[5]

CLINICAL PATHOLOGY

Thiamin status and metabolism

The biochemical changes occurring in cattle and sheep with the thiamin-deficiency PEM have not been well-defined diagnostically based on thoroughly investigated naturally occurring clinical cases. However, some estimates are available including the changes which occur in the experimental disease. Interpretation of the values may also be unreliable if the animals have been treated prior to death.

The **erythrocyte transketolase activity** is decreased and the thiamin pyrophosphate (TPP) effect is increased. The erythrocyte transketolase activities in normal sheep will range from 40 to 60 iμ/mL red blood cells. A TPP effect of 30–50% is commonly found in normal healthy cattle and sheep and an increase to above 70–80% occurs in animals with polioencephalomalacia.

The **thiamin concentrations** of blood of animals with polioencephalomalacia have varied widely and may be difficult to interpret because of the possibility of thiamin analogs inducing deficiency even when blood thiamin levels are normal. However, this would not apply when blood thiamin levels are below normal. A normal reference range of 75–185 nmol/L is suggested for both cattle and sheep, and levels below 50 nmol/L are considered indicative of deficiency.[28] In normal goats, the mean thiamin content of blood was 108 nmol/L, with a range of 72–178 nmol/L.[12] In goats with polioencephalomalacia, blood thiamin levels were less than 66 nmol/L with a mean of 29 nmol/L. Levels as low as 1.8–3.6 μg/dL (6–12 nmol/L) have been found in suspected cases of polioencephalomalacia. The thiamin concentrations of liver, heart, and brain of cattle and sheep with polioencephalomalacia are decreased. The levels of blood pyruvate and lactate are also increased and thiamin pyrophosphate-dependent enzymes such as pyruvate kinase are decreased.[3] The thiaminase activity of the feces is increased.[5]

The hemogram is usually normal; the total and differential leukocyte counts may indicate a mild stress reaction, a finding which may be useful in differentiation

from encephalopathies due to bacterial infections.

Cerebrospinal fluid pressure taken at the cysterna magna is increased from a normal range of 120–160 mm saline to levels of 200–350 mm. The level of protein in the CSF may be normal to slightly or extremely elevated. A range from 15 to 540 mg/dL with a mean value of 90 mg/dL in affected cattle is recorded. There may also be a slight to severe pleocytosis in the CSF in which monocytes or phagocytes predominate.

Ruminal sulfide measurement. Changes in rumen gas cap H_2S concentrations are larger than changes in rumen fluid H_2S concentrations and estimation of rumen gas H_2S concentration may be a practical method of detecting pathological increases in ruminal hydrogen sulfide gas.[29,30] A simple, rapid, minimally invasive method may be useful for estimating the H_2S concentration of ruminal gas under field conditions. A sterile 8.9 cm 18 g needle with stillete is introduced into the gas cap of the rumen by way of the left paralumbar fossa. The needle is then connected to calibrated H_2S detector tube. In cattle, with sulfate-induced polioencephalomalacia, increases in ruminal gas H_2S may be as high as 100 times more than control animals.[29]

Brain function. The effects of high dietary sulfur on brain function have been examined using evoked potentials techniques.[31] Altered nerve conduction pathways occur in sheep fed high sulfur diets without supplemental thiamin compared to animals which have received thiamin.[31] The visual evoked potentials are abnormal in ruminants with thiamin-responsive polioencephalomalacia.[32]

NECROPSY FINDINGS

Diffuse cerebral edema with compression and yellow discoloration of the dorsal cortical gyri is evident and the cerebellum is pushed back into the foramen magnum with distortion of its posterior aspect.

In recovered animals, there is macroscopic decortication about the motor area and over the occipital lobes. The lesion can be identified grossly using ultraviolet illumination which results in a fluorescence that indicates necrosis of brain and engulfment of necrotic tissue by lipophages. In general, there is a good correlation between the presence of characteristic fluorescence and the biochemical changes in cases of polioencephalomalacia. A small percentage of false negatives may occur.

Histologically the lesions are widespread but most common in the cerebral cortex. There is bilateral laminar necrosis and necrosis of deeper cerebral areas. The necrosis is most prominent in the dorsal occipital and parietal cortex, but bilateral areas of necrosis are also seen less frequently in the thalamus, lateral geniculate bodies, basal ganglia, and mesencephalic nuclei. Lesions of the cerebellum are also present. The severity and distribution of the lesions probably depend on the interrelationships between clinical severity, age of affected animal, and length of illness before death.

Subnormal levels of thiamin are detectable in the liver and brain of calves with the natural disease and low levels are also found in the experimental disease.[21] In the molasses-induced disease in Cuba, the tissue thiamin levels were within the normal range.

In some cases of sulfur-associated polioencephalomalacia, the rumen contents have a strong odor of hydrogen sulfide – the rotten egg smell.

DIFFERENTIAL DIAGNOSIS

None of the biochemical tests described under clinical pathology is practical. The diagnosis must be made on the basis of clinical findings and the readily available simple tests which rule out other diseases that resemble polioencephalomalacia. A careful consideration of the epidemiological history often assists in the diagnosis.

Cattle

The differential clinical diagnosis for cattle is summarized in Table 32.3.

Polioencephalomalacia in cattle occurs primarily in young growing animals 6–9 months of age on concentrate rations and is characterized clinically by a sudden onset of blindness, muscular tremors of the head and neck, head-pressing, nystagmus, and opisthotonos. The disease also occurs in mature beef cattle on pasture containing a high level of sulfate in their water and feed.

In cattle the disease must be differentiated from:

- **Acute lead poisoning** which is most common in calves after spring turnout but occurs in adult cattle too and is characterized by central blindness, tremors, convulsions, uncontrollable activity with bellowing, champing fits, hyperexcitability, rumen stasis, and death in several hours. Early treatment may be successful
- **Subacute lead poisoning** characterized by blindness, stupor, head pressing, rumen stasis, weak palpebral reflexes, and no response to therapy
- **Hypovitaminosis-A** characterized by a history of a vitamin A deficient diet and nyctalopia, peripheral blindness, dilated and fixed pupils, optic disk edema, and transient convulsions followed by recovery
- **Histophilus meningoencephalitis** characterized by sudden onset of ataxia, recumbency, fever, depression with eyes closed, lesions of the fundus, marked changes in hemogram, enlarged joints, and death in several hours if not treated eary.

Sheep

In sheep polioencephalomalacia must be differentiated from:

- **Enterotoxemia (pulpy kidney disease) due to *Cl. perfringens* type D** in unvaccinated sheep, especially feedlot lambs, in which the clinical findings are almost identical; it occurs under the same management conditions as polioencephalomalacia. Enterotoxemia in lambs usually develops within several days after being placed on a grain ration, whereas polioencephalomalacia occurs after several weeks of grain feeding. Glycosuria in pulpy kidney disease may assist the diagnosis but a necropsy is usually more informative
- **Focal symmetrical encephalomalacia** also resembles polioencephalomalacia but is sporadic, usually involves only a few animals and will not respond to treatment.

Goats

In goats the disease must be differentiated from caprine leukoencephalomyelitis, listeriosis, enterotoxemia, pregnancy toxemia, lead poisoning, and meningoencephalitis.

TREATMENT

Thiamin hydrochloride

The treatment of choice for thiamin deficiency PEM is thiamin hydrochloride at 10 mg/kg BW IV initially and followed by similar doses every 3 hours for a total of 5 treatments. When treatment is given within a few hours of the onset of signs, a beneficial response within 1–6 hours is common and complete clinical recovery can occur in 24 hours. Goats and sheep will commonly respond within 1–2 hours. For those which take longer to recover, the eyesight and mental awareness will gradually improve in a few days and the animal will usually begin to eat and drink by the third day after treatment. Rumen transplants of rumen juice from roughage-fed cattle may improve appetite and rumen function in those responding slowly. In sheep, following treatment with thiamin the blood transketolase activity begins to return to normal in 2–4 hours and is considered normal 24 hours after treatment.

Some cattle improve to a subnormal level within a few days and fail to continue to improve. These are usually affected with diffuse cortical and subcortical necrosis and will usually not improve further in spite of continued treatment. Those which return to a clinically normal state will usually do so by 48 hours or sooner after initial treatment. Those which are still clinically subnormal and anorexic by the end of the third day will usually remain at that level and should be slaughtered for salvage.

Treatment is ineffective in advanced cases, but unless an accurate history is

available on the length of the illness, it is usually difficult to predict the outcome until 6–12 hours following treatment. Thus, it is usual practice to treat most cases with thiamin at least twice and monitor the response. If there is no beneficial response in 6–8 hours, emergency slaughter for salvage should be considered.

The oral administration of thiamin or thiamin derivatives is indicated when thiaminases are thought to be in the alimentary tract. Thiamin hydrochloride at a rate of 1 g for goats and lambs and 5 g for calves, in a drench, is recommended. However, because the action of thiaminase type I on thiamin may result in the production of thiamin analogs which may act as inhibitors of thiamin metabolism, the use of thiamin derivatives which are resistant to thiaminases, lipid soluble and absorbed from the intestine are being explored as therapeutic and prophylactic agents. Thiamin propyldisulfide can depress the thiaminase activities in the ruminal fluid of sheep with polioencephalomalacia within 2 hours after oral administration. The blood pyruvate levels and transketolase activities are also restored to normal and treated animals recovered clinically.

Outbreak management

In outbreaks, the in-contact unaffected animals on the same diet as the affected animals may be on the brink of clinical disease. The diet should be changed to one containing at least 50% roughage or 1.5 kg of roughage per 100 kg BW. Thiamin may be added to the ration at the rate of 50 mg/kg of feed for 2–3 weeks as a preventive against clinical disease, followed by a level of 20–30 mg/kg of feed (cattle and sheep) if the animals remain on a diet that may predispose them to the disease.

Sulfur toxicity polioencephalomalacia

There is no specific treatment for PEM caused by sulfate toxicity. The use of thiamin hydrochloride in doses given above is recommended.[7]

CONTROL

Thiamin supplementation

A rational approach to the control of PEM associated with thiamin inadequacy is to supplement the rations of concentrate-fed cattle and sheep with thiamin on a continuous basis. The daily requirements for protection have not been determined using controlled feeding trials but a rate of 3 mg/kg DM of feed for cattle and sheep has been recommended. This level may not be protective in all situations and response trials may be necessary to determine protective levels for different situations. Levels up to 20–30 mg/kg of feed may be necessary for protection. Most natural feedstuffs for ruminants contain thiamin at about 2 mg/kg DM which when combined with the thiamin synthesized in the rumen will meet the requirements. However, the presence of thiaminases in the rumen will necessitate dietary supplementation with thiamin, but the optimal amount that will provide protection under practical conditions is uncertain.

The IM injection of 500 mg thiamin 3 times weekly into 6-month-old calves raised under practical farm conditions will steadily reduce the percentage thiamin pyrophosphate effect to zero in about 6 weeks. The daily oral administration of 100 mg thiamin to young calves fed initially on milk substitutes and then on concentrates and hay results in a decrease in percentage pyrophosphate effect.

For animals which are fed diets associated with thiamin inadequacy, it is recommended that thiamin be added to the diet at the rate of 5–10 mg/kg DM.[12] Cattle and sheep on concentrate-fed rations must also receive supplements containing all necessary vitamins and minerals, especially cobalt, a deficiency of which may be associated with some outbreaks of the disease.

Feeding roughage

The minimum amount of roughage which should be fed to feedlot cattle and sheep in order to prevent the disease and still maintain them on high levels of concentrates is unknown. A level of 1.5 kg of roughage per 100 kg BW has been recommended but this may not be economical for the feedlot whose profits are dependent on rapid growth in grain-fed cattle. Supplementation of the diet with thiamin appears to be the only alternative.

The prevention of the disease in sheep which are being moved long distances or gathered together for shearing and other management practices will depend on insuring an ample supply of roughage and water and avoiding drastic changes in management.

Sulfate toxicity PEM

The prevention of the disease associated with a high sulfur intake in the feed and water supplies will depend on analysis of the feed and water for sulfate and making appropriate adjustments in the sources of feed and water in order to decrease the intake of sulfur to safe levels.

EQUINE NEONATAL ENCEPHALOPATHY (NEONATAL MALADJUSTMENT SYNDROME OF FOALS, DUMMY FOAL, BARKERS, AND WANDERERS)

This is a syndrome of foals less than 36 hours of age characterized by a spectrum of changes in mentation ranging from failure to suckle, abnormal behavior, seizures, through coma in otherwise apparently healthy foals.

ETIOLOGY

A number of diseases cause the clinical signs consistent with this syndrome. These include antenatal, natal or postnatal hypoxia, congential and metabolic anomalies, placental abnormalities, intracranial hemorrhage, prematurity, and thoracic trauma.[1] Of these causes, hypoxia before, during or soon after birth is considered the most common cause of neonatal encephalopathy, although hypoxia is rarely documented. It is important to realize the neonatal encecphalopathy is one of many manifestations of hypoxia of the fetus or neonate, the other manifestations including gastrointestinal and renal damage.[2,3]

EPIDEMIOLOGY

The disease is sporadic and occurs worldwide with an annual **incidence** in foals of approximately 1%.[4] Foals of either sex and of any breed born to mares of any age

Table 36.2 Differential diagnosis of comatose ('sleeper') neonatal foals

Disease	Epidemiology	Clinical findings	Clinical pathology	Lesions	Treatment and prognosis
Actinobacillus equuli septicemia	Foals to 3 months but usually <2 weeks. Enzootic to some farms.	Sudden onset recumbency, fever, abdominal pain, diarrhea, joint distension. Death.	*A. equuli* in blood or joint fluid	Septicemia, septic synovitis/arthritis, nephritis with abscesses in renal cortex.	Penicillin and gentamicin or other broad spectrum antibiotic, supportive care. Fair prognosis if treated early.
Septicemia	*E. coli, Klebsiella* sp., *Streptococcus* sp., *Salmonella* sp., *Actinobacillus suis*, Equine herpesvirus-1. Failure of transfer of passive immunity.	Abrupt onset of depression, fever, failure to nurse and recumbency. Later diarrhea, pneumonia and joint distension.	Culture of organism from blood or lesions (joints, lungs, feces).	Consistent with septicemia. Pneumonia. Septic synovitis, arthritis, osteomyelitis.	Broad spectrum antibiotics, supportive care (see 'Principles of providing care to the critically ill neonate'). Guarded to poor prognosis.
Isoimmune hemolytic anemia	Incompatible mating of Aa+ or Qa+ stallion with negative mare.	Normal at birth. Subsequent depression, cessation of nursing, exercise intolerance, icterus, anemia. Hemoglobinuria in severe cases.	Positive Coomb's test to demonstrate immunoglobulin on foal's red cells. Dam's colostrum agglutinates or lyses foal red cells.	Anemia, icterus. Death due to anemic hypoxia.	Transfusion of washed dam's red blood cells or of compatible donor (check dam's plasma with donor's red cells). Fair prognosis.
Uroperitoneum	Ruptured bladder, urachus or ureteral defect. Colts 1 to 3 days of age. Foals of either sex with other systemic diseases.	Normal at birth. Onset of abdominal distension, mild colic, depression and recumbency. May urinate small volumes.	Peritoneal fluid has high creatinine concentration. Hyperkalemia, hyponatremia, hypochloremia.	Uroperitoneum. Rupture bladder, urachus or ureter.	Surgical correction AFTER drainage of abdomen and resolution of hyperkalemia with intravenous dextrose or 0.9% NaCl. Good prognosis with appropriate care.
Hypogylcemia	Failure to nurse. Rejection by mare. Mare has no milk (agalactia)	Normal at birth, repeated attempts to nurse. Gradual onset (hours) of weakness and depression.	Low blood glucose concentration (<60 mg/dL, 3 mmol/L).	None. No food in stomach.	Excellent response to feeding or intravenous glucose.
Neonatal maladjustment syndrome	Sporadic	Onset of abnormal behavior, recumbency, failure to nurse or orient to mare. Aimless wandering and vocalization.	None characteristic. Frequently failure of transfer of passive immunity.	Usually none apparent. Occasional intracranial vascular accidents.	Supportive care (see 'Principles of providing care to critically ill neonates'. Good prognosis.
Congenital defects	Sporadic	Depends on nature of cardiac, gastrointestinal or central nervous system defect.	None	Consistent with defect.	Usually no treatment. Poor prognosis depending on defect.

or reproductive history can be affected. The **case fatality rate** is very low for appropriately treated foals without other systemic illness.

PATHOGENESIS

It is speculated that hypoxia resulting from intracranial vascular accidents,[5] asphyxia at birth or placental insufficiency before birth damages the central nervous system. Neurological abnormalities and a failure to nurse, result in a failure of the transfer of maternal immunoglobulins, which predisposes the foal to septicemia and hypoglycemia.

CLINICAL SIGNS

Foals that are abnormal at birth can display a range of behavioral abnormalities, from lack of suckle reflex to convulsions with extensor rigidity. The placenta of affected foals is often abnormal or there is a history of prolonged parturition. Affected foals either do not develop or lose the suck reflex, and have no affinity for the mare and are unable to locate the udder or teat. Aimless wandering and a characteristic 'barking' vocalization are sometimes present. Recumbent foals struggle wildly and in an uncoordinated fashion to stand. Convulsing foals usually display opisthotonos with extensor rigidity. Other signs of convulsive activity include facial twitching and grimacing, nystagmus, rapid blinking, sucking, chewing, and drooling.[1] Between episodes foals are usually depressed or somnolent. Affected foals display little or no interest in the mare. Convulsing foals are tachypneic, tachycardic (>180 bpm), and hyperthermic (>39°C, 102°F) during and immediately after convulsions. It is important to recognize that the severity of clinical signs varies from very mild (foals are often described by owners as being a bit slow or dimwitted) through to grand mal seizures.

Foals that are normal at birth may develop signs by 24 hours of age. The signs are similar to those described above, with the exception that the foals are initially able to ambulate. It is important to realize that healthy newborn foals lack a mence reflex, have a hypermetric gait and intention tremor, and become flaccid when restrained.

Affected foals can take days to weeks to recover completely. Blind foals that do not have ocular lesions can take as long as 4–6 weeks to regain vision.

Ancillary testing is not usually indicated unless the foal fails to respond after approximately 7 days. At that time, CT or MRI examination of the brain might be indicated to detect congenital anomalies such as hydrocephalus. Examination of cerebrospinal fluid should be performed in any foal with signs of CNS dysfunction in the presence of fever or other signs of sepsis.

CLINICAL PATHOLOGY

There are no hematological or serum biochemical abnormalities characteristic of the disease:

- Affected foals usually have **failure of transfer** of maternal immunoglobulins (serum IgG <400 mg/dL)
- They may be **hypoglycemic** (<80 mg/dL, 4 mmol/L)
- **Cerebrospinal** fluid is often normal, although it may contain red blood cells or apper xanthochromic as a result of bleeding.

DIAGNOSTIC CONFIRMATION

Definitive diagnosis of the disease is difficult and is based on exclusion of other diseases that can cause similar signs and, at necropsy, demonstration of intracranial lesions consistent with the disease.

NECROPSY FINDINGS

Gross changes are typically limited to diffuse pulmonary congestion with a variable degree of atelectasis. In cases in which dystocia has been a contributing factor, fractured ribs, and foci of subcutaneous edema and hemorrhage are sometimes noted. Occasionally, macroscopic cerebral hemorrhages are visible. Histologicially, the key findings are hemorrhagic foci within the brain and areas of ischemic necrosis in the cerebral cortex.[6] Meconium and other components of aspirated amniotic fluid accompanied by atelectasis and a mild inflammatory response may be present within the lung. In less affected foals the brain lesions are restricted to hemorrhage, cerebral swelling, and edema. Many affected foals have evidence of intracranial vascular accidents.[7] Affected foals that are euthanased often have no detectable lesions in the brain.

Samples for post-mortem diagnostic confirmation

Formalin-fixed brain, including cerebral cortex, cerebellum and brain stem, and lung for light microscopic examination.

DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from other diseases that cause neurological or behavioral abnormalities in foals including: sepsis; renal, hepatic, or gastrointestinal disease, which can occur secondary to fetal hypoxia; hydrocephalus; hypoglycemia; meningitis; neonatal isoimmune hemolytic anemia; and prematurity, dysmaturity, or immaturity.

TREATMENT

The principles of treatment are:

- Control of convulsions
- Treatment of cerebral edema and hemorrhage
- Correction of failure of transfer of passive immunity
- Nutritional support and general nursing care. The management of affected foals is mainly supportive and is time consuming and labor intensive.

Provision of nutritional support, treatment of failure of passive transfer of maternal immunoglobulins, and nursing care is dealt with in detail in the section 'Principles of care of the critically ill neonate'.

For other than emergency treatment of seizures, in which **diazepam** (0.1–0.4 mg/kg, intravenously, as required) or **midazolam** (0.05–0.1 mg/kg IV, as required) are useful, **phenobarbital** (phenobarbitone), **phenytoin** and **primidone** are the drugs of choice for long-term control of seizure activity. Phenobarbital is administered initially at a dose of 1–3 mg/kg intravenously in 30 mL of isotonic saline infused over 15–30 minutes. Maintenance therapy is a similar dose intravenously or orally, every 8 hours, and the dose adjusted to provide control of seizures while minimizing the degree of sedation. Because of the long elimination half life of phenobarbitol in foals (~200 hours) and the transient nature of the disease, once seizure control is achieved administration of phenobarbitol can be discontinued. Drug concentrations will be at or above the target concentration (5–30 μg/mL) for several days after the final dose. **Phenytoin** (5–10 mg/kg intravenously or orally initially, then 1–5 mg/kg every 4 hours) or **primidone** (20–40 mg/kg orally every 12–24 hours, to effect) are also used to control convulsions.

Definitive demonstration of the presence of cerebral edema or intracranial hemorrhage is impossible without sophisticated imaging devices, such as magnetic resonance imaging or computed tomography (CT).[8] However, treatment is often initiated on the basis of clinical signs. None of the treatments have demonstrated efficacy, and some are controversial. **Dimethyl sulfoxide** (DMSO) is given intravenously at 0.5–1 mg/kg once or twice daily for 3 days as a 10% solution. **Mannitol** (0.25 g/kg, intravenously as a 20% solution) may be effective in treating cerebral edema but is contraindicated if intracranial hemorrhage is present. **Glucocorticoids** (dexamethasone, 0.2–1 mg/kg or prednisone, 1–2 mg/kg) might reduce intracranial inflammation and swelling. They might be contraindicated in foals with sepsis.

Magnesium sulfate (0.05 mg/kg per hour for one hour, then 0.025 mg/kg/h IV for up to 48 hours) is often administered to foals with suspected hypoxic encephalopathy in an attempt to minimize neuronal damage. There is no objective evidence of its efficacy in foals.

Foals with respiratory depression can be administered caffeine (10 mg/kg orally once and then 3.0 mg/kg orally q 24 hours).[3] Adverse effects include agitation, hyperesthesia, tachycardia, and convulsions.

Good nursing care is critical in affected foals, and a concerted and persistent effort should be made to encourage the foal to nurse the mare. Encouraging the foal to nurse can be frustrating for the handler and mare, but should be done regularly, about every 4 hours, and preferably when the foal is hungry. Affected foals often begin to nurse quite suddenly.

