DEDICATION

To those veterinary professionals who made the critical observations and performed the key experiments that provided the intellectual foundation for the discipline of Veterinary Hematology. Whether or not their names appear as authors in this text they have contributed to the concepts presented herein and have inspired those of us whose names appear.

Douglas J. Weiss

To my friends and colleagues for their continual support, and to those mentors who have nurtured my interest in clinical and investigative hematology. I am indeed fortunate to be able to work in an area that both challenges and rewards me.

Also dedicated to my family: Marv, Jessica, Michael, and Evan, for bringing such joy and balance into my life.

K. Jane Wardrop

CONTENTS

Contributors xv

Preface to the Sixth Edition xxiii

SECTION I

Hematopoiesis 1

Maxey L. Wellman

CHAPTER 1
Embryonic and Fetal Hematopoiesis 3
KELLI L. BOYD and BRAD BOLON

CHAPTER 2
Structure of Bone Marrow 8
LESLIE C. SHARKEY and SARA A. HILL

CHAPTER 3
Stem Cell Biology 14
JED A. OVERMANN, JAIME F. MODIANO, and TIMOTHY O. O'BRIEN

CHAPTER 4
Cluster of Differentiation (CD) Antigens 20
MELINDA J. WILKERSON and CINZIA MASTRORILLI

CHAPTER 5
The Hematopoietic System 27
BRUCE D. CAR

CHAPTER 6
Erythropoiesis 36
CHRISTINE S. OLVER

CHAPTER 7
Granulopoiesis 43
M. JUDITH RADIN and MAXEY L. WELLMAN

CHAPTER 8
Monocytes and Dendritic Cell Production and Distribution 50
TRACY L. PAPENFUSS

CHAPTER 9
Thrombopoiesis 56
MARY K. BOUDREAUX

CHAPTER 10
Lymphopoiesis 61
MARY JO BURKHARD

CHAPTER 11
Vasculogenesis/Endothelial Progenitor Cells 65
DEBRA A. KAMSTOCK

SECTION II

Hematotoxicity 69

Douglas J. Weiss

CHAPTER 12
Design and Methods Used for Preclinical Hematotoxicity Studies 71
WILLIAM J. REAGAN, FLORENCE M. POITOUT-BELISSENT, and ARMANDO R. IRIZARRY ROVIRA

CHAPTER 13
Interpretation of Hematology Data in Preclinical Toxicological Studies 78
FLORENCE M. POITOUT-BELISSENT and JEFFREY E. MCCARTNEY

CHAPTER 14
Preclinical Evaluation of Compound-Related Cytopenias 85
LAURIE G. O'ROURKE

CHAPTER 15
Preclinical Evaluation of Compound-Related Alterations in Hemostasis 92
KAY A. CRISWELL

CHAPTER 16
Drug-Induced Blood Cell Disorders 98
DOUGLAS J. WEISS

CHAPTER 17
Myelonecrosis and Acute Inflammation 106
DOUGLAS J. WEISS

CHAPTER 18
Chronic Inflammation and Secondary Myelofibrosis 112
DOUGLAS J. WEISS

CHAPTER 19
Infectious Injury to Bone Marrow 118
K. JANE WARDROP

SECTION III
Erythrocytes 121
Joanne B. Messick

CHAPTER 20
Erythrocyte Structure and Function 123
CHRISTINE S. OLVER, GORDON A. ANDREWS, JOSEPH E. SMITH, and J. JERRY KANEKO

CHAPTER 21
Erythrocyte Biochemistry 131
JOHN W. HARVEY

CHAPTER 22
Erythrokinetics and Erythrocyte Destruction 136
JOHN A. CHRISTIAN

CHAPTER 23
Erythrocyte Morphology 144
ANNE M. BARGER

CHAPTER 24
Laboratory and Clinical Diagnosis of Anemia 152
HAROLD TVEDTEN

CHAPTER 25
Erythrocytosis and Polycythemia 162
JOHN F. RANDOLPH, MARK E. PETERSON, and TRACY STOKOL

CHAPTER 26
Iron and Copper Deficiencies and Disorders of Iron Metabolism 167
DOUGLAS J. WEISS

CHAPTER 27
The Porphyrias and Porphyrinurias 172
J. JERRY KANEKO

CHAPTER 28
Hereditary Erythrocyte Enzyme Abnormalities 179
URS GIGER

CHAPTER 29
Erythrocyte Membrane Defects 187
MUTSUMI INABA and JOANNE B. MESSICK

CHAPTER 30
Congenital Dyserythropoiesis 196
DOUGLAS J. WEISS

CHAPTER 31
Anemias Caused by Rickettsia, Mycoplasma, and Protozoa 199
ROBIN W. ALLISON and JAMES H. MEINKOTH

CHAPTER 32
Anemia Associated with Bacteria and Viral Infections 211
CASEY M. RIEGEL and STEVEN L. STOCKHAM

CHAPTER 33
Immune-Mediated Anemias in the Dog 216
MICHAEL J. DAY

CHAPTER 34
Immune-Mediated Anemias in the Cat 226
TRACY STOKOL

CHAPTER 35
Immune-Mediated Anemias in Ruminants and Horses 233
KATHY K. SEINO

CHAPTER 36
Anemias Associated with Oxidative Injury 239
MICHEL DESNOYERS

CHAPTER 37
Anemia of Inflammatory, Neoplastic, Renal, and Endocrine Diseases 246
MICHAEL M. FRY

CHAPTER 38
Pure Red Cell Aplasia 251
DOUGLAS J. WEISS

CHAPTER 39
Aplastic Anemia 256
DOUGLAS J. WEISS

SECTION IV
Leukocytes 261
Erik Teske

CHAPTER 40
Neutrophil Structure and Biochemistry 263
MARY B. NABITY and SHASHI KUMAR RAMAIAH

CHAPTER 41
Neutrophil Distribution and Function 268
DOUGLAS J. WEISS, SHASHI KUMAR RAMAIAH, and BRUCE WALCHECK

CHAPTER 42
Neutrophil Function Disorders 275
DOUGLAS J. WEISS

CHAPTER 43
Eosinophils and Their Disorders 281
KAREN M. YOUNG and RICHARD L. MEADOWS

CHAPTER 44
Basophils, Mast Cells, and Their Disorders 290
LISA M. POHLMAN

CHAPTER 45
Monocytes and Macrophages and Their Disorders 298
DOUGLAS J. WEISS and CLEVERSON D. SOUZA

CHAPTER 46
Interpretation of Ruminant Leukocyte Responses 307
SUSAN J. TORNQUIST and JOHANNA RIGAS

CHAPTER 47
Interpretation of Equine Leukocyte Responses 314
ELIZABETH G. WELLES

CHAPTER 48
Interpretation of Canine Leukocyte Responses 321
A. ERIC SCHULTZE

CHAPTER 49
Interpretation of Feline Leukocyte Responses 335
AMY C. VALENCIANO, LILLI S. DECKER, and RICK L. COWELL

CHAPTER 50
Determination and Interpretation of the Avian Leukogram 345
KENNETH S. LATIMER and DOROTHEE BIENZLE

CHAPTER 51
Biology of Lymphocytes and Plasma Cells 358
MICHAEL J. DAY

CHAPTER 52
Structure, Function, and Disorders of Lymphoid Tissue 367
V.E. TED VALLI and ROBERT M. JACOBS

CHAPTER 53
Disorders of the Spleen 376
JOHN L. ROBERTSON and ERIK TESKE

CHAPTER 54
Systemic Lupus Erythematosus 383
LUC S. CHABANNE

CHAPTER 55
Feline Immunodeficiency Virus 393
HANS LUTZ and MARGARET HOSIE

CHAPTER 56
T cell, Immunoglobulin, and Complement Immunodeficiency Disorders 400
PETER J. FELSBURG

CHAPTER 57
Severe Combined Immunodeficiencies 406
STEVEN E. SUTER

CHAPTER 58
Benign Lymphadenopathies 412
C. GUILLERMO COUTO, RANCE M. GAMBLIN, and ERIK TESKE

SECTION V
Hematologic Neoplasia 419
Jaime F. Modiano

CHAPTER 59
Cell Cycle Control in Hematopoietic Cells 421
JAIME F. MODIANO and CATHERINE A. ST. HILL

CHAPTER 60
Epidemiology of Hematopoietic Neoplasia 427
MICHELLE G. RITT

CHAPTER 61
Genetics of Hematopoietic Neoplasia 433
JAIME F. MODIANO and MATTHEW BREEN

CHAPTER 62
Transforming Retroviruses 440
MARY JO BURKHARD

CHAPTER 63
Bone Marrow-Derived Sarcomas 447
LESLIE C. SHARKEY and JAIME F. MODIANO

CHAPTER 64
Classification of Leukemia and Lymphoma 451
V.E. TED VALLI and WILLIAM VERNAU

CHAPTER 65
General Features of Leukemia and Lymphoma 455
STUART C. HELFAND and WILLIAM C. KISSEBERTH

CHAPTER 66
Myelodysplastic Syndromes 467
DOUGLAS J. WEISS

CHAPTER 67
Acute Myeloid Leukemia 475
LAURA A. SNYDER

CHAPTER 68
Mast Cell Cancer 483
CHERYL LONDON

CHAPTER 69
B Cell Tumors 491
V.E. TED VALLI

CHAPTER 70
Plasma Cell Tumors 511
ANTONELLA BORGATTI

CHAPTER 71
Hodgkin's Lymphoma 520
V.E. TED VALLI

CHAPTER 72
T Cell Lymphoproliferative Diseases 525
DAVIS M. SEELIG, PAUL R. AVERY, WILLIAM C. KISSEBERTH, and JAIME F. MODIANO

CHAPTER 73
Histiocytic Proliferative Diseases 540
PETER F. MOORE

CHAPTER 74
Gene Therapy 550
BRUCE F. SMITH and R. CURTIS BIRD

SECTION VI
Platelets 559
Mary K. Boudreaux

CHAPTER 75
Platelet Structure 561
MARY K. BOUDREAUX

CHAPTER 76
Platelet Biochemistry, Signal Transduction, and Function 569
MARY K. BOUDREAUX and JAMES L. CATALFAMO

CHAPTER 77
Platelet Kinetics and Laboratory Evaluation of Thrombocytopenia 576
KAREN E. RUSSELL

CHAPTER 78
Immune-Mediated Thrombocytopenia 586
MICHAEL A. SCOTT and L. ARI JUTKOWITZ

CHAPTER 79
Non-Immune-Mediated Thrombocytopenia 596
JENNIFER S. THOMAS

CHAPTER 80
Essential Thrombocythemia and Reactive Thrombocytosis 605
TRACY STOKOL

CHAPTER 81
Von Willebrand Disease 612
MARJORY B. BROOKS and JAMES L. CATALFAMO

CHAPTER 82
Inherited Intrinsic Platelet Disorders 619
MARY K. BOUDREAUX

CHAPTER 83
Acquired Platelet Dysfunction 626
MICHAEL M. FRY

SECTION VII
Hemostasis 633
Marjory B. Brooks

CHAPTER 84
Overview of Hemostasis 635
STEPHANIE A. SMITH

CHAPTER 85
Acquired Coagulopathies 654
MARJORY B. BROOKS and ARMELLE DE LAFORCADE

CHAPTER 86
Hereditary Coagulopathies 661
MARJORY B. BROOKS

CHAPTER 87
Thrombotic Disorders 668
SUSAN G. HACKNER and BARBARA DALLAP SCHAER

CHAPTER 88
Disseminated Intravascular Coagulation 679
TRACY STOKOL

CHAPTER 89
Vascular Diseases 689
SEAN P. MCDONOUGH

CHAPTER 90
Treatment of Hemostatic Defects 695
DANIEL F. HOGAN and MARJORY B. BROOKS

CHAPTER 91
Overview of Avian Hemostasis 703
KENDAL E. HARR

SECTION VIII
Transfusion Medicine 709
Mary Beth Callan

CHAPTER 92
Erythrocyte Antigens and Blood Groups 711
GORDON A. ANDREWS and MARIA CECILIA T. PENEDO

CHAPTER 93
Granulocyte and Platelet Antigens 725
JENNIFER S. THOMAS

CHAPTER 94
Principles of Canine and Feline Blood Collection, Processing, and Storage 731
ANTHONY C.G. ABRAMS-OGG and ANN SCHNEIDER

CHAPTER 95
Red Blood Cell Transfusion in the Dog and Cat 738
MARY BETH CALLAN

CHAPTER 96
Transfusion of Plasma Products 744
MARJORY B. BROOKS

CHAPTER 97
Platelet and Granulocyte Transfusion 751
ANTHONY C.G. ABRAMS-OGG

CHAPTER 98
Blood Transfusion in Large Animals 757
MARGARET C. MUDGE

CHAPTER 99
Blood Transfusion in Exotic Species 763
JAMES K. MORRISEY

CHAPTER 100
Transfusion Reactions 769
NICOLE M. WEINSTEIN

CHAPTER 101
Major Histocompatibility Complex Antigens 776
ANNE S. HALE and JOHN A. GERLACH

CHAPTER 102
Hematopoietic Stem Cell Transplantation 783
RAQUEL M. WALTON

CHAPTER 103
Clinical Use of Hematopoietic Growth Factors 790
STEVEN E. SUTER

SECTION IX
Species Specific Hematology 797
Rose E. Raskin and K. Jane Wardrop

CHAPTER 104
Normal Hematology of the Dog 799
THERESA E. RIZZI, JAMES H. MEINKOTH, and KENNETH D. CLINKENBEARD

CHAPTER 105
Normal Hematology of the Cat 811
THERESA E. RIZZI, KENNETH D. CLINKENBEARD, and JAMES H. MEINKOTH

CHAPTER 106
Normal Hematology of the Horse and Donkey 821
TANYA M. GRONDIN and SHANE F. DEWITT

CHAPTER 107
Normal Hematology of Cattle 829
DARREN WOOD and GERARDO F. QUIROZ-ROCHA

CHAPTER 108
Normal Hematology of Sheep and Goats 836
STACEY R. BYERS and JOHN W. KRAMER

CHAPTER 109
Hematology of the Pig 843
CATHERINE E. THORN

CHAPTER 110
Hematology of Laboratory Animals 852
ANNE PROVENCHER BOLLIGER, NANCY E. EVERDS, KURT L. ZIMMERMAN, DAVID M. MOORE, STEPHEN A. SMITH, and KIRSTIN F. BARNHART

CHAPTER 111
Hematology of the Ferret 888
KURT L. ZIMMERMAN, DAVID M. MOORE, and STEPHEN A. SMITH

CHAPTER 112
Hematology of the Guinea Pig 893
KURT L. ZIMMERMAN, DAVID M. MOORE, and STEPHEN A. SMITH

CHAPTER 113
Hematology of the Mongolian Gerbil 899
KURT L. ZIMMERMAN, DAVID M. MOORE, and STEPHEN A. SMITH

CHAPTER 114
Hematology of the Syrian (Golden) Hamster 904
STEPHEN A. SMITH, KURT L. ZIMMERMAN, and DAVID M. MOORE

CHAPTER 115
Hematology of Camelids 910
SUSAN J. TORNQUIST

CHAPTER 116
Hematology of Cervids 918
KATIE M. BOES

CHAPTER 117
Hematology of Water Buffalo (*Bubalia bubalis*) 927
TAMARA B. WILLS

CHAPTER 118
Hematology of the American Bison (*Bison bison*) 931
KURT L. ZIMMERMAN, DAVID M. MOORE, and STEPHEN A. SMITH

CHAPTER 119
Hematology of Reindeer 936
BRIDGET C. GARNER

CHAPTER 120
Hematology of Elephants 942
KENDAL E. HARR, RAMIRO ISAZA, and JULIA T. BLUE

CHAPTER 121
Hematology of Marine Mammals 950
THOMAS H. REIDARSON

CHAPTER 122
Hematology of Chickens and Turkeys 958
PATRICIA S. WAKENELL

CHAPTER 123
Hematology of Psittacines 968
TERRY W. CAMPBELL

CHAPTER 124
Hematology of Waterfowl and Raptors 977
TERRY W. CAMPBELL, STEPHEN A. SMITH, and KURT L. ZIMMERMAN

CHAPTER 125
Hematology of Ratites 987
ALICE BLUE-McLENDON and ROBERT A. GREEN

CHAPTER 126
Hematology of Fishes 994
TERRY C. HRUBEC and STEPHEN A. SMITH

CHAPTER 127
Hematology of Reptiles 1004
ARMANDO R. IRIZARRY ROVIRA

CHAPTER 128
Hematology of Elasmobranchs 1013
MICHAEL K. STOSKOPF

SECTION X
Quality Control and Laboratory Techniques 1019
Andreas Moritz

CHAPTER 129
Quality Control 1021
MADS KJELGAARD-HANSEN and ASGER LUNDORFF JENSEN

CHAPTER 130
Diagnostic Test Validation 1027
ASGER LUNDORFF JENSEN and MADS KJELGAARD-HANSEN

CHAPTER 131
Reference Intervals 1034
MADS KJELGAARD-HANSEN and ASGER LUNDORFF JENSEN

CHAPTER 132
Evaluation of Bone Marrow 1039
ANDREAS MORITZ, NATALI B. BAUER, DOUGLAS J. WEISS, ANNE LANEVSCHI, and ALAA SAAD

CHAPTER 133
Hematopoietic Cell Culture 1047
CHRISTINE S. OLVER

CHAPTER 134
Radiolabeling and Scintigraphic Imaging of Platelets and Leukocytes 1051
DOUGLAS J. WEISS

CHAPTER 135
Automated Hematology Systems 1054
ANDREAS MORITZ and MARTINA BECKER

CHAPTER 136
Reticulocyte and Heinz Body Staining and Enumeration 1067
HAROLD TVEDTEN and ANDREAS MORITZ

CHAPTER 137
Flow Cytometry 1074
DOUGLAS J. WEISS and MELINDA J. WILKERSON

CHAPTER 138
Laboratory Testing of Coagulation Disorders 1082
GEORGE LUBAS, MARCO CALDIN, BO WIINBERG, and ANNEMARIE T. KRISTENSEN

CHAPTER 139
Clinical Blood Typing and Crossmatching 1101
K. JANE WARDROP

CHAPTER 140
Testing for Immune-Mediated Hematologic Disease 1106
K. JANE WARDROP, MELINDA J. WILKERSON, and CINZIA MASTRORILLI

CHAPTER 141
Evaluation of Neutrophil Function 1114
STEFANO COMAZZI

CHAPTER 142
Evaluation of Platelet Function 1123
INGE TARNOW and ANNEMARIE T. KRISTENSEN

CHAPTER 143
Immunophenotyping and Determination of Clonality 1133
ANNE C. AVERY

CHAPTER 144
Cytochemical Staining 1141
ROSE E. RASKIN

CHAPTER 145
Electrophoresis and Acute Phase Protein Measurement 1157
JOSE J. CERÓN, MARCO CALDIN, and SILVIA MARTINEZ-SUBIELA

CHAPTER 146
Measurement of Serum Iron Concentration, TIBC, and Serum Ferritin Concentration 1162
GORDON A. ANDREWS

CHAPTER 147
Molecular Techniques and Real-Time PCR 1165
CHRISTIAN M. LEUTENEGGER

CHAPTER 148
Genetic Evaluation of Inherited and Acquired Hematologic Diseases 1170
CHRISTIAN M. LEUTENEGGER and URS GIGER

Index 1176

PREFACE TO THE SIXTH EDITION

The sixth edition of *Schalm's Veterinary Hematology* has undergone significant updating, reorganization, and refocusing. Several global changes have been made with the goal of making the information more accessible and improving cohesiveness and readability of the text. First, we grouped topics within established disciplines in hematology. Secondly, we introduced informative chapter outlines at the beginning of each chapter and extensively refer the reader to other chapters within the text. Finally, we edited the text in an attempt to make the presentation as clear and uniform as possible.

In addition to organizational changes, we added two new sections; Hematotoxicity and Quality Control and Laboratory Techniques. The Hematotoxicity section was thought necessary because of the large number of clinical pathologists now involved in preclinical safety assessment and toxicology and because of present concerns about environmental toxicants. In that regard, we also expanded the laboratory animal hematology chapter in the book. The Quality Control and Laboratory Techniques section was added for several reasons. First, this section acknowledges and supports the growing group of veterinary laboratory technicians. Secondly, this section may help to standardize testing and quality control in clinical and industrial laboratories. Thirdly, this section may support and encourage research in veterinary and comparative hematology.

We have also expanded other sections in the book. The Hematologic Neoplasia section was extensively reorganized using the World Health Organization classification system as the basis for classification of leukemias and lymphomas. This expansion reflects the dramatic progress made in this discipline in recent years. The Species Specific Hematology section has also been expanded by increasing the number of photographs of blood cells and by adding discussions of bone marrow where appropriate. This should be helpful when veterinary clinical pathologists encounter blood or bone marrow preparations from species with which they are not familiar.

We hope that you will find the many changes made in this edition to be beneficial. We thank the previous editors, section editors, and authors for their wisdom, knowledge, time, and commitment.

Douglas J. Weiss
K. Jane Wardrop

SECTION I

Hematopoiesis

Maxey L. Wellman

CHAPTER I

Embryonic and Fetal Hematopoiesis

KELLI L. BOYD and BRAD BOLON

Basic Principles of Hematopoietic Development
  Cell Structure and Function
Primitive Hematopoiesis
  Erythroid Cells
  Other Cells
Definitive Hematopoiesis
Hemoglobin Switching
Molecular Mechanisms Regulating Hematopoietic Development

Acronyms and Abbreviations

AGM, aorta-gonad-mesonephros; Bmp, bone morphogenetic protein; 2,3-DPG, 2,3-diphosphoglycerate; E#, day of embryonic development, where the number indicates age of the embryo in days after conception; EPO, erythropoietin; fL, femtoliter; Gata1, 2, and 4, GATA-binding proteins 1, 2, and 4; HSC, hematopoietic stem cell; Ihh, Indian hedgehog; IL, interleukin; P#, day of postnatal development, where the number indicates age of the neonate in days after delivery; pg, picogram; PU.1, purine box-binding transcription factor; Scl/Tal-1, stem cell leukemia/T-cell acute leukemia factor.

The complexities of hematopoietic system development have been highly conserved throughout vertebrate evolution. Understanding the embryonic and fetal origins of hematopoiesis provides important insights regarding the function of the adult hematopoietic system. Hematopoiesis in embryonic and fetal animals has been studied intensively for several decades as a model for hematopoietic progression in humans. Recent technical advances have allowed researchers to characterize the spatial and temporal relationships as well as the cellular and molecular mechanisms of hematopoietic development.

This chapter reviews the basic biology of hematopoietic development in the mouse (*Mus musculus*). This appraisal will emphasize hematopoietic events during the embryonic and fetal stages of development, but also will cover selected features of neonatal hematopoiesis.

BASIC PRINCIPLES OF HEMATOPOIETIC DEVELOPMENT

Cell Structure and Function

Blood cells produced at different stages of development differ in morphology and function. Thus, primitive ("fetal") cells fabricated early in gestation have markedly different properties from their definitive ("adult") counterparts produced during late gestation and in postnatal life. This principle has been characterized most completely in erythroid lineage cells. Primitive erythrocytes (RBCs) are formed in the yolk sac, whereas definitive RBCs are produced by the liver and later spleen and bone marrow. Primitive RBCs are nucleated in circulation until approximately day 12.5 (E12.5) of gestation, after which nuclei gradually become condensed before being shed between E14.5 to E16.5.[35] Enucleated primitive RBCs retain their large size and can remain in circulation until as late as postnatal day 5 (P5). Both primitive and definitive RBCs are released during most of the latter half of gestation (E10 to E18), although the ratio shifts as time progresses from mainly primitive to mainly definitive RBCs.

Primitive and definitive RBCs can be distinguished by their size. The volume of primitive RBCs varies from 465 to 530 femtoliters (fL) which is approximately six times larger than that of definitive RBCs.[35] The hemoglobin content of primitive RBCs, 80 to 100 picograms (pg)/cell, also is nearly six times the amount found in definitive RBCs.[35] Both primitive and definitive RBCs have basophilic cytoplasm when first produced due to abundant rough endoplasmic reticulum, but basophilia recedes as maximal hemoglobin content is achieved.

Other hematopoietic lineages also differ in cell structure and function during the course of development. Primitive megakaryocytes from the yolk sac contain fewer nuclei of lower ploidy, are about half the size, and respond differently to cytokine stimulation relative to definitive megakaryocytes.[47] Primitive macrophages that originate in the yolk sac[42] lack certain enzyme activities, are capable of division, and survive for extended periods compared to definitive monocyte-derived macrophages. These functional differences are related to the roles that the two cell populations appear to play. Primitive macrophages are the source for many tissue macrophages in embryonic through juvenile stages of development, whereas definitive macrophages are the source for circulating monocytes and resident macrophages characteristic of the adult immune system.

PRIMITIVE HEMATOPOIESIS

The processes that drive primitive and definitive stages of hematopoiesis as well as the events that regulate transition between the two stages are mediated by a constellation of factors.[1,30,45,46] Cell adhesion factors, growth factors, and transcription factors that participate in this process often support differentiation of multiple hematopoietic cell types,[10,29,36] and the dependence of a given cell lineage on any particular molecule may differ between primitive and definitive hematopoiesis.

Erythroid Cells

Hematopoiesis occurs at multiple sites within the embryo and in extraembryonic tissues. The first phase of blood cell production, referred to as *primitive hematopoiesis*, is responsible for producing blood elements during the earliest stage of embryogenesis. Primitive hematopoiesis takes place in the visceral yolk sac beginning at approximately E7.0.[15,34] Thus, primitive hematopoietic cells are among the earliest distinct tissues to differentiate in the embryo. Formation of primitive cells declines rapidly after E11. The visceral yolk sac or extraembryonic splanchnopleure (the term for a structure in which mesoderm and endoderm are directly apposed) arises from the migration of extraembryonic mesoderm streaming from the caudal primitive streak along the inner surface of the visceral endoderm. The mesodermal cells committed to initiate and support hematopoiesis have been termed *hemangioblasts* because the contiguity of primitive hematopoiesis and vasculogenesis in both space and time suggests that primitive hematopoietic and endothelial cells in the yolk sac share a common ancestor.[1,9] Hemangioblasts arise as undifferentiated cells at the primitive-streak stage and commit to producing a particular cell lineage before blood island formation.[34,44] These pluripotent cells also can differentiate into other mesenchyme-derived tissues.

Between E7.5 and E9.0, hemangioblasts form multiple aggregates termed *blood islands*.[35] Each blood island contains a central core of unattached inner hemangioblasts (hematopoietic progenitors) surrounded by a rim of spindle-shaped outer hemangioblasts (endothelial progenitors).[15] Nucleated erythroid cells are first recognized in the cores of the blood islands at E8.0 and are evident circulating in the cardiovascular system starting at E8.25.[18] At this stage embryonic erythroblasts enter the circulation, where they continue to divide until approximately E13.0.

The majority of cells produced during primitive hematopoiesis are of the erythroid lineage. Committed erythroid colony-forming cells arrive in the yolk sac at approximately E7.25. These cells expand until E8.0 and then differentiate into primitive erythroblasts; all colony-forming cells have regressed completely by E9.0,[34] which corresponds approximately to the earliest phase of definitive erythropoiesis. Primitive erythroblasts serve as the sole source of RBCs in the early embryo from E8.0 to approximately E10.5[34] and remain an important source of RBCs until E13. Thus, embryos with a developmental age between E8.0 and E11 that are anemic suffer from a defect in primitive erythropoiesis.[26,38] Interestingly, seemingly profound defects in primitive hematopoiesis leading to persistent functional defects in adulthood may not elicit an aberrant hematologic profile in the embryo.

Other Cells

Recent studies suggest that other hematopoietic cell lineages also are generated in the yolk sac during this primitive stage of hematopoietic development. Primitive lymphoid precursors and even some adult stem cells evolve at E7.5 and subsequently seed other sites of hematopoiesis, including the aorta-gonad-mesonephros region (AGM), umbilical vessels, and liver.[40] Primitive macrophages have been identified in the yolk sac by E8.0[4] to E9.0.[34] In vitro experiments have demonstrated that E7.5 yolk sac cells can give rise to functional megakaryocytic precursors by E10.5.[47] Many hemangioblasts actually serve as bi- or oligo-potent progenitors, including those capable of commitment to erythrocytic/myeloid,[4] erythrocytic/megakaryocytic,[27] granulocyte/macrophage,[34] and lymphoid (B cell and T cell)/myeloid lineages. Stem cells for mast cells have also been reported to arise in the yolk sac during primitive hematopoiesis.[34]

DEFINITIVE HEMATOPOIESIS

The second stage of blood cell production, termed *definitive hematopoiesis*, is thought to arise primarily from the AGM.[3,27] The AGM is an amorphous band of intraembryonic splanchnopleure that encompasses the dorsomedial wall of the abdominal cavity. The AGM domain is the main source of mesenchyme-derived, definitive hematopoietic stem cells (HSCs) that will serve the developing animal during late gestation and postnatal life. Initiation of definitive hematopoiesis ranges between E8.5 and E9.25, with definitive HSCs evident in the AGM by no later than E10. Peak production of

HSCs in the AGM occurs between E10.5 and E11.5, at which time they comprise almost 10% of all AGM cells. Although controversial, some AGM-independent HSCs may also arise from the allantois, chorion, definitive placenta, umbilical arteries, and yolk sac. The actual contribution of these secondary sites to the overall HSC population has yet to be defined. However, the placenta appears to serve a particularly important role. The yolk sac also appears to be an essential secondary site because it is a source of multiple progenitor cell lineages and remains for at least a day after the AGM has halted HSC production.[28]

Regardless of their original site of de novo synthesis, HSCs migrate to seed other locations that support definitive hematopoiesis: embryonic liver, followed by embryonic thymus, fetal spleen, and bone marrow (in that order). These latter destinations do not produce HSCs de novo but rather contain niches suitable for expansion of newly arrived HSCs.[33] The suitability of such niches is controlled by specific characteristics of their stromal support cells.[33] The embryonic liver is colonized first, apparently because it shares many molecular and functional similarities with the yolk sac.[31] It provides the major locus for definitive hematopoiesis from E12 to E16.[39] The HSCs enter the embryonic liver in several succeeding waves between E9.0 or E10.0 and E12.[12] The first HSCs to enter the liver are pluripotent and can form any type of hematopoietic cell. Their first step in intra-hepatic maturation is to commit to a more limited range of lineage options, typically as either an erythromyeloid progenitor or a common myelolymphoid progenitor.[22] Definitive erythroid precursors mature and become enucleated within erythroid islands in the liver before entering the circulation.[27] Liver-derived myelolymphoid progenitors subsequently develop into bi-potent cells (B cell and myeloid, or T cell and myeloid) before committing to produce a single cell lineage.[22] Some T cell progenitors have a bi-potent commitment to NK cell lineage. T cell precursors destined for transfer to the embryonic thymus are produced even in athymic mice, indicating that the fetal liver may play a role in promoting early T cell differentiation.[20,21]

Embryonic thymus and fetal spleen are seeded either from the liver or AGM, or both, beginning about E13 for thymus and E15 for spleen. The thymus typically accepts only those HSCs that are committed to make T cells, whereas other multi-potent myelolymphoid elements are directed to other sites.[20] The number of T cell precursors in liver is abundant at E12 but decreases thereafter, whereas the population of intra-hepatic B cell progenitors exhibits a reverse trend.[19] Most types of definitive hematopoietic cells in the spleen arise from precursor cells that commit to a specific lineage before leaving the liver. Multi-potent HSCs entering the spleen cease proliferating and differentiate into mature macrophages. These cells may regulate intra-splenic erythropoiesis.

The bone marrow first receives HSCs from hepatic depots at about E16.[39,45] Thereafter, the allocation of colony-forming hematopoietic precursors shifts from a primarily hepato-centric localization at E18 through a more dispersed distribution (bone marrow, liver, and spleen in approximately equal numbers) at P2 to a profile favoring bone marrow and to a lesser extent spleen at P4 and after.[49] Thus the bone marrow, liver, and spleen function cooperatively to regulate definitive hematopoiesis. While cooperating, each organ supports a molecularly distinct subset of hematopoietic progenitors.

Committed hematopoietic progenitors necessary to foster all lineages observed in adult animals arise during definitive hematopoiesis. The AGM-derived HSCs contribute to all major hematopoietic cell lineages. The HSC population from the placenta reportedly supports the genesis of erythroid, lymphoid (both B cell and T cell lineages), and myeloid elements. By comparison, the lineages sustained by yolk sac-derived HSCs are limited to lymphoid and myeloid cells.[40] Whether or not progenitors for a given definitive cell lineage arising from distinct HSC populations exhibit different functional and molecular properties during late fetal and/or postnatal life has yet to be determined.

Late-stage embryos (E13 to E15), fetuses (E16 to birth), and neonates which present with anemia are afflicted with a defect in definitive erythropoiesis. Abnormalities associated with this presentation include the total absence of definitive hematopoiesis,[25,41] and an inability of progenitor cells to properly colonize intra-embryonic sites of hematopoiesis. Multiple cell lineages may be affected; such a combined effect suggests that the hematopoietic defect occurs in a bi- or multi-potent stem cell rather than in one committed to forming a specific cell lineage.[43] Presentation with late-stage anemia also might result from a general delay in growth and development rather than a focused anomaly in the erythrocytic lineage.[7]

Young animals have circulating blood cell numbers is that are different from adults.[39] RBC numbers more than double between birth and young adulthood. Circulating leukocyte counts at birth are approximately 20% of adult levels before increasing to adult numbers by 6 to 7 weeks of age. Platelet counts in neonates are approximately one-third numbers.

HEMOGLOBIN SWITCHING

Primitive and definitive RBCs bear a battery of seven α- and β-globins, the mix of which varies with the developmental stage. The α-globins are encoded by three genes (ζ, α_1, and α_2), whereas β-globins are encoded by four main genes (εγ, βH1, β*min*, and β*maj*). The globins of a given type (e.g. α- or β-globins) typically exist as a series of closely linked homologous genes and related pseudo-genes located on the same chromosome;[16,24] mouse globin genes are carried on chromosomes 7 (β-globins) and 11 (α-globins). All seven mouse globin genes are transcribed during erythroid development, but the production of three—ζ, εγ, and βH1—is limited to primitive RBCs.[23] A consequence of this limitation is that mouse β-globin genes, although

closely related to human globins in most respects, do not follow the human pattern of up-regulation in the sequence of their chromosomal arrangement.[23,24]

The extent of individual globin gene expression and the blend of globin genes that are expressed vary over time. For example, enucleated primitive RBCs contain relatively more β*min* than do definitive RBCs. At E11.5, β*min* constitutes approximately 80% of the β-globin in circulation. This level is reduced by approximately 60% at birth. Primitive RBCs express increasing levels of adult globins as gestation progresses, whereas definitive RBCs harbor only the adult protein variants. This evolution indicates that the pattern of globin expression switches as the primitive RBCs are replaced by definitive RBCs. Molecular mechanisms which regulate the switching process are complex.[17] The timing of this switch, between E10.5 and E12.5, coincides with the initial escalation in definitive erythropoiesis. Perturbed timing of this switch is a feature of some murine models of hematopoietic disease.[6]

Successful maintenance of the developing conceptus depends on preferential capture of oxygen in embryonic and fetal tissues. Therefore, primitive RBCs generally have a higher affinity for oxygen than do maternal RBCs, although domestic cats are an exception. This sequestration of oxygen is mediated by two primary mechanisms. The mechanism pertinent to the early embryonic period is the greater affinity of embryonic hemoglobin in primitive RBCs for oxygen relative to that of adult hemoglobin.[2] Alternatively, definitive RBCs in the late embryo and fetus possess a lower concentration of 2,3-diphosphoglycerate (2,3-DPG) than do maternal RBCs. Higher levels of 2,3-DPG facilitate oxygen release into tissues. After birth, levels 2,3-DPG content of RBCs rise to adult levels within 10 to 15 days.

MOLECULAR MECHANISMS REGULATING HEMATOPOIETIC DEVELOPMENT

A wide spectrum of growth factors, hormones, and transcription factors are required to specify the various stages of hematopoietic development in mammals. The entire meshwork responsible for directing any given event has not been completely characterized. Shifting levels of several transcription factors have been shown to modify blood cell production. Insufficiencies in many of these molecules act by forestalling primitive hematopoiesis in the yolk sac. For example, genesis of erythroid precursors is impacted by deficits in GATA-binding protein 1 (Gata-1),[13] shown in vivo to prevent erythroid maturation; Gata-2,[48] demonstrated in vivo to abort precursor expansion; and Gata-4,[5] for which an in vitro shortage thwarts hemangioblast-mediated specification of blood islands and their associated vessels. These effects occur because the GATA consensus elements are critical regulatory regions in many erythroid-specific genes. All cell lineages are affected by stem cell leukemia/T-cell acute leukemia factor 1 (Scl/Tal-1).[38] Abnormal levels of transcription factors can also act later in gestation to disrupt definitive hematopoiesis. For example, purine box-binding transcription factor 1 (PU.1) is required for production of definitive (monocyte-derived) macrophages but not their primitive (yolk sac-derived) counterparts. This disparity in response is intriguing in that PU.1 is highly expressed during early hematopoiesis but fluctuates in various cell lineages as time progresses.[10] Normal genesis of many progenitor cells, including bi-potent erythroid/megakaryocytic progenitors as well as B cell and T cell progenitors, requires that PU.1 levels be reduced, whereas production of myeloid progenitors necessitates an increase in PU.1.[10]

Secreted molecules also are important regulators of hematopoietic development during gestation. For example, erythropoietin (EPO) sustains both primitive and definitive erythropoiesis by stimulating proliferation and differentiation of immature primitive and definitive RBCs.[25] Reduction in EPO activity within the yolk sac greatly reduces the number of colony-forming cells and erythroblasts via excessive apoptosis. Thrombopoietin fulfills a similar function for megakaryocytes, although other cytokines (interleukin-3 [IL-3], IL-6) and growth factors (granulocyte-colony stimulating factor, stem cell factor) also are required.[47] Other ligand/receptor signaling pathways shown to affect hematopoietic development include the endoderm-derived molecule Indian hedgehog (Ihh)[8] and bone morphogenetic protein 4 (Bmp4),[11] both of which participate in blood island production and vasculogenesis in the yolk sac. In general, secreted molecules act via their interaction with a specific transcription factor.

Cell adhesion molecules of the integrin family are essential for the proper migration of hematopoietic precursors. For instance, β_1-integrins are essential if HSC are to reach the embryonic liver, and later the fetal spleen and bone marrow, at the appropriate developmental stages.[37] A loss of β_1-integrins prevents adhesive interactions between HSCs and endothelial cells, thereby stranding the HSCs within vessels.[32] Some integrins have functions in addition to their targeting role. For example, β_4-integrins are required not only for correct homing but also for expansion and differentiation of erythroid and B cell precursors in liver, spleen, and bone marrow. As with secreted factors, the activities of some integrins relate more to late gestation and neonatal stages rather than earlier stages of hematopoietic development. This chronology has been documented for β_4-integrin with respect to lymphoid and myeloid differentiation.[14]

Lymphoid Cells and Macrophages
Stem Cell Niches

Acronyms and Abbreviations

HSC, hematopoietic stem cell; RBC, red blood cell; WBC, white blood cell.

Bone marrow is the major hematopoietic organ in adults, and a primary lymphoid organ. Bone marrow is a diffuse organ which constitutes approximately 3% of the body mass in rats, 2% in dogs, and 5% in humans.[39] Marrow tissue is present in the central cavities of axial and long bones, and consists of a sinusoidal system, hematopoietic cells, adipose tissue, supporting reticular cells, and extracellular matrix. The complex vasculature and rich innervation of the marrow reflect the multiplicity of signals contributing to the control of hematopoiesis. Bone marrow is a dynamic organ capable of structural and functional remodeling in response to nutritional factors, endocrine signals, and variations in demand for the production of red blood cells (RBCs), white blood cells (WBCs), and platelets. This chapter will review the structure of bone marrow with a brief conceptual framework for structural and functional relationships among the different components of bone marrow. For a more thorough discussion of the biochemical and molecular control of hematopoiesis and the hematopoietic microenvironment, the reader is referred to Chapters 1 and 5.

SUPPORTING STRUCTURES

Hematopoietic tissue resides within a rigid boney cortex, and is further supported by a meshwork of trabecular bone that serves as a partial scaffold for additional structural components including adipose, reticular cells, and extracellular matrix. In addition to providing physical support, each of these structures contributes to the biochemical microenvironment of hematopoietic tissue, either directly or via vascular connections.

A one to two cell thick layer of flat endosteal cells with a thin layer of connective tissue lines all of the boney surfaces within the medullary cavity. This layer is punctuated with occasional osteoblasts and osteoclasts, and may be traversed by endosteal blood vessels connecting the hematopoietic space with bone. Osteoblasts contribute to bone production and are derived from multipotent mesenchymal stromal progenitor cells that also give rise to bone marrow stromal cells and adipocytes.[30] Osteoclasts are multinucleated cells derived from fused monocyte-macrophage precursors under the influence of numerous signals, including those from osteoblasts.[30] Osteoblasts and osteoclasts remodel bone within the marrow space, influencing the endosteal environment and probably contributing to regulation of hematopoietic stem cell proliferation and trafficking.[25] Osteoblasts and osteoclasts also produce hematopoietic cytokines, and interplay between bone and hematopoietic cells can influence bone turnover and remodeling.[30,36]

Fine, spindloid to stellate stromal cells extend from endosteal regions into the parenchyma of hematopoietic tissue. These cells probably derive from fibroblasts in the bone marrow, and form a supporting meshwork for hematopoietic cells, adipose tissue, and blood vessels. Stromal cells produce soluble factors that contribute to regulation of hematopoiesis, and communicate with hematopoietic precursors via direct cell to cell contact. Bone marrow stromal cells produce structural fibrils such as collagen, reticulin, laminin, and fibronectin, and ground substance composed of water, salts,

glycosaminoglycans, and glycoproteins, which collectively are called the extracellular matrix. Like the supporting cellular structures of the marrow, the extracellular matrix participates in both the structural and biochemical support of hematopoiesis.[26]

Bone marrow contains predominantly types I and III collagen, which take their final form after secretion into the extracellular space, where they undergo enzymatic modification. Reticulin is distinguished from collagen in the marrow by the presence of fine argyrophilic fibers, which are composed of a core of type I collagen surrounded by type III collagen fibrils embedded in a matrix of glycoproteins and glycosaminoglycans.[26] Although the fine connective tissue structure of bone marrow is not prominent on routinely processed histology sections, special stains can enhance its visualization. Collagen can be visualized with Mallory's or Masson's trichrome stains, whereas Gomori's silver stain highlights the presence of reticulin. This can be important in pathologic conditions in which production of excess matrix material contributes to disease. Differentiation of collagen and reticulin fibrosis may have diagnostic implications and influence the likelihood of reversibility of the lesion. Expanded extracellular matrix characterizes other bone marrow disorders beyond classical syndromes of myelofibrosis.[26,41]

Adipose tissue interspersed with hematopoietic tissue is enmeshed in the same supporting structures. The relationship between formation of bone and adipose tissue is not clearly understood.[15] Adipocytes probably are derived from the same mesenchymal progenitors that produce stromal cells and osteoblasts, and there is some evidence for interconversion of cells originating from committed osteoblastic and adipogenic lineages derived from the mesenchymal progenitor population.[3] Adipocytes are the most numerous stromal cells in bone marrow. In health, adipose tissue takes up approximately 25% to 75% of the bone marrow space, depending on the age of the animal. Adipose tissue also contains other cell types that are less visible than adipocytes on routine histologic sections. These cells also contribute to the structural and functional roles of adipose tissue in hematopoiesis, and include endothelial cells, macrophages, and adipocyte progenitor cells.[24] Both brown and white adipose tissue are present in bone marrow; differences in biological function of these types of fat are not fully understood. Bone marrow adipose tissue tends to be relatively resistant to lipolysis during starvation compared with adipose tissue elsewhere in the body.

In addition to providing structural support, adipose tissue also may participate in the hematopoietic microenvironment. Cells derived from bone marrow adipose tissue are capable of supporting differentiation of hematopoietic progenitors in vitro.[8,10] The endocrine and paracrine functions of adipose tissue also are important.[12,37] Adipokines, which are biologically active substances produced by adipose tissue, include regulators of hematopoiesis and the immune response.[10,24,27,28,35]

VASCULATURE AND SINUS ARCHITECTURE

The nutrient artery provides the major blood supply to bone marrow (Fig. 2.1). Nutrient arteries enter the medullary cavity via one or more nutrient canals, which also may contain one or two nutrient veins. There often are two nutrient arteries for long bones, and flat bones may contain several.[39] Once the vessels have penetrated the

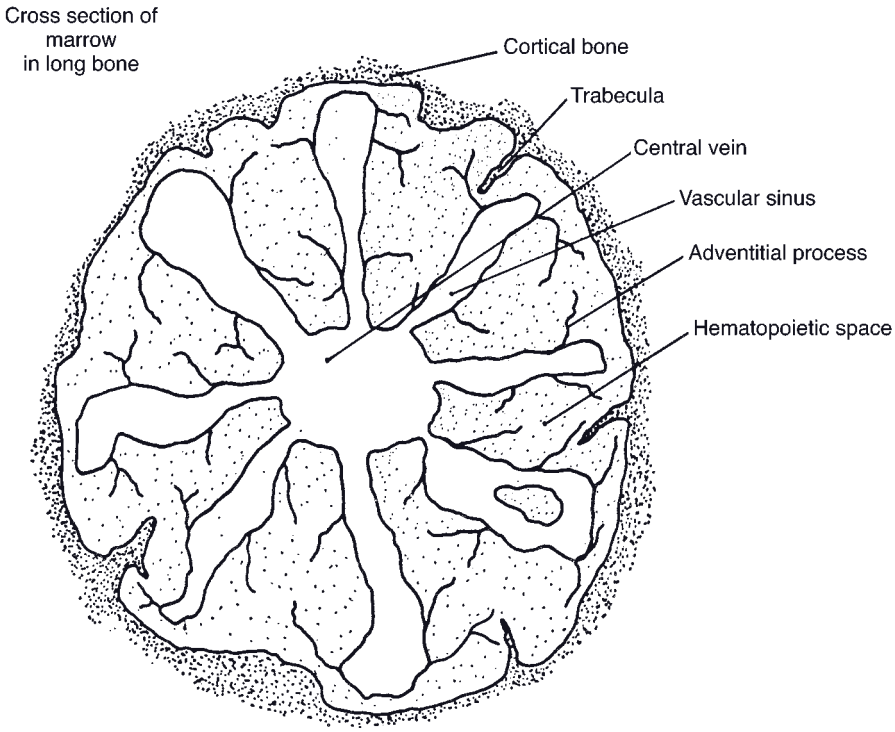

FIGURE 2.1 Organization of the venous vasculature of the marrow of a long bone. Thin-walled vascular sinuses originate at the periphery from termination of transverse branches of the nutrient artery (not shown). The vascular sinuses run transversely toward the center to join the CV. Hemopoiesis takes place in the space between the vascular sinuses. Adventitial processes project into the hematopoietic space, producing partial compartmentalization. (Reproduced from Lichtman MA. The ultrastructure of the hemopoietic environment of the marrow: a review. Exp Hematol 1981;9:391–410, with permission.)

cortex, ascending and descending branches bifurcate from the main vessels, coiling around the main venous bone marrow channel and central longitudinal vein. These branches form numerous arterioles and capillaries that penetrate the endosteal surface of the bone to communicate with cortical capillaries derived from arteries that supply surrounding muscle tissue (Fig. 2.1). These interactions facilitate communication and reciprocal regulation between hematopoietic cells and bone.[30] Capillaries derived from the nutrient artery extend as far as the Haversian canals before coursing back to the bone marrow and opening into the venous sinuses.

Periosteal arterioles penetrate cortical bone to form a second arterial system for the bone marrow. These vessels form branching networks of medullary venous sinuses. Medullary venous sinuses collect into the large central venous sinus from which blood enters the systemic circulation via the emissary vein, which exits through the nutrient foramen.[1]

Hematopoiesis occurs in the extravascular spaces between the venous sinuses, and has a close morphologic and functional relationship with the cells that line the venous sinuses. Venous sinuses are lined by a complete luminal layer of broad, flat endothelial cells and an incomplete outer layer of abluminal reticular cells (Fig. 2.2). Reticular cells maintain close physical relationships with the hematopoietic cells close to the sinus walls, frequently wrapping around or otherwise contacting hematopoietic precursors. The basement lamina between the sinusoids and the hematopoietic space is thin and interrupted to facilitate release of mature hematopoietic cells into the circulation.[29] Sinus endothelial cells may regulate translocation of cells and other substances into the systemic circulation. Ultrastructurally, sinus endothelial cells have distinct cell junctions that are not tight, and egress of hematopoietic cells through migration pores in endothelial cells has been observed. Other particulate matter may traverse sinus endothelial cells by the process of endocytosis.[29]

INNERVATION

Primary innervation of the bone marrow is via myelinated and more numerous non-myelinated fibers. These fibers originate in the spinal nerve corresponding to the location of the nutrient foramen, although some innervation may originate from the epiphyseal and metaphyseal foramina.[6,39] Once inside the medullary cavity, the mixed myelinated and non-myelinated nerve bundles, surrounded by a thin perineurium, divide to parallel the arterial vasculature of the bone marrow.[6] The main branches of the arterial vessels are surrounded by several nerve bundles, whereas arterioles and capillaries may be accompanied by only a single fiber, with nerve endings contacting vascular smooth muscle cells or periarterial adventitial and reticular cells.[43]

The sinusoidal system is less richly innervated than the arterial vasculature, with nerve endings frequently contacting the walls of sinusoids. Other nerve fibers appear to terminate within the hematopoietic parenchyma or along the endosteum.[6,11] It is not clear if there is shared or separate innervation of bone and hematopoietic tissue, although at least some nerve fibers in the bone marrow appear to originate from mineralized bone.[31,34] Bone marrow contains efferent noradrenergic and peptidergic sympathetic and presumptive sensory nerve fibers.[9,34] There is some evidence that

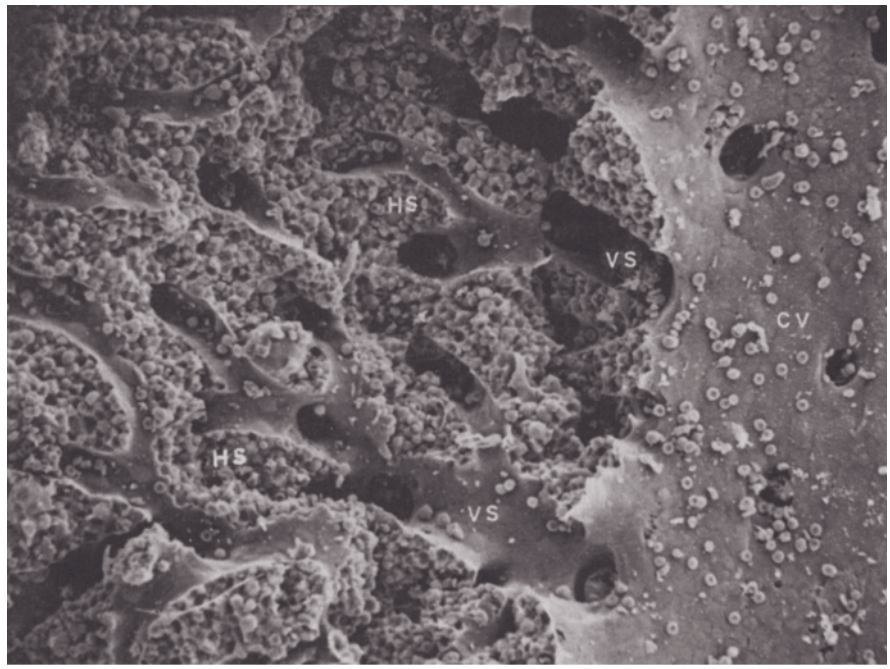

FIGURE 2.2 Scanning electron micrograph of a rat bone marrow showing developing cells in hematopoietic spaces (HSs), anastomosing venous sinusoids (VS), and central vein (CV). 290×. (Prepared with assistance of Dr. Prem Handagama.)

signals from the sympathetic nervous system may contribute to regulation of hematopoiesis, immune function, and hematopoietic stem cell trafficking.[2,5,9,20,22,32,38]

CELLULAR ORGANIZATION

An intricate three-dimensional complex of hematopoietic cells forms cords or wedges between vascular sinuses within the medullary cavity (Fig. 2.3). Different cell lineages occupy specific locations: granulocytes, lymphocytes, and macrophages are concentrated near the endosteum and arterioles, and megakaryocytes and erythroid cells are located near venous sinuses.[1,14,33]

Hematopoietic cells are derived from a common pluripotent stem cell which gives rise to lymphoid and myeloid progenitor cells. Lymphoid progenitor cells generate lymphocyte progeny, whereas the myeloid progenitor cells generate erythroid cells, megakaryocytes, basophils, eosinophils, and a common granulocyte-macrophage cell that produces neutrophils and macrophages. Each cell line exhibits a pyramidal progression of cell numbers with the least mature cells present in the smallest numbers and cells in subsequent stages of development present in increasing proportions.

Megakaryocytes

Megakaryocyte development begins with the megakaryoblast, progresses to promegakaryocytes and basophilic megakaryocytes, and culminates with formation of mature megakaryocytes. Megakaryocyte precursors progressively enlarge as they differentiate to become the largest cell in the bone marrow.[4,16] Their nuclei mature from a single nucleus to a large multilobulated nucleus through a process termed endomitosis, which is replication of DNA without cellular division.[4,16] The cytoplasm of early megakaryocytic precursors is scant and deeply basophilic, becoming more abundant, lightly basophilic, and filled with numerous eosinophilic granules as the cell matures.[16]

As megakaryocytes mature, they migrate toward the venous sinuses and may compose part of the endothelial cell layer.[1,4,13,17,19,33,39,40] This location enables

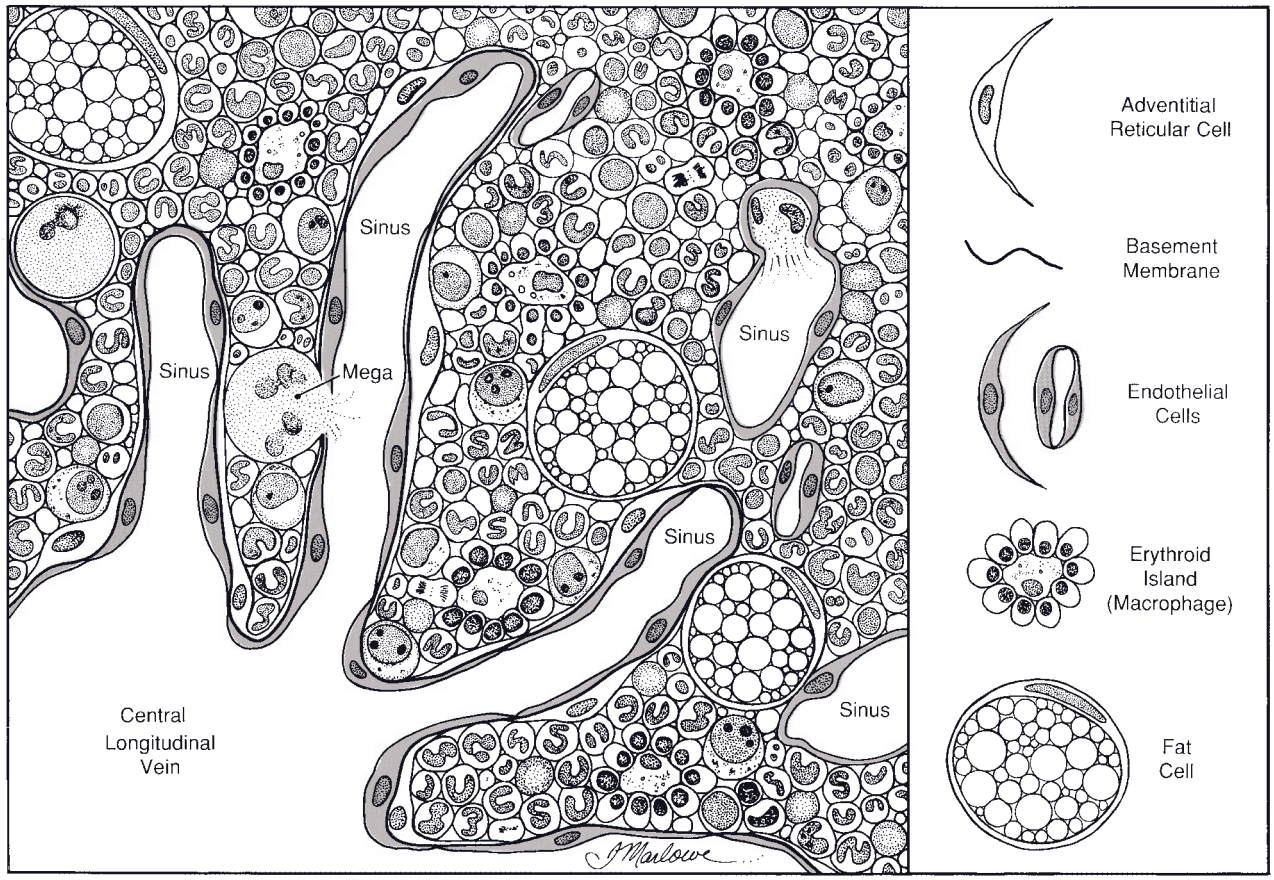

FIGURE 2.3 Schematic depiction of the hematopoietic compartment of the medullary cavity. Hematopoiesis occurs in cords composed of differentiating hematopoietic cells, stromal cells, adventitial reticular cells, adipocytes, and endothelial cells. Megakaryocytes (Mega) reside near the sinuses, shedding platelets directly into the sinus. Erythropoiesis occurs around macrophages, termed erythroid islands. Some evidence suggests structural variation in the location of primitive versus differentiated cells, with more primitive cells located nearer the bone surface. (Reproduced from Sieff C, Williams D. Hemopoiesis. In: Handin R, Lux S, Stossel T, eds. Blood: Principles and Practice of Hematology. Philadelphia: JB Lippincott, 1995, with permission.)

cytoplasmic processes to extend through endothelial gaps and discharge of proplatelets directly into the lumen of the sinus. Platelets are released from proplatelet processes into the peripheral circulation (see Chapter 9).[13,17,19,39]

Erythroblastic (Rubriblastic) Islands

Stages of erythropoiesis include rubriblasts, prorubricytes, rubricytes, metarubricytes, reticulocytes, and mature RBCs (see Chapter 6).[13,16,17] As erythroid precursors mature, the cells become smaller, the nuclear to cytoplasmic ratio decreases, the cytoplasm becomes less basophilic and more polychromatophilic, and the nuclear chromatin becomes condensed. In mammals, the nucleus is extruded before maturation to a mature RBC.[16,17] Erythropoiesis occurs in distinct erythroblastic islands (Fig. 2.3), which are clusters of cells that occasionally can be observed in cytologic samples of bone marrow.[1,7,39,44] Erythroblastic islands form around a central macrophage that projects membranous processes to assist erythropoiesis by providing iron and probably other nutrients and hematopoietic cytokines. These macrophages also phagocytize extruded nuclei and defective cells.[1,7,13] Erythroid progeny are found in concentric circles surrounding the central macrophage with younger forms closer to the macrophage.[1] Central macrophages are recruited from a subset of resident macrophages derived from monocyte precursors. Erythroblastic islands are located near venous sinuses.[1,39,40] A recent study of erythropoiesis in rat bone marrow suggests that erythroblastic islands are motile and migrate towards sinusoids as they mature, and that erythroblastic islands are composed of cells in similar stages of erythroid development.[7,44]

Granulocytes

Neutrophils, eosinophils, and basophils develop in a parallel fashion from myeloblasts, promyelocytes, myelocytes, metamyelocytes, and band forms, to mature cells. Granulocytes, like RBCs, decrease their cellular size and nuclear to cytoplasmic ratio as they mature. Secondary specific granules appear in the myelocyte stage and allow differentiation of the various granulocytic lineages.[16,17] At the metamyelocyte stage, the round nucleus elongates and indents to form a bean-shaped nucleus before ultimately forming segmentations at full maturation. The location of granulocytic cells is dependent on their stage of maturity. Immature forms are located near arterioles and boney trabeculae. As maturation proceeds, precursors migrate toward venous sinusoids, where they access the peripheral circulation by diapedesis.[1,13,33,40]

Lymphoid Cells and Macrophages

Lymphoid progenitors produce B cells, which develop further in the bone marrow, and T/NK progenitors, which leave the bone marrow for further development in the thymus and other tissues. Immature lymphoid cells and macrophages are located near the endosteum and arterioles,[1,18,33] whereas mature lymphocytes are relatively uniformly distributed with the bone marrow parenchyma.[1,18,33] Morphologic changes in lymphoid cells during maturation are relatively minimal compared to other lineages and include decreasing cell size, decreasing cytoplasmic basophilia, and increasing condensation of nuclear chromatin.

Stem Cell Niches

Hematopoietic stem cells (HSCs) are morphologically indistinct, and evaluation of surface proteins is required for definitive identification (see Chapter 3). HSCs reside in the bone marrow within stem cell niches, the specialized microenvironments created by supporting cells that provide the necessary signals for stem cell maintenance and function.[21,23] Current evidence indicates that there are two niches: an endosteal or osteoblastic niche and a vascular niche.[21,23,42] The endosteal niche is located adjacent to the endosteal surface of the bone marrow, in a location influenced by osteoblastic activity, and it promotes HSC quiescence and trans-marrow migration.[21,23] The vascular niche is located near the sinusoidal endothelium and is involved in HSC expansion and egress into the circulation.[21] The relationship between the two stem cell niches is still under investigation.[23,42]

Acronyms and Abbreviations

ABC transporter, ATP-binding cassette transporter; BMP, bone morphogenic protein; CD, cluster of differentiation; EPC, endothelial precursor cell; EPO, erythropoietin; ERK, extracellular signal related kinases; ESC, embryonic stem cell; FGF, fibroblast growth factor; GM-CSF, granulocyte/macrophage colony stimulating factor; HSC, hematopoietic stem cell; IGF-2, insulin-like growth factor 2; IL, interleukin; JAK/STAT, Janus kinase/signal transducers and activators of transcription; LIF, leukemia inhibitory factor; Lin⁻, lineage negative; miRNA, microribonucleic acid; MSC, mesenchymal stem cell; PE, phycoerythrin; PI3k, phosphoinositide-3 kinase; Sca-1, stem cell antigen 1; SCF, stem cell factor; SCID, severe combined immunodeficiency; SP, side population; Tie, tyrosine kinase with immunoglobulin-like and EGF-like domains 1; TNK, T cell and natural killer cell progenitor; TPO, thrombopoietin.

DEFINING STEM CELLS

Characteristics

Stem cells are a population of unspecialized precursor cells that have capacity for self-renewal and the ability to differentiate, leading to formation of mature cells and tissues. This latter function is clearly evident in embryonic stem cells (ESCs), as they lead to the establishment of the numerous different cells and tissues of the mature organism. Small numbers of stem cells are retained throughout life as adult stem cells and are a reservoir for replacement of short-lived cells or regeneration of damaged tissues. Hematopoietic stem cells (HSCs) are the reservoir for replacement of blood cells and are present in a frequency of 1 in every 10,000 to 100,000 blood cells.[3] (Fig. 3.1; see Chapters 6–10).

Two general functional characteristics are used in defining stem cells. The first of these is the ability of long term self renewal. Stem cells have the capability, through mitotic cell division, to maintain a population of undifferentiated cells within the stem cell pool for months to years, and over many cycles of cell division. As stem cells divide, on average, one daughter cell is a replica and remains in an undifferentiated state, while the second daughter cell is programmed to differentiate. This production of two daughter cells with different properties is termed asymmetric cell division. The second characteristic of stem cells is the capacity to form differentiated or specialized cell types.

Potency is a term that is used to describe the degree or extent to which multiple functional cell lines can be formed. Totipotent stem cells are those cells that have the ability to form entire organisms, including extra-

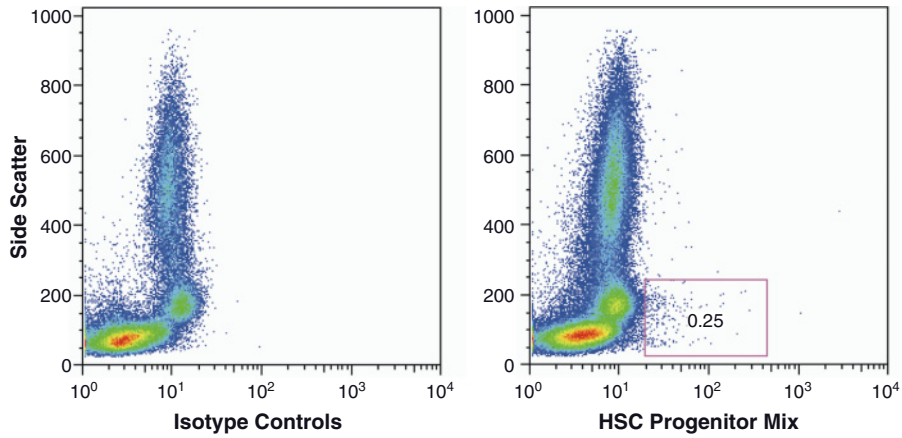

FIGURE 3.1 Hematopoietic progenitor cells in the peripheral circulation. Hematopoietic progenitor cells can be defined by expression of specific cell surface markers such as CD34, c-Kit, and CD133. In this case, such cells are detectable in blood from a normal dog using flow cytometry. Each panel shows a two-dimensional dot plot of FL2 (fluorescence channel-2 set to detect wavelength emission maxima at 575 ± 13 nm) vs. right angle side scatter. Cells were stained using routine protocols; dead cells were excluded using a vital dye. The left panel shows cells stained using an isotype control antibody. The right panel shows cells stained using a mix of antibodies against CD34, c-Kit, and CD133, each labeled with phycoerythrin (PE). In this healthy adult dog, approximately 0.25%, or ~2/1,000 viable leukocytes expressed one or more of the progenitor markers. While the frequency is almost 20-fold greater than that seen in most healthy dogs, this case serves to illustrate the presence of hematopoietic progenitor cells in circulation with no associated pathology. (Analysis and figure courtesy of Megan Duckett, Masonic Cancer Center, University of Minnesota.)

embryonic tissues (e.g. placenta). This type of stem cell can be derived from the zygote or early blastomere. Pluripotent stem cells are able to form all cell types of the body (e.g. ESCs). Multipotent stem cells generate all differentiated cells of a particular lineage (e.g. HSCs), and will be of particular interest to the topics in this text. Finally, unipotent stem cells give rise to only a single cell line (e.g. spermatogonial stem cells).[13]

Tests and Markers

Functional assays to demonstrate the pluripotent or multipotent nature of stem cells have been achieved through in vitro formation of embryoid bodies, in vivo generation of teratomas in mice with severe combined immunodeficiency (SCID) after grafting of ESCs, and, in the case of HSCs, repopulation of the hematopoietic system of lethally irradiated mice following transplantation of unpurified bone marrow derived cells.[12,21,24] The ability to identify and isolate stem cells, however, relies largely on the use of a variety of markers such as surface molecules, transcription factors, and dye efflux. Numerous markers are available, and frequently are used in combination, to identify pluripotent cells and stem cells within certain types of tissue. While some markers and tests are used more universally to recognize stem cells, special attention will be paid to those used in identifying bone marrow-derived stem cells.

Cluster of Differentiation (CD)34

CD34 is a cell surface glycoprotein that has traditionally been used in identification and purification of HSCs and progenitor cells.[1] This marker appears to be highly conserved among mammalian species. Experimental evidence suggests that CD34 may be involved in cell adhesion of hematopoietic cells to stromal cells in the bone marrow microenvironment.[10] More recently, however, CD34-negative HSCs called side population (SP) cells were identified. SP cells are thought to be some of the most primitive HSCs because of their high proliferative potential and extreme efficiency at homing to sites of hematopoiesis when injected into recipient mice.[19] CD34 expression on HSCs may thus be related to the degree of activation of these cells, with CD34-negative cells being the most primitive and quiescent.[1]

Stem Cell Antigen

Stem cell antigen-1 (Sca-1) is a cell surface protein often used in identification of murine HSCs. This molecule may play a role in lineage determination.[5]

Dye Efflux

The ability of some primitive HSCs to efflux florescent dye allows for identification of this population, termed SP cells, by flow cytometry.[8,19] This ability appears to be due to increased number or activity of membrane pumps (e.g. ATP-binding cassette transporter [ABC-transporter]), a hypothesis supported by the finding of blockage of dye efflux by the drug verapamil, a known inhibitor of these efflux pumps.[8] SP cells lack CD34 expression and have been described in multiple species.[9] As stated earlier, these CD34-negative cells have been proposed to be some of the most primitive HSCs.

c-Kit

c-Kit is a transmembrane tyrosine kinase receptor found on HSCs of multiple species. It binds the ligand stem cell factor (SCF, also called Steel factor), and is important in the maintenance, proliferation, and differentiation of HSCs.[28]

Lin⁻

As an adjunct to the presence of certain markers (e.g. CD34, c-Kit, Sca-1), the absence of markers present on differentiated cells has been used to isolate and purify HSCs. A lineage negative (Lin⁻) classification generally indicates that cells are negative for a combination of anywhere from 6 to 14 different lineage markers of mature blood cells.

Transcription Factors

Transcription factors that appear to be important in regulation of stem cell pluripotency and their undifferentiated state have been identified. Most notable are the transcription factors Oct-4, Nanog, and Sox-2, which have been used as markers of embryonic and adult stem cells.[6]

BONE MARROW-DERIVED STEM CELLS

Within the bone marrow, there appear to be at least three different types of stem cell. HSCs are multipotential stem cells that give rise to the mature cellular elements of the blood (e.g. RBCs, neutrophils, monocytes, platelets, etc.). The stromal components of bone marrow such as bone, cartilage, fat, and fibrous connective tissue are derived from mesenchymal stem cells (MSCs), also termed marrow stromal cells. Finally, endothelial precursor cells (EPCs) are a population of bone marrow-derived cells that function in angiogenesis. EPCs are mobilized from the bone marrow into the peripheral blood, where they home to sites of neovascularization such as those present in areas of inflammation, tumor vascularization, or wound repair (see Chapter 11).[1]

STEM CELL BIOLOGY

Regulation of Survival and Pluripotency

Niche

The niche concept is important to the discussion of stem cell survival and differentiation. Niches are local tissue microenvironments that function to support, maintain, and regulate stem cells. These microenvironments are found in various tissues throughout the body, for example the bulge region of the hair follicle, near the base of crypts in the gastrointestinal tract, and, in the case of HSCs, adjacent to endosteum and bone marrow sinusoids.[20] Regulation of stem cells by their niche occurs through physical contact and cell-cell interactions with adjacent cells, as well as elaboration of soluble factors.[20] Evidence also indicates that stem cells have the ability to influence the cellular elements of their niche. For example, HSCs from mice subjected to an acute hematopoietic stress have an increased ability to direct bone marrow mesenchymal cells toward osteoblastic differentiation as a result of HSC-derived bone morphogenic proteins (BMPs).[15]

Molecular Mechanisms

What are the factors that cause stem cells to go down a pathway of self-renewal and remain undifferentiated versus progression toward lineage differentiation and mature cell phenotypes? The answer to this question is constantly evolving as specific molecular mechanisms are elucidated. Several factors important in the maintenance of stem cell survival, self-renewal, and pluripotency have been revealed in murine ESCs. These factors have been divided into extrinsic factors (e.g. cytokines) and intrinsic factors (e.g. transcription factors).

Leukemia Inhibitory Factor (LIF) LIF is an interleukin (IL) 6 class cytokine that prevents differentiation of mouse ESCs in culture. Binding of LIF to its membrane receptor results in activation of multiple molecular signaling pathways such as Janus kinase/signal transducers and activators of transcription (JAK/STAT), phosphoinositide-3 kinase (PI3K), and extracellular signal related kinases (ERK). Although these pathways are common downstream signals of many cytokines, in this context, their activation tends to promote maintenance of self-renewal and pluripotency. Activation of ERK in this example, however, appears to favor differentiation of mouse ESCs. Thus, LIF can activate signals that either promote or inhibit maintenance of an undifferentiated state, and it is the balance between these downstream effects (generally favoring self-renewal and pluripotency) that determines the outcome.[6]

Bone Morphogenic Protein 4 (BMP4) and Basic Fibroblast Growth Factor (FGF) BMP4 and basic FGF are additional examples of extrinsic factors that promote self-renewal and pluripotency in mouse ESCs. In the case of BMP4, it appears to work in a synergistic state with LIF.[6] Discovery of additional signaling pathways and factors is likely, as factors important for mouse ESCs are not universal when applied to human ESCs.