Affected foals can require up to 4–6 weeks to recover completely, although most do so within 1 week of birth, and hasty decisions regarding euthanasia should not be made without recognition of the sometimes long time required for complete recovery.

CONTROL

Prevention of hypoxia in neonates by close monitoring of the health of the mare and of parturition may reduce the incidence of the disease.

CONGENITAL TREMOR SYNDROMES OF PIGLETS

Tremors in pigs are not a common clinical sign. Recently, generalised tremors have been described in grower pigs[1] but until this report the condition has only been described as a neonatal condition. The condition has been known for a long time in Britain.

This group of at least four etiologically distinct congenital diseases of the nervous system has a similar clinical and pathological identity. In particular they all have congenital tremor (myoclonia congenita) and these rhythmic tremors are most evident while the piglet is standing, are reduced when it lies down, and disappear when it is asleep. It is therefore not encephalitis but an increased sensitivity of the spinal cord reflexes.

Although the tremor is present at birth it may not be observed until the piglets are 2 or 3 days old and beginning to move about actively. The tremor varies from a very rapid twitch affecting only the head to a slow tremor causing the pig to 'dance'; there may be such a severe tremor that the body and head tremble violently and rock from side to side. There is no muscular weakness and the piglets get up and scamper about, but there may be ataxia and dysmetria so that the gait may be badly affected. Mildly affected piglets are not greatly incapacitated and can survive and eventually recover in 2–8 weeks; the tremor fades gradually, and near the end of the course it may be evident only during exercise. Badly affected piglets may be unable to get to the teat to suck and may die of starvation. Many are fatally crushed or trampled by the sow.

For convenience, entities within the syndrome have been classified into two types.

Type A has morphological lesions and there are 5 types AI, AII, AIII, and AIV for which the causes are known.

Type AI (*myoclonia congenita*) results from transplacental infection of the fetus by particular strains of swine fever virus.[2–4] In litters affected by swine fever virus usually about 40% of the litter is affected. The characteristic lesions are cerebellar hypoplasia and cerebrospinal dysmyelinogenesis. When the disease caused by the unidentified viral infection of the fetus first appears in a piggery all litters are affected. Most pigs in each litter have the disease, but after a period of several months the disease disappears, apparently because of herd immunity. The principal sign as in the swine fever induced disease is myoclonia, and most piglets recover. Spinal dysmyelinogenesis is the characteristic lesion.

Type AII (*myoclonia congenital*) is caused by transplacental infection with an agent presumed to be a virus and it is believed to be the most common type of congenital tremor.

Type AIII (congenital cerebrospinal hypomyelinogenesis) is a hereditary form so far found only in Landrace and known as Landrace trembles.[5] The inherited sex-linked disease occurs in the progeny of Landrace or Landrace-cross sows. Up to 11% of Landrace piglets may be affected compared to only 0.3–0.8% in the Yorkshire, Hampshire, and Duroc breeds. The mode of transmission is via a monogenic sex-linked recessive character, and half of all male pigs born are affected. Histologically, there is cerebrospinal myelinogenesis. Most affected pigs die. It is essentially a deficiency of oligodendrocytes.

Type AIV is also a genetically determined condition due to an autosomal recessive condition found in Saddlebacks. It is seen in about 25% of the progeny, and is fatal in most of them. Cerebrospinal dysmyelinogenesis is the characteristic lesion. It is characterised by a deficiency of myelin throughout the CNS.[6] A type distinct from this has also been reported in Saddleback x Large White sows.[7]

Type AV occurs naturally in Scandinavia[8] and is characterized by cerebellar hypoplasia and has been experimentally produced following dosing of pregnant sows between 45 and 75 days of gestation with trichlorfon.[9]

Type B is a form of congenital tremor not yet adequately characterized and without morphological lesions and is of unknown etiology. The differentiation of these diseases is now possible on the basis of histopathological and neurochemical findings and relating these to the epidemiological data. In piglets born from sows inoculated with the Weybridge congenital tremor strain of the swine fever virus in early pregnancy, the severity of the clinical signs was related to the degree of spinal myelin deficiency. Semiautomated planimetry can be used to determine the cross-sectional areas of spinal gray and white matter of affected piglets. The spinal cord cross-sectional area is significantly reduced in piglets affected with Type AI congenital tremor. The reduction is similar to Type AII. The neurochemical findings relate to the presence of particular fatty acid profiles in the cholesterol esters in the lipids of the spinal cord.

Control of the disease depends on its cause. If it is inherited the recommended procedure is to keep none of the affected recovered pigs for breeding. If the cause is one of the maternal infections of early pregnancy it is recommended practice to deliberately expose empty females to affected piglets so that they become immunized before pregnancy. Failure to identify the cause may necessitate adopting both procedures.

The disease appears to occur sporadically but when it does occur it may assume great importance. As many as 15% of litters born in a piggery may be affected, and of these 72% of the piglets may be affected and the case fatality rate amongst these may be as high as 50%. There is a feeling amongst veterinarians that the condition has increased recently but this may just be an increased awareness. If there is an increase, the specific cause of the increased prevalence has not been identified but it is possibly the unidentified virus referred to above: the virus of congenital tremor Type AII. There is also the possibility that the observed concurrent increase in prevalence of both splayleg and congenital tremor may indicate that they are possibly caused by the same virus. In this context, there is conjecture, that the PCV2 virus which is extremely small and similar in size to the particles that were described in the early electron micrographs of the spinal cord of affected piglets may be responsible. As yet there is no confirmation that splayleg and congenital tremor are PCV2 associated disorders.[10]

OVINE HUMPYBACK

This is a disease of sheep, mainly Merino wethers, in western Queensland, characterized by stiffness and shortness of steps when forced to walk for about a kilometer. The sheep stops walking and adopts an arched back posture. At this time the body temperature is significantly elevated and the level of lymphocytes in the blood is lowered. The greatest incidence is in summer after rain and when the sheep are in full wool, and the hyperthermia and ataxia disappear when the sheep are shorn. Environmental temperatures at the time of the greatest prevalence of the disease are high,

commonly 40°C. This occurs in spite of the presence of a characteristic degeneration of spinal cord tracts.[1] The obvious explanation of the phenomenon is that it is a form of heat stroke and that the nervous system lesions are incidental.

EQUINE CERVICAL VERTEBRAL STENOTIC MYELOPATHY, (WOBBLER, 'WOBBLES', EQUINE SENSORY ATAXIA, CERVICAL VERTEBRAL INSTABILITY)

Synopsis

Etiology Unknown.
Epidemiology Sporadic or endemic disease of young horses. Young, rapidly growing male horses are most commonly affected. Separate presentation in middle-aged horses in which it is sporadic.
Clinical signs Spinal ataxia evident as truncal sway, ataxia and paresis usually more severe in the hind limbs. Radiographic evidence of narrow spinal canal.
Clinical pathology None.
Lesions Malacia and Wallerian degeneration in the cervical spinal cord.
Differential diagnosis Equine degenerative myelopathy, equine protozoal myeloencephalitis, trauma, equine infectious anemia, cerebrospinal nematodiasis, West Nile encephalomyelitis, equine herpesvirus-1 myelopathy, aorto-iliac thrombosis, congenital vertebral malformation, diskospondylitis, and rye-grass staggers.
Diagnostic confirmation Radiography. Positive contrast myelography. Necropsy.
Treatment Anti-inflammatory drugs. Surgical fusion of vertebrae.
Control None.

ETIOLOGY

The cause of neurologic disease is compression of the cervical spinal cord, hence the term compressive myelopathy. The compression may be **static**, that is the compression is present constantly with the neck in a neutral position, or **dynamic** and only present intermittently when the neck is either flexed or extended. The second situation is often referred to as cervical vertebral instability. The etiology of equine cervical stenotic myelopathy (CSM) in most cases is not known. Several basic syndromes of compressive myelopathy, based on age of occurrence, are recognized:

- Equine stenotic myelopathy (ESM) in immature horses (<3 years of age, depending on breed) that is often associated with developmental joint disease in the axial and appendicular skeleton. The fundamental underlying defect appears to be a narrow diameter of the cervical vertebral canal.
- Cervical vertebral instability (CVI), a disease of horses less than 1 year of age, is often associated with malformations of one or more of the cervical vertebrae.[1]
- Compressive myelopathy in mature horses, >4 years (usually >7 years) of age, associated with osteoarthritis of the articular facets of the caudal cervical vertebrae, with subsequent impingement of the vertebral canal by bony and soft tissue proliferative lesions.
- Miscellaneous causes of cervical cord compression by neoplasia (melanoma, sarcoma, lymphoma),[2–4] trauma (cervical vertebral fractures), arachnoid or synovial cysts[1] or, rarely, discospondylitis.[5]

An alternative categorization is based on the nature of the bony lesion and not on the cause of compression of the spinal cord. **Type 1 cervical vertebral malformation** occur in horses <2 years of age that have vertebral changes that likely began in the first few months of life, and include malformations causing stenosis of the vertebral canal, malformations at the articulations of the vertebrae including osteochondrosis, and enlarged physeal growth regions.[6] **Type II cervical vertebral malformations** tend to occur in older horses with severe osteoarthritic lesions of the vertebral articulations.[6]

EPIDEMIOLOGY

Occurrence

The disease in mature horses occurs sporadically throughout the world.

The disease in young horses is sometimes endemic on farms or studs, and in particular lines of horses. There is a suggestion of a familial tendency for the disease, although this has not been well documented.

The **morbidity rate** may be as high as 25% of each foal crop on individual Thoroughbred farms, although the overall frequency of the disease in the general horse population is much lower.[7]

Risk factors

Animal risk factors

The disease in young horses is commonly recognized in Thoroughbred, Standardbred, Warmblood, and Quarter horses, but other breeds can be affected. Ponies are rarely, if ever, affected. The disease occurs in horses less than 4 years of age, with most cases occurring in 1–3-year-old horses. Males are more commonly affected than are females. Horses with cervical stenotic myelopathy have a narrower spinal canal than do unaffected animals and this condition, with degenerative joint disease of the articular facets and thickening of the ligamentum flavum, contributes to the greater likelihood that the horse will have spinal cord compression.[7–9]

It is suspected that predisposition to the disease is heritable, but this has not been demonstrated by appropriate studies. The stenotic myelopathy is believed to be the result of a combination of fast growth rate and over nutrition, and dietary restriction may reduce the incidence of the disease.[7] A relationship of ESM to developmental bone disease (osteochondrosis) and dietary copper has been suggested, but is unproven.

The disease in mature horses tends to be in horses used for athletic endeavours, and is uncommon in brood mares or retired animals.

PATHOGENESIS

The disease is attributable to injury to the spinal cord as a result of compression by either soft tissue (joint capsule, intervertebral ligaments, or, rarely, intervertebral disk material) or cartilage and bone.

Constant or intermittent pressure on the spinal cord causes necrosis of white matter and neurons at the site of compression, and degeneration of fibers of ascending tracts cranial to the site of compression, and of descending tracts caudal to the compression.[10] The ascending tracts are those associated with general proprioception whereas the descending tracts are upper motor neurons. These tracts are located superficially in the dorsolateral aspect of the cervical spinal cord and damage to them results in signs of ataxia and weakness. Tracts from the caudal limbs are more superficial, and therefore more easily injured, than ar tracts associated with the cranial limbs. Consequently, clinical signs are usually more severe in the hind limbs. The spinal cord lesions are usually, but not always, bilaterally symmetrical, as are the clinical signs.[10] Proprioceptive pathways are disrupted, causing the signs of ataxia (incoordination) typical of the disease. Clinical signs vary depending on the site of the lesion (see below).

CLINICAL FINDINGS

The onset of clinical signs is sometimes acute in both ESM and CVI in young horses and there may be a history of trauma, such as falling. However, the onset of clinical signs in ESM in both young and mature horses is usually gradual and insidious and in mildly affected horses the nervous disease may be mistaken for lameness of musculoskeletal origin. Affected horses are bright and alert and have a normal appetite. There may be evidence of pain on manipulation of the neck, especially in mature horses, or on firm pressure over the lateral facets.

The severity of clinical signs varies from barely detectable to recumbency. There are no defects of cranial nerves, with the exception of the cervicofacial reflex.

Mildly affected horses may have deficits that are difficult to detect and only apparent under saddle or at high speed. The owner may complain of poor performance of a race horse or dressage animal, of an animal that frequently changes leads or that is poorly gaited. Careful examination may reveal excessive circumduction of the hind feet, stumbling, and pacing when the head is elevated.

Moderately affected animals have truncal sway, the body of the horse and hind quarters swaying laterally when the horse is walked in a straight line, and excessive circumduction of the hind feet. Having the horse move in a very tight circle about the examiner often causes the circumduction to become worse in the outside hind leg and the horse to place one foot on top of the other. Affected horses will sometimes pace when walked in a straight line with the head elevated. Blindfolding the horse does not exacerbate the signs. Affected horses will stumble when walked over low objects, such as a curb, and will **knuckle** at the fetlocks and stumble when walked down a steep hill.

Severely affected horses often fall easily when moved or are unable to stand. The horses are bright and alert, but anxious, and display marked truncal sway and ataxia. When standing they will often have their legs in markedly abnormal positions.

Mature horses with disease secondary to arthritis of the articular facets can have hypalgesia of the skin overlying those regions and atrophy of the cervical musculature.

Horses with lesions in the cervical spinal cord cranial to C6–C7 have signs in both fore and hind limbs. The hindlimbs are more severely affected and the signs are usually, but not always,[10] bilaterally symmetrical. Lesions of the cervical intumescence (C6 to T2) may cause signs that are more severe in the forelimbs than in the hindlimbs. Lesions at this site may also cause signs typical of brachial plexus injury. Focal muscle atrophy is not characteristic of ESM or CVI and there are never signs of cranial nerve, cerebral, or cerebellar disease.

After initial progression the clinical signs usually stabilize or partially resolve. However, complete spontaneous recovery is very unusual. Death is unusual unless it is by misadventure, although many affected animals are killed for humane reasons.

Ancillary diagnostic tests

The 'slap test', in which the response of the arytenoid cartilages to a slap on the thorax is examined through an endoscope, has poorer sensitivity and specificity for detecting spinal cord disease than does a routine neurological examination.[11]

Acupuncture has no proven value in the diagnosis of ESM or CVI and should not be used for this purpose.

Radiographic examination

Radiographic examination of cervical vertebral column of affected horses reveals narrowing of the spinal canal.[7,8] This has diagnostic utility, e.g. a ratio of spinal canal to vertebral body diameter of less than 50% for C4 is associated with a 28-fold increase in the probability of ESM.[8] Other measures of spinal canal diameter are useful in the detection of stenosis and compressive myelopathy.[12–14] Other radiographic signs consistent with ESM or CVI include:

- Encroachment of the caudal vertebral physis dorsally into the spinal canal ('ski jump lesion')
- Extension of the arch of the vertebra over the cranial physis of the next vertebra
- Sclerosis of the spinal canal
- Kyphosis between adjacent vertebra
- Degenerative joint disease of the articular facets.

However, these signs are also common in normal horses and have poor predictive value.[1,8,12,13]

Myelography has been considered to provide the definitive ante mortem confirmation of spinal cord compression.[4] However, the sensitivity of this technique, using a 50% reduction in the width of the dorsal dye column as a cut-off for diagnosis of the disease is 53% (95% confidence interval 34–72%, n = 22) and the specificity is 89% (95% confidence interval of 84–93%, n = 228).[16] Others have found similar values for sensitivity and specificity.[12] These results indicate that a positive finding on myelography is highly suggestive of the disease, but that a negative finding does not eliminate the possibility of the disease. The false-positive rate is increased to 12–27% for compression at mid-cervical sites during neck flexion.[16] Myelography is superior in diagnosing compressive lesions at C6–C7 than at more proximal sites.[16] Occasionally the compression is lateral rather than dorso-ventral and is not readily apparent on routine myelography.

CLINICAL PATHOLOGY

Hematological and serum biochemical values are usually within reference ranges in affected horses. Cerebrospinal fluid from affected horses may have increased protein concentration, but this finding is neither characteristic nor specific for ESM or CVI. However, other causes of spinal ataxia may cause characteristic changes in the cerebrospinal fluid. Measurement of creatine kinase activity in CSF has no diagnostic value in horses.[17]

NECROPSY FINDINGS

Gross examination reveals degeneration of the articular facets in many affected horses.

Impingement of soft tissues, especially the ligamentum flavum and joint structures, or cartilage and osteophytes into the spinal canal may be apparent. The spinal canal may be narrow. The spinal cord may be indented and soft at the site or sites of compression. Histologically, there is nerve fiber swelling, widespread degeneration of myelin, and astrocytic gliosis. Cranial to the compressive lesion, Wallerian degeneration is evident in the dorsal and lateral funiculi, while caudal to the compression these changes are most evident in the ventral and central lateral funiculi.[10] Slight atrophy of cervical muscles is sometimes evident. There is histological evidence of stretching and tearing of the ligamentum flavum and joint capsule at affected joints especially C6 or C7.

DIFFERENTIAL DIAGNOSIS

Equine degenerative myelopathy, equine protozoal myeloencephalitis, trauma, equine infectious anemia, cerebrospinal nematodiasis (*Hypoderma* spp., *Setatia* sp., *Halicephalobus deletrix*), equine herpesvirus-1 myelopathy, aorto-iliac thrombosis, West Nile encephalomyelitis, congenital vertebral malformation (especially in Arabian foals), discospondylitis, tumors involving the spinal canal (melanoma, lymphoreticular neoplasia), and rye-grass staggers. See Table 36.3.

TREATMENT

Medical treatment of the acute disease consists of rest and administration of anti-inflammatory drugs (dexamethasone 0.05–0.25 mg/kg, IV or IM every 24 hours; flunixine meglumine 1 mg/kg, IV every 8–12 hours; phenylbutazone 2.2–4.4 mg/kg, orally every 12–24 hours; and/or dimethyl sulfoxide, 1 g/kg as a 10% solution in isotonic saline, IV every 24 hours for 3 treatments).

Treatment of arthritis of the facets of mature horses can be achieved by injection of the articular facet joints with corticosteroids (40 mg methylprednisolone acetate).[18] Injection of the joint is facilitated by ultrasonographic guidance.[18] Injection of the joints with anti-inflammatory drugs is assumed to result in reduction in inflammation and soft tissue swelling with consequent reduced compression of the cervical spinal cord.

Table 36.3 Differential diagnosis of disease causing spinal ataxia in horses

Disease	Etiology and epidemiology	Clinical signs and lesions	Treatment and prognosis
Cervical compressive myelopathy (cervical stenotic myelopathy, cervical vertebral instability)	Sporadic. Young, rapidly growing males. More common in Thoroughbreds, Standardbreds, and Warmblood horses. Syndrome in mature horses caused by arthritis or articular facets.	Symmetrical ataxia often of sudden onset. May be associated with trauma. Hind limbs most severely affected. Compression of cervical spinal cord demonstrated by myelography. CSF normal.	Medical treatment of rest and antiinflammatory drugs. Poor prognosis. Surgical correction by ventral stabilization. Guarded prognosis.
Equine degenerative myelopathy	Young horses (<3 years). Familial incidence of increased requirement for vitamin E.	Gradual onset symmetric ataxia that stabilizes at about 3 years of age. No radiographic abnormalities in cervical spinal cord. CSF normal.	Vitamin E 5–20 iu/kg per day in feed may prevent progression. No cure. Death uncommon.
Equine protozoal myeloencephalitis	*Sarcocystis neurona* in spinal cord or brain. Americas only. Infectious but not contagious.	Any sign of central nervous system dysfunction. Usually gradual onset of asymmetric spinal ataxia, focal muscle atrophy or weakness. CSF contains antibody to *S. neurona*, but also found in normal horses.	Ponazuril 5–10 mg/kg orally daily for 28 days. Older, but effective, treatment is pyrimethamine, 1 mg/kg orally and sulfadiazine, 20 mg/kg orally every 24 hours for 90–120 days. Nitazoxonide 25 mg/kg orally once daily for 2 days followed by 50 mg/kg orally for 26 days. Vaccination not recommended.
Equine herpesvirus-1 myeloencephalopathy	EHV-1. Infectious and contagious. Sporadic. Outbreaks occur often preceded by fever or upper respiratory tract disease.	Ascending paralysis with fecal and urinary incontinence, recumbency, normal mentation. CSF xanthochromic and increased protein concentration. Lesion is vasculitis and malacia.	Corticosteroids controversial. Nursing care. Poor prognosis. Vaccination minimally effective.
West Nile encephalitis	West Nile virus. Transmitted by bite of infected mosquito. Horse is 'dead end' host and does not develop sustained viremia. Enzootic to Mediterranean littoral and North America. Peak disease risk is late summer.	Weakness, muscle fasciculations, altered mentation. Recumbency.	No specific treatment. Nursing care. Corticosteroids controversial. Hyperimmune serum available in some areas. Interferon has been used but efficacy uncertain.
Trauma	Sudden onset. More common in young horses.	Spinal ataxia, varying degrees of weakness and proprioceptive deficits. Recumbency. Radiographic lesions present occasionally. CSF may contain red blood cells.	Anti-inflammatory drugs. Rest.
Rye grass staggers	Intoxication by lolitrems produced by *Acremonium lolii* growing on perennial rye grass. Outbreaks of disease in horses on affected pasture.	Ataxia, stiff gait, tremor, hypersensitivity, recumbency. No histologic lesions.	Remove source of toxin. Rapid recovery without other treatment.
Parasite migration	Sporadic. *Strongylus* sp., *Hypoderma* sp., and filaroids (*Setaria* sp.).	Wide variety of clinical signs. Progressive ataxia. CSF may contain eosinophils.	Ivermectin 200 µg/kg. Antiinflammatory drugs.
Congenital anomalies	Sporadic. Cause spinal cord compression or lack of neural tissue, e.g. spina bifida.	Recumbency, ataxia present at birth.	No treatment.

A 'paced growth' program of slowed growth achieved by nutritional restriction of young horses (foals and weanlings) has been suggested as conservative treatment for immature horses with compressive myelopathy or at high risk of developing the disease.[19]

Surgical fusion of cervical vertebrae is useful in the treatment of mildly to moderately affected horses,[20,21] although because of issues of safety of future riders there are concerns by some authorities about the advisability of this treatment.

CONTROL

Control measures are not usually employed, although insuring an appropriate diet and growth rate of at-risk animals would be prudent. Because of the possible inherited nature of the disease, a corrective breeding program may be advisable.

STRINGHALT

Stringhalt is an involuntary, exaggerated flexion of the hock during walking. It can affect one or both hindlimbs. Classic

stringhalt occurs sporadically, is usually unilateral, and is usually irreversible without surgical intervention. Stringhalt can also occur secondarily to injury to the dorsal metatarsus.[1]

A clinically identical disease, Australian stringhalt, occurs in outbreaks in Australia, New Zealand, California, Japan, and Chile.[2,3] The outbreaks tend to occur in late summer or autumn and are related to drought conditions or overgrazing of pasture with consequent ingestion of plants that would otherwise not be eaten.[4] Outbreaks in Australia, California, and Virginia are related to the ingestion of *Hypochoeris radicata* (flatweed, cats ear).[4–8] Other plants suspected to play a role in the etiology include *Taraxacum officinale* (dandelion), *Arctotheca calendula* (capeweed) or *Malva parviflora* (mallow) but good evidence of the role of any of these plants is lacking.