Wnt Specific extrinsic factors involved in self-renewal of HSCs have been identified. The Wnt signaling pathway stimulates self-renewal of HSCs while concurrently inhibiting HSC differentiation. Inducing β-catenin activation, a downstream component of the Wnt signaling pathway, results in increased self-renewal of murine HSCs and limits differentiation of these cells. When inhibitors of the Wnt pathway are added to murine HSCs and growth factors, HSC proliferation is repressed.[22]

Tyrosine Kinase with Immunoglobulin-Like and Endothelial Growth Factor-Like Domains 2 (Tie2) and Angiopoietin-1 Tie2/Angiopoietin-1 signaling has also been implicated in survival of HSCs. Tie2 is a receptor tyrosine kinase expressed on some HSCs. Angiopoietin-1 is the ligand for the Tie2 receptor and promotes quiescence and increased adhesion of murine HSCs to bone marrow stromal cells. Regulation of the quiescent state and maintenance within the HSC niche is thought to be important in HSC survival through a protective effect against myelosuppresive stresses.[2]

Other Cytokines Other cytokines important in regulation of HSC survival include SCF, thrombopoietin (TPO), BMP, FGF, insulin-like growth factor 2 (IGF-2), and interleukin (IL)-10. SCF and TPO are common components of most cytokine combinations used in the culture and propagation of HSCs. Although TPO is the primary cytokine involved in megakaryocyte and platelet production, it also has been shown to have significant effects on HSCs. In vitro, TPO promotes survival and expansion of HSCs, and mice that have been genetically altered to lack TPO or its receptor have significantly fewer stem cells.[16,29]

Transcription Factors The intrinsic factors governing the undifferentiated state of ESCs consist primarily of transcription factors. Most notable are Oct-4, Nanog, and Sox-2. These factors are found in pluripotent cell lines and, in general, down-regulation results in differentiation of stem cells. Presence of Oct-4 and Sox-2 appears to be essential for pluripotency; however, the target genes for these transcription factors have not been completely characterized.[6] Several transcription factors and cell cycle regulators governing self-renewal of HSCs also have been described.

Microribonucleic Acids (miRNAs) miRNAs are an additional intrinsic molecular mechanism proposed to be involved in maintenance of pluripotent stem cells. miRNAs are short, single-stranded RNA molecules that regulate gene function by suppression of translation through annealing and sometimes degradation of mRNA. Novel miRNAs have been found that appear to be expressed preferentially in undifferentiated ESCs. In addition, evaluation of miRNA expression profiles from ESCs of varying degrees of differentiation as well as cells from mature tissues show repression or loss of specific miRNAs as cells progress to a more differentiated state.[11]

Regulation of Differentiation

Differentiation of stem cells into specific lineages is controlled or directed by factors including cytokines, niche interaction, and regulators of self-renewal and pluripotency. Cytokines influence and guide lineage determination of stem cells and many have been described in the context of HSCs and hematopoietic progenitor cell differentiation (Fig. 3.2; see Chapters 6–11).

Stromal cells that constitute the stem cell niche influence differentiation and lineage determination through physical cell-cell interaction and elaboration of soluble or cell-bound factors (e.g. cytokines). Finally, as previously described, there are regulators that promote self-renewal and the pluripotent state of stem cells. For differentiation to occur, these regulators must be inhibited or suppressed. Mechanistically, there may be two general categories by which cells restrict lineage commitment.[23] The first of these involves the spectrum of surface receptors, adhesion proteins, and signaling pathways expressed by a given cell. For example, cytokines play an important role in lineage development. However, if a stem or progenitor cell lacks a cytokine receptor then that cytokine would have little or no effect on its target. Gene silencing is a second mechanism by which lineage restriction may occur. For cells to differentiate, specific genes are activated or silenced, guiding cells toward a particular lineage. This may be accomplished through mechanisms such as DNA methylation and histone modification, which alter the transcriptional state of the chromatin.

STEM CELL-ASSOCIATED DISEASES

Stem Cell Failure

The hematopoietic system offers a clear illustration of the effects of stem cell failure. HSCs are responsible for the constant replacement of all cellular components of blood, with HSC failure, cytopenias (e.g. anemia, leukopenia, thrombocytopenia) and their associated clinical manifestations (e.g. lethargy, infection, hemorrhage) ensue. HSC failure can be the result of a number of underlying pathologic processes, including toxic or drug-mediated damage, immune-mediated damage, infectious agents (e.g. parvovirus, feline leukemia virus, and *Ehrlichia* spp.), insufficient stimulation by cytokines and growth factors, and disruption of or damage to the stem cell niche (e.g. myelophthisis, ischemia, inflammation).[4,7,25,26] (See Section II.)

Stem Cells and Proliferative Disorders

Just as adult stem cells are responsible for replacement of mature cells and tissues, there is strong evidence that cells with stem cell properties underlie the pathology of at least some types of cancer. The hypothesis of cancer stem cells is based on a few basic observations. The first of these is the observation of tumor heterogeneity. Many tumors comprise cells with different morphologies and phenotypes that in some cases loosely resemble the tissue of origin. This suggests a certain degree of differentiation within a population of tumor cells, leading to variability in structure and function. A more primitive precursor cell (i.e. cancer stem cell) could presumably give rise to the different phenotypes within a tumor. The second observation is that transplantation of a tumor required relatively large numbers of cancerous cells, an indication that only small numbers of cells in a given tumor have the ability to form a tumor. Cancer stem cells are present in small numbers within

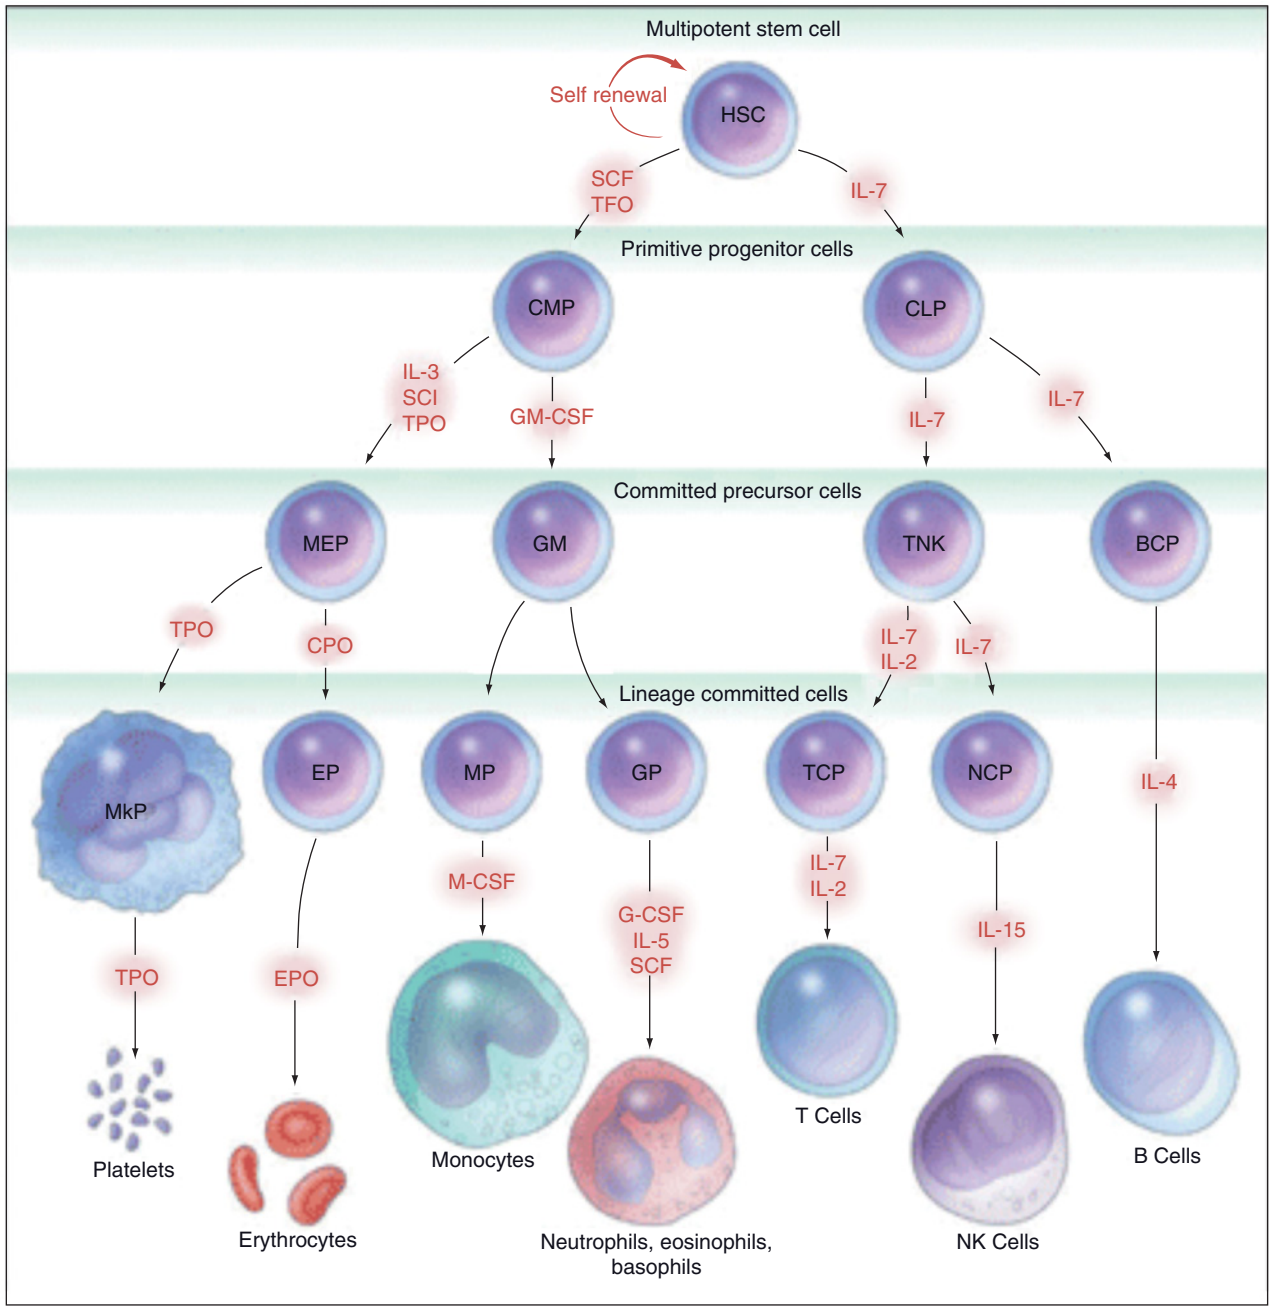

FIGURE 3.2 A general model of hematopoiesis. Blood cell development progresses from a hematopoietic stem cell (HSC), which can undergo either self-renewal or differentiation into a multilineage committed progenitor cell: a common lymphoid progenitor (CLP) or a common myeloid progenitor (CMP). These cells then give rise to more differentiated progenitors, comprising those committed to two lineages that include T cells and natural killer cells (TNKs), granulocytes and macrophages (GMs), and megakaryocytes and erythroid cells (MEPs). Ultimately, these cells give rise to unilineage committed progenitors for B cells (BCPs), NK cells (NKPs), T cells (TCPs), granulocytes (GPs), monocytes (MPs), erythrocytes (EPs), and megakaryocytes (MkPs). Cytokines and growth factors that support the survival, proliferation, or differentiation of each type of cell are shown in red. For simplicity, the three types of granulocyte progenitor cells are not shown; in reality, distinct progenitors of neutrophils, eosinophils, and basophils or mast cells exist and are supported by distinct transcription factors and cytokines (e.g. interleukin-5 in the case of eosinophils, stem-cell factor [SCF] in the case of basophils or mast cells, and G-CSF in the case of neutrophils). IL denotes interleukin, TPO thrombopoietin, M-CSF macrophage colony-stimulating factor, GM-CSF granulocyte-macrophage CSF, and EPO erythropoietin. (Reprinted from Kaushansky K. Lineage-specific hematopoietic growth factors. New Engl J Med 2006;354:2034–2045, with permission. ©Massachusetts Medical Society 2006.)

a tumor, and thus relatively large amounts of tissue would be needed to ensure the presence of these cells. Just like normal stem cells, cancer stem cells share the basic functional properties of self-renewal and the ability to differentiate.

In humans, evidence for cancer stem cells has been shown in hematopoietic, brain, breast, colon, prostate, bone, and ovarian cancers, and there is some evidence for the existence of cancer stem cells in animals.[14,17,18,27] Support for the existence of cancer stem cells in humans consists of identification of a subset of tumor cells that express stem cell markers and have exclusive or enhanced ability to form tumors in vitro or in vivo. Evidence exists that cancer stem cells may arise from normal stem cells and/or progenitor cells that have reacquired the ability of self-renewal. The origins of cancer stem cells continue to be explored.

The existence of cancer stem cells has clear implications for understanding cancer biology and treatment in at least certain types of cancers. For example, many chemotherapeutics target rapidly dividing cells. However, cancer stem cells are relatively slowly cycling, thus allowing them to persist with these conventional treatments. Newer therapeutic modalities directed at elimination of cancer stem cells will be important for effective treatment of these types of neoplasia.

  Multipass Transmembrane Protein (III)
  Glycosyl Phosphoatidylinositol Transmembrane Protein (V)
Tissue Distribution

Acronyms and Abbreviations

CD, cluster differentiation; CLAW, Canine Leukocyte Antigen Workshop; ER, endoplasmic reticulum; FIV, feline immunodeficiency virus; GP, glycoprotein; GPI, glycolyl phosphatidylinositol transmembrane protein; Ig, immunoglobulin; IL, interleukin; Mab, monoclonal antibody; MDR-1, multidrug resistance transporter protein; MHC, major histocompatibility antigen; NK, natural killer; PROW, The International Protein Reviews on the Web; VLA, very late antigen.

DEFINITION AND HISTORY

Cluster differentiation (CD) nomenclature was first introduced at an international conference in Paris (1982) during the boom in monoclonal antibody (MAb) technology.[2] This nomenclature was established to standardize the classification of cell surface antigens and to define the biological functions of molecules expressed by various hematopoietic lineages. Several international workshops have been held to exchange human and other species-specific MAbs and to compare their reactivity with cells and cell proteins from veterinary species.[7,27,28,40,46] Based on these workshops, MAbs that have similar reactivity with tissues or cell types are assigned to a cluster group. Therefore, an antigen that is recognized by a cluster of MAbs is assigned a "cluster of differentiation" (CD) number. If MAbs defining a cluster of antigens are derived from the same laboratory, the suffix "w" is appended to the CD designation. Only eight CD antigens are internationally accepted as defined by the 1st Canine Leukocyte Antigen Workshop (CLAW) and include the following homologues to the human system: CD4, CD5, CD8, CD11a/18, CDw41, CD44, CD45, and CD45R.[7] The final meeting of the Human Leukocyte Differentiation Antigen 8-workshop was held in December, 2004, in Adelaide, Australia, and 376 MAbs from various companies, mainly directed against human leukocytes, were tested for their reactivity with cells from 17 different animal species. A special issue of the journal *Veterinary Immunology and Immunopathology* described these efforts.[39]

Today there are over 339 CD molecules defined. This explosion in CD molecules is the result of the use of molecular biology techniques to identify new molecules. The purpose of this chapter is to provide the most current listing of CD antigens recognized by various antibodies in veterinary species. Table 4.1 summarizes the current knowledge of important veterinary CD antigens, including MAb clones that react with dog, cat, ruminant (cattle, sheep, and goats), pig, and horse CD antigens; relative molecular size(s); topology in the membrane; tissue distribution; known physiology; and species reactivity of MAbs. Selected key references for each CD antigen are included.

More in depth information is available for the currently described CD molecules on several websites, including the taxonomic key program maintained by Washington State University that is designed to provide information of the specificity of MAbs specific for leukocyte differentiation molecules intra- and cross-species (http://www.vetmed.wsu.edu/tkp/). There are links from this website to commercial companies that are the major suppliers of veterinary-specific MAbs, including Serotec (http://www.ab-direct.com/antibodies/_-500.html) and Veterinary Medical Research & Development (VMRD) (http://www.vmrd.com/). The International Protein Reviews on the Web (PROW) (http://mpr.nci.nih.gov/prow/) provides an

TABLE 4.1 Cluster Differentiation Antigens

CD Antigen (MAb Clone)	MAb reactivity (*primary species in italic*)	Size (M_r)	Topology	Distribution	Physiology	Selected References
CD1a (CA9.AG5)	*Canine*	49	I	Thymocytes dendritic cells, Langerhans cells	Nonpolymorphic CD1 family of glycoproteins includes CD1a, b, c, d, and e isoforms involved in presentation of foreign and self lipid antigens and glycolipids; 43–49 subunits interact with a 12 kDa subunit (α_2-microglobulin)	35, 26
CD1a8.2 (CA13.9H11)	*Canine*	43				26
CD1a6 (Fe1.5F4)	*Feline*	49				26, 53
CD1a (Fel5.5C1)	*Feline*					
CD1b (CC20)	*Bovine*	45				19
CD2 (MCA833F)	*Bovine*	45–58	I	T cells, NK cells	Enhances adhesion between T cells and antigen presenting cells	13, 23
(HB88A)[b]	*Equine*					
CD3 (CA17.2A12)	*Canine*	12, 16, 22, 32, 44	I	T cells	A family of proteins that forms a signal transduction complex for T cell receptor when it binds antigen)	11, 50
(MM1A)[b]	*Bovine*					
CD4			I		Receptor for MHC class II, facilitates recognition of peptide antigens	
(CA13.1E4)	*Canine*	60		Neutrophil, T cells		7, 34
(vpg34)	*Feline*	55		T cells		51
CD5 (YKIX322.3), (DH13A)[b]	*Canine*	67	I	T cells	Receptor for CD72, facilitates signals transduced by T cell receptor for antigen	3, 7
(HB19A), (HT23A)[b]	*Equine*					21, 23
CD8 alpha		32, 36	I	Thymocytes, T cells	Forms a heterodimer with CD8β; receptor for MHC class I; facilitates recognition of peptide antigens	
(CA9.JD3)	*Canine*					34
(Fe1.10E9)	*Feline*					53
(73/6.9.1)[b]	*Equine*					49
CD8 beta		39	I	T cells	Forms a heterodimer with CD8α (see above)	
(CA15.4G2)	*Canine*					34
(vpg9)	*Feline*					44
(HT14A)[b]	*Equine*					49
CD9 (vpg15) (MM2/57)	*Feline* Human, canine, feline, bovine, horse	24	III	Activated lymphocytes, monocytes, lymphocytes, granulocytes, platelets	Important for signal transduction, cell activation, adhesion, aggregation; co-receptor for FIV; associates with tetraspan superfamily (CD63, CD81, CD82)	18, 52 39, 41
(RHIA)[b]	Bovine	30–45				47
CD11a (Ca11.4D3, Ca11.7H11)	*Canine*, feline	180, 95	I	Monocytes, granulocytes, lymphocytes	Associates with CD18 to form a heterodimner receptor to facilitate adhesion	9
CD11b (CCA16.3E10)	*Canine*, ruminants, porcine, feline, mink, human	180	I	Granulocytes, monocytes, lymphocyte subset	Associates with CD18 to form a heterodimer receptor to facilitate adhesion	3, 9, 10
CD11c (Ca11.6A1, Ca11.7D1)	*Canine*	150, 95	I	Dendritic cells, granulocytes, macrophages, lymphocytes	Associates with CD18 to form a heterodimer receptor to facilitate adhesion	9
CD11d (Ca11.8H2)	*Canine*	155	I	CD8+ T cells, γδ– T cells, macrophages in splenic red pulp	Associates with CD18 to form a heterodimner receptor to facilitate adhesion	10

TABLE 4.1 ***Continued***

CD Antigen (MAb Clone)	MAb reactivity (*primary species in italic*)	Size (M_r)	Topology	Distribution	Physiology	Selected References
CD13		150	II		Aminopeptidase N, a metalopeptidase in humans which removes NH_2 terminal amino acids from peptides	
(CVS19)	*Equine*			Granulocytes and monocytes		22, 23
(CC81)	*Bovine*			Dendritic cells in afferent lymph		17, 20
CD14 (CAM36)[b]	*Ruminant*, canine, feline, porcine, llama	53	V	Monocytes, myeloid cells	Receptor for lipopolysaccharide that transduces signals, leading to oxidative burst and proinflammatory cytokine synthesis	3, 31
CD18 (CA1.E49)	*Canine*	95	I	All leukocytes	Beta subunit of the integrin heterodimer and combines with the alpha subunit of either CD11a, CD11b, CD11c, CD11d; plays a role in adhesion to endothelium	33
	Bovine					21
(H20A)[b]	Equine					41
CD21	*Canine*	145–160	I	B-cells, monocytes follicular dendritic cells	Receptor for C3d fragment and CD23; enhances B cell antigen receptor signal transduction	3, 4
(CA2.1D6)	Equine, feline, human					3, 4
(LB21)	*Feline*					31
CD22	*Human*	130, 140	I	Early B-cell stages, mature B-cells	Binds sialoglyco-conjugates on some CD45 isoforms to modulate B cell signal transduction	16, 42, 47
(RFB-4)	Canine					
(Mc64-12)	Bovine					
CD23	*Human*	44	II	B-cells and monocytes	Involved in the regulation of IgE synthesis following binding to IgE Fc and IgE-containing immune complexes	3
(M763)[a]	*Ruminants, canine, feline, porcine*	52				
CD25		50–55	I	Mitogen stimulated T or B lymphocytes, LPS stimulated monocytes	IL2-receptor-alpha subunit	36–38
(CACT116A, CACT108A)[b]	*Ruminants*					
(9F23)	*Feline*					
CD29 (12G10, 3S3)	*Human*, canine	110	I	Platelets	Beta chain of VLA, platelet GPIIa	42
CD34 (1H6)	*Canine*	110	I	Lymphohematopoietic stem cells and progenitors, endothelial cells	Leukocyte-endothelial interactions through binding with CD62L and CD62E	29, 30
CD35 (To5)[a]	*Feline*	190, 220	I	B-cells,erythrocytes, granulocytes, monocytes	Receptor for C3b and C4b (CR1) bound to immune complexes	31
CD41 (Canine 20-4), (CL2A)[b], (M7057)[a]	*Canine*	125	I	Platelets, megakaryocytes	Integrin αIIB CD41/CD51 complex, receptor for fibrinogen	3, 7
CD44 (YKIX337.8)	*Canine*	90	I	Most cell types including epithelial cells, activated T cells	Receptor for hyaluronate that facilitates lymphocytic binding to high endothelial venules	7
(BAG40A)[b]	Feline, bovine					7, 47
CD45 (CA12.10C12)	*Canine*	180, 200, 220	I	Pan leukocyte	Membrane-bound tyrosine phosphatase critical for antigen-receptor-mediated activation of leukocytes	4, 6, 7, 50
CD45RA (CA4.1D3)	*Canine*	205, 220, 180–240	I	Naïve T/B lymphocytes	Largest of the CD45 isoforms	4, 6, 7, 50

TABLE 4.1 ***Continued***

CD Antigen (MAb Clone)	MAb reactivity (*primary species in italic*)	Size (M_r)	Topology	Distribution	Physiology	Selected References
CD47 (HUH69A), (HUH71A)[b]	*Human* Canine Bovine	47–55	III	Lymphocytes, macrophages, granulocytes	Associates with CD61 integrins to form receptor for thrombospondin; role in chemotaxis and adhesive interactions with leukocytes and endothelial cells	39 42 47
CD49d (Fe 2.9F2), (P4G9)[a]	*Feline,* canine, bovine	180	I	Lymphocytes, macrophages, granulocytes	VLA binds with 39CD29; binds fibronectin and mucosal addressin	3, 31
CD49e (JBS5)	*Human*, canine	155	I	Macrophages, granulocytes	VLA antigen binds to CD29 and together is the fibronectin receptor and binds to RGD sequence of fibronectin	42
CD56 (MOC-1), (T199)[a]	Human, canine	175–220	I or V	Subset of lymphocytes	Homotypic adhesion and natural killer cell cytotoxicity	42
CD61 (Y2/51)[a]	*Human*, canine	90	I	Platelets, megakaryocytes, monocytes	Associates with CD41 to form the GPIIb-IIIa heterodimer that facilitates platelet aggregation	42
CD79a (HM57)[a]	*Human*, canine	44–49	I	B lymphocytes	Cytoplasmic molecule that mediates sIg expression and B cell receptor cell transduction	16, 32
CD88 (S5/1)	*Human*, bovine	30–45	III	Monocytes, B cells, T-cell subset	C5a receptor homolog; G-coupled receptor that triggers chemotaxis, respiratory burst and degranulation of granulocytes in humans	45
CD90 (CA1.4G8), (CA9.GA11)	*Canine*, equine Porcine, mink Guinea pig	18–44 24 or 26 27	V	Pro-thymocytes, T-cells, monocytes; weak on granulocytes, renal tubular cells	May contribute to formation of neuron memory and to growth regulation of hematopoietic stem cells	3, 4, 7
CD91 (A2MR-2)[b]	*Human*, canine	600	I	Macrophages of liver, lung and lymphoid tissues	Member of low density lipoprotein receptor family that binds to α_2 macroglobulin	39, 42
CD94 (HP-3D9)[b]	*Human*, canine	30	II	Lymphocyte subset (NK)	Binds to NKG2 and plays a role in recognition of MHC class I molecules by NK cells and some cytotoxic T cells; ligation of CD94 can inhibit or stimulate killing by NK cells	42
CDw119 (BB1E2)	*Bovine*	90–100	I	Monocytes, B cells, epithelial cells	Interferon gamma receptor	47
CD134 (7D6)	*Feline*	43	I	CD4+ activated T cells	Tumor necrosis factor receptor superfamily; regulator of T cell-dependent immune responses; receptor for FIV in conjunction with CXCR4	14, 43
CD163 (Ber MAC3)	*Bovine*	130	I	Monocytes	Scavenger receptor cysteine rich family	47
CD172a (DH59b)[b]	*Bovine*, canine, equine, feline	90	I	Monocytes, granulocytes	Member of the signal regulatory protein family involved in negative regulation of receptor tyrosine kinase-coupled signaling processes	12, 15, 31, 39, 42
CD235a (JC159)[a]	*Human* Canine	35 20	I	Erythrocytes	Glycophorin A, major sialoglycoprotein on erythrocytes	42

Column 1: CD designation of the antigen with the monoclonal antibody (MAb) clone published to have primary reactivity shown below in parentheses. Column 2: primary species of reactivity (italics) and those species with cross reactivity (all antibodies are commercially available; those with superscripts are obtainable from Serotec, Inc.[a] and VMRD[b]). Column 3: relative molecular mass of the reduced CD antigen. Column 4: integration of antigen to plasma membrane. Column 5: cell types and tissues known to express a CD. Column 6: proposed or known physiology of a CD antigen based on studies in animals or humans. Column 7: key references concerning identification and characterization of the CD antigen and/or characterization of the antibodies.

exhaustive database of the complete listing of CD antigens and links to primary nucleic acid and protein sequences of human CD antigens.

STRUCTURE AND INTEGRATION OF MEMBRANE ANTIGENS

CD antigens are principally membrane proteins defined by their location within or at the surface of the phospholipid bilayer. Membrane proteins are classified into three categories: integral, lipid-anchored, and peripheral, depending on the nature of membrane-protein interactions.[24] The CD antigens are grouped as integral membrane proteins or transmembrane proteins and consist of cytosolic, membrane spanning, and exoplasmic (luminal) domains. The cytosolic and exoplasmic domains have hydrophilic exterior surfaces with either C-terminus or N-terminus group endings. The membrane-spanning domains usually contain hydrophobic amino acids and consist of one or more alpha helix or multiple beta strands.[24] Most integral membrane proteins fall into one of five classes, depending on how they anchor themselves in the membrane.[1] Type I and II proteins have a single transmembrane region, whereas Types III and IV have multiple transmembrane regions also referred to as tetraspanins. Type IV proteins (not shown in the table) are distinguished from type III proteins by the presence of a water-filled transmembrane channel. Type V proteins use lipid to attach to membranes. These lipids are either a glycosyl-phophatidylinositol (GPI) anchor or lipid moieties such as myristoyl groups, which include cytoplasmic signaling proteins that will not be described in the this chapter.[1,25] Each class pertinent to CD antigens used in veterinary medicine will be described briefly, and examples of common CD antigens used in diagnostic veterinary medicine will be highlighted in the text and are listed in Table 4.1.

TRANSMEMBRANE PROTEINS

Single Pass Type I Transmembrane Protein (I)

Type I and II transmembrane proteins have only one membrane-spanning α-helix containing 20–25 hydrophobic amino acids. Type I proteins have an N-terminal endoplasmic reticulum (ER) signal sequence that is cleaved after the molecule passes into the ER. This is the most common mode of membrane integration among the CD antigens listed in Table 4.1. The protein is glycosylated in the Golgi apparatus if the protein has a glycosylation site and then is expressed on the cell surface. Type I proteins are anchored in the membrane with their hyprophilic N-terminal region on the exoplasmic face and their hydrophilic C-terminal region on the cytoplasmic face. These proteins commonly represent cell surface receptors and/or ligands (like CD4), of which many belong to the immunoglobulin (Ig) superfamily.[1]

Single Pass Type II Transmembrane Protein (II)

Type II transmembrane proteins lack a cleavable ER signal sequence and are oriented with their hydrophilic C-terminus on the exoplasmic face and the hydrophilic N-terminus on the cytoplasmic face. These proteins have an internal hydrophobic ER signal and membrane anchor sequence. Because these proteins can be released from the cell surface, they also can act as plasma proteins with physiologic effect(s) on cells bearing the counter ligands.[1] CD13, a zinc-binding metalloprotease that acts to facilitate antigen presentation by trimming the N-terminal amino acids from MHC Class II-bound peptides, is an example of a type II protein.[1]

Multipass Transmembrane Protein (III)

Type III transmembrane proteins cross the membrane multiple (2, 3, 4, 5, 7, or 12) times and also are called tetraspanins. The most frequently found tetraspanins include those that span the membrane four and seven times. Structural studies indicate that the transmembrane regions are alpha helices. If the type III protein has an even number of transmembrane alpha helices, its N- and C-temini are oriented toward the same side of the membrane. Many of these cell surface molecules function as receptors for soluble molecules such as prostaglandins and chemokines. Examples of seven transmembrane type III proteins are interleukin-8 (IL-8) receptor (CD128) and C5a receptor (CD88). CD9 is an example of a four multi-pass transmembrane protein.[1] CD47 is an example of type III protein with five transmembrane sequences. The multidrug resistance transporter protein MDR-1 (CD243) has 12 transmembrane regions.[1]

Gpi Transmembrane Protein (V)

Type V transmembrane proteins utilize GPI anchors attached to the C-terminal residue of the protein. GPI-anchored molecules have a secretion signal sequence at their N-terminus and C-teminus that is cleaved and replaced by the GPI-anchor after synthesis of the molecule and entry into the ER.[25] CD14, a surface protein involved in the clearance of Gram-negative pathogens bound to lipid polysaccharide binding protein (Fig. 4.1), is an example of a GPI-linked glycoprotein. Other examples of GPI-linked glycoproteins include CD56 and CD90.[1]

TISSUE DISTRIBUTION

Cell surface antigens commonly used in immunophenotyping of hematologic neoplasia initially were determined by studies of hematopoietic cell differentiation and maturation.[8,50] Lineage-associated markers can be broadly classified into groups that recognize B cell, T cell, natural killer (NK) cell, myeloid/monocytic, and erythroid lineages. Noncommitted hematopoietic stem cells express CD34, a glycoslyated surface glycoprotein.

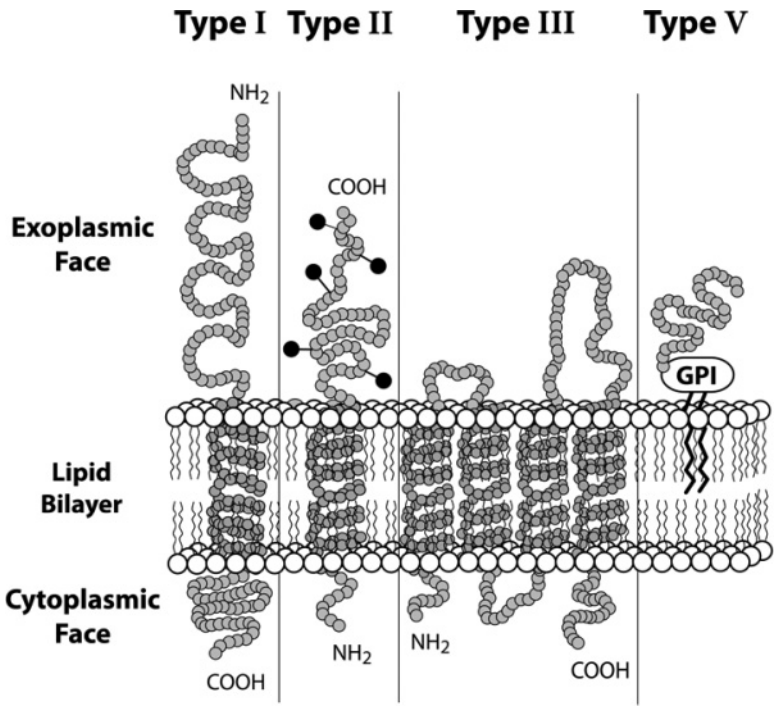

FIGURE 4.1 Major integral membrane proteins and their topology or interaction in the lipid bilayer. The types of membrane proteins are indicated at the top. CD4 is a type I transmembrane protein that passes through the membrane once, has four extracellular immunoglobulin domains, a carboxyl terminus on the cytoplasmic face of the bilayer, and N-terminus (NH_2) on the exoplasmic face. CD13 is a type II transmembrane protein with the N-terminus on the cytoplasmic face and the carboxyl terminus on the exoplasmic face. The extracellular domain of CD13 is heavily N-glycosylated (thin pegs extending from the polypeptide backbone). CD9 is a type III multi-pass membrane protein with four transmembrane regions, and N- and C-termini on the cytoplasmic face. CD14 is a type V glycosyl-phosphatidylinositol (GPI) anchored protein. (Courtesy of Mal Rooks Hoover, Graphic Design Specialist.)

This marker is frequently used to differentiate acute immature leukemias of lymphoid or myeloid origin from chronic lymphocytic leukemia or leukemic stages of lymphoma.[1] Lineage-specific cell surface antigens that are useful for delineating leukocyte cell lineages include CD3, which is exclusively expressed on mature T cells, and CD79α and β, which form part of the B cell surface antigen receptor. Non-lineage restriction surface antigens include antigens such as CD45, which is found on all leukocyte lineages (myeloid and lymphoid). Although the last CLAW was in 1993, it was an important collaborative effort because anomalous expression of the CD4 antigen was identified in dogs, which express a high density of CD4 on neutrophils in addition to helper T cells.[34] Many other differences in CD antigen expression are unique among domestic animals compared to humans (e.g. high expression of the γδ T cell receptor in pigs and ruminants[5,36] and co-expression of CD4 and CD8 on mature T cells in swine).[48]

Acronyms and Abbreviations

Ang1, angiopoietin 1; BFU-E, burst-forming unit erythroid; CD, cluster of differentiation; CFC-S, splenic colony-forming cell; CFU-E, colony forming unit erythroid; CFU-GEMM, colony forming unit granulocyte erythroid monocyte megakaryocyte; CFU-GM, granulocyte-macrophage colony forming cell; CLP, common lymphoid progenitor; CXCR4, CXC chemokine receptor 4; ECM, extracellular matrix; EDTA, ethylenediaminetetraacetic acid; EPO, erythropoietin; G-CSF, granulocyte colony stimulating factor; GM-CSF, granulocyte macrophage colony stimulating factor; GTPase, guanosine triphosphatase; HSC, hematopoietic stem cell; ICAM-4, intercellular adhesion molecule-4; IL, interleukin; JAK, Janus tyrosine kinase; JH, Janus homology; NK cell, natural killer cell; PCR, polymerase chain reaction; PI3K, phosphoinositol 3 kinase; PTH, parathyroid hormone; qPCR, quantitative polymerase chain reaction; Rac1 and Rac2, Ras-related C3 botulinum toxin substrate 1 and 2; RBC, red blood cell; SCF, stem cell factor; SCID, severe combined immunodeficiency; SDF-1, stromal derived factor 1 (CXCL12); SH, src homology; SOCS, suppressor of cytokine signaling; STAT, signal transducers and activators of transcription; TGF-β, transforming growth factor beta; Tie2, tyrosine kinase with immunoglobulin-like and EGF-like domains 2; TNFα, tumor necrosis factor alpha; TPO, thrombopoietin; TRAIL, TNF-related apoptosis inducing ligand; VCAM-1, vascular cellular adhesion molecule 1; VLA-4, very late antigen 4.

Current understanding of the hematopoietic system draws heavily from clinical observations and research in humans and mice. Numerous gene-deleted mice targeting transcription factors, hematopoietic cytokines and their receptors, and extracellular matrix (ECM) components and their receptors are central to our knowledge of hematopoiesis at the molecular level.[7] More recent studies have contributed information about the critical role of the bone marrow microenvironment. In domestic animals, research on spontaneous hematopoietic neoplasia, the roles of retroviruses and viral oncogenes that mimic hematopoietic tyrosine kinases, cyclic neutropenia of gray collies, and other species-specific hematopoietic diseases, has added to our understanding of hematopoiesis, which is remarkably conserved across mammalian species.[32]

HEMATOPOIETIC STEM CELLS

Hematopoietic stem cells (HSCs), which are considered to have lost their potential for mesenchymal differentiation, arise first in the embryonic yolk sac, then in fetal para-aortic splanchnopleura, from which liver and finally bone marrow are seeded (see Chapter 1). In the conventional view of hematopoiesis, pluripotential

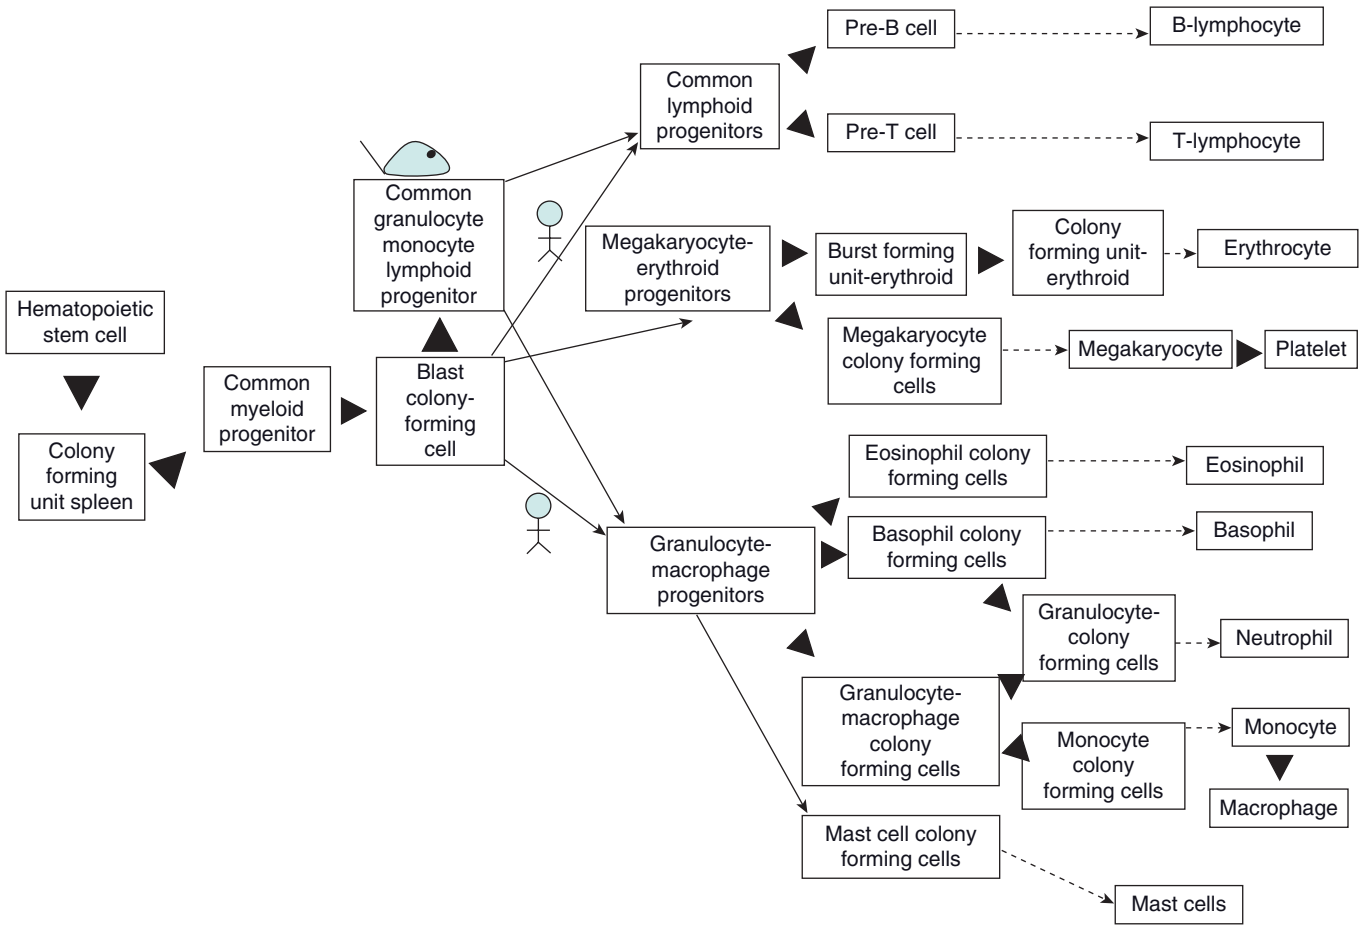

FIGURE 5.1 Hierarchical scheme of hematopoiesis. This figure depicts the conventional view of human and murine hematopoiesis. Larger block arrowheads indicate differentiation from pluripotent to oligopotent hematopoietic stem cells. Smaller block arrowheads indicate lineage commitment of oligopotent stem cells driven by cytokines and the JAK-STAT pathway. Dotted line arrows illustrate the multiple stages of differentiation that can be visually discriminated in Wright-Giemsa-stained bone marrow specimens. The figure has been modified from human and murine illustrations to indicate the mouse-specific GM-lymphoid precursors. (Modified from Iwasaki H, Akashi K. Hematopoietic development pathways: on cellular basis. Oncogene 2007;26:6687–6696 and Metcalf D. Hematopoietic stem cells and tissue stem cells: current concepts and unanswered questions. Stem Cells 2007;25:2390–2395.)

HSCs with unlimited self-generative capacity progressively differentiate to multipotent or oligopotent stem cells with reduced self-replicative capacity, to lineage committed progenitors with minimal ability to self renew, to lineage-specific precursors with no self-regenerative ability, and finally to the mature cells of blood (Fig. 5.1).[26] In a recent modification in this scheme in mice, hematopoiesis matures through a common granulocyte-monocyte-lymphoid oligopotent progenitor that has not been identified in higher species.[18] The strict division of common granulocyte-monocyte-erythroid-megakaryocytic progenitors and common natural killer (NK)/B and T cell progenitors occurs for human hematopoiesis, and likely applies to hematopoiesis in domestic species.

Lineage commitment typically follows expression of lineage-restricted transcription factors (Table 5.1). Induction of these transcription factors occurs through a combination of specific cytokine receptor and ligand interactions, less specific signal transduction pathways, and an overlay of highly specific, permissive microenvironmental influences from stromal cells, endothelial cells, adipocytes, osteoblasts, ECM proteins, adherent cytokines, and trabecular bone.

Because of the short life-span of differentiated hematopoietic cells, mature blood cell production is an ongoing process; estimates suggest production of 1.5×10^6 cells/second in humans. It is unlikely that HSCs supply a continuous flux of cells from left to right as shown in Figure 5.1 because HSCs and multipotent cells are non-dividing or very slowly dividing during normal hematopoiesis. Newer evidence suggests that information determined from experiments in lethally-irradiated mice may not necessarily recapitulate normal or physiologically accelerated hematopoiesis and that there may be other homeostatic mechanisms that control hematopoiesis.[26]

A somewhat confusing nomenclature has evolved around early committed hematopoietic progenitors based on in vivo experiments in mice. Splenic colonies

TABLE 5.1 Hematopoietic Transcription Factors[a]

Early hematopoietic development
- SCL (TAL 1) (stem cell leukemia, T-cell acute lymphocytic leukemia-1)
- GATA-2
- LMO2 (Rbtn-2) (Lim finger protein)
- AML-1 (acute myeloid leukemia 1 protein)
- Tel
- Notch 1

Erythropoiesis
- HIF-1 (Hypoxia-inducible factor-1)
- GATA-1
- EKLF-1 (erythroid kruppel-like factor 1)
- p45/NF-E2 (nuclear factor erythroid-2)
- STAT5a, STAT5b
- CBP/p300 (CREB binding protein/p300)
- SP1

Erythropoietic regulators
- FOG-1 (friend of GATA-1)
- TRAP220 (thyroid hormone receptor-associated protein 220)
- BRG1 (Brahma-related gene 1)
- CBP/p300 (CREB binding protein/p300)

Myelopoiesis
- Notch
- GATA-1
- C/EBPα (CCAAT/enhancer binding protein α)
- STAT5a, STAT5b

Granulocytopoiesis
- RAR (Retinoic acid receptor)
- C/EBPα and C/EBPε
- CBF (core binding factor)
- c-Myb
- STAT3
- NFκB (nuclear factor of kappa B) – late precursor
- AML1 – precursor

Monocytopoiesis
- EGR-1, EGR-2 (early growth response genes 1 and 2)
- Vitamin D receptor
- c-Fos, c-Fos
- PU.1
- RAR (retinoic acid receptor)
- C/EBPβ and C/EBPε
- MafB/c
- PU.1

Osteoclast differentation from monocyte precursor
- NFκB

Megakaryocytopoiesis
- Notch
- GATA-1
- PU.1
- Fli-1/NF-E2 (platelet production)
- FOG
- SCF (stem cell factor)
- STAT5a, STAT5b

Lymphoid
- PU.1
- Ikaros
- STAT3, STAT5a, STAT5b, STAT4, STAT6

B-cell
- E2A
- EBF (early B-cell factor)
- Pax 5
- NFκB (progenitors and late maturation)

T-cell
- HEB (TCF12 – T-cell factor 12)
- Notch/HES-1 (Hairy Enhancer of Split-1)
- NFAT (Nuclear Factor of Activated T cells) late maturation
- GATA-3
- TCF-1 (T cell factor 1)
- NFκB (progenitors and late maturation)

Mast cell
- GATA-2^{+}
- Elf-1
- MITF (microphthalmia-associated transcription factor)

Eosinophilopoiesis
- STAT1, STAT3, STAT5a, STAT5b
- GATA-1

[a]All transcription factors are involved in early lineage commitment and exert their effects on committed progenitors unless otherwise stated.

that appear in lethally irradiated mice reconstituted with HSCs are called splenic colony forming cells (CFC-Ss), which have limited capacity for self-renewal. Whether similar cells occur in other species is unknown, because CFC-Ss are defined by specific experimental conditions in mice.

HEMATOPOIETIC PROGENITORS AND PRECURSORS

The term progenitors typically refers to cells whose presence is inferred from cytokine-driven differentiation of colonies in culture, such as granulocyte-macrophage colony forming cells (CFU-GMs) and erythroid colony-forming units (CFU-Es), whereas the term precursors refers to stages of hematopoietic differentiation recognized by cytologic evaluation. HSCs, oligopotent stem cells, and committed progenitors appear similar to small lymphocytes, although they can be separated by flow cytometry based on expression of surface proteins.

Towards the right of Figure 5.1, clonigenic cell types exist putatively without any capacity for self-generation. However, mature cells types such as macrophages and mast cells may have substantial

self-generative properties. The initial model of hematopoiesis did not include the concept of plasticity.[26] In the current model, the concept of plasticity suggests that lineage fidelity and progressive restriction of proliferative capacity in the traditional model are not absolute. Plasticity is recognized as a property of both proliferation and lineage commitment. How plasticity is regulated under physiologic and pathologic conditions is not well understood. It is clear though that neither HSC nor any of the oligopotent progenitors have the unlimited capacity for self-generation possessed by embryonic stem cells.

SPECIES SPECIFICITY OF HEMATOPOIESIS

In contrast to detailed information about murine hematopoiesis,[45] there are few detailed descriptions about the structure and function of the bone marrow in domestic species. Stem cell function, the biochemical nature of the bone marrow microenvironment, hematopoietic cytokines and their receptors, and lineage specific and non-specific transcription factors are assumed to apply to species other than mice or humans.[5,21] Studies have confirmed some common cytokines between domestic species and humans.[14,24,25,27,28,30,31,38,39] Research involving animal models of human diseases, toxicology, or other unique diseases such as cyclic hematopoiesis in dogs has provided additional information about hematopoiesis in domestic animals.[4,11,20,26] The gene sequences for many hematopoietic cytokines, receptors, and transcription factors for multiple species now are available in publically accessible databases so they can be assessed specifically by high density microarray or more broadly by quantitative reverse transcription polymerase chain reaction (qPCR).[10,12,33]

Certain critical differences exist between human and murine hematopoiesis. Human HSCs express Flt3, the tyrosine kinase receptor for FLT3 ligand, whereas murine HSCs do not.[18] However, both murine and human common lymphocyte progenitors (CLPs) express Flt3. Such differences are important because certain human acute myelogenous leukemias are associated with constitutive activation of Flt3.[8] Whether other species express similar mutations governs the potential utility of therapy with Flt3-kinase inhibiting drugs. Although the hierarchical relationships observed in murine hematopoiesis are generally preserved in other species (Fig. 5.1), expression of a number of surface antigens at each developmental stage is different between mice and humans, and these and other differences may occur in other species. However, important similarities also have been recognized. Based on the recent molecular and genetic understanding of cyclic neutropenia in gray collie dogs and cyclic hematopoiesis in humans, some features of hematopoiesis appear similar. For example, allometric scaling correctly predicts granulopoietic cyclicity in mice (3 days), dogs (14 days), humans (19–21 days), and elephants (60 days).[4,26]

THE BONE MARROW MICROENVIRONMENT

The heterogeneous cellular elements in Figure 5.1 are intimately associated with adipocytes, macrophages, endothelial cells, nerves, osteoclasts, osteoblasts, ECM, sinusoids, and cytokines, collectively termed the bone marrow microenvironment. Cell-cell and cell-ECM interactions are important in the regulation of cell proliferation and differentiation of hematopoietic cells.[9] These interactions involve receptors and integrins, which are regulated by growth factors, cytokines, and transcription factors. The ultrastructure of the interactions between hematopoietic cells, stromal cells and noncellular components of the bone marrow microenvironment were described in detail in 1978,[29] but the molecular mechanisms have more recently been characterized.

The best characterized integrin on HSC is very late antigen 4 (VLA-4 or α4 β1) which binds to fibronectin in the ECM as well as to vascular cellular adhesion molecule 1 (VCAM-1) on adjacent stromal cells. The binding of VLA-4 to fibronectin mediates adhesion of HSC and progenitors to the microenvironment, homing of circulating HSC and progenitors to specific areas within the bone marrow, and signal transduction. The Rho guanosine triphosphatases (GTPases), Ras-related C3 botulinum toxin substrate 1 (Rac1), and Rac2 also are key regulators of adhesion and migration of cells in the hematopoietic microenvironment.

The bone marrow microenvironment has highly specialized and integrated microanatomic functional units called niches. The two most clearly elucidated hematopoietic niches are the HSC niche (see Chapter 3) and the erythroblastic islands (Figs. 5.2 and 5.3; see Chapter 6).[1]

The Hematopoietic Stem Cell Niche

Survival, proliferation, and differentiation of HSCs depend on their spatial and functional relationships with the cells and ECM of the microenvironment.[29] HSCs are enriched at sites adjacent to the endosteal surface of bone. A specialized subset of activated osteoblasts display ligands and receptors that facilitate homing and transient docking of HSC, and regulate slow cycling or rapid mobilization of HSCs as needed.[1] The interaction between stromal-derived factor 1 (SDF-1 or CXCL12) elaborated by osteoblasts and CXC chemokine receptor 4 (CXCR4), its cognate chemokine receptor on HSC, is central to this HSC niche. SDF-1 recruits quiescent progenitors, participates in their cycling and survival, and sensitizes them to further synergistic action of cytokines, thus contributing to hematopoietic homeostasis under both physiologic and stress conditions. HSC function also is regulated by osteoblasts through parathyroid hormone (PTH), the Notch signaling pathway, and interactions between angiopoietin 1 (Ang1) and its tyrosine kinase with immunoglobulin-like and EGF-like domains 2 (Tie2) receptor.[6] Disruption of this HSC niche may result in abnormal cell mobilization and contribute to extramedullary infiltration in leukemia.

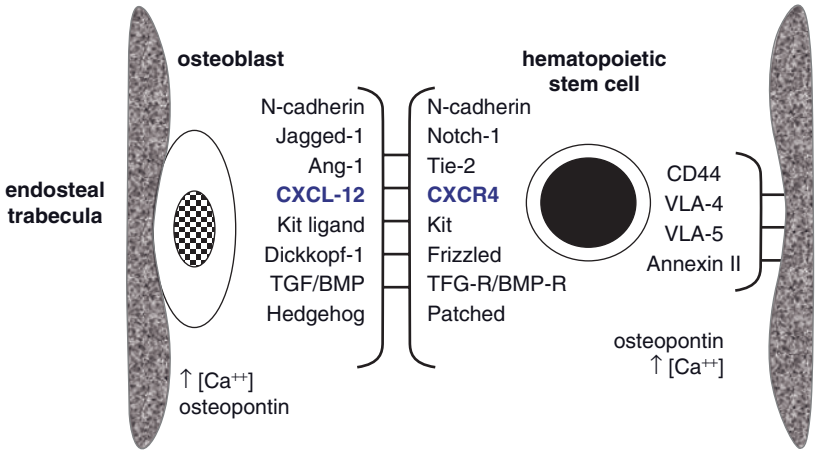

FIGURE 5.2 Hematopoietic stem cell niche (reciprocal molecular interactions). The relationship between a specialized subset of osteoblasts and the hematopoietic stem cell is shown, with reciprocal molecular interactions depicted between the two cell types, and between these cell types and endosteal bone.

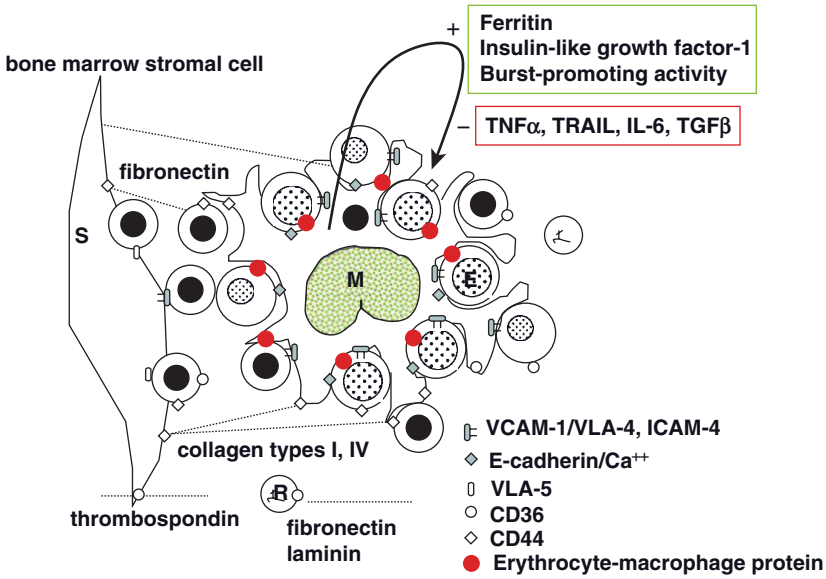

FIGURE 5.3 The erythropoietic niche. The erythroblastic island is illustrated with rubriblasts of graded levels of maturity surrounding macrophage (M) cytoplasm. Specific molecular interactions between macrophages and rubriblasts, between the erythroblastic island and marrow stromal cell(s), and of all these cellular elements with marrow stroma are shown. Autocrine cytokine loops involved in stimulation of erythropoiesis (green bordered box) and in the negative regulation of erythropoiesis (red bordered box) are shown. Dotted lines indicate extracellular matrix components. Arrow indicates factors elaborated by macrophages that influence growth and maturation of rubricytes.

The Erythropoietic Niche

Erythropoiesis occurs in distinct niches called erythroblastic islands that consist of a central macrophage surrounded by a ring of developing erythroblasts in bone marrow, fetal liver, and spleen, and even in long term marrow cultures.[17] The macrophage contributes important signals to developing rubriblasts, phagocytoses expelled metarubricyte nuclei, and transfers iron to developing rubriblasts. Unlike megakaryocytes that localize exclusively to marrow sinusoids, erythroblastic islands are located throughout the marrow.[9]

Adhesion molecules mediating important structural and functional interactions between developing erythroid cells and central macrophages include VCAM-1/VLA-4, α4β1/VLA-4, intercellular adhesion molecule-4 (ICAM-4)/αv, and E-cadherin. For example, ICAM-4 is postulated to enable reticulocytes to detach from central macrophages, allowing them to enter the circulation.[9] Laminin and fibronectin and their receptors expressed on late-stage rubriblasts also are key components in differentation of reticulocytes. VLA-4 and VLA-5 are involved in binding of erythroid burst forming units (BFU-Es) to hematopoietic stromal cells. Expression of these adhesion molecules is highest on BFU-Es and erythroid colony forming units (CFU-Es) and is progressively lost during erythroid maturation. Hemonectin and collagen type I support binding of BFU-Es in vitro, and a role for tenascin-C has been inferred from knockout mice. Hemonectin is absent from anemic mice with Kit ligand or c-*kit* deficiency.

The surface antigen cluster differentiation 44 (CD44) is highly expressed on almost all hematopoietic cells in bone marrow and is responsible for interaction of these cells with collagen types I and IV, fibronectin, and hyaluronate.[44] Reticulocytes express only low levels of a few surface adhesion receptors, such a CD36 (thrombospondin receptor) and VLA-4. Thrombospondin serves as an adhesive ligand for committed progenitors including colony forming units-granulocyte erythroid monocyte megakaryocyte (CFU-GEMM) and BFU-E. Adhesion molecule interactions of reticulocytes with bone marrow stromal cells and ECM may facilitate their egress into bone marrow sinuses. Mature red blood

cells (RBCs) do not express adhesion molecules under normal conditions.

CYTOKINES AND CYTOKINE SIGNALING IN HEMATOPOIESIS

Hematopoiesis is the cumulative result of intricately regulated signaling pathways mediated by soluble cytokines and their receptors (Table 5.2).[2] Evaluation of cytokine-receptor interactions in hematopoiesis has largely been achieved through creation of gene-deleted mice and conditional knock-out mice, the phenotypes of which range from severe lethal embryonic, fetal, and neonatal defects to redundant null phenotypes.[7] These mice have provided much of our current insight into the regulation of physiologic and pathologic alterations in hematopoiesis.

Most hematopoietic cytokine receptors are multiple subunit complexes, with the exception of those that signal through a single chain, such as erythropoeitin (EPO), granulocyte-macrophage colony-stimulating factor (GM-CSF), and thrombopoietin (TPO). Hematopoietic cytokines are approximately 200 amino acids in length and carry a conserved sequence of tryptophan-serine-X-tryptophan-serine (W-S-X-W-S) in their extracellular domain, which functions as part of the ligand binding domain.

Cytokine receptors contain docking regions for Janus tyrosine kinases (JAK1, JAK2, JAK3, TYK2) in their cytoplasmic termini, that when attached to the ligand-bound form of the cytokine receptor, recruit JAKs which then autophosphorylate. The JAK kinase then phosphorylates tyrosine residues on a specific signal transducer and activator of transcription (STAT) protein, which is STAT1, 3, or 5 for most hematopoietic cytokine receptors. JAKs contain a catalytic Janus homology (JH) 1 domain and a JH2 catalytic-like but inactive domain critical to the ability of JAKs to regulate themselves and to mediate cytokine-induced responses. Src kinase activation of STATs also is important for myeloid cell proliferation.

In unstimulated cells, STATs are present as cytoplasmic monomers in the unphosphorylated state. Phosphorylation by JAK kinases leads to dimerization through reciprocal interactions of SH2 domains with phosphotyrosine residues, and thereby activation of STAT, which then translocates to the nucleus.[15] STATs are transcription factors that prevent apoptosis or positively regulate prosurvival genes of late progenitor and early precursor cells.[15] Although there are numerous STAT responsive genes in many different cell types, STAT regulation of hematopoietic precursors occurs in a cell-type restricted manner.

Lineage-committed colony-forming cells respond to cytokines in an absolute lineage-restricted fashion. The specificity of hematopoietic cytokines is determined by progenitor and precursor cell expression of their cognate receptors. For example, rubriblasts express EPO receptors but myeloblasts do not, which is different from the relatively promiscuous expression of JAK/STAT pathways. Given the importance of JAK-phosphorylation events in driving proliferation of hematopoietic precursors, it is not surprising that mutations leading to constitutively active JAK2 result in myeloproliferative disorders and leukemia. In addition to the prominent role of JAK-STAT interactions in hematopoiesis, the functional involvement of Ras and phosphoinositol 3 kinase (PI3K) pathways also has been shown following interleukin (IL)-3/IL-5 and GM-CSF stimulation of bone marrow cultures in vitro.[2]

TABLE 5.2 Hematopoietic Cytokines[a]

Lineage/Function	Key Hematopoietic Cytokine
Early hematopoiesis	Stem Cell Factor (SCF) Interleukin 3 (IL-3) Wnt ligands (Jagged) and receptors Kit ligand SDF-1/FGF-4
Common myeloid progenitor/ myelopoiesis	Stem cell factor (SCF) Thrombopoietin (TPO)
Erythropoiesis	Erythropoietin (EPO)
Megakaryocytopoiesis	Thrombopoietin Interleukin-6 (IL-6)
Lymphocytopoiesis T cells NK cells B cells	IL-7 IL-7, IL-2 IL-7, IL-15 IL-4
Regulatory	Transforming growth factor-β (TGF-β) Bone morphogenetic protein (BMP) Activin

[a]Note that this table oversimplifies the actions of these cytokines. With further refined analyses of murine models it has become apparent that even lineage restricted cytokines such as EPO exert pleiotrophic effects within and external to the hematopoietic system.

Negative Regulation of JAK-STAT Signal Transduction

Suppressors of cytokine signaling (SOCSs) are a family of proteins that regulate the strength and duration of the hematopoietic cytokine-driven signaling cascade.[42] They are transcriptionally induced by JAK-STAT signaling. SOCS proteins contain src homology (SH) 2 domains and a SOCS-box which mediate binding to cytokine receptors and associated JAKs, and attenuate signal transduction directly. In addition to their transcriptional induction by hematopoietic cytokines and subsequent self-limiting stimulation of hematopoiesis, other cytokines including tumor necrosis factor-α (TNF-α), IL-1, and Toll-like receptor ligands (e.g. lipopolysaccharide) also induce SOCS expression, providing negative regulation for granulocyte colony stimulating factor (G-CSF) signaling.

Another level of regulation is provided by phosphatases. The signaling and subsequent hematopoiesis

induced by phosphorylated dimers of STAT proteins is terminated by removal of phosphates from STAT tyrosines by three specific protein tyrosine phosphatases.

Transforming growth factor-β (TGF-β) is perhaps the most potent endogenous negative regulator of hematopoiesis.[19] TGF-β suppresses expression of the SCF receptor, the response of progenitors to SCF, and cell cycle progression of progenitors. The expression of receptors for TGF-β on primitive hematopoietic progenitors and subsequent stages of maturation suggests a broad role for this cytokine. Negative regulation of erythropoiesis by TNF-α, TNF-related apoptosis inducing ligand (TRAIL), IL-6, and TGF-β occurs when chronic inflammatory disease increases systemic and local bone marrow concentrations of these cytokines (see Chapter 37).[9]

EVALUATION OF HEMATOPOIETIC FUNCTION

Hematopoiesis is studied to gain insight into mechanisms of cytopenias, leukemias, and other pathophysiologic responses. Evaluation of hematopoiesis begins with careful examination of peripheral blood and is complemented by cytologic or histologic assessment of bone marrow. Short and long term in vitro culture of bone marrow-derived cells, genetically modified mice, animal models of retarded and accelerated hematopoiesis, syngeneic and xenogeneic hematopoietic stem cell transplantation, retroviral-mediated gene transfer, and gene therapy also have been used to study hematopoiesis.[43]

Gene-deleted and transgenic mice provide a special challenge to the hematologist because these mice frequently die during the embryonic, fetal, or early neonatal period. Peripheral blood examination may still provide valuable information. A 3 µL volume of heart blood obtained with a fine gauge needle is sufficient to prepare a blood smear; as little as 20 µl of heart blood may be diluted with 2 mg/mL ethylenediaminetetraacetic acid (EDTA) in saline and analyzed with an electronic counter. Potential artifacts of dilution of small quantities can be overcome by comparing results from treated or genetically altered mice with similarly diluted volumes from control or wild type mice.

Bone Marrow Evaluation in Mice

Direct examination of bone marrow complements information gained from assessment of blood. The technique of bone marrow collection and analysis in mice is described in Chapter 132. In fetal mice, which lack developed medullary hematopoiesis, cytologic examination of liver imprints for hematopoietic precursors is useful in assessing early hematopoietic function.

Evaluation of Hematopoiesis with Bone Marrow Culture

Hematopoietic interactions are best evaluated in vitro where culture systems permit evaluation of effects of individual cytokines, growth factors or their regulators, and combinations of factors (see Chapter 133). Target gene expression may be transiently induced by gene transfection or inhibited by transfection with antisense RNA. The significance of in vitro studies must be confirmed in vivo. For example, deficiency of hematopoietic cytokines or growth factors which would predictably have severe phenotypes based on in vitro work, such as IL-2 and GM-CSF, have much milder hematologic phenotypes than expected (i.e. failure to develop lymphopenia and neutropenia), underscoring the redundancy and pleiotrophy which characterize many of these factors.

Bone marrow cells can be cultured from aspirates or core samples obtained from diseased or healthy animals. These cells are cultured in semisolid methylcellulose-based media with cocktails of cytokines, EPO, transferrin, bovine fetal serum, and albumin. Whereas EPO is active across species and has been cloned from a variety of species, other cytokines have more limited cross-species effects. When a species-specific cytokine is not available, conditioned spleen cell media obtained from phytohemaglutinin, endotoxin, or phorbol ester-stimulated cells may serve as a useful source of cytokines. Conditions for culture of bone marrow progenitors from dogs, cats, sheep, cattle, horses, chickens, and other species have been described.[13,16,40,37] In general, methodologies applicable to murine and human culture systems apply to those of other species, when care is taken to ensure the quality of collected bone marrow specimens and species-specific reagents or appropriate substitutes are used. Short-term bone marrow cultures from mice, rats, and dogs are routinely performed to assess the potential toxicity of xenobiotics and define hematopoietic phenotypes of genetically altered animals.[37] These culture systems may be used to study hematopoiesis by the addition of individual cytokines, growth factors or their regulators, or combinations thereof. Alternatively, neutralizing antibodies to these components or small molecules (<1000 kDa) produced by medicinal chemistry can be used to dissect regulatory pathways. Similarly, hematopoietic progenitors from clinical cases can be studied in vitro by direct culture following aspiration biopsy. Plasma or plasma components from animals with bone marrow disorders may be added to bone marrow cells of clinically normal animals to study the nature of potential humoral myelosuppressive activities.

Long term cultures of hematopoietic cells on established stromal cell layers (Dexter cultures) more closely recapitulate the hematopoietic microenvironment and allow long term survival of pluripotent HSC. These culture systems were used to identify the stromal cell defect (defective SCF production) in Sl/Sl^d mouse (Steel anemia) and the complementary defect in W/W^v (white spotted) mouse (SCF receptor alternatively known as c kit). Long term bone marrow cultures have been described for dogs[36,37] and sheep.[22]

Lethal Irradiation and Bone Marrow Transplantation

Lethally irradiated mice receiving bone marrow or hematopoietic cells with a capacity for partial or

complete renewal of hematopoiesis develop large splenic foci of extramedullary hematopoiesis thought to be initiated by a single pluripotent stem cell. These colonies are grossly visible after 8–14 days, creating hemispherical distortions of the splenic contour which may be visually enumerated.[34] These CFU-S have since been found to represent a multipotent committed progenitor cell rather than the pluripotent stem cell as originally hypothesized. Irradiation and stem cell transplantation methodologies are described in detail for dogs.[37]

Genetically Altered Mice

Through technology that permits homologous recombination of partially homologous, generally noncoding, genetic sequences in cultured murine stem cells, mice deficient in the protein product of specific target genes can be created. This technology has been extensively exploited to study the function of individual hematopoietic cytokines, growth factors, their cognate receptors, and hematopoietic transcription factors.[33] Without this technology, the study of transcription factors associated with primitive oligopotent progenitors (Tables 5.1 and Table 5.2) would not have been possible. The hematologic evaluation of mouse embryos or feti is a critical part of the phenotypic assessment of knockout mice. By rendering gene-deleted mice (−/−) transgenic (+/+) for a deficient gene under the control of an inducible or repressible tissue-specific promoter, the function(s) of a gene in adults, for which deletion otherwise results in nonviable feti, can be examined. Using the Cre-loxP system, genes may be removed or reactivated in a tissue specific manner in the adult mouse.[23]

The development of methods to transplant human hematopoietic cells into severe combined immunodeficient (SCID) mice (scid-hu) has provided an experimental tool with potential use in modeling leukemias, infectious diseases, autoimmune diseases, and a variety of primary nonneoplastic bone marrow disorders. Potential deficiencies of this model include incomplete cross-species functionality between murine cytokines and cytokine receptors and human receptors and ligands, since the absence of human bone marrow stroma in mice transplanted with human hematopoietic cells creates a chimeric hematopoietic microenvironment. Impaired passage of mature cells into and out of the bone marrow or circulation may occur when adhesion molecules and their receptors on leukocytes, platelets, and endothelial cells fail to recognize their respective murine or human counterparts.

Models of Accelerated Hematopoiesis

Several methods have been used to accelerate hematopoiesis. The intraperitoneal administration of a single 150 mg/kg dose of 5-fluorouracil or appropriate dosing regimen of cyclophosphamide completely depopulates murine bone marrow. Treatment with 5-fluorouracil spares the slowly cycling or noncycling stem cells.[46] Recovery of hematologic parameters is first detectable 5 days post-treatment, with complete recovery occurring after 15–20 days. This model has been used extensively to study accelerated hematopoiesis in gene-deleted mice with apparently normal basal hematopoiesis or in mice treated with agents that do not alter basal hematopoietic function. In this manner, the immunosuppresant rapamycin was shown, by virtue of its ability to inhibit signal transduction of a variety of proliferation-inducing cytokines, to have potential liability when administered in concert with cytotoxic agents.[35] Accelerated erythropoiesis is readily induced in rodents by a single 60 mg/kg intraperitoneal injection of phenylhydrazine. This regimen produces Heinz body hemolytic anemia with approximately 30% decrease in hematocrit after 2 days and a robust reticulocytosis by 5 days post-treatment.[41] Alternatively, a fixed volume of blood (up to 3% of body weight) can be removed from a rodent and replaced with intraperitoneal saline, stimulating erythropoiesis. To mobilize granulocytes and accelerate granulopoiesis, Bacto-tryptone (a potent chemotactic casein digest, 1 mL of a 10% solution) is administered intraperitoneally. A similar effect is achieved with intravenous G-CSF, which generally is species cross-reactive, at a dose of 5 µg/kg.[3]

Lessons learned from evaluation of hematopoiesis in genetically-altered rodents may be extended to the study of hematopoiesis in domestic species and provide a better understanding of dysregulation in primary diseases of bone marrow. The availability of specific reagents for domestic species and accessibility to bone marrow culture, flow cytometry, and polymerase chain reaction (PCR) technologies permit increasingly sophisticated examination of bone marrow function, providing greater insight into abnormalities recognized by traditional hematologic methods.

Acronyms and Abbreviations

BFU-E, burst-forming unit erythroid; CD, cluster of differentiation; CFU-E, colony-forming unit erythroid; CMP, common myeloid progenitor; DNA, deoxyribonucleic acid; EKLF, erythroid Kruppel-like transcription factor; EMP, erythrocyte macrophage protein; EPO, erythropoietin; EPOR, erythropoietin receptor; FasL, Fas ligand; FOG-1, friend of GATA; GATA1 and GATA2, GATA binding protein 1 and 2; GM-CSF, granulocyte/macrophage colony stimulating factor; HIF-1, hypoxia inducing factor-1; HSC, hematopoietic stem cell; ICAM-4, intracellular adhesion molecule-4; IGF-I, insulin like growth factor I; IL, interleukin; IFN-γ, interferon gamma; JAK2, Janus kinase 2; kDa, kilodalton; mRNA, messenger ribonucleic acid; MEP, megakaryocyte/erythroid progenitor; RBC, red blood cell; RNA, ribonucleic acid; RT-PCR, reverse transcriptase polymerase chain reaction; TNF, tumor necrosis factor; SCF, stem cell factor; SCL, stem cell leukemia; SOCS, suppressor of cytokine signaling; STAT, signal transducers and activators of transcription; TNF, tumor necrosis factor; TPO, thrombopoietin; TRAIL, TNF-related apoptosis inducing ligand; VCAM, vascular cell adhesion molecule; VLA-4, very late antigen-4.