The abnormal movement is only elicited when the horse begins to move forward. The characteristic movement occurs in mildly affected horses when they are backed or turned. Most cases are manifested by a flexion of the hock that can be violent enough for the horse to kick itself in the abdomen. The hoof is held in this position for a moment and then stamped hard on the ground. If both hind legs are affected progress is very slow and difficult and the horses often use a 'bunny hopping' gait. In the most severe cases the horse is unable to rise without assistance. The horse's general health is unaffected although it may be difficult for it to graze. Some cases have other signs of neurologic disease such as stiffness of the forelimbs or respiratory distress due to laryngeal paralysis. Many affected horses have unilateral (usually left) laryngeal hemiplegia evident on endoscopic examination of the larynx. Electromyographic examination reveals markedly abnormal activity including prolonged insertion activity, fibrillation potentials, and positive waves at rest and enhanced EMG activity in the right lateral digital extensor muscle on muscle contraction consistent with denervation. The changes are most severe in the long digital extensor muscle.[6] Most horses recover without treatment, although complete recovery might not occur for over 1 year.[2,5]

There are no characteristic abnormalities in a complete blood count or serum biochemical profile. Pathological findings are restricted to a peripheral neuropathy in the tibial, superficial peroneal and medial plantar nerves and in the left and right recurrent laryngeal nerves.[9,10] Lesions in affected muscles are consistent with denervation atrophy and fiber type grouping.

The signs of the disease are characteristic. Differential diagnosis of the disease involving one leg is ossifying myopathy of the semimembranosus and semitendinosus muscles. Lead toxicosis can induce similar signs in horses.

Treatment with phenytoin (15 mg/kg orally daily for 14 days) effected some improvement but the signs recurred within 1 or 2 days after treatment was discontinued.[11] Myotenectomy of the lateral digital extensor muscle and tendon is reported to provide immediate relief in affected horses, even in those horses with severe bilateral disease.[12] However, recovery is spontaneous in most cases and there might only be a need for surgery in the most severely affected horses. Control involves the prevention of overgrazing of pastures, particularly during droughts.

OVINE 'KANGAROO GAIT'

Synopsis

Etiology Not known
Epidemiology Seasonal occurrence involving only adult female sheep that are lactating, or in some cases, pregnant. Spontaneous recovery following cessation of lactation.
Clinical findings Bilateral forelimb locomotor disorder
Lesions Axonal degeneration of the radial nerve followed by regeneration.
Treatment Supportive
Control None recognized

ETIOLOGY

A neuropathy of unknown cause.

EPIDEMIOLOGY

Occurrence

This condition is recorded in New Zealand and the United Kingdom and is manifest with acute onset of bilateral radial nerve paralysis followed by spontaneous recovery.

Risk factors

It occurs only in adult ewes with an onset in late pregnancy or early lactation.[1–5] Spontaneous recovery occurs following cessation of lactation[1–3] but also occasionally while ewes are still nursing lambs.[4] Average annual cumulative incidence varies between flocks but is less that 1%.[5]

In the areas of northern England and southern Scotland the condition is significantly more common in upland and lowland flocks than in those hill grazing. Stocking density is higher in affected flocks than that in non-affected flocks. Onset occurs while on pasture between March and June with a separate smaller peak in October. This seasonal occurrence could be a reflection the parturition status of flocks or an effect of seasonal influences.[5]

PATHOGENESIS

Clinical signs can be attributed to the generalized polyneuropathy affecting principally the radial nerves. Subsequent to the axonal degeneration a remyelination of the radial nerve occurs, explaining the clinical recovery. Bilateral compression of the radial nerves appears to be the cause but there is no indication of how such an injury can occur.[3]

CLINICAL FINDINGS

The name comes from the gait exhibited by affected ewes which are unable to move their forefeet except in a synchronized bounding action. There is bilateral forelimb paresis, a palpable loss of muscle bulk in the forelimbs, and some cases also have proprioceptive deficits. The hind limbs are normal. Affected ewes lie down more frequently and may graze on their knees but continue to eat and effectively suckle their lambs.

CLINICAL PATHOLOGY

There are no consistent abnormalities in haematology, blood biochemistry, or trace element analysis of affected sheep.[4]

NECROPSY FINDINGS

There is axonal degeneration of the myelinated fibers of the radial nerve fibers and regeneration in recovering cases.[1–3] Ventral root gangliopathy and neuronal degeneration within the spinal cord is reported[1–3] but may not be evident in all cases.[4]

DIFFERENTIAL DIAGNOSIS

Foot rot or foot abscess involving the front feet can have the same grazing behaviour but there is no problem in differentiation when the limbs and feet are examined.

Hypocalcemia in sheep occurs in late pregnancy or during lactation and in the developing stages there is incoordination and muscle weakness. However there is rapid progression to complete muscular paresis and a dramatic response to treatment.

Spinal abscess or fracture.

TREATMENT

Without the knowledge of etiology there is no specific treatment. Easy access to food and water should be provided.

EQUINE MOTOR NEURON DISEASE

Equine motor neuron disease is a recently recognized **neurodegenerative disease** of horses in the US and Canada, with a small number of cases being recorded in Europe and South America. The disease affects horses of all breeds, with Quarter horses most commonly affected, and the incidence of the disease increases with age.[1] Horses older than 2 years of age are affected. The disease is associated with stabling and lack of access to pasture, and the risk of the disease increases with decreasing serum vitamin E concentration.[2,3] The etiology of the disease is unknown but is suspected to be due to oxidative injury to neurons subsequent to vitamin E deficiency.[3] The clinical signs are attributable to degeneration of motor neurons in the ventral horns of the spinal cord, with subsequent peripheral nerve degeneration and widespread neurogenic muscle atrophy.

The onset of clinical signs is usually gradual but in a small proportion of affected horses the first sign is an acute onset of profound muscle weakness. Chronically affected horses have weight loss in spite of a normal or increased appetite, pronounced trembling and fasciculation of antigravity muscles, increased recumbency, and a short-strided gait; they often assume a posture with all feet under the body and a low head carriage, and frequently shift weight – all signs attributable to muscle weakness.[4] The tail head is elevated in a large proportion of severely affected horses, likely a result of atrophy of the *sacrocaudalis dorsalis medialis* muscle. Retinal examination often reveals accumulation of lipofuscin-like pigment in the tapetal fundus.[5] Electromyography, under either general or regional anesthesia, is a useful diagnostic aid.[6,7] Characteristic findings include spontaneous fibrillation potentials and trains of positive sharp waves. The prognosis is poor and most affected horses do not return to normal function and are destroyed, although the disease stabilizes in some cases that can then live for a number of years after diagnosis.

There is often a mild increase in serum creatine kinase activity. Horses with equine motor neuron disease have abnormal oral and intravenous glucose tolerance tests characterized by peak glucose concentrations that are lower than expected.[8] The lower peak plasma glucose concentration is attributable to a 3x greater rate of glucose metabolism (removal from blood) in affected horses compared to normal horses.[9] There is also evidence that horses with equine motor neuron disease are more sensitive to insulin than are normal horses.[9] Affected horses often have serum vitamin E concentrations that are below the reference range (<1.0–2.0 μg/dL, <1.0–2.0 μmol/L).[3] Horses with equine motor neuron disease have higher spinal cord copper concentrations than do normal horses, but the diagnostic or clinical significance of this observation is unclear.[10] Examination of cerebrospinal fluid is not useful in arriving at a diagnosis.

Examination of muscle from horses with equine motor neuron disease reveals a coordinated shift from characteristics of slow muscle to those of fast twitch muscle including contractile and metabolic functions of muscle.[11] There is a lower percentage of myosin heavy chain type 1 fibers, higher percentages of hybrid IIAX and IIX fibers, atrophy of all fibers, and reduced oxidative capacity, increased glycolytic capacity, and diminished intramuscular glycogen concentrations, among other changes, in affected horses compared to normal horses.[11]

Diagnostic confirmation can be achieved by examination of a biopsy of the *sacrocaudalis dorsalis medialis* muscle or the spinal accessory nerve.[7,12] The *sacrocaudalis dorsalis medialis* muscle is preferred because that muscle is predominantly composed of type 1 fibers and is severely affected by the disease.

Necropsy examination reveals moderate to severe diffuse muscle atrophy. Predominant histologic findings at necropsy examination include degeneration of neurons in ventral horns at all levels of the spinal cord.[13] Muscle atrophy is evident as angular fibers, with predominantly type 1 fibers, or a combination of type 1 and type 2 fibers, affected.[10,11] There is accumulation of lipofuschin in the fundus and in capillary endothelium of the nervous tissue.

Treatment consists of administration of vitamin E, although the efficacy of this treatment has not been determined. Administration of lyophilized, water soluble D-α-tocopherol is apparently superior to administration of the DL-α-tocopherol acetate in increasing concentrations of vitamin E in blood of horses. The usual dose is 4 iu of D-α-tocopherol per kg body weight orally once daily. Control measures should insure that horses have adequate access to pasture or are supplemented with good quality forage and/or vitamin E.

CRUSHED TAIL HEAD SYNDROME IN CATTLE

The crushed tail head syndrome is a recently recognized neuromusculoskeletal disease of dairy cattle which has occurred in the US and UK.[1–3] It occurs most commonly in housed lactating dairy cattle in mid-lactation and that have calved 60 days or more previously. The onset is sudden and characterized clinically by hindlimb weakness, prolonged recumbency in alleyways, but still able to stand. The hindlimbs are drawn forward under the abdomen. Walking is awkward because of hindlimb weakness or pain and affected animals walk with a still rolling gait. Knuckling of the fetlocks and hock joints are characteristic. There is flaccid paralysis of the tail and defecation and urination are not usually affected. During urination and defecation the tail is not lifted and becomes covered with feces and wet with urine. The anal reflex is commonly diminished. There may be some evidence of traumatic injury to the sacral area of the vertebral column with either visible abnormal alignment of the sacral area on movement by the animal or if the animal is rocked from side to side. In other cases, there is no external evidence of trauma or misalignment of the sacrum. No other clinical abnormalities have been observed; appetite is normal, vital signs are normal, and rumen function and the feces are normal in amount and character.

The cause is unknown. In some cases, estrus activity was observed a few days before the onset of signs which suggests that affected animals were mounted by others in the herd causing injury to the tail head and sacrum. It is suggested that traumatic injury to the sacral nerves is the cause of the paresis.

Most cases respond spontaneously and recover within a few weeks. Some reports describe the successful use of long-acting corticosteroids[1] but there insufficient clinical information available to make any useful recommendation.

POLYNEURITIS EQUI (EQUINE CAUDA EQUINA SYNDROME)

Polyneuritis equi (formerly cauda equina neuritis) is a demyelinating, inflammatory disease of peripheral nerves of adult horses. The **etiology** of the disease is unknown although infectious (adenovirus, equine herpesvirus type 1), immune (autoimmune disease), and toxic etiologies have been suggested, without conclusive substantiation. Adenovirus was isolate from 2 of 3 horses with the disease, but this observation has not been repeated and it appears unlikely at this time that adenovirus is the cause of polyneuritis equi.[1] Equine herpesvirus-1 is not consistently isolated from affected horses.[2]

The disease occurs in adult horses in Europe and North America but has not been reported from the Southern Hemisphere. The disease is usually sporadic with single animals on a farm or in a stable affected. However, outbreaks of the disease can affect multiple horses from the same farm over a number of years.

The **pathogenesis** of the disease involves nonsuppurative inflammation of the extradural nerves and demyelination of peripheral nerves. Initial inflammation of the nerves causes hyperesthesia which is followed by loss of sensation as nerves are demyelinated. Both motor and sensory nerves are affected, with subsequent weakness, paresis, muscle atrophy, urinary and fecal retention and incontinence, and gait abnormalities.

The **acute disease** is evident as abrupt onset of hyperesthesia of the perineum and tail head, and perhaps the face, evident as avoidance of touching, and chewing or rubbing of the tail. The hyperesthesia progresses to hypalgesia or anesthesia of the affected regions.

The disease usually has a more **insidious onset** with loss of sensation and function occurring over days to weeks. The most common presentation is that of cauda equina syndrome with bilaterally symmetrical signs of posterior weakness, tail paralysis, fecal and urinary incontinence and retention, and atrophy of the gluteal muscles. Tail tone is decreased or absent and the tail is easily raised by the examiner. The anus is usually atonic and dilated. There are signs of urinary incontinence with urine scalding of the escutcheon and hind legs. Rectal examination reveals fecal retention and a distended bladder that is readily expressed. Male horses can have prolapse of the penis with maintained sensation in the prepuce – a finding consistent with the separate innervation of these anatomic regions. Affected horses can also have ataxia of the hind limbs, but this is always combined with signs of cauda equina disease.

Signs of **cranial nerve dysfunction** occur as part of the disease, but not in all cases. Cranial nerve dysfunction can be symmetrical, but is usually asymmetric. Nerves prominently involved in the genesis of clinical signs are the trigeminal (cranial nerve V), facial (CN VII), and hypoglossal nerve (CN XII), although all cranial nerves can be affected to some extent. Involvement of the cranial nerves is evident as facial paralysis (CN VII), weakness of the tongue (CN XII), and loss of sensation in the skin of the face (CN V). There can be loss of movement of the pinnae (CN VII) and head tilt (CNVIII). Laryngeal paralysis can be present (CN X). The buccal branches of CN VII can be enlarged and palpable over the masseter muscles ventral to the facial crest.

Electromyography is consistent with denervation with prolonged insertion potentials, positive sharp waves, and fibrillation.

Not all clinical signs occur in all horses and, depending on the stage and severity of the disease, some animals can have loss of sensation as the only abnormality, especially during the early stages of the disease.

The disease is inexorably progressive, the prognosis for life is hopeless, and the course of the disease is usually less than 3 months.[3]

Clinical pathologic abnormalities are not diagnostic. There is sometimes a mild neutrophilic leukocytosis and hypergammaglobulinemia. Serum vitamin E concentrations are usually normal. Analysis of cerebrospinal fluid demonstrates mild mononuclear pleocytosis and increased protein concentrations, but these changes are not diagnostic of the disease. Horses with polyneuritis equi have antibodies to P2 myelin protein in serum, but the diagnostic value of this test has not been determined.[4]

Necropsy findings are definitive for the disease. Gross findings include thickening of the epidural nerve roots that is most severe in the cauda equina. The bladder and rectum can be distended. There can be evidence of fecal and urine scalding and self-trauma of the perineum. There can be thickening of the facial nerves. Microscopic changes are characterized by a granulomatous inflammation of the extradural nerves although radiculoganglioneuritis and myelitis can also occur. There is loss of axons with demyelination and signs of remyelination. The inflammatory cells are initially lymphocytes, plasma cells, and macrophages. As the inflammation becomes more severe or chronic there is extensive proliferation of fibroblasts and fibrocytes in addition to infiltration of lymphocytes and macrophages.[2] There is axonal degeneration with proliferation of the perineurium. The chronic inflammatory changes result in loss of peripheral neural architecture. Lesions are present in many regions of the spinal cord, but are most severe in the sacral division and cauda equina.[2] Lysosomal accumulations are present in the semilunar, geniculate, and sympathetic chains and granulomatous lesions in the celiaco-mesenteric ganglion.[5] Lesions of the cranial nerves similarly involve infiltration with lymphocytes and histiocytes, and the inflammation can extend to the terminal branches of the nerves.[3]

The **diagnosis** of polyneuritis equi is based on the presence of clinical signs of the disease, rule out of other diseases causing similar clinical signs, and necropsy examination. Diseases with manifestations similar to polyneuritis equi include:

- Equine herpesvirus-1 myeloencephalopathy
- Migrating parasites (Table 36.3)
- Sorghum–Sudan grass neuropathy
- Equine protozoal myeloencephalitis
- Rye grass staggers (*Acremonium lolii*)
- Dourine
- Trauma to the sacral vertebral column
- Abscess or neoplasia involving the sacral or caudal lumbar vertebral column
- Meningitis
- Intentional alcohol sclerosis of tail head nerves in Quarter horses.

There is no definitive **treatment** for polyneuritis equi. Administration of anti-inflammatory agents, including corticosteroids, appears to be without sustained benefit. Supportive care includes evacuation of the rectum and bladder and maintenance of hydration and provision of adequate nutrition. Feeding a diet that softens feces, or administration of fecal softeners or lubricants can be beneficial. Bethanacol (0.05 to 0.1 mg/kg q8–12 hours, orally) might increase bladder tone. Topical administration of petroleum jelly or similar products can protect the skin of the perineum and escutcheon from fecal and urine scalding.

HEAD SHAKING IN HORSES

Headshaking by horses is a perplexing and troubling syndrome for which there is often no readily identifiable cause or treatment. The disorder is characterized by repeated, sudden shaking or tossing of the head.

ETIOLOGY

The etiology is complex and often unclear and conditions associated with head shaking include:[1,2]

- Ear mites
- Otitis interna/externa
- Ophthalmic disease (uveitis)
- *Trombicularis autumnalis* (chiggers) infestation of the muzzle
- Guttural pouch disease (mycosis)
- Stylohyoid arthropathy
- Osteitis of the petrous temporal bone
- Dental disease (wolf teeth, ulceration, periodontal disease, periapical abscess)
- Behavioral abnormalities
- Trigeminal neuralgia
- Optic neuritis
- Photic head shaking (optic-trigeminal summation)
- Neck pain
- Rhinitis or sinusitis
- Ethmoidal disease including hematoma
- Infraorbital neuritis
- Excessive neck flexion by rider
- Equine protozoal myeloencephalitis
- Ill-fitting tack including bit and bridle
- Obstructive airway disease (heaves, laryngeal hemiplegia, epiglottic cysts, etc.).

Most cases of the disease are idiopathic despite intensive investigation of affected horses.[1] Photic head shaking is a common cause of the disease.[3] Most cases have some seasonal distribution, though the reason for this is undetermined. Trigeminal neuralgia is considered an important cause of the disease.[3]

EPIDEMIOLOGY

The epidemiology of the disease is not well defined. The syndrome occurs in horses throughout the world.[4] The syndrome is sporadic, usually affects only one horse on a farm, and does not occur as outbreaks. The syndrome has a seasonal occurrence in approximately 60% of horses with the majority first demonstrating head shaking, or being most affected, during spring and summer.[4,5] Head shaking is worst on sunny days and less severe on cloudy days, in approximately 60% of horses.[5] Seventy five percent and 80% of affected horses have less severe signs at night or when ridden indoors, respectively.[5]

Affected horses are usually mature adults with onset of head shaking at 7–9 years of age in over one-half of cases,[4,5] although signs can occur in horses as young as 1 year. The disease is reported twice as often in geldings as in mares.[4,5] There is an apparent predisposition to the disease in Thoroughbred horses[4] but this is not consistently reported.[5] Most affected horses are used for general riding, although this might represent an age effect because the syndrome tends to occur in older horses which are not used for racing.[5] There is no apparent association of temperament and risk of head shaking.

PATHOGENESIS

The pathogenesis of headshaking depends on the cause, but is assumed to involve the trigeminal nerve in most cases because of its role in sensory function of the nose and nasal mucosa.[2] Headshaking is related to exposure to bright light in some animals, a condition referred to as photic or optic-trigeminal summation because of its similarity to a syndrome in people. Trigeminal neuralgia is believed to cause acute, sharp, and intense pain in the face. Although this cannot be definitively diagnosed in horses, its presence is inferred from the horse's behavior and response to analgesia of the infraorbital or posterior ethmoidal nerves.

CLINICAL FINDINGS

The **clinical signs** of head shaking are unmistakable. Movements of the head are sudden and apparently spontaneous and involve lateral, dorsal, ventral, or rotatory movement of the nose usually during exercise. Horses rarely have the behavior only at rest, with most being affected both at rest and during exercise and about 10% exhibiting signs only during exercise.[4,5] The action often resembles that of a horse trying to dislodge something from its nose. Approximately 90% of horses have vertical movement of the head (as if flipping the nose).[5] The headshaking can be so severe as to cause lateral, dorsal, or ventral flexion of the neck to the level of the caudal cervical vertebrae, although more commonly on the rostral one-third of the neck is involved, if it is involved at all. Some horses rub their nose on objects, the ground, or their front limbs, sometimes during exercise. Affected horses often snort or sneeze. There can be twitching of the facial muscles and flipping of the upper lip. The movements are sudden and at times appear to catch the horse by surprise. The frequency and/or severity of movements are usually increased during exercise. Severely affected horses can stumble and fall if headshaking occurs during exercise, rendering the horse unsafe to ride.

A grading system to classify the severity of signs is[1]:

0. No signs of head shaking
1. Intermittent and mild clinical signs. Facial muscle twitching. Rideable.
2. Moderate clinical signs. Definable conditions under which head shaking occurs. Rideable with some difficulty.
3. Rideable to unpleasant to do so. Difficult to control.
4. Unrideable and uncontrollable.
5. Dangerous with bizarre behavior patterns.

This system might be useful for assessing response to therapy and concisely describing the severity of the signs.

Ancillary testing involves radiography of the skull; endoscopic examination of both nostrils and ethmoidal regions, nasopharynx, larynx, and guttural pouches; otoscopic examination of the external auditory canal and tympanic membrane (difficult to achieve in a conscious horse, a small endoscope is necessary); desensitization of the infraorbital and posterior ethmoidal nerves; biopsy of the nasal mucosa (in horses with suspected rhinitis); radiographic examination of the neck; and therapeutic trials including application of contact lenses or masks, or administration of medications (see 'Treatment').

CLINICAL PATHOLOGY

There are no characteristic hematologic or serum biochemical abnormalities.

NECROPSY FINDINGS

There are no characteristic findings on necropsy, apart from those of any underlying disease. Evidence of lesions in the trigeminal nerve is lacking.

DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from the stereotypic weaving that occurs during stabling and not during exercise.[6]

TREATMENT

The principles of treatment include relief of specific underlying diseases, removal of management or environmental conditions that cause head shaking, and administration of medications.

If underlying conditions are detected, such as ear mites, dental disease, and others listed under 'Etiology', then these conditions should be treated effectively. Effective treatment of these conditions will alleviate head shaking, if in fact the condition was the cause of the disease. However, most horses with head shaking have seasonal or photic disease and treatment is more difficult. A survey of owners of 254 horses with head shaking revealed that

only 129 horses had been treated by a veterinarian and, of those, only 6% had complete resolution of head shaking, whereas 72% had no response to treatment.[7] Other treatments used were on the advice of lay 'back specialists', homeopathy, alternative therapies or face or head masks. Success rates for these interventions varied between 6 and 27%, with the most success obtained by use of a nose net (27%).[7] Nose nets provided better control of signs than did face or eye masks. These figures on the success of treatment illustrate the refractory, and therefore frustrating, nature of the disease.

Fitting of **nose masks** alleviates or lessens head shaking in some horses.[7,8] The design of the nose mask does not appear to be important at least in regard to whether it covers the entire rostral face or just the nostrils.[8] The nose masks were most effective for treatment of up-and-down head shaking, but not for side-to-side or rubbing behavior.[8]

Blue tinted **contact lenses** have been suggested for use in horses with photic head shaking.[9] Others have not found this intervention useful.[4]

Sclerosis of the infraorbital or posterior ethmoidal nerves is performed in those horses that have reduced or eliminated head shaking after injection of local anesthetic into the infraorbital foramen or around the posterior ethmoidal nerve.[1] Sclerosis is achieved by injection of 5 mL of 10% phenol in oil.[1] Care must be taken to ensure that the phenol is deposited only around the nerve. The procedure should be done under general anesthesia.