Erythropoiesis is the proliferation and progressive differentiation of hematopoietic stem cells (HSCs) (see Chapters 3 and 5) into hemoglobinized, red blood cells (RBCs). In normal animals, erythropoiesis and RBC mass are regulated by cellular oxygen levels. RBCs originate from HSC in a stepwise manner, wherein each step includes cell division and differentiation, and is initiated and regulated by specific humoral, microenvironmental, cell surface, and transcription factors. First, HSCs commit to erythroid lineage to form erythroid progenitor cells, which resemble lymphocytes. Second, erythroid progenitors differentiate into erythroid precursors that can be identified morphologically. Precursor cells undergo a series of division and differentiation steps until the nucleus is extruded (in mammals) and reticulocytes are formed. This chapter describes erythropoiesis in adult animals, and is a synthesis of knowledge gained primarily from studies in mice, rats, and humans. Species-specific information is provided when available.

DEFINITIONS

Basal erythropoiesis is erythropoiesis that occurs to replace naturally senescent RBCs and therefore maintain normal RBC mass. Stress erythropoiesis refers to erythropoiesis that occurs in response to an anemic stimulus such as blood loss, hemolysis, or pregnancy.

STEM CELL TO ERYTHROCYTE

General

HSCs are multipotent and can divide into copies of themselves or into cells committed to specific blood cell

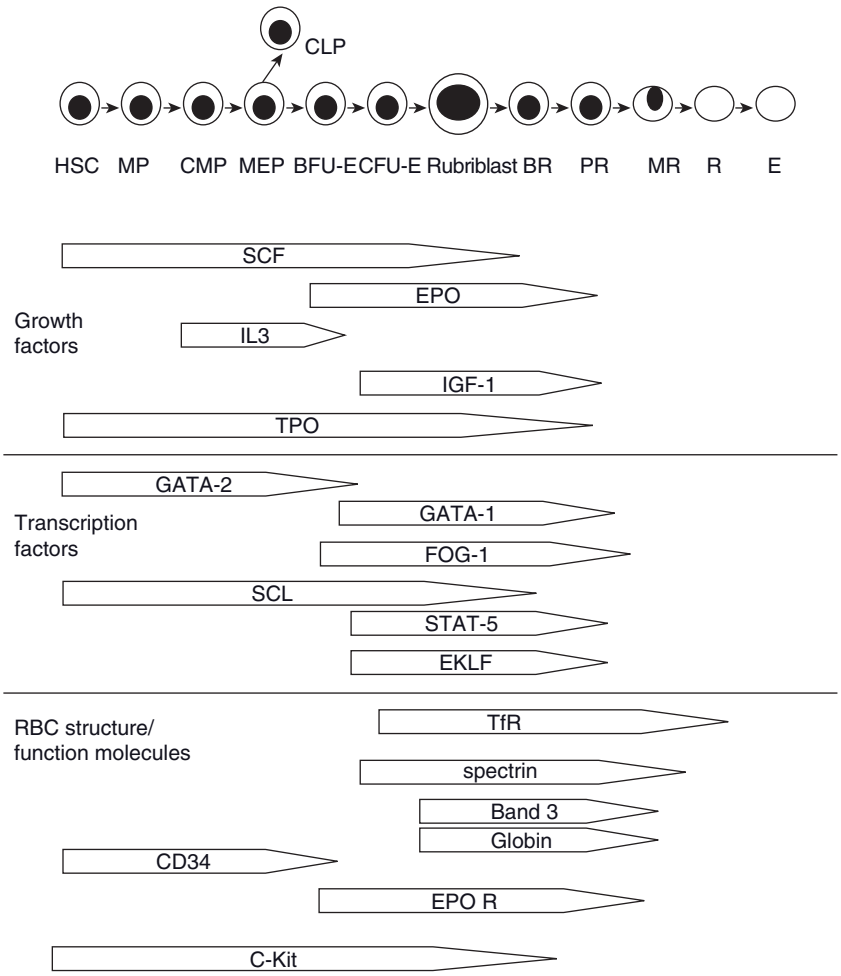

FIGURE 6.1 Approximate timing of the response to certain growth factors, activation of transcription factors, and expression of erythroid specific molecules in erythropoiesis. Abbreviations: BFU-E, burst forming unit erythroid; BR, prorubricyte/basophilic rubricyte; CFU-E, colony forming unit erythroid; CLP, common lymphoid progenitor; CMP, common myeloid progenitor; E, RBC; EKLF, erythroid Kruppel-like factor; EPO, erythropoietin; EPOR, erythropoietin receptor; FOG-1, friend of GATA–1;HSC, hematopoietic stem cell; IGF-1, insulin-like growth factor–1; IL3, interleukin 3; MEP, megakaryocytic/erythroid progenitor; MP, multipotential progenitor; MR, metarubricyte; PR, polychromatophilic rubricyte; R, reticulocyte; Rub, rubriblast; SCF, stem cell factor; SCL, stem cell leukemia gene; STAT, signal transducer and activator of transcription; TfR, transferrin receptor; TPO, thrombopoietin.

lineages. A multipotent HSC (Fig. 6.1) first differentiates into a common myeloid progenitor (CMP), which is then capable of differentiating into any blood cell except lymphocytes.[2] The CMP has limited self-renewing capacity, and, depending on environmental signals, is capable of differentiating into a granulocyte/macrophage progenitor or a megakaryocyte/erythroid progenitor (MEP). CMPs and MEPs in humans and mice can be identified by their specific cell surface phenotype.[2] Differentiation from CMP to MEP is associated with expression of various gene-specific transcription factors, growth factor receptors, and functional proteins, and is influenced by a variety of growth factors. Gene-specific transcription factors are predominantly activators of transcription and usually function as a complex of proteins that bind to specific deoxyribonucleic acid (DNA) sequences.

MEPs differentiate into burst-forming units-erythroid (BFU-Es). Although BFU-Es are programmed to differentiate only into erythroid cells, they resemble lymphocytes microscopically. These cells are identified by their growth from a single cell to several thousand cells in culture (see Chapter 133). The colony-forming unit-erythroid (CFU-E) differentiates from BFU-E. In culture, each CFU-E divides into 8–32 cells. Thus, BFU-Es have a higher proliferative potential than the more differentiated CFU-E. These progenitor cells differentiate into precursor cells that can be recognized as erythroid cells based on morphologic characteristics. The earliest precursor is a rubriblast (Fig. 6.2). This is a large cell with deeply basophilic cytoplasm; a round, centrally located nucleus; finely granular but deeply staining nuclear chromatin; and one or more prominent nucleoli (see Chapter 132). The deeply basophilic cytoplasm helps distinguish early erythroid from early myeloid precursors. Rubriblasts undergo a series of differentiation steps that result in a progressive decrease in cell size, a gradual increase in cytoplasmic hemoglobin concentration, and gradual condensation of nuclear chromatin. The prorubricyte is similar to the rubriblast except that it does not contain a nucleolus. Subsequent stages are called basophilic rubricytes, polychromatophilic rubricytes, and metarubricytes. These cells have increasing amounts of hemoglobin, which affects the staining quality of the cytoplasm. Basophilic rubricytes have the lowest hemoglobin concentration, and therefore still have deeply basophilic cytoplasm. Polychromatophilic rubricytes have cytoplasm that varies from blue-gray to gray, depending on hemoglobin concentration. Metarubricytes have the most hemoglobin, and therefore have gray to reddish cytoplasm. Metarubricytes also have dense, homogeneous nuclear chromatin. At

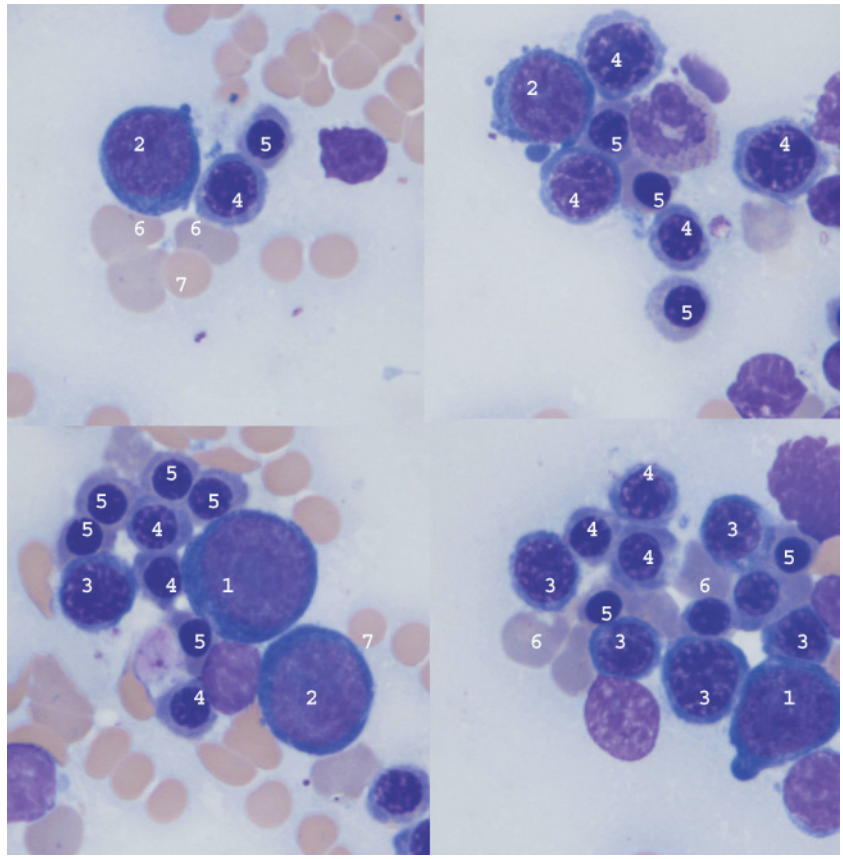

FIGURE 6.2 The various stages of erythroid precursors are shown. The progression or maturation is described in the text. (1) Rubriblast; (2) prorubricyte; (3) basophilic rubricyte; (4) polychromatophilic rubricyte; (5) metarubricyte; (6) reticulocyte; (7) RBC.

this point the nucleus is extruded to produce polychromatophilic RBCs, which stain as reticulocytes with vital stains such as new methylene blue. All of the precursors except metarubricytes are capable of division.

The nomenclature for erythroid precursors in humans and mice differs from that used in veterinary medicine. The earliest erythroid precursor is called a proerythroblast and subsequent cells are called basophilic erythroblasts, polychromatophilic erythroblasts, and orthochromatic erythroblasts (Table 6.1).

TABLE 6.1 Nomenclature of Erythroid Precursors

Veterinary Terminology	Human/Mouse/Research Terminology
Rubriblast	Proerythroblast
Prorubricyte	Basophilic erythroblast
Basophilic rubricyte	Basophilic erythroblast
Polychromatophilic rubricyte	Polychromatophilic erythroblast
Metarubricyte	Orthochromatic erythroblast
Reticulocyte	Reticulocyte
Erythrocyte	Erythrocyte

Development and Maturation of Reticulocytes

Nuclear expulsion from metarubricytes is associated with changes in intermediate filaments and microtubules that result in rearrangement of the membrane cytoskeleton.[24] Extruded nuclei are rapidly ingested by bone marrow macrophages. Reticulocytes then exit the bone marrow, although the exact mechanism is unknown. Reticulocytes contain residual mitochondria, Golgi membranes, ribosomes, and microtubular components, and can have approximately 35% more volume than mature RBCs.[50] During maturation in the circulation, reticulocytes gain hemoglobin and lose organelles, membrane surface area, volume, and numerous cell surface proteins. Cell surface proteins are lost in the form of exosomes, or membrane blebs, that contain proteins specifically selected for removal (see Chapter 22).[20]

Stress reticulocytes are released from the bone marrow during times of erythropoietic stress.[33] Stress reticulocytes are larger and less mature than normal reticulocytes, and contain more mitochondria, ribosomes, and other organelles. Their membranes are more mechanically rigid and unstable, and they possess adhesive proteins that are normally lost before release.

Cell Surface Molecules on Developing Erythroid Cells

Erythroid cells express a variety of cell surface molecules, some of which are developmentally regulated.[29,32,41,51] A summary of important erythroid cell surface molecules is presented in Table 6.2.

Reticulocytes in Veterinary Species

The number of reticulocytes circulating during health varies among species (see Chapter 136).[18] Some species

TABLE 6.2 Erythroid Cell Surface Molecules

Molecule	Function	Expression
CD34	Possibly signal transduction	BFU-E
CD36 (platelet glycoprotein IV)	Binds to thrombospondin	CFU-E to mature erythrocyte (decreasing)
CD71	Transferrin receptor (iron intake)	CFU-E to reticulocyte
CD49d/CD29 (VLA-4)	Binds to thrombospondin, VCAM-1, fibronectin	CFU-E to reticulocyte
CD105 (endoglin)	TGF-β receptor	BFU-E to rubriblasts
CD117 (c-kit)	Signal transduction	BFU-E to basophilic rubricyte
CD232 (ICAM-4)	Binds to integrins	CFU-E to reticulocyte

have circulating reticulocytes in health (dogs, cats, rodents, rabbits, pigs, guinea pigs), whereas others (cows, goats, sheep) have circulating reticulocytes only during a regenerative response. Horses, with rare exceptions,[55] do not have circulating reticulocytes even during a regenerative response.[9]

MOLECULAR CONTROL OF ERYTHROPOIESIS

Proliferation and differentiation of erythroid cells include cell divisions accompanied by a serial reduction of proliferative ability and increased erythroid-specific gene expression. The general sequence of molecular events for erythroid proliferation and differentiation is: (1) growth factor binding to its receptor; (2) activation of membrane-associated kinases; (3) phosphorylation of the cytoplasmic portion of the receptor and of other intermediate molecules; (4) activation of transcription factors; and (5) transcription factor-dependent synthesis of either additional transcription factors or erythroid-specific functional proteins, depending upon the stage of erythropoiesis. Examples of erythroid specific functional proteins include RBC specific spectrins, globins, ankyrin, band 4.1, and glycophorins (cell surface molecules).[24] Details of the molecular control of self-renewal, proliferation, and differentiation are complex and not yet entirely understood, although Zhu and Emerson provide an excellent review.

Cytokines and Growth Factors Regulating Erythropoiesis

Erythropoietin (EPO) is the principal hormonal regulator of erythropoiesis. EPO is a 34.4 kilodalton (kDa) glycoprotein (165 amino acids) that is produced primarily by peritubular interstitial fibroblasts of the kidney in adult animals. A small amount of EPO is produced in the liver during anemia.[23] Low tissue oxygen tension induces *EPO* gene expression through transcriptional activation and also induces *EPO* messenger ribonucleic acid (mRNA) stabilization.[8,10,57] Hypoxia up-regulates EPO by allowing accumulation of hypoxia inducible factor-1 (HIF-1). This transcription factor, along with cofactors, binds a responsive element in the 3′ flanking region of the EPO gene. In severe hypoxia, production of EPO is increased up to 1,000-fold.[10] EPO production by erythroid progenitors themselves also has been shown using reverse transcriptase polymerase chain reaction (RT-PCR), suggesting autocrine stimulation.[44] EPO is highly conserved among species, and recombinant human EPO can support proliferation and differentiation of erythroid progenitors from a variety of species including horses and cats (see Chapter 133).

The EPO receptor (EPOR) is an integral membrane protein with seven tyrosine phosphorylation sites in its cytoplasmic domain. Each of these domains appears to regulate different aspects of erythropoiesis. Some phosphorylation sites may be dispensable for steady-state erythropoiesis, but required for stress erythropoiesis.[26,56] EPOR-deficient mice die in utero with anemia and deficient hepatic erythropoiesis. Signaling through the EPOR is mediated by pre-bound Janus kinase 2 (JAK2), a phosphokinase. JAK2 phosphorylates several tyrosine residues in the cytoplasmic domain of the EPOR, which results in recruitment of a number of cytoplasmic signaling proteins. Several pathways critical to survival and differentiation of erythroid progenitors and precursors are then activated. The signal transducers and activators of transcription (STAT) 5 pathway, which results in up-regulation of the Bcl-x_L anti-apoptotic protein, is an important example of one of these pathways. The EPOR is expressed on early cluster of differentiation 34-positive (CD34+) hematopoietic progenitors and decreases gradually as erythroid differentiation progresses (Fig. 6.1). Neither EPO nor EPOR is required for generation of BFU-E or CFU-E, but both are required for development of later stages of erythroid precursors and for production of mature RBCs.[57]

Interleukin-3 (IL-3) is a multilineage cytokine produced by macrophages, activated T lymphocytes, mast cells, eosinophils, and bone marrow stromal cells. IL-3 acts on HSC and progenitor cells to induce proliferation and self renewal. It also primes progenitor cells to respond more vigorously to EPO.[1]

Stem cell factor (SCF), also known as Steel factor, mast cell growth factor, and c-kit ligand, is expressed by bone marrow stromal cells and acts through its receptor, c-kit (CD117).[6] Its mRNA is also expressed in BFU-E, suggesting a potential autocrine or paracrine function.[27] SCF is important for stem cell maintenance,[30] and is synergistic with other cytokines to produce differentiated cells. SCF exists as a soluble form and a membrane associated form.[46] SCF markedly enhances the activity of EPO, allowing for proliferation and differentiation of progenitors and precursors. Mice with deficiencies in the membrane-associated form have macrocytic anemia, in spite of having the secreted form of SCF.

Granulocyte-macrophage colony stimulating factor (GM-CSF), produced by T cells, stimulates production of primarily neutrophils, monocytes, and eosinophils. GM-CSF may enhance erythroid progenitor development, although GM-CSF knockout mice are hematologically normal.

Thrombopoietin (TPO) is a 45–70 kDa (depending on glycosylation) glycoprotein produced in the liver, kidney, skeletal muscle, and bone marrow stroma.[6] It appears to be required for maintenance of HSCs in G_0 and therefore their self-renewal capacity.[38] TPO also acts as a co-stimulatory agent with EPO to promote BFU-E growth in vitro and to support proliferation and maintenance of erythroid progenitor cells in vivo.[3,21,49,58,59]

Insulin-like growth factor-1 (IGF-1) and insulin both enhance the growth and differentiation of erythroid cells. IGF-1 decreases apoptosis of progenitors and enhances heme synthesis and nuclear condensation and enucleation.[31]

Glucocorticoids enhance erythroid colony formation in vitro[7] and in vivo[4] by stimulating erythroid progenitor proliferation and inhibiting differentiation.[54] Glucocorticoids act through a nuclear glucocorticoid receptor that subsequently directly affects transcription by binding to glucocorticoid response elements in DNA.[55]

Humoral inhibitors of erythropoiesis include tumor necrosis factor (TNF), TNF-related apoptosis inducing ligand (TRAIL), IL-1, and interferon gamma (IFN-γ).[42] TNF and IL-1 not only inhibit erythroid progenitors, but also suppress EPO secretion. Immature erythroid cells are susceptible to cell death due to TNF and IFN-γ up-regulation of "death" receptors.[12]

Transcription Factors

Several transcription factors are activated during RBC development as a result of binding of hematopoietic cytokines to cell surface receptors. Activated transcription factor then translocates to the nucleus to enhance transcription of specific genes. The DNA that is transcribed is either an erythroid-specific structural or functional gene (e.g. spectrin and globin) or a gene encoding a protein that is involved in initiation of the next step in differentiation (e.g. another transcription factor).

Pleiotropic Transcription Factors

The stem cell leukemia (*SCL*) gene is a pleiotropic (not erythroid-specific) transcription factor that is crucial for hematopoiesis; *SCL* null mice die in utero at day 8 without any blood cell formation[37,45] *SCL* also enhances erythroid proliferation and differentiation[2] while repressing myeloid differentiation.

GATA binding protein 2 (GATA2) is expressed in early HSCs. It appears to be necessary for proliferation and survival of stem cells but dispensable for terminal erythroid differentiation.[2,22,52] Erythroid progenitor cells of GATA2 null mice stop differentiating at the rubriblast stage.[52]

PU.1 is an Ets transcription factor that appears very early in the lineage commitment of HSCs. Its expression is associated with preferential commitment of CMP to granulocyte/monocyte lineage, although an increased ratio of GATA1 to PU.1 expression may cause commitment to erythroid lineage. PU.1 probably does have some direct influence on erythropoiesis, however, by enhancing self-renewal of erythroid progenitors.[5]

Erythroid-Specific Transcription Factors

STAT5 is required for erythropoiesis and is enhanced by EPO and SCF. STAT molecules are mobile cytoplasmic transcription factors that are activated by the JAK family of protein tyrosine kinases.[36] STAT molecules are latent but become activated and translocate to the nucleus upon tyrosine phosphorylation. STAT5 binds to specific DNA sequences to up-regulate genes involved in tissue specific functions and regulation of cell growth.[47] STAT5 knockout mice are severely anemic in utero and their fetal liver cells show increased apoptosis. Some adult STAT5 knockout mice have normal hematocrits, but have ineffective hematopoiesis during erythropoietic stress.[47] These mice generate increased numbers of proerythroblasts during erythropoietic stress, but have increased apoptosis in the more mature stages.

GATA binding protein 1 (GATA1) is essential for both primitive and definitive erythropoiesis, and plays a key role in the differentiation of rubriblasts to mature red blood cells (RBCs).[60] GATA1 is responsible for expression of many erythroid-specific or erythroid-predominant genes, including cytoskeletal proteins, the transferrin receptor, EPOR, and the friend of GATA1 transcription factor (FOG-1). GATA1 also maintains expression of Bcl-x_L and EPOR, which promote late erythroid precursor survival and differentiation, while repressing GATA2, a molecule that induces proliferation of earlier stages.

Erythroid Kruppel-like transcription factor (EKLF) is essential for primitive and definitive erythropoiesis and for adult β-hemoglobin production. Its disruption in mice results in accumulation of fetal γ-globin and inability to produce adult β-globin.[35] EKLF appears also to regulate expression of other erythroid-specific genes including dematin, cytoskeletal proteins, transcription factors, and heme synthesis proteins.[17]

Other Molecules

Bcl-x_L is an anti-apoptotic protein that is associated with the mitochondrial membrane. Bcl-x_L prevents apoptosis of hemoglobinizing rubricytes.[39] Mice that have a conditional knock-out of the Bcl-x_L gene have severe anemia and splenomegaly. The bone marrow and spleens of these mice accumulate early rubricytes but are deficient in maturing cells. Bcl-x_L expression is EPO-dependent via STAT5, and is increased during terminal differentiation stages when hemoglobin synthesis is greatest.[15]

JAK2 is associated with the EPOR and is responsible for downstream signaling. EPO binding to the EPOR

changes conformation of the receptor and thereby activates JAK2, which causes tyrosine phosphorylation of the cytoplasmic domain, and subsequent recruitment of signaling proteins including STAT5. JAK2 knockout mice die during embryogenesis with severe anemia. The most important function of JAK2 appears to be activation of STAT5.[14]

FOG-1 is a nuclear protein that binds to GATA1 and acts as its cofactor in transcription.[19,25] FOG-1 mediates both transcriptional activation as well as repression (e.g. of GATA2).[25] FOG-1 knockout mice die of anemia in utero.[53] GATA2 repression is dependent on FOG-1, and thus FOG-1 may facilitate GATA switching, leading to erythroid differentiation.

Negative Regulators of Erythropoiesis

Fas and Fas ligand (FasL) are members of the TNF receptor and TNF superfamilies, respectively, and are expressed as integral membrane proteins. When FasL from one cell interacts with Fas from another cell, clustering of Fas initiates an intracellular caspase cascade and apoptosis. These molecules are co-expressed on a small percentage of immature erythroid cells in murine bone marrow and are responsible for erythroid precursor apoptosis during basal erythropoiesis.[31] Both of these molecules are down-regulated in response to EPO, allowing erythroid precursor survival and differentiation.

Suppressor of cytokine signaling (SOCS) competes for the binding site of STAT5 on the cytoplasmic tail of the EPOR.[40] STAT5 can then no longer bind or be activated to produce its downstream effects. SOCS also participates in the degradation of JAK2. SOCS is induced by a number of cytokines, including EPO.[43]

MICROENVIRONMENT

Erythroblastic islands are one component of the microenvironment (see Chapters 2 and 5) that is essential for erythropoiesis. Erythroblastic islands comprise a central macrophage surrounded by 10–30 erythroid cells from CFU-Es to reticulocytes.[28] The macrophage projects cytoplasmic processes to which erythroid cells adhere via erythroblast macrophage protein (EMP), very late antigen 4 (VLA-4), and intercellular adhesion molecule-4 (ICAM-4). These proteins bind to the macrophage receptor proteins EMP, vascular cell adhesion molecule-1 (VCAM-1), and integrins αv and α4, respectively. The macrophage cell surface molecule CD163 also may be important in binding to erythroid cells and in promoting erythropoiesis.[11]

The central macrophage has a unique phenotype, including a high level of expression of F4/80 and the Forssman glycosphingolipid (a 7 transmembrane spanning receptor), marked adhesiveness, a pronounced ability to endocytose, and inability to generate a respiratory burst. Although erythroblastic islands are critical for erythroblast proliferation and differentiation, macrophage function related to erythropoiesis is incompletely understood. Central macrophages may produce positive and negative regulators of erythropoiesis, supply iron for hemoglobin production, and play a role in nuclear extrusion and phagocytosis of the extruded nucleus.

Molecules Involved in Adhesion

ICAM-4 is a transmembrane protein belonging to the immunoglobulin superfamily of adhesion receptors, and is predominantly expressed on erythroid cells.[48,49] ICAM-4 mediates binding of rubricytes to rubricytes and rubricytes to macrophages. It is expressed during terminal differentiation of erythroid cells, beginning with the rubriblast. EMP is a 36 kDa transmembrane protein expressed on the surface of erythroid cells and macrophages, and is involved with interactions between erythroid cells and between erythroid cells and macrophages.[28] Absence of EMP severely limits the number of erythroblastic islands and results in marked apoptosis of erythroid cells. Very late antigen-4 (VLA-4), also known as $\alpha 4\beta_1$ integrin, is expressed on immature erythroid cells and binds to VCAM-1 on macrophages. Integrin αV is expressed on macrophages and binds to ICAM-4 on immature erythroid cells. Fibronectin is an extracellular matrix glycoprotein that binds to all stages of immature erythroid cells via the VLA-4 and VLA-5 integrins.[34]

ERYTHROKINETICS

Massive amplification from HSC to mature RBCs is required to create 4×10^{11} mature RBCs from 2×10^4 stem cells.[6] Erythrokinetics encompasses the rates of proliferation and maturation from HSC to mature RBCs. Long term and short term repopulating cells have been identified in transplantation experiments in mice, and probably represent hematopoietic cells that are less mature than BFU-Es. These cells take months to differentiate into later stages of erythroid cells.[16] BFU-Es take about 10–14 days to develop into rubriblasts in culture, whereas CFU-E maturation takes about 3–5 days. In health, there are approximately 50 rubricytes and 113 reticulocytes for every rubriblast in the bone marrow.[13] Approximately five mitotic divisions occur over 5 days before a rubriblast loses its nucleus and becomes a reticulocyte. In most species, reticulocytes spend 2–3 days maturing in bone marrow before being released to the circulation.

Acronyms and Abbreviations

BaP, basophil progenitor; βc, common beta chain for GP140 type cytokine receptors; BMCP, basophil/mast cell progenitor; C/EBP, CCAAT enhancer binding protein; CD, cluster of differentiation; CLP, common lymphoid progenitor; CMP, common myeloid progenitor; CSF, colony stimulating factor; CXCL12, CXC-chemokine ligand 12; CXCR4, CXCL12 receptor; EoP, eosinophil progenitor; G-CSF, granulocyte colony stimulating factor; GATA-1, GATA binding protein-1; G-CSFR, granulocyte-colony stimulating factor receptor; GFI1, growth factor independent 1; GM-CSF, granulocyte-macrophage colony stimulating factor; GM-CSFR, granulocyte-macrophage colony stimulating factor receptor; GMP, granulocyte/monocyte progenitor; HSC, hematopoietic stem cell; ICAM-1, intercellular adhesion molecule-1; IgE, immunoglobulin E; IL, interleukin; IL-3R, interleukin-3 receptor; IL-5R, interleukin-5 receptor; c-kit, receptor for SCF; M:E, myeloid:erythroid ratio; MCP, mast cell progenitor; MDP, macrophage/dendritic cell progenitor; MEP, megakaryocyte/erythroid progenitor; MPP, multipotential progenitor; mSCF, membrane bound stem cell factor; NeuP, neutrophil progenitor; NGF, nerve growth factor; NK, natural killer; PECAM-1, platelet cell adhesion molecule; SCF, stem cell factor; TGF-β, transforming growth factor-β; VCAM, vascular cell adhesion molecule; VLA, very late antigen.

In adult mammals, granulopoiesis occurs primarily in the bone marrow with expansion to extramedullary sites in times of increased demand or with bone marrow disease. Most information about development and regulation of the various granulocytic lineages has been obtained from studies using human-derived cells and from rodent models. Conditions for culture of bone marrow influence commitment to and development of various cell lineages from hematopoietic stem cells (see Chapter 133). Culture of bone marrow has been accomplished in most of the common domestic species, and those studies have demonstrated that granulocyte development is similar to rodents and humans.[19,22,55,57,60]

ROLE OF THE MICROENVIRONMENT

The hematopoietic inductive microenvironment provides the physical structure as well as a chemical milieu permissive for granulopoiesis. The microenvironment is composed of the extracellular matrix and stromal cells that include mesenchymal stem cells, osteoblasts, endothelial cells, fibroblasts, and adipocytes. Granulopoiesis is regulated by movement of hematopoietic precursor cells through niches in bone marrow in response to a series of factors produced by cells in the microenvironment, interactions with the extracellular matrix, and factors delivered from the blood. Commitment and differentiation are coordinated through changes in expression of cell surface markers, receptors, transcription factors, and signal transduction pathways in the hematopoietic precursors.

In adult mammals, the various granulocytic lineages originate from pleuripotential hematopoietic stem cells (HSCs) within the bone marrow. HSCs reside in close association with osteoblasts along the endosteal border of bone marrow (endosteal niche).[47,48] Homing of HSCs to the endosteal niche is mediated by chemotactic calcium receptors on HSCs, responding to a calcium concentration gradient generated by osteoclast activity.[1]

In addition, HSCs are attracted into the endosteal niche by CXC-chemokine ligand 12 (CXCL12) released by osteoblasts. Chemotaxis is mediated by binding of CXCL12 to the CXCL12 receptor (CXCR4) on HSCs.[47] The endosteal niche probably is critical for long term survival of HSCs in a quiescent state with a low level of self-renewal.[47,48,56] Maintenance of HSCs within the endosteal niche appears to be regulated by cell-cell interactions between osteoblasts and HSCs. Osteoblasts express a variety of adherence factors such as VCAM-1 (CD106), N-cadherin, and CD44 that bind respectively to α4β1 integrin (VLA-4 or CD49d/CD29), N-cadherin, and hyaluronic acid on the surface of the HSCs. Osteopontin on osteoblasts binds to both CD44 and α1 integrins on HSCs. Close cell-cell contact permits osteoblast surface ligands to bind to their respective receptors on HSCs, activating intracellular signal transduction within the HSCs. HSCs are maintained in a quiescent state by interactions between membrane bound stem cell factor (mSCF) on osteoblasts with the c-kit tyrosine kinase on HSCs and by angiopoietin-1 binding to Tie-2 tyrosine kinase.[56] Apoptosis of HSCs is inhibited by mSCF/KIT and Flt ligand/Flt-3 tyrosine kinase initiation of the Mcl-1 pathway.[26] Self-renewal is promoted by Jagged-1/Notch-1 and m-SCF/c-kit signaling.

Proliferation, mobilization, and commitment of HSCs to granulocytic differentiation occur in proposed vascular niches along the vascular sinuses of the central bone marrow.[32] Homing of HSCs and hematopoietic progenitor cells to the vascular niche occurs in response to CXCL12 secreted by endothelial cells. Retention in vascular areas of the bone marrow results from binding of HSCs and progenitors to PECAM-1 (CD31), VCAM-1 (CD106), P-selectin, and E-selectin found on the surface of endothelial cells. The vascular niche may facilitate differentiation of HSCs to CD34+ multipotential progenitors (MPPs) that have multilineage potential but have lost the ability of self-renewal. Subsequent to this stage, progenitors for lymphocyte and myeloid lineages commit to either common lymphoid progenitors (CLPs) or common myeloid progenitors (CMPs).

It is currently proposed that CMPs give rise to several lineages including granulocyte/monocyte progenitors (GMPs), megakaryocyte/erythroid progenitors (MEPs), and macrophage/dendritic cell progenitors (MDPs).[42] Granulocytic lineages differentiate from GMPs to produce neutrophil progenitors (NeuPs), eosinophil progenitors (EoPs), and basophil/mast cell progenitors (BMCPs).[2] BMCPs subsequently give rise to basophil progenitors (BaPs), which complete their maturation in bone marrow, and mast cell progenitors (MCPs), which circulate and undergo maturation in tissues such as gastrointestinal mucosa, skin, lung, and heart. An alternate proposed origin of MCP is directly from MPP.[8]

Although it is conceptually helpful to think of progenitor development in a linear model, lineage differentiation may vary with species or may be more plastic than a linear model implies. This is evident in leukemic cell lines that express markers for more than one hematopoietic lineage and by the capacity to change differentiation of cultured cells by altering patterns of transcription factor expression.

TRANSCRIPTION FACTOR REGULATION OF GRANULOPOIESIS

Commitment, differentiation, and maturation of granulocytic progenitors results from a coordinated program of transcription factor expression that activates genes required for differentiation and maturation of a specific cell type (Fig. 7.1).[17,38,42,50,54] Suppression of genetic programs required for differentiation along other cell lines is equally important in lineage determination. The coordinated hierarchy of transcription factor activation and suppression results in expression of receptors for colony stimulating factors (CSF) on the surface of hematopoietic progenitors, affects the timing of adhesion molecule expression, and activates genetic programs that allow transition to committed lineages and functional maturation within a lineage. Shifts in the balance of transcription factors may allow transition of progenitors to alternate cell lineages.

Differentiation of MPPs to CMPs requires activation of PU.1, a member of the Ets transcription factor family.[17,54] PU.1 in conjunction with expression of CCAAT/enhancer binding protein-α (C/EBP-α), a basic-region leucine zipper transcription factor, promotes transition to GMPs. Continued presence of C/EBP-α and a lower level of expression of PU.1 results in formation of early neutrophil precursors. This is in contrast to those GMPs that maintain high levels of PU.1 but no longer express C/EBP-α, which results in commitment to monocyte production. Maturation of neutrophils beyond the promyelocyte stage is dependent on increasing expression of PU.1 as well as C/EBP-ε, another C/EBP family member, and growth factor independent-1 (GFI-1). Production of EoP results from expression of GATA-1 (zinc finger family transcription factors) and continued high levels of C/EBP-α, whereas BMCP formation requires GATA-2 expression but inactivation of C/EBP-α.[2,20,21] For BMCPs to commit to production of basophils, there must be reactivation of C/EBP-α to produce BaPs, whereas continued down-regulation of C/EBP-α is required for differentiation to MCPs.

CYTOKINE REGULATION OF GRANULOPOIESIS

Granulopoiesis is regulated by cytokines that include stem cell factor (SCF) and CSFs.[4,6] Expression of receptors for these cytokines on the surface of hematopoietic cells is controlled by the activity of transcription factors so that sensitivity to individual cytokines coordinates with and facilitates proliferation and differentiation of the various cell lineages. Most hematopoietic cytokines are constitutively produced at low levels by a variety of cell types to maintain steady state granulopoiesis but increase in response to inflammation.

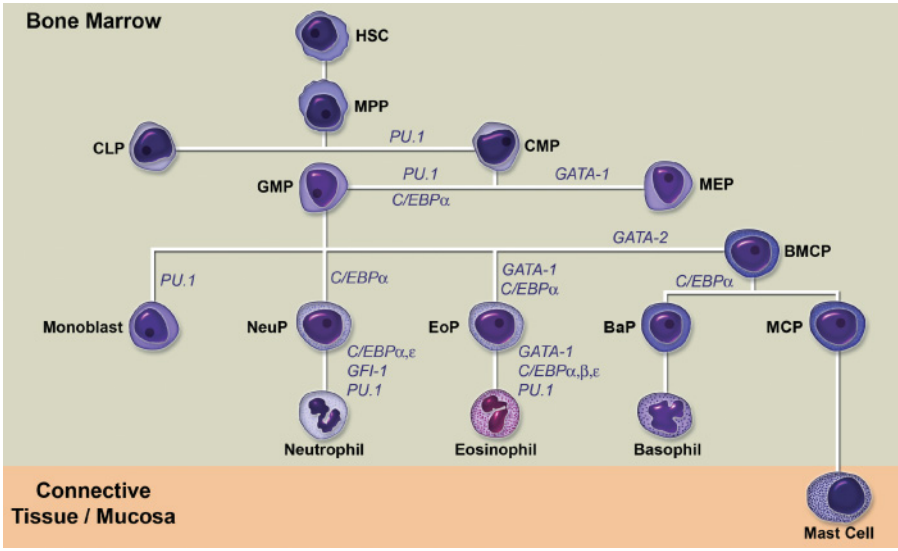

FIGURE 7.1 Proposed scheme for granulopoiesis. Transcriptional regulation of granulopoiesis is indicated. MCP also may arise directly from MPP. (BaP, basophil progenitor; BMCP, basophil/mast cell progenitor; C/EBP, CCAAT enhancer binding protein; CLP, common lymphoid progenitor; CMP, common myeloid progenitor; EoP, eosinophil progenitor; GMP, granulocyte/monocyte progenitor; HSC, hematopoietic stem cell; MCP, mast cell progenitor; MEP, megakaryocyte/erythroid progenitor; MPP, multipotential progenitor; NeuP, neutrophil progenitor). (Illustrated by Tim Vojt, Biomedical Media, The Ohio State University College of Veterinary Medicine.)

Stem Cell Factor

Stem cell factor (SCF; kit ligand, Steel factor, mast cell growth factor) acts on some of the earliest hematopoietic progenitors and is required for survival and self-renewal of HSCs (see Chapter 3).[6,46] Stem cell factor is produced as either a membrane-bound (mSCF) or soluble form. mSCF appears to be critical for effective hematopoiesis as soluble SCF is unable to compensate for lack of production of the membrane-bound form in genetically engineered mice.[6] mSCF is found on osteoblasts, endothelial cells, and fibroblasts in the bone marrow, and plays a role in establishing progenitors in their appropriate bone marrow niches. SCF acts to both inhibit apoptosis as well as promote entry of cells into the S phase of the cell cycle. SCF also potentiates the effects of other cytokines and CSF to promote proliferation, especially of early committed progenitors. c-kit (CD117), a member of the type III receptor tyrosine kinase family, is the receptor for SCF. Binding of SCF to c-kit results in homodimerization and autophosphorylation of the receptor. Expression of c-kit varies depending on the stage of hematopoietic cell development.[25] c-kit expression is present at low levels on quiescent HSCs and increases to its highest levels on early, actively proliferating granulocytic progenitors. With the exception of mast cells, c-kit expression declines with further maturation of the granulocytic lineages.

Interleukin-3

Interleukin-3 (IL-3), a member of the short chain α-helical bundle type 1 cytokine family, acts on some of the earliest hematopoietic progenitors.[4] It is primarily produced by activated T-lymphocytes; however, other cell types such as bone marrow stromal cells, natural killer (NK) cells, eosinophils, and mast cells also can produce IL-3. Its effects are mediated through binding to a specific receptor (IL-3R). IL-3R is a heterodimer consisting of α and β chains. The α chain (IL-3Rα or CD123) conveys ligand specificity. The common β chain (βc or CD131), upon dimerizing with the α chain–ligand complex, initiates signal transduction. Transcription of the IL-3Rα is controlled by transcription factors PU.1, GATA-1, and C/EBPα, whereas constitutive expression of the βc appears to be controlled by PU.1. IL-3R is found on early progenitors such as CD34+ HSCs, MPPs, and CMPs. The primary effects of IL-3 are to promote proliferation, differentiation, and survival of the most primitive precursors by shortening the time in the G_0 stage of the cell cycle. Although IL-3R may be found on more mature granulocyte precursors, the growth-promoting effects of IL-3 continue to be important for eosinophils and basophils.

Granulocyte-Macrophage Colony Stimulating Factor

Granulocyte-macrophage CSF (GM-CSF), a member of the short chain α-helical bundle type 1 cytokine family, is produced by a variety of cells including macrophages, T and B cells, bone marrow stromal cells, osteoblasts, fibroblasts, endothelial cells, neutrophils, eosinophils, and mast cells.[4] The receptor for GM-CSF (GM-CSFR) is also a member of the GP140 cytokine receptor superfamily. GM-CSFR is a heterodimer that is structurally related to and shares the same βc with the IL-3R but has a unique α chain (GM-CSFRα or CD116) that confers ligand specificity. Like IL-3R, transcription of the GM-CSFRα is controlled by PU.1, GATA-1, and C/EBP. GM-CSFR is expressed as progenitor cells commit to granulocytic and monocytic differentiation. Binding of GM-CSF to its receptor promotes progenitor survival by inhibiting apoptosis. GM-CSF promotes proliferation and maturation of granulocytes and macrophages.

Granulocyte Colony Stimulating Factor

Granulocyte CSF (G-CSF) is produced primarily by macrophages and monocytes. However, it also

may be produced by fibroblasts, endothelial cells, T-lymphocytes, and bone marrow stromal cells.[4] The receptor for G-CSF (G-CSFR) is a member of the GP130 cytokine receptor superfamily and forms a homodimer or homo-oligomer upon ligand binding. G-CSFRs are expressed in highest concentrations by neutrophilic progenitors through mature neutrophils. Sensitivity to G-CSF increases with neutrophil maturation and is related to increasing numbers of G-CSFR.[38] The effects of G-CSF are wide ranging and include stimulation of survival, proliferation, and terminal differentiation of neutrophils. G-CSF is constitutively produced at low levels to support basal neutrophil production. Concentrations of G-CSF increase markedly in response to endotoxin and inflammatory mediators, thus driving increased neutrophil release and production during an inflammatory response.[38] G-CSF also shortens maturation time of neutrophilic precursors, decreases marrow transit time, stimulates release of neutrophils from bone marrow, and prevents apoptosis. High concentrations of G-CSF result in release of HSCs into the circulation. This technique has been used to harvest circulating HSCs for bone marrow transplantation procedures in humans. Release of HSC in response to G-CSF appears to be mediated in part by elaboration of neutrophil enzymes, such as neutrophil elastase, cathespin G, and matrix metalloproteinase-9 within the bone marrow microenvironment.[32] These enzymes cleave adhesion molecules on HSCs and osteoblasts, thereby releasing HSCs.

Interleukin-6

IL-6 is a member of the GP130 cytokine family, and receptors for IL-6 are found on some CD34+ hematopoietic precursors.[24] IL-6 can stimulate granulopoiesis via binding to membrane bound IL-6 receptor. GP130 signaling can also be initiated through the mechanism of "transsignalling" wherein IL-6 is bound to a soluble form of its receptor and this complex heterodimerizes with GP130 to activate signaling. This latter mechanism appears to be important in granulopoiesis.[23,39] IL-6 can act synergistically with SCF to enhance granulopoiesis in culture and can partially compensate for lack of G-CSF in knockout mice.[33,39] IL-6 can act alone or synergistically with G-CSF to mediate bone marrow granulocytic hyperplasia during times when there is increased demand for neutrophils.[53]

DEVELOPMENTAL STAGES OF GRANULOPOIESIS

Committed neutrophil, eosinophil, and basophil precursors undergo a similar maturation sequence (Fig. 7.2). The myeloblast is the first member of granulocytic lineage that is recognizable by light microscopy. The myeloblast is characterized by finely stippled chromatin, one to multiple nucleoli, and moderately basophilic cytoplasm. Initially, the cytoplasm lacks granules (Type I myeloblast), but small numbers of primary or azurophilic granules begin to appear as the myeloblast matures (Type II myeloblast). The promyelocyte (progranulocyte) is larger than the myeloblast and is characterized by increasing numbers of primary granules and decreasing cytoplasmic basophilia. A Golgi area may be apparent and is free of granules. The chromatin pattern remains finely stippled and nucleoli may or may not be present. As promyelocytes mature, primary granules become less apparent by light microscopy and secondary granules appear. The myelocyte is smaller than the promyelocyte and is characterized by a round to slightly oval nucleus with partially condensed chromatin and lightly basophilic cytoplasm containing secondary granules. The myelocyte is the stage that commitment to a specific granulocytic line can most easily be discerned by light microscopy due to the presence of lineage specific secondary granules. The myelocyte is considered the last stage at which cellular division occurs. For each myeloblast, there is the potential to produce 16–32 offspring.

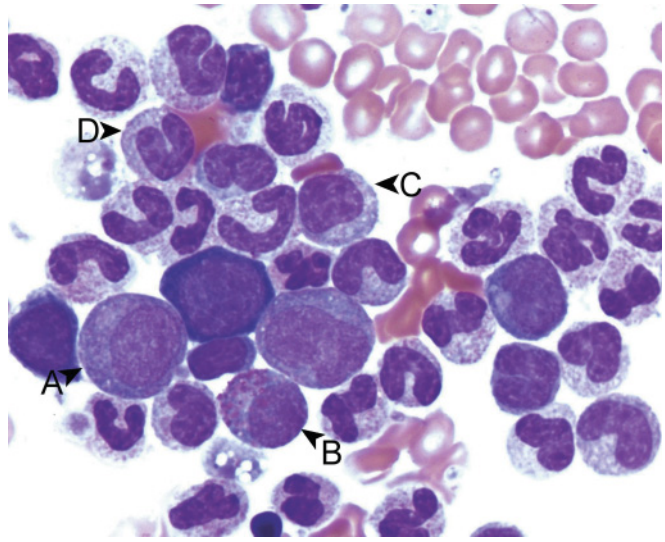

FIGURE 7.2 Granulocytic precursors in canine bone marrow. (A) promyelocyte, (B) eosinophilic myelocyte, (C) metamyelocyte, (D) band neutrophil. Wright Giemsa stain; original magnification 1000×.

Metamyelocytes and band granulocytes are no longer capable of cell division, but undergo nuclear maturation characterized by increasing condensation of chromatin and progressive segmentation of the nucleus. The metamyelocyte has a bean-shaped to elongated nucleus whereas the band has a U- or an S-shaped nucleus with smooth, parallel sides. As these cells mature from metamyelocyte to bands, the cytoplasm becomes less basophilic and granule contents mature. Mature granulocytes have condensed chromatin and a segmented nucleus with multiple lobes separated by thin strand-like areas. The degree of segmentation varies with the granulocyte type and species. In general, segmented neutrophils have 3–5 lobes whereas eosinophils may be bilobed. Mature basophil nuclei may appear monocytoid to bilobed.

GRANULOCYTES

Neutrophils

Differentiation from CMPs to GMPs is stimulated by IL-3, GM-CSF, and IL-6. Commitment of GMPs to neutrophil production and proliferation, and maturation of myeloblasts to mature polymorphonuclear neutrophils is primarily driven by G-CSF. Although IL-6 can stimulate granulopoiesis and partially compensate for a lack of G-CSF in knockout mice, G-CSF is required for functional maturation of neutrophils by increasing adhesion factors, chemotaxic activity, phagocytosis, and production of bactericidal factors.[38]

Development of myeloblasts to segmented neutrophils is associated with changes in cell surface expression of adhesion molecules and receptors.[14] In humans, maturation from myeloblasts to segmented neutrophils is accompanied by decreased surface expression of adhesion molecules that regulate retention in bone marrow such as CD29, CD31 (PECAM-1), CD33, CD49d (binds to VCAM), and CD49e (binds to fibronectin). There is increased expression of other adhesion molecules associated with neutrophil rolling and adherence (e.g. CD11b, CD11c) as cells mature. There is decreased expression of CD54 (ICAM-1) during neutrophilic maturation, but its expression may be reactivated when neutrophils are exposed to high concentrations of G-CSF during inflammation. Receptors for immunoglobulin (CD16 and CD32) and receptors for or modifiers of complement activity (CD11b, CD11c, CD35, and CD55) tend to increase with maturation.

Kinetics of Neutrophil Production

Neutrophil development can be divided conceptually into proliferation (mitotic), maturation, and storage compartments. The proliferation pool encompasses those precursors that are capable of cell division, including myeloblasts, promyelocytes, and myelocytes. These precursors constitute approximately 10–30% of bone marrow granulocytes in most species. The maturation and storage compartments comprise 65–90% of the granulocytes in the marrow. The maturation compartment consists of metamyelocytes and band granulocytes that are no longer capable of mitosis but are still undergoing nuclear and cytoplasmic maturation. The storage compartment comprises those bands and segmented neutrophils that are readily released into circulation.

Under basal conditions, bone marrow transit time for neutrophils (the time to go from myeloblast to segmented neutrophil) is approximately 6 days in dogs, cats, and horses.[5,7,13,40] Production time for neutrophils in calves is 6 days, but neutrophils are held in the bone marrow for one additional day before release.[51,52] Delivery of neutrophils to blood is related to the rapidity with which neutrophils are depleted from the circulation.[51] Although the steady state bone marrow reserve of neutrophils is similar in dogs and calves, the proliferative capacity of bone marrow in calves appears to be less than the dog. This is reflected in the lower M:E ratio in cattle. If neutrophils are depleted from the circulation, dogs react with a leukocytosis and bone marrow hyperplasia characterized by a shortening of production time from 6 to 2–3 days.[5,51] Calves also deliver existing neutrophils and bands from the maturation and storage pools to the blood in response to increased movement of neutrophils out of the circulation. However, unlike in other species, there is no apparent shortening of transit time as part of the bone marrow response in calves.[51,52] The mechanism underlying the failure of cattle to increase granulopoiesis and shorten bone marrow transit time is uncertain. Increased demand for neutrophils results in release of inflammatory cytokines and increased production of G-CSF.[38] G-CSF is a key mediator of neutrophil mobilization from bone marrow reserves, stimulation of granulopoiesis, and functional maturation of neutrophil precursors. Dogs, cats, horses, and cattle all show a robust response to administration of G-CSF characterized by neutrophilia and granulocytic hyperplasia in the bone marrow.[9,10,18,35,37,44]

Eosinophils

EoPs originate from GMPs, the same progenitors that give rise to neutrophils. However, commitment to eosinophil development occurs in response to a different pattern of transcription factors and cytokines.[20,58] The main cytokines driving eosinophil production are IL-3, GM-CSF, and IL-5. Eosinophils appear to lack receptors for G-CSF.[36] IL-3 and GM-CSF play a role in the early steps of proliferation and commitment of the eosinophil progenitor pool, whereas IL-5 is required for proliferation, terminal differentiation, and functional maturation of eosinophils.[43] The receptor for IL-5 (IL-5R) shares the same signal transducing βc with IL-3 and GM-CSF but has a unique α-chain (IL-5Rα or CD125) to permit specific binding of IL-5. Thus, eosinophils differ from neutrophils in that βc signal transduction is required through all stages of eosinophil production and maturation. Th2 T-helper cells are the primary source of IL-5. However, IL-5 can be produced by other cells such as mast cells, eosinophils, Tc2 cells, γδT cells, NK cells, and epithelial cells.[49] In addition to its role in proliferation and differentiation of eosinophils, IL-5 prevents apoptosis, stimulates release of eosinophils from the bone marrow, promotes adhesion of eosinophils to endothelial cells, and activates eosinophil effector function. Overproduction of IL-5 is associated with peripheral eosinophilia in transgenic mice and is observed in various naturally-occurring and experimentally-induced hypereosinophilic conditions. Interestingly, IL-5 knockout mice have normal basal numbers of eosinophils in their bone marrow but fail to develop tissue or blood eosinophilia when stimulated by parasite infection or inhalant allergen.[16,29] This suggests that IL-5 is necessary for an expanded eosinophilic response to inflammatory stimuli.

Bone marrow production time from myeloblast to mature eosinophils takes 2–6 days.[59] Secondary or

specific granules begin to form at the late promyelocyte stage and granule contents continue to mature through the segmented stage. Production of specific granule proteins occurs in response to genetic pathways activated by the transcription factors described above. For example, production of major basic protein is controlled by C/EBPε, GATA-1 and PU.1.[20]

Basophils

Committed basophil progenitors (BaPs) originate from CD34+ myeloid progenitors in the bone marrow. However, the sequence of intermediaries between MPPs and BaPs remains unclear. Studies of bone marrow cells from humans suggest that basophils and eosinophils share a bipotential progenitor because eosinophils and basophils develop within the same colony under some experimental culture conditions.[12,31] This may reflect the fact that the proliferation and differentiation of eosinophils and basophils are stimulated by many of the same cytokines such as IL-3 and GM-CSF.[3] Studies using bone marrow cells from mice suggest that basophils share a common progenitor with mast cells (BMCP) and originate from GMPs.[2,21] Subsequent differentiation to either BaPs or MCPs is regulated by sequential expression of transcription factors. Up-regulation of GATA-2 in conjunction with down-regulation of C/EBPα induces differentiation to BMCPs capable of differentiating into either basophils or mast cells. Subsequent reactivation of C/EBPα results in committed BaPs and production of basophils.[2,21] Maturation of BaPs occurs in bone marrow, and transit time from myeloblasts to mature basophils takes 2–3 days.[45] Basophil precursors require βc signal transduction initiated by IL-3 and GM-CSF for proliferation and differentiation. IL-5, nerve growth factor (NGF), and transforming growth factor-β (TGF-β) also act as growth factors.[15] However, unlike other granulocytes, a lineage specific factor (a specific basophilopoietin) has not been identified. It has been speculated that differentiation to basophil lineage is a default pathway, which may contribute to the conflicting findings as to their origin.[3] Although IL-3 appears to be the main growth factor promoting differentiation and maturation of basophil precursors, it is not absolutely required for production of mature basophils in steady state conditions as evidenced by studies with IL-3 deficient mice.[30] However, IL-3 is needed for accelerated production leading to basophilia in response to parasites.[30] Both IL-3 and GM-CSF increase effector function of basophils by increasing histamine production through induction of histadine decarboxylase, increasing regulatory cytokine production (such as IL-4 and IL-13), and enhancing migration of mature basophils into tissues.

Mast Cells

Mast cell progenitors originate from CD34+ hematopoietic progenitors in the bone marrow. Early developmental pathways remain unclear and studies suggest various schemes, including common BMCPs descended from GMPs or by direct derivation from MPPs.[2,8,21] Unlike granulocytic lineages, committed MCPs exit the bone marrow and undergo proliferation, differentiation, and maturation in mucosal and connective tissues. At the time of migration, these MCPs lack mature granules and the high affinity receptor for the Fc portion of IgE.[41]

IL-3 and SCF are the primary growth factors for mast cell development.[27,28] Unlike the other granulocytic lineages, MCPs maintain high levels of c-kit, the receptor for SCF.[34] Stimulation of c-kit supports proliferation and differentiation of mast cells, and its effects may be potentiated by co-incubation with IL-3. In addition, SCF binding to KIT inhibits apoptosis and prolongs survival of mast cells. SCF is a chemotactic agent for immature and mature mast cells and helps localize mast cells to tissues.[11]

Acronyms and Abbreviations

C/EBP-α, CCAAT/enhancer binding protein-alpha; CD, cluster of differentiation; CFU-GM, colony forming unit granulocyte macrophage; CLP, common lymphoid progenitor; CMP, common myeloid progenitor; cDCs (conventional DCs); DCs, dendritic cells; DNA, deoxyribonucleic acid; FIV, feline immunodeficiency virus; Flt3L, Flt3-ligand; GM-CSF, granulocyte macrophage colony stimulating factor; GMP, granulocyte/monocyte progenitors; HSC, hematopoietic stem cells; iNOS, inducible nitric oxide synthase; IDO, indoleamine-2,3-dioxygenase; IL, interleukin; IRF8, interferon-γ-responsive transcription factor; KO, knock-out; LC, Langerhans cells; M-CSF, macrophage colony stimulating factor; MDP, macrophage/dendritic cell progenitors; MHC, major histocompatibility antigen; MEP, megakaryocyte/erythroid progenitors; MPP, multipotential progenitors; MPS, mononuclear phagocytic system; NF-κB, nuclear factor kappa-light-chain-enhancer of activated B cells; pDCs, plasmacytoid DCs; SCF, stem cell factor; TGF-β, transforming growth factor-beta; TIP DCs, tumor necrosis factor-α (TNF-α) inducible nitric oxide synthase (iNOS)-producing DCs; TLR, Toll-like receptor; TNF-α, tumor necrosis factor-alpha; Treg, regulatory T (cell);V-RelB, reticuloendotheliosis viral oncogene homolog B SCF.

The mononuclear phagocytic system (MPS) is a term that is commonly used to describe monocytes, macrophages and their progenitor cells. Although a somewhat imprecise term, the MPS is useful in describing the heterogeneity yet inter-relatedness of these cells. Dendritic cells (DCs) are bone marrow-derived cell that are not traditionally included in the MPS but can arise from common myeloid precursor cells or monocytes and share characteristics with monocytes and macrophages. The term histiocyte is relatively imprecise but is a useful term to describe cells in cytologic or histopathologic specimens considered to be of MPS origin, but whose precise identity is unknown. In this chapter, DCs, monocytes, and macrophages will be discussed together despite the fact the DCs are distinct in many ways. Cells of the MPS play an important role in phagocytosis and killing of infectious agents, digestion of cellular debris, and are key players in both innate and adaptive immune responses.

This chapter will discuss the formation of monocytes, macrophages, and DCs, and contrast differences in form and function between these cells.

MONOCYTE AND DENDRITIC CELL PRODUCTION

The hematopoietic stem cell (HSC) is a pluripotent progenitor cell that gives rise to common lymphoid and common myeloid progenitoris (CLPs and CMPs, respectively). The CMP gives rise to numerous progenitors including granulocyte/monocyte progenitors (GMPs), macrophage/dendritic cell progenitors (MDPs) and megakaryocyte/erythroid progenitors (MEPs), while a

subset of DCs arise from CLPs.[11] The fact that CLPs and CMPs can give rise to DCs led to original classification of DCs as lymphoid or myeloid based on cluster of differentiation (CD)8α expression with proposed distinct functions of these subsets. More recent work indicates that these subsets can arise from either CLP or CMP and are currently referred to as conventional DCs (cDCs). Although plasmacytoid DCs (pDCs) also can arise from either CLP or CMP, their unique function sets them apart from cDCs. Through an orchestrated sequence of transcriptional events and local cytokine microenvironmental stimuli, GMPs, MDPs and CLPs give rise to monocytes, macrophages and DCs.

TRANSCRIPTIONAL AND CYTOKINE REGULATION

When discussing the origin and development of monocytes, macrophages, and DCs, it is important to understand the role and diversity of stem cells. Our understanding of hematopoiesis has arisen primarily from human and mouse studies and through the use of genetically engineered (i.e. knock-out) mice (GEMs). Although such GEMs are powerful tools, they have limitations, particularly when the altered gene plays a critical or multi-factorial role in hematopoiesis or embryological development. However, even with such limitations, GEMs are powerful tools that have been instrumental in unraveling key events, transcriptional regulators, and cytokines involved in hematopoiesis and the development and regulation of monocytes, macrophages, and DCs.

Transcriptional Regulation

PU.1 is an early transcription factor important in differentiation of CMPs and CLPs from MPP whose presence allows differentiation along the myeloid lineage and whose absence promotes erythroid development.[11] The coordinated expression of transcription factors PU.1, CCAAT/enhancer binding protein-α (C/EBP-α) and interferon-γ-responsive transcription factor (IRF8) influence development of granulocytic versus monocytic/macrophage lineages.[11] GMPs under the influence of decreasing PU.1 levels and increasing C/EBP-α will form granulocytes. Conversely, high PU.1, lower C/EBP-α and increased expression of IRF8 will promote generation of monocytes and macrophages, with IRF8 acting through unknown influences on M-CSF signaling.[11] Due to the CMP and CLP origin of some DCs, Ikaros, an important transcription factor involved in lymphopoiesis, plays an essential role in development and differentiation of DCs such as lymphoid DCs.[2] DC subset lineage commitment may be influenced by additional transcription factors such as V-rel reticuloendotheliosis viral oncogene homolog B (RelB), a member of the nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) family which is expressed in higher amounts in CD8α– cDCs, and inhibitor of differentiation 2 (Id2) which is upregulated during DC development and required for the development of cDCs and Langerhans cells (LCs).

Cytokine Regulation

Numerous cytokines play an important role in shaping the microenvironment and promoting differentiation of specific cell populations. Under the influence of interleukin-1 (IL-1), IL-3, IL-6 and stem cell factor (SCF) Multipotential progenitors (MPPs) will form CFU-GM/CMP from which either the granulocytic or monocytic lineage will develop.[3,15] Monocyte production is stimulated by SCF, macrophage-colony stimulating factor (M-CSF), granulocyte-macrophage colony stimulating factor (GM-CSF), IL-1, IL-3, and IL-6 and increased PU.1 expression.[3] Monocytes arise through sequential differentiation of CFU-GM to monoblasts, promonocytes, and finally to monocytes (Fig. 8.1). M-CSF is a critical cytokine involved in the formation of macrophages and monocyte-derived cells with macrophage functions such as osteoclasts. Subsequent maturation and function of tissue macrophages is determined by the local tissue microenvironment. Flt3-ligand (Flt3L) is the most important cytokine involved in generating all DC subsets and plays an important role in maintaining steady-state levels of DCs. GM-CSF promotes development of inflammatory DCs and induces differentiation of monocytes and bone marrow cultures to DCs. Similar to macrophages, local tissue environment alters DC phenotype and function. One such example is the critical role played by TGF-β in generating LC.[1]

Effects of Altering Key Cytokines

Our understanding of the importance of various cytokines in the generation of monocytes, macrophages and DCs has arisen primarily by GEM knock-out (KO) mice.

The absence of M-CSF or its receptor results in decreased numbers of monocytes and certain macrophage subsets. M-CSF does not appear to be critical for steady-state DC production because DC numbers, ratios, and function appear to not be affected in these KO mice. Surprisingly, GM-CSF does not appear to be essential during normal hematopoiesis because KO mice have normal hematopoiesis. GM-CSF does appear to play a primary role in generating and maintaining DCs in inflammatory states and can act synergistically with Flt3L.[13,17] Flt3L is the major cytokine driving steady-state DC production in vivo because mice with knock out of the Flt3L or Flt3L signaling pathways have a significant deficiency in DCs.[8] However, these mice have normal monocyte development and GM-CSF-mediated DC development. Flt3L administration in vivo increases DCs and appears to act synergistically with GM-CSF to expand DCs in vivo while GM-CSF alone has little effect on DC numbers in vivo.[4] TGF-β plays an essential role in the generation of skin DCs (i.e. LC) because mice that lack TGF-β are deficient in LC.[9]

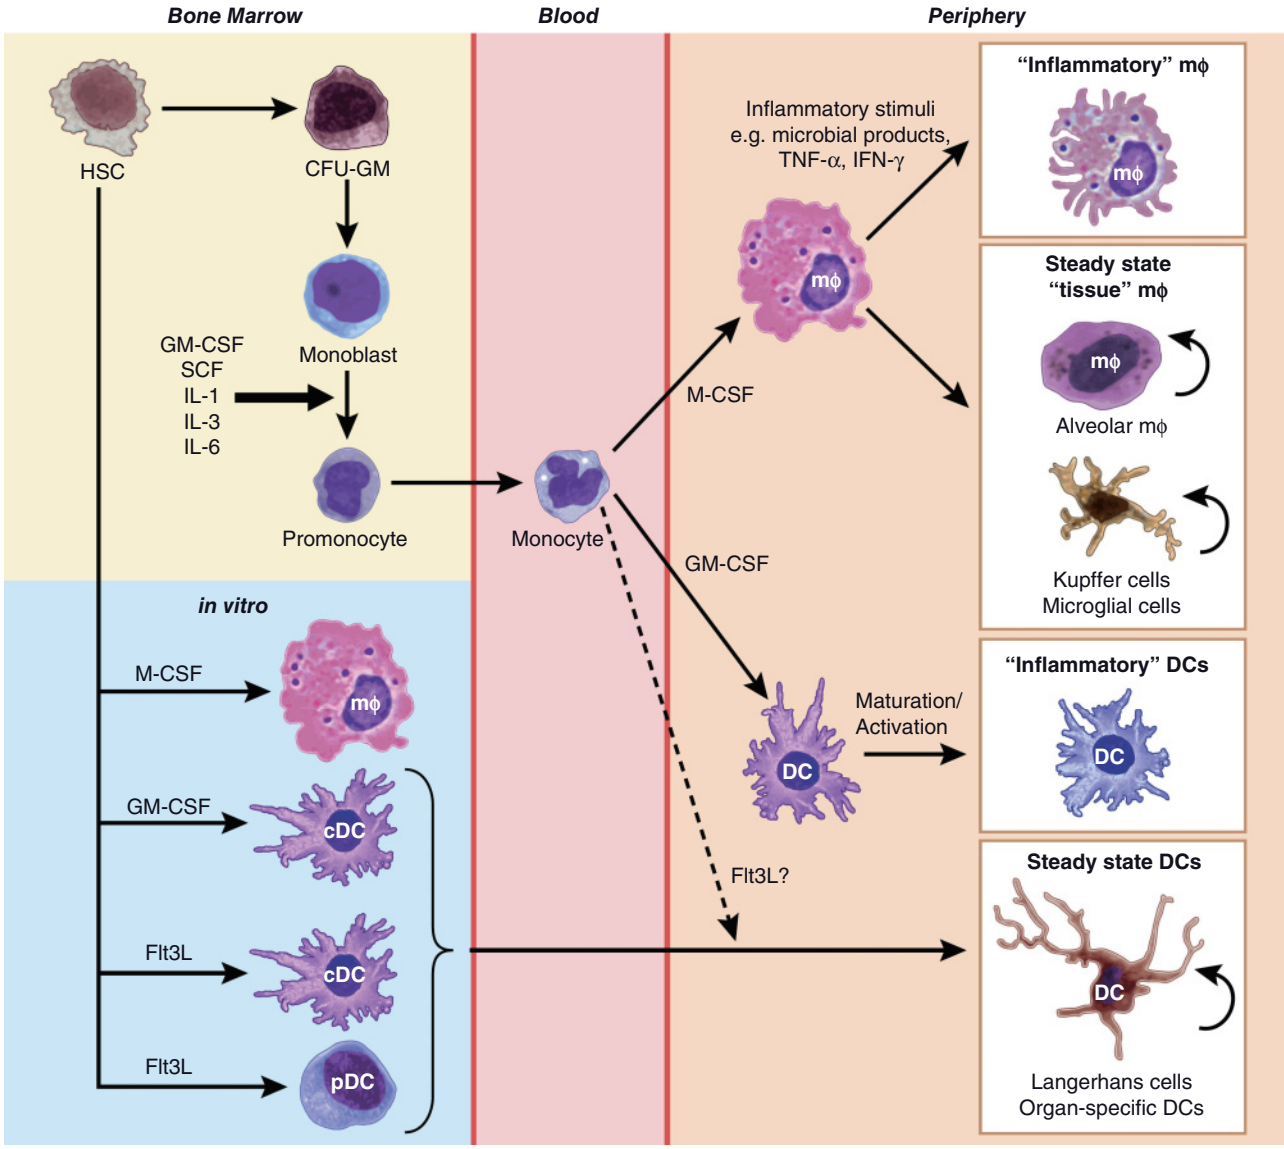

FIGURE 8.1 Location and developmental pathways of monocytes, macrophages (mΦs) and dendritic cells (DCs). Hematopoietic stem cells (HSCs) give rise to CFU-GM which can then give rise to monocytic (and granulocytic) precursors. Monocytes circulate in blood and can develop into either macrophages or DCs. M-CSF promotes development of mΦs from monocytes. GM-CSF promotes development of DCs. Inflammatory stimuli and other mΦ factors can give rise to "inflammatory" mΦ and DC populations. In steady state, tissue mΦs and DCs are replenished by either circulating monocytes or self-renewal. In vitro, HSCs give rise to mΦs when cultured with M-CSF, conventional DCs (cDCs) when cultured with GM-CSF, and cDCs and plasmacytoid DCs (pDCs) when cultured with Flt3L. Flt3L acts on bone marrow to generate both cDCs and pDCs that represent "steady state" DCs. GM-CSF acts on monocytes to generate DCs with an "inflammatory" phenotype.

Generation and Expansion

Monocyte precursors and monocytes can give rise to macrophages or DCs in vitro depending on culture conditions, cytokines, and growth factors. M-CSF is a primary cytokine used to generate macrophages from monocyte precursors or bone marrow mononuclear cells in culture.[16] GM-CSF is the primary growth factor used to generate DCs in vitro, whereas Flt3L has been used in vitro and in vivo to generate DCs.[17] Flt3L is capable of generating all DC subsets in vitro including both cDCs and pDCs, while GM-CSF prevents the generation of pDCs. In vivo, DC expansion is effectively accomplished by administration of Flt3L.[4] GM-CSF does not expand DCs in vivo but does appear to amplify in vivo expansion if administered with Flt3L.[4] Flt3L binds Flt3 expressed on early bone marrow progenitors, which stimulates proliferation, differentiation, mobilization, and survival of these cells. Although Flt3L can generate a monocytosis and is important in producing steady-state DCs, Flt3L alone is not capable of producing monocyte-derived DCs, probably due to low Flt3 expression on monocytes.

CIRCULATION, TISSUE DISTRIBUTION, AND FUNCTION

Macrophages

Macrophages are rarely present in blood. In tissues, multinucleated giant cells, syncytial cells, and epithelioid macrophages may develop in chronic inflammation or in response to specific infectious agents (see Chapter 45). Tissue-specific macrophages have been recognized for decades and have various names depending on location. Two such examples include Kupffer cells in the liver and microglial cells in the central nervous system. Such tissue macrophages often establish in specific organs during embryogenesis and maintain steady-state levels primarily by local replication with only a small contribution from monocytes during homeostasis. The majority of inflammatory tissue macrophages arise from monocytes recruited from blood. Regardless of location, tissue macrophages have similar functions which include surveillance, removal of dead cells and cellular debris, defense against pathogens, and promotion of wound healing, tissue remodeling, and repair. Tissue macrophages have a life span of years and can divide, but often do so at a very low rate.

Dendritic Cells

DCs can arise from HSCs, before an absolute commitment of HSCs to CMPs or CLPs. This fact makes DCs unique as cells in the MPS and challenges a linear model of DC genesis. Thus, unlike the lineage-specific model of development where CMPs differentiate into monocytes which give rise to macrophages, a graded commitment model of DC development has been proposed. In this model, early precursors (HSC and CMP) are more likely to generate both pDCs and cDCs while more differentiated stages of DCs (e.g. pro- or pre-DCs) will more likely give rise to cDCs including the CD8+ and CD8–DC subtypes.[9] Thus, DC development results from a combination of transcription factors and external cytokine signals influencing pDC and cDC development from both the myeloid and lymphoid pathways.

Similar to macrophages, DCs are not typically found in the circulation. However, circulating pre-DCs have been demonstrated in both humans and mice and arise from bone marrow rather than recirculation of DCs.[9] Once mature, DCs can be classified as migratory, resident, circulating, or inflammatory and be inactive or activated in each of these capacities.[9]

Differentiation of monocytes to DCs is more rapid during inflammation (18 h) than generation time of DCs in vitro. The half-life for activated DCs in inflammation is 3–5 days. Approximately 5–10% of resting or tissue DCs are in cell cycle at any given time, and the relative contribution of monocytes and bone marrow precursors to normal DC replenishment, turnover, and recruitment is less well characterized than for tissue macrophages.[7]

Dendritic cells have a wide tissue distribution and are located in all organs throughout the body. In such sites, DCs are positioned to serve as sentinels of the immune response and can initiate and direct subsequent immune responses. Many cells previously identified as tissue macrophages are now recognized as DCs or mixed populations of DCs and macrophages. LC are DCs in the skin and, together with dermal macrophages, are important in cutaneous immune responses.[10] DCs and macrophages in the lamina propria of the gut play distinct roles in directing immune responses that may influence development of autoimmune and inflammatory diseases.

Cell surface markers are commonly used to identify DCs and their subsets. In general, CD8α+ cDCs are thought to play a role in maintaining homeostasis and tolerance to self and are commonly found in T cell-rich areas of the spleen and lymph nodes. In contrast, CD8α– cDCs comprise nearly 80% of resident DCs in the spleen, are a minor population in lymph nodes, and tend to be found in the marginal zones with subsequent redistribution to T cell areas upon stimulation through toll like receptors (TLRs).[9] These CD8α– cDCs are thought to be the primary DCs that initiate immune responses.