Cyproheptadine (0.3 mg/kg, orally q12 hourly) improved head shaking in 43 of 61 horses, based on owner reported efficacy.[4] Responses were usually observed within 1 week of the start of therapy. Others have not replicated this success[1] but found that the combination of **carbamazepine** (4 mg/kg orally q6–8 hours) and cyproheptadine improved clinical signs in 7 horses within 3 to 4 days of starting treatment.[1]

Acupuncture and **chiropractic** manipulation appear to be minimally effective.[4,7]

Prevention of exposure to bright light is an obvious recommendation, but not practical for most horse owners.

CONTROL

There are no recognized measures for preventing development of the disease.

CONGENITAL NECROTIZING ENCEPHALOPATHY IN LAMBS

This condition is reported as the most common diagnosis of neurological disease in lambs under 7 days of age by VLA diagnostic laboratories in the north of England and is defined by its pathology.[1] Affected flocks have single or multiple cases with up to 10% morbidity in lambs of a flock. Cases have all come from ewes carrying multiple fetuses. There is variation in the clinical manifestations between sibling lambs. The most severely affected may be stillborn. Less severely affected lambs are born weak, are small, maybe unable to rise or show ataxia and head tremor. Some lambs survive but may have residual signs of cerebellar dysfunction. The common lesion is superficial cerebrocortical neuronal necrosis. A significant proportion also has necrosis of the Purkinje cells in the cerebellum and leucoencephalopathy of the thalamus and brainstem. It is possible that this syndrome reflects hypoglycemia consequent to negative energy balance in late pregnancy.

Diseases characterized by involvement of the musculoskeletal system

HYENA DISEASE OF CATTLE

Hyena disease of cattle occurs worldwide and is characterized clinically by a lateral body appearance similar to the hyena.[1,2] The cause is unknown but excessive intake of vitamins A and D may be contributing factors.

In some naturally occurring cases in yearlings from one large dairy herd approximately 1% of calves were affected annually. Affected calves had received vitamins A and D_3 immediately after birth, and from birth to weaning received the same vitamins from fresh milk, whole corn, a customized feed mix, and a milk supplement.[2] The mean daily intake of vitamin A from birth to 6 weeks of age was approximately 80 000 iu and 6300 iu of vitamin D_3, and progressively less vitamin A and D_3 was fed from 6 weeks until weaning at 3 months. The National Research Council recommendations for daily vitamin intake are 2100 iu of vitamin A at birth, increasing to 6360 iu at 2 months and 330 iu of D_3 increasing to 990 iu over the same period.[2] Experimentally, the IM injection of vitamins A and D (2 000 000 iu and 300 000 iu, respectively) on the first day after birth followed by 30 000 iu/kg BW added to the milk replacer daily results in gross lesions in the proximal tibial growth plates in 3 weeks.[3] Excessive vitamin A and vitamin D_3 administration to young calves can cause hyena disease by suppression of the activity of differentiation and proliferation in chondrocytes and osteoblasts.[4,5] The administration of excessive amounts of vitamins A, D_3, and E to Holstein sucking calves can cause hyena disease characterized clinically by severe emaciation, generalized alopecia, dome-like cranial deformation, and high mortality.[6]

There is premature closure of the growth plates of the long bones resulting in a marked dissimilarity in growth and development between the forequarters and the hindquarters, the latter being comparatively underdeveloped. This gives the animal the classic contours of the hyena and this resemblance is heightened by a crest of thick, stiff bristles along the back in the midline. An aggressive attitude also develops. Affected calves are normal at birth and only develop the abnormality at 5–6 months of age. There is no apparent abnormality of sex hormones. The femur and tibia are shorter in affected than in normal animals. There are accompanying difficulties of locomotion with a tendency to fall sideways, and to frequently adopt a position of lateral recumbency. The gait is described as 'bunny-hopping'.

German Simmental, Charolais, Black Pied, German Holstein-Friesian, and German Red Pied cattle have been involved. Genetic analysis appears to indicate that the disease is inherited as a simple recessive with incomplete penetrance but this is obviously not so in some herds.

The lesion is a chondrodystrophy affecting particularly the long bones and the lumbar vertebrae. Gross examination and radiography of the longitudinal slabs of the humeri, tibias, and femurs reveal focal to almost complete closure of the physes and physes subjected to compression are affected more than those subjected to tension.[2]

ASYMMETRIC HINDQUARTER SYNDROME OF PIGS

This condition was first reported in Germany[1] and Belgium[2] and was recognized in the UK in 1968 and reported later.[3] In these cases perineurial fibrosis was a feature and it was thought that the condition resulted from either a neurogenic atrophy or a periarticular fibrosis extending to the peripheral nerves. There is variable asymmetry of the hindquarters which is generally evident during the early grower period and obvious by 80 kg liveweight stage. An asymmetrical distribution of subcutaneous fat is also noted and possibly skin dimpling.[4,5] The muscle most frequently affected was the *M. semimembranous*, followed by the *M. semitendinosus*, *M. biceps femoris*, *M. adductor femoris*, and *M. gracilis*. The muscles show changes that can be described as myofibre degeneration, interstitial fibrosis, and dystrophic changes. Several breeds, including Landrace, Large White, and Hampshire have been found affected but the problem is generally restricted to certain herds and to certain families within these herds, suggesting that a genetic liability exists for this condition.[2] The mechanism of inheritance studied from test matings is not simple.[3] Whatever the cause, there is a marked reduction in the number of muscle fibres. Both sexes may be involved and the condition may involve either hindlimb. Despite a marked reduction in muscle mass there is no detectable abnormality in gait. The cause is unknown, although it appears to result from suboptimal muscle growth rather than degenerative loss.[6] In the only cases recorded from outside Europe a group of 7 Australian pigs were examined in detail[7] and in one of these the affected *M. semitendinosus* weighed only 41% of the normal unaffected one. Perineural fibrosis and myopathy have been observed in some cases but have not been found consistently.[6]

SPLAYLEG SYNDROME IN NEWBORN PIGS

This syndrom is also called spraddle leg, but more usually myofibrillar hypoplasia. This may be an erroneous term as this hypoplasia occurs in many normal pigs and may be a normal feature of post-natal muscle growth. This clinical condition of splayleg occurs in newborn piglets in most countries and is characterized by a temporary inability to stand with the hindlimbs.[1]

ETIOLOGY

The etiology is unknown, but based on epidemiological evidence it is multifactorial.[1] The current hypothesis is that the disease is caused by an interaction of genetic and non-genetic factors, a polygenic mode or expression of many genes without dominance.

The studies of Czech workers[2,3] have suggested that the pathomorphology of the condition resembles that of glucocorticoid induced myopathy in man and animals.[4] Dexamethasone given to minisows from the first to the last days of pregnancy produced in newborn piglets a disorder characterized by the splayleg syndrome with retardation of both muscle growth and myofibillogenesis.[3,5] It has also been experimentally produced following the administration of pyrimethamine.[6]

EPIDEMIOLOGY

The prevalence of the disease in the UK is 0–4% and the morbidity in affected herds varies from 2 to 27%. The case fatality rate is approximately 50% and is due to crushing, chilling, and starvation because affected piglets are not able to move around normally. The disease is more common in the Pietrain, Welsh, Landrace, and Large White breeds of swine; Landrace pigs may be especially susceptible. This suggests a genetic basis, but test-matings, with the exception of a few, have not been successful in reproducing the disease.[1] On most farms the disease affects both male and female piglets. In a recent retrospective analysis of the incidence of the disease in a swine herd over a period of 5 years, the overall frequency was 1.74 times more in males than females and the birth weight of splayleg piglets tended to be subnormal.[7] The environmental factors which have been associated with some outbreaks include slippery floors, a dietary choline deficiency and the ingestion of **Fusarium toxin** by pregnant sows. Choline deficiency is unlikely to be a factor[8] and none of the other factors have been substantiated as etiological factors or epidemiological determinants.[1]

PATHOGENESIS

The pathogenesis of the disease is unclear. In affected pigs there is myofibrillar hypoplasia[9,10] but this is also a feature of many muscles in normal pigs. There are simply too few maturing type 1 fibrils in the muscles, particularly of the foreleg, lumbar epaxial group and the hind limb to carry weight. The *Mm semitendinosus* appears to be the worst affected muscle. However, because myofibrillar hypoplasia may also be present in normal unaffected littermates[1] it has been difficult to explain the pathogenesis of the muscular weakness. The use of morphometrics has enabled the detailed determination of the myofibrillar hypoplasia.[11] In addition to myofibrillar hypoplasia, in splayleg pigs there is a higher content of sarcoplasmic RNA, reflected ultrastructurally by the presence of numerous ribosomes.[12] The extramyofibrillar space was also filled with glycogen in splayleg pigs.[13] In myofibrillar hypoplasia induced with glucocorticoids given to the pregnant sow, none of the pigs had splaylegs but the extramyofibrillar space contained little glycogen. There were also many glycogen-filled phagosomes and residual bodies which indicate a difference in the metabolism of glycogen in the first 2 or 3 days after birth. In a study of natural cases there was hypoplasia but there was an increased accumulation of glycogen especially within the large extramyofibrillar spaces in comparison with the normal pigs.[14] These authors also found an anomalous distribution of glucose-6-phosphatase in splaylegged muscles in that the activity was concentrated at the periphery of the extremely dilated cisternae of the sarcoplasmic reticulum. In the normal muscles this enzyme activity was normal. This distribution could account for the slower utilization of glycogen in affected muscles and therefore would account for the build up.[14] Quantitative image analysis of skeletal muscle revealed that the arrangement of the myofibrils within the fascicles of affected and unaffected pigs was different.

Some studies have found both quantitative (hypoplastic-type) and qualitative (dystrophic-type) insufficiencies in affected pigs which represent a temporary perinatal developmental disturbance. This could explain the muscular weakness and the recovery which occurs.

CLINICAL FINDINGS

Larger litters may be more affected possibly because these tend to be born earlier. The clinical signs are usually obvious in 2–3 hours after birth when the litter should be standing and walking around the creep area. Affected piglets are unable to stand, and their hindlimbs are splayed sideways or forwards and the animals are resting in sternal recumbency. Sometimes the fore limbs are also splayed. Most severely affected piglets are unable to move; less severely affected animals are able to move slightly. Many pigs have soiled hindlimbs and perineum as a result of being unable to stand. As a result, the piglets are likely to be crushed or have difficulty gaining access to their source of

nourishment. Affected piglets are normal in other respects and have a normal appetite and will suck the sow if placed near a teat. In the experimental induction[5] there was hypoplasia but there were no clinical signs, which is further evidence for suggestions[15] that the condition has a threshold for clinical signs and has strong maternal influences.

TREATMENT

Treatment can be successful.[16] If the pigs are able to suck or if they are fed artificially for 2–4 days, recovery will occur within 1 week in about 50% of cases. The ambulatory capacity of affected pigs can be improved, and mortality reduced, by taping or loosely tying together the hindlimbs for a period of up to 1 week. The method of loose tying of the hindlimbs consists of a figure-of-eight bandage (2.5 cm wide adhesive tape) being fixed around the metatarsal bones, leaving a space between the legs of up to 7 cm depending on the size of the piglet. The legs should be tied together within a few hours after the syndrome is obvious; a delay of several hours will decrease the prognosis. The provision of a non-slip floor surface such as a carpet or sack may also be helpful. Many farmers will tell you that repeated massaging of the limbs will also improve the survival rate.

CONTROL

Whether or not to cull the boar depends on the pedigree value of the animal, the incidence of the disease, and the probability that the boar is responsible. There is no evidence that the disease is monogenic. However, the incidence is highest in the Landrace breed, which suggests a hereditary predisposition. In deciding whether to use a suspected carrier animal, there is a need to distinguish between different situations. The consequences of disease are felt differently at the different levels of organization of the pig industry. A boar of high merit for performance traits may be more economical to retain as breeding stock even though some progeny are affected with the disease than a less superior boar whose progeny are unaffected. If stress of the pregnant sow is a factor, control of the disease may be dependent upon the selection of stress-resistant boars and sows.

Concurrent disease should be controlled as producers will tell you that after a period of PRRS infection they had a higher percentage of splayleg piglets. There are also suggestions that induced early farrowing and zearalenone poisoning may also be complicating factors to prevent.

DEGENERATIVE JOINT DISEASE (OSTEOCHONDROSIS, OSTEOARTHROSIS, EPIPHYSEOLYSIS AND APOPHYSIOLYSIS, LEG WEAKNESS IN PIGS)

Leg weakness in pigs is a very loose term which includes a wide variety of conditions and is best discarded. In Finland 15% of gilts are culled due to leg weakness.[1] Degenerative joint disease would be a much better general term to describe the lameness of young rapidly growing pigs affected with a non-infectious joint disease which includes osteochondrosis (OC), epiphyseolysis, and degenerative osteoarthrosis (OA). The disease is characterized by varying degrees of intermittent but progressive lameness in rapidly growing pigs from 4 to 8 months of age, and pathologically by the presence of OA and OC. The disease is of major economic importance because of the high culling rate of breeding age swine.

Synopsis

Etiology The cause is unknown.
Epidemiology Occurs in majority of breeds of rapidly growing pigs and young breeding females and males. Lesions are commonly present at slaughter. May be related to nutrition and rapid growth rate, genetic predisposition, and type of flooring but no reliable correlations.
Signs These may be no clinical findings or possibly lameness and inability to breed.
Clinical pathology Radiographic evidence of osteochondrosis.
Lesions Osteochondrotic lesions of varying degrees of development, severity and healing.
Diagnostic confirmation Lesions at necropsy.

Differential diagnosis list
Other causes of lameness include:

- Polyarthritis due to infectious causes
- Laminitis
- Nutritional osteodystrophy due to calcium, phosphorus, and vitamin D imbalance
- Hypovitaminosis A causing hindlimb paresis.

Treatment None.
Control Uncertain. Select breeding stock with sound legs and gait.

ETIOLOGY

The cause of the articular abnormalities is not known. The etiology and factors underlying these syndromes are poorly defined, partly because of the difficulty of definitive clinical examination of affected pigs and the frequent lack of apparent significant pathological changes in necropsy examination of mild cases. There are no specific associations between degenerative joint disease and infectious diseases.[2]

EPIDEMIOLOGY

Occurrence

Recently, a study of 9411 newborn piglets showed that 9.8% were treated for lameness. For parity 3 sows, the level had risen to 11.4%, but by parities 4–7 only 8% were treated. The treatments were in pigs of less than 3 weeks of age in 73% of the cases. Litters with 12 or more pigs had the highest incidences of lameness.[3] Osteoarthritic changes are strongly associated with osteochondrotic changes in the humeral and femoral condyles.[4] Osteochondrosis has been recorded as early as 1 day of age so the lesions may be congenital. There may be some degree of change in up to 85% of pigs.

The intensification of the swine industry has required that pigs grow rapidly and with high feed efficiency. Under such intensified conditions, rapidly growing pigs develop lesions of the bones and joints, especially the femur. Most pigs near market weight have varying degrees of osteochondrosis (OC). Except for severe lesions, which usually occur in a relatively small proportion of the total population examined, the lesions seen at slaughter often have no detrimental effect on growth rate of pigs up to market weight. An advanced degree of OC however, can result in severe degenerative joint disease and lameness in breeding stock. It is not associated with adventitious bursitis.[5]

The disease occurs in both male and female pigs and the incidence of lame pigs can be as high as 20–30%. It is a particular problem in gilt and boar testing stations where it may necessitate slaughter of affected animals before the testing period is complete. The lesions develop

most commonly in growing pigs, particularly boars from 20 to 30 weeks of age, raised in confinement. The onset occurs when pigs are between 4 and 8 months of age which coincides with a period of maximal growth rate. The peak period of clinical manifestation is from the late grower stage until 18 months of age, although the effect of OA may carry through to the adult period. Extensive multicentric degenerative joint disease in adult sows and boars can cause severe lameness which often warrants euthanasia.[6] However, sows ranging in age from 1.5 to 3.0 years and culled for impaired reproductive performance, with no history of lameness may have lesions of the femoral condylar surface.[7]

Risk factors

Numerous risk factors contribute to the disease. They include nutrition and rate of growth, genetic, and breed predisposition, sex, type and quality of floor, and exercise and confinement. The pig carries 53–51% of its weight on the fore limbs and 46–48% on the hind but the weight supported on the hind is higher at 90 and 105 kg body weight.[8] In a study of gilts and sows in Denmark about 12% of gilts showed stiff locomotion but at some point 53% of gilts had at some time showed the same sign. Buck-kneed forelegs, upright pasterns, legs turned out wide, standing under position, and swinging hindquarters were associated with stiff locomotion or lameness. Weak pasterns on the hind feet were associated with stiff locomotion and lameness.[9] Weak pasterns on hindlegs and splayed digits on forelegs were associated with brisk movement (freedom from locomotor problems). The following leg weakness signs at the gilt stage were found to have a significant effect on the longevity of the sows: buck-kneed forelegs, swinging hindquarters, and standing under position on the hind legs.

Nutrition and rate of growth. The disease is associated with rapid early growth,[10] but it does not appear to be related to protein, vitamins A and D or calcium and phosphorus imbalance in the ration.[11] Maximal mineralization of bones is not necessary to prevent leg weakness. Only almost complete absence of calcium and phosphorus causes lameness. Disturbances of the Ca:P ratio below 0.5 or over 3.0 are necessary to produce lameness. Recently, it has been suggested that long-term acidosis may be associated, as bone is not formed as phosphorus is removed from the bone. In this context the acidification of pig diets has been suggested as a contributory cause. It has also been shown that the presence of deformed forelimbs is not associated with low levels of vitamin C in plasma.[12] Rapid growth, especially during the early period, was thought to have a significant influence on the occurrence[13] and there is also some breed variation in susceptibility. However, in some feeding trials of pigs from weaning to slaughter weight there was no direct effect of rapid growth rate on the incidence and severity of OC. In other feeding trials, average daily gain of gilts was an important factor in the severity of lesions of OC. Decreasing the rate of gain by restricting energy intake appeared to decrease the prevalence and severity of OC when gilts were slaughtered at 110 kg.[14] However it was shown that when pigs were fed waste food, and grew more slowly, they had an increased prevalence and score for OC when compared with pigs fed a commercial feed concentrate.[15] Decreasing the concentration of protein in the diet of gilts from 16 to 12% resulted in less longitudinal bone growth but did not decrease the incidence of OC.[16,17] A simple association between growth rate and the incidence or severity of joint lesions has not been consistently demonstrated and a reduction in growth rate of pigs does not control the disease. A significant favourable association between leg action and daily gain has been noted.[18] There has also been speculation that growth hormone could influence the development of lesions of OC by exerting a direct effect on differentiation and colonization of epiphyseal chondrocytes. There is no consistent relationship between the incidence of osteochondrosis and selection of pigs for lean tissue growth rate.[19] It may be simply that more feed means more growth which makes stress on developing cartilage worse and therefore predisposes to OC.

Genetic and breed predisposition. It has been proposed for many years that selection of pigs for increased growth rate resulted in a concomitant increase in the incidence and severity of musculoskeletal disease. Genetic studies indicate that the heritabilities of leg weakness are low to moderate (0.1–0.3).[20] A more recent study suggested from 0.01 to 0.42 for leg weakness and OC and that both are associated with production traits (lean% and backfat thickness).[14] Genetic analysis of the incidence of OC and leg weakness in the Swedish pig progeny testing scheme revealed a low to moderate heritability. Genetic control of leg weakness has been achieved by various researchers and thus inheritance is probably an important risk factor for this disease complex. The genetics of leg weakness have been described in Finnish Large White and Landrace populations.[21] Meaty breeds are worst affected including the Duroc and the Dutch and Swedish Landrace.

Osteochondrosis also occurs in cross-bred Wild boar-Yorkshire pigs with a genetically decreased growth rate, raised under the same conditions as finishing pigs.[22] The distribution and extent of OC was similar to that of purebred Swedish Yorkshire pigs. This suggests that it is not limited to rapidly growing pigs. Synovial bursae at the hock joints were higher in Large White pigs with straight or bowed hind legs and in Landrace with sickle shaped hind legs.[23] There are significant breed differences in the peri-articular and meniscal ossifications seen on X-ray.[24] Recently, the quantitative trait loci for locomotion and osteochondrosis-related traits have been identified in Large White x Meishan pigs.[25] Correlations between breeding values for longevity and for OC were low but significant, and in a favourable direction. Higher OC scores were associated with a higher risk of being culled.[26] It has been seen in wild boar in Slovenia.[27]

Sex. The differences in the incidence and severity of OC between the sexes of different breeds has also been analyzed. The degree of leg weakness and OC of one sex in a breed can neither be translated to the other sex within that breed nor to the same sex of another breed.

Type of floor. Insecure footing because of unfavorable floor surfaces and the presence of foot lesions may change the posture of the animal and cause local overloading of certain joints. The effect of the quality of floor has been examined and there is no clear evidence that hardness of floor contributes to an increased incidence of leg weakness associated with joint disease. However, the incidence and severity of joint lesions may be related to the duration of confinement in pigs confined individually. Exercise will prevent abnormalities such as bow legs, flexion of the carpus and sickle-legs from impairing the mobility of boars, but does not influence the severity of joint lesion. The milder syndromes of poor movement and lameness associated with defects in leg conformation in the grower stage are not necessarily associated with bone or joint lesions and may regress spontaneously or improve if affected pigs are placed on pasture. However, severe lameness at this age, and that which occurs in replacement stock and young adults is frequently associated with severe bone and joint lesions which may be irreversible. A recent study has looked at type of floor (solid floor plus straw, solid floor no straw, and fully slatted).[28] The slatted floors were worst for leg weakness and the floors with straw best. The different types of floor affected leg weakness and claw disorders differently.

Exercise and confinement. There is some limited evidence that high lean growth rate may predispose toward leg weakness under confinement rearing. Trauma during handling, penning, and transportation may be associated with a relatively high frequency of OC but the evidence is very limited.[29] A high stocking density had an adverse effect on 4 of the leg weakness signs (knock knees, turned out front or hind limbs, standing with the legs under the body).[28] A recent study of housing and treadmill training did not show any adverse effects on leg weakness.[30] It has even been seen in pigs on grass, on deep litter and in wild boar

Economic importance

In Scandinavia, breeding pigs culled because of lameness had a 100% frequency of OC or OA, and up to 40% of boars in a performance test station had osteochondrosis or osteoarthrosis.[6] A conservative estimate suggests that 3% of sows and 10% of boars are culled for unsoundness associated with OC and OA.[6] The hidden costs include a reduced pool for selection of high-performance boars and gilts, the maintenance of pigs which cannot be used for breeding, increased mortality among piglets crushed by lame sows, reduced feed intake and growth rate in lame pigs, and transportation costs of replacement stock.