Activation of immature DCs results in migration to lymph nodes, up-regulation of surface expression of major histocompatibility antigens (MHC) Class II and co-stimulatory markers, and production of cytokines (e.g. IL-1, IL-6, IL-10, IL-12, IL-23, TGF-β, TNF-α, type I interferons), chemokines, and other soluble factors (e.g. indoleamine-2,3-dioxygenase IDO).[12] DCs then interact with numerous other cells including both immune and non-immune (e.g. endothelial cells) to initiate and direct an immune response (see Chapter 51).

The microenvironment plays an important role in determining whether DCs become immunogenic or regulatory. An inflammatory stimulus causes DCs to mature from processing antigen to actively presenting antigen and initiating an immune response. Immunogenic DCs up-regulate MHC Class II and co-stimulatory molecules, and migrate to local lymph nodes. One example of immunogenic DCs is "Tip DCs". "Tip DCs" are large and granular DCs that are associated with bacterial, viral, and parasite infections and autoimmune diseases. They produce TNF-α and inducible nitric oxide synthase (iNOS) in response to TLR agonists.[9] Regulatory or tolerogenic DCs are important in controlling inflammation, and preventing autoimmunity and fetal allograft rejection during pregnancy. The microenvironment also determines the function of regulatory DCs. IL-10, TGF-β, vitamin D, glucocorticoids, and other steroid hormones have been shown to generate regulatory DCs.[12] Regulatory DCs are able to regulate the immune response through a variety of mechanisms including IL-10 production or expanding regulatory T (Treg) cell populations.[12] Plasmacytoid DCs are a subset of DCs that produce large amounts of type I interferons (i.e. IFN-α and IFN-β) after stimulation by viral or microbial infections. Such plasmacytoid DCs are located throughout the body but are in high

concentrations at immune sites exposed to the external environment (e.g. mucosal sites).

DIFFERENTIATING MONOCYTES, MACROPHAGES, AND DENDRITIC CELLS

DC can be round to stellate in appearance and can appear very similar to macrophages in tissue sections or aspirates. The prototypical "veiled" morphology with numerous thin projections resembling neuronal processes, used to originally define DCs, are difficult to appreciate in cytological and histological preparations. DCs in culture have limited or transient adherence and may resemble large lymphocytes with only small pseudopodia or dendritic processes. Upon activation or maturation, DCs demonstrate the more typical stellate morphology as seen in vivo in LCs (Fig. 8.2).

Monocytes, macrophages, and DCs express cell surface markers that are important in cellular function and useful in cell identification (see Chapters 4, 45, and 71). While many of these markers have been described in humans and mice, reagents in veterinary species are becoming increasingly available.[3,14,15]

At present, there is no single marker that definitively differentiates monocytes, macrophages, and DCs. Rather, it is a combination of phenotypic markers, cellular morphology, tissue location, and functional characteristics that is used to identify cells of the MPS. CD14 expression is highest on monocytes and decreases as monocytes differentiate to macrophages or DCs. However, loss of CD14 expression on macrophages and DCs differs among species.[3,15] Conversely, MHC class II, a molecule important in antigen presentation, is low in monocytes but is up-regulated with maturation and differentiation into macrophages and DCs. F4/80 is present on nearly all macrophage populations and is useful in fixed tissue sections.[5] CD11b (Mac-1) is expressed on myeloid cells such as macrophages and myeloid DCs. CD11c is the most commonly used marker to specifically identify DCs because monocytes and macrophages typically are negative for CD11c.[6] However, CD11c is not a universal marker for all DCs because lung DCs and plasmacytoid DCs express little or no CD11c.[6]

SUMMARY

In summary, monocytes, macrophages and DCs are important hematopoietic cells that play critical roles in defense and maintaining homeostasis. Monocytes often are a direct indication of the health of the myelomonocytic lineage. Although the tissue locale of macrophages and DCs often limits extensive ctyologic evaluation of these cells, function and dysfunction of these cells have important implications in health and disease.

Acronyms and Abbreviations

Arp, actin-related protein; BFU-MK, burst forming unit-megakaryocyte; BMEC, bone marrow endothelial cell; CalDAG-GEFI, calcium diacylglycerol guanine nucleotide exchange factor I; CBF, core binding factor; CD, cluster of differentiation; CFU-MK, colony-forming unit-megakaryocyte; CXCR, chemokine receptor; DMS, demarcation membrane system; E#, day of embryonic development, where the number indicates age of the embryo in days after conception; FGF-4, fibroblast growth factor 4; FCR, receptor for the FC portion of immunoglobin; Fli1, Friend leukemia integration 1; FOG1, Friend of GATA1; GABP, GA-binding protein; GATA1 and 2, GATA binding proteins 1 and 2; G-CSF, granulocyte colony stimulating factor; GM-CSF, granulocyte-macrophage colony stimulating factor; GP, glycoprotein; IL, interleukin; LIF, leukemia inhibitory factor; Lin^-, lineage negative; JAK, Janus kinases; MAPK, mitogen activated protein kinases; Meg-CFC, megakaryocyte-colony forming cells; MEP, megakaryocyte-erythroid progenitor; Mpl, myeloproliferative leukemia; NF-E2, nuclear factor-erythroid 2; PECAM-1, platelet endothelial cell adhesion molecule-1; PF4, platelet factor 4; PIP4Kα, phosphatidylinositol-5-P-4 kinase; SCF, stem cell factor; SDF, stromal cell-derived factor; STAT, signal transducers and activators of transcription; TPO, thrombopoietin; VCAM-1, vascular cell adhesion molecule-1; WASp, Wiskott-Aldrich syndrome protein; WAVE, WASp-family verprolin-homologous protein.

THROMBOPOIESIS OVERVIEW

Megakaryocyte-Erythroid Progenitor

Megakaryocytes are derived from a bipotent megakaryocyte-erythroid progenitor (MEP).[6] Although the MEP was once thought to arise from a committed common myeloid progenitor, recent evidence suggests that the MEP may arise directly from an uncommitted short-term hematopoietic stem cell.[1] Primitive MEPs and megakaryocyte colony-forming cells (Meg-CFCs) have been detected in mouse embryo yolk sacs and give rise to primitive GPIbβ-positive platelets that are of large diameter, highly reticulated and relatively hypogranular.[26] These early platelets can be detected in circulation in mouse embryos as early as embryo day (E) 10.5. By day E11.5, definitive MEPs and Meg-CFCs within fetal liver become the predominant source of megakaryocyte progenitor expansion and produce platelets that are more similar in size and granularity to adult platelets. It is not known whether primitive platelets produced within the yolk sac represent a population of platelets distinct from those produced by the fetal liver and ultimately the bone marrow because specific markers are unavailable.

Bipotent MEPs cannot be distinguished morphologically from small lymphocytes in bone marrow but have a unique cell surface protein expression pattern that includes interleukin (IL)-7Rα$^-$/lineage negative (Lin^-)/c-Kit+/Sca-1$^-$ clusters of differentiation (CD)34$^-$/FcRγ^{lo}.[14] Once commitment to megakaryocyte lineage occurs, cells begin to express CD41 and CD61 (integrin αIIbβ3 or GP IIb and IIIa), CD 42 (glycoprotein Ib), and glycoprotein V. Two morphologically distinct colonies leading exclusively to megakaryocyte production have been identified in vitro: burst-forming unit-

megakaryocyte (BFU-MK) and colony-forming unit-megakaryocyte (CFU-MK).[14]

Bone Marrow Endothelial Cells

The bone marrow can be divided into two anatomical and functional entities with respect to development of hematopoietic cells: the endosteal zone, where non-dividing stem cells reside, and the more centrally located vascular niche that promotes stem cell differentiation and eventually mobilization of mature hematopoietic cells to the blood (see Chapter 3). Within the bone marrow, bone marrow endothelial cells (BMECs) support proliferation and differentiation of hematopoietic cells as a consequence of direct contact and release of cytokines. In turn, megakaryocytes nurture BMECs by secreting survival and growth factors. Platelet-endothelial cell adhesion molecule-1 (PECAM1) may play a role in movement of megakaryocytes toward the vascular sinuses. Transendothelial migration and proplatelet formation and release are dependent on the interaction of megakaryocytes with BMECs via adhesion molecules, including vascular cell adhesion molecule-1 (VCAM-1) and integrin α4-β1.

TRANSCRIPTION FACTORS

Several transcription factors are critical for normal thrombopoiesis in humans and mice that probably also regulate thrombopoiesis in other species.

GATA1 and GATA2

GATA binding protein (GATA1) is an X-chromosome encoded transcription factor that plays a key role in megakaryopoiesis and erythropoiesis. GATA2 is a closely related transcription factor that has early effects on maintenance of hematopoietic stem cells and multipotential progenitors.[28] GATA1 possesses distinct structural elements necessary for binding promoters and cofactors involved in progenitor cell development and differentiation. Several erythroid- and megakaryocyte-specific genes contain GATA motifs in critical *cis*-regulatory elements. For megakaryocytes these genes include those encoding for GPIIb, GPIbα, GPIbβ, GPIX, platelet factor (PF)4, and the thrombopoietin receptor, myeloproliferative leukemia (c-Mpl). GATA1 activity is necessary for the divergence of megakaryocytic and erythroid progenitors from the MEP. Megakaryopoiesis is more sensitive to levels of GATA1 than erythropoiesis.[23] Several GATA1 mutations in humans are accompanied by a role reversal in which megakaryocytes are small and possess nuclei with reduced lobulation and erythroblasts are large and multinucleated.[5,8]

Friend of GATA1, Friend Leukemia Integration 1, and GA-Binding Protein

Friend of GATA1 (FOG1) is an essential cofactor of GATA1. Mutations in GATA1 that result in impairment of GATA1 binding with FOG1 result in X-linked macrothrombocytopenia in people. Friend leukemia integration 1 (FLi1) is a member of the Ets-family of transcription factors and interacts in a synergistic manner with GATA1 in the activation of megakaryocyte-specific genes. The heterodimeric GA-binding protein complex (GABP) is another Ets-binding factor that regulates gene expression in megakaryocytes. GABP, a complex composed of alpha and beta subunits, binds to promoters of early megakaryocyte-specific genes such as GPIIb and cMpl, whereas FLi1 primarily affects expression of late megakaryocyte-specific genes, including GPIbα, GPIX, and PF4. The alpha component of GABP mediates DNA binding of the complex whereas the beta component mediates transcriptional activation and nuclear localization of GABPα.[20] GABP and FLi1 both can bind to promoters of early and late megakaryocyte-specific genes and regulate activity of the GATA1/FOG complex. This overlap in function allows partial compensation if either activity is lost.

Core Binding Factors

A family of transcription factors referred to as core binding factors (CBFs) are critical in megakaryopoiesis and megakaryocytic differentiation. The CBF family contains three DNA binding proteins (RUNX1, RUNX2, RUNX3) and a non-DNA binding protein (CBFβ). RUNX1 is a heterodimer composed of core-binding factor α-2 (CBF α-2) and CBFβ. RUNX1 interacts with GATA1 and has an essential role in early hematopoiesis and vasculogenesis.[25] RUNX1 may also play a role in lineage determination. RUNX1 mutations in humans are associated with thrombocytopenia and platelet function abnormalities associated with decreased dense granule formation.[17] In humans, CBF α-2 mutations have been associated with decreased levels of protein kinase C-θ,[24] resulting in impaired activation of platelet integrin αIIb-β3.

Nuclear Factor-Erythroid 2

Nuclear factor-erythroid 2 (NF-E2) is a key transcription factor involved in enhancing early megakaryopoiesis and in promoting megakaryocyte maturation. NF-E2 is a heterodimer consisting of a hematopoietic-specific p45 subunit and two p18 subunits, MafG and MafK. Mice with deleted genes for NF-E2 are severely thrombocytopenic, and megakaryocytes have reduced granules, a disorganized demarcation membrane system, fail to form proplatelets, and are unable to generate signals necessary for fibrinogen binding.[22] Megakaryocyte targets for NF-E2 include genes encoding for thromboxane synthase, β1-tubulin, Rab27b, caspase-12, calcium diacylglycerol guanine nucleotide exchange factor I (CalDAG-GEFI), and PINCH1. PINCH1 is an adaptor protein that interacts with integrin-linked kinase which in turn binds with cytoplasmic tails of integrins and thus may be important in mediating migration and interaction of megakaryocytes in the bone marrow microenvironment.[31]

MEGAKARYOCYTE MATURATION AND PLATELET FORMATION

In humans and domestic animals, megakaryocytes are located primarily in bone marrow. However, in adult mice, the spleen is considered a primary hematopoietic organ and generates all hematopoietic cell lineages, including megakaryocytes. Megakaryocytes undergo some degree of fragmentation in the pulmonary circulation in most mammalian species.

Endomitosis

During the early stages of megakaryocyte development, progenitor cells undergo typical cell division as they acquire lineage specific markers. In later stages of development, megakaryocytes begin several rounds of endomitosis in which anaphase, telophase, and cytokinesis are skipped, resulting in DNA division without cell division.[29] Mature megakaryocytes are polyploid cells and DNA content or ploidy correlates with the number of platelets a megakaryocyte will ultimately produce. The progression of megakaryocytes from dividing normally to dividing "atypically" is due to the lack of formation of a normal functioning mitotic spindle.[10]

Studies using a K562 erythroleukemia cell line suggest that down-regulation of stathmin expression may be necessary for induction of endomitosis in megakaryocytes. Stathmin is a phosphoprotein that promotes microtubule depolymerization and is phosphorylated and dephosphorylated in a cell cycle-dependent fashion. Stathmin is phosphorylated/inactivated as cells enter mitosis to allow for assembly of the mitotic spindle and then dephosphorylated/activated at the end of mitosis to allow dissolution of the mitotic spindle. Studies with K562 cells suggest that during early megakaryocyte development, stathmin expression levels are high, corresponding with normal cell division. During later stages of megakaryocyte development stathmin expression levels are reduced, resulting in abortive mitosis and polyploidization.[10]

Demarcation Membrane System and Proplatelet Formation

Terminal megakaryocyte differentiation occurs after endomitosis is completed and is associated with tubular invagination of the plasma membrane resulting in formation of the demarcation membrane system (DMS).[21] The current model of platelet formation suggests that the DMS functions to provide a membrane reservoir for the formation and extension of proplatelets.[21] Prior to proplatelet formation there is an accumulation of the phospholipid PI-4,5-P2 as a result of megakaryocyte lipid kinase activity. Specifically, phosphatidylinositol-5-P-4 kinase α (PIP4Kα) is thought to generate PI-4,5-P2 by acting on the substrate PI-5-P. PI-4,5-P2 is thought to trigger actin polymerization by enhancing binding of Wiskott-Aldrich syndrome protein (WASp) to actin-related protein (Arp2/3). WASp-Arp2/3 complex formation probably triggers Rho-family GTPases with activation of WASp-family verprolin-homologous protein (WAVE) proteins resulting in actin fiber assembly.[19] Actin polymerization is associated with dilation and movement of the DMS to the cell periphery in preparation for microtubule assembly.[19]

Synthesis of platelet granules occurs simultaneously with formation of the DMS and granules are packaged and mobilized as microtubule assembly occurs in the extension of proplatelets. The microtubule motor kinesin is probably responsible for transport of organelles and granules along microtubules.[18] Movement is bidirectional as microtubules slide past each other. Once organelles and granules enter the proplatelet tip they are captured there for packaging within the developing platelet.[18] In addition to organelles, spliceosomes and pre-mRNAs are packaged into newly forming platelets, thus providing platelets with the capacity for protein synthesis.

Microtubule assembly is a dynamic process: time-lapse photography shows alternating extension and retraction as well as bending and branching of proplatelet shafts. Platelets form from the tips of proplatelet shafts; thus branching provides a mechanism for formation of more platelets per proplatelet extension. Branching and bifurcations of proplatelet extensions are mediated by actin forces. Elongation of proplatelets, however, is mediated by dynein, a molecular motor protein that mediates microtubule sliding necessary for proplatelet extension.

Microtubules are hollow polymers formed by α/β-tubulin dimers. β1-Tubulin is the most abundant platelet β-tubulin isoform. β1-Tubulin null mice attempt to compensate by up-regulating other β-tubulin isoforms, but other isoforms are unable to fully compensate. As a result, null mice have thrombocytopenia and platelets have reduced numbers of marginal microtubule bands. A missense mutation in β1-tubulin causes macrothrombocytopenia in Cavalier King Charles Spaniels.

Proplatelets are formed in a spiraling manner starting at the periphery and moving centripetally towards the nucleus. Proplatelets consist of long beaded strands that fragment in circulation when subjected to shear. Shear stress within bone marrow sinusoids probably assists in fragmentation of proplatelets from megakaryocyte bodies after proplatelets are extended through the subendothelium. Activation of proplatelets is thought to be avoided by extension of large, cytoplasmic fragments into the lumen of sinusoidal vessels.[11] Proplatelet formation consumes the entire megakaryocyte cytoplasm leaving behind only the nucleus which enters an apoptotic pathway.

THROMBOPOIETIN AND OTHER KEY HORMONES

Thrombopoietin

Thrombopoietin (TPO) is a key humoral regulator of platelet production[3,15] TPO initially was identified as the

ligand for c-Mpl, the normal mammalian proto-oncogene version of a murine myeloproliferative leukemia virus.[30] The open reading frame for human TPO protein, including the signal peptide, encodes 353 amino acids. In cats, dogs, horses, cattle, pigs, and mice the open reading frame encodes 349, 352, 350, 349, 353, and 356 amino acids, respectively.[3,16] At the amino acid level TPO is highly homologous across species and is 79%, 85%, 89%, 83%, 82%, and 81% homologous when comparing human to cat, dog, horse, cow, pig, and mouse, respectively.[9] The amino-terminal end of TPO is highly homologous with erythropoietin in all species and is the portion of the protein that engages the TPO receptor. The carboxy-terminal domain is highly glycosylated which may be necessary for TPO survival in circulation and for secretion of TPO from cells. Truncated forms of TPO are found in circulation, particularly in thrombocytopenic animals.[13] TPO is cleaved by thrombin at two sites, generating polypeptides that vary in activity. Cleavage of TPO at Arg^{191} in the carboxy-terminal domain results in a polypeptide with enhanced activity; however, activity is destroyed by thrombin cleavage at Arg^{117} within the amino-terminal domain.

Studies have documented that although TPO is critically important for normal megakaryopoiesis, TPO also is important for overall hematopoiesis and plays a role in enhancing expansion of hematopoietic stem cells.[2] TPO binding to c-Mpl results in activation of Janus kinases (JAKs) and signal transducers and activators of transcription (STAT) factors STAT3 and STAT5. JAK2 is bound constitutively to c-Mpl and upon activation phosphorylates tyrosine residues within c-Mpl and within STATs, PI3K, and mitogen activated protein kinases (MAPKs). STAT3 and STAT5 are required for regulation of normal megakaryopoiesis and have been found to be dysregulated in some myeloproliferative disorders and in megakaryoblastic leukemias in humans.

TPO is synthesized primarily by the liver and to a lesser extent in kidney and by bone marrow stromal cells. TPO receptors are located on platelets, megakaryocytes, and vascular endothelial cells. Although the numbers of TPO receptors on endothelial cells far exceed the numbers found on megakaryocytes and platelets, endothelial TPO receptors are not involved in regulation of TPO levels. Under steady-state conditions, TPO is produced constitutively and is bound by platelets and megakaryocytes via specific TPO receptors referred to as c-Mpl. Bound TPO is internalized and degraded and not available for stimulating thrombopoiesis above steady-state levels.

During episodes of thrombocytopenia, TPO levels increase, resulting in enhanced thrombopoiesis. The responsiveness of megakaryocytes to TPO is regulated somewhat by the maturity of the megakaryocyte. Megakaryocytes that are GPIIb+ GPIb+ undergo fewer endomitotic cycles in response to TPO compared to younger megakaryocytes that are GPIIb+ GPIb−. The enhanced endomitotic capability of GPIIb+ GPIb− megakaryocytes is due to lack of binding of 14-3-3ζ adaptor protein to the cytoplasmic tail of GPIbα. Lack of sequestration of 14-3-3ζ results in enhanced phosphorylation and activation of Akt by phosphoinositol-3-kinase (PI3K). Activated Akt increases the post-translational stability of cyclins, which play a role in promoting endomitosis and increasing ploidy. Although TPO production is constitutive under steady-state conditions, severe thrombocytopenia can result in enhanced production of TPO by bone marrow stromal cells. Inflammatory conditions can result in enhanced TPO production by hepatocytes (mediated by IL-6) resulting in reactive thrombocytosis.[12] During certain pathologic conditions the steady-state mechanism of TPO production can be altered, resulting in TPO levels that are discordant with levels expected based on platelet numbers. In some cases of severe idiopathic thrombocytopenia, particularly where megakaryocytes are markedly increased in number and size, TPO levels may not be as high as expected due to binding of TPO to c-Mpl receptors on megakaryocytes.

Stromal Cell-derived Factor-1

cMpl-null mice are markedly thrombocytopenic but still capable of platelet production. Stromal cell-derived factor-1 (SDF-1) can function alone or synergistically with TPO to enhance thrombopoiesis and may be responsible for maintaining low level thrombopoiesis in *cMpl*-null mice. SDF-1 interaction with chemokine receptor 4 (CXCR4) may be responsible for movement of megakaryocyte progenitors to the vascular niche necessary for initiation of thrombopoiesis. Movement of megakaryocytes to the vascular sinusoid compartment of bone marrow, mediated by SDF-1 and fibroblast growth factor 4 (FGF-4), induces megakaryocyte maturation and platelet formation.[5]

Other Cytokines and Growth Factors

Although TPO is an important regulator of thrombopoiesis throughout all stages of megakaryocyte development, other cytokines act in synergy with TPO primarily in early stages of megakaryopoiesis. IL-3 synergizes with TPO to produce several hematopoietic lineages, but IL-3 effects are limited to the CFU-MK stage. Stem cell factor (SCF) and granulocyte-macrophage colony stimulating factor (GM-CSF) act in synergy to enhance proliferation and expansion of bone marrow progenitors and megakaryocyte lines. Granulocyte colony stimulating factor (G-CSF) combined with TPO can trigger hematopoietic stem cells to enter the cell cycle and support colony formation. In later stages of megakaryocyte development, G-CSF has been shown to suppress megakaryopoiesis. IL-11, IL-12, and erythropoietin also stimulate proliferation of megakaryocyte progenitors whereas IL1-α and leukemia inhibitory factor (LIF) affect later stages of megakaryocyte maturation and platelet release. PF4 has been shown to inhibit megakaryocytopoiesis in vitro. PF4 is stored in platelet alpha granules; aberrant platelet activation within bone

marrow with subsequent PF4 release (e.g. radiation, chemotherapy) may contribute to thrombocytopenia.

MEGAKARYOCYTE PLOIDY AND PLATELET MASS

There are four to five times more megakaryocytes in mouse bone marrow than in human bone marrow, and mouse megakaryocytes are smaller. The difference in size is not related to ploidy distribution since the modal ploidy value for both species is 16N. Megakaryocyte modal ploidy is 32N for dogs and rabbits. In cats the modal value is evenly split between 32N and 64N.[7] In 1 week old calves, the modal ploidy of cultured megakaryocytes was 64N, whereas in cattle aged 12–17 months the modal ploidy value was 32N.[27] Megakaryocyte ploidy is not consistently related to platelet mass and platelet mass is not constant across species. In dogs and cats, platelet size is inversely proportional to platelet number, whereas there is no correlation between platelet number and size in cows, goats, or ponies. Platelet number and size are directly proportional in horses. Mean platelet mass ranges from 1.8×10^6 to 2.5×10^6 fL/μL in cows, dogs, goats, and cats. In mice platelet mass is 5.2×10^6 fL/μL while in horses platelet mass is 0.72×10^6 fL/μL.[4]

Acronyms and Abbreviations

αβ, alphabeta; AIRE, autoimmune regulatory gene; BCR, B cell receptor; Blimp-1, B lymphocyte-induced maturation protein-1; CCR, chemokine receptor; CD, cluster of differentiation; DNA-PK, DNA-dependent protein kinase; Flt3, FMS-like tyrosine kinase 3; γδ, gammadelta; GATA3, GATA binding protein 3; HSC, hematopoietic stem cell; Ig, immunoglobulin; IFNγ, interferon gamma; IGF1, insulin-like growth factor 1; IL, interleukin; MHC, major histocompatability antigens; NK, natural killer (cell); Rag, recombination activating gene; RSS, recombination signal sequences; TCR, T cell receptor; TdT, terminal deoxynucleotidal transferase; TGFβ, transforming growth factor beta.

Lymphopoiesis is the production and maturation of new lymphocytes. Much of what we know about lymphopoiesis has been derived from studies in genetically engineered mice. Although these pathways probably represent those seen in other species, there are known species differences in lymphocyte development, phenotype, and function.[1]

Lymphocytes develop from a bone marrow derived pluripotent hematopoietic stem cell (HSC) that further differentiates into myeloid or lymphoid lineages. However, recent studies suggest that some lymphoid and myelomonocytic precursors maintain the capacity to differentiate along the other lineage pathway.[5] The common lymphoid progenitor gives rise to three types of lymphocytes: B cells, T cells, and natural killer (NK) cells.

IMMUNOLOGIC DIVERSITY

Combinatorial diversity, junctional diversity, and somatic hypermutation are mechanisms that permit the immune system to generate B and T cells that detect a large number of diverse antigens while maintaining a relatively small number of genes.

Combinatorial Diversity

Combinatorial diversity occurs in both immunoglobulin (Ig) and T cell receptor (TCR) genes through joining of different V, D, and J segments during VDJ rearrangement. Recognition of recombination signal sequences (RSS) by recombination activating gene (Rag) enzymes is crucial for VDJ rearrangement.

VDJ Rearrangement

VDJ rearrangement is a highly ordered, complex process requiring cleavage of DNA, addition or deletion of nucleotides to the cut ends of DNA, and finally DNA ligation. VDJ rearrangement is initiated by joining of one diversity (D) region with one junctional (J) region. A variable (V) region is then added and the intervening DNA is deleted, resulting in a single recombined V(D)J genomic sequence.

VDJ rearrangement defines specific stages of B and T cell development. In B cells, successful heavy chain rearrangement is required before light chain rearrangement can begin. Because kappa and lambda light chains lack a D segment, light chain rearrangement produces a VJ complex. In T cells, rearrangement of the TCR loci follows a specific order starting with delta, then proceeding through the gamma, beta, and finally alpha genes. Two distinct subpopulations of TCR expressing cells are formed from these chains: αβ and γδ T cells.

Recombination Signal Sequences

Ig and TCR gene segments are flanked by unique RSS containing a heptamer, a 12 or 23 base pair spacer, and then a nonamer. RSS orientation and spacer size are used during recombination to ensure orderly recombination and inhibit the recombination of similar gene segments (e.g. V-V).

Role of Rag 1 and Rag 2

Rag-1 and Rag-2 proteins are nuclear recombination enzymes that recognize RSSs and nick DNA to form hairpins where nucleotides can be added or deleted to create blunt-ended double-stranded DNA breaks. These ends are then aligned by the protein heterodimer Ku80/Ku86. Ku80/Ku86 are non-catalytic subunits of DNA-dependent protein kinase (DNA-PK). KU80/KU86 bring the broken DNA ends together for covalent ligation by the DNA ligase IV complex, which is critical for the DNA joining process in VDJ recombination. DNA-PK also recruits proteins for substrate phosphorylation, cleavage of the hairpin loops, and nucleotide addition. In general, Rag enzyme production ceases at the end of VDJ rearrangement. However, activated germinal center B cells can re-express the Rag genes during affinity maturation.

Junctional Diversity

Junctional diversity is created by the addition of nucleotides to the DNA ends that are cleaved during recombination.

Terminal Deoxynucleotidal Transferase

Terminal deoxynucleotidal transferase (TdT) is a DNA polymerase that adds variable numbers of nucleotides to the V, D, and J exons during rearrangement. These additional nucleotides at the VDJ junctions are called N regions and provide additional diversity of the Ig heavy chain and the TCR. TdT expression declines as B cells mature and thus does not increase light chain diversity.

Somatic Hypermutation

In B cells, diversity also is introduced through programmed hypermutation within the Ig variable genes when B cells are stimulated to proliferate. During hypermutation, uracils are introduced through cytosine deamination and error prone DNA polymerases. This marked mutation within the B cell receptor locus enhances the development of diverse B cells that recognize novel antigens.

B CELL DEVELOPMENT

B cell lymphopoiesis is a life-long process that begins in the fetal liver and transitions to the bone marrow after birth. After leaving the bone marrow, B cells seed peripheral lymphoid tissues.

Growth Factors

In mice, the earliest B cells require soluble factors such as interleukin (IL)-7 as well as direct physical interaction with bone marrow stromal cells. It is likely that non-functional and autoreactive cells are deleted through these direct stromal interactions. IL-7 is not required for B cell development in people.[4] Later stages of B cells require only soluble factors for development. IL-1α, IL-3, IL-4, IL-11, transforming growth factor beta (TGFβ) interferon gamma (IFNγ) insulin-like growth factor (IGF1), c-Kit ligand, FMS-like tyrosine kinase 3 (Flt3) ligand, and estrogen also are known to play a role in B cell proliferation, differentiation, and negative regulation.

Stages of B Cell Development

The earliest defined cells of B lineage are pro-B cells. These cells have limited proliferative ability and are characterized by rearrangement of the Ig heavy chain. As maturation proceeds to pre-B cells, a cytoplasmic heavy chain protein is produced that combines with a surrogate light chain to form a transient pre-B cell receptor (BCR). Expression of the pre-BCR inhibits further heavy chain rearrangement, stimulates cell replication, and is necessary for the survival and positive selection of pre-B cells. Light chain rearrangement occurs in late pre-B cells. Kappa rearrangement proceeds first. Lambda rearrangement will occur only if kappa rearrangement is unsuccessful. Light chain and heavy chain proteins combine to produce IgM. At this stage, cells also express cluster of differentiation (CD)10, CD19, and human lymphocyte antigen-DR (HLA-DR) markers.

As cytoplasmic IgM is exported to the surface membrane, cells transition into immature B-cells that express CD21. Surface IgM expression is used to delete cells reacting with self-antigen. Surviving immature B cells migrate to peripheral lymphoid tissues where they begin to express surface IgD as well as IgM. As these cells interact with antigen and T cells, they undergo the process of class switching, somatic hypermutation, and affinity maturation.

Class Switching (Isotype Switching)

Class switching is the process by which the mu and delta heavy chain constant regions are substituted with

constant region genes of IgG, IgA, or IgE. During this process, the heavy chain variable region and light chains remain the same; thus class switching results in the production of a different antibody class that has the same antigen binding area. Because IgG, IgA, and IgE have different Fc regions, these antibodies can be secreted or interact with different effector molecules. Heavy chain class switching is regulated by T cells through direct interaction and cytokine production.

T CELL DEVELOPMENT

T Cell Types

T cell development proceeds down two primary pathways as defined by expression of either an αβ or γδ TCR. In most species, approximately 90% of immature cells develop into αβ T cells through thymic selection, while the remaining cells develop into γδ T cells. αβ T cells are CD3+ and the majority also will express either CD4 or CD8.

Natural killer T or NK1.1 T cells are a unique subpopulation of αβ TCR expressing cells that express NK1.1, a marker typically found on NK cells. They are CD8 negative but may be either CD4 positive or negative. NK1.1 cells have a normal TCR rearrangement but then undergo selection via interactions with CD1 ligands in the cortical region.

T Cell Growth Factors

IL-7 is necessary for T cell development. Defects in the IL-7/IL-7receptor complex and signaling pathway are responsible for several reported T cell defects. Several transcription factors are important in T cell development. Notch1 is important for the transition from a common lymphocyte progenitor to a T/NK progenitor and, with GATA3, for the transition from the T/NK progenitor to sole T cell commitment.[8] Notch1 alone directs cells towards γδ TCR development, but HEB (one of the basic helix-loop-helix E-box binding proteins) directs cells towards αβ TCR.[7] B cell-induced maturation protein (Blimp-1), long established as critical for development of cells committed to the plasma cell lineage, recently has been shown to be essential for terminal differentiation of T cells.[3,6]

Role of the Thymus

The thymus is seeded with lymphocytes during embryonic development. Thymic precursors enter at the cortico-medullary junction via molecules such as CD44, CD62P, and chemokine receptor 9 (CCR9), and begin to seed the subcapsular cortex. Marked T cell production continues until puberty at which time the thymus begins to involute. Developing thymocytes undergo both positive and negative selection (see Chapter 52). Greater than 95% of developing lymphocytes fail one of these selection processes. Thymocytes begin as $CD4^{-}CD8^{-}$ double negative cells, transition to double positive $CD4^{+}CD8^{+}$ cells, and finally mature as single positive $CD4^{+}$ or $CD8^{+}$ T cells that are released from the thymus.

Thymic Stroma

The thymic stroma is a uniquely organized epithelial network on a mesenchymal cell backbone with interspersed dendritic cells and macrophages (see Chapter 52). This cellular network provides the extracellular matrix ligands and growth factors critical for T cell selection and development.

The Beta Selection Checkpoint

Expression of the TCR occurs during the double negative stage of T cell development. To survive the beta selection checkpoint, cells must express a functional beta chain, which results in combination of the TCR chains with CD3 to create a functional surface TCR complex. Rearrangement of the TCR beta chain is required for successful rearrangement of the TCR alpha chain and subsequent formation of the TCR. While TCR beta selection does not appear to be tightly coupled to CD4 or CD8 regulation, production of a functional TCR is needed for CD4 and CD8 expression and development of double positive cells.[2]

Positive Selection

Positive selection occurs in the cortex where double positive thymocytes interact with low to moderate affinity major histocompatibility antigen (MHC) peptide ligands on cortical epithelial cells to receive a survival signal. Cells that lack adequate affinity to bind the MHC ligand complexes undergo apoptosis. Although the basis of positive selection is the TCR-MHC interaction, CD4 and CD8 are also required for selection. Double positive cells that select MHCII molecules will become CD4 T cells while those that select MHCI molecules will become CD8 T cells. This forms the basis for lineage commitment.

During the initial interaction, TCR signaling induces down-regulation of both CD4 and CD8. CD4 is then re-expressed. CD4+ cells that recognize MHCII receive a second signal and persist as single positive CD4+ thymocytes. Cells that previously recognized MHCI will not receive a second signal which induces down-regulation of CD4 and up-regulation of CD8.

Negative Selection

Thymocytes that survive positive selection up-regulate cell-surface expression of the chemokine receptor CCR7 and migrate to the thymic medulla for elimination of autoreactive T cells through negative selection. Medullary epithelial cells are induced to express peripheral antigens (e.g. those expressed by the pancreas, liver, etc.) through the autoimmune regulator gene called AIRE. In the medulla, thymocytes interact with

high affinity self-ligands on the medullary epithelium. Cells that react strongly receive an apoptotic signal. Surviving cells undergo final maturation and then exit the thymus.

Extrathymic Development

Most γδ, and some αβ, T cells are generated at extrathymic sites after being seeded by HSCs during fetal development. Unlike αβ T cells, γδ T cells are not selected through gene rearrangement but rather have specific invariant gamma and delta combinations. Furthermore, many γδ TCR expressing cells primarily interact with lipid antigens rather than peptide antigens.

NATURAL KILLER CELLS

NK cells are part of the innate immune system and are named because of their ability to kill cells lacking MHCI expression. NK development occurs in the fetal liver and thymus, and in the bone marrow after birth. While the earliest NK-restricted progenitor has not yet been clearly identified, T and NK cells share a common CD7+ precursor. Three stages of NK development currently are recognized: lineage commitment, NK receptor selection, and functional maturation. The transition from a common lymphocyte precursor to the T/NK precursor is mediated, at least in part, by Notch1 and the transcription factor Ets-1. Il-15 is required for NK growth and maturation.

CHAPTER II

Vasculogenesis/Endothelial Progenitor Cells

DEBRA A. KAMSTOCK

Terminology
Endothelial Progenitor Cells
Antigenic Determinants
Mobilization, Recruitment, and Homing
Clinical Relevance and Therapeutic Application

Acronyms and Abbreviations

Ang1, angiopoietin-1; CD, cluster of differentiation; CECs, circulating endothelial cells; CEPs, circulating endothelial progenitors; EPCs, endothelial progenitor cells; G-CSF, granulocyte colony stimulating factor; GM-CSF, granulocyte-macrophage colony stimulating factor; HGF, hepatocyte growth factor; HIF-1α, hypoxia-inducible factor-1α; HSCs, hematopoietic stem cells; KDR, kinase insert domain receptor; MAPCs, multipotent adult progenitor cells; SDF-1α, stromal derived growth factor-1α; VEGF, vascular endothelial growth factor.

The development of vasculature, is a complex multimechanistic process. This chapter introduces vasculogenesis and endothelial progenitor cells (EPCs). To lay the foundation for understanding this topic, this chapter begins with an explanation of terminology. The remainder of the chapter addresses phenotypical identification of bone marrow-derived EPCs and signaling events involved in mobilization and recruitment. Clinical relevance of these physiological processes in health and disease are briefly highlighted followed by an introduction to potential therapeutic applications and the promises that future investigation in this field may hold.

Terminology

The term *vasculature* encompasses both blood and lymphatic vessels. *Neovascularization*, and the less commonly used term *angiopoiesis*, refer to the development of new vessels. Neither term implies the mechanism by which new vessel growth occurs nor differentiate between blood and lymphatic vessel development. Neovascularization, however, has become accepted in the literature to indicate blood vessel formation whereas "lymphatic neovascularization" has been introduced to reflect development of lymphatic vessels.

Angiogenesis, by definition, is the sprouting of new vessels from a pre-existing vascular network.[4,19] The term thus defines the mechanism of vessel production; however, is often used loosely. *Vasculogenesis* is the production of new vessels via recruitment of bone marrow-derived endothelial progenitor cells.[2] As vasculogenesis is also the mechanism of vascular development embryologically, it is often further characterized as pre- or postnatal vasculogenesis. Like angiogenesis, vasculogenesis is currently accepted to reflect blood vessels. As research in the area of lymphatic vascular production progresses, new terminology will likely continue to develop (i.e. lymphatic vasculogenesis). *Lymphangioblasts* give rise to the lymphatic vasculature and *hemangioblasts* give rise to the blood vasculature. Currently, lymphanginogenesis is utilized as an all-encompassing term for lymphatic vessel development regardless of the mechanism.

Endothelial Progenitor Cells

Endothelial progenitor cells (EPCs), a recently recognized cell population in bone marrow and circulation, are bone marrow-derived cells that participate in vasculogenesis and vascular homeostasis. Neovascularization, occurs via two distinct mechanisms: (1) vasculogenesis (i.e. development of new vessels by recruitment of bone marrow-derived EPCs); and (2) angiogenesis (i.e. development of new vessels through sprouting of pre-existing vasculature). Although each individual process exists, neovascularization is likely combinatorial with both processes occurring simultaneously.[2]

ANTIGENIC DETERMINANTS

Endothelial progenitor cells were identified just over a decade ago.[2,21] As such, phenotypical and functional characterization of this population continues to be elucidated. Hematopoietic cells and endothelial cells come from a common progenitor, the hemangioblast, present in both embryonic and adult life. Ontogenic development of these cells is dependent on expression of vascular endothelial growth factor receptor-2/kinase insert domain receptor/Flk-1 (VEGFR-2/KDR/Flk-1).[6,20] In addition to VEGFR-2, cluster of differentiation (CD) 34 and AC133 (CD133/Prominin-1) also have been identified and are now accepted antigenic determinants for this cell population. EPCs, in both bone marrow and blood, have an accepted phenotype of AC133+/CD34+/VEGFR-2+.[18,21] The stage at which hematopoietic stem cells (HSCs) and EPCs develop lineage commitment has not been clearly defined. However, it is recognized that EPC maturation results in rapid down regulation of AC133.[18] It has been proposed that the AC133+/CD34+/VEGFR-2+ phenotype represents a more primitive EPC with high proliferative potential, which then gives rise to AC133–/CD34+/VEGFR-2+ EPCs with a more limited proliferative capacity.[24] AC133+ cells also have been found in a number of other tissues, as well as in acute and chronic myeloid leukemias and lymphoblastic leukemia.[14] More recently, AC133 expression has been proposed as a marker for cancer stem cells, but this is controversial. The AC133 antigen is a glycoslyation-dependent epitope of CD133. Thus, it is not synonymous with CD133 and its expression is restricted to undifferentiated cells, whereas CD133 has been shown to retain expression upon differentiation.[10,23]

Other bone marrow-derived cells also contribute to vasculogenesis and vascular homeostasis and are considered subsets of EPCs. Myelo/monocytic CD14+ cells can give rise to an EPC-like cell, acquiring an endothelial cell phenotype, especially when influenced by factors such as VEGF and angiopoietin-1 (Ang1).[7,22] Thus, CD14+ cells are considered to be a plastic reserve of EPCs with a phenotype that can be modulated based on their local microenvironment. Another subset of EPCs includes multipotent adult progenitor cells (MAPCs). Bone marrow-derived MAPCs phenotypically are AC133+/CD34–/VEGFR-2+/CD144(VE-cadherin)– cells which, when co-purified with mesenchymal stem cells can differentiate into multiple cell types, including endothelial cells.[11]

In addition to circulating EPCs, mature terminally differentiated endothelial cells, which slough from the pre-existing vasculature, may also be present in the circulation. These are termed circulating endothelial cells (CECs). CECs increase in circulation subsequent to vascular injury yet differ from CEPs in that they have minimal proliferative capacity, contribute minimally, if any, to new vessel formation, and phenotypically are AC133–/CD146(P1H12)+.[16,23] Similar to EPCs and CEPs, CECs can express CD34 and VEGFR-2.[8,24]

MOBILIZATION, RECRUITMENT, AND HOMING

EPCs in homeostasis reside predominantly in the bone marrow. However, in response to specific signaling, EPCs are mobilized into circulation with recruitment and homing to designated tissues for vasculogenesis or vascular repair. Common conditions that induce mobilization of EPCs include ischemia, vascular trauma, and tumor growth.[9,12,17] Initiation is dependent on secretion of pro-angiogenic factors such as VEGF, Ang1, stromal-derived growth factor-1α (SDF-1α), and granulocyte-macrophage colony stimulating factor (GM-CSF) from the tissue of interest.[5] Tissue hypoxia, as occurs at sites of ischemic injury and in central necrotic regions of tumors, results in a marked increase in VEGF expression subsequent to up-regulation of VEGF transcription factor hypoxia-inducible factor-1α (HIF-1α).[3,19] Once at the tissue site, EPCs may further perpetuate recruitment via their own release of VEGF, hepatocyte growth factor (HGF), granulocyte colony stimulating factor (G-CSF), and GM-CSF.

CLINICAL RELEVANCE AND THERAPEUTIC APPLICATION

EPCs have been isolated from circulation in health and disease, demonstrating their role in both physiological and pathological vascular development. In health, the number of CEPs is extremely low. Increased numbers have been identified in cardiovascular disease, vascular injury, ischemia, fracture repair, and neoplasia.[1,9,15] As such, this cell population and their regulatory molecules can be exploited as biomarkers of disease, prognosis, or response to therapy.[13]

With a continued understanding of molecular mechanisms regulating mobilization, recruitment, and incorporation of EPCs into new vessels, modulatory therapies to either stimulate or inhibit vascular development carry the potential to have a significant therapeutic impact. Additionally, in conditions where increased vascular development is specifically desired (i.e. bone repair and regeneration, myocardial infarction, and ischemic injury), direct EPC therapy with or without exogenous stimulatory factors may also hold promise for the future.[12,15]

This chapter is dedicated to Dr. Moses Judah Folkman, the Father of Angiogenesis, 1933–2008.

CBC, complete blood count; CBER, Center for Biologics Evaluation and Research; CDER, Center for Drug Evaluation and Research; CFSAN, Center for Food Safety and Applied Nutrition; CO_2, carbon dioxide; CVM, Center for Veterinary Medicine; EDTA ethylenediaminetetraacetic acid;EMEA, European Medicines Agency; FDA, Food and Drug Administration; Hct, hematocrit; Hgb, hemoglobin concentration; MCH, mean corpuscular hemoglobin; MCV, mean corpuscular volume; MCHC, mean corpuscular hemoglobin concentration; MHLW, Ministry of Health, Labor and Welfare; O_2, oxygen; PLT, platelet; RBC, red blood cell; WBC, white blood cell.

The complete blood count (CBC) is the foundation of the evaluation of the hematopoietic system in preclinical toxicology studies and clinical trials in humans. The unique advantage of preclinical studies is that most studies are terminal, and therefore histopathological assessment of the bone marrow is routinely performed. Microscopic evaluation of the bone marrow, together with concurrent evaluation of the CBC, provides a more complete evaluation of the health of the hematopoietic system than assessing the CBC alone. Any xenobiotic-induced changes in the hematopoietic system can then be correlated to other microscopic changes in tissues. Ideally the same animals should be used for hematological and histological assessment so that these correlations can be made on an individual animal basis.[30] Because of the benefits associated with the concurrent evaluation of the CBC and the bone marrow it is not surprising that these two procedures are specifically mentioned in regulatory guidelines that outline the design of preclinical toxicology studies of pharmaceuticals. The goal of this chapter is to briefly review the regulatory guidelines pertaining to the evaluation of the hematopoietic system in preclinical toxicology studies, how and when to obtain samples, and the general approach to integration of the different hematological tests.

REGULATORY GUIDELINES

Governmental agencies responsible for ensuring the safety and efficacy of health products, such as the United States Food and Drug Administration (FDA), European Medicines Agency (EMEA) and Japan's Ministry of Health, Labor and Welfare (MHLW), have guidance documents for preclinical toxicology studies that contain recommendations for hematological testing, as well as bone marrow histological and cytological evaluation. The FDA has four centers that are involved in food and drug safety, including the Center for Food Safety and Applied Nutrition (CFSAN), the Center for Drug Evaluation and Research (CDER), the Center for Biologics Evaluation and Research (CBER), and the Center for Veterinary Medicine (CVM). The EMEA and MHLW have several bureaus or committees that regulate medicinal products for human and veterinary use.

Overall these agencies have published similar recommendations for blood and bone marrow evaluation, although the amount of detail and guidance varies.

The types of toxicology studies that are needed for approval of new drugs consist of acute, subacute (or subchronic), chronic, and carcinogenicity toxicity studies. In acute toxicity studies, the test article is administered once at different doses followed by an observation period of 14 days.[24] Subacute and chronic toxicity studies are repeated dose studies where the test-article is administered multiple times at different doses for at least 2–4 weeks and for 6 or more months, respectively. Carcinogenicity studies are repeated dose studies where the test-article is administered for most of the lifetime of a rodent.

Hematologic evaluation is infrequently performed in acute toxicity studies. MHLW does not specifically request hematology assessment in single dose toxicity studies.[32] In contrast, CDER guidelines indicate that if the acute toxicity study is to provide the primary safety data supporting single dose studies in people, clinical pathology and histopathology should be monitored at an early time, at maximal drug effect, and at termination.[13] They do not define which parameters need to be assessed. In contrast to acute toxicity studies, hematologic testing is routinely performed in sub-chronic and chronic studies. The EMEA gives very broad guidelines for clinical pathology testing.[8,12] Pharmaceuticals should be tested in two species, a rodent and a non-rodent, and both sexes should be evaluated in both species. For rodents and non-rodents, historical control data should be available for morphological, biochemical and physiological variables studied. The evaluation should be done at relevant time points to detect changes over time, and specific parameters to be measured are dependent on the animal species and study design. In addition EMEA refers to the recommendations of the Joint Scientific Committee for International Harmonization of Clinical Pathology Testing for which specific core hematological parameters to assess and the timing of these samples.[30] EMEA suggests that evaluation should be done in all animals in studies with low numbers of animals. In rodent studies specialized examinations may be performed in a subset of animals. Blood smears and bone marrow (sternebrae, femur or vertebrae) should be examined. Bone marrow cellularity should be assessed in at least one rodent study, although they do not define how this is to be done. Histopathology is done on all non-rodents, but in rodent studies is done first on control and high dose animals. If changes are identified in the high dose, additional dose groups should be examined to clarify the dose relationship. Bone marrow cytology is not mentioned. However, the International Conference on Harmonization (ICH) S8 guideline, which the EMEA adopted, states that bone marrow smear evaluation should be considered if unexplained alterations in blood or bone marrow histology occur.[9]

The MLHW guidelines for repeat dose testing are very similar to EMEA's guidelines.[32] They recommend blood samples be taken before necropsy in rodents, including interim sacrifice, and in non-rodents pretreatment samples should be evaluated. Although they recommend hematologic testing be done at the time of interim sacrifice of rodents, if these animals are in poor condition, many of the changes in the parameters may reflect secondary changes and thus may not be particularly useful in assessing the primary compound effect. In non-rodent studies of 1 month or longer duration, at least one interim blood sampling should be considered. Hematological parameters to assess, include red blood cells (RBCs), white blood cells (WBCs) including a WBC differential cell count, platelet (PLT) count, hemoglobin concentration (Hgb), hematocrit (Hct), and reticulocyte count. Histopathology recommendations include bone marrow (sternum, femur). There is no mention of bone marrow cytological examination. For veterinary drugs, the Japanese Food Safety and Consumer Affairs Bureau, indicates that blood should be collected for hematology in sub-acute and chronic studies from moribund and surviving animals.[24]

FDA's Center for Veterinary Medicine has a recent draft guidance.[16] It recommends hematology (RBC count, Hct, Hgb, MCV, MCH, MCHC, WBC count and WBC differential cell counts, and platelet counts) at several time points including the beginning and end of study. Two baseline samples are also recommended. Histopathology of bone marrow, site not defined, and bone marrow smears are listed as tissues to consider for microscopic examination. FDA's CFSAN has the most detailed recommendations for 3–12 month rodent studies and includes the same parameters listed above by the CVM, but the timing of the sampling is very well defined.[15] Sampling for hematology should be done during the first two weeks of the study, midway through the study and at termination. Both bone marrow smears and reticulocyte counts (either automated or by microscopic evaluation) should be available on all animals and be used if there are effects on the hematopoietic system. Bone marrow histopathology should be done on the sternum. CDER and CBER do not have recent guidelines for hematologic testing in repeated-dose toxicity studies.

The guidelines governing the clinico-pathological evaluation of carcinogenicity studies vary between regulatory agencies. FDA and MLHW guidelines for drugs intended for humans, do not explicitly indicate that hematological assessment is mandatory.[14,32] However, MLHW suggests that blood samples should be taken if appropriate to measure RBCs and WBCs, and to make blood smears in animals that are sacrificed before or at the end of the study. Blood smears may be useful to assess anemia or changes in lymph nodes, liver and spleen that may be present. For veterinary drugs, the Japanese Food Safety and Consumer Affairs Bureau indicates that blood should be collected for WBC and RBC counts from moribund and surviving animals. Blood smears should be examined in animals suspected of blood dyscrasia.[24] In contrast, the EMEA suggests that monitoring hematological parameters should be considered during the study and should be performed at study termination.[10] This recommendation is in con-

trast to the one made by the Joint Scientific Committee for International Harmonization of Clinical Pathology Testing that stated that blood smears at unscheduled and scheduled terminations should be made to help in the detection and differentiation of hematopoietic neoplasia, but other hematologic testing is not recommended because of the variability of the data.[29,30] Histopathological evaluation of bone marrow is expected in carcinogenicity studies.[32]

There are two key hematological testing position papers, one that was endorsed by several international scientific organizations, for preclinical toxicology studies, both of which are very similar in their recommendations and are cited by regulatory agencies.[12,29,30] The core parameters recommended include RBC count, Hgb and Hct, RBC indices (MCV, MCHC, MCH), RBC morphology, WBC count, absolute WBC differential counts and PLT count. In the absence of an automated reticulocyte count, blood smears should be prepared and examined, if needed, based on the test article effect on the hematopoietic system. At the time these guidelines were written, automated reticulocyte analysis was not easily accomplished, but now is a routine parameter. Bone marrow cytology smears should also be prepared from each animal at termination but only need to be reviewed if indicated on the basis of the test article effect on the hematopoietic system. These guidelines did not specifically address histopathological assessment of bone marrow.

PREANALYTICAL VARIABLES

General

Several preanalytical variables, including age, sex, source of the animals, fasting state, randomization and time of bleeding, anesthesia, diet, housing, animal, and sample handling should all be considered; controlling these variables will help ensure robust hematology data. First, animals of similar ages should be utilized. The rationale to maintain consistent age animals, especially in rats, is that hematological parameters change with animal age (e.g. RBC, Hgb, Hct, and neutrophil numbers increase, reticulocyte count decreases as animals mature).[23] Although dogs of similar age can be easily obtained, obtaining non-human primates of similar age can be more challenging, especially if wild-caught animals are used. Animals should also be obtained from the same commercial and geographical source because this can affect hematological parameters. For example Cynomolgus monkeys (*Macaca fascicularis*) from Mauritius, Philippines, or Indonesia have smaller RBCs than those from China or Vietnam and they are not affected similarly by *Plasmodium* sp. (W.J. Reagan, unpublished observation) which is endemic in this species.[18]

Randomization of the order of blood collection in toxicology studies also increases the uniformity of the data. This is especially true in rodents. It has been shown that transportation of mice within a facility to mimic what may be done prior to collection of blood can increase plasma corticosterone and lead to decreases in lymphocyte counts.[7] However, because the order of blood collection is sometimes determined by the dosing time, it is important to randomize the dosing order. If hematology sampling occurs on the same day as collection of a toxicokinetic sample, the hematology specimen should be taken first to minimize the effect of changes in hematology parameters due to repeated phlebotomy.

Inconsistencies in how the animals are handled can have a major effect on hematological parameters, especially for non-human primates where epinephrine-induced excitement responses readily occur. This results in a marked leukocytosis due to increases in lymphocytes and usually neutrophils. All these preanalytical variables will be minimized by a well-planned study that is carried out in a well-managed facility with appropriately trained personnel.

Fasted State

An important preanalytical variable to control is fasting. Fasting will be dependent on the objectives of the study, the species used, and the biological activity of the test compound.[30] Typically the in-life samples are collected from rats and large laboratory animals with an overnight fast (15–16 hours). Because rats are night feeders, an overnight fast is almost equivalent to 24 hours of fasting. Collecting samples in the fasted state will help increase the homogeneity of the data as well as minimize chances of potentially inaccurate analysis due to post-prandial lipemia. Thirty percent of non-fasted rat serum samples were found to be lipemic.[28] Fasting of rats will have significant effects on hematological parameters, mainly caused by hemoconcentration resulting in increases in RBC count, Hct, Hgb, and PLT count, but also decreases in WBC count and prolongation of prothrombin time and activated partial thromboplastin time.[1,23] Although some publications have shown that clinical chemistry parameters are more homogeneous in fasted rats, who reach a non-absorptive state after a 16–24 hour fast, these principles are being challenged by animal care committees and thus some facilities are no longer fasting rats.[28] If the fasted state is chosen, animals should be fasted for each subsequent blood sampling period to allow for the best comparison. In contrast to large laboratory animals and rats, mice should not be fasted overnight as they tend to dehydrate rapidly; however, some facilities will use a 3–5 hour fast.[17]

Timing of Blood Collection

The timing of sample acquisition from the peripheral blood is somewhat dependent on the regulatory requirements, but also dependent on the goal of the study, the species of animal used, the blood volume of the test animal, the number of other samples needed to assess other parameters, the dosing time, and the results of previous studies. For repeated-dose studies in non-

rodent species, hematologic testing is recommended at study termination and at least once at an earlier interval. For studies of 2–6 weeks' duration in non-rodent species, testing is also recommended within 7 days of dosing initiation, unless it compromises the health of the animals.[11,12,16,30] Additional sampling time points are included depending on the design of the study and should include the recovery period if present. In dog and nonhuman primates, one or two pre-study baseline samples are always taken. Measurements from the second baseline taken 2–3 weeks from the first one are often different as animals have acclimated to their new environment and there are less excitement-induced hematologic responses. Due to the small number of animals per dose group and the variability of the hematological results, the baseline sampling is critical to accurately assess any changes that occur during the study. The comparison of the in-life and end of study hematological results to the baseline sample(s) will allow for the most accurate assessment of the relevant changes in the hematological parameters. Hematologic testing is necessary at study termination in rodent repeated-dose studies. Interim study testing may not be necessary in long-duration studies if it has been done in short-duration studies using similar dose levels.[11,12,16,30] Testing should be done at the end of the recovery period, if included.[30]

In rodent studies, baseline sampling is not typically done. This is in part due to less variability in the hematological parameters of rats versus large animals. In addition, the number of rats used per dose group is greater (typically 10 rats per sex per group versus 3 or 4 per sex per group in large animal studies) which increases the confidence of the mean data in this species. The mean data of each dose group is then compared to the respective vehicle-control, although individual animal data should also be evaluated. In addition, in longer-term studies, the hematological parameters will change with age, which make comparison to pretreatment values difficult.

Method of Blood Collection

In dogs, interim in vivo samples are taken from the jugular vein with manual restraint of the animals. Other sites including the cephalic and saphenous veins could be used. In non-human primates the animals are either manually restrained, typically with help of specialized chairs or cages, or anesthetized. The femoral vein is frequently used, but cephalic and saphenous veins can also be used. If chair restraint is used without anesthesia, it is critical to have a good acclimatization period for these animals before the start of the study to minimize the excitement of the animals during sampling.

Samples can be obtained terminally from large laboratory animals and are typically collected from the caudal vena cava, aorta or cardiac puncture. There are differences in hematological parameters depending on which vessel is sampled, so having the site of sampling consistent throughout the study is ideal.

Sites of interim in vivo sampling in rats are the jugular vein, lateral tail vein, tail artery, and sublingual vein, and these procedures can be done with either manual restraint or with anesthesia. Retro-orbital sinus bleeds have also been utilized, but due to animal welfare concerns this technique is not used frequently for in-life sampling. Anesthesia is recommended if the retro-orbital sinus technique is used.

In mice, limited amounts of blood can be obtained from the lateral tail vein or retro-orbital sinus. Anesthesia is recommended if the retro-orbital sinus technique is used. Some facilities are able to obtain a larger volume from the jugular vein with manual restraint or anesthesia. Coating the needle and syringe with a solution of 7.5% EDTA before sampling may help to avoid clotting. Terminal samples are taken at the time of necropsy from the caudal vena cava, aorta, or via cardiac puncture, and due to the greater volume these samples are easier to use for hematological analysis.

The use of anesthesia will have an effect on the hematologic results. Anesthesia is not typically used in dogs and may be used in non-human primates. If anesthesia is utilized in non-human primates, ketamine is typically used and will decrease WBC counts, mainly due to decreased lymphocytes.[20] Two of the more commonly used anesthetics for rats include isoflurane and different mixtures of CO_2 and O_2 (60/40, 80/20, 100/0 %).[5] For example, when hematological results were compared between rats that had CO_2 anesthesia and no anesthesia, the most consistent results in both males and females exposed to CO_2 were increased MCV, increased Hct, decreased MCHC, and increase in WBC count, mainly due to lymphocytosis. With isoflurane anesthesia, male rats did not have significant effects on the hematology parameters compared to animals bled without anesthesia, but females had minor decreases in RBC count, Hgb, Hct, but no changes in WBC or PLT counts.

Amount of Blood Collected

The amount of blood that can be taken will be dictated by recommendations of the Animal Care and Use Committee at each facility. Although there are few studies to assess what are the ill effects of excessive bleeding, a good review on blood sampling has recently been published and makes recommendations on how much blood volume can be safely withdrawn.[6] The blood volume is estimated to be 850 mL (85 mL/kg) in a 10 kg dog. Of this volume, 85 mL (10%) of the blood can be removed in a single sample or with multiple samplings over 24 hours if animals are allowed to recover for 2 weeks.[6] Blood volume is more of an issue in monkeys due to the small size. A 5 kg Cynomolgus macaque would have 280 mL (65 mL/kg) of blood. Therefore, a total of 32 mL of blood (10%) can be removed in a single sample or with multiple samples over 24 hours if the animals are allowed to recover for 2 weeks.[6] Although these volumes are adequate for routine hematological assessment, multiple blood samples taken for other analyses such as toxicokinetic

analysis, frequently result in reaching of maximal allowable amounts, and can lead to iatrogenic decreases in RBC mass.

Interim sampling can be done in rats, although the overall amount of blood and frequency of the bleeding will be limited. A 250 g rat has approximately 16 mL (64 mL/kg) of blood. Of this volume, a total of 1.6 mL (10 %) can be safely removed in a single sample or with multiple samples over a 24 hour period if animals are allowed to recover for 2 weeks.[6] Typically samples for interim hematological analysis are collected in microtainer tubes (usually 0.5 mL) in order to achieve an adequate blood/anticoagulant ratio and enough sample to assess on most hematological analyzers.

Interim sampling in mice is infrequently done due the limited blood volume. A 25 g mouse has 1.8 mL (72 mL/kg) of blood. A total of 0.2 mL (10.0%) can be removed in a single sample or with multiple samples over 24 hours if the animals are allowed to recover for 2 weeks.[6]

HEMATOLOGICAL ANALYSIS AND PARAMETERS

A few types of automated hematology analyzers work well for the laboratory animal samples used in preclinical toxicity studies. These analyzers should have multispecies software to ensure proper analysis because typically the automated WBC differential cell count features of these instruments are utilized. It is recommended that the blood be analyzed within a few hours after collection in all species. In addition, blood smears from all animals should be made soon after collection for possible review. Reticulocyte smears are not necessary if the hematology analyzer has been validated for reticulocyte counts. In dogs and non-human primates, making the blood smears within 2 hours after collection is sufficient for retention of good cellular morphology, although the sooner the slides are made after collection the better. In some strains of rats, if blood smears are not made immediately after collection there may be secondary artifacts of preparation such as crenation of the RBCs.

Each laboratory needs proper review criteria in place to ensure good quality hematological results from hematological analyzers. Although not clearly defined in regulatory guidelines, it is the primary author's (WJR) opinion that blood smears should be reviewed in all good laboratory practice-regulated studies. This review would include assessment of RBC, WBC and PLT morphology, as well as identification of other rare cell types. At a minimum, blood smears should be made from all animals in a study for potential review if warranted. Most laboratories that review blood smears, will often review all blood smears from the study. An alternative is to review blood smears from all large animals, due to the low number of animals per dose group, and have a tiered response for rat studies where high dose male and female rats as well as control samples are evaluated. If there are significant changes in morphology then additional dose groups are evaluated. Another approach is to review a randomized subset of slides in high dose and control groups for all species.

The hematological parameters that should be measured are those recommended by the International Committee for Clinical Pathology Harmonization and include RBC count, Hgb and Hct, RBC indices (MCV, MCHC, MCH), RBC morphology, WBC count, absolute differential WBC count and PLT count.[30] Automated reticulocyte analysis should also be done as part of core hematology parameters on all studies. In addition RBC distribution width and mean platelet volume may sometimes be useful to assess changes in RBC populations and PLTs, respectively. The CBC should be evaluated in conjunction with the bone marrow histopathological analysis.

BONE MARROW HISTOPATHOLOGY

In large animals the sternebrae or rib are the preferred sites for histologic analysis because these sites will be hematopoietically active (see Chapter 132). In contrast, sternebrae and long bones of rodents, such as the femur, are frequently used. An overall assessment of bone marrow cellularity can be obtained with histopathology. The cellularity of bone marrow is dependent on the species, the site of collection, and the age of the animal. In addition, food restriction will affect bone marrow cellularity and blood cell counts.[22,25] Concurrent vehicle controls and historical knowledge of what is typical cellularity of bone marrow for that aged animal and species is necessary to make an accurate assessment. If there are changes in cellularity, one should try to differentiate the cell types that are changed (i.e. myeloid versus erythroid). In large animals relative changes in the myeloid population compared to the erythroid population should be assessed if possible, but in rodents, due to the high percentage of lymphoid cells, differentiation of erythroid changes from lymphoid changes is difficult. Combining the evaluation of the blood results and histopathology results will allow for accurate assessment of the hematopoietic system.

BONE MARROW CYTOLOGY

Bone marrow cytological examination should be considered if there are significant or unexplained changes in the CBC and/or in the bone marrow histopathology results that need further clarification. Ideally, bone marrow smears should be made immediately or soon after euthanasia. Smears can be done by several different techniques, including push smears, pull smears and paintbrush technique (see Chapter 132). The slides made with any of the above techniques are air dried and then stained with a Romanowski-type stain such as Wrights or Wright-Giemsa stain.

Cytological analysis may consist of qualitative evaluation of the marrow smears alone and/or enumeration of the relative percentages of cells, typically by

doing a 300–500 cell differential cell count. Enumeration of hematopoietic cells can be done by detailed classification of the different cell types and stages of maturation or by classifying hematopoietic cells into the major categories of myeloid, erythoid, and lymphoid lineages. If the latter technique is used, a qualitative assessment can then be made of the maturation of the different lineages. Megakaryocytes should be noted as present or absent, but not enumerated. These cytological results will then be used in conjunction with the CBC and histopathological results to make an accurate assessment of the effect of xenobiotics on the hematopoietic system.

FLOW CYTOMETRY

An alternative to counting hematopoietic cells manually is flow cytometric evaluation of bone marrow. Flow cytometry provides rapid analysis of cell types present in the bone marrow.[2–4,19,21,24,27,31,33] Percentages of the different cell lineages, and with some techniques a subdivision into proliferating and non-proliferating populations, can be assessed (see Chapter 132).[3] These results are then interpreted in conjunction with the CBC and histopathology to determine which population is affected. In addition to these semi-quantitative assessments, a total nucleated cell count can be determined, and absolute counts of the different cell populations can be assessed (see Chapter 132). In contrast to only determining relative percentages of the different cell populations, absolute counts provide more definitive data to allow accurate assessment of which cell populations are truly affected.

OTHER TECHNIQUES

Rarely, other techniques such as bone marrow clonigenic assays or electron microscopy may be useful. Bone marrow clonigenic assays involve the in vitro differentiation of bone marrow using a mixture of growth factors to drive the differentiation of the different lineages. The advantage of this technique is to have an in vitro system to test the effect of xenobiotics on the specific bone marrow lineages and thus differential sensitivity of the bone marrow precursors can be assessed. This technique could then be used to assess a series of similar compounds to try to minimize toxicity. Electron microscopy, mainly transmission electron microscopy, is also rarely used when there is a morphological feature identified based on routine assessment of blood and bone marrow that needs further investigation.

In vitro hemolysis testing is commonly used to assess the potential direct hemolytic effect on RBCs of compounds that will be administered intravenously. Whole blood is typically incubated with various concentrations of test article and hemolysis is monitored either grossly or by measurement of RBC count and Hgb before and after incubation with the test article.

Acronyms and Abbreviations

EPO, erythropoietin; GLP, Good Laboratory Practice; Hgb, hemoglobin; Hct, hematocrit; MCV, mean corpuscular volume; MCH, mean corpuscular hemoglobin; MPV, mean platelet volume; N, number of individuals per group; M, male; NOAEL, no observed adverse effect level; NOEL, no observed effect level; PLT, platelet; RBC, red blood cell; RETIC, reticulocyte count; RDW, range distribution width; SOP, Standard Operating Procedures; SD, standard deviation; WBC, white blood cell.

The principal objective of toxicological studies is to determine the potential toxicity of novel pharmaceutical compounds and chemicals. Many synthesized compounds are screened each year through the drug development process, but only one or two out of 10,000 reach the consumer market. Short term studies are initiated during the drug discovery process to help identify compounds with potential for development and quickly screen out undesirable molecules. These studies are designed with small numbers of animals and different doses of compound. Usually, only basic clinical pathology measurements are applied to these studies. Longer term studies are initiated to identify the target organs of toxicity, the lesions induced, the parameters that can be monitored to identify a developing toxicity, and the no observed adverse effect level (NOAEL) or no observed effect level (NOEL). These studies typically involve one rodent species (mouse or rat), and one non-rodent species (e.g. dog, minipig, or non-human primate). They are tightly regulated by government regulatory health agencies (see Chapter 12).[20] Basic hematological, clinical chemistry and coagulation measurements are also applied to these studies, and bone marrow histopathological evaluation is performed in at least one of these studies.[10,13,29,31] Further investigations, such as bone marrow cytology, are optional depending on the initial findings and evaluation of the hematology data.

Therefore, interpretation of hematological data is important at all stages of drug discovery and development. It is usually combined with the interpretation of clinical chemistry and urinalysis data, and with immunology and immunochemistry measurements if performed. Final interpretation and conclusion should

distinguish compound-related effects and biological variations. Results are part of a toxicology report and/or a clinical pathology report. These are written in collaboration with histopathologists and study toxicologists in order to provide not only a description of the study data, but also an accurate conclusion and an opinion on the significance of the changes.[2,21,27]

METHODS OF ANALYSIS – GOOD LABORATORY PRACTICE REGULATIONS

Evaluation of hematology data should be done with knowledge of the inherent precision and variability of the assays used. Analytical data must be reliable and the laboratory should validate all analytical methods and operate internal and external control procedures. Agencies responsible for the investigation of the safety and efficacy of human health products regulate the conduct of non-clinical laboratory studies under good laboratory practice (GLP) regulations. GLP regulations provide the framework for performing scientifically valid studies and generating reliable safety data (see Chapter 12). GLP regulations must be applied to all non-clinical health and environmental safety studies required for registering or licensing pharmaceuticals, pesticides, food additives, cosmetic products, veterinary and drug products, and industrial chemicals. Some countries may have additional GLP regulations but differences in regulations are minor. There are memoranda of understanding with several countries whereby each country agrees to accept GLP studies and data from another country.[6]

The GLP clinical laboratory must have written approved standard operating procedures (SOPs), record systems, and quality assurance for sample handling, analysis, and reporting. A company employee or a consultant under contract may perform quality assurance activities. Quality assurance personnel audit the study protocol, and perform in-process audits of study conduct, including generation of clinical pathology data and evaluation of the report.

REFERENCE VALUES

Good Laboratory Practice and non-GLP laboratories currently establish reference ranges (or historical intervals) from healthy non-treated animals when new measurement methodologies are validated. Reference ranges can be calculated from non-treated control animals in toxicological studies. They are usually determined by the smallest and largest values if 20 or fewer animals are sampled or by the 2.5th and 97.5th percentile range if more than twenty animals are sampled (see Chapter 131). Consequently, reference ranges display values observed in 95% of a healthy population. Values outside the reference range do not necessarily indicate an abnormal condition and, conversely, values within the reference range do not imply a normal condition.[19]

Reference ranges are influenced by many variables, including species, strain, sex, age, animal supplier, animal husbandry or handling practices, diet and fasting, anesthesia, sample matrix, instrumentation, and test methodology. It is important to use reference ranges produced by the laboratory performing the study rather than published reference ranges. Animals used for establishment of reference ranges are most often housed, fed, and handled differently than those used in a particular study. Therefore, there is no substitute for age- and sex-matched control animals from the same supplier undergoing the same procedures as the test animals.[11] Reference ranges, however, are adequate to evaluate a single animal, pre-study data, data from controls, and to understand analyte variability. They may also be used to identify group means falling outside the reference range when no dose-response relationship or no correlating histopathological findings are identified.

Reference ranges should not be used as the only set of control values to determine potential test article effects on hematology data. In many cases, compound-related changes are small and post-treatment values fall within the reference range; therefore comparison of hematologic data to historical data, and to age-, sex-, and breed-matched control groups is essential.

STATISTICAL ANALYSIS

Laboratory data produced for a study may be voluminous, particularly for rodent studies. Statistical analysis of the data will frequently identify significant differences between control and treatment groups. These differences should be interpreted with caution, and not be used as a substitute for thorough review of the data. A change may be statistically significant but have little biologic or toxicologic significance.[5] This is particularly true for hematology parameters that tend to reflect changes occurring in another organ or system.[1] Conversely, compound-related changes that are not statistically significant may be considered biologically significant. Both parametric and non-parametric statistical models are used in preclinical studies. Most parametric statistical models are suitable for data that are normally distributed and exhibit homogeneous variance. Non-parametric procedures are used when data are not normally distributed. The power of a statistical test is proportional to the number of animals per group. As the number of animals increases, more differences of small magnitude become statistically significant, although they may not be toxicologically relevant. Conversely, with small groups of animals, the numbers of statistically significant values tend to be low.

The mean or average is another less sophisticated tool that is appropriate for normally distributed data. Standard deviation describes the variability around the mean. When evaluating group hematologic measurements, evaluation of group means alone is not

sufficient, but standard deviations of each group should be carefully evaluated as an indication of variability.