PATHOGENESIS

The condition has been seen as early as 1 day and with age the lesions develop. The essential lesion is the necrosis of cartilage canals and surrounding cartilage.[31,32] They may be seen to be developing and healing at the same time. In growing animals, the superficial layer of joint cartilage is articular cartilage, and the deeper layer is epiphyseal cartilage which undergoes endochondral ossification as the animal matures. The articular cartilage persists in the mature animal while the epiphyseal cartilage becomes a layer of calcified cartilage and underlying subchondral bone. The cartilage of the physis is known as the growth plate and is involved in metaphyseal growth. The normal growth plate cartilage has a well-ordered structure with the chondrocytes of the proliferative and hypertrophic regions arranged into columns.

Osteochondrosis is a generalized disease in which there are focal areas of failure of endochondral ossification in the physeal (metaphyseal growth) and epiphyseal growth cartilages. The underlying defect may be an abnormality of the chondrocytes which do not undergo normal hypertrophic ossification. They accumulate rough endoplasmic reticulum, lipid droplets and mitochondria. The surrounding matrix contains deposits of electron-dense material which may prevent normal vascularization and therefore ossification. The hypertrophic region is disorganized and greatly extended compared to normal tissue.[33] The matrix surrounding the clustered chondrocytes is altered compared to that in normal cartilage.[34] The primary abnormality is an increased thickness of the joint cartilages combined with degenerative changes which result in infoldings and erosion of articular cartilages. Defects of the growth plates (physes) result in short deformed bones.

Pathologically, severe clinical cases are characterized by osteochondrosis and secondary degenerative joint disease especially involving the medial aspects of the larger joints, epiphyseolysis and lumbar intervertebral disc degeneration and spondylosis. Osteochondrosis has been used to encompass lesions involving the physes and the articular epiphyseal complexes. However, because of morphological changes that have been observed in growing pigs, dyschondroplasia is now the preferred term to be used generically and then qualified by the location and nature of the morphological description since the causes may be different.

Osteochondrosis occurs commonly in growing pigs at predilection sites of the medical condyle of the humerus and femur, the epiphyseal plates of the distal ulna and the femoral head and the intervertebral joints. The 6th–8th costochondral junctions may also be affected. It may heal spontaneously or it may progress to *osteochondritis dissecans* and OA. Its progression in either direction is influenced by local loading and by joint stability which depends upon joint shape and muscle and ligamentous support. The age-related changes and OC in the articular and epiphyseal cartilage have been described.[35] The cartilage increases with age up to 5 weeks and then begins to decrease in thickness. Deleterious influences such as defects in conformation, heavy muscling with skeletal immaturity, muscular weakness resulting from myofibrillar hypoplasia, myopathies or lack of exercise, inadequate flooring or even simple trauma may adversely affect this progression and lead to severe skeletal change.

Porcine synovial fluid contains both hyaluronic acid and chondroitin sulfate and the chondroitin sulfate-to-hyaluronic acid ratio is not influenced by relatively advanced stages of osteochondrosis. Treatment of lame boars with glycosaminoglycan polysulfate improves leg soundness score and results in an increase in the hyaluronic acid concentration of the cubitus joint synovial fluid, and an increase in the proportion of aggregated proteoglycans in the articular cartilage of the medial femoral condyle. It is suggested that the hyaluronic acid accounts for most of the viscosity of synovial fluid and for efficient lubrication of the joint.

Well-established lesions typical of OC associated with the physes can be found in young pigs between 25 and 30 days of age.[6] The earliest change associated with a dyschondroplasia of the physis is a focus of persistent hypertrophied chondrocytes which do progress but heal. Lesions associated with physes and articular epiphyseal complexes develop continuously and regress as pigs grow older. Changes in cartilage canal vessels appear to be important in the pathogenesis.[36] There is no evidence that vascular damage is a factor in the pathogenesis of the lesions.

Because foci of dyschondroplastic lesions are associated with physes of pigs between birth and the stage of rapid growth, they could be regarded as part of the usual growth patterns in contemporary commercial swine. However, clinical signs of dyschondroplasias, or degenerative joint disease secondary to dyschondroplasias, usually do not appear until pigs are almost 6 months of age.

Radiological monitoring of lesions

Osteochondrosis can be diagnosed radiologically.[13] Radiologically the lesions were similar in Yorkshire, and Landrace[37] but more severe in the Landrace and similar to the Danish Landrace.

The development of epiphyseal osteochondrosis in pigs from 42 to 147 days of age has been followed radiologically.[38] Osteochondrotic lesions were seen radiologically in the articular-epiphyseal (A–E) complexes of the humeral condyles of 42-day-old pigs and in the femoral condyles at 63 days of age in contrast to earlier reports which indicated that lesions were not visible radiologically until 100 days of age. The osteochondrosis lesions of the A–E complexes develop, become progressive, and subsequently become either stable, regressive, or even more progressive as the pigs grows. This supports the observations that the lesions develop and become progressive and regress as the pigs grow. The humeral medial condyles have more pronounced lesions and are more frequent than the lateral ones.

Radiological monitoring of the development and sequelae of physeal osteochondrosis lesions of the growth plate cartilage and A–E complexes of the fore and hind limbs in young breeding swine found that the majority of distal ulna lesions healed by 18–20 months and some started fusing at 18–21 months. The distal ulna healed without complications in most animals and the most severe lesions healed faster than the mild or moderate ones.[38] In a recent study periarticular ossifications at the elbow joint

were found in the radiographs at a prevalence of 0.9%.[4] Meniscal ossifications were seen as single or multiple foci at the cranial aspect of the joint at a prevalence of 2.6% and had a bilateral occurrence of 20%.[4,39] Meniscal ossifications were associated with hind legs turned out and stiff locomotion in the hind leg and negatively associated with growth rate.

CLINICAL FINDINGS

The syndrome is called leg weakness and varies in severity from locomotor abnormality that results from conformation and leg defects such as narrow lumbar area and broad hips, hyperflexion of the carpus, bowing of the forelimbs and 'knock knees', hyperextension of the phalanges, lateral angulation of the foot and sickle hocks to more severe lameness and, in the extreme, inability to rise and paresis. Nine leg weakness signs were described.[28] The signs listed include buck kneed forelegs, steep hock joints, fore and hind limbs turned out, upright pasterns on the hind legs, stiff locomotion, standing under on the hind limbs, swaying hindquarters, goose stepping hind legs, lameness and tendency to slip,[4] and the four most common signs were buck knees, small inner claws on forefeet, small inner claws on hind feet, and upright pasterns on the hind legs.[4,40]

The clinical syndrome is a locomotor disorder usually involving the hindlimbs. Often the most rapidly growing pigs are lame. The lameness may be acute, intermittent, chronic, progressive, or a combination of these. An insidious onset is common, and pigs are unwilling to move, the stride is shortened, and the limbs are held in partial flexion. The carpal joints may be under extended, the metacarpophalangeal joints are overextended, giving the limb an abnormal S-shaped profile.[6] The pelvic limbs are commonly held straight and the back is slightly arched. In some cases, affected animals will assume a kneeling position with flexed carpal joints and walk on those joints.

Mild cases show stiffness, especially immediately after a period of lying down and lameness. Slowness to rise and a tendency to walk with short steps on tiptoes frequently in association with a marked inward curve of hindlimb motion during forward progression and side-to-side motion of the buttocks is frequently seen. More severely affected pigs sit on their hindquarters and are reluctant to stand. They carry one or both hindlimbs more forward under the body and walk with a short goose-stepping gait. Wasting is not a feature except in severely affected animals and the locomotor disorder may be minor unless exacerbated by physical exertion.

The syndrome is of particular importance in breeding animals where it may interfere with successful mating. Boars may show initial interest in mounting but subsequently slide off the sow or dummy before mating is complete, presumably due to the pain of the limb lesions. In Europe this problem has been called *impotentia coeundi*.

There may be no meaningful association between visual scores for physical soundness in the live animal and the degree of joint damage.[41] Some pigs with severe lesions are not lame and conversely other pigs are severely lame with minor lesions. Epiphyseolysis of the femoral head produces severe unilateral lameness and if bilateral is usually manifest by marked reluctance to rise and severe locomotor disability. Initial signs are frequently deceptively mild and follow physical exertion such as mating, transport, farrowing, or fighting but they progress to severe lameness over a 7–10-day period.

Epiphyseolysis of the tuber ischii (Apophysiolysis) may also occur following physical exertion but is more common in second or third parity sows and is manifest by 'paralysis' with the hindlimbs in forward extension under the body of the sow.[42] These animals 'dog sit', and are unable to rise. In many instances the injury occurs when the animals arrive on the farm or are first mated.

Because of the pain and muscle contraction, it is frequently difficult to determine the site and severity of the lesion by simple clinical examination, and palpation following general anesthesia or radiography may be required for proper clinical assessment. Physical examination should include complete palpation of all limbs for warmth, swelling, and pain. The palpable parts of the pelvis should be examined with particular emphasis on the ischial tuberosities. Passive flexion, extension and rotation of each limb along with auscultation over the joint may reveal evidence of crepitus or a pain response.

While the lesions of the physes and articular epiphyseal complexes are detectable in pigs under 14 days of age they are not detectable radiographically in live animals until the pigs are over 100 days of age. Only 21% of the lesions associated with the physes and 22% of the lesions associated with the articular epiphyseal complexes were detectable in radiographs of bones of live pigs.

Meniscal ossifications were observed as simple or multiple small smooth firm and irregular swellings in the cranial horn of the lateral meniscus.[24] The peri-articular osseus foci were seen as focal firm swellings at the cranio-medial aspect of the elbow joint.[24]

CLINICAL PATHOLOGY

The carpal, elbow, tarsal, and stifle joints can be radiographed for evidence of joint lesions, and the lesions scored according to a system.[38] It is also possible to use ultrasonics for diagnosis.[43]

NECROPSY FINDINGS

The histological, radiological, and angiomicrographical findings of dyschondroplasias of the growth cartilages in crossbred commercial pigs at 1 and 15 days of age have been described. The bone lesions in clinically normal and lame pigs have been described.[44,45] The scapulohumeral, humeroradioulnar, carpal, coxofemoral, femorotibial, and tarsal joints should be examined. Typically, in osteochondrosis, the changes are feathery hypertrophy of villi, focal full-thickness cartilage buckles, ulcers of flaps, and no change in the draining lymph node. Joint mice and synovitis may also be seen. Deformation may take place in the long bones or even fractures. Histologically, osseus trabeculae may be seen with clusters of chondrocytes, and between the trabeculae lined by flat osteoblasts there are adipocytes. The osseous center was formed of mineralized cartilage that blended into more or less fibrous cartilage but towards the joint cavity the meniscal ossifications were covered by hyaline cartilage.[24]

Occasional cases involve the patella in breeding age pigs.[16]

The ultrastructural characteristics of normal epiphyseal cartilage of the articular epiphyseal cartilage complex in growing swine has been examined and found to be different from the articular cartilage and the cartilage of the physis.[46] Histochemical techniques are now used to characterize lesions of osteochondrosis and the lesions associated with articular-epiphyseal cartilage complexes should be considered as different entities.[35] Osteopenic lesions have been described.[47]

DIFFERENTIAL DIAGNOSIS

The syndrome must be differentiated from other diseases which cause lameness and paralysis in growing and young adult pigs which includes: infectious polyarthritis, laminitis, traumatic foot lesions, foot lesions produced by biotin deficiency and footrot, osteodystrophy resulting from calcium, phosphorus and vitamin D imbalance in rations, vitamin A deficiency and viral encephalomyelitis.

TREATMENT

There is no effective treatment. Early cases may recover spontaneously after being placed outside on pasture or housed individually inside on deep straw litter. Recently, it has been suggested that meloxicam at a dosage of 0.4 mg/kg is

efficacious and safe for the treatment of non-infectious locomotor disorders in pigs. Treatment with 2,5-D vitamin D had no effect on the incidence and severity of OC/OA lesions.[48] Animals that are affected with clinical signs should be removed from the herd quickly and, if necessary, should be humanely destroyed as soon as possible.

CONTROL

Because the etiology is unknown, it is not possible to provide specific control measures. The hereditary nature of the disease suggests that the selection of breeding stock with sound legs and a low incidence of lesions would be an effective long-term control measure. Genetic control of leg weakness has been documented by various researchers.[41] Selection of boars for leg soundness has dramatic effects on the structural soundness of their crossbred progeny and therefore selection of structurally sound replacements must be maintained if leg weakness in market or breeding pigs is to be avoided.[49] Divergent selection for leg soundness in Duroc pigs has been dramatic.[49] Progeny of leg-soundness sires had significantly better measures for all leg traits at 104 kg than did progeny of leg-weakness sires.[35] Differences between the two progeny groups indicated that the realized heritability for front leg soundness exceeded 0.50.[35]

Selection of breeding stock will require careful genetic selection, examination of all pigs which are to be retained for breeding, necropsy of siblings of affected pigs and of the same gender, to identify genetic lines of pigs which have a low incidence of lesions. A recent study showed that the increase in wild boar alleles in crosses with Large White pigs reduced the prevalence of OC.[50] It has been suggested that the selection of pigs based on the joint lesion score could lead to a better leg and joint condition both optically and pathologically.[51] The reduction of growth rate and exercise may help but are not a real method of control. Increase in calcium and phosphorus in the diet also does not help.

SPORADIC LYMPHANGITIS (BIGLEG, WEED)

This is a non-contagious disease of horses characterized by acute fever, lymphangitis and severe swelling of one or both hindlegs – forelimbs are rarely, if ever, affected. The disease commences abruptly with fever (40.5–41°C, 105–106°F), shivering and a rapid pulse rate and respiration. Pain in the acute disease can be severe. There is severe pain on palpation of the affected leg and lameness may be so severe that the horse may refuse to put its foot to the ground. The limb is swollen and hot; the swelling extends from the top of the leg and down to the coronet. There is cording of the lymphatics on the medical aspect of the leg and palpable enlargement of the lymph nodes in some horses. The acute disease resolves into a chronic phase with persistent and variable swelling of the leg, intermittent fever, and variable lameness. Occasionally abscesses develop in the lymph nodes and vessels but usually there is no localization of the infection. There is a tendency for the disease to recur and cause chronic fibrotic thickening of the lower part of the limb extending to the level of the stifle in many horses. Swelling of the leg is often exacerbated by late pregnancy.

Sporadic lymphangitis can be associated with superficial wounds and ulcers on the lower parts of the limbs, but often there are no wounds detected. The disease is thought to develop as a lymphangitis and, potentially, lymphadenitis of the deep inguinal nodes as a result of these wounds. The affected lymph nodes and swelling of the limb obstruct lymphatic and venous drainage causing lymphatic obstruction, edema and, in some cases, cellulitis.[1] Ultrasonographic examination reveals distended lymph vessels that contain fluid that is not echogenic. Ultrasound guided aspiration of this fluid yeilds fluid with a low total protein concentration and mild neutrophilia (high proportion of the cells present in the fluid are neutrophils, although the absolute count is usually less than 1.0×10^9 cells/L. Culture of the fluid is recommended, and *Actinobacillus* sp. have been obtained. The clinical significance of results of culture of the fluid is unknown, but results could be used to guide choice of antibiotics. Radiographic examination is usually unremarkable apart from demonstrating the soft tissue swelling. Affected horses, in both the acute and chronic stages, have a mild neutrophilia and hyperfibrinogenemia.

Acutely affected horses should be treated aggressively. The principles of treatment are control of the presumed infection, reduction of inflammation, and reduction of swelling. Penicillin or other antimicrobials should be administered parenterally to control the infection. Non-steroidal antiinflammatory drugs (phenylbutazone, flunixin meglumine, carprofen, or similar) should be administered to

control the inflammation and provide pain relief. The limb should be hosed with cold water once to twice daily to reduce heat and provided with gently massage therapy. Manual massage of the limb might be beneficial. Supportive, compressive bandaging of the limb can reduce the swelling. The horse should be exercised as much as is practical and humane.

Horses with chronic disease should be treated with prolonged courses of antimicrobials (penicillin, sulfonamide-trimethoprim combinations, enrofloxacin, or rifampin in combination with sulfonamides-trimethoprim), non-steroidal drugs, and local therapy. Acute exacerbations can be managed by administration of dexamethasone (40 µg/kg orally or parenterally, once daily for 5 days, and then gradually tapering). This dose is not abortifacient in pregnant mares. Exercise and supportive bandaging are important in minimizing the swelling. The chronic disease requires prolonged and intermittent therapy, often for the rest of the horse's life.

Prevention of the disease necessitates prompt and careful treatment of all wounds of the lower limbs. Provision of daily exercise, restriction of the diet during prolonged rest periods and dry standing in the stable also help to prevent the disease.

LAMINITIS OF HORSES

Synopsis

Etiology Degeneration of the sensitive laminae of the hoof.
Epidemiology Disease involving single animals. As a sequela to severe systemic disease including colic, diarrhea, metritis, and grain engorgement. Horses or ponies at pasture. Horses worked on hard surfaces. Obese horses and ponies. Horses with unilateral lameness may develop laminitis in the contralateral, supporting limb.
Clinical signs Lameness, ranging from mild to sufficiently severe to cause the horse to be recumbent, involving both front feet, and occasionally all four feet.
Clinical pathology None characteristic of the disease.
Diagnostic confirmation Physical examination. Radiography.
Treatment There is no single effective treatment. Non-steroidal anti-inflammatory drugs, dimethyl sulfoxide, vasodilatory agents, anticoagulants, frog and sole support, and corrective hoof trimming and shoeing are all used with variable success.
Control Prophylaxis for acute, severe diseases. Aggressive treatment of metritis, colic and diarrhea. Prevent unrestricted access to feeds rich in soluble carbohydrates. Maintain optimal body condition.

ETIOLOGY

Laminitis is caused by **acute degeneration of the sensitive primary and secondary laminae** of the hoof. The cause of this degeneration is unknown although a number of theories have been propounded and are summarized under 'Pathogenesis'. Situations that are associated with increased risk of laminitis include access to lush pasture (suspected as the cause in 46% of field cases), grain overload (7%), retained placenta (2%), and colic or diarrhea (3%).[1] Ingestion of large quantities of soluble carbohydrate, such as grain, bread, calf feed, or exposure to shavings of black walnut (*Juglans nigra*) causes laminitis.

EPIDEMIOLOGY

Occurrence

Single sporadic cases are the rule for **horses** in which the disease is usually related to individual risk factors such as obesity, systemic illness, or lameness. An estimated 13% of horse operations in the United States have a horse with laminitis at any one time, and laminitis accounts for 7.5 to 15.7% of all lameness in horses.[1] Laminitis accounts for up to 40% of hoof problems in horses, depending on the use of the horse.[1] Approximately 5% of horses with laminitis die or are euthanized.[1] Among cases occurring in the field (as opposed to veterinary hospitals) approximately 74% recover and become sound, with 8% improving but continuing to be lame.[1] However, approximately 10% of horses that developed laminitis had a permanent change in their primary use as a result of having developed laminitis.[1]

Risk factors

Animal risk factors

With the exception of overweight ponies and horses with systemic disease, there are only a few identified innate factors that predispose individual horses to the development of laminitis:

- Any association between the disease and age, sex or breed is weak, again, with the exception of ponies.[2] There is no difference in risk among horses used for pleasure riding, showing, breeding, racing, or farm and ranch work.[1]
- The disease is more common in the United States during spring and summer (1.3% in spring and 0.4% in winter in the central US).[1]
- The disease is very uncommon in foals and horses < 8 months of age, and then increases in frequency with increasing age such that horses >20 years of age have an incidence of the disease roughly 3 times that of horses between 5 and 20 years of age.[1]
- **Overweight ponies** appear to be most susceptible and the disease occurs four times as commonly in them as in other classes of horse.[3] Fat ponies at pasture and getting little exercise commonly develop the chronic form of the disease.
- Laminitis is common in horses with tumors of the intermediate lobe of the pituitary (pars intermedia dysfunction, equine Cushing's disease).

Trauma and other physical factors such as excessive work on hard surfaces, increased weight bearing on one limb, and persistent pawing contribute to the development of the disease in horses. Standing for periods of days during transport may predispose to laminitis. For horses that are severely lame, and not bearing weight in the affected limb, the risk of developing laminitis in the contralateral limb is related solely to the duration of lameness and not to body weight.[4]

Laminitis is associated with many **systemic illnesses** of horses. Horses with illness attributable to colic, diarrhea, pleuropneumonia, and metritis are prone to develop laminitis. **Potomac horse fever** (equine neorickettsiosis) is frequently a cause of laminitis in horses and laminitis is the major cause of mortality from this disease. Approximately 28% of horses with **anterior enteritis** (duodenitis/proximal jejunitis) develop laminitis, usually within 2 days of developing enteritis.[5] There are anecdotal reports that suggest that administration of **corticosteroids** (dexamethasone, triamcinolone) causes or exacerbates laminitis, but this association has not been proved. Laminitis is common in horses that engorge on grain or similar feeds containing a high concentration of soluble carbohydrates. Ingestion of large quantities of lush pasture has been anecdotally associated with increased risk of laminitis, especially amongst ponies. It is believed that the presence of a high concentration of soluble carbohydrates fructans in the grass is responsible for the increased risk of laminitis.[6] Fructans are metabolized in the large colon and may mimic the situation after ingestion of a large quantity of soluble carbohydrate.

Importance

Death is unusual, but the severe lameness may cause a great deal of inconvenience and affected horses may develop permanent deformities of the feet. Many have to be euthanized.

PATHOGENESIS

The basic lesion of laminitis is the separation of the sensitive laminae of the third phalanx from the interdigitating laminae lining the internal surface of the hoof, so that the third phalanx drops through the hoof and comes to rest on the sole. Exactly

what the mechanism is that links the risk factors listed above to the laminar degeneration, the basis of the separation, is unknown. Briefly, the theories are:

- Ischemia of the laminae with subsequent necrosis. Proposed causes of ischemia include vasoconstriction, development of arterio-venous shunts, interstitial edema, and presence of microthrombi in digital vessels.[7–13] Ischemia due to microthrombus formation is considered an unlikely cause of laminitis.[7,8] However, there is evidence from experimental laminitis that changes in circulating concentrations of vasoactive amines or contractile activity of vessels in the hoof might contribute to ischemia. Alternatively, increases in capillary filtration pressure, resulting from venoconstriction, might cause edema and increased interstitial pressure with subsequent ischemia of the laminae.[13] It is plausible that there is a combination of these mechanisms, beginning with digital venoconstriction and ending in arteriovenous shunting and development of microthrombi [14] There is evidence in horses with gastrointestinal disease treated by emergency celiotomy that endotoxemia after surgery is associated with lower digital blood flow and higher concentrations of endothelin-1, providing evidence for a role of decreased laminar blood flow in the pathogenesis of the natural disease.[15]
- Inflammation, with subsequent degeneration of sensitive laminae.[16–18]
- Enzymatic digestion of laminae by matrix metalloproteins (MMPs) induced by circulating factors including products of *Streptococcus bovis* infection.[19,20]
- Abnormalities in local (hoof) metabolism of corticosteroid resulting in increased glucocorticoid activity in lamellar tissues [21]

There is evidence of each of these mechanisms. The evidence is often based on experimental models of laminitis and the findings differ somewhat with respect to the model used and markedly with the stage of disease studied. More recent studies, focusing on the developmental stage before clinical signs are apparent, have identified evidence of inflammation associated with a marked increase in expression of cycloxygenase-2, an enzyme critical in the metabolism of vasoactive and inflammatory prostaglandins and inhibited by non-steroidal antiflammatory drugs.[16]

It is speculated that a **pain-hypertension-vasoconstriction** cycle develops in horses with acute laminitis. The pain associated with the laminar degeneration causes release of vasoconstrictor substances such as the catecholamines, angiotensin II, and vasopressin. These substances then cause peripheral vasoconstriction with a subsequent reduction in blood flow to the foot, and systemic hypertension.