EVALUATION AND CLASSIFICATION OF CHANGES

The main difference between the biopharmaceutical approach and veterinary medical practice approach in laboratory data interpretation is that toxicologic pathologists evaluate groups of animals and compare results with a vehicle-treated control group and/or pre-treatment values rather than evaluating individual animals. For most rodent toxicity studies, pre-treatment testing is not done. In non-rodents studies (e.g. monkey and dog), one or two sets of pre-treatment values are usually collected. When comparing data to pre-treatment values, comparison to the second set of pre-treatment data is usually preferred because these data are less likely to be influenced by stress, food intake, and other variables. In longer term studies, comparison with a concurrent control group is also important.[30] For example: if multiple blood samplings are performed during a study, RBC parameters of treated groups might vary if they are compared to their pre-treatment values, but differences in RBC values will not be observed if compared to control group values.

The objectives of these interpretations are:

1. To determine if there is a real difference between control and treated groups due to an effect of the compound or study procedure.
2. To differentiate the changes observed from analytical or biological variations.
3. To differentiate major and minor compound-related effects.
4. To determine if the compound-effect is related to the dosage.[12]

Biological variation is due to inter-animal components (i.e. differences between individuals) and intra-animal components (i.e. changes within an individual over time).[5] Multiple physiological and procedural variables may influence hematology measurements, such as age, sex,[26] diet, fasting, restraint, circadian effects, blood sampling site,[8,22,25] collection technique, order of collection, transport time, and sample preparation.[12] Sources of preanalytical variations should be avoided as these will broaden the confidence interval of results and interfere with interpretation. They must be considered and avoided when designing the study.

A treatment- or compound-related effect can be defined as follows:

A response to administration of a test compound in an animal that is considered to have substantial or noteworthy effect (positive or negative).

Although the principles of clinical hematology, as applied to veterinary patients with spontaneous disease, generally apply to the toxicological assessment of a drug, identification of very subtle effects which would not be noted on individual patients in veterinary care are frequently described as compound-related effects. Several factors should be considered when determining a compound-related effect:

1. presence of a dose-response
2. presence of outliers which may influence the analysis
3. known class effects of the test compound
4. correlation with clinical chemistry data, clinical observations, necropsy and histopathological findings.

A *dose-response* is characterized by increased magnitude of the changes with increased treatment dosages. Identification of toxic effects in animals is generally expected to follow a dose-response pattern relative to incidence and severity, allowing the determination of dose levels where important or relevant effects occur, and dose levels where these effects do not occur. However, absence of a dose-response cannot exclude a compound-related effect. This is particularly true with immunostimulating drugs where compounds may have a dramatic effect in mid-dose groups, and little or no effect in the high-dose groups due to a saturation effect. In some cases overt toxicity and high mortality in the high dose group may mask a dose-related effect. Changes restricted to the high dose groups are considered to be dose-response effects. *Outliers* are extreme individual values (low or high) that are widely divergent from the mean of a group of data. These values may be due to a technical error, or directly related to another cause or disease considered non-compound-related. For example, an animal with renal disease might have moderate decreases of RBC parameters that would influence the group mean. In these situations, the group mean is affected and the standard deviation of the group is increased. Individual outlier values should be correlated to specific histopathological findings or clinical signs when possible. Differences identifiable only on the inclusion of outlying values are usually not considered to be dose-response effects, especially in studies involving large numbers of animals. In some instances, it may be helpful to recalculate the group mean with omission of the extreme values to determine whether an underlying trend remains. However, important individual changes should be reported if they are considered compound-related.

Transient effects are common. They should be reported and distinguished from transient procedure-related effects (e.g. increased reticulocyte counts following excessive blood sampling). Clinical pathology findings that are related biologically or that support a common pathophysiologic process should be grouped. Any evidence of an effect in control samples should also be reported.

Data interpretation has a subjective component. If a change is small, it is often interpreted as not important, and within pre-analytical or biological variability. As the change becomes larger, it is more likely to be significant and compound-related. However, there is frequently a range of results that are difficult to classify, and not possible to clearly differentiate as compound-related effects or biological effects. Therefore, these

changes may be reported as of uncertain relationship to the test article. Simplistic approaches to data interpretation such as statistics and comparison to reference ranges using a cut-off point decision method, with no consideration of a *gray zone*, may be a source of inappropriate decision making in the drug development process.[4]

HEMATOLOGY CHANGES

Minor effects of test-article effects on clinical pathology results are frequently observed. Clinical terms (e.g. anemia, leukocytosis) should be avoided unless major effects are observed and there is a deliberate attempt to underline an important effect. Compound-related effects are usually described as increases or decreases.

Increases in Peripheral Blood Cells

Increases in Red Blood Cell Parameters

Relative erythrocytosis is frequently observed with subclinical or clinical dehydration in preclinical studies, especially in animals with decreased food consumption or in rodents with prolonged fasting. With relative erythocytosis, increases in RBC parameters (RBC count, Hgb, Hct) most often correlate with increases in total protein levels or albumin and/or urea. Absolute erythrocytosis resulting from a persistent increase in RBC mass and associated expansion of blood volume is rarely observed in toxicity studies, but may be seen when testing recombinant erythropoietin or other cytokines, or when the test article influences the production of erythropoietin.

Increases in Leukocyte Parameters

Increases in neutrophil and/or monocyte counts are observed with inflammation, excitement, steroid or stress response, or when testing pro-inflammatory cytokines.[24] Physiological leukocytosis in response to excitement can double leukocyte counts in minutes. In laboratory primates it is evenly distributed between neutrophils and lymphocytes. Increased neutrophil counts are most obvious in dogs, and increased lymphocyte counts are most evident in rats. Neutrophil counts increase in response to a variety of inflammatory conditions. Monocyte counts increase secondarily to any conditions with substantial tissue destruction, including inflammation, necrosis or hemolysis. Increases in lymphocyte counts may be observed with excitement in dogs and monkeys, and with chronic inflammatory lesions, especially in rodents, or with administration of antigenic compounds that elicit an immune response. Increases in eosinophil and/or basophil counts are infrequent in toxicological studies unless the test material is a hematopoietic growth factor or a cytokine. Leukemias are sometimes observed in 2-year carcinogenicity studies using rodents.[12,28]

Increases in Platelet Counts

Physiologic increases in platelet (PLT) counts are usually transient, and result from increased mobilization of PLTs from storage pools during mild muscular activity or excitement. Healthy rodents have high PLT counts. Compound-related increases in PLT counts may be associated with blood loss, iron deficiency, or inflammation. Direct compound-related increases in PLT counts, presence of atypical PLTs in peripheral blood, and/or large numbers of megakaryocytes on tissue sections are rarely observed. Some test articles induce PLT dysfunction, characterized by normal PLT count, increased bleeding time and normal coagulation times.

Decreases in Peripheral Blood Cells

Decreases in Red Blood Cell Parameters

A frequent compound effect is a decrease in RBC parameters (RBC count, Hct, Hgb). The reticulocyte count is considered a reliable and early indicator of RBC regeneration when sufficient time has elapsed in species with circulating reticulocytes.[3] Laboratory animals normally have low (dogs and non-human primates) to moderate (rodents) numbers of circulating reticulocytes. Decreases in RBC numbers with evidence of regeneration are either hemorrhagic or hemolytic, while decreases in RBC in the absence of regeneration indicate suppressed erythropoiesis. A frequent hematology finding in preclinical toxicology studies is mildly decreased RBC parameters with no evidence of regeneration. The animals may exhibit mild reductions in body mass and food consumption. Decreased food intake may have a major impact on the hematopoietic system and has been shown to decrease white blood cell (WBC), PLT, and reticulocyte counts.[12,17,23] Numerous compounds impair erythropoiesis, either directly by injuring pluripotent hematopoieitic stem cells, or their stromal microenvironement, or indirectly by inhibiting erythropoiesis (e.g. chronic inflammatory diseases).[14]

Decreases in Leukocyte Parameters

Leukocytes are frequently the first target of cytotoxic drugs because they have a shorter lifespan than PLTs and RBCs. In dogs and primates, marked acute inflammation and endotoxin-mediated pro-inflammatory cytokine release produces marked decreases in neutrophil counts, which is usually followed by a rebound neutrophilia. Recognition of decreased neutrophil counts is more difficult in mice and young rats that normally have low neutrophil counts. Immunotoxic drugs may trigger alterations in blood lymphocyte counts. Involution of the thymus is often interpreted as stress-related and correlates frequently with decreased lymphocyte counts. The significance of decreases in circulating monocytes, eosinophils, and basophils can be difficult to determine because these cells are normally present in low numbers and should not be over interpreted. Decreases in eosinophils or monocytes may be

observed with chemotherapeutic agents, and decreases in eosinophils are sometimes observed with stress or steroid-like compounds.

Decreases in Platelet Count

Decreased PLT counts are frequently associated with difficult venipuncture or PLT aggregation subsequent to inadequate blood coagulation, especially in dogs and rodents. Compound-related decreases in PLT counts can also result from impaired production or accelerated destruction or utilization. Test-material that reduces erythroid and myeloid production frequently inhibits PLT production as well. An example of hematology data interpretation is provided in Tables 13.1 and 13.2.

ADVERSE AND NON-ADVERSE EFFECTS

To be able to determine safe conditions for exposure in humans, it is necessary to identify in preclinical toxicological studies the lowest dose at which an adverse effect is first observed or the highest dose at which it is absent. For this reason, doses of exposure used in preclinical studies are based on multiples of the expected human dose. The clinical pathologist is expected:

1. To recognize and interpret hematology changes in the treated animals.
2. To determine if the effects are important toxic effects or minor responses to the drug.
3. To assist in the determination of the NOEL (i.e. the highest exposure level at which there are no effects observed).

TABLE 13.1 Group Mean RBC Parameters for a 13-Week Study With Daily Subcutaneous Injection of Human Recombinant Erythropoietin (EPO-R) in the Sprague Dawley Rat[a]

Group	Summary Information	RBC ($\times 10^6/\mu L$)	Hgb (g/dL)	Hct (%)	MCV (fL)	MCH (pg)	MCHC (g/dL)	RDW (%)	PLT ($\times 10^3/\mu L$)	MPV (fL)	RETIC (%)	RETIC ($\times 10^9/\mu L$)

[a]Group 1 is the control group given vehicle control. Groups 2, 3 and 4 were given low, medium, and high doses EPO-R respectively. Interpretation of data: A treatment-related increase was observed in RBC, Hgb, Hct, and reticulocytes (RETIC) in groups 2 and 3 rats compared to control group. A treatment-related increase was also observed in RBC, Hgb, Hct, RETIC and PLT in high dose group (4) compared to control group. High standard deviations in group 4 were indicative of large individual variations within the high dose group (see Table 13.2).

TABLE 13.2 Individual RBC Measurements from High Dose Group Sprague-Dawley Rats Given Human Recombinant Erythropoietin[a]

Group/Sex	Animal Number	RBC ($\times 10^6/\mu L$)	Hgb (g/dL)	Hct (%)	MCV (fL)	MCH (pg)	MCHC (g/dL)	RDW (%)	PLT ($\times 10^3/\mu L$)	MPV (fL)	RETIC (%)	RETIC ($\times 10^9/\mu L$)

[a]Large individual variations were observed in RBC, Hgb, Hct, and RETIC. The majority of individuals had marked increases in RBC, Hgb, Hct and RETIC compared with control group, consistent with erythrocytosis and the pharmacological action of the compound. Some individuals (nos 4002, 4003, 4008) had a marked non-regenerative anemia due to anti-erythropoietin antibodies inducing an immune-mediated anemia in these individuals.

However, with a variety of agents, it is impossible to establish a no effect dose; therefore the term NOAEL is preferred. NOAEL is defined as the highest exposure level at which there is no adverse effect between the exposed population and its appropriate control. There is no standard definition for the term *adversity* from the literature and regulatory guidelines, although some and recommendations exist and have been published.[9,16,18] One of the definitions proposed is:[18]

An adverse effect is a biochemical, morphological, or physiological change (in response to a stimulus) that, either singly or in combination, affects the performance of the whole organism or reduces the organism's ability to respond to an additional environmental challenge.

It may impair performance and generally have a detrimental effect on growth, development, or lifespan of a non-clinical toxicological model. More specifically, an adverse effect would be unacceptable if it occurred in a human clinical trial.

Alterations in hematology test results are infrequently the only evidence of important adverse toxicological effects. Clinical observations and pathology findings usually corroborate pathologically meaningful laboratory findings. Several factors can be used to differentiate an adverse effect from a non-adverse effect. An effect of treatment is less likely to be adverse if the severity of the change is minimal and not related to a change in other parameters. Non-adverse effects are usually adaptive or compensatory responses or findings that are below a threshold level. Effects that are adaptive responses to general chemical exposure will not be considered adverse. For example, increases in reticulocytes and bone marrow hyperplasia are induced by hemolytic drugs. Although changes in RBC count might be considered adverse, increases in reticulocytes and bone marrow hyperplasia will be considered an adaptive response to the compound-related decrease in RBC count. Reversibility is an important factor in the interpretation of toxicological studies. A change that is readily and completely reversible on cessation of treatment often indicates a lower level of concern, although it should not be used to discriminate adversity from non-adversity. Also, with potential new drugs, not every effect seen in non-clinical studies can be considered as unwanted or harmful, as some may result from the pharmacological action of the compound. For example, chemotherapeutic agents are usually cytotoxic and significant decreases in WBCs would be expected in non-clinical studies using healthy animals.

The NOAEL should be established for each study type for a particular compound. The initial determination of the NOAEL may change as additional information related to the molecule is generated. Data from long-term studies may give the toxicologist new or additional perspective as to whether or not an observation thought to be subtle or minor in a short-term study is an early indicator of a harmful effect. Species-to-species and within-species study-to-study variation may also occur. This may be due to normal biological variations or study design differences.[9] Defining adversity depends on a precise interpretation of all data of a preclinical study (e.g. food consumption, body mass gain, clinical signs, histology and immunology data, clinical biochemistry data). It is subject to discussion, challenge and reinterpretation.

TOXICOKINETICS

Toxicokinetics is a subdiscipline of pharmacokinetics exploring the absorption, distribution, metabolism, and elimination of xenobiotics at doses higher than those expected to produce therapeutic effects. Toxicokinetic evaluations are usually done in animal species used in safety assessment of drugs. They are determined directly from animals involved in non-clinical safety studies or from a designated toxicokinetic group of animals. The objectives of these measurements are:

1. To describe the systemic exposure obtained.
2. To determine the relationship between the dose and the toxicity observed.
3. To aid the determination of the margin of safety between non-clinical safety studies and human plasma concentrations achieved in clinical trials.
4. To judge inter-animal variability.[7]

Interpretation of hematological alterations must take into account the amount of drug-derived material to which the animals have been exposed and the route of exposure. Knowledge of the bioavailability of a drug and the kinetics of absorption, distribution and elimination are important to consider when interpreting hematology data.[15] For example, it is sometimes possible to observe compound-related changes between groups that are caused by differences in drug exposure levels.

CORRELATION OF HEMATOLOGY CHANGES WITH OTHER STUDY DATA

The description of compound-related findings should include any association with clinical toxicology findings, any other clinical pathology data, gross pathology findings, body mass changes, organ mass differences and histopathologic findings. The correlation of compound-related hematology and histopathologic findings is particularly important as this plays a significant role in determining the NOAEL. Decreases in RBC parameters should be correlated with histopathologic evidence of hemorrhage, extramedullary hematopoiesis, and hepatic bile accumulation and/or hemosiderin deposits in liver and/or spleen. Lymphoid decreases often correlate with histologic atrophy of lymphoid organs. Increases in leukocytes may be correlated with microscopic evidence of inflammation in tissues. Decreases in blood cells should be correlated with bone marrow histopathology.

REPORT WRITING

Toxicology laboratories generally produce either an integrated final study report or separate pathology and

clinical pathology reports appended to the final study report. Each pharmaceutical company has its own way of presenting data, but as a general rule, data are presented in one or two tables including group and individual values for each treated group. Group values include mean, standard deviation, and statistical analysis applied to each group. Group and individual values are generally presented in a conventional order: control group given vehicle or group given the lowest dosage is presented first, followed by treated groups classified in increasing order of dosage (e.g. Table 13.1). When reporting the data, mean percentage differences or fold differences between treated and control groups can be used, and significance of the changes can be qualified by usage of modifiers: mild or slight, moderate or marked. When referring to fold difference, the method of comparison (e.g. pre-test values, second pre-test value, control group mean) should be stated.

CONCLUSION

Principles of hematologic interpretation used to characterize a disease in veterinary patients apply in preclinical toxicological studies. The main differences between these practices result from the evaluation of groups of animals rather than a single patient. Interpretation is based on an accurate utilization of reference values and statistical analysis, and correlation of hematology data with chemistry and urinalysis data, clinical observations, toxicokinetics, necropsy, and histopathological results. Clinical pathology data interpretation will help define the NOEL and/or NOAEL for each toxicology study in order to determine the potential toxicity of a drug for humans.

Acronyms and Abbreviations

AIHA, autoimmune hemolytic anemia; AITP, autoimmune thrombocytopenia; BFU-E, burst forming unit erythroid; CFU-E, colony forming unit erythroid; CFU-GM, colony forming unit, granulocytic monocytic; DIA, drug-induced agranulocytosis; DIIMHA, drug-induced immune-mediated hemolytic anemia; DIMT, drug-induced immune-mediated thrombocytopenia; GP, glycoprotein; IMHA, immune-mediated hemolytic anemia; IMT, immune-mediated thrombocytopenia; IgG, immunoglobulin G; IL, interleukin; PRCA, pure red cell aplasia; RBC, red blood cell; RDW, red cell distribution width; REDOX, reduction-oxidation reaction; TNF-α, tumor necrosis factor-alpha; TNFR, TNF-α receptor.

This chapter will focus on the susceptibility of the highly proliferative hematopoietic system to intoxication by exposure to xenobiotics or their metabolites. The ease with which blood can be sampled and analyzed makes it one of the most important target organs of the risk assessment process.

COMPOUND-RELATED CYTOPENIAS IN PRECLINICAL STUDIES

Predicting Hematotoxicity

Compound-related blood cell injury includes oxidative damage (see Chapter 36), non-oxidant mechanisms, immune-mediated damage (see Chapters 33, 38, 41, 78) and very rarely, induced apoptosis. Fortunately, in silica high throughput systems are available that screen potential new chemical entities for known toxicities. This allows chemists to design and modify molecules to eliminate or mitigate the offending portions while retaining the active moiety. These designer compounds can then be screened for efficacy. With the exception of compounds deliberately designed to kill cells (e.g. anti-cancer drugs, antiviral drugs, pesticides, herbicides), prescreening of new chemical entities has greatly reduced or even eliminated the occurrence of hematopoietic toxicity. The intended purpose of the test molecule determines the acceptability of any impact on the hematopoietic system. For example, marketed antihypertensive drugs are extremely safe and effective when used properly but have been infrequently associated with adverse effects on the hematopoietic system. A potential new antihypertensive must be less toxic and

more efficacious than anything currently marketed to warrant development; therefore any evidence of toxicity targeting the hematopoietic system is unacceptable. However, hematopoietic toxicity produced by a molecule being developed as an anticancer drug, particularly when used as second line therapy after all other drugs have failed, might be considered acceptable.

The bioavailability of a compound provides detailed information regarding absorption, distribution, metabolism, and excretion, and in some cases, metabolite information, that can be helpful when evaluating compound-related effects. In particular, knowing the distribution, binding properties, metabolism, and $t_{1/2}$ of parent or active metabolites can aid in predicting both nadir and recovery of circulating cell counts before initiation of safety studies.

Compound-related effects can be directly or indirectly induced by the parent molecule (active molecular entity) or its metabolites. Secondary effects are consequences of direct or indirect toxic effect, such as renal failure due to nephrotoxicity. Less well understood or predictable are results that may be termed as hyperpharmacology. This form of adverse effect is frequently observed with recombinant molecules that have direct action on key biochemical pathways, thereby altering specific protein synthesis, secretion or catabolism, blocking key receptors, or gene regulation: this results in unpredictable consequences associated with induction of endogenous signaling molecules.

Compound-related effects can occur at one or more levels of hematopoiesis (from earliest stem cell to mature cells). Both in vitro and in vivo methods to define mechanisms of hematotoxicity or predict the degree of myelosuppression have been described. In vitro toxicity testing, using fresh primary target cells (hematopoietic and mesenchymal) from the species of interest, is now available through commercial sources.[14,28] The author has found this approach invaluable for assessing comparative hematotoxicity between animal models and humans. In vivo mechanistic models, based on pharmacokinetic-pharmacodynamic data, are used to study the entire time course of myelosuppression and separate drug-specific parameters from system-related parameters, with the goal of optimizing dosing in clinical studies.[15] The complexity of cytokine and hormonal effects on the bone marrow, peripheral cell counts, and cell function are the most unpredictable.[3,36] Cytokines may induce changes in the myeloid population, the erythroid population, megakaryocytes, or other resident bone marrow cells, by up-regulation or down-regulation and may mediate these changes directly or indirectly. Changes are highly dynamic; therefore the timing of peripheral blood and bone marrow evaluations relative to dosing will produce different observations and interpretations. In vitro studies may be helpful in predicting cytokine release and establishing safety margins for clinical safety studies in healthy human cohorts. The use of transgenic mice has added significantly to our understanding of cytokine signaling pathways.[3] For example, transgenic mice null for tumor necrosis factor-alpha (TNF-α) receptor (TNFR) or double stranded RNA-dependent protein kinase receptor are protected from polycylic aromatic hydrocarbon-induced bone marrow hypocellularity, demonstrating the role of TNF-α in this compound's mechanism of toxicity.[25]

Route of Exposure and Vehicles

Each route of exposure will require safety testing and may introduce variables that can alter the effect of the compound on the hematopoietic system. Parenteral administration may prolong exposure. Intravascular administration introduces the molecule directly to circulating cells. Vehicles used for these routes may have no effect when tested separately, but may enhance or alter exposure to the test molecule. An example of this occurred in Europe with an upsurge in the incidence of antibody-mediated pure red cell aplasia (PRCA)in dialysis patients receiving recombinant human erythropoietin.[13] This coincided with a change in the formulation, to comply with new regulations, where human serum albumin was replaced by glycine and polysorbate 80.[29] The variables that may have increased the immunogenicity of the product include formation of epoetin-containing micelles, interaction with leachates released from uncoated rubber stoppers of prefilled syringes, and denaturation or aggregate formation due to improper storage and handling. The incidence of PRCA returned to very low levels following replacement of the uncoated rubber stoppers with coated stoppers.

Test Species

Species that have been used most extensively are mouse, rat, dog, marmoset, and macaque. Baboon and chimpanzee have been used less frequently. Familiarity with the test species is important, as differences in response may occur between species (primates) and strains (rodents), and within species and strains based on vendor source. Some strains of rodents are genetically prone to hematopoietic abnormalities or have increased sensitivity to certain compounds, particularly knockout animals. Extra care must be exercised when interpreting data from these animals and determining if an adverse effect is strain-specific.

MECHANISTIC CLASSIFICATION OF DRUG-INDUCED CYTOPENIAS

Drug-induced Immune (Mediated) Cytopenias

Preclinical observations are usually considered proprietary and are rarely reported in the public domain; thus, no estimate is available for the incidence of drug-induced immune cytopenias identified at toxicological exposures. Only 6–10% of all adverse drug reactions identified in clinical trials or post-marketing are recognized as idiosyncratic.[18] Frequently, the mechanisms of these reactions are unknown, but the majority are believed to be immune-mediated. The incidence of

reported drug-induced immune-mediated hemolytic anemia (DIIMHA) in the human population is estimated to be one in one million individuals per year.[5] Drug-induced agranulocytosis (DIA), defined as $\leq 0.5 \times 10^9$/L, is estimated at an annual incidence of 2–15 per million people and the mechanism may be direct toxicity, immune-mediated or a combination thereof.[4] Drug-induced immune-mediated thrombocytopenia (DIMT), in contrast, is more frequent.[7]

Idiosyncratic reactions appear to arise from a combination of genetic predisposition and environmental factors in susceptible individuals, and are frequently non-dose-dependent. A minimum of four events has been suggested as necessary for the initiation of an idiosyncratic reaction:

1. adequate amount of reactive metabolite(s)
2. binding with a protein with high epitope density
3. up-regulation of co-stimulatory signals on antigen presenting cells to activate T cells
4. failure of immune system to down-regulate a harmful immune response (see Chapters 16, 33, and 51).[18]

Sites of reactive metabolite formation usually correlate with the target of idiosyncratic reactions.[18] For example, drugs oxidized by myeloperoxidase to reactive metabolites may induce immune-mediated agranulocytosis.[18] It has also been suggested that glucuronide conjugation of metabolites may increase immunogenicity.[11]

There are two types of drug-induced antibodies: drug-independent antibodies and drug-dependent antibodies.[5] No drug is required in the test system for the detection of drug-independent antibodies, which may be "true" autoantibodies or antibodies that react like autoantibodies in vitro and can be found in combination with drug-dependent antibodies. The mechanism of drug-independent antibody production is unknown, but is hypothesized to be the result of a direct effect by the drug or its metabolites on the immune system that induces an autoimmune disease. Reactions attributed to "true" autoantibodies are detectable by direct antiglobulin test (Coombs' test). Well documented cases of autoimmune hemolytic anemia (AIHA) have been induced by α-methyldopa and procaine amide.[6] Heavy metals are also incriminated, and depot injections of gold salts have often induced chronic autoimmune thrombocytopenia (AITP).[35] The drug-dependent antibodies require the presence of the drug in the test system for their detection and are frequently described as "hapten type", "hapten-induced", "penicillin-type" or "drug adsorption type".[6] Hemolytic anemias induced by this type of antibody response are associated with a high immunoglobulin G (IgG) titer and extravascular RBC destruction. This mechanism may also be responsible for some types of drug-induced thrombocytopenia.[7] A second type of drug-dependent antibody, associated with complement activation and acute, severe intravascular hemolysis, is referred to as "immune complex type" or "non-penicillin type". A proposed mechanism is that drug and/or metabolites interact with the cell membrane (without covalent bonding) and lead to a polyclonal response to several epitopes. Antibodies that react with epitopes shared with the drug and the cell membrane produce immune complexes that trigger the reaction.[5] The fibrinogen receptor, glycoprotein IIb/IIIa, von Willebrand factor receptor, or GPIb/IX, may become selected epitopes, but the mechanism is not hapten-specific.[6] Immunoglobulins only react with these platelet membrane glycoproteins when drug or sensitizing metabolite is present in soluble form. How the drug facilitates antibody binding to cause platelet destruction or how the immune system is triggered by the drug to recognize these epitopes is not understood.

Drugs developed as ligand-mimetic GPIIb/IIIa inhibitors have produced acute and often severe thrombocytopenia in a subset of patients during clinical trials.[10] Naturally-occurring antibodies present in otherwise normal patients recognize GPIIb/IIIa complexed with the drug on the surface of platelets and produce DIMT.

Drug-specific antibodies may be naturally occurring or induced. The cephalosporins are particularly prone to producing this response, and the problem has become more frequently observed with the newer generations of the drug. These DIIMHA can be very severe, with hemoglobinemia and hemoglobinuria. Differences in response to these drugs are found between age groups, with children often developing severe hemolysis within minutes after administration while similar problems occur in adults only after several days.[5]

Drug-induced immune disease against granulocytes has been associated with:

1. no significant effect on circulating numbers of neutrophils
2. moderate to severe neutropenia with normocellular to hypercellular bone marrow, or
3. neutropenia with bone marrow hypoplasia or maturational arrest.[12]

Identification of anti-neutrophil antibodies using various detection methods is difficult because they tend to be present in low titers and bind with low avidity. Autoantibodies that have been characterized in humans are directed against various membrane glycoproteins, including adhesion molecules. Anti-neutrophil antibodies can produce neutrophil dysfunction resulting in defects in adhesion, aggregation, chemotaxis, phagocytosis or killing.

Aplastic anemia may be a predictable or idiosyncratic reaction that presents as pancytopenia (leukopenia and thrombocytopenia will be detected before anemia) due to bone marrow failure (see Chapter 39). Radiation toxicity is the classic example of a dose-related, predictable aplastic anemia hematotoxin, but most drug-related cases are believed to be immune-mediated.[9]

PRCA is an infrequent idiosyncratic drug reaction in which marrow suppression is limited to the erythroid lineage. Although selective suppression of erythropoiesis may be the cause, an immune-mediated

mechanism has been speculated as the mechanism behind PRCA.

Drug-induced Marrow Suppression (see Chapters 17 and 18)

In addition to direct cellular injury, hematopoiesis may be suppressed or enhanced by alterations in the cytokine network. For example, based on the *in vitro* observation that interleukin-12 (IL-12) works synergistically with the c-kit ligand to promote hematopoietic stem cell proliferation, mice dosed with recombinant mouse IL-12 were expected to develop accelerated myelopoiesis.[33] Instead, treatment with IL-12 produced myelosuppression in bone marrow while enhancing splenic extramedullary hematopoiesis. The complexity of the cross-talk that occurs in the hematopoietic microenvironment is not restricted to compounds designed to impact hematopoiesis or regulate inflammation. Cytokines, growth factors, and receptors in tissues outside the hematopoietic system that are seen as potential drug targets may impact bone marrow as well. Blockade of neurokinin receptors has been pursued as a potential anti-anxiety target by allowing accumulation of Substance P. However, the same receptors exist in the bone marrow and play a critical regulatory role in hematopoiesis.[27] Depending on the receptor and the cross-talk, Substance P can either inhibit or stimulate hematopoiesis.

Anemia

Anemia may be caused by decreased circulating lifespan, hemolysis, hemorrhage, blood loss, decreased or ineffective production, or a combination of processes. The mechanism(s) of toxic effect(s) determines the type of anemia, time to onset, duration of effect, and whether persistence of the inciting agent is required for anemia to be maintained or progress.

Hypoproliferative Anemia

Mild normocytic normochromic anemia that is poorly regenerative and reverses when administration of the compound is discontinued is frequently seen in repeat-dose toxicity studies. Usually, histological and cytological evaluation of the bone marrow from these animals is unremarkable and there is no impairment of leukocyte or platelet production. Decreased erythropoiesis may be secondary to inanition associated with inappetence and other systemic toxicological effects of the administered compound.[21]

Compounds that have toxic effects on proliferating bone marrow cells or stromal cells may produce a non-regenerative or hypoproliferative anemia. Examples include anti-neoplastic drugs that target DNA and drugs that interfere with hemoglobin synthesis (see Chapters 16–18).

Hypoproliferative anemia may also occur secondary to decreased availability of iron, and may be induced by chronic administration of xenobiotics (e.g. recombinant cytokines or cytokine receptor inhibitors) that induce chronic inflammatory changes (see Chapter 37).[30] Long term studies with compounds that produce renal toxicity, such as cadmium, will also present with anemia due to decreased erythropoietin.[17]

Hemorrhagic Anemia

Hemorrhagic anemia, caused by blood loss, may be a direct or indirect effect of a xenobiotic. Acute hemorrhagic anemia, occurring over 2–3 days, will present with a decrease in the erythron and no evidence of regeneration. Thereafter, a regenerative response (polychromasia, anisocytosis, increased RDW, reticulocytosis) is generally observed. More protracted hemorrhage may present as regenerative or non-regenerative, or with characteristics consistent with iron deficiency anemia (hypochromasia, microcytosis, poikilocytosis). Changes in platelet counts and plasma protein concentrations will vary depending upon cause, duration, severity, and whether blood loss is internal or external. Mechanisms of compound-related hemorrhage include enhanced fibrinolysis, impaired platelet function, single or multiple coagulation factor deficiencies, and/or coagulation factor inhibition.[23] Secondary or indirect compound-related hemorrhage may occur as a result of compound-related gastrointestinal lesions, impaired vitamin K absorption, or disseminated intravascular coagulopathy. Examples of compound classes that may be associated with hemorrhage include non-steroidal anti-inflammatory drugs (secondary to gastrointestinal erosion, ulceration secondary to local irritation, inhibition of prostaglandin synthesis), vitamin K antagonists, platelet aggregation inhibitors, and gene therapy molecules (L.G. O'Rourke, personal observations).

Anemia Secondary to Induced Suicidal Erythrocyte Death

The normal wear and tear on RBCs exposes them to osmotic shock, oxidative stress and energy depletion. Eventually the cell is no longer able to perform adequately and is removed from circulation.[20] RBCs have their own process of programmed cell death which has been termed eryptosis because it mimics apoptosis.[19] In addition to the triggers mentioned above, in vitro eryptosis can be induced by a number of endogenous molecules (e.g. ceramide, prostaglandin E2, platelet activating factor) and many xenobiotics (paclitaxel, azathioprine, amantadine, amiodarone, chlorpromazine, cyclosporine, methyldopa, retinoic acid, cisplatin and zidovudine).[19] The degree to which this mechanism may contribute to drug-related anemia has yet to be determined, but the hypothesis of drug-induced eryptosis is very compelling, particularly in circumstances where RBC lifespan appears to be reduced without explanation.

Hemolytic Anemia

Direct effects on circulating RBCs can produce acute or chronic hemolytic anemia. Hemolysis may be intravas-

cular, extravascular, or both, depending upon the insult. Intravascular hemolysis is accompanied by hemoglobinemia and hemoglobinuria. When damage is due to direct contact of a compound or its metabolite with the RBC, hemolysis is immediate and often severe. Examples of compounds capable of producing direct hemolysis include saponin, phenylhydrazine, arsine, or naphthalene.[31]

Drug-induced Non-immunologic Adsorption of Protein Non-immunologic protein adsorption onto the RBC membrane, possibly influenced by the patient's plasma IgG concentration, is a possible mechanism of hemolytic anemia.[6,27] Some drugs may be able to modify the RBC membrane, allowing adsorption of plasma proteins (e.g. immunoglobulins, albumin, complement, fibrinogen).[32] Unfortunately, diagnostic tests are not available to differentiate this mechanism from immune-mediated mechanisms.[5]

Oxidative Damage Strong oxidants are able to overwhelm the capacity of RBCs to remain in a reduced state, resulting in the production of methemoglobin and/or denatured hemoglobin (see Chapters 16 and 36). Oxidation results in Heinz body formation and altered ion transport with subsequent intravascular hemolysis and removal by the mononuclear phagocyte system.[9,31] Many species will form Heinz bodies when exposed to aniline, nitrobenzene, and related homologs. Blood film should be examined for evidence of Heinz bodies, eccentrocytes, and keratocytes. Unless there is continual exposure, it may be difficult to detect Heinz bodies in some species due to their rapid removal by the mononuclear phagocyte system. The ability of a molecule to function as an oxidant depends upon the concentration of exposure, the reducing ability of the RBCs of the species involved, and the susceptibility of the hemoglobin molecule. Obtaining an accurate measurement of methemoglobin is difficult due to the constant REDOX activity in the RBC, particularly in rodents. Some species are more susceptible to methemoglobin formation than to Heinz body formation, other species demonstrate the reverse, and still others are highly susceptible to both. Human RBCs have a relatively slow rate of methemoglobin reductase relative to laboratory species, and are particularly susceptible to Heinz body formation;[31] therefore detection of either or both in a preclinical study is a major toxicological finding that must be carefully weighed against potential benefits of the compound.

Leukopenia

Drug-induced leukopenias may be transient or persistent. Transient depressions in leukocyte counts that return to baseline or are comparable to concurrent control data despite continued exposure to the compound may represent various compensatory mechanisms. Leukocyte depressions that persist throughout the dosing period of the study but return to baseline at the end of the study represent reversible suppressions. Drug-induced neutropenia may be due to direct damage to progenitor cells in bone marrow, or damage to stromal cells that support granulopoiesis.[16] Marrow damage may be limited to granulopoiesis, or affect all cell lineages. Mechanisms by which cytokines modulate the hematopoietic system are being continually studied because in vitro effects cannot predict the complex synergistic or antagonistic interactions within the cytokine network in vivo.[34] Time of evaluation can greatly influence interpretation. Some drugs, such as clozapine, may interact with intracellular myeloperoxidase or NADPH-oxidase to produce highly reactive products that are toxic to granulocytes.[24] Neutropenia can occur after prolonged exposure, and may be due to decreased production secondary to hypoplastic bone marrow.[22] Immune-mediated granulocytopenia may be directed against precursor cells and/or against circulating cells. Criteria established to define idiosyncratic drug-induced agranulocytosis include:

1. neutropenia ($\leq 0.5 \times 10^9$/L)
2. onset during treatment or within 7 days of exposure with recovery within 1 month of discontinuation
3. recurrence upon re-exposure.[4,8]

A recent review of non-chemotherapy drug-induced agranulocytosis found the median duration of exposure before onset ranged from 19 to 60 days, though one drug (dipyrone) had a median exposure of only 2 days.[2] Agranulocytosis caused by nonimmunological mechanisms appeared to have a later onset than when attributed to immune-mediated mechanism. Impaired granulopoiesis was responsible for 67% of the cases reviewed. This finding contrasts significantly with drug-induced thrombocytopenia or drug-induced hemolytic anemia, where blood cells are the main target of the immune reaction.[5,7]

Thrombocytopenia

Thrombocytopenia may be a result of generalized bone marrow suppression, increased consumption, sequestration, or immune-mediated platelet destruction. Thrombocytopenia in preclinical studies is rarely associated with gross or microscopic hemorrhage unless there is concurrent platelet dysfunction. Although the most frequent cause of thrombocytopenia reported in clinical patients is drug-induced, thrombocytopenia is not a common finding in preclinical studies (L.G. O'Rourke, personal observation).[5,9,31] Compounds that indiscriminately attack actively dividing cells will produce bone marrow panhypoplasia. Selective megakaryocytic toxicity, either through toxicity or an immune-mediated mechanism, is associated with a paucity of megakaryocytes in bone marrow. Conversely, with platelet destruction or consumption, as happens with DIMT, the marrow will show a marked increase in megakaryocyte numbers. Because the majority of reported drug-related thrombocytopenias are idiosyncratic and occur post-marketing, preclinical predictability of this important adverse effect remains underestimated. Any signal in the data from preclinical

studies that suggest that platelets are a target should be carefully and fully evaluated.

DISPARATY BETWEEN PRECLINICAL AND CLINICAL SAFETY DATA

Preclinical studies may unfairly incriminate a compound or overestimate or underestimate the risk of exposure in humans receiving pharmacological doses. For example, during development of omalizumab (XOLAIR®), a recombinant humanized anti-IgE monoclonal antibody that neutralizes circulating IgE, thrombocytopenia was identified and reproduced in preclinical safety studies in monkeys receiving the drug at 5–27 times the maximum clinical dose.[1] The thrombocytopenia observed in the monkeys was never severe enough to produce clinical hemorrhage. No effect on circulating platelet numbers was identified in clinical studies. After a temporary hold on development, it was determined that the observation was likely species-specific and platelet counts in further clinical trials were intensely monitored. To date, this has not materialized as an adverse effect in humans.[37]

Conversely, preclinical testing can fail to predict toxicity at intended exposure. An example of this problem occurred when a low incidence (<0.3%) of agranulocytosis was detected in the late phase of clinical trials with prinomide, a pyrroleprioprionitrile, non-steroidal anti-inflammatory drug, resulting in immediate termination of further development of the drug.[26] No effect on hematopoiesis or circulating numbers of cells was evident in the preclinical studies (rodents, dog, monkey) conducted before these adverse reports. The unique difference between the individuals enrolled in the late phase studies who developed agranulocytosis and those in early phase clinical trials and animal models was that the late phase patients were experiencing active inflammatory conditions such as chronic arthritis. Because the metabolism of xenobiotics by myeloperoxidase has been associated with the formation of reactive metabolites capable of affecting normal cell function, further investigative work using the active metabolite of prinomide was conducted.[26] Mass spectroscopy revealed that the reactive metabolite was 1,4-benzoquinone, a compound implicated in myelotoxicity associated with benzene. The authors concluded that these reactive metabolites, produced under conditions of increased hydrogen peroxide (e.g. active inflammation) might explain the agranulocytosis identified in the late phase studies.

When test species have different abilities to detoxify by conjugation or reductive properties compared to humans, the toxic potential of a new chemical entity may not be identified until the first human studies are conducted. For example, a potential new drug administered to healthy adults unexpectedly produced methemoglobinemia during dose escalation studies (L.G. O'Rourke, personal observation). Again, full review of all preclinical data failed to predict this occurrence.

These examples are presented to first illustrate that classical animal models and preclinical studies, despite their rigors, may fail to predict life threatening adverse effects on the hematopoietic system in the intended species, or may overestimate risk of exposure. They also serve as reminders of the importance of understanding both species differences as well as similarities. Clinical safety studies function as a second line of defense, where discrepancies from preclinical studies usually can be detected. However, when toxicity occurs only in certain individuals within the human population, it may be difficult to determine if the responsible mechanism is due to a property of the drug or to the unique biology of an individual. Depending upon the incidence of this idiosyncrasy within the test population, this may not be detected in the pre-marketing phase of development. Many case reports in the literature present other instances of drug-induced hematotoxicity that were either not predicted in preclinical safety evaluation studies or were not identified until enough individuals were exposed post-marketing to detect an adverse effect.

INVESTIGATIVE WORK

Identification of cytopenia in individual or treatment group data needs to be addressed immediately. It is important to review all clinical observations, treatments, and handling to differentiate a direct compound-related effect on the hematopoietic system from a secondary effect such as blood loss (e.g. excess phlebotomy; gastrointestinal bleeding) or illness. Actions that may follow identification of a cytopenia in a safety study include:

- no change in protocol
- temporary suspension of dosing
- dose reduction
- cessation of dosing and initiation of a monitoring period
- humane termination

or a combination of the above. Obviously, if dosing is suspended and the findings resolve only to return when dosing is reinstated, the compound or its metabolites are clearly implicated.

It may be difficult to determine if an effect on the hematopoietic system is idiosyncratic when the incidence of an adverse finding is extremely low and is only found in one species. When a hematotoxicologic finding is identified in a preclinical study, it must be taken seriously and critically assessed. Depending upon the seriousness of the finding and the mechanism(s) involved, redesign of the molecule or termination of a project may ensue. On the other hand, when findings are limited to one species they may be interpreted as species-specific. In these instances, and depending upon the seriousness of the finding, there may be minimal impact on further development of the compound, although all clinical trials should be carefully monitored.

In addition to the in vitro and in vivo testing, efforts to develop animal models to test basic hypotheses con-

tinue. It is, however, challenging to identify animal models because reactions to xenobiotics in animals are as idiosyncratic as they are in humans.

CONCLUSIONS

Preclinical safety evaluation studies in animals and clinical safety evaluation studies in humans are designed to rigorously test new chemical entities for evidence of toxicity based on their relative risk/benefit. Because the number of animals exposed to a new chemical entity is relatively small, an adverse effect on the hematopoietic system must always be fully evaluated. When evidence of hematotoxicity occurs in human studies, either pre- or post-marketing, both in vivo and in vitro studies specifically designed to define the mechanism(s) are indicated. At present, many of these mechanisms remain a mystery. As the tools of pharmacogenomics and pharmacogenetics are advanced, our abilities to examine and understand interspecies drug-, class- and organ-specific pathways underlying toxicity, and to explore portions of the genome that may detect potential unanticipated impacts will improve, further enhancing our ability to select useful new xenobiotics that are not associated with hematotoxicity.

CHAPTER 15

Preclinical Evaluation of Compound-Related Alterations in Hemostasis

KAY A. CRISWELL

Routine Laboratory Testing in Preclinical Studies
Investigation of Compound-Related Increases in PT or aPTT
Investigation of Compound-Related Clinical Signs of Altered Hemostasis
Biomarker Development for New Anticoagulant Therapies
Ex Vivo Experiments (New Anticoagulant Development)
Effect of Thromboplastin on Absolute Prothrombin Time
Conclusions

Acronyms and Abbreviations

aPTT, activated partial thromboplastin time; DIC, disseminated intravascular coagulopathy; FDA, Food and Drug Administration; FDP, fibrin degradation product; FX:C, Factor X clotting activity; ISI, international sensitivity index; PT, prothrombin time.

Hemostasis is a fundamental defense mechanism common to all vertebrates. It involves a delicately balanced process of blood clot (thrombus) formation that impedes blood loss from damaged blood vessels and thrombus dissolution (i.e. fibrinolysis, see Chapter 84). Species-specific differences in hemostasis do exist, so that direct translation of human-based assays can be problematic. Preclinical evaluation of compound-associated alteration in hemostasis is a prerequisite for new compound registration. Inadequate efficacy or poor safety margins are the two main reasons for compound attrition and are key to the success or failure of new compounds that are either purposefully designed to alter coagulation processes or inadvertently perturb hemostasis. This chapter will provide an overview of routine and non-routine laboratory testing requirements of blood coagulation among species important in designing preclinical trials and interpreting compound-related hematotoxicity, and in biomarker development during development of new anticoagulant therapies.

ROUTINE LABORATORY TESTING IN PRECLINICAL STUDIES

Harmonization of animal clinical pathology testing requirements for toxicity and safety studies was achieved by the Joint Scientific Committee for International Harmonization of Clinical Pathology Testing in 1996.[8] Prothrombin time (PT), activated partial thromboplastin time (aPTT), and platelet count were the minimum recommended laboratory tests for hemostasis in small animals (mouse or rat) and large animals (dog or monkey).[2]

Clinical signs provide additional information to categorize acquired abnormalities in hemostasis. Clinical signs of primary hemostatic defects (failure of platelet plug formation) typically consist of bleeding from mucosal surfaces, cutaneous bruising, and hemorrhage following trauma or surgery. The pathways involved in secondary hemostasis comprise a cascade of enzymatic reactions that result in a stabilized fibrin clot. Clinical signs associated with defects in secondary hemostasis

include hemorrhage into joints, chest, or abdomen and subcutaneous or intramuscular hematoma formation. Excessive bleeding from sites of trauma or surgery are seen with secondary hemostatic defects as well as primary defects. Excessive bleeding following blood sample collection is often the first evidence of compound-related hemostatic defects in preclinical trials.

Changes in the intrinsic (contact system) coagulation pathway are routinely monitored using the aPTT, whereas changes in the tissue factor pathway (extrinsic pathway) are assessed by increases or decreases in PT. Both assays are assessed are expressed as the time to clot formation after addition of an exogenous clot activating agent. PT and aPTT are advantageous in that these assays are routine. Testing reagents are also standardized and instrumentation has undergone rigorous scrutiny to pass Food and Drug Administration (FDA) requirements because of their routine usage in clinical diagnostic laboratories. Reference intervals for PT and aPTT among species are variable, and experimental studies suggest that there is a marked difference in the rate of thrombin generation and fibrin formation among species.[3] Use of non-species-specific laboratory reagents and instrumentation optimized for human testing may contribute to these differences. Therefore, it is important to generate species-specific reference intervals that are characterized by both reagent and instrumentation, and to select reagents and instrumentation that are compatible with the species required for preclinical examination.

Assessment of plasma fibrinogen is often included in assessment of compound-related effects on hemostasis as well as in general veterinary medicine. Decreases in fibrinogen, especially when accompanied by decreased platelet count, can be indicative of consumption of coagulation factors associated with disseminated intravascular coagulopathy (DIC). In contrast, an increase in fibrinogenesis is suggested by an elevation in plasma fibrinogen levels. Hyperfibrinogenemia can be associated with infectious or inflammatory conditions including those associated with compound administration.[4] Although effects on PT, aPTT, platelet count, and fibrinogen are valuable in screening for compound-related hematotoxicity, they are usually inadequate to provide a mechanistic explanation, particularly for unexpected compound-related toxicities.

INVESTIGATION OF COMPOUND-RELATED INCREASES IN PT OR APTT

Evidence of compound-related prolonged clotting times with or without decreases in fibrinogen requires investigation to determine the possible mechanism of action (Table 15.1). The most likely causes are specific or non-specific inhibitors of procoagulant plasma proteins in the coagulation cascade or consumption of these factors. The source of acquired alterations in hemostasis could arise from several compound-related issues. The liver is a common target for compound-related toxicity. Most coagulation factor proteins are synthesized in the liver. Therefore, hepatotoxicity can result in a decreased synthesis of coagulation proteins, and the resulting deficit is responsible for the prolongation of clotting times. If this is the case, decreases in other serum proteins such as total protein and albumin may be present, markers of hepatotoxicity such as aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase, and/or bilirubin

TABLE 15.1 Useful Assays or Techniques to Determine the Mechanism of Action of Prolonged PT and/or aPTT in Preclinical Studies

Assay or Technique	Possible Compound-related Effect
Fibrinogen	↓ – Decreased production or consumption (possible DIC) ↑ – Inflammation
Hepatoxicity screening assays	Serum/plasma chemistry assays (↑ALT, AST, alkaline phosphatase, bilirubin, GGT) Histopathology
Vitamin K plasma levels	Decreased absorption Decreased production by microflora
Coagulation factor-specific activity assay	Acquired compound-related factor deficiencies often affect multiple factors Single factor deficiencies can occur particularly for known anticoagulant compounds (i.e. anti-FXa inhibitors) ↓Factor II, VII, IX, and X for vitamin K-dependent processes
Vitamin K supplementation	Reversal of vitamin K-dependent toxicity
DIC panel	PT, aPTT, platelet count, FDP, D-dimer

are frequently elevated, and histologic evidence of liver pathology is also present.

Another possible explanation of decreased coagulation proteins is a compound-related effect on vitamin K-dependent proteins. Vitamin K is a fat-soluble vitamin that is either consumed in the diet or synthesized by bacterial microflora in the ileum and colon.[7] Vitamin K-dependent coagulopathies are rarely observed in short-term preclinical studies because liver stores of vitamin K are adequate for several days. However, in studies exceeding two weeks duration, inflammatory or toxic disorders may lead to a relative or absolute deficiency of vitamin K. Compound-related vitamin K deficiencies are most frequently associated with:

1. studies conducted in neonatal animals due to decreased protein synthesis in the immature liver
2. studies using broad-spectrum antibiotics which decrease the bacterial flora in the intestines
3. studies that impact the absorption of fat soluble vitamins usually due to gastrointestinal, hepatic, renal or pancreatic disorders
4. studies using known antagonists of vitamin K such as warfarin.[6]

Factors II, VII, IX, and X are vitamin K dependent.

Several laboratory techniques can be used to identify vitamin K deficiency. Assessment of plasma vitamin K levels is possible but requires access to expensive and time-consuming mass spectrometry equipment. More commonly the quantitation of specific coagulation factors is based on the ability of test plasma to correct the clotting time of human plasma from an individual with an inherited deficiency of a single clotting factor. To accommodate for species differences in coagulation factors it has been suggested that a species- and reagent-specific standard curve be constructed using a pool of healthy individuals from the representative species. However, human-deficient plasma has adequate homology for diagnostic interpretations.[3] Decreases in factor activity assays for vitamin K-dependent factors II, VII, IX, and X with no effect on factors that are vitamin K-independent, such as factor VIII, strongly suggest a vitamin K deficiency or antagonism. Reversal of these effects in animals given vitamin K supplementation further corroborates the finding.

If absolute factor activities are required, chromogenic assays should be used in lieu of factor activity assays. In these assays, prothrombin is activated by specific cleavage with the enzyme Ecarin, which is extracted from the venom of the *Echis carinatus* viper. Interspecies homology for the complete prothrombin molecule has been estimated at only 41%. However, there is no variance in the 10 glutamate residue required for vitamin K-dependent carboxylation.[3] The prothrombin chromogenic assay has been shown to be effective in detecting prothrombin deficiency in a dog with vitamin K deficiency. This finding suggests that the assay could be useful in determination of compound-related effects on vitamin K.

Compound-related production of disseminated intravascular coagulopathy (DIC) can also be responsible for increases in PT and aPTT in preclinical studies (see Chapter 88). This condition is frequently accompanied by oozing of blood from venipuncture sites, hematomas, and hemorrhage. Coagulation factor proteins are consumed by an activation of the coagulation system and the fibrinolytic system is usually simultaneously activated. The underlying initiators of compound-related DIC can be diverse including systemic inflammation, uncontrolled immune-mediated cellular destruction (e.g. hemolysis), metabolic acidosis, and hepatosplenic disease. Diagnostic testing for DIC in preclinical studies typically includes PT, aPTT, platelet count, antithrombin III (ATIII) quantitation, and fibrin degradation products (FDPs) so that effects on accelerated coagulation and fibrinolysis are evaluated (see Chapter 138). Early assessments of FDPs used a rather non-specific precipitation of the protein fragments with protamine sulfate. These assays were useful in animal studies since they are not antibody dependent. More recently, D-dimers have been used to diagnose DIC in animals.[6] D-dimers result only from the degradation of the stabilized fibrin clot. Therefore, the D-dimer assay is more specific for active coagulation and fibrinolysis and has proven to be useful in compound-related DIC observed in dogs and monkeys (KA Criswell, personal observation).

INVESTIGATION OF COMPOUND-RELATED CLINICAL SIGNS OF ALTERED HEMOSTASIS

In some preclinical studies clinical signs of bleeding or bruising may occur without effects on PT, aPTT, or other clotting assays (Table 15.2). The most frequent

TABLE 15.2 Useful Assays to Determine the Type of Hemostatic Alteration in Preclinical Studies

Initial Assay or Observation	Expanded Observation and/or Testing
Observation of clinical signs	Bleeding Hematomas Oozing of blood following collection of blood samples
Platelet count (decreased)	Histologic and/or cytologic evaluation of bone marrow for cellular depression Platelet lifespan (flow cytometry) Megakaryocyte ploidy (flow cytometry)
Platelet count (normal or increased)	Bleeding time (standardized template) Platelet activation (flow cytometry) Platelet aggregation (platelet-rich plasma or whole blood)

toxicity is a compound-related effect on platelet number or function. Drug-induced suppression of thrombopoiesis is a commonly reported syndrome for chemotherapeutic agents, estrogenic compounds, sulfadizines, quinidines, and non-steroidal anti-inflammatory drugs (see Chapter 16). Platelet lifespan can be measured in most species by injecting sulfo-NHS-biotin and using flow cytometry to assess the time required to completely lose the bioatinylated platelet label.[5] Megakaryocyte ploidy can also be determined by flow cytometry.[1] Average megakaryocyte ploidy is 16N in nearly all species. Increased megakaryocyte ploidy in the presence of a decreased platelet count in preclinical trials suggests compound-related increased platelet turnover. Determining that reversal of bone marrow toxicity and depression of platelet counts occurs with withdrawal of compound administration is an important component of determining compound safety. Reversal studies should be a minimum of two weeks in length but are preferably four weeks in length to allow adequate time for bone marrow regeneration.

If clinical signs are apparent in the absence of effects on clotting factors or platelet count, effects on platelet function or effects on vasculature should be considered. In preclinical studies, functional assessment of vasculature defects can be problematic and identification of histologic abnormalities is often determined in lieu of functional assays. Functional platelet defects are more readily determined by laboratory assays (see Chapter 142). Bleeding time measurements can be rapidly and easily performed. Unfortunately, standardization of the bleeding time technique can be difficult in animals and may complicate interpretation of results. Variation of skin thickness in dogs and the site of bleeding time assessment in large or small animals can be particularly problematic. A spring-loaded device (Simplate II® or Surgicutt®) has been used to successfully standardize the bleeding time in the buccal mucosa of dogs, the ear tip of rats, and the forearm of monkeys (KA Criswell, personal observation). For rats, the pediatric version of the Surgicutt instrument should be used.

Low platelet counts may also be attributed to platelet activation and subsequent increased clearance of platelets. Platelet activation may be assessed by flow cytometry using a fluorescent marker for P-selectin (see Chapter 142). This technique requires very low volumes of blood so it is ideal for small animals, including mice. Urinary assessment of thromboxane A2 metabolites can also provide an indirect assessment of platelet activation.[1] Platelet aggregation is the most frequently used methodology to assess platelet function (see Chapter 142). In contrast to the use of citrate for platelet aggregation assays in human, dog, or monkey samples, heparinized blood may be needed to adequately potentiate platelet aggregation results in rodents.[1] The most critical component of platelet function assays is appropriate sample collection. Platelet function assays should not be conducted when difficult sample collection is noted or any evidence of sample clotting is apparent on blood smears.

BIOMARKER DEVELOPMENT FOR NEW ANTICOAGULANT THERAPIES

Specific inhibitors of the coagulation pathway are actively being explored as new candidates for anticoagulant therapy. One of the documented areas is the utilization of biomarkers to measure activated coagulation factor X (FXa) to predict the clinical outcomes of FXa inhibitor compounds. FXa occupies a pivotal position within the coagulation cascade and is an attractive candidate as a target for coagulation intervention. This enzyme links the intrinsic and extrinsic coagulation pathways and is the rate-limiting step in thrombin formation. Rivaroxaban is an oral direct inhibitor of FXa. In a rat venous model of inferior vena cava thrombosis, Rivaroxaban produced a dose-dependent inhibition of FXa and an increase in PT. However, in a rabbit model, Rivaroxaban induced a 92% inhibition of FXa but only a 1.2-fold increase in PT. This demonstrates a marked species-specific variation in monitoring the newer anticoagulants with standard coagulation tests.

Rarely is a single biomarker considered definitive for evaluation of safety or efficacy. The drug development approach for Otamixaban and DU-176b incorporated a series of clotting assays and assays to measure the effects on thrombus formation.[4] For Otamixaban, in vitro coagulation parameters were assessed for their ability to produce a doubling of PT and aPTT. This testing allowed a rank ordering of anticoagulant effect per species with rabbit > human > monkey > rat > dog. Additionally, aPTT appeared to be the more sensitive biomarker in all species. Multiple pharmacological models of thrombosis in rats, dogs, and pigs were also conducted with Otamixaban. In rats, thrombus mass was markedly reduced by nearly 95% with a corresponding increase in aPTT of 2.5-fold and PT of 1.6-fold.[4] In contrast, intravenous administration of 1, 5, or 15 μg/mL of Otamixaban in the pig model effectively eliminated coronary flow reserves related to this stenosis model at the middle and high dose. PT was also prolonged at the middle and high dose, but aPTT was only prolonged at the high dose.

Ex Vivo Experiments (New Anticoagulant Development)

Development of new anticoagulants provides a unique opportunity of assessing drug efficacy ex vivo before conducting preclinical studies. This is important in planning preclinical studies because factor X concentrations vary between species and the level of drug-induced FXa inhibition produced is also variable. In typical studies, human or animal plasma is spiked with various concentrations of test compound. Chromagenic anti-FXa assays and factor X activity, using the factor X clotting (FX:C) assay can be used to determine efficacy of the drug. The FX:C assay provides several unique features that may make it a valuable biomarker for monitoring FXa inhibitor therapy:

1. The assay provides a rapid, reliable assessment of drug concentration and the percent inhibition of FXa achieved during drug inhibitor administration.
2. The assay can be performed on a high throughput automated system that is available in most hospital or veterinary coagulation laboratories.
3. Individual factor X concentrations range from 60% to 150% among human or preclinical subjects. This fairly high level of inter-subject variability suggests that a standard dose of drug may have a substantially different effect on total Factor X inhibition. The FX:C assay defines baseline factor X activity and thereby allows continued dosing to achieve a targeted factor X concentration.
4. Literature is available concerning factor X concentrations and bleeding history in patients with factor X deficiency, so minimally there is some understanding that correlates the impact of reductions in FX:C evaluations and bleeding potential in humans and animals.[3]

By determining the actual concentration of functional factor X remaining, individuals conducting preclinical or clinical trials have increased confidence in the administration of new FXa inhibitors.

As with other coagulation biomarkers used for monitoring FXa inhibition, it was not immediately clear whether the FX:C assay was applicable in multiple species. Ex vivo experiments allowed this evaluation. To provide effective anticoagulant activity, a 30% reduction in FX:C activity was predicted to be a minimal requirement. Table 15.3 shows the intended concentrations of a FXa inhibitor in each species, the resulting FX:C activity, and percent inhibition achieved. Concentrations selected provided assessment of drug concentrations that induced FXa inhibition of approximately 20% to >90%, showing that the targeted range could be predicted and achieved in all species but the

TABLE 15.3 Factor X Activity and Percent Inhibition in Plasma Samples Containing Increasing Concentrations of the FXa Inhibitor[a]

Species	Intended Drug Concentration (μg/mL)	FX:C Activity[b] (%)	Inhibition[c] (%)

drug concentrations required to produce similar levels of FXa inhibition across species were markedly different. The FX:C assay helped determine drug concentration required for complete inhibition of FXa in these species and the relative bleeding risk associated with a range of factor X concentrations.

Effect of Thromboplastin on Absolute Prothrombin Time

Typically, the higher the international sensitivity index (ISI) value for thromboplastin, the less sensitive the reagent and the longer the PT produced. The most commonly used thromboplastin reagents for PT evaluation are either rabbit brain thromboplastin (variable ISI values depending on manufacturer) or human recombinant thromboplastin (typical ISI of 1.0). To more fully evaluate the effect of FXa inhibitors, PT was evaluated using rabbit brain thromboplastin with ISI values of 1.24, 1.55, and 2.21 and a human recombinant thromboplastin (0.98 ISI). The source and sensitivity of thromboplastin used in the assay affected the absolute PT value in all species, demonstrating the need to standardize this reagent in preclinical assessment and to be cognizant of the impact in clinical trials or in post-marketing where reagents are less likely to be standardized (Table 15.4).

CONCLUSIONS

Understanding compound-related effects of hemostasis continues to be an important aspect of marketing safe compounds and developing new anticoagulant therapies. Further, understanding of species-specific differences in hemostatic processes and interactions in assays typically optimized for human samples is critical in translating preclinical study data for the accurate prediction of safety and efficacy in humans.

Acronyms and Abbreviations

ADR, adverse drug reaction; FDA, Food and Drug Administration; IMHA, immune-mediated hemolytic anemia; RBC, red blood cell.

A growing number of therapeutic drugs have been incriminated in adverse drug reactions (ADRs) associated with the hematologic system, with the greatest number being reported in dogs and cats.[39,64,69] No attempt has been made to standardize the definition of drug-induced cytopenias in animals or to quantify the severity of these reactions. Standardized definitions of human drug-induced hematologic dyscrasias and evaluation of their severity have been described.[8] This document defines cutoff values for neutropenia, leukopenia, thrombocytopenia, and anemia. It also defines the likelihood that a drug caused a hematologic dyscrasia as suggestive, compatible, incompatible, or inconclusive based on assessment of the time course between the beginning of exposure to the drug and discovery of the hematologic dyscrasia. Neutropenia is defined as <1,500 neutrophils/μL.[8]

Neutropenia is defined as compatible with an ADR if it is discovered during drug treatment. Neutropenia is considered inconclusive if it is discovered within 1 month after stopping exposure or more than 1 month after exposure if no leukocyte count was done in the interim. An increase in neutrophil count to >1,500/μL within 1 month after stopping drug treatment is also suggestive of an ADR. Thrombocytopenia is defined as <100,000 platelets/μL.[8,70] Occurrence of thrombocytopenia within 1 month after initiation of drug treatment or remission within 3 weeks after stopping treatment is suggestive of an ADR.

Although this document cannot be directly adapted to drug-induced hematologic dyscrasias in animals, it

provides a general framework for evaluation of drug-induced hematologic dyscrasias in domestic animal species.

MECHANISMS OF DRUG TOXICITY

Drug-induced blood dyscrasias have been categorized as Type A or Type B reactions.[42] Type A ADR are dose-dependent while Type B ADR are idiosyncratic reactions that are unrelated to the drug's pharmacologic effects.[42] Idiosyncratic drug reactions are the most challenging to define and may involve a variety of mechanisms.[14,42,69] Unique genetic or acquired susceptibility of the individual is usually involved. Genetic susceptibility may involve mutations that alter drug metabolism or induce an immune response to a drug or its metabolites.[61] Acquired susceptibility may occur because of hepatic or renal disease leading to altered metabolism or excretion of a drug or its metabolites.[61]

The site and mechanism by which a drug acts is important in determining the clinical syndrome and prognosis; however, some drugs act at multiple sites or by several mechanisms making this determination difficult (Table 16.1). Destruction of cells in the peripheral blood results in rapid onset of cytopenias. Because the bone marrow can compensate by increasing production, decreased cell lifespan in the blood can be compensated and cell numbers may return to normal despite continued administration of the drug. Red blood cells (RBCs) are particularly sensitive to oxidative injury.[21] Many drugs have oxidant properties or are metabolized to oxidants.[21] These drugs tend to be dose-dependent because tissue injury is largely dependent on the degree of oxidative injury (see Chapter 36). Drugs associated with oxidative injury in dogs include acetaminophen, aspirin, menadione, methylene blue, benzocaine, phenacetin, and phenylhydrazine.[15,21,30] Cats are more sensitive to the oxidant effects of many drugs because of the presence of eight reactive sulfhydryl groups per molecule compared to two in most other species.[21] Drugs associated with Heinz body anemia in cats include acetaminophen, aspirin, cetacaine, methylene blue, phenazopyridine, DL-methionine, and propofol (see Chapter 36).[15,21,30]

Rapidly proliferating progenitor and proliferative cells in bone marrow are susceptible to chemotherapeutic agents. Destruction of these cells results in predictable changes in the blood. Neutropenia occurs initially followed by thrombocytopenia.[16] Anemia develops more slowly depending on the RBC lifespan of the particular species. Discontinuation of the drug usually results in hematologic recovery. Bone marrow aspiration smears in some affected animals may reveal toxic changes in precursor cells. One drug-associated change is the presence of multiple distinct cytoplasmic vacuoles that are most prominent in granulocyte precursors (Fig. 16.1).

Some drugs induce hematopoietic stem cell destruction or alter the hematopoietic microenvironment. The timing of development of cytopenias is more

unpredictable and recovery is uncertain and delayed when it occurs. Endothelial cells of marrow capillaries and sinusoids are vulnerable to toxic injury (see Chapter 17). Vascular injury can be seen in bone marrow core biopsy sections as interstitial edema, hemorrhage, necrosis, myelofibrosis, or acute inflammation.[68]

EVALUATION OF SUSPECTED ADVERSE DRUG REACTIONS

The mere temporal association of a drug treatment with a hematologic disorder does not in itself provide proof of an ADR. In each case other potential causes of the hematologic condition should be eliminated by evaluation the history, and clinicopathologic findings. When an ADR is suspected, the temporal relationship between onset of treatment and detection of the hematologic dyscrasia, previous exposure to the drug in question, and recovery from the hematologic dyscrasia after drug withdrawal should be documented.[8,42] This information not only documents the likelihood of a cause and effect relationship but may suggest a possible mechanism for the drug toxicity. When multiple drugs have been administered before detection of hematologic dyscrasias, the Food and Drug Administration (FDA) database (http://www.fda.gov/cvm/adetoc.htm) can be reviewed or a literature search conducted to determine if other similar toxicities have been reported.[42] The FDA database can also be used to report suspected toxicities. Usually this information combined with serial complete blood counts, tests for immune-mediated hematologic diseases, and bone marrow aspirates and core biopsy specimens are the only data available to link a drug to a clinical ADR. Other tests that might be done include evaluation of the hemolytic effects of the drug and evaluation of the suppressive effects of the drug, serum, or patient lymphocytes on blood cell or bone marrow cytotoxicity or on in vitro bone marrow cell culture.[24,40,50]

ADVERSE DRUG REACTIONS IN DOGS

Antineoplastics

Chemotherapeutic agents cause Type A ADR. Because of their high mitotic rate, progenitor and proliferative cells in bone marrow are predisposed to injury by chemotherapeutic drugs. The myelosuppressive potential of chemotherapeutic agents varies (Table 16.2).[16]

Cytopenias are the most frequent chemotherapeutic toxicity identified and often necessitate temporary or permanent discontinuation of treatment. Bone marrow suppression follows a predictable course based primarily on the half-life of cells in the blood. Neutropenia occurs 5–7 days after myelosuppression followed by thrombocytopenia 9–14 days after myelosuppression.[16] Anemia as a direct result of chemotherapy is usually not seen because of the comparatively long half-life of RBCs.[16] Neutrophil and platelet counts usually return to baseline values within 72–96 hours after discontinuing therapy.[16]

Beyond destruction of hematopoietic cells, chemotherapeutic drugs have few adverse effects on the hematopoietic system. Multifocal areas of coagulation-type necrosis have been reported in association with administration of cyclophosphamide and vincristine.[65] An increase in dysplastic hematopoietic cells and atypical mitotic figures (i.e. secondary dysmyelopoiesis) is a frequent finding and should not be confused with a myelodysplastic syndrome (see Chapter 66).[1,67] Doxorubicin administration to dogs has been association with poikilocytosis including the presence of ovalocytes, echinocytes, schistocytes, and keratocytes.[5] Doxorubicin is thought to bind to spectrin, a major cell membrane structural protein.[5]

Estrogen

Dog and ferret bone marrow is highly susceptible to estrogen-induced suppression, and both dose-dependent (Type A ADR) and idiosyncratic (Type B ADR) reactions have been documented in dogs (aplastic anemia is discussed in Chapter 39).[34,55,69] In dogs, both a single large dose of estradiol and therapeutic doses of estradiol

as well as therapeutic doses of diethylstilbestrol result in hematologic dyscrasias. Therapeutic doses of estradiol or diethylstilbestrol, used in treatment of mammary tumors or prostatic hyperplasia, consistently cause a transient decrease in platelet count and neutrophilia 10–20 days after administration.[22] Administration of a single large dose of estradiol to dogs results in consistent hematologic dyscrasias. Leukocytosis, thrombocytopenia, and mild but progressive nonregenerative anemia develop in the first 3 weeks after injection of 1–3 mg/kg body mass of estradiol. Pancytopenia with bone marrow aplasia develops between 3 and 4 weeks after injection and most dogs begin to recover after 4 weeks. Although the mechanism is complex and poorly understood, serum inhibitors of hematopoiesis produced by T cells have been identified.[23]

Individual dogs appear to be uniquely sensitive to the effects of estrogen and develop severe aplastic anemia. Dogs given repeated therapeutic doses of estradiol or dogs having elevated endogenous estrogen levels resulting from cystic ovarian follicles, ovarian granulosa cell tumors, or Sertoli cell tumors may develop hematologic dyscrasias. Dogs with endogenous estrogen toxicity typically are pancytopenic but some are bicytopenic.[34,55,69] The bone marrow is typically aplastic.[2,22,23] This appears to be the result of hematopoietic stem cell destruction. The prognosis for these dogs is poor but recovery after weeks to months of supportive care has been documented.[69] Myelofibrosis, bone marrow necrosis, and dysmyelopoiesis have been observed in dogs given a therapeutic doses of estradiol propionate.[34,69]

Anti-Inflammatory

Phenylbutazone/Meclofenamic Acid

Many cases of phenylbutazone-associated hematologic dyscrasias have been reported and one case of meclofenamic acid-associated aplastic anemia has been reported. Phenylbutazone-associated neutropenia or pancytopenia occurs sporadically in dogs.[15,54] Several types of Type B ADR have been observed. One is a transient agranulocytosis that typically occurs within 2 weeks after starting treatment. Affected dogs frequently recover promptly when the drug is discontinued. This condition is most probably immune-mediated but inhibition of bone marrow cell division or DNA synthesis is also a possible explanation. In another type of hematologic dyscrasia, dogs develop aplastic anemia months or years after initiation of treatment, presumably as a result of bone marrow toxicity.[63,69] In the experience of the author, the prognosis for recovery is poor. Additionally, phenylbutazone therapy has been associated with myelonecrosis and myelofibrosis.[63,69]

Carprofen

Coagulation-type myelonecrosis has been reported in bone marrow from several dogs treated with therapeutic doses of carprofen.[65] Another dog was reported to have a neutrophilic dermatitis, vasculitis, immune-mediated hemolytic anemia, and thrombocytopenia associated with carprofen adminstration.[43]

Azathioprine

Neutropenia and thrombocytopenia or pancytopenia have been observed one to several months after initiation of treatment with immunosuppressive doses of azathioprine.[36,52] Bone marrow is aplastic and some dogs have mild myelofibrosis. Peripheral blood cell numbers slowly return to normal once the drug is discontinued but complete recovery may be delayed.

Naproxen

Naproxen administration has been associated with blood loss anemia.[20,27] Gastrointestinal erosions or ulcerations are suspected to be the cause of the blood loss. This may result from local irritation or inhibition of prostaglandin synthesis.

Antibacterials

Sulfonamides

Adverse drug events have been reported for sulfadiazine, sulfamethoxazole, and sulfadimethoxine.[26,66,69] These drugs induce an idiosyncratic syndrome that includes neutropenia, thrombocytopenia, hemolytic anemia, fever, polyarthropathy, or hepatopathy.[26] Doberman pinschers may be at increased risk of sulfonamide hypersensitivity.[26] Others have reported sulfadiazine-associated aplastic anemia (Fig. 16.2).[66,69] The mechanism appears to be immune-mediated and does not appear to be related to folate deficiency.[26,60] Evidence of an immune-mediated etiology includes demonstration of drug-dependent anti-platelet antibodies and a positive direct Coombs' test.[26] In dogs

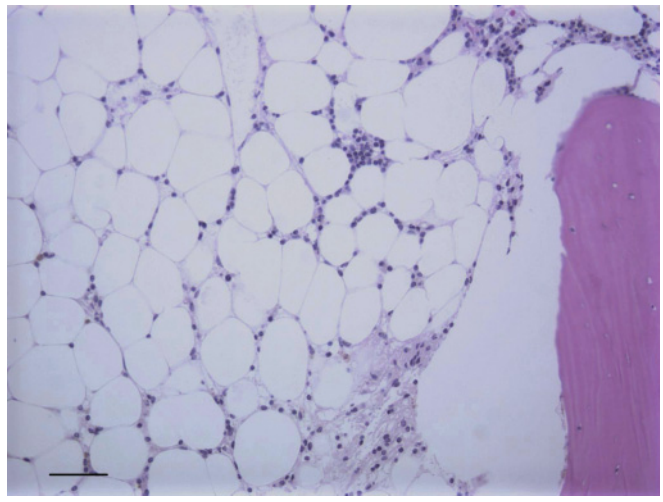

FIGURE 16.2 Bone marrow core biopsy from a dog treated with trimethoprim-sulfadiazine for 15 days. Note the presence of marrow aplasia. Cells present are mostly small lymphocytes. Hematoxylin & Eosin stain; bar, 200 µm.

with sulfadiazine-induced aplastic anemia, pancytopenia usually occurs 10–14 days after initiation of treatment.[25,66] The bone marrow is typically aplastic with the hematopoietic space replaced by adipose tissue. The hematologic dyscrasia usually resolves within 2 weeks after discontinuing treatment. In another study, recovery occurred in 90% of non-thrombocytopenic dogs but in only 63% of thrombocytopenic dogs.[60]

Chloramphenicol

Severe aplastic anemia has been reported as an idiosyncratic reaction in humans treated with chloramphenicol but has not been reported in dogs given therapeutic doses.[64] One apparent idiosyncratic reaction was reported.[31] This dog had a moderate non-regenerative anemia with large numbers of siderocytes and ringed sideroblasts. This response suggests a reversible dysmyelopoiesis perhaps secondary to drug-induced mitochondrial damage.

Cephalosporins

Certain cephalosporins have been associated with several types of hematologic dyscrasias.[9,18] High-dose or prolonged administration of cephalosporins can induce agranulocytosis, thrombocytosis, and a positive direct Coombs' test.[13] Approximately half of dogs given high doses of cefonicid or cefazedone intravenously developed pancytopenia within 6–10 weeks after initiation of treatment.[9,18] The mechanism appears to be complex. In one study, the presence of anti-RBC, anti-neutrophil, and anti-platelet antibodies was consistent with immune-mediated destruction.[9] Cephalosporins also induce alteration in the bone marrow. Granulocytic and erythroid maturation arrest have been reported in dogs treated with cephalosporins.[18] The most prominent ultrastructural change in bone marrow was mitochondrial damage to hematopoietic and non-hematopoietic cells.[18] The hematologic dyscrasia resolved rapidly after discontinuing the drug. Aplastic anemia associated with persistent suppression of hematopoietic stem cell activity also has been reported when dogs were administered high doses of cefazedone.[13] Further, cefoperazone, cefamandole, and moxalactam inhibit synthesis of vitamin K-dependent clotting factors and can lead to hypoprothrombinemia and a resultant coagulopathy.[13]

Anticonvulsants

Phenobarbital/Primidone

Phenobarbital and primidone therapy have been associated with several types of hematologic dyscrasias in dogs. Because primidone is metabolized to phenobarbital, the mechanism of toxicity may be similar for both drugs.[41] The mildest hematologic disorder is neutropenia and thrombocytopenia.[37,59,65] The presence of granulocyte hyperplasia in bone marrow indicates that the neutropenia is due to destruction of mature granulocytes. A more frequent ADR is myelonecrosis or myelofibrosis (Fig. 16.3).[65,71] Dogs with myelonecrosis are frequently bicytopenic or pancytopenic. Bone marrow is characterized by multifocal areas of coagulation-type necrosis with variable degrees of myelofibrosis present.[71] Dogs with myelofibrosis, without concurrent necrosis, frequently have a severe non-regenerative anemia. The myelofibrosis may represent the chronic stage of myelonecrosis.

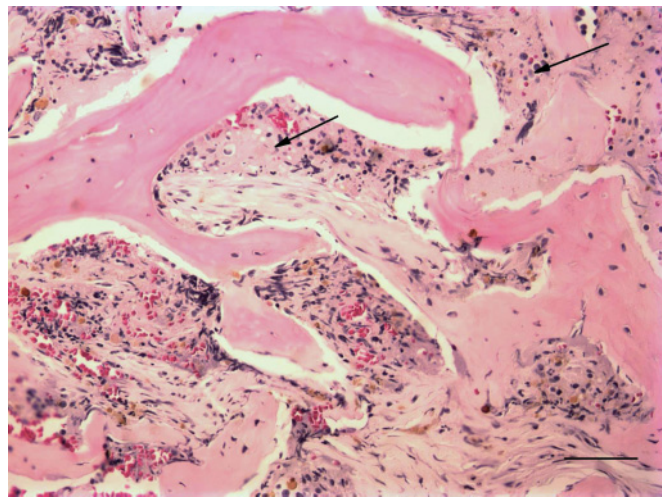

FIGURE 16.3 Bone marrow core biopsy from a dog treated with therapeutic doses of phenobarbital. Note the presence of coagulation-type necrosis (arrows) and myelofibrosis. Hematoxylin & Eosin stain; bar, 200 µm.

Phenytoin

Long-term administration of phenytoin to dogs results in RBC macrocytosis, neutropenia, thrombocytopenia, and neutrophil hypersegmentation.[11] These changes were thought to be due to folate deficiency; however, folate deficiency does not cause RBC macrocytosis in dogs.[11] One dog undergoing long-term phenytoin therapy developed a severe normocytic non-regenerative anemia associated with severe myelofibrosis in the bone marrow.[71]

Antiparasitics

Several antiparasitic drugs have been associated with Type B ADR. Levamisole-induced thrombocytopenia and direct Coombs' positive hemolytic anemia have been reported in several dogs.[3,4] All dogs had hyperplasic bone marrow and recovered after discontinuing levamisole treatment. Albendazole toxicity has been documented in one dog.[57] The dog had pancytopenia and an aplastic bone marrow, but recovered within 1 week after discontinuing treatment. Three dogs treated with metronidazole had coagulation-type myelonecrosis.[65] All dogs had pancytopenia but recovered after discontinuation of treatment. Fenbendazole administration has been associated with bone marrow coagula-

tion-type necrosis.[65] One dog had pancytopenia after repeated weekly administration of the organic arsenical, thiacetarsamide for treatment of demodectic mange.[62] The bone marrow was hypercellular and the dog recovered after discontinuation of treatment. However, the dog subsequently developed bone marrow RBC aplasia and died.

Cardiovascular

Several cardiovascular drugs have been associated with Type B ADR. Amiodarone is an antiarrhythmic drug that has been associated with hemolytic anemias and hepatopathies in dogs.[12,35,38] Hematologic alterations were characterized by thrombocytopenia and positive direct Coombs' test results with or without the presence of anemia. Affected dogs recover when treatment is discontinued. One dog developed pancytopenia and aplastic bone marrow after 18 months of continuous administration of captopril for treatment of a heart murmur.[35] Withdrawal of the drug and treatment of the dog with human granulocyte-colony stimulating factor and erythropoietin resulted in prompt hematologic recovery. In vitro studies using canine bone marrow cell cultures indicate that the toxic effects of captopril are dependent on a reactive thiol group.[28] This thiol group reacts with copper to generate hydrogen peroxide which is toxic to canine neutrophil progenitor cells. One dog developed neutropenia and anemia after prolonged administration of quinidine gluconate.[69] Three days after discontinuing the drug the neutrophil count returned to normal and bone marrow cellularity was normal.

Others Drugs

Many dogs given human erythropoietin for a prolonged period of time develop antibodies to the recombinant protein.[17,51] In addition to blocking the biologic effects of human erythropoietin, the antibody cross-neutralizes endogenous canine erythropoietin resulting in profound erythroid hypoplasia.[17,51] The onset of the immune response is typically 2–3 months after initiation of treatment. Administration of recombinant canine erythropoietin to dogs suffering from recombinant human erythropoietin-associated red cell aplasia does not appear to be effective in resolving the anemia in dogs with blocking antibodies.[51]

Several dogs given mitotane or colchicine were reported to have coagulation-type myelonecrosis consistent with drug-induced bone marrow hematotoxicity.[65] Withdrawal of drug treatment resulted in hematologic recovery.

ADVERSE DRUG REACTIONS IN CATS

Antineoplastics

Neutropenia and thrombocytopenia are frequently dose-limiting factors in chemotherapy.[16] As in other species, rapidly proliferating progenitor and proliferative cells in bone marrow are susceptible to destruction by chemotherapeutic agents. Beyond cytopenias, dysplastic hematopoietic cells and atypical mitotic figures (i.e. secondary dysmyelopoiesis) are frequently found in bone marrow.[67] Doxorubicin administration to cats has been associated with poikilocytosis including the presence of ovalocytes, echinocytes, schistocytes, and keratocytes.[45]

Azathioprine

Cats appear to be highly sensitive to azathioprine-induced bone marrow suppression. Of five cats given 2.2 mg/kg of azathioprine on alternate days, four developed multiple cytopenia.[7] Azathioprine-induced bone marrow suppression in humans has been associated with homozygosity for the gene for thiopurine methyltransferase.[7] This enzyme plays an important role in the catabolism of azathioprine.

Propylthiouracil/Methimazole

Severe Type B ADR, consisting of agranulocytosis and severe thrombocytopenia, has been reported in 8.6% of hyperthyroid cats treated with propylthiouracil and 3.8 % of cats treated with methimazole.[48,49] Mild hematologic alterations, including eosinophilia, lymphocytosis, and mild leukopenia, were reported in 16.4% of cats treated with methamisole.[49] Clinical signs develop within 1–2 months after initiation of treatment and include lethargy, weakness, anorexia, and platelet-related bleeding diathesis. Many affected cats were fluorescent antinuclear antibody test and direct Coombs' test positive, indicating that the hematologic dyscrasia was immune-mediated. These hematologic abnormalities resolved within 2 weeks after discontinuing methimazole treatment.

Griseofulvin

Griseofulvin is a fungistatic antibiotic used for treatment of mycotic diseases.[33] Neutropenia or panleukopenia occur as an idiosyncratic reaction to griseofulvin in cats.[33,53] In most cases, this occurs several weeks after initiation of griseofulvin treatment.[33] The bone marrow is typically hypoplastic. The majority of cats recover after treatment is discontinued.

Albendazole

Albendazole toxicity has been reported in two cats.[57] Both animals were pancytopenic but had hypercellular bone marrow. Both cats had rapid hematologic recovery within 1 week after discontinuing treatment.

Azidothymidine

Azidothymidine is a dideoxynucleoside derivative reverse transcriptase inhibitor used for treatment of

feline immunodeficiency virus and feline leukemia virus infections. A transient or progressive nonregenerative anemia develops after several weeks of treatment.[32] The anemia is primarily the result of bone marrow erythroid hypoplasia but Heinz body formation may also be a contributing factor.

ADVERSE DRUG REACTIONS IN HORSES

Drugs associated hematologic ADRs in horses include penicillin and trimethoprim-sulfamethoxazole-associated immune-mediated hemolytic anemias (IMHAs), heparin-associated thrombocytopenia and RBC agglutination, dimethyl sulfoxide-L-tryptophan-indole, and phenothiazine-induced hemolysis, and phenylbutazone-associated aplastic anemia.

Drug-induced Immune-mediated Hemolytic Anemia

Penicillin administration to horses has been associated with acute allergic reactions and with IMHA.[10,56] These allergic reactions consist of acute anaphylaxis, collapse, shaking, urticaria, fever, leukopenia, eosinophilia, thrombocytopenia, and anemia, and are thought to be an adverse response to procaine.[10] Penicillin and its metabolites bind firmly to the RBC membrane. These penicillin-protein complexes appear to frequently induce detectable antibody formation; however, the anti-penicillin antibodies tend to be IgM, are present in low titer, and do not cause hemolysis.[10,56] Anti-penicillin antibodies, that induce immune-mediated hemolytic anemia, tend to be IgG.[10]

One horse developed IMHA during treatment with trimethoprim-sulfamethoxazole.[58] Prompt recovery after withdrawal of drug treatment incriminated the drug in the causation of the anemia.

Drug-induced Hemolysis

Phenothiazine poisoning has been associated with hemolytic anemia in a horse.[6] Although this was thought to be an oxidant-induced hemolysis, few Heinz bodies were seen.

Oral or intravenous administration of L-tryptophan or indole to ponies results in acute hemolytic anemia and hemoglobinuria.[46,47] Indole is the major metabolite of L-tryptophan that induces hemolysis. Indole has lipophilic properties and interacts with RBC membranes, perhaps explaining their hemolytic properties. However, some ponies treated with indole had Heinz bodies present in RBCs suggesting a possible Heinz body anemia.

Rapid intravenous administration of a 40% solution of dimethyl sulfoxide results in intravascular hemolysis in horses.[2] The hemolytic effects of dimethyl sulfoxide appear to be concentration dependent and administration of a more dilute solution significantly reduces or eliminates the hemolysis.[2] The mechanism of dimethyl sulfoxide-induced hemolysis is uncertain but appears to involve potassium leakage from erythrocytes before hemolysis.

Heparin

Unfractionated heparin has been reported to cause marked thrombocytopenia as an idiosyncratic reaction in human patients within 4–14 days after initiation of treatment.[29] Heparin appears to exert a direct effect on platelets causing platelet activation and aggregation, and also induces anti-platelet antibodies. In horses, the most frequent complication associated with heparin administration is anemia.[19] This is associated with RBC agglutination. Heparin may act as a hapten for anti-RBC antibodies.[44] Rapid increases in hematocrit occur after discontinuing heparin treatment. Because the increase in hematocrit exceeds the expected capacity of the bone marrow to replace erythrocytes, it is suspected that heparin causes in vivo agglutination of RBCs in the microvasculature.[44] Thrombocytopenia, fatal hemorrhage, and swelling at injection sites have also been reported. In humans, the thrombocytopenia is immune-mediated.

Acronyms and Abbreviations

DDT, chlorophenothane; DNA, deoxyribonucleic acid; EDTA, ethylenediaminetetraacetic acid; IMHA, immune-mediated hemolytic anemia; ppm, parts per million; RBC, red blood cell.

As a rapidly proliferating tissue, bone marrow is sensitive to toxic injury. Sites most vulnerable to injury include progenitor and proliferating hematopoietic cells and the microvasculature. Microvascular injury results in altered vascular permeability and manifests as edema, hemorrhage, inflammation, or ischemia.[42] Myelonecrosis occurs when ischemia is severe and in the chronic stage necrotic areas may become fibrotic.[16,39]

Hematopoietic cell injury can result in hematopoietic cell death at various stages of maturation and arrested development with dysplastic changes.[32] Hematopoietic cell destruction usually results in a hypocellular marrow. In the acute stages of hematopoietic injury, myelotoxic changes can be seen. These are best observed in the cytoplasm of metamyelocytes and band neutrophils. These cells have a foamy basophilic cytoplasm that results from the clumping of RNA. Some cells may contain Dohle bodies.[32] Drugs toxic to bone marrow may induce distinct cytoplasmic vacuoles (Fig. 16.1, p. 100).[32] Toxic changes in the nucleus are less frequent but consist of hypersegmention or bizarre segmentation of neutrophils. Donut-shaped nuclei are abnormal in dogs and primates but are a normal finding in rodents. Arrested maturation frequently is characterized by cytopenias in the blood, a cellular bone marrow with arrested development, and dysplastic changes in one or more cell lines. Dysplastic changes can be seen as nuclear or cytoplasmic maturation defects. Nuclear maturation defects result from interference with DNA synthesis and include megaloblastosis, large cell size, atypical mitotic figures, fragmented nuclei, and binucleation. Dysplastic cytoplasmic changes are most frequently seen in erythroid precursor cells where hemoglobin production is inhibited. Bone marrow is characterized by large numbers of small metarubricytes that frequently have indistinct cytoplasmic margins.

MICROVASCULAR INJURY

The bone marrow microvasculature is susceptible to toxic injury.[36] This is supported by experimental studies in which mouse bone marrow was evaluated after injection of endotoxin and rabbit bone marrow was evaluated after saponin injection.[19,48] Early ultrastructural lesions in bone marrow are characterized by degeneration of sinusoidal endothelial cells. Later lesions consisted of dilated sinusoids, interstitial edema, hemorrhage, and necrosis. Chronic lesions consisted of myelofibrosis.

Similar lesions have been described in humans and a variety of animal species.[4,10,23,36,44] Acute vascular

injury is accompanied by dilated sinusoids, interstitial edema, and hemorrhage.[10,36] Acute inflammation is characterized by exudation of fibrin that may be accompanied by an infiltration of neutrophils.[10,44] Vascular injury also results in varying degrees of ischemia. When severe, ischemia induces ischemic necrosis. Depending on which change is most prominent, the pathologic process may be defined as acute inflammation or as myelonecrosis.[39,44]

Myelonecrosis

Myelonecrosis is usually associated with bone marrow ischemia.[16,39] Ischemia can be enhanced if anemia, hypoxemia, or hypoperfusion is present. Acute severe hematopoietic cell injury can also result in myelonecrosis. Myelonecrosis is difficult to appreciate in bone marrow aspiration smears. The necrotic marrow smears unevenly, resulting in irregular elongated clumps of necrotic cells. Microscopically, the slides have a diffuse amorphous eosinophilic background and cells stain poorly. Many cells are lysed and in others nuclei appear smudged and the cytoplasm is vacuolated with indistinct borders. In histopathologic sections, myelonecrosis can appear as multifocal areas of coagulation-type necrosis or as individual cell necrosis (Fig. 17.1).[39] Coagulation-type necrosis appears as a central area of karyorrhectic and pyknotic cells enmeshed in an amorphous eosinophilic background material. Macrophages are frequently increased in number. Coagulation-type necrosis occurs frequently in dogs but is rarely seen in cats.[40] Individual cell necrosis is observed in approximately 8% of cat clinical bone marrow specimens and is characterized by large numbers of degenerating, frequently anuclear, hematopoietic cells and increased pink amorphous background material (Fig 17.2).[40] In the acute stage of myelonecrosis, necrosis is frequently accompanied by acute inflammation or hemorrhage, whereas in subacute myelonecrosis, necrosis is associated with phagocytic macrophages presumably removing the necrotic cells. In chronic myelonecrosis, reticulin or collagen myelofibrosis is frequently present.

Frequent causes of myelonecrosis in cats and dogs include immune-mediated hemolytic anemia (IMHA), sepsis, and leukemia/lymphoma. Other causes identified in dogs are idiopathic causes, systemic lupus erythematosus, disseminated intravascular coagulopathy, and drug treatments.[39,41] Drugs associated with myelonecrosis include estradiol, phenobarbital, carprofen, mitotane, colchicine, metronidazole, fenbendazole, cephalosporins, and chemotherapeutic agents including cyclophosphamide and vincristine (see Chapter 16).

The mechanisms responsible for myelonecrosis have not been extensively investigated. In immune-mediated diseases and disseminated intravascular coagulopathy, thrombotic events may induce marrow ischemia. The necrosis associated with systemic lupus erythematosus in humans has been attributed to the presence of antiphospholipid antibodies. In sepsis, endotoxin or other bacterial toxins may induce sinusoidal injury as well as being toxic to hematopoietic precursor cells. Leukemic cells in bone marrow frequently outgrow their blood supply resulting in myelonecrosis.

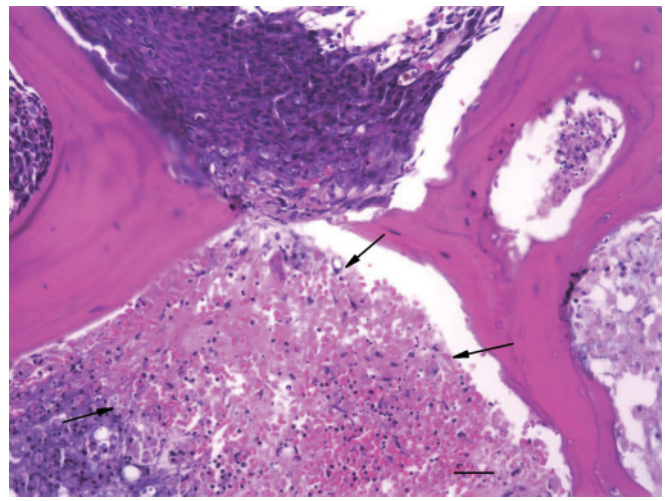

FIGURE 17.1 Coagulation necrosis (arrows) associated with a metastatic pancreatitic carcinoma (top) in a bone marrow core biopsy specimen from a dog. Hematoxylin & Eosin stain; bar, 200 µm.

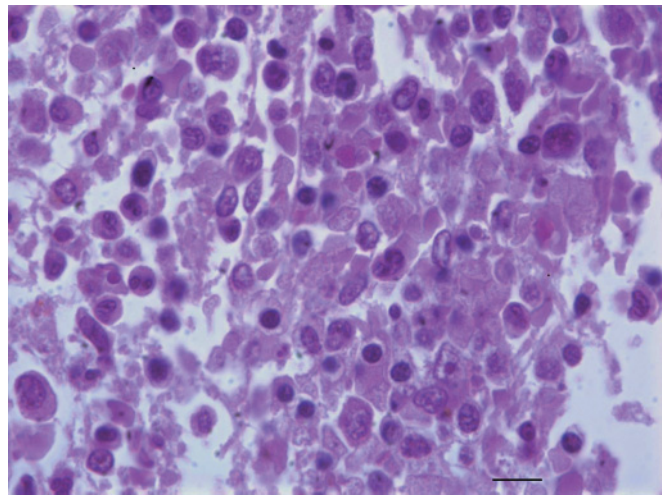

FIGURE 17.2 Individual cell necrosis in a core biopsy section from a cat with non-regenerative immune-mediated hemolytic anemia. Note the presence of many anuclear cells and cellular debris. Hematoxylin & Eosin stain; bar, 20 µm.

Dogs and cats with myelonecrosis have various combinations of non-regenerative anemia, leukopenia, and thrombocytopenia.[39,41] In some instances the cytopenias may be the result of myelonecrosis whereas, in other animals, they are the result of a combination of the primary disease process and myelonecrosis. Treatment and prognosis for myelonecrosis should be based on the cause of the necrosis.[39,41] In general, if the primary condition can be successfully treated, the prognosis for complete recovery is good.[39]

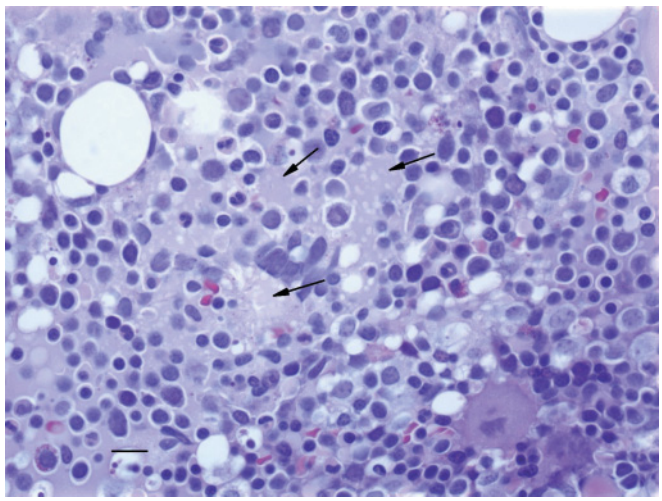

FIGURE 17.3 Interstitial edema (arrows) in a bone marrow core biopsy section from a dog with immune-mediated hemolytic anemia. Hematoxylin & Eosin stain; bar, 20µm.

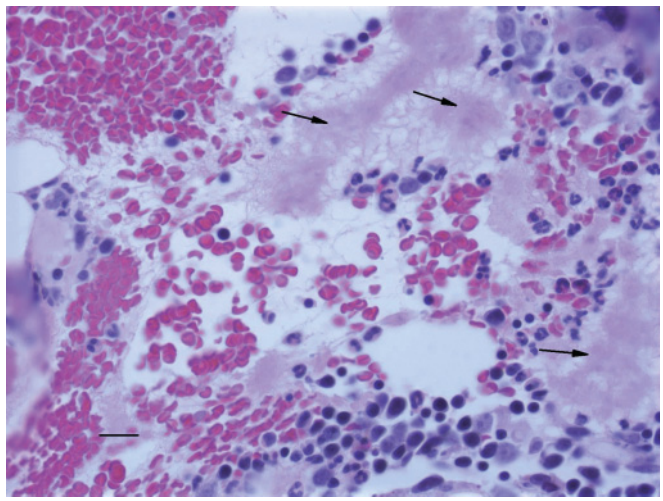

FIGURE 17.4 Fibrinous inflammation in a bone marrow core biopsy section from a dog with immune-mediated hemolytic anemia. Note the presence of fibrin (arrows), and hemorrhage. Hematoxylin & Eosin stain; bar, 20µm.

Acute Inflammatory Response

Acute inflammation in bone marrow, like myelonecrosis, is thought to result from acute injury to bone marrow sinusoids.[10] These changes are not usually seen in bone marrow aspirates but are visible in bone marrow sections. Acute inflammation has been observed in approximately 3 % of canine clinical bone marrow specimens.[42] The initial lesion in bone marrow is altered vascular permeability. Histopathologic alterations include dilated or congested sinusoids, interstitial edema, and hemorrhage. Interstitial edema is seen as amorphous pink proteinaceous material between hematopoietic cells (Figs. 17.3 and 17.4).[42,43] Pathologic hemorrhage must be differentiated from artifactual hemorrhage induced by the biopsy procedure. When the sample is obtained by needle biopsy, artifactual hemorrhage is frequently present on either end of the biopsy specimen and may be present on the edges of the specimen. Pathologic hemorrhage should be observed within the hematopoietic space away from the ends or edges of the specimen and should be accompanied by evidence of vascular alterations or interstitial edema. These alterations cannot be reliably evaluated in bone marrow specimens obtained post-mortem. Dilated sinusoids and altered permeability can occur as agonal changes or perhaps be induced by administration of euthanasia solution.

Microvascular injury can also result in exudation that is characterized by multifocal fibrin deposits or by multifocal infiltrates of neutrophils (Fig. 17.5).[42,43] Fibrin deposits are particularly prominent in cat bone marrow.[41,43] Fibrin appears as pink fibrillar material. The presence of fibrin can be confirmed by selective staining with Frazier-Lundrum stain.[44] Frequently, these fibrin deposits contain variable numbers of segmented neutrophils. In cases of sepsis, such as septicemia or endocarditis, discrete microabscesses may be present in bone marrow (Fig 17.4).[42] These structures may represent septic thrombi.

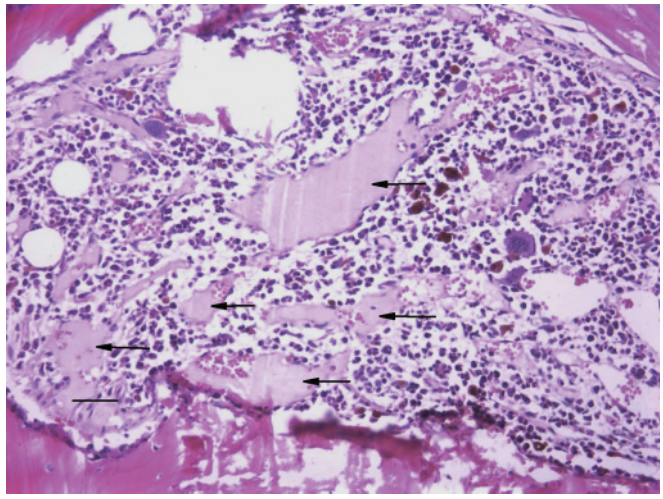

FIGURE 17.5 Sinusoidal dilation (arrows) in a bone marrow core biopsy section from a dog with bacterial sepsis. Also note the presence of large numbers of segmented neutrophils consistent with acute inflammation. Hematoxylin & Eosin stain; bar, 100µm.

Causes of acute inflammation in dog bone marrow include nonregenerative IMHA, systemic lupus erythematosus, and infectious diseases; in cat they include IMHA and infectious diseases.[41-43] Therefore, identifying acute inflammation in bone marrow should prompt a search for these conditions.

In horses and cattle, acute inflammatory responses in bone marrow have been associated with bacterial sepsis.[44] Acute inflammation has been identified in septicemic foals. Lesions are characterized by large multifocal infiltrates of neutrophils resembling microabscesses. Neutrophils in the lesions may appear degenerate and

the centers of the microabscesses may be necrotic. Other lesions included dilated sinusoids, hemorrhage, and fibrin deposition. Bacteria are usually not seen in bone marrow sections but can be cultured from bone marrow in some cases. Perivascular neutrophilic infiltrates in bone marrow were reported in a steer with chronic pneumonia caused by *Mannheimia haemolytica*.[44] Other cattle with a diagnosis of bacterial pneumonia and septicemia had fibrin deposits in bone marrow.

Eosinophilic inflammatory responses are less well defined. A cow and a sheep with fibrinous inflammation and large numbers of eosinophils in bone marrow have been described.[44] The cow had bacterial enteritis and the sheep had a systemic vasculitis of unknown origin.

HEMATOPOIETIC CELL INJURY

A variety of heavy metals, chemicals, drugs (see Chapter 16), toxins, and infectious agents (see Chapter 19) injure hematopoietic precursor cells. Hematopoietic cell injury frequently results in hypocellular marrow and if all cells lines are affected can result in aplastic anemia. Some drugs and toxins induce dysplastic changes that can result in peripheral cytopenias with normocellular or hypercellular bone marrows.

Heavy Metals

Several heavy metals, including lead, mercury, and arsenic cause bone marrow alterations in addition to significant toxic changes in other tissues.

Lead

Lead poisoning occurs in domestic species, including dogs, cats, and cattle, as well as in waterfowl and some exotic species. The source of lead exposure varies by species. In dogs and cats, lead-containing paints; in cattle, discarded batteries and industrial contamination of pastures; and in waterfowl, lead shot are the major sources of exposure.[1,21,24] In dogs and cats, anemia can be associated with chronic lead poisoning. In dogs, basophilic stippling and metarubricytosis have been described as classical features. However, these changes appear to be infrequent findings. Collection of blood in ethylenediaminetetraacetic acid (EDTA) may cause the stippling to disappear.[45] The pathogenesis of the anemia involves a shortened red blood cell (RBC) lifespan and dyserythropoiesis. Lead may shorten RBC survival by inhibiting membrane ATPase.[15] Lead poisoning in dogs is also associated with an increase in the myeloid-to-erythroid ratio and dyserythropoiesis. Lead interferes with several enzymes in the heme synthesis pathway and inhibits pyrimidine 5′-nucleotidase that is involved in depolymerization of reticulocyte ribosomal RNA. Resultant retention of RNA in reticulocytes may be responsible for the basophilic stippling seen in some animals.

Mercury

Mercury has hematotoxic and immunotoxic effects.[5] Fish, waterfowl, and shore birds are at greatest risk of exposure to environmental mercury contaminants.[37] Exposure of egrets or ducks to low dose methylmercury results in anemia with increased bone marrow cellularity.[37] This suggests a hemolytic anemia. Hemolysis may be due to the capacity of mercury to inhibit several RBC enzymes including glutathione reductase, glutathione-6-phosphate dehydrogenase, and aectylcholinesterase. Mercury also induces idiosyncratic immune-mediated hematologic disorders. Exposure of egrets to high dose methylmercury results in bone marrow hypoplasia and depletion of lymphocytes in lymph nodes and thymus.[37] Mercury has been shown to be cytotoxic to hematopoietic cells and to cause dysmyelopoiesis in laboratory animals.[6]

Arsenic

Arsenic poisoning causes both hemolytic anemia and dyserythropoiesis, and has genotoxic effects. Arsenic in the form of arsine gas is a potent hemolytic agent; however, the main source of exposure is to humans in industrial settings.[18] In the environment, arsenic exists in inorganic forms and the main source of exposure is though contaminated drinking water.[2] Severe poisoning in humans results in marked anemia, and in some cases neutropenia and thrombocytopenia.[8] Arsenic poisoning causes marked dyserythropoiesis characterized by karyorrhexis, megaloblastosis, and multinuclearity. This is thought to result from a direct toxic effect on DNA synthesis that results in altered nuclear division.[8,22] Results of several studies conclude that inorganic arsenic has genotoxic effects in a variety of laboratory animal species.[2] These conclusions are based on results of studies evaluating the presence of micronuclei and DNA strand breaks in bone marrow.

Chemicals

A large variety of chemicals have the potential to alter hematopoiesis depending on the dose and duration of exposure. A few examples of chemicals with relatively high hematotoxic potential will be discussed here.

Benzene

Benzene and its metabolites are highly toxic to the hematopoietic system.[31,47] Benzene is widely used as a solvent in the manufacture of drugs, chemicals, dyes, and explosives. Because of work-related exposure, benzene toxicity is primarily a problem in humans. Benzene has both cytotoxic and genotoxic effects on the hematopoietic system. A variety of hematologic dyscrasias have been observed including hemolytic anemia, bone marrow hyperplasia, leukopenia, dysmyelopoiesis, aplastic anemia, myelodysplastic syndromes, leukemia, and lymphoma.[31,47] Concentrations as low as 100 parts per million (ppm) have been associated with

leukopenias in approximately one-third of exposed workers.[14]

Experimental inhalation or injection of benzene produces aplastic anemia in rabbits and mice.[13] The aplasia is preceded by dysmyelopoiesis. Despite the typical aplastic marrow and pancytopenia, stem cell numbers in marrow are normal suggesting that committed progenitor cells rather than stem cells are damaged by benzene. However, benzene-treated lethally irradiated marrow is not reconstituted by transplantation of normal marrow. This suggests that benzene damages the marrow microenvironment.

Chlorinated Hydrocarbons

A variety of chlorinated hydrocarbons are toxic to bone marrow and have the potential to cause clinical disease. These drugs include carbon tetrachloride, hexachlorophene, lindane, chlordane, chlorobenzene, chlorophenothane (DDT), chlorinated dioxins, pentachlorophenol, and trichloroethylene. Some of these compounds, including DDT, lindane (i.e. gamma-benzene hexachloride), and pentachlorophenol, are derivatives of benzene. Chlordane, DDT, lindane, and pentachlorophenol have been implicated as causes of aplastic anemia in humans and trichloroethylene has been implicated as a cause of aplastic anemia in cattle (see Chapter 39).[9,30,33] Although the pathogenesis of the injury is uncertain, these compounds have multiple injurious effects on hematopoietic tissue. Chlorinated hydrocarbons appear to be toxic to primitive hematopoietic cells. Exposure of mice to various doses of lindane transiently reduced the number of pleuripotent stem cells and progenitor cells.[17] In addition, residual long term progenitor cell depletion has been demonstrated.[17] Dysmyelopoiesis is also a frequent finding associated with chlorinated hydrocarbon toxicity. Many chlorinated hydrocarbons also have genotoxic effects. The genotoxic potential of 1,1-dichlorethane has been evaluated in Swiss-Webster mice by evaluation of mitotic index, micronuclei, and chromosomal aberrations.[28] A dose-related increase in the number of chromosomal aberrations and micronuclei formation was observed.

Many fatal cases of aplastic anemia in cattle in Minnesota in the 1950s were traced to feeding of trichloroethylene-extracted soybean oil meal.[30] Although no longer used for this purpose, trichloroethylene is widely used as a solvent.[11] In experimental studies, tetrachloroethylene-treated mice had a reduction in erythroid and granulocytic progenitor cells but no decrease in pleuripotent stem cells following inhalation exposure for 7.5 weeks.[34] Trichloroethylene has been shown to inhibit delta-aminolevulinate dehydratase, an enzyme involved in heme synthesis, in rats.[11] Trichloroethylene also appears to have genotoxic effects.[38]

Chlorinated dioxins cause anemia and progressive leukopenia in a variety of species including chickens, primates, and rats.[26] Chickens appear to be highly sensitive and develop clinical signs after ingestion of feeds containing fats industrially contaminated with dibenzo-*p*-dioxin. Administration of this material to chickens, primates, and rats resulted in hypoplasia of bone marrow and lymphoid tissue in all three species.[26]

Toxins

Toxins that are directly cytotoxic to hematopoietic precursor cells include mycotoxins and bracken fern. Myelotoxicity results in hypoplastic or aplastic changes in bone marrow.

Mycotoxins

A variety of mycotoxins produce aplastic anemia in animals and people. Mycotoxin exposure occurs with ingestion of food contaminated with fungal organisms. For animals, this is frequently the result of ingestion of grain that has been allowed to become damp during storage. Aplastic anemia has been documented in horses and cattle ingesting feed contaminated with *Stachybotrys alternans*. Many other mycotoxins, including T-2 mycotoxin, trichothecene mycotoxin, trichothecene vomitoxin, ochratoxin, and zearalenone, produce toxicity in humans.[7] These toxins appear to be directly cytotoxic to a variety of cells including hematopoietic precursor cells and lymphocytes. As a result, many mycotoxins cause bone marrow hypoplasia/aplasia and lymphocyte depletion.[12] Depletion of stem cells and granulocyte-macrophage progenitor cells was detected when mice were exposed to ochratoxin.[3] A marked increase in apoptotic hematopoietic cells was detected in bone marrow after injection of T-2 mycotoxin into mice.[35] The effect of mycotoxins on bone marrow and the immune system appears to be amplified by exposure to lipopolysaccharide. Genotoxic effects of some mycotoxins have also been documented in mouse studies.

Bracken Fern

Bracken fern (*Pteridium aquilinum*) is one of the most widely distributed plants on earth. Animals repeatedly ingesting bracken fern develop aplastic anemia (see Chapter 39).[20] Cattle, horses, sheep, and pigs may be affected. The major toxin in bracken is ptaquiloside.[46] Ptaquiloside is a thiaminase.[46] After repeated exposure and thiamine depletion, cattle tend to develop aplastic anemia. This results in anemia, hemorrhage, and increased susceptibility to infection. Other species develop neurological signs due to polioencephalomalacia.[20]

Chronic enzootic hematuria in cattle has also been linked to development of urinary bladder neoplasia after prolonged ingestion of bracken fern.[25] Metabolites of ptaquiloside are carcinogenic and induce bladder and intestinal carcinomas in cattle and other farm animals as well as in laboratory animals.[25,29] Lymphocytic leukemia and pulmonary tumors have also been detected in mice exposed to ptaquiloside.[27]

CHAPTER 18

Chronic Inflammation and Secondary Myelofibrosis

DOUGLAS J. WEISS

Chronic Inflammation
- Lymphocytosis
- Plasmacytosis
- Lymphoid Aggregates
- Macrophage Proliferation
  - Reactive
  - Hemophagocytic syndrome (see Chapter 45)
  - Malignant histiocytosis (see Chapter 73)
  - Acute monocytic and myelomonocytic leukemia (see Chapter 67)
  - Chronic myelomonocytic leukemia (see Chapter 65)
  - Lipid storage disorders
- Granulomatous Inflammation

Secondary Myelofibrosis
Osteosclerosis
Serous Atrophy of Fat/Gelatinous Transformation

Acronyms and Abbreviations

FeLV, feline leukemia virus; IMHA, immune-mediated hemolytic anemia; PRCA, pure red cell aplasia.

Chronic bone marrow injury can occur as a sequela of acute bone marrow injury or after prolonged or recurrent exposure to a toxic agent.[22] Acute injuries that incite a chronic bone marrow response include myelonecrosis and acute inflammatory responses (see Chapter 17).[34,38] These chronic responses in bone marrow include chronic inflammatory responses (e.g. lymphocytosis, plasmacytosis, macrophage proliferation, and granulomatous inflammation), secondary myelofibrosis, osteosclerosis, osteomyelitis, and serous atrophy of fat/gelatinous transformation.[2,10,31,42] As with acute bone marrow injury, many of these lesions are difficult or impossible to detect in bone marrow aspirates. Therefore it is essential to evaluate both bone marrow aspirates and histopathologic sections to detect chronic bone marrow injury.

CHRONIC INFLAMMATION

Lymphocytosis

Lymphocyte numbers in bone marrow vary with species and age. Rodents have relatively large numbers of lymphocytes, whereas domestic animals, avian species, and primates typically have less than 10% lymphocytes in cellular bone marrow specimens.[12,30] However, reference intervals reported for the percentage of lymphocytes in cat bone marrow vary with most indicating that up to 15% should be considered normal.[19,35] In healthy animals, most lymphocytes in bone marrow are small lymphocytes.[12] Benign lymphocytosis is the most frequent type of chronic inflammation in cats but occurs infrequently in dogs.[36,37] In a retrospective study of 203 consecutive feline bone marrow reports, lymphocytosis (defined as lymphocytes >15% of all nucleated cells) was observed in 15.6% of the specimens.[36] In some cats, lymphocyte numbers exceeded 50% of all nucleated cells in bone marrow.[35] Greater than 80% of cats with lymphocytosis had a diagnosis of non-regenerative immune-mediated hemolytic anemia (IMHA) or pure red cell aplasia (PRCA).[35,36] Differentiating benign lymphocytosis from chronic lymphocytic leukemia can be problematic. Lymphocyte distribution and phenotype may be useful in differentiating these conditions. Benign lymphocytes are frequently arranged in small multifocal aggregates in bone marrow, whereas, in chronic lymphocytic leukemia, they are diffusely distributed throughout the marrow.[35,43] Immunophenotyping of a few cases has revealed that most lymphocytes in reactive lymphocytosis are B cells, whereas malignant lymphocytes in chronic lymphocytic leukemia are usually T cells.[35,43]

Unlike the cat, only 1% of canine clinical bone marrow specimens had lymphocytosis.[37] These cases were associated with immune-mediated diseases including IMHA and PRCA. Therefore, at least in the Northern USA, bone marrow lymphocytosis in both cats and dogs correlates with immune-mediated hematologic diseases.

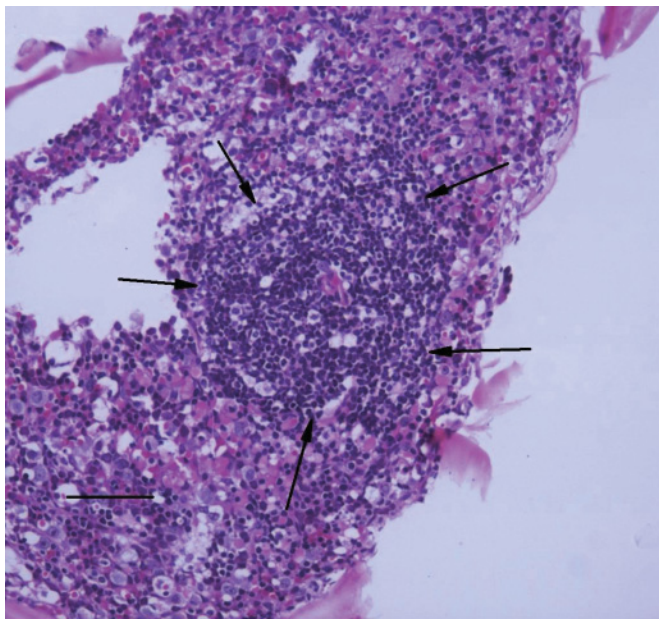

FIGURE 18.1 Lymphoid aggregate (arrows) in a bone marrow core biopsy section from a cat with nonregenerative immune-mediated hemolytic anemia. Hematoxylin & Eosin stain; bar, 200 µm.

Plasmacytosis

Plasmacytosis is usually evaluated subjectively in bone marrow aspirates or core biopsy specimens because of their low numbers and uneven distribution.[12] Plasmacytosis has been observed in approximately 10% of canine clinical bone marrow specimens and in 6% of cat bone marrow specimens.[36,37] Plasmacytosis in cats has been associated with IMHA, PRCA, immune-mediated thrombocytopenia, and feline infectious peritonitis. Plasmacytosis in dog bone marrow has been associated with IMHA, PRCA, and immune-mediated thrombocytopenia. Other causes of plasmacytosis that should be considered include *Ehrlichia* and *Leishmania* infections.

Lymphoid Aggregates

In a review of 17 species of mammals, lymphoid aggregates were identified only in humans and cats.[13,14] Lymphoid aggregates are small clusters of mature small lymphocytes with no evidence of organized structure (Fig. 18.1). However, results of large retrospective studies indicate that lymphoid aggregates occur infrequently in cat and dog bone marrow core biopsy specimens.[36,37] When present, lymphoid aggregates correlate with the presence of immune-mediated hematologic diseases or other chronic systemic immunologic stimulation.[35,41]

Macrophage Proliferation

The presence of increased numbers of macrophages in bone marrow is associated with a variety of disorders. Macrophages can range from relatively immature cells with minimal phagocytosis to mature cells that have a foamy cytoplasm or contain cells, cytoplasmic debris, or hemosiderin. Four general types of mononuclear phagocyte proliferations can be observed in bone marrow. Differentiating these types can be problematic and may require the use of flow cytometry or immunophenotyping.[33] The four types of proliferation include reactive macrophage proliferation, reactive hemophagocytic syndrome[16,39] (see Chapter 45), lipid storage diseases, and malignant proliferations of monocytes (acute monocytic or myelomonocytic leukemia, chronic myelomonocytic leukemia; see Chapters 65 and 67), and dendritic cells (malignant histiocytosis, see Chapter 73). Reactive macrophage proliferations are macrophages responding to a need to remove necrotic debris or to infectious agents. Increased necrotic debris is present in the subacute stages of myelonecrosis and in conditions of ineffective hematopoiesis.[35] Ineffective hematopoiesis is present in instances of myelodysplastic syndromes, immune-mediated hematologic diseases, and in some leukemias. In each of these conditions the presence of increased numbers of macrophages is commonplace.

A variety of infectious agents cause reactive macrophage proliferations in bone marrow. These vary with the species and geographic distribution of infectious organisms. In dogs, leishmaniasis, parvovirus infection, and deep fungal infections have been associated with macrophage proliferations (see Chapter 19).[4,11] In leishmaniasis and deep fungal infections macrophages appear to be part of an inflammatory response in that organisms are found in the marrow in these conditions. Additionally, the presence of increased numbers of neutrophils is consistent with a diagnosis of a pyogranulomatous inflammation. In parvovirus infection, macrophages may be reacting to the need to remove necrotic cells.

Lysosomal storage disorders are a group of genetic deficiencies in lysosomal enzymes classified by the substance that accumulates in lysosomes. This results in the presence of large numbers of foamy macrophages in many tissues including the bone marrow. These cells tend to have a characteristic appearance.

Granulomatous Inflammation

Granulomatous inflammation can consist of a mixed infiltrate of macrophages, giant cells, small lymphocytes, or plasma cells, or can consist of distinct granulomas. Granulomatous inflammation has been associated with disseminated histoplasmosis in dogs and cats and *Mycobacterium avium* subsp. *avium* infection in dogs (see Chapter 19).[7,8,18]

Granulomas are distinct compact aggregates of macrophages (Fig 18.2). These may contain epithelioid macrophages that have a large amount of pale cytoplasm and elongated nuclei with a dispersed chromatin pattern. Epithelioid cells may fuse to form giant cells. Other cells associated with the granuloma may include lymphocytes, plasma cells, and neutrophils. Granulomas

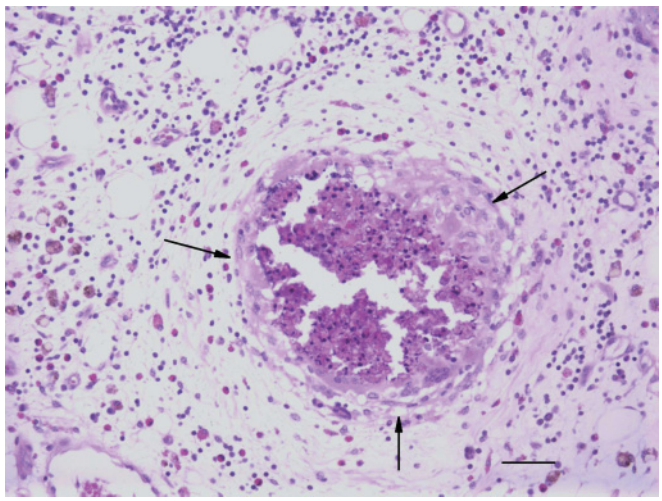

FIGURE 18.2 Granuloma (arrows) in a bone marrow core biopsy section from a dog with a disseminated fungal infection. Hematoxylin & Eosin stain; bar, 200 µm.

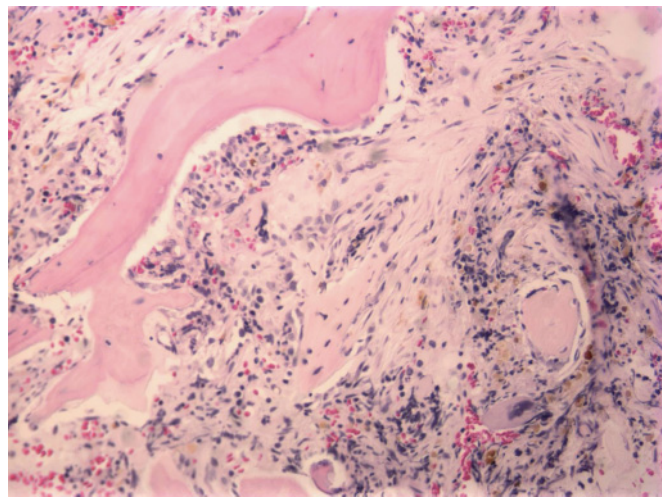

FIGURE 18.3 Secondary myelofibrosis in a bone marrow core biopsy section from a dog. Hematoxylin & Eosin stain.

are infrequently seen in dog and cat bone marrow.[36,37] Granulomas have been associated with systemic fungal infections in dogs and a horse with an idiopathic systemic granulomatous disease.[42] Lipid granulomas have been observed in a cow with serous atrophy of fat.[42] Lipid granulomas consist of aggregates of lipid-laden macrophages. Other cells that may be present in lipid granulomas include lymphocytes, plasma cells, epithelioid cells, and giant cells.[10] In humans, bone marrow granulomas have been associated with a variety of drug hypersensitivities. These drugs include phenytoin, procainamide, phenylbutazone, chlorpropamide, sulfasalazine, ibuprofen, indometacin, allopurinol, and carbamazepine.[2]

SECONDARY MYELOFIBROSIS

Secondary myelofibrosis is a bone marrow disorder characterized by proliferation of fibroblasts or collagen or reticulin fibers in the hematopoietic space (Fig. 18.3).[1,2] Secondary myelofibrosis must be differentiated from idiopathic myelofibrosis that is a rare chronic myeloproliferative disease (see Chapter 65). Secondary myelofibrosis occurs relatively frequently and is associated with moderate to severe non-regenerative anemia and less frequently with thrombocytopenia or leukopenia.[32] Collagen and fibroblastic myelofibrosis has been observed in 4.2% of canine clinical bone marrow specimens and in 9% of feline clinical bone marrow specimens evaluated at a veterinary teaching hospital.[36,37] The distribution of fibrosis in marrow sections varies. Reticulin fibers are most frequently diffusely distributed in the marrow but in some early lesions can be focally distributed around blood vessels. Fibrosis can be random and multifocal, diffuse, or paratrabecular. When paratrabecular myelofibrosis is detected, renal osteodystrophy and primary hyperparathyroidism should be considered (Fig. 18.4).[2] The fibrosis is thought

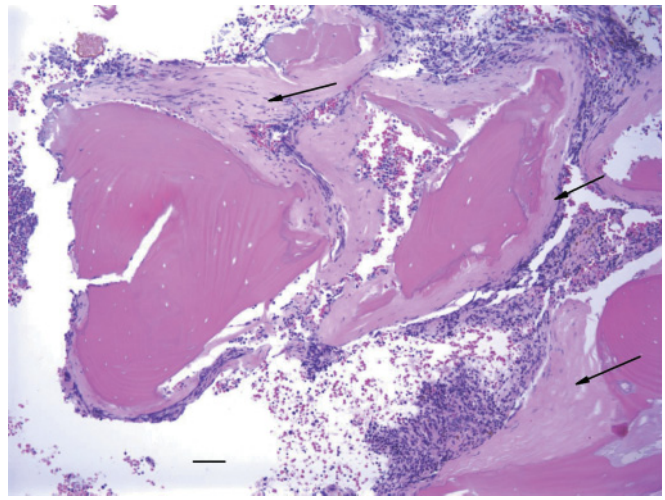

FIGURE 18.4 Paratrabecular fibrosis (arrows) in a bone marrow core biopsy section from a dog. Hematoxylin & Eosin stain; bar, 200 µm.

to be a reactive change frequently resulting from acute bone marrow injury.[32,34,38] As such, the fibrosis is regarded as a stage of the repair process much as occurs in other tissues. If the noxious agent is removed or effectively treated, the fibrosis is frequently reversible with the tissue reverting to normal hematopoietic tissue.[28,32]

Secondary myelofibrosis has been identified in several species including dog, cat, goat, and horse.[1,34,38] Multiple causes of secondary myelofibrosis have been identified. Fibrosis is frequently present in the subacute or chronic stages of myelonecrosis.[34,38] The necrosis may or may not be evidenced when the fibrosis is identified but if present is evidence of ongoing bone marrow injury.

In dogs, secondary myelofibrosis has been associated with IMHA, acute leukemias/lymphomas, idiopathic

myelonecrosis, congenital pyruvate kinase deficiency, congenital non-spherocytic anemia, non-hemic malignant tumors, whole body irradiation, and certain drug treatments.[20,27,32,38,41] Drugs associated with myelofibrosis include phenobarbital, phenylbutazone, and cholchicine (see Chapter 16).[32] Approximately half the cases of secondary myelofibrosis are associated with IMHA and intramedullary and extramedullary neoplasia.[32] Most affected dogs have a moderate to severe non-regenerative anemia, some are thrombocytopenic, but leukopenia is a rare finding. Ovalocytes are infrequently seen in the peripheral blood. In one study of 19 dogs with secondary myelofibrosis, half of the dogs recovered from their anemia with supportive therapy. When the tumor-associated group was eliminated, 66% of dogs survived more than 8 months. Treatments with immunosuppressive doses of prednisone or with erythropoietin may be useful.

A periparturient myelofibrosis, associated severe non-regenerative anemia, has been reported in young female beagle dogs.[21] Myelonecrosis was identified in 1 of 3 dogs reported; therefore the fibrosis may have occurred secondary to acute bone marrow injury.

Secondary myelofibrosis is a frequent finding in cat bone marrow.[3,38] Both collagen and reticulin fibrosis are frequent causes of failure to obtain a sample when aspirating cat bone marrow. Major causes of secondary myelofibrosis in cats include myelodysplastic syndromes, acute myeloid leukemia, IMHA, feline infectious peritonitis, and chronic renal failure.[3,32] Myelonecrosis is present in many cats with secondary myelofibrosis suggesting that the fibrosis occurs in response to necrosis.

Myelofibrosis has been reported as an inherited disorder in pigmy goats.[5] At birth, these goats have a non-regenerative anemia, neutropenia, and thrombocytopenia. All animals die at 6–12 weeks of age. Severe myelofibrosis was identified at necropsy. Other necropsy findings included extramedullary hematopoiesis and megakaryocytic hyperplasia and dysplasia.

Myelofibrosis has been described in aged mice.[25] Myelofibrosis was observed in 43% of female mice but <1% of male mice. In another study of aged NMRI mice, >90% of females and ovariectomized females had evidence of myelofibrosis as well as some castrated males.[24] This study indicates that estrogen may not be a major factor in development of myelofibrosis.

The etiopathogenesis of secondary myelofibrosis is uncertain. The coexistence of myelofibrosis and myelonecrosis in many dog and cat bone marrow specimens indicates that fibrosis may be equivalent to scar tissue in other damaged tissues. Several fibrogenic cytokines have been identified. These include transforming growth factor-β, platelet-derived growth factor, and epidermal growth factor. In bone marrow, fibrogenic cytokines are produced by megakaryocytes and macrophages. Excessive production of fibrogenic cytokines by megakaryocytes is thought to induce myelofibrosis in human idiopathic myelofibrosis, acute megakaryoblastic leukemia, and subtypes of myelodysplastic syndrome characterized by dysmegakaryopoiesis.[23] Constant high levels of thrombopoietin in mice also induce megakaryocyte hyperplasia and myelofibrosis.[6,44] Myelofibrosis has been induced in rodents by injection of a variety of cytokines, including thrombopoietin, erythropoietin, and megakaryocyte growth factor.[44,45] Increased megakaryocytes or dysmegakaryopoiesis has been seen infrequently in dogs with secondary myelofibrosis.[32] Hemosiderosis has also been incriminated as a cause of secondary myelofibrosis. Increased hemosiderin has been identified in 28% of dogs with secondary myelofibrosis.

OSTEOSCLEROSIS

Osteosclerosis (also termed myelosclerosis) is a condition of excessive and unorganized production of trabecular bone. Alternatively osteopetrosis is a congenital condition of dogs and humans characterized by severe non-regenerative anemia or pancytopenia and generalized increased bone density.[17] Osteosclerosis appears as irregular fingers or spurs of bone extending from the trabeculae into the hematopoietic space (Fig. 18.5). These sites usually contain increased numbers of osteoblasts and osteoclasts.[20] When severe, the associated marked thickening of bone can be visualized radiographically.[9,15,20] Osteosclerosis is almost always associated with concurrent severe myelofibrosis. Severe osteosclerosis can obliterate or markedly reduced the size of the hematopoietic space. Osteosclerosis along with severe myelofibrosis occurs terminally in dogs with pyruvate kinase deficiency and has been associated with feline leukemia virus (FeLV) infection.[9,15,20] These changes are seen in core biopsy sections as markedly thickened trabeculae with irregular edges that contain increased numbers of osteoblasts.

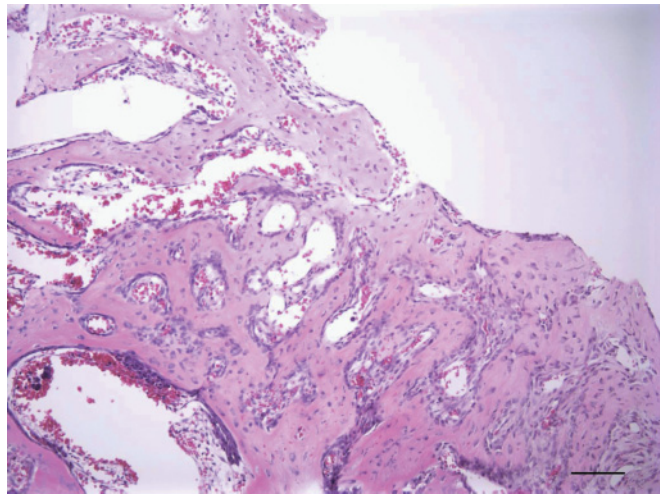

FIGURE 18.5 Osteosclerosis in a bone marrow core biopsy section from a feline leukemia virus-infected cat. Hematoxylin & Eosin stain; bar, 200 µm.

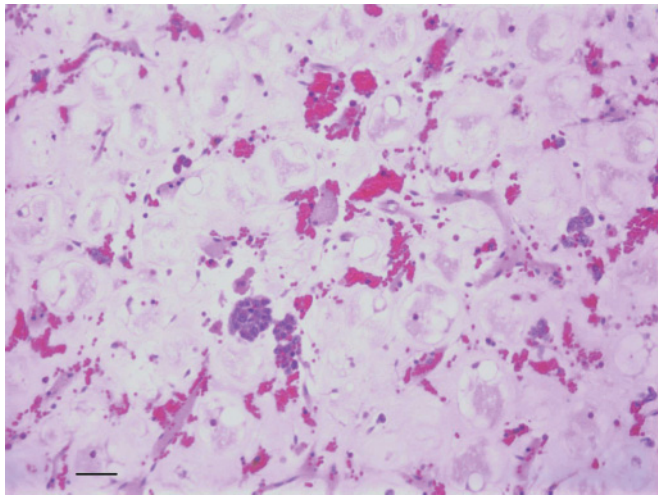

FIGURE 18.6 Gelatinous transformation in a bone marrow core biopsy section from a cat with chronic renal failure. Hematoxylin & Eosin stain; bar, 100 µm.

SEROUS ATROPHY OF FAT/GELATINOUS TRANSFORMATION

The paratrabecular space within normal marrow is occupied almost totally by hematopoietic cells or adipocytes. In processing paraffin-embedded tissues the lipid is dissolved out. Therefore, the space within adipocytes normally appears clear and homogeneous. Serous atrophy of fat/gelatinous transformation is a condition in which there is loss of fat cells and hematopoietic cells from bone marrow and replacement by increased amounts of ground substance (Fig. 18.6).[26] This is usually associated with starvation or cachexia. Foci of gray or pink gelatinous material may be grossly visible in bone marrow at necropsy. Histopathologic sections of bone marrow are characterized by marrow hypoplasia/aplasia, fat atrophy, and amorphous granular extracellular material. This material is thought to be composed of acid mucopolysaccharides.[26]

Serous atrophy of fat/gelatinous transformation has been documented in sheep, goats, primates, and cats.[29,40] In sheep and goats, it has been associated with neglect or loss of teeth. In cats, it has been associated with cachexia associated with the combination of chronic disease and prolonged anorexia. Affected cats had pancytopenia in the blood and marked hypoplasia of bone marrow. Associated conditions included chronic renal failure and oral and gastric ulcers.

CHAPTER 19

Infectious Injury to Bone Marrow

K. JANE WARDROP

See Chapters 17 and 18
Rickettsial Infection
Protozoal Infection – Leishmania
Viral Infection
  Parvovirus
  Retrovirus
  Equine Infectious Anemia virus
  Bovine Viral Diarrhea Virus and Classical Swine Fever Virus
Fungal Infection

Acronyms and Abbreviations

BLV, bovine leukemia virus; BMSC, bone marrow stromal cell; BVDV, bovine viral diarrhea virus; CFU-GM, colony-forming units-granulocyte-monocyte; CPV, canine parvovirus; CSFV, classical swine fever virus; EIAV, equine infectious anemia virus; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; FPV, feline panleukopenia virus; PCR, polymerase chain reaction.

The response of the bone marrow to infectious agents is variable, depending on the organism involved, the nature and chronicity of infection, and the presence of other diseases. Responses are generally nonspecific, and can occur with other, non-infectious disease. Visualization of the organism on marrow cytology or histology can occur in some infections, facilitating the diagnosis. The marrow response to common companion or domestic animal infectious diseases known for their marrow involvement is described below.

RICKETTSIAL INFECTION

Bacteria within the families *Rickettsiaceae* and *Anaplasmataceae* of the order *Rickettsiales* cause a variety of diseases in dogs, cats, horses, and cattle; however, marrow changes are best documented for infections caused by *Ehrlichia canis*. *Ehrlichia canis* is the etiologic agent of canine monocytic ehrlichiosis, and is transmitted most commonly by the vector *Rhipicephalus sanguineus*. The disease has acute, chronic, and subclinical syndromes. Bone marrow in the acute phase of the disease is typically hypercellular. An increase in the bone marrow myeloid to erythroid ratio was described 3–4 weeks post-infection in experimental canine ehrlichiosis.[17] Megakaryocytes were increased 1 week after infection, reflecting the hematopoietic response to the persistent thrombocytopenia seen with this disease (see Chapter 78). Morulae can be present in bone marrow but are difficult to find, with 1–4 morulae per 1,000 oil immersion fields seen in one study of acute ehrlichiosis.[11] Chronic ehrlichiosis produces a pancytopenia, secondary to severe bone marrow hypocellularity (see Chapter 31). Marrow aspirates are poorly cellular, with cells consisting of low numbers of stromal cells, fibroblasts, and macrophages. Hematopoietic precursors are few or absent. Core biopsies show a severely hypocellular marrow filled with adipose tissue.[3] Mastocytosis also has been reported in the chronic phase of ehrlichiosis.[13] Bone marrow plasmacytosis has been reported with ehrlichiosis, and is independent of the phase.[12,25]

PROTOZOAL INFECTION – LEISHMANIA

Leishmaniasis is a disease caused by protozoal organisms of the genus *Leishmania*, and is transmitted in Mediterranean regions by the bite of an infected female sand fly. The vector in North America is not known. Several forms of the disease, including cutaneous, mucocutaneous, and visceral forms, have been identified in dogs. A mild anemia and thrombocytopenia are the most frequent hematologic findings. Microscopic examination of fine needle aspirates of lymph nodes or bone marrow, along with serology and polymerase chain reaction (PCR), are frequently used diagnostic methods (Fig. 19.1). In one study, *Leishmania* spp. amastigotes were observed in the marrow of 92.6% of clinically affected dogs.[20] Severe histiocytosis of the marrow has been reported.[14]

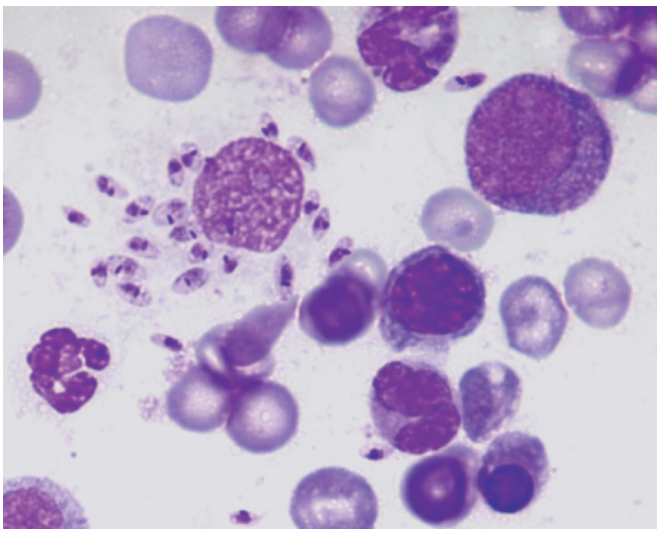

FIGURE 19.1 *Leishmania* organisms in bone marrow from a dog; Wright-Giemsa stain. (Courtesy of Dr. Rick Cowell, Idexx Laboratories.)

VIRAL INFECTION

Parvovirus

Feline panleukopenia virus (FPV) and canine parvovirus (CPV) are both parvoviruses that cause bone marrow injury and leukopenia, neutropenia, and lymphopenia. These viruses have a broad tropism for mitotically active cells. It is unknown whether the reduction in marrow cells is due primarily to virus replicating in and killing cells, or due to more indirect effects. FPV can kill both erythroid and myeloid colony progenitor cells in bone marrow cultures, although at low viral doses there is greater suppression of the formation of myeloid colony-forming units-granulocyte-monocyte (CFU-GM).[7] Viral replication of FPV in myeloid cells may lead to the neutropenia seen after FPV infection. In a study of 76 cats with clinical FPV, 84% showed complete bone marrow depopulation and dilation of the vascular sinuses, 5% had no significant marrow change and 6% had marrow hypercellularity with granulocytic hyperplasia.[4]

In 75 dogs with clinical CPV, 92% had marrow depopulation, one dog showed no changes, and five dogs had marrow hypoplasia.[4] In another study using experimentally infected puppies, leukopenia and neutropenia only occurred in dogs with severe enteric disease. Viral replication in the bone marrow was sparse.[9] In both FPV and CPV, the severe neutropenia observed is probably the result of both neutrophil loss or consumption in the infected gut and bone marrow suppression.[15]

Retrovirus

Feline leukemia virus (FeLV, subfamily *Oncornavirinae*) and feline immunodeficiency virus (FIV, subfamily *Lentivirinae*) are retroviruses that are major infectious pathogens in domestic cats (see Chapters 55 and 62). FeLV infects hematopoietic cells, lymphoid cells, and accessory cells in the hematopoietic microenvironment. Marrow nucleated cells become infected with the virus 2–6 weeks after exposure, and virus can be detected in circulating leukocytes at that time.[8] After regression, one third to one half of cats transiently harbor latent virus in marrow myelomonocytic cells and stromal fibroblasts.[8] The types of marrow change seen in FeLV are highly variable. Early viremia can be accompanied by pancytopenia and marrow hypocellularity.[16] Marrow necrosis, with nuclear swelling and karyolysis has rarely been described.[22] FeLV-C-induced pure red cell aplasia shows almost a total lack of marrow erythroid precursor cells, with normal myeloid and megakaryocytic precursors (see Chapters 38 and 62).[21] FeLV-induced myelodysplastic syndromes can show marrow hypercellularity, megaloblastic maturation abnormalities, increased reticulin fibrosis, and increased numbers of immature cells and blast cells (see Chapter 66).[2,10] Marrow myelophthisic disease, where the marrow is filled with blast cells, can be observed in FeLV-induced leukemias or lymphoma.

FIV produces progressive CD4 T cell lymphopenia. Marrow morphologic abnormalities, marrow suppression, and peripheral blood cytopenias can be seen. Cytopenias (neutropenia, anemia) have been attributable to direct infection of the bone marrow stromal cell (BMSC) population.[19] BMSC types include fibroblastic/advential/reticular cells, macrophages, endothelial cells, adipocytes, and myofibroblasts, of which macrophages are productively infected with FIV.[1]

Bovine leukemia virus (BLV) is an oncogenic retrovirus which produces lymphoma in adult cattle. Bone marrow involvement is not a prominent feature.

Equine Infectious Anemia Virus

The equine infectious anemia virus (EIAV) is a lentivirus of the family *Retroviridae* (see Chapters 32 and 35). Infection of horses with EIAV produces a persistent viremia and recurrent episodes of anemia, thrombocytopenia, and fever. In one study using experimentally infected foals with severe combined immunodeficiency, bone marrow changes were described after the onset of thrombocytopenia.[24] The post-thrombocytopenia samples had a moderate to marked decrease in bone marrow cellularity, with an increase in intercellular homogeneous eosinophilic material. Individual cell necrosis or apoptosis was not observed. A moderate increase in adipocytes and reticulin fibers was noted. Denuded megakaryocyte nuclei were also observed. In another study, the total megakaryocyte area and megakaryocyte nuclear area were increased. Numbers of megakaryocytes were slightly increased.[18]

Bovine Viral Diarrhea Virus and Classical Swine Fever Virus

Bovine viral diarrhea virus (BVDV) and classical swine fever virus (CSFV) are related viruses (family

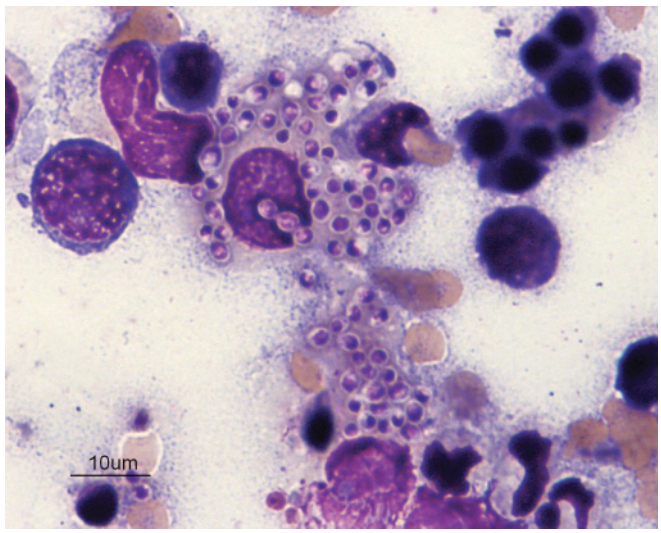

FIGURE 19.2 Histoplasma organisms in bone marrow from a cat; Wright-Giemsa stain. (Courtesy of Dr. James Meinkoth, Oklahoma State University.)

Flaviviridae, genus Pestivirus) both known to infect and damage megakaryocytes of the marrow and produce a subsequent thrombocytopenia, but other marrow lesions are not present. In a study using calves infected with type II BVDV, histologic evaluation of the bone marrow showed an increased number of megakaryocytes. Approximately one-half of the megakaryocytes were immature or had undergone nuclear loss or pyknosis.[23] Infection of calves with type II BVDV also reduced the number of GFU-GM cultured from bone marrow. This suggests that suppression of granulopoiesis may contribute to the prolonged neutropenia associated with BVD infection. Experimental infection of pigs with a virulent strain of CSFV also produced changes in megakaryocytes, with abnormal nuclei and micromegakaryocytes seen.[6]

FUNGAL INFECTION

Blastomycosis, histoplasmosis, coccidiomycosis, and cryptococcosis are common systemic fungal diseases of the dog and cat. Although all of these diseases can involve the bone marrow, marrow involvement is most frequently described in histoplasmosis.

Histoplasma capsulatum is a soil-borne, dimorphic fungus that infects dogs and cats through inhalation of conidia from the mycelial phase, which subsequently convert to yeast in the body. The disseminated form of the disease predominantly affects the liver, spleen, gastrointestinal tract, bone, bone marrow, integument, and eyes. Primary gastrointestinal and pulmonary histoplasmosis can also occur.