The common thread is that degeneration of the sensitive laminae. Loss of the connection between the third phalanx and hoof allows the third phalanx to **rotate** within the hoof capsule, likely in response to the torque applied by the deep digital flexor tendon, and to displace ventrally (**sink**) within the hoof as a result of weight transmitted through the third phalanx; or there may be a combination of these changes. Rotation of the third phalanx causes the sole to be pushed downward or'dropped', and the point of the toe of the third phalanx may actually penetrate the sole. Serum accumulates in the space created by degeneration of the laminae and displacement of the third phalanx and there is breakdown of the white line.

Many of the inciting causes of laminitis are diseases that may be associated with **endotoxemia**, and in experimental models endotoxin was detectable in the blood of horses that developed laminitis, suggesting that endotoxin may contribute to the development of the disease. However, infusions of endotoxin do not cause laminitis, although endotoxin does impair endothelium-dependent relaxation and augments adrenergic contraction of palmar digital arteries.[22]

The disease occurs in 3 distinct phases: (1) a developmental stage in which lesions are detectable in the sensitive laminae but during which there are no clinical signs; (2) the acute phase from the development of the first clinical signs through to rapid resolution or to rotation or ventral displacement of the third phalanx; and (3) the chronic stage evidenced by rotation of the third phalanx with or without ventral displacement and characterized by variable but persistent pain.

CLINICAL FINDINGS

The disease presents as both an acute disease and as a chronic disease.The severity of the acute disease varies considerably from very mild with rapid (5–7 days) recovery, to severe with progression to the chronic, refractory stage.

The acute disease develops rapidly; apparently normal horses can founder within hours. Signs of the disease are entirely attributable to pain in the feet. All hooves may be affected, but more commonly the fore feet are affected and the hind feet are spared. The disease is rarely unilateral except in cases in which the disease develops because of severe lameness in the contralateral limb or repeated pawing. Mild, or early, disease is apparent as a resistance to movement and repetitive and frequent shifting of weight from one foot to the other. There is a characteristic shuffling gait.

More severe disease is apparent as refusal to move or to lift a hoof. At this stage the horse wears an expression of great **anxiety**, accompanied by **muscle fasciculation, sweating**, a marked increase in heart rate to as high as 75/min, rapid, shallow respiration, and a moderate elevation of temperature. There is a **characteristic posture** with all four feet being placed forward of their normal position, the head held low, and the back arched. There is usually a great deal of difficulty in getting the animal to move and when it does so the gait is shuffling and stumbling and the animal evidences great pain when the foot is put to the ground. The act of lying down is accomplished only with difficulty, often after a number of preliminary attempts. There is also difficulty in getting the animals to rise and some horses may be recumbent for long periods. It is not unusual for horses to lie flat on their sides. In occasional cases the separation of the wall from the laminae is acute and the hoof is shed. There may be exudation of serum at the coronet and this is considered a sign of impending sloughing of the hoof and a poor prognosis.

The diagnostic signs in laminitis include pain on palpation around the coronet and a marked withdrawal response when hoof testers are applied to the hoof. The **intensity of the pulse** in the palmar digital artery, palpable over the abaxial aspects of the proximal sesamoid, of affected feet is markedly increased over normal. In horses in which the third phalanx is displaced distally (sinks), a concavity may be palpable at the coronary band. Infiltration of the palmar digital nerves at the level of the proximal sesamoid with local anesthetic agents provides marked, but not complete, relief.

In the chronic stages of the disease there is separation of the wall from the sensitive laminae and a consequent dropping of the sole. The hoof wall spreads and develops marked horizontal ridges, and the slope of the anterior surface of the wall becomes accentuated and concave. Horses with chronic or refractory laminitis may continue to feel much pain, lose weight, and develop **decubitus ulcers** over pressure points because of prolonged recumbency. Loss of integrity of the sole and disruption of the white line may

allow **infection** to develop in the degenerate laminae. The infection may spread to involve the pedal bone, causing a septic pedal osteomyelitis. The lameness may abate but the animal becomes lame easily with exercise and may suffer repeated, mild attacks of laminitis.

Radiographic examination of the feet may not reveal, initially and in mild cases, changes in the position of the pedal bone. Radiographs of more severe or advanced cases will demonstrate **rotation of the pedal bone** within the hoof, evident as a tilting of the most distal aspect of the third phalanx toward the sole. The space created by rotation of the pedal bone may fill with gas or serum and be evident as a radiolucent line between the pedal bone and the dorsal hoof wall. **Displacement of the pedal bone** toward the sole will be evident in approximately 25% of cases as a thickening of the dorsal hoof wall and reduction of the distance between the sole and solar aspect of the pedal bone. Chronic or refractory cases may have **osteopenia** of the pedal bone with proliferation of bone at the toe.

Prognosis. The **radiographic examination** provides information of **prognostic value**. Horses that return to their previous level of athletic function after a bout of laminitis have pedal bone rotation of less than 5.5°, whereas horses that can no longer perform as athletes usually have more than 11.5° of rotation.[23] However, there is considerable overlap between groups and these values should only be used as rough guidelines. The general rule is that the greater the degree of rotation, the worse the prognosis for return to function and pain-free living.

Objective radiographic variables include the distance between the proximal aspect of the hoof wall (marked on the radiographic image by a piece of wire or strip of metal stuck to the dorsal hoof wall) and the proximal limit of the extensor process of the distal phalanx (the 'founder' distance), and the distance between the dorsal hoof wall and the dorsal cortex of the distal phalanx.[24] While values for these measures vary among breeds and with the size of the horse, most normal horses will have a 'founder' distance of 4.1 ± 2.2 (standard deviation) mm and a wall thickness of 16.3 ± 2.4 mm.[24]

CLINICAL PATHOLOGY

There are no changes that are characteristic of the disease.

NECROPSY FINDINGS

The disease is not usually fatal but if a necropsy examination is carried out on an acute case, the stomach usually contains excessive amounts of grain, which has a pasty, mealy consistency and an odor suggestive of putrefaction of protein. Retained placenta and metritis may be present in postparturient laminitis in mares. No other reliable gross findings are visible, although the vessels of the sensitive laminae of the digital cushion may appear engorged if the cut surface of the hoof is examined.

In subacute and chronic cases the diagnosis can easily be confirmed by gross examination of sagittal sections of the foot. This permits assessment of the horny, soft, and osseous components of the foot. In some cases the degree of rotation of P3 results in perforation of sole.

Histological examination is required only in acute cases and confirmation of the diagnosis in such instances demands that the foot be cut into slab sections and fixed shortly after the death of the animal, before even moderate autolysis can ensue. Microscopically, the sequence of acute changes in experimentally induced laminitis begins with the loss of some of the keratogenic structures of the epidermal laminae. This is followed by vascular engorgement, edema and some necrosis of laminar tissues.

DIFFERENTIAL DIAGNOSIS

Horses

Rhabdomyolysis, tetanus, colic, and spinal ataxia may all mimic the immobility and pain of laminitis, but there is no pain in the feet in these diseases, and other distinguishing characteristics are apparent on careful clinical examination.

TREATMENT

Acute laminitis is an emergency and treatment should be started without delay, as early and aggressive therapy might enhance the chances of recovery.

The adage 'where facts are few experts are many' (Donald R. Gannon) applies well to the treatment of laminitis. There are no well-designed studies of the treatment of naturally occurring laminitis and thus the choice of treatment is based on personal experience, extrapolation from our imperfect understanding of the pathogenesis of the disease, the availability of certain drugs, and current fashion. In general, the treatments can be grouped into several classes, based on the intended intervention. These are:

- **Removal of the causative agent or treatment of the inciting disease**
- **Pain relief and minimization of inflammation**
- **Vasodilation of blood vessels in the foot**
- **Prevention of formation of microthrombi in dermal capillaries**
- **Prevention of rotation or distal displacement of the pedal bone**
- **Promotion of keratinization and hoof growth.**

The efficacy of administration of analgesic, anti-inflammatory, anticoagulant and vasodilatory drugs, local therapy such as ice baths of the hoof or having the horse stand in cold water, and mechanical support of the hoof has never been demonstrated in appropriate clinical trials.

Treatment of inciting disease

The inciting disease should be treated aggressively and every attempt made to remove any causative agent. Horses with traumatic laminitis should be rested and housed in stalls that are well bedded with sand or soft shavings. Horses suspected of having a tumor of the intermediate lobe of the pituitary gland should have the diagnosis confirmed and appropriate therapy instituted.

Analgesics and anti-inflammatory drugs

A mainstay of the treatment of both acute and chronic laminitis is the use of non-steroidal anti-inflammatory drugs (NSAIDs). Apart from the obvious humane requirement of providing pain relief, the use of NSAIDs is speculated to be beneficial by breaking the pain-hypertension-peripheral vasoconstriction cycle that may be important in the pathogenesis of laminitis. Furthermore, recent evidence suggesting that inflammation mediated by COX-2 plays a role in the developmental phase of laminitis supports the early and aggressive use of NSAIDs.[16] **Phenylbutazone**, at doses of 2.2–4.4 mg/kg intravenously or orally every 12–24 hours, is an effective analgesic in cases of mild to moderate laminitis. Higher doses (6.6 mg/kg every 12–24 hours) may be required in severe cases. However, the potential for phenylbutazone toxicosis, evident as colic, gastrointestinal ulceration, nephrosis, hypoproteinemia, leukopenia, and hyponatremia, is dose related and high doses of phenylbutazone should only be used for at most several days and only in severely painful horses. **Flunixin meglumine** (1.1 mg/kg, IM or IV every 8–12 hours) and **ketoprofen** (2.2 mg/kg, IM every 12–24 hours) are also effective analgesics.[25] Their concurrent use with phenylbutazone may enhance pain relief but also increases the risk of NSAID toxicosis. The use of aspirin is dealt with under Anticoagulants.

Dimethyl sulfoxide (DMSO), a putative anti-inflammatory drug that is also reputed to scavenge free radicals, has been used in the treatment of acute laminitis, again without clear demonstration of its efficacy. DMSO is administered at a rate of 1 g/kg, intravenously as a 10% solution in isotonic sodium chloride. The treatment can be repeated daily for several days.

Narcotic analgesics such as butorphanol and meperidine (pethidine) provide some pain relief but in general are not as effective as the NSAIDs. Similarly, α-2 agonists such as **xylazine and detomidine** provide only brief respite from the pain, and may be contraindicated because of the vasoconstriction associated with their use.

Local analgesia of the foot with agents such as lidocaine or bupivacaine provides marked pain relief. However, analgesia is usually only brief, depending on the agent used, and has the disadvantage of causing the horse to bear more weight on the affected limbs. Local analgesia may be useful in facilitating relocation of the horse, hoof trimming, corrective shoeing, or application of sole and frog support but not as a routine treatment.

Because of suspicion that **corticosteroids** induce or exacerbate laminitis, at this time their use is contraindicated in the treatment of laminitis.

Vasodilatory drugs

Vasodilatory drugs are used on the premise that vasoconstriction is an important mechanism underlying the development or progression of acute laminitis. Several classes of drugs have been used including α-adrenergic antagonists such as phenoxybenzamine and phentolamine, drugs with multiple mechanisms of action such as acetylpromazine and isoxuprine, and nitric oxide donors including glyceryl trinitrate (nitroglycerine) and L-arginine.[26] None of the vasodilatory drugs should be used in horses with compromised cardiovascular function or dehydration.

Phenoxybenzamine and phentolamine are not readily available and have limited use. Phenoxybenzamine causes sedation. **Acetylpromazine** is a potent vasodilator, principally because of its α-adrenergic antagonist activity, that is currently used frequently in the treatment of acute laminitis. Acetylpromazine increases blood flow to the digit, but its effect on nutritive flow to the laminae is unknown, as is the case for all the vasodilators.[27] The effect of acetylpromazine persists for approximately 90 minutes after intravenous administration.[27] Acetylpromazine can be administered at dose rates ranging from 0.01 to 0.05 mg/kg, IM, every 6–12 hours. Sedation may be considerable at the higher doses and/or with more frequent administration. **Isoxuprine** is a combined α-antagonist and β-agonist that increases blood flow to the leg but not to the foot in normal horses.[27,28] It has been used at doses of 1–1.5 mg/kg orally every 12 hours. Pentoxyfilline (4.4 mg/kg orally q8 hours) does not increase digital blood flow in normal horses.[27]

Application of **glyceryl trinitrate**, a nitric oxide donor, to the palmar digital arteries of affected horses has been reported to increase or not affect blood flow to the dorsal hoof wall.[29,30] However, the effect of these substances on the course of the disease is unknown. In spontaneous cases of acute laminitis glyceryl trinitrate has been applied to the skin over both palmar digital arteries of affected feet at a dose of 15–30 mg per artery, once daily. However, because of lack of evidence of efficacy and the potential for systemic hypotension secondary to systemic absorption of the drug, its use is no longer recommended.

Anticoagulants

Anticoagulant drugs are administered to prevent the development of microthrombi within the hoof. **Aspirin and heparin** are commonly used. Aspirin is a very poor analgesic in horses but is used because it reduces platelet aggregation in normal horses by blocking formation of thromboxane A_2. However, thromboxane may not be an important cause of platelet aggregation in horses.[31] Aspirin is administered at a dose of 10 mg/kg orally every 48 hours.

Heparin in sufficient doses prolongs blood clotting, provided that there is adequate antithrombin III in the patient's blood. Heparin has been reported to prevent or to have no effect on the development of laminitis in horses with anterior enteritis or colic, respectively. Heparin can be administered at 40 to 80 iμ/kg IV or subcutaneously every 8–12 hours for 3–5 days. Anemia may develop during heparin administration, but resolves rapidly when administration of the drug is stopped.

Mechanical support

Mechanical support to provide pain relief and in an attempt to prevent rotation or distal displacement of the pedal bone is an important part of the care of horses with acute laminitis.

Support of the frog and/or sole can be achieved using packing material such as dental acrylic or firm plastic that is molded to conform to the shape of the sole. Some clinicians prefer to use **wedge pads** to elevate the heel and reduce tension in the deep digital flexor tendon with the aim of preventing rotation of the pedal bone.

Housing the horse on sand or other soft bedding is frequently recommended.

Corrective shoeing of horses with chronic laminitis is widely practiced and there are proponents of a wide variety of shoe types (fullered egg-bar, heart bar, glue-on shoes). Appropriate hoof care, which might include shoeing, is important in managing horses with chronic laminitis. Interestingly, there was not a difference among shoe types in efficacy for pain relief in horses with chronic laminitis.[32]

Promotion of healing

Methionine has been given to both acute and chronic laminitis cases on the known requirement for methionine in the chondroitin complex of collagen. There is some rationale for the treatment but it seems more appropriate as a supportive than as a principal treatment. The recommended oral dose rate is 10 g/day for 3 days followed by 5 g/day for 10 days.

Antibiotics may be indicated to prevent secondary infection of the degenerate laminae.

Rest is important in the convalescent phase. Horses with no rotation or sinking of the pedal bone should be given 21 days of rest after resolution of the clinical signs. Return to work should be gradual. Horses that develop rotation or sinking of the pedal bone should be monitored both by physical examination and radiographic examination. It will be many months before horses with even mild rotation can be returned to work. Horses with severe rotation will likely never resume active work, although they may become pasture sound.

Summary of treatment of acute laminitis

Depending on the cause, treatment of acute laminitis should include:

- The administration of non-steroidal anti-inflammatory drugs (preferably phenylbutazone)
- Vasodilators (acetylpromazine)
- Support of the frog and/or sole
- Housing on sand or similar soft bedding
- The inciting disease should be treated aggressively
- After the acute phase has passed, likely in 5–7 days, attention should be given to trimming the hoof and corrective shoeing.

Chronic, refractory laminitis

The **prognosis** for chronic or refractory laminitis (laminitis of more than 1 week's duration) is poor (see above for the use of radiography to determine prognosis). Treatment includes NSAIDs for pain relief, corrective shoeing (egg bar or heart bar shoes), and trimming of the hoof (shortening the toe or complete removal of the dorsal hoof wall). **Tenotomy** of the deep digital flexor may provide temporary relief but does not affect the long-term prognosis.

CONTROL

The disease is not readily subject to control because of its sporadic nature. Heavily fed or fat horses should be given some exercise when not working; if possible, horses in transit should be removed from the transport vehicle, given light exercise and rested for several hours at the end of each day; retained placenta in mares should

be treated promptly. Heavy carbohydrate feeding should be avoided. Susceptible ponies should have limited access to pasture either by limiting the time that they spend at pasture or by application of a grazing muzzle.

LAMINITIS IN RUMINANTS AND PIGS

Synopsis

Etiology Degeneration of the sensitive laminae of the hoof.
Epidemiology
Cattle: An endemic disease of some herds of high producing dairy cattle, and in feedlots. Associated with ruminal acidosis, either clinical or subclinical.
Clinical signs
Cattle: Inapparent to severe lameness, most common in the hind feet. Predisposition to other infectious or traumatic diseases of the foot.
Clinical pathology None characteristic of the disease.
Diagnostic confirmation Physical examination. Radiography.
Treatment
Cattle: Non-steroidal anti-inflammatory drugs. Corrective hoof care.
Control
Cattle: Dietary control to prevent ruminal acidosis. Correction of housing and flooring problems.

ETIOLOGY

Laminitis is caused by acute degeneration of the sensitive primary and secondary laminae of the hoof. The cause of this degeneration is unknown. The disease is less well characterized than that of horses and several conditions are often classified as laminitis.

EPIDEMIOLOGY

Occurrence

In **cattle** the disease may occur as clusters in herds and on farms where a predisposition appears to be inherited or where access to large quantities of soluble carbohydrate are available such as for high producing dairy cows or feedlot cattle. On farms of high-producing dairy cattle the prevalence may be as high as 78%.[1] The disease is also reported in calves and first calf heifers.

Risk factors

Cattle and sheep

Subclinical laminitis that predisposes to the development of other diseases of the hoof occurs in calves and first calf heifers and is common in intensively fed feedlot cattle.[2] Laminitis, conditioned by the inheritance of an autosomal recessive gene, is recorded in Jersey heifers.[3] There may be an association between the disease in feedlot ruminants and **ruminal acidosis**.

Beef cattle being prepared for shows are often grossly overfed on high grain rations and become affected with a chronic form of the disease which markedly affects their gait and may cause permanent foot deformity. The disease occurs in dairy cattle fed improper rations, and especially first calf heifers and cattle of herds attempting to increase milk production[1,4] and it is not uncommon for the disease to present as a herd problem.

Among **dairy cattle** the heifers are usually worst affected and the disease usually develops soon after calving, with more than 50% of cases occurring in the period 30 days before and 30 days after calving. There may be a relationship between being introduced to the herd, with the frequent harassment by dominant cows, when heavily pregnant and when the surface of the yards is rough. Housing may be important including standing in slurry or having to twist and turn in narrow passageways and races, and there is an association between the prevalence of the disease and rough concrete floors.[5,6]

Diet is an important risk factor for development of laminitis in heifers. Diets of wet, fermented grass silage are associated with a greater risk of laminitis than are diets rich in dry unfermented straw and a concentrate.[7] Furthermore, transition from a low net energy diet to a high net energy diet immediately after calving increases the risk of subclinical mastitis in Holstein dairy cows.[8]

The disease is also reported to occur after metritis, retained placenta, mastitis, and mammary edema but the incidence is not usually very high.

Pigs

Laminitis has been recorded in pigs but the disease is difficult to diagnose in this species and many cases secondary to other diseases, e.g. postparturient fever, may be missed. The disease is also recorded when pigs are fed very heavy concentrate diets.

Importance

Subclinical laminitis of dairy cattle predisposes to other hoof disease that may decrease milk production.

PATHOGENESIS

The pathogenesis of laminitis in cattle, sheep, and pigs is unclear, but likely has some similarity to that in horses (see Laminitis in horses). Subclinical laminitis can predispose to white line disease.

CLINICAL FINDINGS

Cattle and sheep

In these species the clinical picture is similar to but less marked than that observed in the horse.

In calves 4–6 months of age, and in heifers, an acute syndrome similar to that seen in the horse has been described. Affected animals lie down much of the time, and are reluctant to rise. When they attempt to rise they remain kneeling for long periods. Their standing posture is with all four feet bunched together and the back is arched; they shift their weight from foot to foot frequently and walk with a shuffling painful gait. The feet are painful when squeezed and later become flattened and enlarged and look as though slippers are being worn. There is severe ventral rotation of the third phalanx.

In adult cows some cases have acute signs, others show only local lesions. These include sole ulcers and patchy changes in the horn including softening, waxy yellow discoloration, and red-brown patches suggestive of previous hemorrhage. The cow is chronically lame.[9]

Young bulls are very susceptible to laminitis and may develop abnormalities

of gait and posture, such as a stilted gait and frequent knuckling of the fetlocks, which may mislead the diagnostician.

Chronic laminitis in adult cows is characterized by a smaller anterior hoof wall-sole angle, down from 558 to 358, a concave anterior wall, and the appearance of horizontal grooves (growth arrest lines) around the entire claw. The sole is usually dropped a little and bruising and sole ulcers may be present. Overgrowth of the sole of the lateral claw may reach the point of creating a false or double sole. The white line is greatly widened and disrupted and stones and other debris may be impacted in it.[10]

Chronic, traumatic laminitis is most common in heifers when they are first introduced into the milking or dry herds. Housing them on concrete and exposing them to frequent confrontations with bossy cows lead to the development of sole hemorrhages and inflammation of the laminae.

Radiographic signs in cattle include rarefaction of the pedal bone, particularly the toe, and the development of osteophytes at the heel and on the pyramidal process.

Pigs

In sows the clinical signs are similar and include arching of the back, bunching of the feet, awkwardness of movement, increased pulsation in the digital arteries and pain when pressure is applied to the feet.

CLINICAL PATHOLOGY

There are no changes that are characteristic of the disease.

NECROPSY FINDINGS

Histological findings in the feet of cows affected by laminitis are similar to those in horses.

DIFFERENTIAL DIAGNOSIS

Cattle

White muscle disease, epiphysitis.

TREATMENT

Although similar principles to those used to determine treatment of laminitis in horses are likely to apply to cattle, treatment in cattle is usually limited to administration of NSAID (aspirin 0.3 grains/kg, orally every 12 hours, phenylbutazone 4.4 mg/kg orally every 48 hours or flunixin meglumine 1.0 mg/kg IV every 12 hours). The inciting cause (metritis, ruminal acidosis) should be treated aggressively.

CONTROL

Cattle and lambs which are brought into feedlots should be gradually introduced to grain feeds and a higher forage:grain ratio provided in the feed. Calves should not be fed intensively on grain until they are 14 months old because of the high frequency of internal hoof lesions at the earlier ages. Some protection against laminitis in dairy cattle in intensive units is gained by careful planning of housing cubicles to make them more comfortable and less damaging to the feet, and by providing more straw in the cubicles. Exercise should be provided around calving time. Vaccination with a Gram-negative bacterin-endotoxoid combination vaccine has provided some protection against laminitis induced by grain overload. Dietary supplementation of biotin (20 mg per head per day) improves hoof health of primiparous dairy cows[11] and may be beneficial in reducing the incidence or severity of lameness in a herd. This treatment might not improve objective indicators of hoof health, but it does improve production.[12]

'ACORN' CALVES

A non-inherited condition has been described in the US and Australia which resembles inherited dwarfism.[1] The disease occurs on poor range country and is thought to be due to a maternal nutritional deficiency during the middle trimester of pregnancy. The specific dietary factors involved have not been determined, although supplementary feeding during pregnancy eliminates the condition.

Abnormal osseous development of the head causes it to be either shorter or longer. Shortening of the shafts of the long bones of the limbs is accompanied by bending at the joints, and calves nurse and stand with difficulty. Incoordination, arching of the back and a tendency to bloat, which may cause death, also occur. The dentition is normal. Muscle spasticity, wry neck, circling, falling backwards, and goose-stepping occur rarely.

Most of the calves are born alive and, in badly affected herds, as many as 15% of calves may be affected. The condition derives its name from the common occurrence of acorns in the diet of affected herds, although the acorns are not thought to have any etiological significance.

CONGENITAL JOINT LAXITY AND DWARFISM IN BEEF CALVES (DYSCHONDROPLASIA IN NON-INHERITED CONGENITAL DWARFISM IN BEEF CALVES)

Congenital joint laxity and dwarfism is a skeletal anomaly which has affected beef calves in Canada,[1–3] Australia,[4] and Ireland.[5] The disease has been recognized in beef cattle ranches in north central British Columbia and Alberta, and northwestern Ontario.[1]

ETIOLOGY AND EPIDEMIOLOGY

The etiology is unknown. Epidemiologically, the disease has been associated with feeding clover silage or grass silage without dry feed or grain supplementation to pregnant cows over the winter months.[3] The disease is seen almost exclusively in beef herds where pit silage makes up the bulk of the ration. In an outbreak in a beef herd in Prince Edward Island, Canada, feeding spoiled silage to pregnant cattle may have been a risk factor.[3] An apparent greater incidence in beef herds in the northern part of the UK may be associated with longer periods of winter feeding in the northern part of the country.[6,7] There is no evidence that manganese deficiency is a causative factor.[3,5]

The problem can be eliminated by supplementation of the silage diet with a combination of hay and rolled barley.[2] In one study, calves born to first-calf heifers were 3.2 times more likely to be affected compared to calves born to mature cows.[8] In the Australian report, the pregnant dams had experienced severe nutritional deficiency between 3 and 6 months of gestation.[4]

Controlled feeding trials have supported the epidemiological observations that the disease occurs in calves born to cows fed exclusively grass or clover silage over the winter months.[2] Supplementation of the grass and clover silage diet with hay (2.5–4.5 kg/head per day) and rolled barley (0.75–1.5 kg/head per day) eliminated the problem. Supplementation with grain but no hay reduced the risk of abnormal calves to a lesser degree. The period of gestation during which the fetus is

susceptible to the abnormality ranges from 107 to 230 days. It is suggested that irreversible injury to the fetus occurs by day 180 of gestation.

Prenatal rickets was considered as a possibility in the early stages of the investigations. The overgrowth of chondrocytes and delayed mineralization of the growth plates of affected calves in previous years were similar to those described for neonatal rickets. In addition, the vitamin D concentration of silage may be low and the wavelengths of ultraviolet light necessary for transformation of the provitamin 7-hydroxycalciferol to vitamin D_3 are almost entirely filtered out by the atmosphere during the winter months because of the acute angle of the sun in northern latitudes. In Canada, pregnant beef cows fed exclusively a diet of grass or clover silage during the winter months may have low levels of vitamin D. However, supplementation of pregnant cows with vitamin D_3 during one winter season did not reduce the risk of abnormal calves.

The disease resembles 'acorn calves' which have occurred in California and Australia. One possible hypothesis suggests that the two conditions may share a common pathway.[2] Certain unspecified seasonal and environmental conditions or stressors may convert forage into a teratogenic substance. In areas where acorn calves occur, supplementation feeding of the cows on pasture practically eliminates the problem.

CLINICAL AND PATHOLOGIC FINDINGS

The abnormalities are obvious at birth and characterized clinically by generalized joint laxity, disproportionate dwarfism and, occasionally, superior brachygnathia.[2] The anomaly has occurred in some beef herds for several consecutive years and has affected 2–46% of the calf crop.[9] In a case reported from Ireland, the affected beef herd consisted of Hereford, Simmental, and Friesien cows bred to a Hereford or Charolais bull. The pregnant cattle were self-fed grass silage preserved with Kofasalt (calcium formate, sodium nitrite, and hexamethylene tetramine). Affected calves, were characterized clinically by disproportionate dwarfism, varying degrees of micromelia, limb rotation, joint laxity, and skull abnormalities.[5] Inferior and superior brachygnathia were present. Radiographically, the diaphyses were grossly foreshortened and thickened, the epiphyses were enlarged, misshapen and flared with increased opacity on some radiographs.[5] Histologically, there was chondrodystrophic of the metaphysis of the dwarf long bones. Consistent changes in organ weights or in trace element status were not present, and there was no evidence of infectious agents. There was no evidence of an inherited basis for the abnormal calves.

The epiphyses of the long bones are abnormal with overgrowth of chondrocytes and delayed mineralization. The common defect is one of growth plate maturation. The secondary ossification centers are slow to develop. Perinatal mortality is higher in affected calves than for normal calves in the same herd. The joint laxity may cause problems with dystocia. Within a few weeks after birth, the joints in surviving calves become stable, and calves walk normally.

SLIPPED CAPITAL FEMORAL EPIPHYSIS IN CALVES

This occurs in newborn calves of the well-muscled, rapidly growing European breeds, such as the Charolais, Maine-Anjou, and Simmental. It is characterized by varying degrees of lameness, palpable crepitus over the greater trochanter on passive manipulation of the affected limb, muscle atrophy in longstanding cases, and prolonged recumbency. Some calves carry the affected limb or drag the foot, whereas others tolerate slight weight-bearing during standing or walking. Most calves are lame at birth or within a few days after birth. About 75% of cases are associated with a dystocia and forced traction delivery.[1]

Laboratory stress testing of calf femurs found that mechanically induced fractures had configurations and locations similar to those found in clinical cases associated with forced extraction.[2] The breaking strength of all femurs was within the magnitude of forces calculated to be generated when mechanical devices are used to assist delivery during dystocia. It is suggested that the femur is compressed during force extraction when the pelvis of the calf is wedged in the pelvis of the dam in anterior presentation. Every effort must be employed to avoid premature engagement of the calf's stifle into the pelvic cavity to avoid or correct a 'stifle lock'.

Radiographically, there are varying degrees of displacement of the femoral neck from the head. In chronic cases there is partial resorption of the femoral head. Excision arthroplasty has been attempted with some encouraging results.

The disease must be differentiated from perinatal **femoral nerve degeneration** and neurogenic atrophy of the quadriceps femoris muscle which also occurs most commonly in the same breeds of cattle. The right hindleg is most commonly affected and affected calves are unable to bear weight on the leg; there is obvious neurogenic atrophy of the quadriceps muscle.[3] The problem has been treated by stall rest, femoral head and neck excision, and open reduction by use of Knowles pins, multiple intramedullary pins, or interfragmentary compression screws.[4]

Slipped capital femoral epiphysis has also been reported in cattle 3–5 months and 1.5–2.3 years of age.[3] Trauma is the suspected cause. If early diagnosis can be made, intramedullary pinning can provide a good long-term prognosis in cattle when function as a breeding animal is important to their future value.

TAIL-TIP NECROSIS IN BEEF CATTLE

Tail-tip necrosis occurs in cattle housed in confinement on slatted floors. The disease has occurred in steers, heifers, and bulls being fed for beef production.[1,2]

The lesion is caused by a traumatic injury of the tail caused by tramping of the tail. The lesion begins at the tip of tail followed by varying degrees of extension proximally. Initially, the tip of the tail is swollen, followed by inflammation and suppuration. Histopathological changes are compatible with cutaneous ischemia as a pathogenetic mechanism.[3] Extension of the infection can result in metastases to other parts of the body, resulting in abscesses and osteomyelitis. Affected cattle do not grow normally and deaths from pyemia may occur. The morbidity is about 5%. Approximately 10% of affected animals may be condemned for osteomyelitis and abscessation.

Risk factors

These include slatted concrete floors, close confinement, warm seasons, and a body weight above 200 kg. The risk increases as the space allotment, expressed as kg animal per m^2 pen increases from approximately 165 kg/m^2. Tail tramping is more frequent in slatted-floor pens with lower space allotment (1.5 m^2 per head) than in similar pens

with higher space allotment (2.4 m^2 per pen head). In an Ontario study, no case of tail-tip necrosis was diagnosed in solid-floor barns, while 1.36% of cattle in slatted-floor barns were either treated or slaughtered for tail-tip necrosis.[2] In a mail survey of feedlots in Ontario, 96% of 71 feedlots with slatted floors, but only 5% of 184 feedlots with solid floors, reported a problem with tail-tip necrosis from 1982 to 1986.[3] Of 441 tails inspected at slaughter plants, 34.5% were affected, with 3.4% involving skin lacerations and infection, and 4.3% amputated before slaughter.[3] Most cases occur from May to September when the temperature is above 18°C. This may be associated with increased contamination due to increased humidity and temperature under confinement conditions.

In slatted-floor barns, abnormal locomotor patterns occur from 20 to 25% of the times animals get up and lie down.[2] When animals get up abnormally, they first rise in their front, and consequently assume a dog-like sitting posture. In order to obtain momentum to rise in the rear, they then start to sway back and forth. The tail may become pinched between the hock of the rocking animal and the floor, resulting in blunt trauma to the tip of the tail.

TREATMENT

Treatment consists of early amputation combined with intensive antimicrobial therapy. Early detection is important. During warm months, cattle confined on slatted floors and weighing more than 200 kg should be closely inspected at least 2 or 3 times weekly. This includes palpation of all tail tips because early lesions are difficult to see.

CONTROL

This is dependent on providing sufficient space for housed cattle on slatted floors.

TOE ULCER AND NECROSIS OF THE APEX OF THE PEDAL BONE OF CATTLE

ETIOLOGY

A toe ulcer is a defect in the white line at the apex of the sole in adult cattle.[1] Lameness does not occur in the early stages but discomfort gradually develops at which stage the animal carries the foot further forward than normal. The etiology is not well understood. In one series of cases, overtrimming using a grinding disc and/or perforation of the sole was considered a major cause (49%), laminitis in 30%, and traumatic injuries in 11%.[2]

EPIDEMIOLOGY

In South America, where dairy herds are pastured and supplemented with concentrate and corn silage, toe ulcers are common lesions in heifers from 15 to 60 days after calving.[3] Two types of toe lesions are usually presented. One is a single claw horn defect occurring in Zone 1 which after further examination, granulation tissue is often observed. This lesion responds well to local treatment and the application of an orthopedic block on the healthy claw. The second type of lesion is more severe and includes necrosis of the pedal bone, complicated by secondary infection.

CLINICAL SIGNS

Clinical signs of apical pedal bone necrosis vary widely depending on the severity of the lesions, the number of claws involved and the causative factors. A marked-to-severe lameness may occur in cows with one claw affected, and a severely stilted gait in cows with two or three affected claws. In some cases, the lameness is so severe that the initial impression from a distance was that of a neurological disease because of the severely stilted, convulsive limb movements at rest and walking. The involvement of the pedal bone can be determined by clinical examination, inserting a probe or by direct visualization of the discolored and exposed apex of the distal phalanx.

PATHOGENESIS

The gross pathological findings of affected claws vary from moderate topical inflammatory signs of the corium at the toe of the claw, to severe and extensive necrosis and osteomyelitis of the pedal bone.[1] Histologically, there are different types of demarcation of the necrotic bone. Mixed infections are common.

Radiographically, the degree of involvement of the distal phalanx can be clearly identified, facilitating the choice of surgical therapy.[1]

TREATMENT

Treatment options include excision of necrotid bone using a bone curette, resection of the necrotic apex of the distal phalanx, and digital amputation in severe cases.[2]

DIFFERENTIAL DIAGNOSIS

Toe ulcers must be differentiated from toe abscesses which occur in yearling cattle and beef calves grazing irrigated pastures in the fall at which time they may be lame due to a toe abscess.

Diseases characterized by involvement of the skin

PITYRIASIS ROSEA

Pityriasis rosea is a condition of man. The condition in pigs is not the same because of a prominent component of eosinophils and confluent zones of epidermal necrolysis. Dermatopathological authorities have suggested that the condition be renamed pustular psoriasiform dermatitis of pigs.[1]

This skin disease of pigs resembles ringworm closely but skin scrapings do not reveal the presence of fungal hyphae or spores, and cultures for fungal growth are usually negative. Treatment with standard preparations used for ringworm is usually ineffective, although spontaneous recovery may occur.

The disease occurs in sucking pigs[2] and young pigs in the 10–14 weeks age group. Up to 50% of each litter and herd may be affected and in large groups of feeder pigs there may be only individual pigs or the majority of the group with lesions. The disease is usually innocuous, although digestive disturbances, particularly anorexia and, to a lesser extent, diarrhea and vomiting may accompany the appearance of lesions and affected pigs lose some body weight. There is no fever. Usually the condition resolves spontaneously after 2–4 months.

Lesions occur most commonly on the ventral abdomen but may spread to the rest of the body. They commence as small, red nodules which enlarge to flat plaques and become covered with thin, dry, brown scales. The lesions appear to enlarge centrifugally, leaving a center of normal appearance surrounded by a narrow zone of elevated, erythematous skin covered by typical scales. Individual lesions are generally circular except that they often coalesce to produce a large, irregular lesion. There is little irritation and the skin lesions, although obvious, are superficial. There is no loss of bristles. Histologically, the lesions show a progression from acute to chronic with a dense superficial and deep perivascular infiltrate of eosinophils, lymphocytes, and histiocytes.[1]

The cause is unknown, although infectious, genetic and allergic causes have been suggested and there is strong evidence of familial susceptibility, either through inheritance or by vertical transmission of an infectious agent.[3,4] Transmission experiments have been unsuccessful and the disease has been observed in SPF pigs

produced by cesarean section.[5] By analogy with a similar condition affecting man, it may be a viral infection. Treatment appears to be completely ineffective but in general consists of the local application of a salve containing 5% salicylic or iodized mineral oil. Affected pigs should be isolated from the group. Spontaneous recovery occurs in 6–8 weeks in most instances.

ANHIDROSIS (NON-SWEATING SYNDROME, PUFF DISEASE, DRY COAT)

Reduced ability to sweat affects horses in hot and humid climates. Affected horses are unable to maintain their body temperature within safe limits, especially during or after exercise, and suffer heat stress and a reduction in athletic performance. The only effective treatment is to move the horses to a cooler environment.

ETIOLOGY

The etiology of anhidrosis is unknown, but involves a reduction in the sensitivity of the sweat gland to β-2 adrenergic stimulation, the normal stimulus for sweating in the horse.[1] Hypothyroidism does not contribute to anhidrosis.[2]

EPIDEMIOLOGY

The disease occurs in horses, and rarely in cattle, in countries with hot, humid climates including tropical and semi-tropical regions.[1]

The overall prevalence is approximately 6% in Florida, with the highest prevalence (25%) in horses in training and the lowest prevalence (1%) in young horses.[2] There is no reported sex or color predilection. Both native and imported horses are affected, apparently with similar prevalence.[3] Among native horses the age of onset of the condition ranges from 1 year to 10 years.[3] Foals, especially of draft breeds, can be affected. Horses imported to endemic areas usually do not develop the disease within 1 year.[3] The incidence and severity of the disease are highest in the hotter season.

The disease is rarely fatal unless severely affected horses are exercised in the heat, in which case death from heat stroke can occur. The major importance of the disease is inability of affected horses to exercise and compete in athletic events.

PATHOGENESIS

Sweat is produced in horses by apocrine sweat glands that have a single type of secretory cell. The sweat glands are well innervated, and sweating is controlled by a combination of hormonal (β-2 adrenergic) and neural factors.[4] Sweat production increases with increasing concentrations of epinephrine in blood up to a peak value, after which sweating rates decline.[4] Anhidrotic horses have lower initial and peak rates of sweat production, and lower overall sweat production, than do normal horses during intravenous infusion of epinephrine.[5] Suggested, but unproved, mechanisms for decreased sweat production by anhidrotic horses includes diminished glandular sensitivity to epinephrine, failure of secretory function, blocking of sweat gland ducts, fatigue of the gland, and gland atrophy.

Sweating is the predominant means by which horses dissipate heat. Reduction in the capacity to produce sweat results in an inability to effectively control body temperature during exercise and when temperature and humidity are high. The elevation in body temperature results in tachypnea in an attempt to dissipate heat through the respiratory tract. Hyperthermia impairs performance and, if severe, can result in heat shock, a systemic inflammatory response syndrome, and death.

CLINICAL FINDINGS

The most apparent clinical sign is lack of sweating in response to an appropriate stimulus, such as exercise. In severely affected horses, sweating may be limited to the perineum, brisket, and areas under the mane and saddle. Less severely affected horses have a diminished sweat response and may not lather during exercise. The skin becomes dry and scurfy and loses its elasticity, and there may be alopecia, especially of the face.

Affected animals become extremely tachypneic when heat stressed, leading to the colloquial term for the disease 'dry puffer'. The animal's appetite declines and it loses weight. Athletic performance is severely compromised. High body temperatures are observed after exercise, sometimes reaching 41.5–42°C (107–108°F) and persist for long periods.

The **prognosis** is poor for athletic function for affected animals that remain in hot and humid environments, but the condition may resolve if the horse is moved to a cool climate.

CLINICAL PATHOLOGY

Plasma epinephrine concentrations are reported to be higher in affected horses than in unaffected horses,[6] but this has not been a consistent finding among studies.[5]

Diagnostic confirmation is achieved by demonstrating reduced sweating in response to **intradermal injection of epinephrine**, or the β-2 adrenergic agonists, terbutaline and salbutamol.[7] A crude test involves the intradermal injection of 0.1 mL of a 1:1000 dilution of epinephrine. If the horse sweats then it is not considered to be completely anhidrotic. A **semiquantitative test** using epinephrine, terbutaline, or salbutamol may be useful in identifying partially anhidrotic horses.[7] Normal horses sweat when 0.1 mL of 1:1000 000 epinephrine is injected, while partially anhidrotic horses sweat only with higher concentrations (1:10 000 or 1:1000). Injections are usually made using small gauge needles (25 g) into the skin over the lateral aspects of the neck.

NECROPSY FINDINGS

There are no characteristic gross lesions at necropsy. Histologic examination of the skin of affected horses reveals abnormalities in sweat gland morphology including flattening of cells and loss of luminal microvilli and a reduction in the number of secretory vesicles. These findings are thought to be a consequence, rather than a cause, of the disease.

TREATMENT AND CONTROL

There is **no specific treatment** that restores the horse's ability to sweat, other than movement to a cooler climate. Affected horses for which translocation to a cooler environment is not feasible benefit from housing in air conditioned stables so that exposure to high ambient temperatures is minimized. Exercise of affected horses during the coolest periods of the day is sensible. Affected horses are frequently administered **electrolyte supplements**, but without demonstrated benefit. However, as with all working horses, an adequate intake of sodium, potassium, and chloride should be insured.

Administration of **thyroid hormone supplements** is not warranted, and may be dangerous by increasing the metabolic rate, and therefore heat production, of affected horses. **Vitamin E** administration has no demonstrated efficacy.

Removal of affected animals to cooler climates is often necessary, although air conditioning of stables and maintenance of horses in higher country where they can be returned after a day's racing may enable susceptible horses to be kept locally.

BOVINE OCULAR SQUAMOUS-CELL CARCINOMA

Ocular squamous-cell carcinoma, often referred to as 'cancer eye', is one of the most common neoplasms of cattle.

Synopsis

Etiology Genetic-environmental interaction. Lack of pigmentation around the eye and solar radiation.
Epidemiology One of most common neoplasms of cattle; mostly in beef cattle breeds (Herefords, Simmental) lacking pigment around the eye; animals over 5 years of age.
Solar radiation major risk factor.
Signs Precursor lesions, single or multiple plaques on eyelid or conjunctiva except the cornea or pigmented lid may regress, or lead to carcinomas of sclera resembling papillomas with crumbly, necrotic ulcerated mass attached to the eyelid causing irritation to eye and conjunctiva and excessive lacrimation and pus. Invasion of surrounding tissues of eye and possibly to nearby lymph nodes.
Clinical pathology Histology of lesion.
Lesions Squamous cell carcinoma.
Diagnostic confirmation Biopsy and histology.
Differential diagnosis list

- Pinkeye
- Lymphoma of periorbital tissues.

Treatment Excision by cryosurgery. Radical surgery may be necessary. Immunotherapy with vaccines has been attempted.
Control Breeding program to increase degree of pigmentation in Hereford cattle.

ETIOLOGY

A genetic-environmental interaction has been proposed as the cause. A relative **lack of circumocular and corneoscleral pigmentation**, both of which are heritable, increases the probability of lesion development when the animal is exposed to a carcinogenic agent like the **ultraviolet component of sunlight**. The carcinoma has been regarded as a papilloma-associated tumor because papilloma virus can be found in the precursor lesions, and papillomavirus DNA in the carcinomas. However, advanced virological techniques have failed to reveal any association between the virus and the tumor.[1]

The p53 gene product is highly expressed in bovine BOSCC, which provides support for its role in BOSCC tumorigenesis.[2]

EPIDEMIOLOGY

Occurrence

Bovine ocular squamous cell carcinoma is a common neoplasm of the eyelids and the eyeball of cattle and one of the most common neoplasms of cattle. The disease is most common in beef cattle which are exposed to more sunlight than dairy cattle. The tumors are uncommon in cattle younger than 5 years and are hardly ever seen in cattle younger than 3 years. The condemnation rate of cattle with ocular squamous cell carcinoma in Canada is about 30% of cases.[3] A squamous cell carcinoma of the anal and perianal area of a 15-year-old bull has been recorded.[4]

Risk factors

The heritabilities, phenotypic, and genetic correlations of lid and corneoscleral pigment and eye lesions associated with eye cancer were investigated in 2831 Herefords from 34 herds in 21 states of the US and one Canadian province. The results indicated that lid and corneoscleral pigment were heritable and genetically correlated.[5] These findings lead to the general conclusion that the genetic effect on pigment determines to a large extent the degree to which the eye is susceptible to some carcinogenic agent such as ultraviolet light.

In Zimbabwe, ocular squamous cell carcinoma was frequently observed in five breeding herds of Simmental cattle.[6] In these herds, initial signs of the disease were evident in cattle about 3 years of age and gradually the prevalence increased to over 50% in animals over 7 years of age.[6] It is suggested that because most cattle in Zimbabwe are slaughtered by 10 years of age, that more than 67% of cattle without periorbital skin pigmentation would develop the tumor. The tumors were multiple and commonly bilateral. Simmental cattle have a complete or partly white face and the lack of facial pigmentation risks exposure to intense solar radiation when they are kept at a high altitude (1500 m) in a sunny and warm climate. The prevalence was much lower in white-faced Friesian cattle in the same environment which suggests a genetic predisposition for the tumors in Simmental cattle. In Zimbabwe, the tumor is not recorded in fully-pigmented cattle breeds.