In the bone marrow, large numbers of organisms can be found within macrophages (Fig. 19.2). Anemia is a frequent finding, but pancytopenia accompanied by granulomatous inflammation of the bone marrow has also been reported.[5]

Acronyms and Abbreviations

dCytb, duodenal cytochrome B; DMT-1, divalent metal iron transporter-1; Hgb, hemoglobin; ID, iron deficiency; IRP, iron regulatory protein; kD, kilodalton; MPS, mononuclear phagocyte system; NADH, nicotinamide adenine dinucleotide, reduced form; NADPH, nicotinamide adenine dinucleotide phosphate, reduced form; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; RBC, red blood cell; SM, sphingomyelin; TfR, transferrin receptor.

The main function of red blood cells (RBCs) is to carry oxygen to tissues. All energy in RBCs that is devoted to maintaining cell shape, membrane structure, enzymatic functions, reduced iron in hemoglobin and other functions does so to optimize oxygen delivery to tissues.

ERYTHROCYTE STRUCTURE

Overall Structure

RBCs have no nuclei and no organelles, and thereby no ability to synthesize proteins. The full complement of functional proteins must be present by the time the reticulocyte matures. RBCs are composed (by mass) of 61% water, 32% protein (mostly hemoglobin), 7% carbohydrates, and 0.4% lipids. Isolated RBC membranes in most animals are composed of approximately 20% water, 40% protein, 35% lipid and 6% carbohydrate.[43]

Membrane Structure

Membrane Lipids

The RBC membrane phospholipid bilayer is composed of phosphatidylcholine (PC), phosphatidylethanolamine (PE), sphingomyelin (SM), and phosphatidylserine (PS), as well as other less abundant phospholipids.[59] This composition varies with species. For instance, sheep have no PC and camellids have very low PC,

whereas rats have more PC.[39,51,59] The phospholipids have polar head groups and hydrophobic tail groups. The tail groups associate together in the bilayer to provide a hydrophobic barrier to water while the polar groups face the hydrophilic exterior. The bilayer is vertically asymmetrical, with PS and PE located almost exclusively on an inner PL layer. This asymmetry is maintained by the activities of enzymes termed flippase[14] and floppase.[33,50] There is also horizontal asymmetry, so that there is lipid composition variability within different domains of the bilayer. Other lipids in the bilayer include glycolipids and cholesterol, and these are embedded in the phospholipids.

Lipid Rafts

Lipids rafts are specialized membrane microdomains that are rich in cholesterol and sphingolipids and also contain specific membrane proteins. They are isolated as detergent resistant membranes because of their insolubility in non-ionic detergents.[29] Examples of proteins localized in these microdomains include glycophosphatidylinositol-anchored proteins, flotillins, stomatin, and aquaporin-1.[45]

Maintenance of Membrane Fluidity

Anything that increases the "packing" of the membrane components together will "harden" the membrane, and anything that decreases the packing will "soften" the membrane. Membrane fluidity is, therefore based on several factors. One factor is the degree to which fatty acid chains are esterified with cholesterol. Esterified cholesterol is bulkier, and therefore "packs" more loosely, and creates a more fluid membrane. A second factor is the class of phospholipid and the type of fatty acid contained within the membrane. A third factor is the molar ratio of cholesterol to phospholipids. A fourth factor is the degree of saturation of phospholipid fatty acids (saturation makes PLs "pack" better and, therefore decreases fluidity).

Cytoskeletal Proteins

Cytoskeletal proteins are located on the cytoplasmic side of the plasma membrane and function to help maintain cell shape, membrane deformability, membrane stability, and the lateral mobility of some integral membrane proteins.[62] They are called "peripheral proteins" because they are not embedded within the membrane but rather are anchored to the cytoplasmic side of the bilayer.

Alpha and beta spectrin subunits are the largest and most abundant proteins in the cytoskeleton. They are elongated and self-associate to form $\alpha_2\beta_2$ tetramers which then associate end to end into a hexagonal network of molecules that lies just underneath the plasma membrane. The spectrin lattice is anchored to other proteins and to the bilayer at select areas of the hexagon. The spectrin molecules are secured to the lipid bilayer at "nodes" called junctional complexes (Fig. 20.1). These complexes are made up of actin, 4.1 protein (named for its migration during one dimensional electrophoresis), and the integral membrane protein glycophorin. Spectrin is also affixed to the inner leaflet via an interaction with ankyrin (a peripheral protein) that is bound to band 3 (anion transporter, an integral membrane protein). Additional peripheral membrane proteins comprising the cytoskeleton include adducin, tropomyosin, tropomodulin, and palladin.

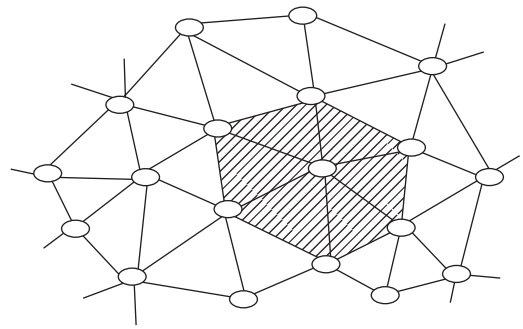

FIGURE 20.1 Lattice structure provided by spectrin tetrameters in the cytoskeleton of erythrocytes.

Integral Membrane Proteins

Band 3 or the anion exchange protein is an integral membrane protein composed of dimers, tetramers and other large oligomers. It is responsible for anchoring the cytoskeleton to the membrane, anion exchange and binding of glycolytic enzymes, hemoglobin and hemichromes. The anion exchange function is primarily for delivering CO_2 to the lungs in exchange for Cl^-.

Glycophorins are heavily glycosylated integral membrane proteins. They carry most of the sialic acid residues and, therefore negative charge on the surface of the RBC. RBCs carry other cell surface molecules, and new ones are being discovered all the time. A select list of these is shown in Table 20.1.

HEMOGLOBIN STRUCTURE, SYNTHESIS, AND METABOLISM

Hemoglobin is an iron-porphyrin-protein complex. Other iron-porphyrin-protein complexes include myoglobin and heme-containing enzymes such as catalase, peroxidase, and cytochromes. The porphyrin-iron-protein hemoglobin molecule occupies a central role in physiology by binding, transporting, and delivering oxygen to tissues. Hemoglobin is synthesized within developing RBCs and its synthesis is coordinated with the developmental stages of the erythroid precursors.

Hemoglobin Structure

Hemoglobin is composed of two α- and two β-polypeptide chains and is approximately 64 kDa in molecular weight. Each chain contains a heme prosthetic group held firmly within a hydrophobic cleft

TABLE 20.1 Selected Erythrocyte Surface Molecules in the Human and/or Mouse

Molecule	Synonyms	Function
CD35	Complement receptor 1	Binds complement fragments
CD36	Platelet glycoprotein IV	Unknown
CD38	N/A	NAD glycohydrolase
CD44	H-CAM, gp85	Hyaluronic acid binding
CD47	Integrin associated protein	May be a senescence marker
CD49d/CD29[a]	VLA-4, α4β1 integrin	Adhesion to fibronectin, V-CAM
CD55	Decay accelerating factor	Neutralizes complement activation
CD59	Complement regulatory protein	Inhibits complement membrane attack
CD71[a]	Transferrin receptor	Iron acquisition
CD147	N/A	Recirculation of RBC from spleen
CD239	Basal cell adhesion molecule/Lutheran	Laminin binding

[a]Reticulocytes only.

(otherwise known as the "heme pocket"). The entire molecule is, therefore a globular tetramer. This globular structure permits a cooperative interaction of oxygen binding that gives the sigmoid oxygen-Hgb saturation curve.

Hemoglobin Synthesis

Heme is a planar molecule composed of two elements, a tetrapyrrole protoporphyrin IX and a central iron molecule. The iron is supplied by ferritin, the cytosolic storage form of iron. Heme biosynthesis is an enzymatic process requiring both mitochondrial and cytosolic enzymes. Figure 20.2 shows the sequence of reactions leading to the synthesis of PROTO IX, heme, and Hgb. The initial step of heme synthesis occurs in mitochondria. It requires vitamin B_6 (pyridoxine) and is catalyzed by δ-aminolevulinic acid (ALA) synthase. ALA is then translocated to the cytosol. In the cytosol, two moles of ALA are condensed to form porphobilinogen (PBG), a reaction catalyzed by ALA-dehydrase (ALA-D). ALA-D is strongly inhibited by lead, leading to the anemia associated with lead poisoning. The remainder of the process is depicted in Figure 20.2.

Synthesis of α and β globin chains occurs in the ribosomes and polyribosomes in the cytoplasm. Each globin chain contains a cleft or heme pocket that is lined by largely nonpolar amino acid side chains that impart a hydrophobic nature to the pocket. The nonpolar (vinyl and methyl groups) side of heme is positioned in the hydrophobic pocket of each globin chain. The addition of heme to the pockets of globin is followed by a dimerization of the α and β globin chains, which is then followed by spontaneous formation of hemoglobin tetramers.

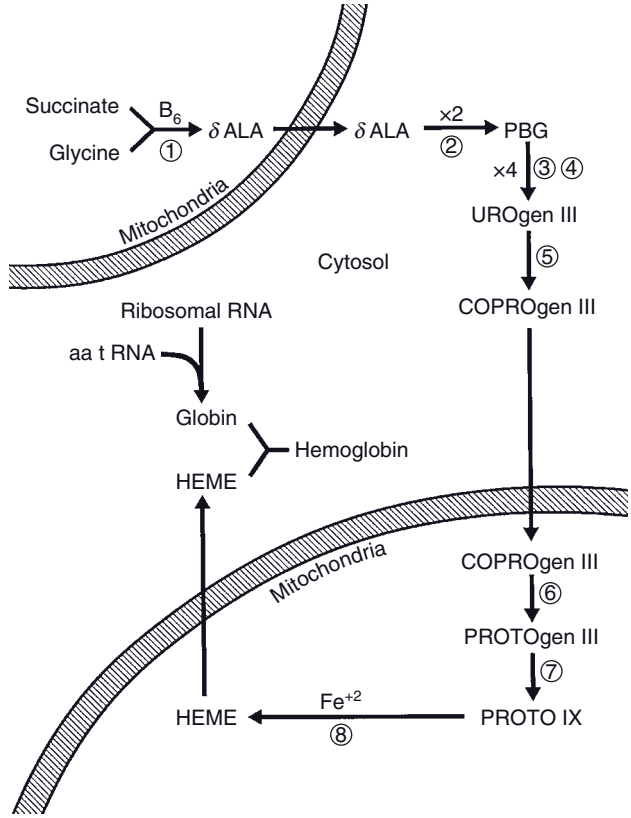

FIGURE 20.2 Pathway for protoporphyrin, heme, and hemoglobin synthesis emphasizing the partitioning of the pathway between the mitochondrial and the cytolic compartments of the cell. The circled numbers represent the following enzymes of heme synthesis: 1, ALA-Syn; 2, ALA-D; 3, UROgenI-Syn; 4, UROgenIII-Cosyn; 5, UROgen-D; 6, COPROgenIII-Ox; 7, PROTOgenIII-Ox; 8, FER-Ch. Control of Hemoglobin Synthesis

Synthesis of heme and globin chains is finely coordinated so that there is little or no free heme or globin in the cytoplasm of developing erythroid cells. Heme governs ribosomal translation of globin chain synthesis.[57] Moreover, α and β chain synthesis is coordinated. Excess α chains inhibit their own synthesis while stimulating β-chain synthesis, while excess β chains inhibit their own synthesis.[27,54]

Hemoglobin Turnover

Hemoglobin is turned over after the extra- or intravascular destruction of RBCs. In health, extravascular hemolysis occurs as RBCs age and are subsequently trapped in the spleen and phagocytosed by splenic macrophages. Hemoglobin is catabolyzed within a cell. When RBCs undergo intravascular hemolysis, the hemoglobin is released into the circulation in its free form. Free plasma Hgb is quickly cleared by several mechanisms. The most important is binding of free Hgb to haptoglobin followed by clearance of the complex by macrophages.[26] The half-time for free Hgb clearance is 20–30 minutes. Minor pathways for Hgb clearance are (1) oxidation to methemoglobin (MetHgb) that can be excreted, (2) hydrolysis of the MetHgb to release its ferriheme (ferric heme, hematin, hemin) that is complexed to hemopexin for transport to the mononuclear phagocyte system (MPS), and (3) binding of ferriheme to albumin (methemalbumin) for transport to the MPS. When there is excess intravascular hemolysis, such that the binding capacity of plasma haptoglobin is exceeded, Hgb may be cleared via glomerular filtration. In this event, hemoglobinuria may occur, or the proximal renal tubular cells may catabolyze Hgb.[16] When Hgb is internalized into macrophages, it is degraded by hydrolysis into its globin and heme moieties. The globin chains are systematically degraded by proteolytic enzymes to release the constituent amino acids.

Heme Catabolism and Bilirubin Formation

The initial step in the heme catabolic pathway is enzymatic cleavage of the heme ring at the α methene bridge to release linear tetrapyrrole biliverdin, iron, and carbon monoxide. This reaction is catalyzed by microsomal heme oxygenase in the presence of cytochrome P-450, oxygen, and reduced NADPH. Heme oxygenase activity is highest in the spleen, and there is some activity in the liver, bone marrow, and renal tubular cells. Iron is oxidized to the ferric form, released and transported as transferrin for storage as hemosiderin or ferritin in the liver and as ferritin in the bone marrow for subsequent reuse.[55] Biliverdin, a green pigment, is reduced in macrophages to bilirubin, a yellow pigment, by the action of the enzyme biliverdin reductase in the presence of NADPH. The virtual absence of biliverdin reductase in birds accounts for the green color of avian bile. Bilirubin is a nonpolar compound and must be bound to albumin to remain soluble in aqueous plasma. The bilirubin-albumin complex is transported to the liver, and at the hepatocyte surface, albumin is released. The first step involving the hepatocyte surface is the uptake or transport of bilirubin across the hepatocyte membrane by a transporter system. The second step in the hepatocyte is conjugation of bilirubin to glucuronic acid, primarily as the diglucuronide and with some monoglucuronide. This reaction is catalyzed by the enzyme glucuronyl transferase. The bilirubin glucuronides are highly polar and are therefore soluble compounds. The third step in the hepatocyte is the transport of bilirubin glucuronide into the bile canaliculi and thence the biliary system. This canalicular transport is the rate-limiting step in hepatic bilirubin metabolism.[28] A small amount of the glucuronides may also be transported back into the circulation so that normally, both unconjugated and conjugated bilirubins are present in the circulation.

Fetal Hemoglobin

The synthesis of α globin chains remains constant during stages of gestational development and throughout adult life. Different types of non-α globin chains are synthesized and account for the different types of Hgb appearing during development and in adult life. At the embryonic stage, most animals synthesize only embryonic chains designated ε chains (i.e. embryonal Hgbs). Fetal Hgb (HgbF) is composed of two γ chains and two α chains, although not all animals produce HgbF. Ruminants possess a mixture of adult and fetal Hgb at birth, and HgbF is replaced by adult Hgb in the first few months of life.[3] Although HgbF rapidly declines after birth, the capacity to synthesize it remains, and HgbF may appear in responsive anemias. Dogs, cats, horses, and pigs lack HgbF and are born with adult Hgb that has replaced the embryonal Hgb during gestation.[9,31]

Hemoglobin Types in Animals

With the possible exception of pigs, two or more types of Hgb normally occur in several domestic animal species.[8,30] Most polymorphisms are determined genetically and are usually associated with multiple amino acid substitutions.[31] The Hgb of cats has a unique structure containing 8–10 reactive sulfydryl groups per molecule compared to other animals that have only 2–4 per Hgb molecule.[36] The presence of the readily oxidizable groups is regarded as the basis for the ease of Heinz body formation in the cat (see Chapter 36). Sheep and goats synthesize HgbC in response to severe anemia.[25] Sheep normally have HgbA and goats HgbA and HgbB, and the switch to HgbC during anemia is mediated by erythropoietin.[4] Carbon dioxide decreases oxygen affinity for HgbC more than it does for normal adult Hgbs.[25,63]

IRON METABOLISM

Iron is an essential component not only of hemoglobin and myoglobin, but also of many enzymes. Iron containing enzymes include NADH dehydrogenase, lipoxygenases, superoxide dismutase, ribonucleotide reductase, fatty acid desaturases and phosphatases.[37] These enzymes function in energy generation, prostaglandin synthesis, free radical detoxification, synthesis of DNA, synthesis of fatty acids, and signal transduction. Iron is provided to cells of the body by three sources: (1) absorption from the gut, (2) recycling from senescent RBCs, and (3) liver storage iron (Fig. 20.3).

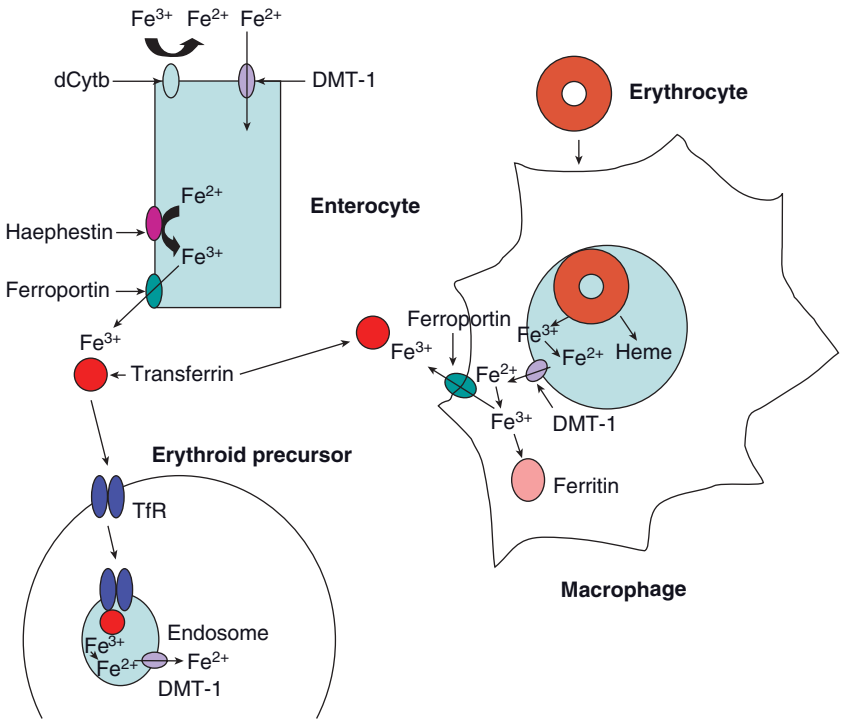

FIGURE 20.3 A schematic of iron metabolism including absorption from enterocytes, transport in circulation, utilization by the erythroid precursors, and recycling by macrophages.

Absorption in Intestine

Absorption of iron is regulated; excretion is not (iron is lost through epithelial sloughing of gut, skin, urothelium). Iron absorption takes place in the proximal duodenum, and it is absorbed either as heme or non-heme iron. Although most iron utilized in physiologic mechanisms is that recycled from hemoglobin iron, total body iron stores are regulated by the duodenum to prevent whole-body iron accumulation or deficit.

Intestinal Absorption of Non Heme Iron

Iron is stabilized in the ferric form by the acidity of the gastric fluid. Apical duodenal cytochrome B (dCytb) reduces ferric to ferrous iron. Ferrous iron is transported to the basolateral membrane by intracellular mechanisms that are unclear. At the basolateral surface, hephaestin, a copper-containing enzyme, re-oxidizes iron to its ferric state. Ferroportin then exports iron out of the cells into the portal circulation, where it is carried bound to transferrin. Once in the circulation, iron is carried to the liver to be stored, or to the erythroid precursors in the bone marrow to be incorporated into hemoglobin. Heme iron is probably absorbed by an apical heme transporter (apical heme carrier protein 1).[46]

Cellular Iron Uptake

Iron is taken up by most cells (i.e. not enterocytes) via the cell surface transferrin receptor (TfR). The expression level of this receptor is directly related to the iron requirements of the cell.[6,15] The cell surface transferrin receptor functions as a dimer, with each 90 kDa monomer embedded in the membrane with one single transmembrane-spanning region. Iron binding transferrin (holotransferrin) binds to the TfR at physiologic pH and the transferrin-iron-TfR complex is internalized into an endosome. The low pH of the endosome causes the release of Fe^{3+} from the transferrin and the iron is then reduced to Fe^{2+}. Ferrous iron is then exported to the cytoplasm.[5,34,41,47] A newly discovered protein, the product of the *HFE* gene, forms a complex with the TfR and appears to regulate its ability to import iron.[7]

Molecules Involved in Iron Metabolism

The uptake of iron by the duodenum and by individual cells in the body is regulated by total body iron levels and intracellular iron levels, respectively.[1]

Many molecules involved in iron regulation have been discovered in recent years.[11,20] Although there are still gaps in our knowledge of the physiologic processes, several important molecules have been identified in research involving humans and rodents, and are described below.

Divalent Metal Iron Transporter-1

Divalent metal iron transporter-1 (DMT-1) is expressed in the enterocytes of the villi and not in the crypts,[10] and is responsible for transporting iron from the enterocyte to the circulation, and from endosomes of macrophages to the cytoplasm. It is associated with phagosomal membranes in macrophages[22] and plasma membranes

and endosomes of cells that use the TfR complex for iron acquisition.[22] One isoform of DMT-1 is strongly regulated by iron; it is markedly increased with an iron-deficient diet and reduced by an iron replete diet.[23]

Ferrireductase Duodenal Cytochrome b

DMT-1 transports Fe^{2+} into the enterocyte from the duodenal lumen. Since Fe^{3+} is the dietary form that exists in the lumen, it must be reduced. The duodenal cytochrome b, located on the apical membrane of the enterocyte, acts as such a reductase.[18]

Hephaestin

Hephaestin, a copper dependent transmembrane ferroxidase, is an approximately 150–160 kDa protein with 50% homology to ceruloplasmin. It is highly expressed in the small intestine, primarily in the basolateral membrane of enterocytes, and is co-localized with ferroportin.[44] Hephaestin is responsible for oxidizing Fe^{2+} to Fe^{3+} so that it can be transported out of the enterocyte into the plasma.

Ferroportin

Ferroportin is expressed on the membrane of duodenal enterocytes (basolateral), placental trophoblasts, and macrophages distributed in various tissues.[1,13,17,18] It is the only mammalian iron exporter out of cells. It exports iron from enterocytes into the circulation (from dietary iron) and from macrophages to the circulation (from recycled erythrocyte iron). Its expression levels are regulated by hepcidin binding and internalization of the protein, and also by iron levels.

Hepcidin

Hepcidin should be considered a molecule that regulates iron systemically. Hepcidin regulates iron export from enterocytes and macrophages by binding to and causing degradation of ferroportin.[21] It is synthesized as a pro-peptide in the liver and circulates as a 25 amino acid disulfide-rich peptide. Synthesis is increased by iron loading to decrease iron absorption, and decreased by anemia and hypoxia to increase iron absorption.[42,60] It is also increased in inflammation, and causes the iron trapping in macrophages during anemia of inflammatory disease.[21] Iron may control hepcidin synthesis through a signaling pathway dependent on proteins called hemojuvelin and bone morphogenic proteins (2 and 4).[35] Kupffer cells also appear to regulate hepcidin expression; when Kupffer cells are eliminated, hepcidin expression is increased and serum iron is decreased.[56]

Anemia and hypoxia decrease hepcidin synthesis by increasing erythropoietic activity. Erythropoietin administration down-regulates hepcidin expression and this is probably due to the erythropoietic activity and not the direct effects of the hormone.[32,60] Inflammation, primarily through interleukin-1 and -6, and possibly transforming growth factor-beta, increases hepcidin expression, thus decreasing intestinal iron absorption and decreasing iron export from macrophages.

Transferrin Receptor

The transferrin receptor is described under the heading Cellular iron uptake.

Transport and Storage of Iron

Transport of Iron

Transport of iron from one compartment or tissue to another through the circulation (e.g. enterocytes to bone marrow cells) is accomplished by the carrier protein transferrin. Serum transferrin is a soluble 78 kDa protein that binds one or two iron atoms in their ferric (3^+) form.

Storage of Iron

Iron is stored in developing RBCs, and other cells, as ferritin, an iron-protein complex.[38,48,49] The protein moiety, apoferritin, consists of at least 24 monomers of either H or L subunits. Each subunit is shaped like a short rod and these rods are assembled as a hollow sphere. Apoferritin has a molecular weight of 441 kDa and can store as much as 4500 molecules (31%) of iron.[34] The maximal weight of ferritin can be approximately 800 kDa, but ferritin more commonly is less than that (620 kDa) with roughly 18% iron. The method of iron movement in and out of the molecule is not precisely known, but it apparently enters as the ferrous form and is oxidized to and stored as the ferric form.[12] Iron is released either by a reversal of the process, or by digestion of ferritin by lysosomes and reduction to the ferrous form.[24] Hemosiderin is found in cells of the monocyte-macrophage system, predominantly in macrophages of the liver (Kupffer cells), spleen, and bone marrow. Hemosiderin can be seen as golden granules in hematoxylin and eosin stained histologic sections, and may appear green to black in Wright-Giemsa stained cytologic preparations. It is a "stripped down" version of ferritin, whereby the apoferritin protein shell has been removed, leaving approximately 25–30% of iron by weight.[19]

Genetic Control of Iron Regulatory Proteins

Proteins involved in iron metabolism are predominantly regulated at the post-translational level by the interplay of iron-responsive elements (IREs) and cytosolic iron-binding proteins referred to as iron regulatory proteins (IRPs). The IREs are stem-loop or hairpin structures located in the 3′ or 5′ untranslated regions of the messenger RNAs (mRNAs) that act as nucleic acid binding sites for the IRPs. The binding affinity of IRPs is reversibly regulated by the intracellular

concentration of iron. When the intracellular concentration of iron is low, IRPs have a high affinity for IREs, and when cells are iron replete, the affinity is low.

Ferritin and aminolevulinate synthase (rate limiting enzyme in heme biosynthesis) mRNAs have a single IRE in the 5′ end at the beginning of the coding region. Binding of the IRP inhibits translation; thus when iron is low, the IRP binds to the IRE and translation is inhibited, whereas when iron is high, IRPs lose affinity and translation of those proteins occurs.[2,52,53,58,61] Thus, when ferritin is required for storage of increased intracellular iron, translation is up-regulated. On the other hand, the transferrin receptor mRNA has an IRE on the 3′ end. When iron is low, the binding of the IRP inhibits the breakdown of the mRNA and thereby stimulates the translation of the protein. Thus, low iron up-regulates TfR so that cells become more iron avid. In summary, IRPs regulate mRNA translation by binding to IREs, and binding is stimulated by low iron. However, sometimes binding stimulates translation (TfR) and sometimes binding inhibits translation (ferritin).[40]

Acronyms and Abbreviations

Cb_5R, cytochrome-b_5-reductase; DPGM, diphosphoglycerate mutase; DPGP, diphosphoglycerate phosphatase activity; 1,3DPG, 1,3-diphosphoglycerate; 2,3DPG, 2,3-diphosphoglycerate; EMP, Embden-Meyerhof pathway; FAD, flavin adenine dinucleotide; GAPD, glyceraldehyde phosphate dehydrogenase; G6P, glucose 6-phosphate; G6PD, glucose-6-phosphate dehydrogenase; GPx, glutathione peroxidase; GR, glutathione reduction; GSH, reduced glutathione; GSSG, oxidized glutathione; HK, hexokinase; HK^+, high potassium; LK^+, low potassium; LMB, leukomethylene blue; MB, methylene blue; O_2^-, superoxide; PFK, phosphofructokinase; 3PG, 3-phosphoglycerate; P_i, inorganic phosphate; PGK, phosphoglycerate kinase; PK, pyruvate kinase; PPP, pentose phosphate pathway; RBC, red blood cell; RNS, reactive nitrogen species; ROS, reactive oxygen species; SOD, superoxide dismutase.

Erythrocytes or red blood cells (RBCs) provide vital functions of oxygen transport, carbon dioxide transport, and buffering of hydrogen ions. These functions do not require energy per se, but energy in the form of ATP, NADH, and NADPH is needed to keep the cells circulating for months in a functional state despite repeated exposures to mechanical and metabolic insults.

Mature mammalian RBCs do not have nuclei; consequently, they cannot synthesize nucleic acids or proteins. The loss of mitochondria during the maturation of reticulocytes results in a loss of Krebs' cycle and oxidative phosphorylation capabilities, and prevents the synthesis of heme or lipids de novo in RBCs. Energy needs of mature RBCs are met solely by anaerobic glycolysis in the Embden-Meyerhof pathway (EMP). Although metabolic demands are lower than in other blood cell types, RBCs still require energy in the form of ATP for maintenance of shape, deformability, phosphorylation of membrane phospholipids and proteins, active membrane transport of various molecules, partial synthesis of purine and pyrimidine nucleotides, and synthesis of glutathione.[9] A minor shunt for carbohydrate metabolism, the pentose phosphate pathway, provides the RBC with additional critical protection against oxidative damage.

MEMBRANE TRANSPORT

The RBC lipid bilayer is impermeable to most molecules. Consequently, various membrane protein transport systems are utilized for movement of molecules into and out of RBCs. Water and carbon dioxide are transported across RBC membranes using water channels called aquaporins.[4] Band 3 appears to function as a channel for the movement of anions, especially bicarbonate and chloride, certain non-electrolytes, and probably cations to some extent. Defective anion transport and marked spherocytosis with membrane instability occurs in anemic cattle with an inherited deficiency of band 3 protein (see Chapter 29).[11]

Major interspecies, and in some cases intraspecies, differences occur in cation transport and subsequently in intracellular Na^+ and K^+ concentrations.[3] Animal species with high intracellular K^+ concentrations (horse, pig, and some ruminants) have an active Na^+,K^+-pump that exchanges intracellular Na^+ for extracellular K^+

with the hydrolysis of ATP. In addition to individuals with high potassium (HK^+) RBCs, some sheep, goats, buffalo, and most cattle RBCs have relatively low potassium (LK^+) and, consequently, high sodium RBCs. These LK^+ RBCs have low Na^+,K^+-pump activity and high passive K^+ permeability.

Red blood cells from cats and most dogs do not have Na^+,K^+-pump activity and have Na^+ and K^+ concentrations near those predicted for the Donnan equilibrium with plasma. However, many clinically normal Japanese and Korean dogs have HK^+ RBCs.[5] Red blood cells from these dogs have substantial Na^+,K^+-ATPase activity, and some of these dogs also have increased glutamate transport, which results in high reduced glutathione (GSH) concentrations. These HK^+, high GSH RBCs promote *Babesia gibsoni* replication compared to LK^+, normal GSH RBCs.[24] Other pathways of sodium and potassium transport occur to variable degrees in certain species.[9]

Excessive intracellular Ca^{2+} promotes the suicidal death of RBCs (eryptosis);[13] consequently, RBCs actively extrude Ca^{2+} using a calcium pump having Ca^{2+}-activated, Mg^{2+}-dependent ATPase activity. The calcium pump is activated by a calcium-binding protein called calmodulin.[9]

Amino acid transport in RBCs provides amino acids for synthesis of glutathione. In addition, amino acid transporters may be responsible for efflux of amino acids during reticulocyte maturation.[21]

Species vary in their permeability to glucose, with human RBCs being very permeable and pig RBCs being poorly permeable. Red blood cells of other domestic animals appear to be intermediate between these extremes.[9] Glucose movement into RBCs is not regulated by insulin; rather facilitative glucose transporters mediate the passive diffusion of glucose into RBCs.[18] Red blood cells from adult pigs lack a functional glucose transporter and, therefore, have limited ability to utilize glucose for energy.[2]

Red blood cell membranes from most animal species have a nucleoside transporter. Rabbit, pig, and human RBCs exhibit substantially more adenosine uptake than those of other species studied. Red blood cells from dogs exhibit more adenosine uptake than those of cats, goats, or cattle, and RBCs from horses and most sheep appear to be nearly impermeable to adenosine. While dog RBCs are permeable to adenosine, they are impermeable to inosine. Dog and cat RBCs exhibit adenine uptake and incorporation into nucleotides, but values are much lower than those of human, rabbit, or rodent RBCs.[9]

CARBOHYDRATE METABOLISM

Although substrates such as ribose, fructose, mannose, galactose, dihydroxyacetone, glyceraldehyde, adenosine, and inosine may be metabolized to some extent, depending on the species, glucose is the primary substrate for energy needs of RBCs from all species except the pig. Inosine appears to be the major substrate for pig RBCs. Its production by the liver is sufficient to meet RBC energy requirements.[25]

Once glucose enters the cell, it is phosphorylated to glucose 6-phosphate (G6P) utilizing the hexokinase (HK) enzyme. The G6P is then metabolized through either the Embden-Meyerhof pathway (EMP) or the pentose phosphate pathway (PPP) as shown in Figure 21.1.

EMBDEN-MEYERHOF PATHWAY AND ATP PRODUCTION

A net of two molecules of ATP is produced for each molecule of glucose metabolized to two molecules of lactate in the EMP. Because mature RBCs lack mitochondria, the EMP is the only source of ATP production in these cells. Reactions catalyzed by HK, phosphofructokinase (PFK), and pyruvate kinase (PK) appear to be rate-limiting steps in glycolysis, with the PFK reaction being most important under physiologic steady-state conditions.[9]

At physiologic pH values, high concentrations of inorganic phosphate (P_i) stimulate glycolysis through the EMP by reducing the ATP inhibition of PFK. Conversely, glycolysis is inhibited by short-term phosphate deficiency, primarily by decreasing intracellular P_i for glyceraldehyde phosphate dehydrogenase (GAPD). Decreased glycolytic rates result in decreased RBC ATP concentrations and hemolytic anemia in experimental dogs made severely hypophosphatemic by hyperalimentation. Hemolytic anemia associated with hypophosphatemia has also been reported in diabetic cats and a diabetic dog following insulin therapy, in a cat with hepatic lipidosis, and in postparturient cattle in which decreased RBC ATP concentrations have been measured.[9]

Because mature RBCs depend solely on anaerobic glycolysis for ATP generation, deficiencies of enzymes involved in glycolysis result in shortened RBC survival. Insufficient ATPgeneration in deficient RBCs can result in echinocyte formation. PK-deficient dogs and cats have mild to severe regenerative hemolytic anemia (see Chapter 28). PK-deficient dogs exhibit marked iron accumulation in the liver and die from liver failure or myelofibrosis.[8] PFK-deficient dogs have compensated hemolytic anemia with sporadic episodes of intravascular hemolysis and hemoglobinuria (see Chapter 28).[8] PFK-deficient dog RBCs are alkaline fragile, because 2,3-diphosphoglycerate (2,3DPG) concentration is decreased in these cells. A decrease in 2,3DPG, the major impermeant anion in dog RBCs, results in higher intracellular pH. Episodes of intravascular hemolysis occur when PFK-deficient dogs develop alkalemia secondary to hyperventilation.[8]

DIPHOSPHOGLYCERATE PATHWAY AND OXYGEN AFFINITY OF HEMOGLOBIN

Molecules of 1,3-diphosphoglycerate (1,3DPG), produced by the GAPD reaction, may be utilized by the phosphoglycerate kinase (PGK) reaction in the EMP or

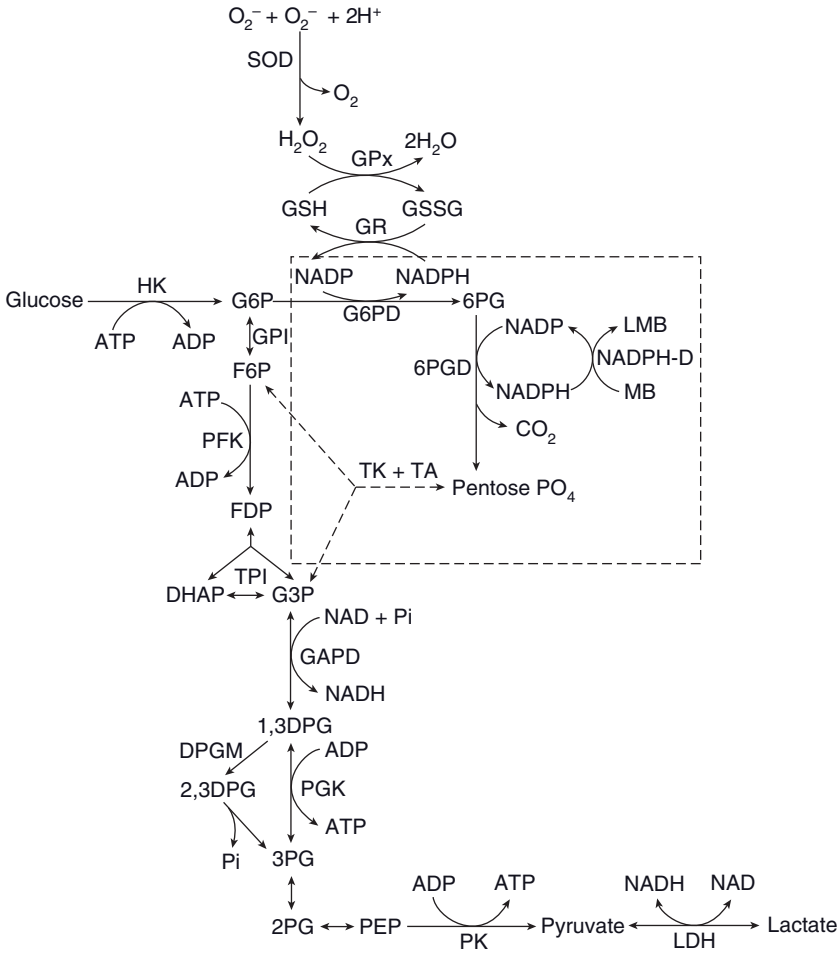

FIGURE 21.1 Metabolic pathways of the mature RBCs. HK, hexokinase; GPI, glucose phosphate isomerase; PFK, phosphofructokinase; TPI, triosephosphate isomerase; GAPD, glyceraldehyde-3-phosphate dehydrogenase; PGK, phosphoglycerate kinase; MPGM, monophosphoglycerate mutase; DPGM, diphosphoglycerate mutase; PK, pyruvate kinase; G6PD, glucose-6-phosphate dehydrogenase; 6PGD, 6-phosphogluconate dehydrogenase; LDH, lactate dehydrogenase; LMB, leukomethylene blue; MB, methylene blue; GR, glutathione reductase; GPx, glutathione peroxidase; TK, transketolase; TA, transaldolase; GSSG, oxidized glutathione; G6P, glucose 6-phosphate; F6P, fructose 6-phosphate; FDP, fructose 1,6-diphosphate; DHAP, dihydroxyacetone phosphate; GAP, glyceraldehyde 3-phosphate; 1,3-DPG, 1,3-diphosphoglycerate; 2,3-DPG, 2,3-diphosphoglycerate; 3PG, 3-phosphoglycerate; 2PG, 2-phosphoglycerate; PEP, phosphoenolpyruvate; ADP, adenosine diphosphate; ATP, adenosine triphosphate; NAD, nicotinamide adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, reduced nicotinamide adenine dinucleotide phosphate; NADPH-D, reduced nicotinamide adenine dinucleotide phosphate diaphorase; GSH, reduced glutathione; P_i, inorganic phosphate; SOD, superoxide dismutase. may be converted to 2,3DPG by the diphosphoglycerate mutase (DPGM) reaction (Fig. 21.1). 2,3DPG degradation to 3-phosphoglycerate (3PG) is catalyzed by diphosphoglycerate phosphatase activity (DPGP). The DPG pathway or shunt bypasses the ATP-generating PGK step in glycolysis; consequently, no net ATP is generated when glucose is metabolized through this pathway.

Red blood cells of dogs, horses, pigs, and man normally contain high concentrations of 2,3DPG, whereas those of cats and domestic ruminants have low concentrations. In RBCs from most mammalian species, 2,3DPG decreases the oxygen affinity of hemoglobin. When the oxygen affinity of hemoglobin is studied in hemolysates, removal of 2,3DPG and ATP (termed "stripping") from species with low 2,3DPG RBCs results in considerably lower oxygen affinities than removal from hemoglobin of species with high 2,3DPG RBCs. Because stripped hemoglobins from species with high 2,3DPG RBCs have high oxygen affinities, it appears that 2,3DPG is needed within RBCs of these species to maintain hemoglobin oxygen affinity within a physiologically useful range.[9]

The flow through the DPG pathway is regulated by the overall glycolytic rate. The formation of 2,3DPG is stimulated by increased phosphate concentration and increased pH. Hypoxic conditions stimulate 2,3DPG synthesis primarily by inducing hyperventilation with resulting alkalosis. Conversely, acidosis and hypophosphatemia result in decreased 2,3DPG concentrations. PFK deficiency inhibits glycolysis above the DPG shunt and results in decreased 2,3DPG concentration. In contrast, the concentration of 2,3DPG is increased in dogs with PK deficiency because the metabolic block occurs below the DPG shunt.[8]

Erythrocyte 2,3DPG increases in anemic dogs and cats. The resultant decrease in hemoglobin oxygen affinity would seem to be beneficial in response to anemia in the dog. 2,3DPG concentration is much lower in cat RBCs than in dog erythrocytes, and cat hemoglobins are generally less responsive to 2,3DPG than dog hemoglobin; consequently, the physiologic significance of this increase in cats in unclear.[9] Increased 2,3DPG has also been reported in RBCs from horses with hypoxic conditions.[6] In the case of severe hypoxic hypoxemia the response might be detrimental, because hemoglobin cannot be fully saturated.[12]

OXIDANTS AND OXIDATIVE INJURY

Animals are exposed to low levels of oxidants in their environment and from normal metabolic processes in

the body. Reactive oxygen species (ROS) and reactive nitrogen species (RNS) are formed as products of normal cellular metabolism. At low to moderate concentrations, nitric oxide and superoxide (O_2^-) free radicals are involved in signal tranductions between cells. When generated at higher concentrations in disease states, these free radicals (and even more potent oxidative metabolites that they produce) can overwhelm protective systems within the body, producing cellular injury and/or destruction.[22]

Cumulative injury from these exposures may account for the normal aging and removal of circulating RBCs (see Chapter 22). Some metabolic disorders, including diabetes, inflammation, hyperthyroidism, neoplasia, RBC parasites, intense exercise, and ischemia/reperfusion can generate oxidants in sufficient amounts to result in increased oxidant injury and shortened erythrocyte lifespans, but the anemia (when present) is generally mild (see Chapter 36). A wide variety of drugs and environmental agents either exist as free radicals or can be converted to free radicals by cellular metabolic processes. These free radicals can be more damaging than ROS and RNS.[9]

Oxidants may damage RBC hemoglobin, enzymes (especially sulfhydryl groups), and membranes (especially polyunsaturated lipids). Methemoglobin forms when hemoglobin iron is oxidized from the ferrous to the ferric state. Methemoglobin is unable to bind oxygen, but its presence alone does not result in shortened erythrocyte lifespan.[9]

Heinz bodies are inclusions that form within RBCs following the oxidative denaturation of the globin portion of hemoglobin (see Chapter 36). They bind to the inner surface of RBC membranes, and their presence can result in premature RBC phagocytosis. Heinz bodies are frequently recognized in RBCs from cats because of the susceptibility of cat hemoglobin to form Heinz bodies, combined with a poor ability of the cat spleen to remove Heinz bodies from RBCs. Even normal cats may have low numbers of Heinz bodies (<5%).[7]

Oxidative membrane damage results in premature phagocytosis of injured RBCs. Oxidative injury to erythrocyte membranes may result in the adhesion of opposing areas of the cytoplasmic face of the RBC membrane and the formation of eccentrocytes and pyknocytes. Eccentrocytes have primarily been recognized in dog and horse RBCs.[7] Intravascular hemolysis may occur when severe membrane injury is present.

PENTOSE PHOSPHATE PATHWAY AND PROTECTION AGAINST OXIDANT

The PPP generates NADPH, the major source of reducing equivalents in the protection of RBCs against oxidative injury. Normally only about 5–13% of glucose metabolized by RBCs flows through the PPP (Fig. 21.1), but this flow can be accelerated markedly by oxidants.[9] NADPH is needed to maintain glutathione and thioredoxin in the reduced state, and it is important in maintaining catalase in a functional form. Defects in the PPP can render RBCs susceptible to endogenous and exogenous oxidant injury. Glucose-6-phosphate dehydrogenase (G6PD) is the rate controlling enzyme in the PPP. A persistent hemolytic anemia with eccentrocytosis has been described in an American saddlebred colt with <1% of normal G6PD activity.[20]

Glutathione is of central importance in the protection against oxidant injury. It is a tripeptide of glutamic acid, cysteine, and glycine that is synthesized de novo in RBCs of animals from constituent amino acids via two ATP-requiring reactions. Glutathione deficiency occurs in some sheep because of a deficiency of γ-glutamylcysteine synthetase, the first enzyme involved in glutathione synthesis, and in other sheep deficient in the amino acid transporter responsible for cysteine transport into RBCs, thereby limiting cysteine uptake and restricting glutathione synthesis.[9]

Reduced glutathione (GSH) has a highly reactive sulfhydryl group that may act nonenzymatically as a free radical acceptor to counteract oxidant damage. GSH also functions as an electron donor in various reductive enzyme reactions including glutathione peroxidase (GPx), phospholipid hydroperoxide glutathione peroxidase, glutathione S-transferase, and glutaredoxin.[9]

Oxidized glutathione (GSSG) produced by these reactions is reduced back to GSH by using the flavin adenine dinucleotide (FAD)-dependent glutathione reduction (GR) reaction that requires NADPH. Horses with RBC FAD deficiency have markedly reduced GR activity, decreased GSH concentration, and prominent eccentrocytosis.[10]

Superoxide dismutase (SOD) within RBCs is a copper- and zinc- containing enzyme that promotes the dismutation of two O_2^- molecules to H_2O_2 and oxygen (Fig. 21.1). The importance of SOD as an oxidant defense in RBCs is unclear. Although generally considered protective, SOD may actually increase oxidant injury in conditions where H_2O_2 catabolism is compromised.[9]

GPx catalyzes the conversion of H_2O_2 to water. It also catalyzes the reduction of fatty acid hydroperoxides, and 1-monoacylglycerol hydroperoxides. Another GPx in RBCs termed phospholipid hydroperoxide glutathione peroxidase participates in the reduction of more complex phospholipid hydroperoxides using GSH.

Catalase is a heme-containing enzyme that also destroys H_2O_2 by conversion to water and oxygen. Except for dogs, mammalian RBCs generally have high catalase activities.[9]

Recent studies suggest that peroxiredoxins may be more important in protecting against H_2O_2 than GPx or catalase.[16] These multifunctional SH-dependent enzymes reduce H_2O_2 and alkyl hydroperoxides to water and alcohol, respectively. Oxidized peroxiredoxins are regenerated using reduced thioredoxin, and oxidized thioredoxin is reduced by NADPH using thioredoxin reductase.[14] Thioredoxin may also be important in the direct scavenging of free radicals. Thioredoxin and glutaredoxin are small proteins with two closely associated cysteines in their active sites. The reduced forms of these proteins interact with and reduce intramolecular protein disulfides that form in oxidatively damaged proteins.[15] Oxidized glutaredoxin is reduced by GSH.

Selenium is incorporated as selenocysteine at the active site of a wide range of selenoproteins, including GPx, phospholipid hydroperoxide glutathione peroxidase, and thioredoxin reductase in RBCs.[1] Heinz body hemolytic anemia has been reported in selenium deficient cattle grazing on St. Augustine grass.[19]

Vitamin E (α-tocopherol) is lipid-soluble and the most important antioxidant in the cell membrane. It donates reducing equivalents to lipid peroxyl radicals, converting them to less toxic lipid hydroperoxides.[22] Oxidized vitamin E can be reduced by ascorbate, presumably at the aqueous-lipid interface of the lipid bilayer.[17] Vitamin E deficiency increases the susceptibility of erythrocytes to peroxidative hemolysis.

Ascorbate donates one or two electrons to a variety of oxidants, including oxygen free radicals and peroxides. Dehydroascorbate can be reduced to ascorbate nonenzymatically by GSH and enzymatically via the glutaredoxin reaction, by a separate GSH-dependent dehydroascorbate reductase enzyme, and by the thioredoxin reductase reaction.[17,23]

METHEMOGLOBIN FORMATION AND REDUCTION

About 3% of hemoglobin within RBCs is oxidized to methemoglobin each day in normal animals; however, methemoglobin usually accounts for less than 1% of total hemoglobin, because it is constantly reduced back to hemoglobin by a cytochrome-b_5-reductase (Cb_5R) enzyme reaction present in RBCs.[9] In this reaction, electrons are transferred from NADH generated in glycolysis to ferricytochrome-b_5 using FAD as the enzyme-bound prosthetic group; then the resulting ferrocytochrome-b_5 reduces methemoglobin nonenzymatically to hemoglobin. Methemoglobin reduction is more corrective than protective. Methemoglobin forms at much higher levels in the presence of oxidative compounds. An inherited deficiency in Cb_5R in dogs and cats results in persistent methemoglobinemia with minimal or no clinical signs.[8] Methemoglobinemia also occurs in horses that have decreased Cb_5R activity secondary to RBC FAD deficiency.[10]

Methylene blue (MB) is used to treat toxic methemoglobinemia. It causes methemoglobin to be reduced faster than occurs by the relatively slow NADH-dependent methemoglobin reductase reaction. MB is reduced to leukomethylene blue (LMB) by NADPH-dependent diaphorase activity (Fig. 21.1), and LMB reacts spontaneously with methemoglobin, reducing it to hemoglobin and regenerating MB.[9]

Acronyms and Abbreviations

Bc, conjugated bilirubin; BRBC, biotinylated RBCs; Bu, unconjugated bilirubin; DGC, density gradient centrifugation; ECM, extracellular matrix; Hct, hematocrit; Hgb, hemoglobin; Hsp 70, heat shock protein 70; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; NMB, new methylene blue; PS, phosphatidylserine; RBC, red blood cell; RNA, ribonucleic acid; RPI, reticulocyte production index; SDS-PAGE, sodium dodecyl sulfate-polyacrylamide gel electrophoresis; SOD, superoxide dismutase; TfR, transferrin receptor.

The anuclear red blood cell (RBC) lifespan is characterized by three phases. A brief reticulocyte maturation period features rapid changes supported by a high rate of metabolism and synthetic function. The mature cell phase involves months of precise functioning under rigorous circulatory conditions. In the final, relatively brief senescence phase RBCs incur age-associated lesions involving rheological fitness, antioxidant defenses, and membrane structure. Less viable cells are removed from the circulation predominantly by cells of the mononuclear phagocyte system. The production activities of reticulocytes, their maturation and release, and processes of erythrocyte aging and destruction are covered in this chapter.

RETICULOCYTE RESPONSE

Reticulocyte Maturation

A reticulocyte is produced when a late stage nucleated erythroid precursor (metarubricyte) expels its nucleus. The reticulocyte then develops into a mature circulating RBC in 3–4 days, but at inception it is in many respects quite distinctive from the mature cell.[28,67] In contrast to the relatively uniform biconcave shape of mature cells in many species, reticulocytes are larger, round to lobulated cells with considerably more surface area and less cytoplasm. They have medium to large irregular invaginations and small superficial clathrin-coated pits used for endocytic activities.[33] Transmembrane receptors, transporter proteins, clathrin-coated pits and other transport/endocytic functions are actively providing essential building blocks (amino acids, iron, etc.) for synthesis of proteins and other components. At this stage 20–30% of total Hb must still be produced.[27,67] These production activities require an actively synthesizing cytoplasm complete with ribosomes, polyribosomes, RNA and mitochondria, all of which will be removed within the next 3–4 days.

Cell maturation requires a degradation and clean-up process for components that will not be needed in mature cells. Proteolytic enzymes and RNAases, such as pyrimidine 5′ nucleotidase, are responsible for degradation of various proteins, ribosomes, and RNA. Low numbers of lysosomes can facilitate limited degradation. A specific 15-lipoxygenase has been shown to initiate degeneration of mitochondria via programmed cell

death (mitoptosis). The enzyme works through production of reactive oxygen species and also binds to endoplasmic reticulum, Golgi apparatus, and peroxisomes.[27]

Exosomes play a major role in the remodeling and extrusion process.[3,27] Briefly, exosomes are formed by endocytic invaginations of membrane that are assembled into multivesicular exosomes. These structures then fuse with the internal cell surface where small (~60 nm) membrane bound vesicles (exosomes) are released. Some estimates suggest that exosomes account for most of the membrane loss associated with maturation, about 30% in rats. The membranes of released exosomes have features (e.g. phosphatidylserine [PS] exposure) that allow recognition and removal by macrophages as apoptotic bodies, avoiding the incitation of inflammation or possibly an autoimmune response.[3] Cell components shown to be selectively enriched in exosomes include receptors for transferrin (TfR), fibronectin, and insulin, and transporters for glucose, nucleosides, and amino acids.[27] Membrane Na-K ATPase is also removed from reticulocytes of carnivores that switch to low K^+:high Na^+ cytoplasm in mature RBCs. Heat shock protein-70 (Hsp-70), a chaperone protein, has been strongly implicated in the enrichment of TfR and probably other membrane proteins into exosomes.[26,27]

Maturing reticulocytes are found primarily in the bone marrow where they can be sheltered until better prepared for circulatory stresses. In vitro studies indicate that the youngest reticulocytes have significantly decreased membrane stability and deformability by as much as 90% compared to later stage reticulocytes and mature RBCs.[7,76,85] As cells mature several changes prepare the cell for release from the marrow into the circulating pool. The membrane receptors that tether reticulocytes to fibronectin and thrombospondin in the marrow extracellular matrix (ECM) are gradually lost, apparently through transfer to exosomes. Exosome release also reduces membrane surface area and aids in remodeling of the membrane. Coupled with cytoskeleton maturation and stability, this leads to smaller size and improved deformability. Surface sialic acids are decreased, which reduces negative charge repulsion between reticulocytes and endothelial cells. Subsequent contact with adventitial and endothelial cells appears to initiate thinning of the adventitia and separation between endothelial cell junctions that allows diapedesis of RBCs through pores into circulation.[2] In species where some reticulocytes are allowed to circulate in health, the cells appear to be preferentially sequestered for a period in the spleen where reticulocyte "ripening" allows for further hemoglobinization, membrane remodeling, and cytoskeletal stabilization. Splenic retention is apparently mediated through residual fibronectin receptors on reticulocytes.[60]

Reticulocyte Identification and Counting

Reticulocytes are identified based on their appearance when exposed to supravital stains (new methylene blue, brilliant cresyl blue, etc.). The dye causes precipitation of ribosomal RNA and organelles into a reticulum that is recognized as clumped aggregates of dark blue material (aggregate reticulocytes) or as two or more small punctate structures (punctate reticulocytes), depending on the amount of RNA present. With Romanowsky-type stains (Wright-Giemsa) no precipitate is formed. RNA remains dispersed and confers a uniform light blue color to the cells that are called polychromatophils. Polychromatophils correspond to aggregate reticulocytes and, although less sensitive, are useful on routine peripheral blood smears for characterizing marrow responsiveness to anemia.

The maturation time for aggregate and punctate cells and the maturation stage at which reticulocytes are normally released from the marrow vary with species. Dogs normally release aggregate reticulocytes from the bone marrow (usually ≤1.0%), which then complete maturation in roughly 24 hours. Punctate forms are short lived and are seen in insignificant numbers. Cats normally release low numbers of aggregate reticulocytes in health (<0.4%). These have a short circulating maturation time of about 12 hours to become punctate cells which then circulate for 10–12 days and may represent 10% of RBCs in health.[16,82] Horses do not release reticulocytes from bone marrow in health and only rarely in regenerative anemia. However, RNA-containing equine RBCs can be recognized by automated technology, which might improve sensitivity in assessing equine anemia.[14] Reticulocytes are typically not seen in the peripheral blood of cattle, sheep, or goats except in response to anemia. Healthy laboratory animal species that have shorter RBC lifespans and higher rates of erythropoiesis typically release reticulocytes at rates equal to or greater than are seen in dogs. Normal reticulocyte information for a wide range of species has been tabulated (see Section IX).[22]

Cat aggregate reticulocyte counts and polychromatophilic cell proportions are lower than seen in healthy dogs or dogs with similar degrees of anemia, suggesting inherently inferior responsiveness to anemia. This species comparison may be misleading because bone marrow regenerative robustness is reportedly greatest in the cat among common domestic species.[82] Accordingly, the feline punctate reticulocyte counts may be quite high, exceeding $4 \times 10^6/\mu L$. It appears that the rapid aggregate cell maturation in circulation masks the overall intensity of regeneration in cats. Historically, punctate reticulocyte counts in cats have been omitted in many laboratories. Because aggregate cells are so short lived and elevated punctate counts in cats do reflect a recent regenerative response, reporting of both types is advisable. Omission of punctate counts may lead to misclassification of anemia.

Although several automated analyzers capable of providing accurate and sensitive reticulocyte counts are available, manual methods are still used (see Chapter 136). The reticulocyte percent can easily be misinterpreted because the percentage depends not only on marrow production, but on the number of mature cells in circulation. The same number of

reticulocytes per μL of blood will represent a very different percentage when accompanied by normal numbers of mature cells (Hct 45) versus greatly reduced mature RBC numbers (Hct 15). To correct for this, the reticulocyte percent is multiplied by the total RBC count to obtain the "absolute reticulocyte count" (reticulocytes/μL). Healthy dogs and cats generally have ≤80,000/μL and ≤60,000/μL absolute reticulocyte counts, respectively. If the RBC count is not available, the Hct can be used to calculate a "corrected reticulocyte percent" which makes a similar adjustment for the effect of relative RBC mass on reticulocyte percent. This value is obtained by multiplying the patient reticulocyte percent times the patient Hct/normal Hct. The normal Hct value is typically 45 for dogs and 37 for cats, values which roughly represent the middle of their respective species reference ranges.

As severity of anemia increases, reticulocytes tend to be released earlier in the marrow maturation process (i.e. shift reticulocytes). Because more immature reticulocytes circulate longer, reticulocyte counts will be higher but this reflects prolonged circulation time rather than increased production. This overestimation of marrow responsiveness can be corrected by calculating the "reticulocyte production index" (RPI). In humans and presumably in dogs, it is estimated that the reticulocyte circulating maturation time increases by 0.5 days for each 10-unit decrease in Hct. At Hct 45 the normal maturation time is 1 day. Therefore, the maturation time at Hct 35 is 1.5 days, at Hct 25 it is 2.0 days, and at Hct 15 it is 2.5 days. The RPI is calculated by dividing the corrected reticulocyte percentage (or absolute reticulocyte count) by the above maturation factor. For example, if a patient has a Hct of 25 (maturation time = 2 days) and a corrected reticulocyte percentage of 3, the RPI is 3.0/2 = 1.5. This substantially reduces the estimation of marrow responsiveness. The RPI adjustment is not recommended in other species due to lack of information on the impact of various Hct levels on circulating maturation times.

RBC LIFESPAN

Species Variation

After release from marrow, RBCs circulate throughout the vascular system thousands of times before being removed, disassembled, and recycled by macrophages. The RBC lifespan varies characteristically with species and the differences are at least partially explained by different metabolic rates. Comparative studies reveal that RBC lifespan correlates positively with species longevity (years) and with body mass. That is, larger mammals tend to live longer and have longer RBC lifespans when compared to smaller species. Smaller species have higher rates of oxidative metabolism and presumably accrue oxidative injury at higher rates, reducing both longevity and RBC lifespan. This relationship is illustrated by comparison among common mammalian species where the RBC lifespan is approximately 140–145 days for horses, 130 days for cattle, 115 days for goats, 100–115 days for dogs, 73 days for cats and 43 days for mice.[74]

Other experimental evidence suggests that RBC lifespan in health may be influenced by RBC antioxidant status. Kurata et al. found that RBC potential lifespan in several mammalian species (n = 10) correlated significantly with the RBC levels of superoxide dismutase (SOD), glutathione peroxidase, and glutathione.[45] Additionally, RBC viability may be negatively influenced by corporal aging, at least in small laboratory animals. RBCs from old rats are reported to have lower quantities of several antioxidant enzymes compared to young rat RBCs.[30] Reticulocytes from old rats have lower SOD activity, and increased quantities of catalytically inactive SOD, suggesting an age-associated defect in erythropoiesis.[30] These differences are associated with altered RBC survival as evidenced by a reported 40–60% shorter RBC lifespan in old mice and rats versus young animals.[1,29] Although limited information is available for larger animals, a similar pattern of shorter RBC lifespan with age has been suggested for greyhounds.[59]

Not all circulating RBCs are removed exclusively based on cell age (senescence-based clearance). In most species of mammals, a variable proportion of RBCs leave the circulation independently of cell age (random clearance). Although the mechanism for random clearance is speculative, the degree of random clearance does appear to correlate positively with metabolic rate.[74] Higher rates of random loss are, therefore found in smaller species (e.g. rabbits, rodents) and, because senescent and random clearance cannot be readily distinguished, random loss confounds studies attempting to characterize mechanisms for senescence-based clearance.

Methods

Red blood cell lifespan studies have traditionally used radioisotopes and such studies usually take one of two forms: random or cohort labeling.[46] A random study labels an aliquot of RBCs having an age distribution similar to that normally found in circulation. As these RBCs circulate, the steady decrease in survival (as measured by a decrease in radioactivity) is ideally a result of normal RBC turnover. For instance, in humans and dogs, where ~1% of RBCs are lost each day, the radioactivity would decrease by 1% per day. Isotopes like ^{51}Cr and ^{14}C-cyanate are typically used for random RBC studies. On the other hand, cohort studies attempt to label RBCs of a similar age so that, barring random RBC loss, radioactivity in circulation remains constant until the cohort becomes senescent. At that time radioactivity decreases rapidly as the cohort of old RBCs is removed from circulation. Isotopes such as ^{15}N-glycine, ^{55}Fe, and ^{59}Fe that are incorporated into developing RBCs are commonly used for cohort studies.

A thorough knowledge of any probe used for measuring RBC lifespan is essential to obtaining accurate

results. An ideal probe will not be: toxic to cells or the host, immunogenic, eluted from the cells before RBC clearance, or reutilized in making new RBCs (recycled). Corrective formulas may help adjust for a failure to meet these criteria, but corrective formulas sometimes must be species-specific. For instance, elution of ^{51}Cr from RBCs in circulation renders determination of RBC survival complicated.[31] The degree of elution can vary considerably between species.[48] Therefore, formulas correcting for elution loss in humans are unlikely to be applicable in other species. Use of iron radioisotopes to measure RBC lifespan is problematic because upon destruction of labeled RBCs the isotope is recycled into the Hb of new cells.[23,70] Corrections are required because recycling increases values for RBC survival. The ^{14}C-cyanate label is a better probe in that it can be used at non-toxic levels, it does not elute from cells, and it is not reused.[6,32,47]

Several nonradioactive, random labeling probes have been developed that increase safety and convenience of measuring RBC lifespan. Most are fluorescence-activated probes that allow detection of the proportion of labeled RBCs over time by flow cytometry.[9,35,64] These probes require similar validation as isotopic methods. Biotinylation of RBCs has been one of the most widely used approaches. Labeled RBCs are detected based on affinity to avidin-conjugated fluorescent probes (e.g. fluorescein derivatives).

MECHANISMS OF RBC CLEARANCE

Methods of Approach

Compared to direct measurement of RBC lifespan, isolation of unequivocally old RBCs for analytical studies has been a formidable task. Historically, isolation of dense RBCs by density gradient centrifugation (DGC) has been the most popular method for collecting presumably senescent RBCs. This approach was first supported by human studies suggesting that as radiolabeled cohorts of RBC aged, fractionation on density gradients resulted in increasing enrichment of labeled cells in more dense centrifugation fractions.[5] It was also reported that the most dense fraction of human RBCs had very short survival upon autologous reinfusion.[72] However, many different separation media and methodologies have been used without standardization and frequently without adequate validation.[15] This has led to inconsistent and often contradictory results so that controversy has plagued these studies.

To bypass these controversies, unique approaches for in vivo aging of RBCs were developed in animal models. These studies use defined RBC populations that circulate for specific time intervals before RBCs are isolated and analyzed. The advantage of these "in vivo" aging approaches is that RBCs are selected based on known time in circulation rather than on a controversial trait that is assumed to correlate with cell age.

The first approach involved serial hypertransfusion of laboratory animals resulting in polycythemic shutdown of erythropoiesis over the lifespan of circulating RBCs. At specific intervals of the normal RBC lifespan, RBCs of known circulatory age range are then collected and analyzed.[25,56,87]

Using a different approach, RBC senescence in several species has been evaluated by covalently linking biotin to RBC membranes.[10,71] After defined periods of circulation, biotinylated RBCs can be isolated from other cells based on affinity to an avidin support, and subsequently analyzed. The purity of biotinylated cells can be determined using a secondary avidin label conjugated to a fluorescent probe.

These approaches have been used to test if increasing RBC density is a significant component of the aging process in various species. Hypertransfused rat RBCs did show increasing cell density (i.e. MCHC) early in the RBC lifespan but not late, suggesting mainly a maturation effect.[25] Hypertransfused mice showed minimal, age-associated changes in RBC density profiles.[56,57] Rabbit biotinylated RBCs did show some senescence-associated enrichment in the most dense RBC fractions generated on Percoll media. But these old biotinylated RBCs only comprised about one-third of the dense RBCs, indicating that density gradient-derived RBCs were poorly representative of the oldest cells.[17] Conversely, the canine biotinylation model has demonstrated quantitatively that the 1% most dense RBCs fractionated on arabinogalactan gradients are at least moderately enriched for old RBCs.[11] Over 75% of these dense cells were between 86 and 115 days old with a mean cell age of approximately 101 days (RBC lifespan 100–115 days). Although clearly enriched for old cells, it is still unclear if the most critical changes occurring in the last few days of RBC survival are well represented in this population.

Indirect Aging Markers

Controversy over the analysis of dense cells as old cells has also led to the search for cellular aging markers that could be used to verify that the isolated RBCs are actually the oldest RBCs. These markers may not be associated with RBC clearance per se, but are intended to simply validate that the RBCs being studied are among the oldest cells. Many markers have been proposed, but most have eventually been shown to reflect maturation rather than aging (e.g. insulin receptor, pyrimidine 5 nucleotidase, ATP levels, glycolytic enzymes, etc.) A couple of candidates remain as valid markers of cell age.

The best characterized aging marker involves changes in RBC membrane protein 4.1. In the mouse hypertransfusion model a relatively constant change in the ratio of membrane skeletal proteins 4.1a and 4.1b was observed by electrophoresis (SDS-PAGE) throughout the lifespan.[57] Although total band 4.1 remained relatively constant, the proportion contributed by 4.1a went progressively from 8% at mean cell age of 4 days to 54% at mean cell age of 57.5 days (mouse RBC lifespan = 60 days). In control cells at mean cell age of 30 days, band 4.1a accounted for 30% of total band 4.1.

With the exception of the cat, this phenomenon is observed in humans and in all of the common domestic mammals.[37,62] The cause of this change in protein ratios has been defined. In the mouse, protein 4.1b is transcribed and inserted into the membrane at an early stage of erythroid development.[37] Protein 4.1a is then formed by post-translational modification of 4.1b. A study using human RBCs demonstrated that the conversion of 4.1b to 4.1a results from deamidation of asparagine 502.[38] This change is responsible for the apparent molecular weight shift seen on electrophoresis. The change is probably not a factor in removal of aged RBCs; however, the ratio has been used to confirm the relative increase in age of the densest RBCs isolated on arabinogalactan[41] and on Percoll[54] media.

Glycated hemoglobin (HbA1c) also has been proposed as a marker of RBC aging. HbA1c is formed by the irreversible, nonenzymatic binding of glucose to hemoglobin (Hgb), which is dependent on plasma glucose concentration and time of exposure (i.e. RBC lifespan).[24] Its primary use has been in monitoring time-averaged glycemic control in diabetics. However, if plasma glucose concentration is held constant, variations in HbA1c should be a function of RBC age. There is evidence that HbA1c levels increase with increasing RBC density.[21]

RBC Clearance Mechanisms

The mechanisms of RBC clearance may be multiple and the importance of each may vary with species. It appears that the best supported clearance mechanisms are designed to remove old RBCs well before significant decrement in individual cells might compromise overall RBC functionality. Thus, redundancy in mechanisms to ensure timely clearance would not be surprising.

Rheological Compromise

Based on evidence that cell density and cell age were positively correlated,[5] early RBC aging studies concentrated heavily on identifying "worn out" cells with severely compromised rheological abilities. Since then, some well-designed comparative studies using in vivo aged rabbit biotinylated RBCs, hypertransfused mouse RBCs, and human dense RBCs have confirmed that some rheological compromise accompanies cell aging.[54,77] But the magnitude and significance of these changes in explaining RBC clearance remain equivocal. Although mild decreases in deformability were observed, fairly constant surface area to volume ratios (sphericity) and a slight decrease in diameter offset that change and convincing support that the RBCs would be compromised in traversing sinusoids was lacking.

In contrast to age-related rheological changes as a primary clearance mechanism, much study has been directed at finding sensitive and specific signals that trigger clearance of aging RBCs long before they become effete. Both immunologic and nonimmunologic pathways of RBC clearance have been identified.

IgG Binding

Autologous immunoglobulin binding to the most dense human RBCs and increased phagocytosis of these RBCs by autologous macrophages was first described by Kay.[42] Fab dependent IgG binding and phagocytosis suggested the involvement of specific receptor recognition by the IgG.[43] Supporting Kay's findings, several other density gradient centrifugation based studies have also reported increased immunoglobulin binding in the most dense RBCs.[29,41,53] Furthermore, using the mouse hypertransfusion model of in vivo aging, autologous IgG was identified only in the oldest RBCs and was associated with in vitro phagocytosis.[66] Increased IgG binding to dog biotinylated RBCs ≥104 days old has been demonstrated, although the ability of the IgG binding to mediate phagocytosis was not tested.[8] By contrast, in vivo aged rabbit biotinylated RBCs failed to show terminal increases in IgG binding,[18] which further highlights the need for caution in extrapolating information between species.

The identity of the epitope responsible for antibody binding to senescent RBCs has been controversial, although it is not unreasonable to consider that more than one epitope may develop and that this could vary between species. The anion transport protein (band 3 on SDS-PAGE) has received the most support as an important site, although other sites such as glycophorin A and aminophospholipids, have also been proposed. Band 3 reportedly becomes antigenic through either proteolytic cleavage revealing a 62 kDa immunoreactive fragment, or by horizontal redistribution of the transmembrane protein into immunoreactive clusters. Exposure of the cryptic 62 kDa antigen by proteolysis is proposed to occur as a consequence of cumulative oxidative injury.[44] Interestingly, cat RBCs exposed to activated neutrophils show evidence of proteolysis and increased IgG binding.[79–81] The changes, that appear to contribute to accelerated clearance of RBCs in the anemia of inflammatory disease, ensued from a combination of oxidation and serine protease activity. Lower level, cumulative injury could conceivably play a role in RBC injury and clearance under normal homeostasis, as described Kay et al.[44]

The role of band 3 clustering in initiating autologous antibody binding has been well documented in senescent and diseased RBCs.[40,41,49,51,55,75,78,86] It is theorized that unclustered band 3 does not sustain antibody binding because the senescent cell IgG binds weakly and requires a two-point attachment to form a stable association. Normally the distance between band 3 molecules is too great for the binding of both Fab portions of IgG. Clustering of band 3 can be accomplished by several methods, including binding of denatured Hgb (i.e. hemichromes or Heinz bodies) at the cytoplasmic domain of band 3 or by chemical agents such as zinc, mellitin, and acridine orange.[12,73,75] Oxidized, denatured Hgb has a specific high affinity binding site on the cytoplasmic domain of band 3. This binding leads to a horizontal redistribution of band 3 into a clustered arrangement that is then recognized on the external

surface by autologous antibodies. This pathway illustrates how an early intracellular compromise in maintaining reduced Hgb could initiate a morphologic change on the external cell surface leading to opsonization and phagocytosis. Membrane aggregates showing enrichment and co-localization for hemichromes, band 3, and IgG have been identified in a variety of conditions, including dense human RBCs, sickle RBCs, and thalassemic RBCs.[40,41,78,86] The pathway of Hgb denaturation leading to band 3 clustering and opsonization is at least partially supported by in vivo RBC aging studies. Hypertransfused mouse RBCs and dog biotinylated RBCs both show increased membrane-bound Hgb and increased IgG binding late in the RBC lifespan, although these changes have not yet been specifically co-localized to band 3 clusters.[56,63] Clustering of band 3 using chemical agents (acridine orange, Zn^{2+}, melittin) also causes autologous IgG binding apart from hemichrome formation, supporting the premise that it is the clustering of band 3 and not the oxidation process per se that creates the signal for IgG binding.[49,73] Removal of the clustering agents in each case, led to reversal of the clustered distribution and elution of antibodies.

Opsonization of RBCs secondary to band 3 clustering may play a notable role in the pathogenesis of several hemolytic anemias of significant importance to veterinary medicine. Heinz body hemolytic anemia occurs in several species as a result of exogenous intoxicants and, in the cat, associated with certain metabolic diseases. Because Heinz bodies bind to the cytoplasmic domain of band 3, subsequent clustering and opsonization may lead to an immune-mediated component in clearance of these cells.