The association between ocular squamous cell tumors and various measures of solar radiation indicate a significant association between increasing risks of developing eye cancer and increasing levels of radiation.[7] Ultraviolet light is generally regarded as an important risk factor. Most tumors are located only in the sun-exposed mucocutaneous areas not protected by hair. Tumors are predominantly localized in the third eyelid and the lateral limbus, and tumor growth usually starts at the outer edge which receives the most sunlight. Cattle exposed to high levels of radiation develop the disease at younger ages.[7]

Economic importance

The disease results in serious economic consequences through lessened productivity and carcass condemnations. Commercial cattle can be culled early without much loss, because only the head is condemned. Purebred cattle are more of a problem because of the difficulty of deciding when euthanasia must be the humane decision, rather than another attempted extirpation of the eye.

PATHOGENESIS

The initial lesion may be on the eyelid or any structure in the conjunctival sac, except the avascular cornea or pigmented eyelid. Lesions can encroach on these tissues from others nearby, carrying a blood supply with them.

The lesions develop through three stages. The first two, a plaque and then a papilloma, are non-malignant and have high regression rates. The third stage is the squamous cell carcinoma which does not regress. The tumor is located in the sclera adjacent to the lateral limbus, in the membrana nictitans (third eyelid), or in the lower eyelid. It is an invasive tumor, metastasizing along the draining lymphatics into cervical lymph nodes. Primary lesions of the lids are most likely to metastasize to these nodes.

Animals do not appear to develop resistance to the cancer; only a few cows with the disease develop measurable antibodies in their sera. It is one of the characteristics of this disease that the carcinomas appear to produce immunosuppressive substances, and removal of tumor mass reduces blood levels of them.

In countries and in herds where ocular carcinoma is common, it is not unusual to encounter lesions on the labia of the vulva especially if there are patches of unpigmented skin.[8]

CLINICAL FINDINGS

Typical precursor lesions are single or multiple plaques of gray-white, smooth or rough, hyperplastic to hyperkeratinized tissue anywhere in the conjunctiva. **Plaques** may develop into papillomas and acanthomas of the skin of the eyelids, also included as precursor lesions. Squamous-cell carcinomas may develop from any of these precursors which may also regress spontaneously. The proportion that regresses is of the order of 80%.

Classic BOSCC lesions resemble papillomas with a fleshy, sometimes crumbly, often necrotic and ulcerated mass attached to the lid or the orbit by a wide base. They are visible even when the eyelids are closed, and cause obvious irritation to the surrounding conjunctiva, resulting in increased lacrimation and sometimes in the discharge of pus. Invasion of surrounding tissues is common but metastases to nearby lymph nodes and to viscera occur in only a few cases and then only late in the course of the disease.

CLINICAL PATHOLOGY

Differentiation between carcinomas and precursor lesions is difficult clinically and cytological examination or biopsy is recommended for definitive diagnoses. The cytology of squamous cell carcinomas in domestic animals has been described.[9]

DIFFERENTIAL DIAGNOSIS

One of the difficulties encountered in the field is the clinical differentiation of benign precursor lesions from the malignant carcinomas; failure to do so may account for the high rates of spontaneous regression recorded, especially in Hereford cattle, where a spontaneous recovery rate of 88% is recorded. To avoid this inaccuracy, exfoliative cytology by the examination of smears of lesions is helpful. Combined with a clinical assessment this is the recommended method of confirming the diagnosis. Differentiation from similar lesions that are not BOSCC can only be achieved by proper laboratory examination of tissues.

BOSCC must be differentiated clinically from:

- Pink eye and its complications which results in excessive lacrimation and purulent material, and
- Lymphoma of the periorbital tissues which usually manifests as exophalthmos.

TREATMENT

Excision, sometimes by cryosurgery, is widely practiced in cattle. Results are good and treatment by the use of radioactive implants has also aroused favorable comment. Recurrence, or the development of new lesions at the same site, is a common sequel. Radical surgery, including removal of the local lymph nodes and parts of the salivary gland, may be desirable in some bovine cases. It is often combined with immunotherapy, e.g. with BCG vaccine injected systemically or into the lesion, or with vaccination with BOSCC tumor material. That there is a significant immune body response at the normal tissue-corneal interface has been demonstrated, but whether this plays any part in the rejection of the tumors is not known. One controlled trial in cattle showed that intralesional injection of BCG vaccine can interrupt neoplastic progression and prevent malignant disease. A permanent regression after BCG vaccination can be expected in 37% of cases, recurrence at the same site in 26%, and continued growth in 37%.[10]

A favorable response to a single injection of a saline phenol extract of fresh tumor tissue can induce a high rate of regression of ocular tumors with a higher recovery rate after the use of 200 mg of lyophilized tumor extract as compared with an injection of 100 mg. The injection may need to be repeated. Occasional tumors show enhancement of growth after vaccination, especially if it is repeated. The vaccine does not need to be autologous, and only one injection is required. A freeze-dried preparation of tumor antigen has been used successfully. In general, the use of a vaccine seems likely to provide a satisfactory method for controlling an esthetically distressing and financially important disease. Reports on the effect of vaccination with a tumor vaccine on the vulvar form of squamous-cell carcinoma vary.[11]

Other treatments which have received favorable comment, but need to be evaluated in the light of the known natural recovery rate of the benign precursor lesions, include electrothermal hyperthermia and combinations of the above procedures.

CONTROL

Because of the strong correlation between absence of pigmentation of the eyelids and the occurrence of the disease, and because of the high heritability of this pigmentation in Hereford cattle, it is suggested that a breeding program aimed at increasing the degree of pigmentation of eyelids could quickly reduce the incidence of the disease in this breed.[5] A positive approach to the problem would be to crossbreed susceptible *Bos taurus* cattle with *Bos indicus* cattle which always have pigmented eyelids and have much less eye cancer. In Ayrshires there is a corresponding predilection for squamous-cell carcinomata of the vulva, but the neoplasm does not occur on both sites in the one cow. Selection on the basis of the occurrence of lesions alone results in only limited reduction in incidence.

EQUINE OCULAR SQUAMOUS-CELL CARCINOMA

Squamous cell carcinoma is one of the most common neoplasms of the horse and is the most common tumor of the eye and orbit but the rate of occurrence is low. The reported frequency has been highest in animals lacking periocular pigmentation and is more common in Appaloosa, albino, and color dilute horses. An increased prevalence for ocular and adnexal SCC has been reported in draft horse breeds, Appaloosas, Paint Horses, Thoroughbreds, and Quarter Horses. A predisposition for the development of ocular and adnexal SCC has also been reported in geldings.[1] The risk has been higher in draft breeds than in other pigmented breeds, probably related to the large expanses of white skin on the face and around the eye of the heavy draft breeds. The overall mean age range of affected animals is 8–10 years.[2] In a series of limbal neoplasms in horses admitted to the Veterinary Teaching Hospital in the Netherlands, squamous cell carcinoma was the most predominant tumor type and Haflinger horses accounted for 69% whereas their occurrence in the hospital population was 5%.[3]

In a retrospective study of 50 cases submitted to the University of Florida Veterinary Medical Teaching Hospital, the Appaloosa accounted for the majority of cases[4] which may be a reflection of the high level of solar radiation in southeastern US. The average age at which the tumor was diagnosed initially was 11.8 years; males accounted for 64% and females 36% of the cases. The rate of metastasis was 18%.

In the Florida study, higher cure rates were associated with surgical excision followed by radiation therapy for a cure rate of 75%; whereas with only surgical excision the cure rate was 55%.[4] Best results with treatment are seen when surgical intervention is early.[5] In horses, treatment is largely surgical but all of the immunological techniques developed for cattle have been used including local irradiation therapy with ^{90}Sr or ^{222}Rn.[2]

The most frequent site for ocular involvement is the nictitating membrane and conjunctiva but the eyelids and cornea are also involved. A case of limbal squamous cell carcinoma with invasion into the cornea and uvea of 12-year-old Haflinger gelding has been described.[6] On initial presentation, a light-pink raised mass on the temporal limbus and conjunctiva of one eye was observed. Squamous cell carcinoma was confirmed histologically after keratectomy and cryotherapy. Seven months later, a smooth pink, progressively enlarging mass was observed within the cornea. Ultrasonographically, the mass was found infiltrating the corneal stroma and the anterior chamber. The globe was surgically removed. Histologically, a diagnosis of corneal ocular squamous cell carcinoma with deep stromal invasion, infiltration of the uveoscleral meshwork and iridocorneal angle and resulting intraocular extension was made.

A pigmented squamous cell carcinoma of the conjunctiva of a 17-year-old horse has been described.[7]

Treatment of ocular and adnexal SCC has included various types of therapy, with and without adjuvant radiation therapy. Types of treatment without adjuvant radiation therapy include excision, cryotherapy, radiofrequency hyperthermia, immunotherapy, chemotherapy with cisplastin, and carbon dioxide laser ablation. Treatment with adjuvant radiation therapy includes use of strontium 90 (^{90}Sr) cobalt 60 (^{60}Co), gold 198, iridium 192 (^{192}Ir), cesium 137, iodine 125 (^{125}I), and radon 222 (^{222}Rn).[1] In a series of 157 cases of ocular and adnexa squamous cell carcinoma, those treated with adjuvant radiation therapy had a significantly lower recurrence rate, compared with those treated without adjuvant radiation therapy, independent of anatomic location.[1]

Superficial keratectomy followed by cryosurgery is a simple and effective procedure for the treatment of small-sized limbal tumors (less than 2 cm) in horses.[3] Sophisticated equipment is not required and the legal restrictions associated with the use of radioactive substances in many countries are not a consideration.

Ocular pseudotumors have been described in horses. They are proliferative inflammatory lesions involving the eye, adnexa or orbit, which clinically mimics true neoplasms.[8] Cases are characterized by a uniocular, pink proliferative limbal or perilimbal lesion. Affected horses may be from 5 to 9 years of age. Most cases occurred during the summer months and none of the affected animals had a history of trauma or recent deworming. The dorsal bulbar conjunctiva was most commonly affected, followed by the third eyelid. Lesions were relatively flat with indistinct margins or discrete and nodular. Histologically, the lesion is inflammatory characterized by predominantly lymphocytic infiltrates. The cause is unknown but an immune-mediated pathogenesis is suspected based on the preponderance of immunocytes consisting primarily of lymphocytes. Treatment consists of surgical excision alone, partial resection with anti-inflammatory therapy, or anti-inflammatory therapy alone.[8]

OCULAR SQUAMOUS CELL CARCINOMA IN GOATS

A well-differentiated ocular squamous cell carcinoma has been described in twin goats.[1] The twin goats, one male and one female, were 3 years of age. Both animals had pigmented eyelids and had been reared at an altitude of 760 m above sea level in Italy. The lesions were very advanced when first examined. There was a history of bilateral ocular disease and impaired vision of 24 months duration. In the affected eyes, a firm mass with a fleshy appearance was evident, covering the entire cornea and protruding through the palpebral fissure. A bilateral ocular mucopurulent discharge, associated with corneal plaques, neovascularization and edema, was also present in both animals.

Histologically, cords and islands of squamous epithelial cells proliferated deeply throughout the cornea and invaded the basal layer, limbus, iris, and cilary body, and other features, characteristic of a well-differentiated ocular squamous cell carcinoma.

Biomolecular studies to the identification of *Papillomavirus*-related DNA sequences within the neoplastic ocular parenchyma of both animals but immunohistochemical and ultrastructural examinations did not demonstrate viral particles.

'COCKLE'

This is a superficial nodular dermatitis of sheep recorded only in New Zealand that results in nodules in the skin that are of economic importance to the leather industry. The presence of cockle downgrades the value of the pelt.

Cockle is not usually diagnosed clinically but examination by close inspection of the skin over the upper shoulder region after close shearing has high specificity for detection.[1] The lesions are the result of an immune response in some sheep to infestation with the biting louse *Bovicola ovis*. The occurrence of cockle and its severity is positively correlated with the severity of the louse infestation[2] and sheep that develop lesions have *B. ovis*-specific homocytotrophic antibody. Serum histamine concentrations are significantly higher in louse-infested lambs than louse-naive lambs.[3]

Lesions commence on the neck and shoulders and may extend over the entire pelt. Widely distributed lesions, 'scatter cockle', are attributed to infestation with *B. ovis*, and this is the most common cause but 'rib cockle' may be a hypersensitivity to infestation with the sheep ked *Melophagus ovinus*. Pelt lesions in the dorsal midline region are usually due to infection with *Dermatophilus congolensis*.[1]

CONTROL

This rests with the control of *B. ovis*. For cockle control sheep should be treated off-shears with pour-on or spray-on insecticide and, as soon as practical after shearing, treated by saturation dipping. Saturation dipping is required to significantly reduce louse populations.[4] Prelambing dipping is also recommended to reduce the risk of lambs acquiring louse infestations.

WOOLSLIP, WOOL LOSS

Woolslip is a condition in which housed ewes, shorn in winter, lose part of their fleece and develop bald patches over a large area of the **rear half of the back**.[1] This commonly starts at the base of the tail and progresses to the rump and back and less commonly the neck. There is no systemic disease; the skin is normal. Histological examination of skin biopsies show that in affected sheep the wool follicles are in the active anogen stage rather than the inactive telogen phase of unaffected cohort sheep and the wool regrows immediately following loss.[1] The loss of wool **starts 2–3 weeks after shearing**. All breeds are equally susceptible and there is no effect of age or whether the sheep are carrying single or twin lambs; up to 40% of a flock may be affected. The wool loss occurs because of a premature and synchronized shedding of wool fibers and not because of a pathological process which damages the wool fiber. Wool shedding can be induced experimentally by prolonged treatments with corticosteroids and the current explanation for the wool shedding that occurs with the woolslip syndrome is that blood corticosteroid levels rise after the stress of shearing and are maintained for a long period because of the trauma of being housed and shorn and kept in the cold. Blood zinc concentrations in woolslip affected sheep are within the normal range and there is no epidermal change as occurs in zinc deficiency.

The **prevention** of the condition is aimed at reducing the severity and length of the stress period by shearing the sheep at the time of entry to winter housing and insuring a good nutritional plane in the post-shearing period.[1] This hypothesis as to cause may not be correct as the syndrome has also been seen in the

summer in Wiltshire shorn sheep which had little history of stress in the period immediately preceding the woolslip.[2]

Woolslip should not be confused with the normal shedding of wool that occurs in breeds such as the Wiltshire or Shetland in the spring period. Loss of wool along the backline also occurs in older longwool sheep and may be exacerbated by lambs playing or sleeping on the ewe.[3]

Impairment of wool growth and a **thinning of fiber diameter** can occur during the course of any **severe disease** such as bluetongue, pregnancy toxemia, or foot rot temporarily affecting the growth of the fleece. This results in a segment of the wool fiber that has decreased tensile strength and the condition has the name **tender wool.** Following recovery from the inciting disease the wool growth is normal but there is a line of wool with poor tensile strength in the staple. This can be observed in the intact fleece as a line of decreased fibre diameter, often with a change in crimp character and discoloration due to entrapment of dust. The wool may break if the staple on either side of this break is sharply snapped between the fingers. The fleece may subsequently be shed in part or in whole at the level of the defect, a condition known as **wool break**. Tender wool downgrades the value of a fleece and has economic significance in wool-producing sheep.

Zinc deficiency can reduce keratinization, reduce wool growth and occasionally result in fleece loss in sheep.[4,5] Wool loss associated with pruritus occurs in association with external parasite infestations (Ch. 27) and with scrapie and pseudorabies in ruminants.

Pelodora dermatitis, characterized by thickening of the skin and complete wool loss in affected skin areas is recorded in winter-housed sheep where there was poor bedding management. The condition affected the majority of the ewes at risk. The parasite, *Peladora (Rhabditis) strongyloides* is a free living nematode commonly present in decaying organic material but can invade hair follicles to produce an inflammatory response. Histological examination of the skin showed the presence of the parasite in wool follicles and infiltration of eosinophils and mast cells in connective tissue. Affected skin areas were those that had contact with the bedding when the sheep were lying down and large numbers of the nematode were found in the bedding. Clinical signs regressed with the more frequent provision of new bedding and disinfection of the stable.[6]

WOOL EATING

Wool eating can occur as a result pica associated with micronutrient deficiency. A condition called **shimao zheng,** occurring in a region of the Gansu province of China has wool eating as its primary manifestation. The disease has a seasonal occurrence with the peak incidence in January through April. Both goats and sheep are affected but the incidence and severity is much higher in goats where 90% may show signs. Affected animals bite the wool or hair off their own or other animals bodies particularly in the hip, belly, and shoulder areas. Histology on biopsies shows heavily keratinized epithelial cells, a decreased number of hair and aggregated foci of lymphocytes in the dermis. Controlled trials have shown the condition can be corrected by supplementation with sulphur, copper, and iron.[7,8] Wool eating is also recorded in Israel possibly associated with trace element copper and zinc deficiency.[9] Wool and hair loss in individual sheep and cattle in association with excessive licking is recorded and are postulated as psychogenic dermatoses.[10]

REFERENCE LABORATORY VALUES

Reference values for some frequently measured variables in blood and serum are provided as a guide. Values of these variables from healthy animals vary depending on many factors including age, breed, sex, diet, geographical habitat and methods of sample collection and laboratory measurement. The values listed below are compiled from a variety of sources including the clinical laboratories of the Western College of Veterinary Medicine at the University of Saskatchewan, the College of Veterinary Medicine at The Ohio State University, and Kaneko JJ. *Clinical biochemistry of domestic animals*, 5th edn. New York: Academic Press, 1997.

Tables of reference values for newborn foals and calves are provided elsewhere.

Appendix 3

DRUG DOSES AND INTERVALS FOR HORSES AND RUMINANTS

Suggested drug doses and intervals for horses and ruminants. Dosages listed are general recommendations and might not be optimal or efficacious in all instances and might need to be adjusted depending on the disease, its severity, patient factors including but not limited to age or diet, and because of regulatory considerations regarding milk and meat withholding times in animals intended as human food. Manufacturer's recommendations should be checked before administering any drug and the effect on withholding time of varying from the manufacturer's recommendation regarding dosing should be considered. Local regulations regarding use of drugs in animals that could be used for human food should be consulted.

Doses are given in milligrams per kilogram body weight (mg/kg) unless otherwise stated (g = gram, iu = international units). Drugs given as total doses, such as intramammary preparations, are denoted by TD. Dosing interval is given in hours, unless otherwise stated, or unless given as a single dose (SD). The route of administration is indicated as: intravenous (IV), intramuscular (IM), oral (PO), subcutaneous (SC), intrarticular (IA), intramammary (IMM), intraperitoneal (IP), inhalation (IH), per rectum (PR), topically (TO), or subconjunctivally (IO). Drugs recommended not to be given to certain species are indicated by NR.

	Horses			**Ruminants (cattle, sheep, goats)**		
Drug	***Dose (mg/kg)***	***Interval (h)***	***Route***	***Dose (mg/kg)***	***Interval (h)***	***Route***
Acepromazine maleate	0.04–0.1	SD	IM, IV, SC	0.03–0.1	SD	IM, IV, SC
Acetazolamide	2.2	6–12	PO			
Acetic acid				10–20	SD	PO
Acetylcysteine	8 g, TD (for (retained meconium) 140	SD 24	PR PO			
Acetylsalicylic acid (aspirin)	10–20	48	PO	50–100	12	PO

Appendix 4

DRUG DOSES AND INTERVALS FOR PIGS

Suggested drug doses and intervals for pigs, and concentrations of medicaments in feed. Dosages listed are general recommendations and may not be optimal or efficacious in all instances and may need to be adjusted depending on the disease, its severity, patient factors such as age or diet, and because of regulatory considerations regarding milk and meat withholding times in food animals. Manufacturer's recommendations should be checked before administering any drug and the effect on withholding time of varying from the manufacturer's recommendation regarding dosing should be considered. Local regulations regarding use of drugs in animals that may be used for human food should be consulted.

Doses are given in milligrams per kilogram body weight (mg/kg) unless otherwise stated (g = gram, iu = international units). Drugs given as total doses are denoted byTD. Dosing interval is given in hours, unless otherwise stated, or unless given as a single dose (SD). The route of administration is indicated as: intravenous (IV), intramuscular (IM), oral (PO), subcutaneous (SC), or intraperitoneal (IP). One ton = 1016 kg.

	Pigs		
Drug	***Dose (mg/kg) or (Concentration in feed or water)***	***Interval (h)***	***Route***
Acepromazine maleate	0.03–0.5	SD	IM, IV, SC

Drug	*Dose (mg/kg) or Concentration in feed*	*Interval (h)*	*Route*
Pancuronium	0.11	SD	IV
Penicillin G, benzathine	4.5 (11 000–22 000 iu)	48–96	IM
Penicillin G, procaine	6–20 (6000–40 000 iu)	12–24	IM
Pentazocine	2.0	SD	IM
Pentobarbital	30 (to effect) 120–200 FOR EUTHANASIA	SD SD	IV IV
Pentobarbitone *see* pentobarbital			
Phenylbutazone	4	24	PO, IV
Phytomenadione (vitamin K1)	0.5–2.5	SD	IM, IV (slow)
Piperazine	110	SD	PO
Prednisolone sodium succinate	0.2–1.0	SD, 24	IV, IM
Pyrantel pamoate	22 6.6 (pot bellied pigs)	SD SD	PO PO
Pyrantel tartrate	22 (96 g/ton)	SD	PO
Pyrilamine maleate	0.5–1.0	SD	IM
Roxarsone	182 g/ton		
Sodium arsanilate *see* arsanilate, sodium			
Sodium chloride (hypertonic, 7.0%)	4 mL	SD	IV
Sodium sulfate	0.25–0.5	SD	PO
Spectinomycin HCl	10 6.6–22	12–24 24	PO IM
Streptomycin	13	12–24	IM
Sulfachlorpyridazine	44–70	24	PO
Sulfadiazine/trimethoprim	48	24	PO
Sulfadoxine/trimethoprim	15	12–24	IM
Sulfonamide/trimethoprim	15–30	24	IM, PO
Suxamethonium chloride	2	SD	IV
Tetracylcine hydrochloride	10–40	12/24	PO
Thiabendazole	50–75	SD	PO
Thiamine hydrochloride (vitamin B1)	5–100	SD	IV, IM, PO
Thiamylal sodium	6.6–11	SD	IV
Tiaprost	0.3–0.6 TD	SD	IM
Thiopental	5.5–11	SD	IV
Tiamulin	2–10 / 10–15 (35–200 g/ton)	24 / 24	PO / IM
Tilmicosin	10–20 (180–360 g/ton)	24	PO
Tripelenamine hydrochloride	1	8–12	IV, IM
Tubocurarine chloride	0.4 then 0.08	SD, to effect	IV
Tylosin	5–10 / 2–5 (40–100 g/ton)	24 / 24	IM / PO
Valnemulin	1.25–10	24 / 24	PO
Virginiamycin	(25–100 g/ton)