Zinc intoxication in dogs is frequently associated with severe hemolytic anemia. Strong regenerative responses with spherocytosis and inflammatory leukograms have led clinicians to initially diagnose this as immune-mediated hemolytic anemia. Given the clear role of zinc in clustering of band 3 with subsequent opsonization, this toxicity is likely an immune-mediated process. Although initially counterintuitive, this condition is consistently reported as Coombs' test negative. But this is very consistent with the reversible nature of band 3 clustering by zinc. RBCs are washed before running the assay. Washing would remove zinc, leading to dispersion of the band 3 clusters and elution of the antibodies. Finally, melittin in bee venom is another band 3 clustering agent. Although other elements in bee venom (e.g. phospholipase A_2) are clearly important in the destruction of RBCs, the potential for an immunologic component secondary to band 3 clustering should also be considered.

Complement

Another factor likely to be important in the efficient removal of IgG-opsonized RBCs is amplification of the signal by complement. Turrini and coworkers showed that when band 3 in human RBCs was clustered using $ZnCl_2$, a sequence of IgG binding, complement binding, and in vitro phagocytosis followed.[73] Phagocytosis was maximal in the presence of clustered band 3, IgG, and complement. Inactivation of complement reduced phagocytosis by 80% which demonstrated IgG's weak capacity to initiate phagocytosis alone and emphasized complement's importance in amplification. However, phagocytosis was virtually eliminated if IgG or band 3 clustering was removed, showing the absolute requirement for these steps. This work complemented previous reports describing the presence of C3b-IgG complexes on oxidatively stressed[50] and density-gradient derived "senescent" human RBCs.[52] Interestingly, only low numbers of IgG (an increase of <20 IgG/RBC) were needed to stimulate significant complement deposition.[50] Quantitative studies on antibody binding to dense RBCs have generally reported an increase of only a few hundred IgG per RBC.[41,43] With amplification, this degree of antibody binding should be a more than adequate signal to initiate phagocytosis.

Oxidation of Proteins

Several indications of compromised antioxidant capacity have been observed in dense and in vivo aged RBCs from various species. A few examples include decreases in total free thiol and reduced glutathione, glutathione reductase activity, and increases in methemoglobin, membrane bound hemichrome, and lipid peroxidation byproducts.[1,36,39,41] Although there has been controversy over the significance of reported compromises in antioxidant defenses,[13] the presence of irreducible denatured hemoglobin bound to membranes is difficult to dismiss as clear evidence of antioxidant decline. At least two different pathways have been proposed whereby interaction of oxidized Hgb with the membrane might lead to RBC removal (see Chapter 36). One is hemoglobin-spectrin cross-linking leading to increased membrane rigidity, decreased deformability and/or stimulation of membrane proteolysis with subsequent breakdown in membrane integrity.[68,69] The other pathway is as described earlier whereby oxidized Hgb binds to and clusters band 3 protein leading to opsonization and clearance.

Other Potential Clearance Mechanisms

A number of other lesions in senescent RBCs have been proposed as playing a role in clearance. With evidence for some decline in antioxidant capabilities there is also a risk of lipid peroxidation that could facilitate RBC removal by either compromising deformability[61] or triggering recognition by macrophages.[65] The latter is suggested to occur through exposure of phosphatidylserine on the outer leaflet of the lipid bilayer. Whether secondary to oxidative injury, depletion of energy, or other mechanisms, there is ample evidence that the presentation of negatively charged phosphatidylserine on the outer layer of RBCs leads to phagocytosis by macrophages.[65] In the rabbit biotinylation model, older RBCs were found to expose more phosphatidylserine than younger RBCs and the increased exposure correlated well with senescence-based removal, but not with

random removal of RBCs.[4] This may well be an important mechanism for clearance of senescent RBCs, particularly in the rabbit where IgG binding does not appear to be a significant factor in the clearance of old RBCs.[18] Recognition of phosphatidylserine exposure on RBCs by macrophages can be at least partially mediated by lactadherin, a phosphatidylserine binding glycoprotein produced by macrophages.[19]

RBC DESTRUCTION

The primary organs of RBC clearance are the spleen, liver, and bone marrow. Phagocytosed RBCs are digested within macrophage phagolysosomes, and hemoglobin is dissociated into heme and globin. Globin is further digested and resulting amino acids are reutilized. Heme breakdown produces iron, biliverdin and small amounts of carbon monoxide. Heme oxygenase-1 (HO-1) is the rate-limiting enzyme in heme degradation and is responsible for release of iron. Heme iron may be stored in macrophages or exported to the circulation by ferriportin.[20,58] Biliverdin is converted within the macrophage to bilirubin (unconjugated, Bu) that is relatively water insoluble. As bilirubin leaves the cell it attaches noncovalently to albumin to improve solubility and to be transported to the liver. Bu uptake by hepatocytes and conjugation with glucuronides (most species) produces the water-soluble conjugated bilirubin (Bc) that is excreted by active transport into biliary canaliculi for excretion in the intestines. There Bc is broken down to urobilinogen which is either reabsorbed or is converted to stercobilinogen, which contributes to the dark brown color of feces, and excreted. Reabsorbed urobilinogen is either taken up by hepatocytes and excreted in the bile or enters general circulation and is excreted in the urine.

Acronyms and Abbreviations

DIC, diffuse intravascular coagulation; FAD, flavin adenine dinucleotide; GN, glomerulonephritis; HJ, Howell-Jolly body; IMHA, immune-mediated hemolytic anemia; MCV, mean corpuscular volume; NMB, new methylene blue; nRBC, nucleated red blood cell; RBC, red blood cell.

Evaluation of red blood cell (RBC) morphology is a critical step in thorough blood smear evaluation and can aid in identifying many different metabolic disorders, indicate oxidative damage or help localize a disease process. There are four features of red blood cell morphology that should be evaluated: color, size, shape and inclusions.

NORMAL ERYTHROCYTE MORPHOLOGY AND DISTRUBUTION

The typical RBC shape for multiple veterinary species is the disc or biconcave disc (i.e. discocyte) resulting in a high surface area to volume ratio making the RBCs deformable. Central pallor can be observed to variable degrees in these species on examination of a peripheral blood smear. Central pallor is most prominent in the dog and less so in cats and horses. Poikilocytosis is a frequent finding in young ruminants and is considered to be normal, especially in goats (Fig. 23.1). In certain deer breeds, antelope and some breeds of sheep and goats, drepanocytes (also termed sickle cells) can be observed in vitro. This phenomenon occurs when the oxygen tension of blood is high (e.g. exposure to atmospheric oxygen during mixing of samples or smear preparation) or the pH is between 7.6 and 7.8. The sickling is due to variants of hemoglobin that form insoluble, elongated polymers under these conditions.[22]

The monolayer of the peripheral blood smear allows for evaluation of red blood cell arrangement. In most species, RBCs are individualized; however, some species are prone to rouleaux formation in which the RBCs line up in a column, resembling a stack of coins (Fig. 23.2). Although it may be a normal finding in cats and horses, it can be accentuated by elevated plasma protein concentrations.[22] Rouleaux must be differentiated from agglutination. Agglutination is disorderly aggregation of RBCs (Fig. 23.3). Agglutination can be observed in immune-mediated hemolytic anemia (IMHA) and as an in vitro change in horses given heparin.[27] Rouleaux will be disrupted by diluting the blood with saline, but agglutination does not (see Chapter 140).

VARIATION IN ERYTHROCYTE MORPHOLOGY

Hemoglobin Content

Many species will have low numbers of circulating reticulocytes. This can result in noticeable polychromasia and anisocytosis. A polychromatophilic RBC contains organelles such as ribosomal RNA and

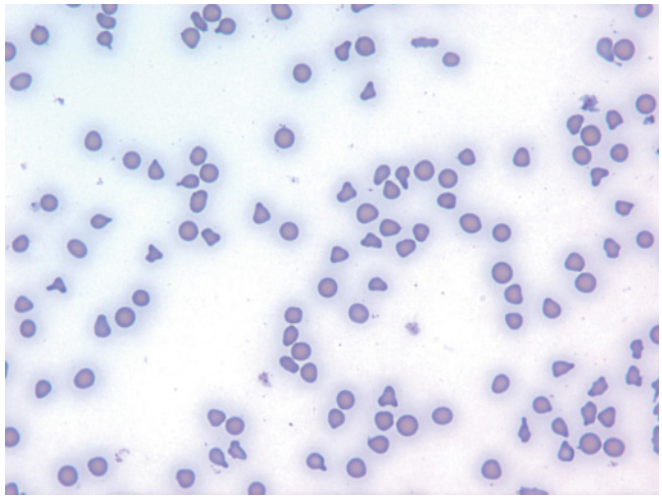

FIGURE 23.1 Blood smear from a goat showing typical poikilocytosis. Wright-Giemsa stain.

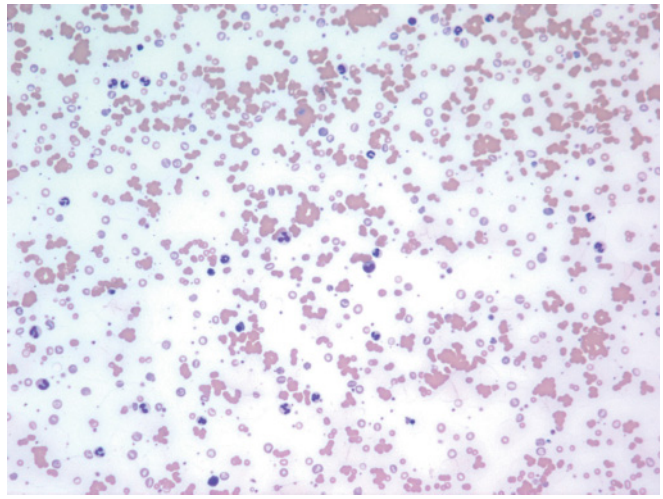

FIGURE 23.3 Blood smear from a dog with marked agglutination associated with immune-mediated hemolytic anemia. Wright-Giemsa stain.

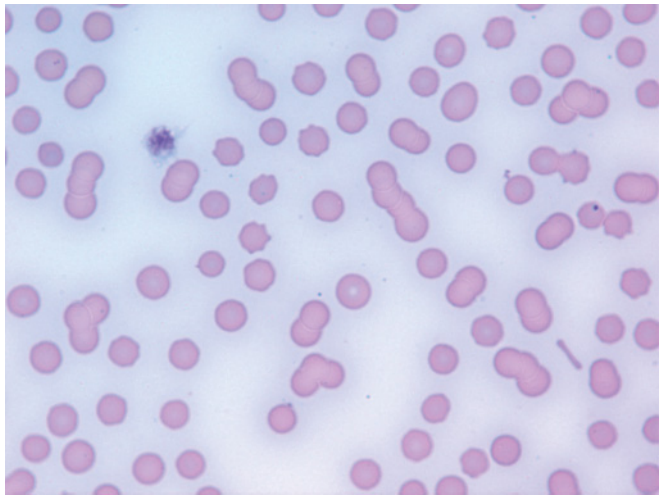

FIGURE 23.2 Blood smear from a cat showing rouleaux formation. Wright-Giemsa stain.

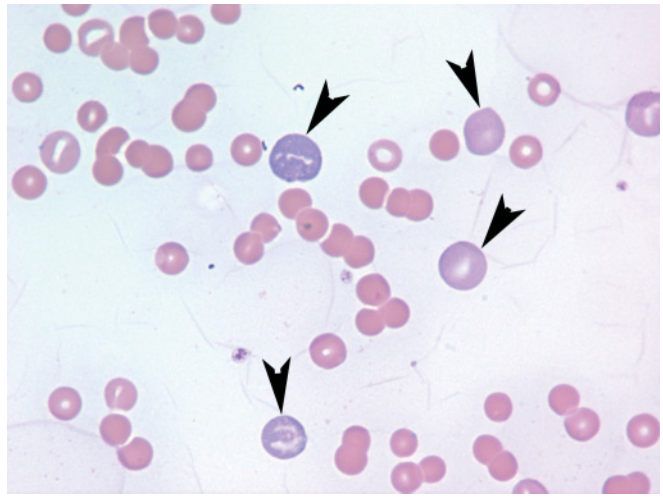

FIGURE 23.4 Blood smear from a dog showing polychromatophilic RBCs (arrows). These cells are larger than mature RBCs with grayish-blue cytoplasm. Wright-Giemsa stain.

mitochondria. When stained with a Romanowski stain, the presence of these structures will cause the cytoplasm to stain grayish-blue (Fig. 23.4). The RNA network and organelles precipitate, becoming more obvious if the blood is stained with new methylene blue (NMB). Increased polychromasia can indicate a regenerative response to anemia, but is not as sensitive as a reticulocyte count because not all reticulocytes are polychromatophilic. Horses do not have circulating reticulocytes and thus do not have polychromasia in their peripheral blood.

Patients with iron deficiency anemia can develop hypochromasia (see Chapter 26). Since iron is necessary for heme synthesis, erythrocytes from patients with iron deficiency can have decreased hemoglobin content. These cells have a thin rim of hemoglobin with increased area of central pallor (Fig. 23.5). True hypochromasia needs to be differentiated from torocytes. A torocyte is usually considered an artifact.[22] These cells have an increase in central pallor but it is an abrupt rather than a gradual decrease in the rim of hemoglobin. Other causes of hypochromasia include prolonged copper deficiency or deficiency of vitamin B6.[17]

Cell Size

Anisocytosis is a general term that describes variation in cell size. Healthy animals will have mild anisocytosis, likely from the presence of low numbers of circulating reticulocytes. Reticulocytes are often larger than mature erythrocytes so they are described as macrocytes. Other causes of macrocytosis include feline leukemia virus, myelodysplastic syndromes, and some congenital and hereditary conditions (see

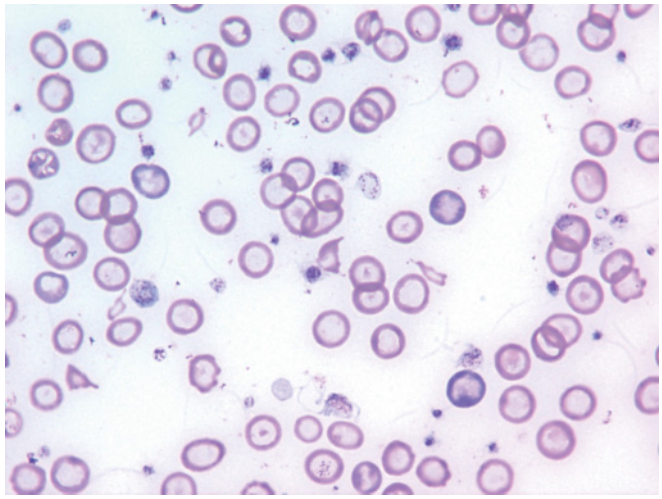

FIGURE 23.5 Blood smear from a dog with iron deficiency anemia. Notice marked hypochromasia. Wright-Giemsa stain.

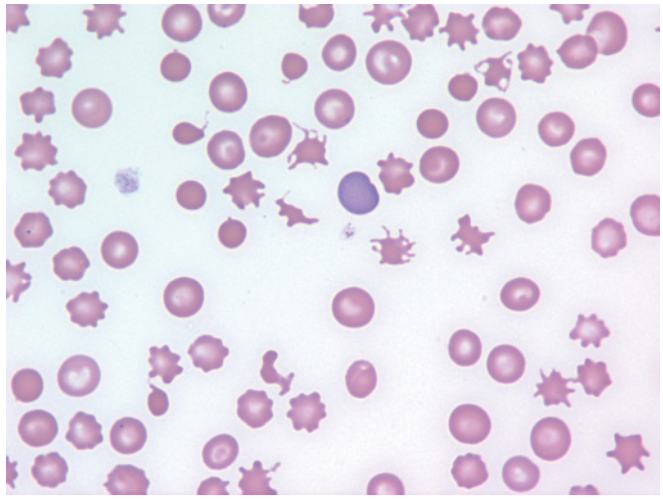

FIGURE 23.6 Blood smear from a dog showing acanthocytes with varying numbers of irregularly spaced projections. Wright-Giemsa stain.

Chapters 29, 30 and 66). Generally animals with these conditions will have an overall increase in their mean corpuscular volume (MCV). Microcytosis or small red blood cells can be observed with several different disease processes, the most common of which is iron deficiency (see Chapter 26). Due to the impaired heme synthesis, the red blood cells undergo an additional division. Other causes of microcytes include hereditary microcytosis (Akita and Shiba Inu) and familial dyserythropoiesis of English Springer Spaniels (see Chapter 30).[15,22]

Poikilocytosis

Poikilocytosis is a general term for variation in RBC shape; it can occur in a variety of conditions, so poikilocytosis is non-specific. Further, some species are more prone to poikilocytosis than others. For instance, echinocytes are a common finding in pigs. Goat kids, less than 3 months of age and some adults, particularly adult angora goats are prone to marked poikilocytosis. Their RBC can vary in shape, and triangular, spindle, fusiform, matchstick, oblong and pear shaped erythrocytes can be observed. Anemic goats can form hemoglobin C which makes them more prone to poikilocytosis.[22,24] Camelids, avians and reptiles have oval RBCs as their normal shape.

Specific changes occurring in the membrane structure, hemoglobin condition and bone marrow architecture can result in specific changes in RBC morphology. Acanthocytes have irregularly spaced spicules generally 2–20/cell. The name is derived from the Greek for "thorn" (Fig. 23.6). The changes in the RBC membrane of these cells are associated with increased cholesterol content of the membrane which is thought to expand the outer layer of the lipid bilayer; however, other studies suggest acanthocytes can also result from RBC fragmentation.[40] In dogs, liver disease, portosystemic shunts, hemangiosarcoma, disseminated intravascular coagulation, lymphosarcoma, glomerulonephritis, and high cholesterol diets have been associated acanthocytosis.[19,40] In cats with liver disease, acanthocytes are reported as the most common poikilocyte.[9]

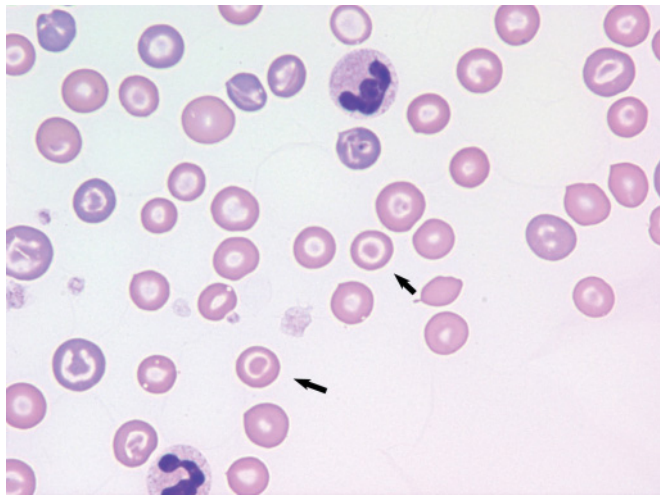

FIGURE 23.7 Blood smear from a dog with iron deficiency anemia. Codocytes are indicated with arrows. Wright-Giemsa stain.

Codocytes

Codocytes (also termed target cells) resemble a bull's eye (Fig. 23.7). They have a central area of hemoglobin surrounded by a pale rim with hemoglobin at the periphery of the cell. Similar to acanthocytes, codocytes have an increased amount of cholesterol resulting in an overall increase in the surface area of the erythrocyte membrane. Codocytes are often observed in patients with iron deficiency, cholestatic liver disease and post-splenectomy; however, codocytes are also frequent findings in regenerative anemias.

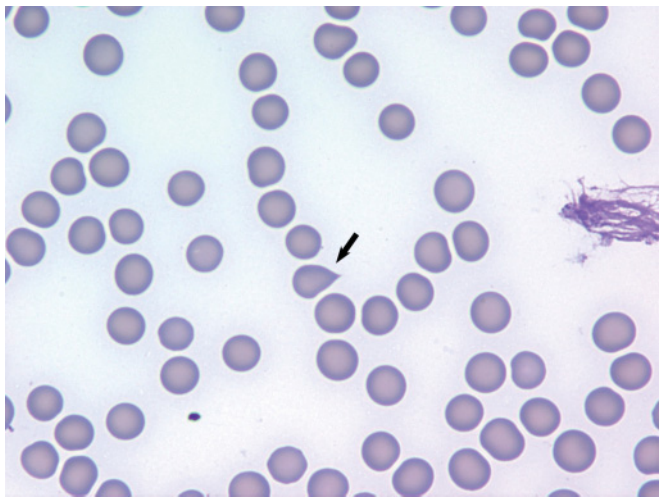

FIGURE 23.8 Blood smear from a dog. Dacryocyte is indicated with an arrow. Wright-Giemsa stain.

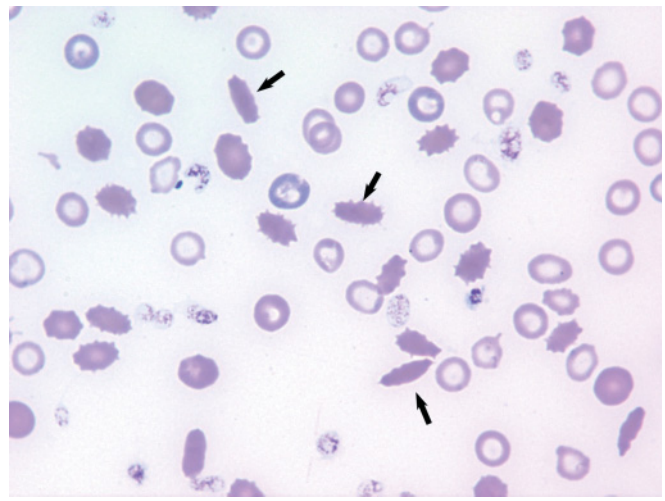

FIGURE 23.9 Blood smear from a dog. Ovaloechinocytes are indicated with arrows. Wright-Giemsa stain.

Dacryocytes

Dacryocytes are teardrop shaped cells that may occur when the RBC membrane is damaged and distorted as cells pass through narrow marrow or splenic sinusoids (Fig. 23.8).[22] In human medicine, these cells are commonly associated with myelofibrosis or myelophthisis. In dogs they have been reported with myeloproliferative disorders and hypersplenism.

Eccentrocytes

Eccentrocytes (also termed erythrocyte hemighosts) are RBCs with eccentrically shifted hemoglobin within the cell, leaving a pale, hemoglobin-free area.[18] These cells may progress to pyknocytes which are eccentrocytes in which the cell membrane has collapsed. Eccentrocytes have been reported to be easier to visualize on NMB stained preparations.[30] These cells are associated with oxidative damage to the erythrocyte membrane and cytoskeleton.[6] In horses, eccentrocytes have been observed with red maple toxicity (*Acer rubrum*), erythrocyte glucose-6-phosphate dehydrogenase deficiency, and flavin adenine dinucleotide deficiency (see Chapter 36).[18,35] In dogs, eccentrocytes have been observed with ingestion of substances known to cause oxidative damage, such as onions, vitamin K, garlic and acetaminophen. Additionally, eccentrocytes have recently been described in dogs with diabetes mellitus, T cell lymphoma and severe infections.[6] Cattle receiving intravenous hydrogen peroxidase may have circulating eccentrocytes.[36]

Echinocytes

Echinocytes are spiculated red blood cells with evenly dispersed, short projections. Their shape can vary from discoechinocytes to highly spiculated spheroechinocytes or even ovaloechinocytes (Fig. 23.9). Echinocytes can be subclassified based on particular morphologic features. Type I echinocytes have irregular or angular edges but do not have distinct spicules. Type II echinocytes have multiple blunt spicules. Type III echinocytes are ovoid or spherical with 10–30 regularly spaced spicules. Echinocytes (also termed crenation) can occur as an artifact from sample handling, prolonged sample storage or during slide preparation. These cells occur commonly in pigs, in vitro.[13] Echinocytes form when the outer leaflet of the lipid bilayer of the RBC membrane is expanded relative to the inner layer. Mechanisms of echinocyte formation include depletion of ATP, administration of amphipathic drugs, calcium loading, or when RBCs are dehydrated. In dogs, echinocytes have been reported with glomerulonephritis, lymphoma, hemangiosarcoma and other neoplasms, immune-mediated hemolytic anemia, pyruvate kinase deficiency, rattlesnake envenomation, and doxorubicin toxicosis among others.[3,5] Cats likely have echinocytes with many of these diseases as well, but echinocytes have been specifically reported with chronic doxorubicin administration.[25] In horses, echinocytes have been observed with diseases causing hyponatremia and hypochloremia, such as colitis or exercise.[14,22]

Elliptocytes

Elliptocytes are oval shaped, non-nucleated RBCs that are normal in camelid species. In people, hereditary ovalocytosis has been associated with a protein band 3 abnormality.[31] In veterinary species, ovalocytes are occasionally described (Figs. 23.9 and 23.10). Hereditary ovalocytosis has been reported in a dog with protein band 4.1 deficiency,[34] but also in myelofibrosis, glomerulonephritis and myelodysplastic disease.[20] In cats, elliptocytes have been reported with myeloproliferative disorders, hepatic disease and with chronic doxorubicin administration.[9,29]

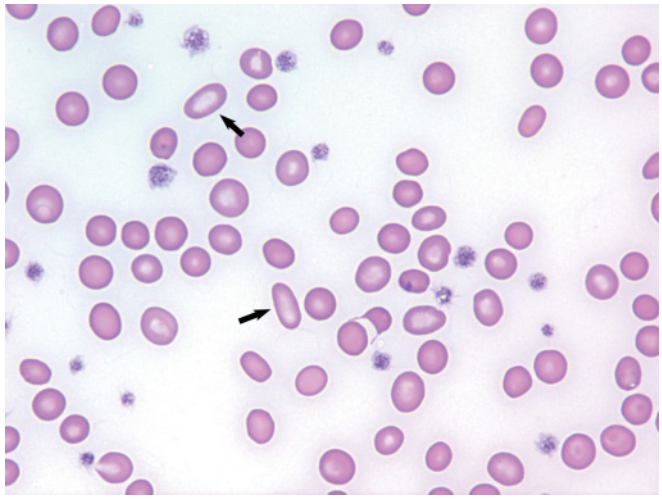

FIGURE 23.10 Blood smear from a dog. Ovalocytes are indicated with arrows. Wright-Giemsa stain.

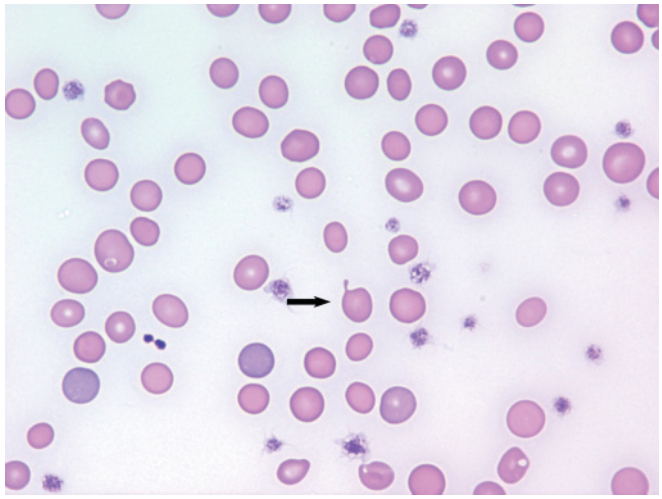

FIGURE 23.11 Blood smear from a dog. Occasional keratocytes are indicated by arrow. Wright-Giemsa stain.

Keratocytes

Keratocytes are spiculated RBCs that frequently have only 1–2 spicules and indicate RBC fragmentation (Fig. 23.11); thus, the RBC appears to have "horns" (kerat is the Latin term for horn). The formation of keratocytes has been associated with microvascular injury, especially when there is deposition of fibrin strands. The opposing sides of the damaged RBC may fuse leading to formation of a blister. Bursting of the blister is thought to result in progression to a keratocyte.[22] Keratocytes have been reported in cats with liver disease[9] and in dogs and cats with chronic doxorubicin administration and hemangiosarcoma.

Leptocytes

Leptocytes are thin RBCs that can fold and take on the shape of other poikilocytes such as codocytes, knizocytes (central fold giving the appearance of a central bar of hemoglobin) or stomatocytes. Leptocytes can be observed in iron deficiency and cholestatic liver disease.[22]

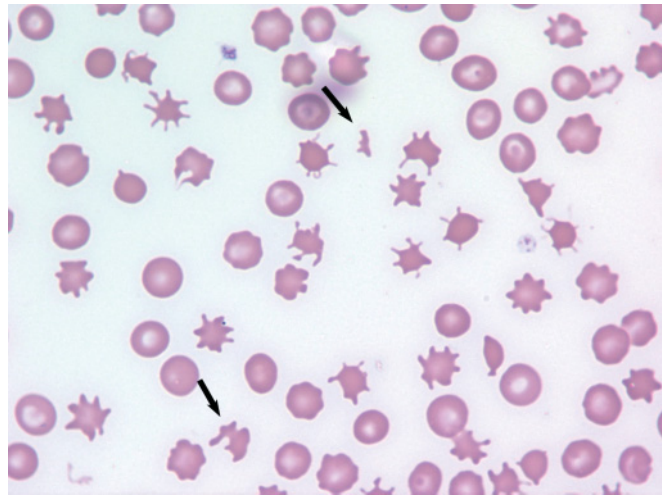

FIGURE 23.12 Blood smear from a dog. Severe poikilocytosis with schistocytes indicated with arrows. Wright-Giemsa stain.

Schistocytes

Schistocytes are red blood cell fragments usually resulting from direct physical damage to RBCs secondary to vascular abnormalities or turbulent blood flow. The shape of the fragments may vary from pointed or triangular to spiculated (Fig. 23.12). Microangiopathic fragmentation has been described in dogs in a several different disorders including disseminated intravascular coagulation (DIC), glomerulonephritis (GN), hemangiosarcoma, myelofibrosis, dyserythropoiesis, and chronic doxorubicin toxicosis.[3,11,40] Schistocytes have also been identified as a common feature of DIC in calves.[34,21] However, they are uncommon in the horse and cat,[12] though schistocytes have been reported in cats with hepatic disease.[9]

Spherocytes

Another result of RBC fragmentation is spherocytes. Spherocytes are RBCs that have lost their biconcave shape and have become round like a sphere. On a blood smear, these cells have lost their central pallor and appear slightly darker and often a little smaller than healthy RBCs (Fig. 23.13). IMHA is a common cause of this poikilocyte. They occur secondary to antibody binding on the membrane or complement fixation. Part of the membrane may be phagocytized or just punctured resulting in the change in shape. These cells have been associated with other diseases as well, including coral snake, rattlesnake and bee sting envenomation, and anaplasmosis infection in cattle.[28] Spheroechinocytes have been reported in Basenji's with pyruvate kinase deficiency and in goat erythrocytes treated with lysolecithin.[5,22,23] Spherocytes are most obvious

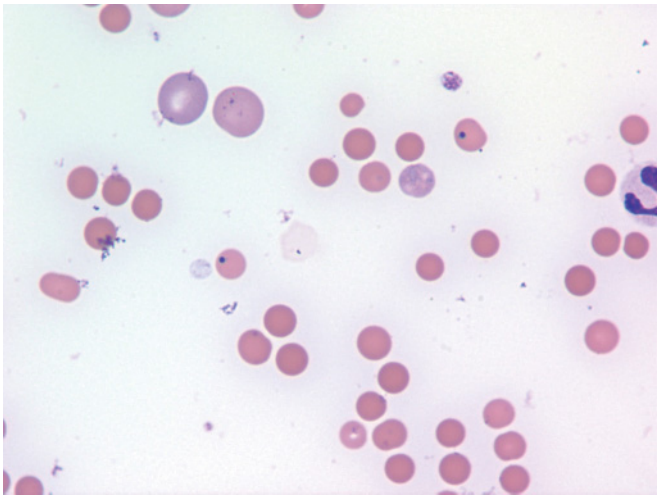

FIGURE 23.13 Blood smear from a dog showing many spherocytes. Wright-Giemsa stain.

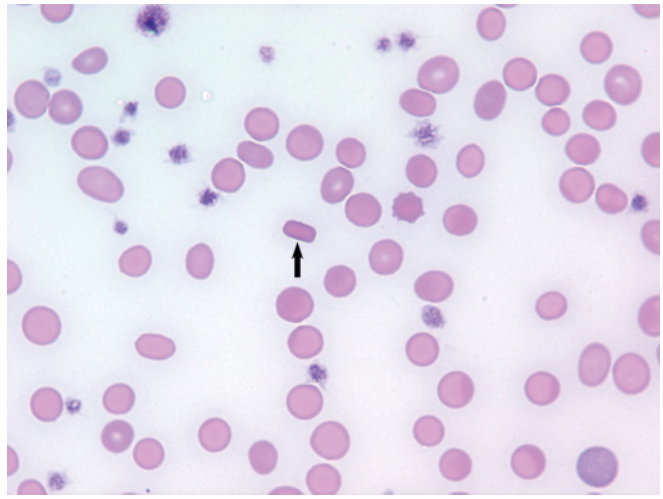

FIGURE 23.14 Blood smear from a dog showing hemoglobin crystals (arrow). Wright-Giemsa stain.

in dogs, likely because they have prominent central pallor. In other species such as the cat and horse, spherocytes are difficult to identify.

Not all spherocytes are formed secondary to fragmentation. Spherocytes can be caused by a molecular defect in one or more of the proteins of the RBC cytoskeletal network. Double knock-out mice with defects in actin binding proteins affect erythrocyte shape and membrane integrity leading to pronounced spherocyte formation.[8] Spectrin deficiency has been identified in a group of Dutch Golden Retrievers (see Chapter 29).[33]

Stomatocytes

Stomatocytes are RBCs that have a narrow elongated band of central pallor resembling a mouth on dried blood smears. In actuality, these cells are more bowl-shaped in wet-mount preparations. Several breeds of dogs have been identified with hereditary stomatocytosis, including Alaskan Malamutes with concurrent chondrodysplastic disease, Drentse patrijshond with stomatocytosis-hypertrophic gastritis and Miniature and Standard Schnauzers (see Chapter 29).[4,32] The Drentse patrijshonds often have a normal MCV whereas the Schnauzers and Malamutes have an increased MCV.[4,32]

Hemoglobin Crystals

Hemoglobin crystals are unstable hemoglobin that precipitates in the RBC. These dense staining, rhomboid or rod shaped crystals lead to decreased deformablity of the cell (Fig. 23.14). Crystals may be found in human patients with Hemoglobin C disease and sickle cell anemia, particularly after splenectomy. In veterinary medicine, hemoglobin crystals are infrequently reported and their cause is uncertain. Nonetheless, they have been described in dogs, llamas and horses with FAD deficiency.[7,35]

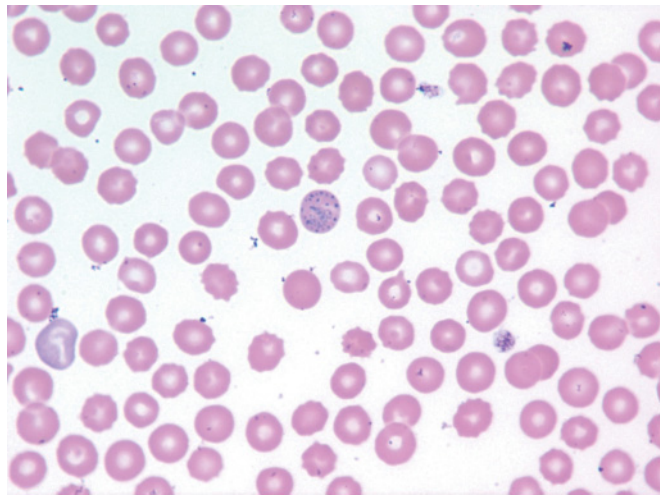

FIGURE 23.15 Blood smear from a dog showing basophilic stippling. Wright-Giemsa stain.

Erythrocyte Inclusions

Basophilic stippling represents the spontaneous aggregation of ribosomes and polyribosomes in RBC. In Romanowsky-stained samples, affected RBCs contain uniformly distributed punctate, basophilic structures (Fig. 23.15). Basophilic stippling may be seen in cattle and other ruminants as a part of the regenerative response to anemia. It may be associated with exuberant regeneration in other species including the dog and cat. However, if basophilic stippling and increased numbers of nucleated RBC (nRBC) are present in the absence of a severe anemia, lead toxicity should be considered.

Nucleated RBCs in circulation can also be part of a regenerative response to anemia. These cells, depending on their level of maturity, usually have polychromatophilic or hemoglobinized cytoplasm and a round

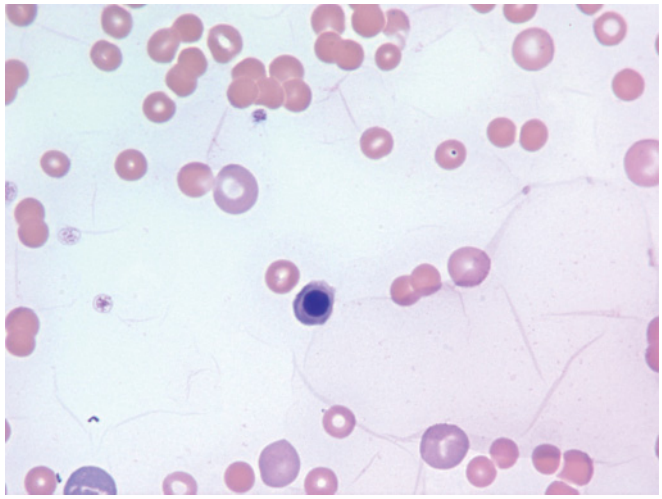

FIGURE 23.16 Blood smear from a dog showing occasional metarubricytes as part of a regenerative response. Wright-Giemsa stain.

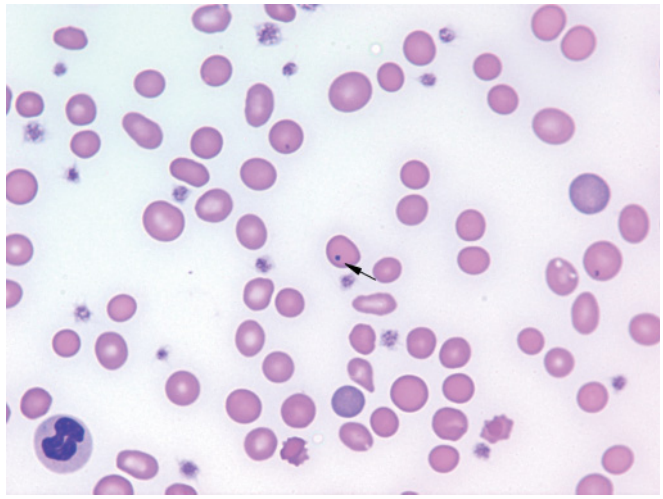

FIGURE 23.17 Blood smear from a dog. Howell-Jolly bodies are nuclear remnants observed in the cytoplasm of red blood cells (arrow). Wright-Giemsa stain.

nucleus (Fig. 23.16). The metarubricytes have a small, pyknotic nucleus but less mature cells have a stippled chromatin pattern. When nRBCs accompany a regenerative response, polychromasia and anemia should also be observed. However nRBCs may occur in the absence of anemia in diseases affecting the spleen and bone marrow. Myeloproliferative disorders and infiltrative marrow diseases such as solid tumor metastases and myelofibrosis can result in high numbers of nRBCs, occasionally with less mature erythrocyte precursors, rubriblasts, and prorubricytes in circulation. Low numbers of circulating nRBCs can be observed in splenectomized animals or in dogs or cats with hemangiosarcoma, hemophagocytic histiocytic sarcoma, and pure red cell aplasia.[16,39] Cats with myelodysplastic sydromes, hepatic lipidosis, upper respiratory infections and hemangiosarcoma can have normoblastemia.[16] Lead toxicity is commonly associated with metarubricytosis; however, these patients are usually not anemic.

Nuclear remnants, not expelled as RBCs leave the bone marrow, are termed Howell-Jolly (HJ) bodies. They are round, deeply basophilic structures that may vary in size (Fig. 23.17). Howell-Jolly bodies are normally removed by the spleen. However, in cats and horses, species having non-sinusoidal spleen, low numbers are normally seen in circulation. Increased numbers of HJ bodies can be seen as part of a regenerative response to anemia, in animals with hypofunctioning spleens, or in splenectomized patients. There also are reports of increased numbers of HJ bodies in non-anemic miniature and toy poodles with hereditary macrocytosis (see Chapter 30).

Oxidative damage can result in a number of morphologic changes to the RBCs including the formation of Heinz bodies.[1,2,10,26,41] Heinz bodies are small aggregates of oxidized hemoglobin that can occur as hemoglobinized projections extending from the cell or as pale areas within the cell (Fig. 23.18A). With Romanowsky stains, the Heinz bodies are pale or hemoglobinized but

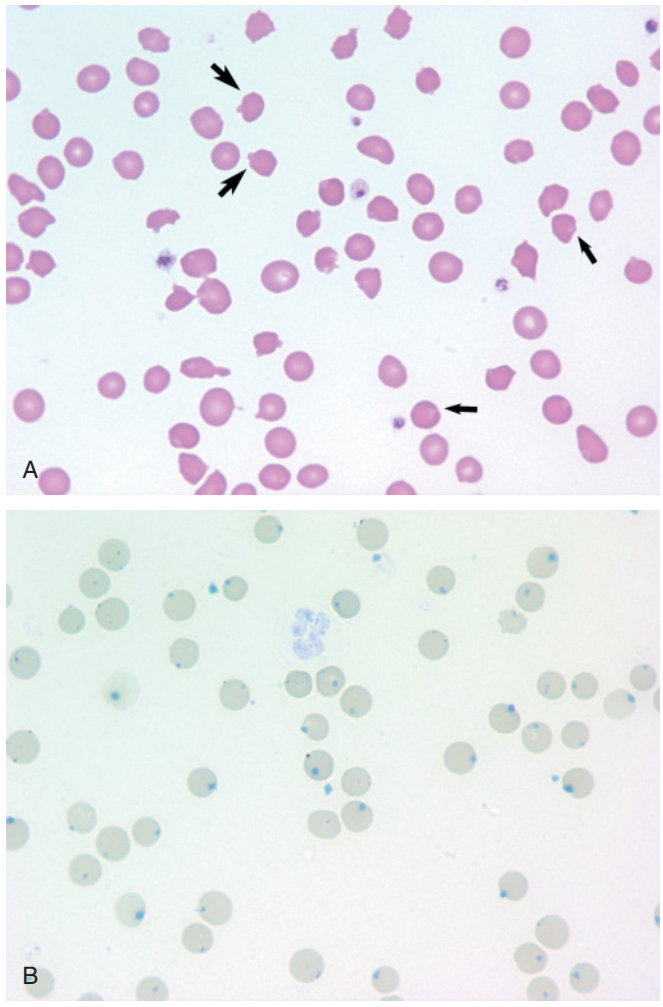

FIGURE 23.18 Blood smear from a cat. (**A**) Wright-Giemsa stain: Many Heinz bodies are observed and can appear as projections from the RBC membrane (large arrow) or as pale areas near the membrane (small arrow). (**B**) New methylene blue stain: Heinz bodies are more obvious with vital stains.

with NMB, they are bluish-green and much more obvious (Fig. 23.18B). Many toxins and diseases have been reported to cause Heinz bodies (see Chapter 36).

Iron observed in mature RBCs is referred to as siderocytes or Pappenheimer bodies. With Romanowsky stain, the iron appears as irregularly shaped, pale basophilic material, whereas ferric iron forms a bright blue pigment when stained with Prussian blue. Siderocytes have been reported in the blood in association with myeloproliferative disorders, lead toxicity, and hemolytic anemia. Sideroblasts are nucleated erythroid precursors with iron in their cytoplasm. These cells have been reported with myelodysplastic syndromes and myeloproliferative disorders and in inflammatory diseases in dogs and cats.[37,38]

Artifactual changes can occur that mimic true pathologic fragmentation or inclusions. Stain precipitate or drying artifact can mimic red blood cell parasites or inclusions such as HJ bodies. A commonly observed artifactual change associated with prolonged drying of blood smear preparations, produces refractile RBC inclusions. Additionally, crenation of RBCs can occur as an artifact of drying. Usually artifactual crenation will occur in thick areas of blood smear.

Acronyms and Abbreviations

Advia, Siemens Advia 2120® hematology system; CBC, complete blood count; CRP, corrected reticulocyte percentage; EDTA, ethylenediaminetetraacetic acid; EIA, equine infectious anemia; FeLV, feline leukemia virus; fL, femtoliter; Hct, hematocrit; Hgb, hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; NRBC, nucleated red blood cell; PCV, packed cell volume; PRCA, pure red cell aplasia; RBC, red blood cell; RDW, red cell distribution width; RPI, reticulocyte production index; Sysmex, Sysmex XT 2000iV® hematology system; WBC, white blood cell.

This chapter discusses diagnosis of anemia based primarily on laboratory findings. Erythrocyte morphology (see Chapter 23) and specific causes of anemia are described elsewhere, except for blood loss anemia which will receive more attention in this chapter. Diagnosis of the cause of anemia uses certain characteristics of blood to place the anemia into pre-established classes or categories useful for diagnosis. Several classification systems are used and are based on various tests and observations. The systems overlap and classifications by one system (e.g. macrocytic hypochromic anemia) may be identifying the same change or process in red blood cells (RBCs) as another classification (e.g. reticulocytosis and regenerative anemia). Thus different names frequently mean the same in terms of diagnosis. Despite the classification system used, the goal of diagnosis should be to provide the most specific and correct diagnosis to allow appropriate treatment or other action by the attending clinician.

CLINICAL MANIFESTATIONS OF ANEMIA

The clinical signs that prompt an animal's owner to seek a clinician to diagnose and then treat an anemia include weakness, lack of stamina, pale mucous membranes, icterus and hemoglobinuria (red urine). The purpose of laboratory testing is to provide unbiased evidence that supports or refutes a clinical or tentative diagnosis. Laboratory diagnosis of the cause of anemia should be based first on laboratory conclusions founded on test results and interpretation of cell morphology in blood smears and graphics from hematology instruments. Only after making those conclusions should clinical signs, age, breed, and other clinical information be considered and allowed to influence the conclusions or diagnosis. This permits laboratory results to indicate new possibilities and avoid "premature closure" too early in diagnosis. Additional, more specific testing may then be needed.

PRESENCE AND SEVERITY OF ANEMIA

The first step in evaluation is to determine if the animal has anemia and, if present, to evaluate severity (Table 24.1). Laboratory parameters routinely used include hematocrit (Hct), total erythrocyte count (RBC count), and hemoglobin (Hgb) concentration. Packed cell volume (PCV) is essentially the same as Hct, though implies a centrifugal method of analysis. These values (Hct, RBC count or Hgb concentration) should be simi-

TABLE 24.1 Guidelines for Classification of Severity of Anemia

	Dog	Horse	Cat/Ruminant
Mild	30–37[a]	30–33	20–26
Moderate	20–29	20–29	14–19
Severe	13–19	13–19	10–13
Very Severe	<13	<13	<10

[a]Values are hematocrit or packed cell volume in percent.

larly reduced in proportion to the reduction of erythroid mass and should similarly reflect the severity of anemia in the animal. Hematocrit will be used in this chapter to describe severity of anemia but Hgb concentration is used more frequently in Europe and also in human medicine.

If Hct, RBC count, and Hgb concentration are not similarly decreased in anemia, then erythrocytes are not normal in size and Hgb content. Changes in erythrocyte indices (MCV, MCHC) should help explain any discordance in relative decreases (see section on classification by erythrocyte volume and Hgb concentration later in this chapter). For example, in iron deficiency anemia with severe microcytosis, RBC count will not be decreased as much as Hgb concentration or Hct and, therefore not reflect the severity of the anemia as well. Even normal numbers of microcytic erythrocytes will not contribute to a normal Hgb concentration per unit volume of blood and the smaller erythrocytes will be packed into a smaller volume of the blood (PCV).

Pre-analytical and analytical errors may also cause discordance among Hct, Hgb concentration, and RBC count. For example, Heinz bodies may make erythrocytes more fragile so they lyse in the microhematocrit centrifuge, lowering the PCV. Heinz bodies remaining in suspension after erythrocytes are lysed, increase the optical density and falsely increase Hgb concentration. Heinz bodies in erythrocytes make them more optically dense to laser hematology instruments also causing a falsely increased cell Hgb concentration and MCHC.

Severity of an anemia is useful in diagnosis. Table 24.1 provides some guidelines for classifying severity. Moderate to severe anemias are more likely important or primary problems. For example, primary bone marrow disorders like chronic myelofibrosis can cause very severe anemia (e.g. Hct 6–8%) while secondary suppression of bone marrow (e.g. anemia of inflammation) is characteristically mild to moderate. Severe anemia or rapid decline in erythroid mass should stimulate more aggressive diagnosis and treatment, while mild to moderate anemia in animals with severe inflammatory or neoplastic disorders is expected as secondary problems.

Clinical information such as breed and age affect interpretation (see Chapter 131). Sight hounds like greyhounds normally have higher Hct (about 50–65%) compared to other dog breeds (37–55%) and, therefore a mild anemia in a greyhound will have a Hct within the reference intervals for dogs in general. Puppies have lower Hct than adult dogs (as well as lower plasma protein and higher reticulocyte numbers). For example a 6-week-old puppy can have a Hct of 26–30%, reticulocytes of 4.5% and plasma protein of 5.0–5.6 g/dL. Thus a normal puppy can appear to have a regenerative, blood loss-type anemia when using adult reference intervals.

Hydration status must be considered. Hematocrit reflects severity of anemia only when the animal has normal hydration and blood volume. It may take 1–2 days after blood loss before blood volume is restored to normal and the Hct shows the severity of the anemia.[2] Even acute hemolytic anemia may not have a Hct reflecting the severity of anemia at the time of presentation to a clinic.

TABLE 24.2 Canine and Feline Relative and Absolute Reticulocyte Guidelines

		Feline	
Strength of Regeneration	Canine Reticulocytes (%)	Aggregate Reticulocytes (%)	Punctate Reticulocytes (%)
Relative			
None	1[a]	0–0.4[a]	1–10[a]
Weak	1–4	0.5–2	10–20
Moderate	5–20	3–4	20–50
Strong	21–50	>5	>50
Absolute			
None	60[b]	<15[b]	<200[b]
Weak	150	50	500
Moderate	300	100	1000
Strong	>500	>200	>1500

[a]Values are percentage of non-nucleated RBCs that are reticulocytes. The percentage of canine reticulocytes or feline aggregate reticulocytes also may be used to convert the percentage of polychromatophils on a blood smear to strength of polychromasia and thus erythropoiesis.
[b]Reticulocytes $\times 10^9$/L or reticulocytes $\times 10^3/\mu$L.

CLASSIFICATION SYSTEMS

Classification by Strength of Erythropoiesis

Evaluation of bone marrow function divides anemia into those with variably reduced or ineffective erythropoiesis (non-regenerative) or with active and effective erythropoiesis (regenerative) (Table 24.2). Anemia not caused by primary or secondary bone marrow dysfunction should have appropriate evidence of erythropoiesis (regeneration or responsive). The anemia is classified as regenerative if signs of increased erythropoiesis seem adequate for the severity of anemia, duration, species characteristics, treatments, and likelihood of multiple etiologies.

Regenerative anemias are caused by loss of erythrocytes from the body (external blood loss) or lysis of the erythrocytes within the body (hemolytic anemia and internal blood loss). These are easier to diagnose than the non-regenerative anemias.

Bone marrow regeneration in species that display consistent reticulocyte responses (e.g. dog, cat, pig, and rat) is primarily evaluated by the reticulocyte response (see chapters on individual species characteristics). The strength of increase in the absolute reticulocyte count per unit volume of blood best reflects how effective bone marrow erythropoiesis is in the patient (Table 24.2). The percentage of reticulocytes is a relative value affected by the severity of anemia and number of mature erythrocytes remaining. Absolute counts (% reticulocytes × erythrocytes) are preferred for interpretation. The corrected reticulocyte percentage (CRP) and reticulocyte production index (RPI) are other methods for interpreting the reticulocyte response when the total erythrocyte count is not available to calculate an absolute reticulocyte count. Guidelines for and the clinical usefulness of CRP or RPI are not well established in veterinary species.

Reticulocyte numbers are best interpreted at the time of an expected peak of reticulocytes at 4–8 days after onset (see Fig 24.5A). Guidelines for interpretation of reticulocyte numbers are for the peak reticulocyte response and may be misleading early in an anemia (i.e. pre-regenerative) when reticulocyte numbers have not increased yet, or late in an anemia when reticulocyte numbers decline (10–14 days).[6] Late in an anemia the number of macrocytic hypochromic erythrocytes (Fig. 24.1) is more reflective of the strength of primary regenerative response than the reticulocyte number, which may be declining or back to normal.

Feline punctate reticulocytes have a long half-life in blood and therefore may accumulate in large numbers (Table 24.2). The kinetics of feline aggregate reticulocyte responses are similar to those of other species but maximal responses are weaker (Table 24.2) than expected in dogs.[6] Aggregate reticulocytes may not be released unless the anemia is severe.

Microscopic identification of aggregate and punctate reticulocytes is time consuming and subjective when many reticulocytes are present (see Chapter 136). The automated reticulocyte counts of the Advia 2120® and Sysmex XT 2000® detect primarily feline aggregate reticulocytes and not punctate reticulocytes.[3] A time saving approach is to use automated feline reticulocyte

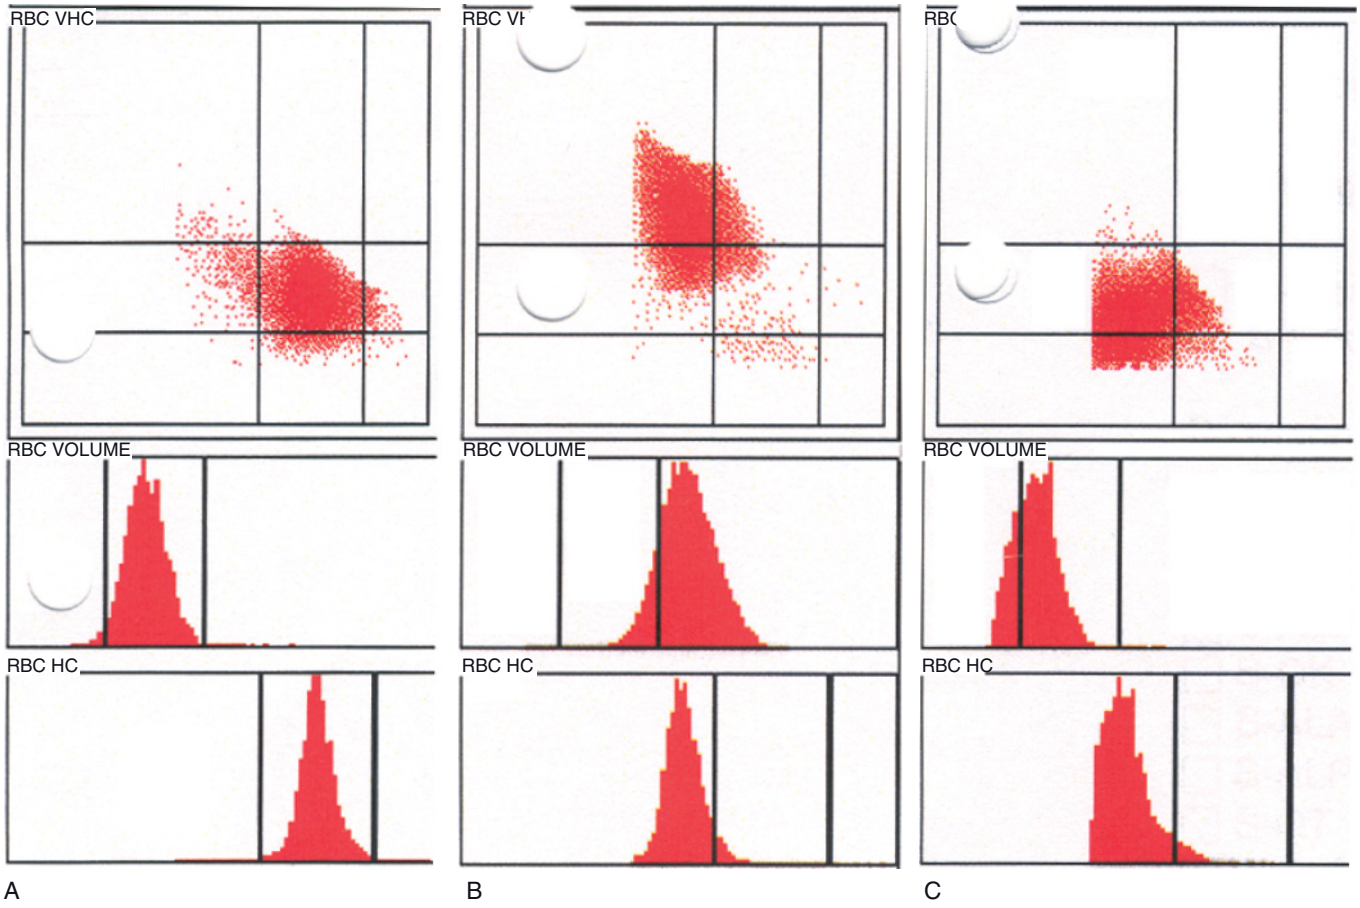

FIGURE 24.1 Advia 2120 RBC cytograms, RBC volume histograms and Hgb concentration histograms from three dogs illustrating the three main types of anemia based on size and hemoglobin concentration of RBCs. (**A**) The first dog had non-regenerative IMHA and had no reticulocytes or macrocytic cells. It was a normocytic normochromic anemia with almost all RBCs in the central box of the 9-box RBC cytogram. (**B**) This dog had phosphofructokinase deficiency and hemolytic anemia. Almost all RBCs were macrocytic hypochromic due to a marked regenerative anemia. Few RBCs remained in the central box of the 9-box RBC cytogram. (**C**) Dog with iron deficiency and microcytic hypochromic anemia. Its erythrocytes were more hypochromic than microcytic. Its reticulocytes were also microcytic.

counts for accurate aggregate reticulocyte counts and a quick screening of a new methylene blue-stained blood smear for an estimate of punctate reticulocyte percentages.

It is important that laboratories indicate the type of feline reticulocyte reported. Sometimes only "reticulocytes" are reported without specifying the type. Note in Table 24.2, that the number of aggregate reticulocytes indicating a strongly regenerative anemia is the same number as the number of punctate reticulocytes indicating no regeneration. Duration of the feline regenerative response may be interpreted by pattern of changes in the two types of reticulocytes. A strong increase in aggregate reticulocytes but mild increase in punctate reticulocytes indicates an early response (3–6 days after onset of anemia), while late in a response (9–20 days) there may be many punctate reticulocytes but no increase in aggregate reticulocytes.[6]

Other indicators of an appropriately active bone marrow in anemia are less specific for erythropoiesis than reticulocytosis; however, these may be useful in species without consistent reticulocyte responses. Nucleated RBCs (NRBCs) are useful indicators in ruminants (e.g. cattle, llamas) to reflect regeneration.[5] NRBC numbers are frequently reported as a relative ratio of NRBC/100WBC, so marked changes in WBC count can affect this ratio. Basophilic stippling, especially in ruminants, and Howell-Jolly bodies suggest a regenerative anemia. RBCs produced during increased erythropoiesis are larger; thus macrocytosis and anisocytosis suggest active erythropoiesis and may be the only indicators in peripheral blood of horses that release very few reticulocytes into circulation. Macrocytosis and anisocytosis can be detected by the MCV (e.g. >52 fL in horses), RBC cytograms and histograms (Fig. 24.2) or blood smear evaluation. RBC distribution width (RDW) indicates the amount of anisocytosis. NRBC, macrocytosis, Howell-Jolly bodies and anisocytosis are caused by factors other than regenerative anemia such as glucocorticoid treatment, heat stroke, dysmyelopoiesis, myeloproliferative disorders, prolonged storage of EDTA blood etc., and are thus not specific indicators of regeneration.

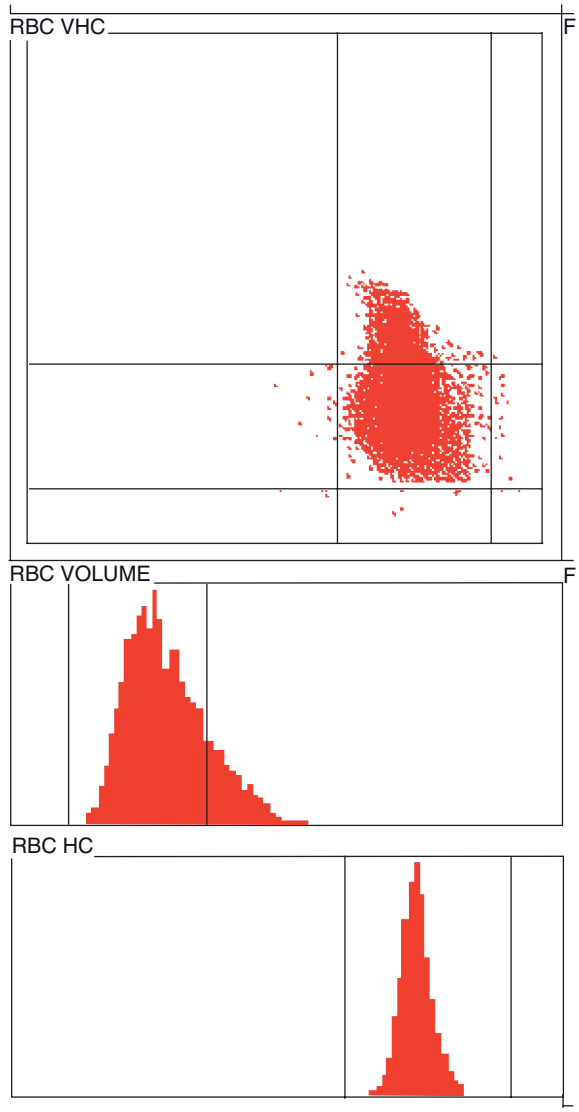

FIGURE 24.2 Regenerative response in a horse with immune-mediated hemolytic anemia. There is a macrocytic normochromic population of RBCs seen in the Advia 2120 RBC graphics. This horse did not have reticulocytes detected by the Advia 2120.

Classification by Erythrocyte Volume and Hemoglobin Concentration

Erythrocyte volume changes are microcytic (smaller), normocytic or macrocytic (larger). Erythrocyte hemoglobin concentration changes are hypochromic (reduced) and normochromic (normal concentration). Hyperchromic changes indicate an erroneous result and not a disease-related change. Pre-analytic and analytic errors, such as hemolysis or Heinz bodies, cause artifacts that imply the erythrocytes contain more hemoglobin per unit volume than a normal cell filled with hemoglobin.

The three important diagnostic patterns are macrocytic hypochromic anemias (regenerative anemias with large, young RBCs that are not fully hemoglobinized), normocytic normochromic anemia (non-regenerative anemias with residual normal erythrocytes), and microcytic hypochromic anemias, that are usually iron deficiency anemias.

The MCV and MCHC have been used for this classification. MCV and MCHC are unfortunately too insensitive and frequently fail to correctly differentiate the three main patterns. The numbers of abnormal erythrocytes are usually small and values for MCV or MCHC frequently remain within reference intervals.

Computer graphics of the Advia 2120® are more sensitive and specific in detecting diagnostic changes in volume or Hgb concentration of RBCs than the MCV or MCHC (Fig. 24.1), especially with small populations of abnormal RBCs. Advia's two dimensional RBC cytogram displays and records each RBC by individual cell volume and cell hemoglobin concentration. Advia's volume and Hgb concentration histogram show well

the relative size of populations of erythrocytes. Percentages of macrocytic, microcytic, or hypochromic RBCs or reticulocytes are also available from the Advia (unfortunately the somewhat round groups of different types of RBCs are not confined to the square shaped, nine counting boxes in the RBC cytograms and these percentages still must be subjectively interpreted while looking at the histograms; Fig. 24.1). However, these are exceptionally good tools in anemia diagnosis. For example, microcytic hypochromic cells can be seen in iron deficiency when the MCV and MCHC are normal. In horses, that have only minimal reticulocyte responses, the Advia cytograms and histograms still demonstrate macrocytosis in strongly regenerative anemias (Fig. 24.2). Cats have relatively weak aggregate reticulocyte responses, which often fail to correctly affect MCHC and MCV, but may be noted in Advia's RBC graphics (Fig. 24.3).

Macrocytic normochromic anemia is the normal regenerative response of horses (Fig. 24.2). In cats macrocytic normochromic erythrocytes in the absence of polychromasia suggests feline leukemia virus (FeLV)

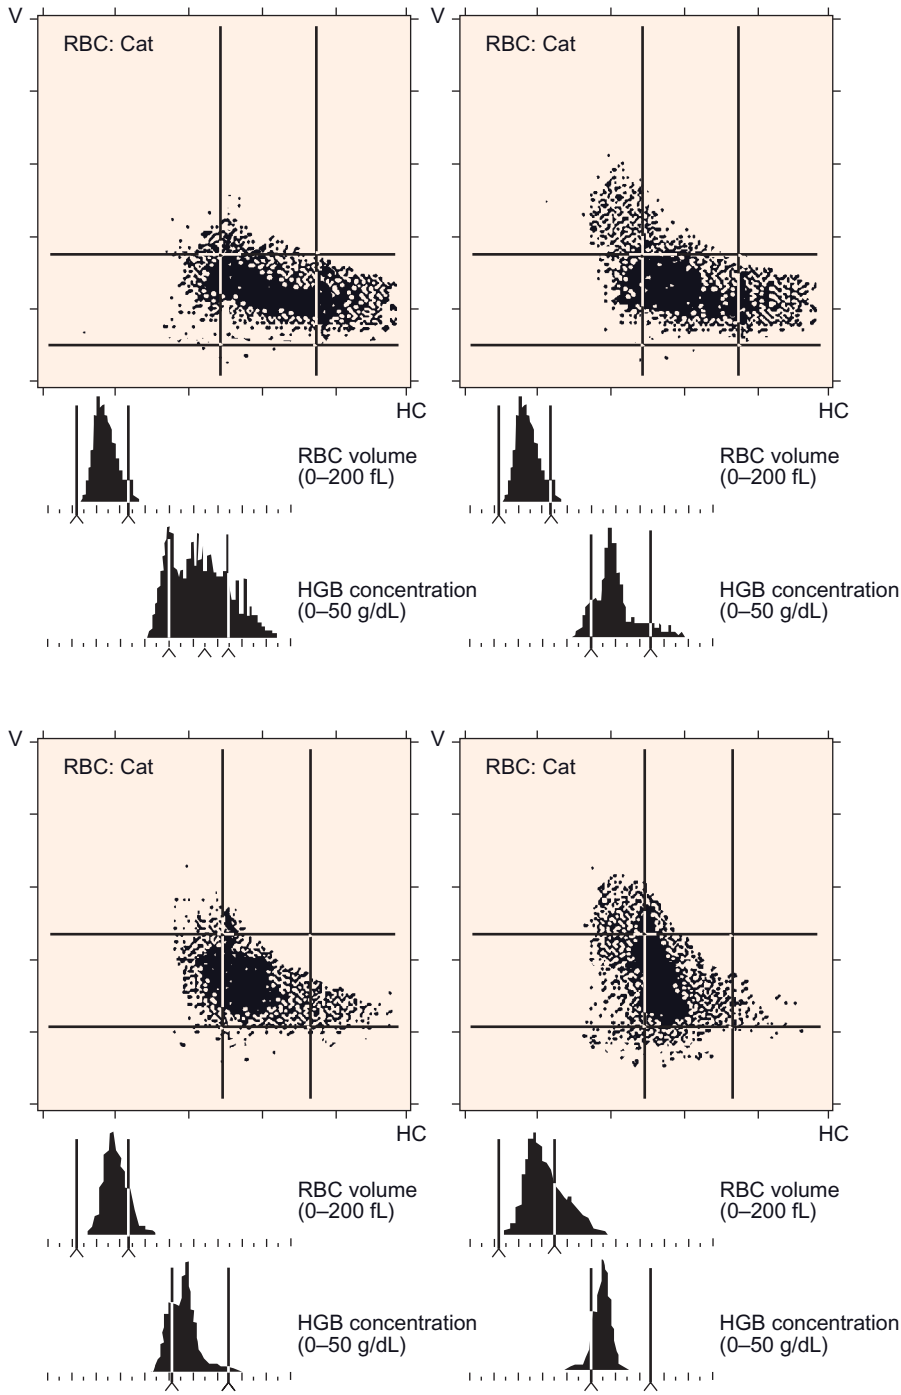

FIGURE 24.3 Composite of four sets of RBC cytograms and histograms over 1 week from a cat with Heinz body anemia from eating baby food containing onion powder. The third set (lower left) looks the most normal and may be used for comparison. The RBC cytogram has one dark, round cluster that is the normocytic normochromic erythrocytes. The cells should be in the center box but the grid was not aligned well. The lightly dispersed dots extending to the right are RBCs with Heinz bodies that appeared hyperchromic. Note on the first set (upper left) this extension is very dark indicating many RBCs appeared hyperchromic because 84% contained large Heinz bodies. The MCHC was falsely high (44 g/dL) on that day. The Hgb concentration histogram was bimodal. The smaller left peak was normochromic cells (grid was offset) and the large, wider right peak was the hyperchromic appearing cells. The final set of graphics (lower right) shows a good regenerative response with mainly macrocytic and slightly hypochromic RBCs extending up and to the left of the normal cells. The RBC volume histogram shows many of the cells were macrocytic. The HGB histogram shows essentially no hyperchromic cells (RBCs with Heinz bodies dropped to 17%) and a small population of hypochromic cells (i.e. reticulocytes). The sequence shows well the loss of hyperchromic erythrocytes with Heinz bodies and the developing regenerative response with young, macrocytic cells.

infection or myelodysplastic syndromes. Some poodles have macrocytic erythrocytes as a familial defect. Swelling of erythrocytes is a common artifact in day old samples. Altered erythrocytes may also swell as in stomatocytosis in dogs. Vitamin B12/folic acid deficiency is a rare condition in domestic animals. Additionally, when it occurs, it is not a cause of macrocytic normochromic anemias. Cobalamine (vitamin B12) malabsorption has been reported in Giant Schnauzers but they had a normocytic normochromic anemia (see Chapter 30).[1]

Classification by Blood Smear Morphology

Blood smear evaluation is an essential procedure in classification of anemia, especially hemolytic anemias. Many observations critical to diagnosis can only be made or are made more accurately by a trained microscopist. Some examples include identification of blood parasites, spherocytes, autoagglutination, Heinz bodies, hypochromasia, eccentrocytes, pyknocytes, erythrocyte fragmentation (Table 24.3), brown color of methemoglobin, and clumping of platelets or leukocytes (see Chapter 23).

Classification by Etiology

The ultimate goal of diagnosis is correct classification of anemia by etiology or etiologies in case of multiple causes (see chapters on specific causes and Tables 24.3–24.5). The path to the final diagnosis varies with each case. The likely etiology may be identified in the history. Substances known to cause Heinz body anemia, such as acetaminophen/paracetamol in cats or red maple tree branches and leaves in horses, can be identified by proper questioning of the owner.

DIAGNOSTIC APPROACHES

Anemia diagnosis usually begins with a complete blood count (CBC) including blood smear evaluation and, in many species, reticulocyte evaluation. If the diagnosis is not obvious from the history, physical examination, and CBC, then additional testing is indicated. Additional tests are chosen based on the situation, species, and probability of different causes of anemia for a location. Examples include hemoglobinuria in a young dog with a tendency to eat foreign bodies, which should indicate that radiographs are taken to look for zinc-containing metallic foreign bodies in the stomach.

A simple, algorithmic approach to selected anemias reflects the previous discussion (Fig. 24.4). One must add one's own interpretation and knowledge to any algorithm to consider additional information or factors in a given situation. After documenting the presence and severity of the anemia, the strength of the bone marrow's response should be determined. Hemolytic anemias are usually the most regenerative (Table 24.4). Blood smear analysis frequently provides specific evidence of the cause of the hemolysis such as spherocytes, autoagglutination, ghost cells, Heinz bodies, eccentrocytes or blood parasites. Icteric or hemolytic plasma or urinanalysis with hemoglobinuria suggests hemolytic anemia, as does splenomegaly. If a regenerative anemia lacks indicators of hemolysis, then a blood loss anemia should be suspected. Macrocytic normochromic anemia is excluded from this veterinary algorithm because it has caused more misdiagnosis than correct diagnosis.

BLOOD LOSS ANEMIA

Blood loss can be external or internal (Table 24.5). Internal blood loss mimics hemolytic anemia in that erythrocytes are broken down within the body and plasma proteins are not lost from the body. External blood loss causes loss of plasma proteins as well as erythrocytes, so plasma protein concentration should be evaluated. Hypoproteinemia or low-normal plasma protein combined with regenerative anemia strongly suggests external blood loss. Plasma protein is replaced much quicker than erythrocytes so hypoproteinemia is more associated with recent and large volume blood loss. Evidence of bleeding comes from history, diagnostic imaging, fluid cytology, etc. Chronic blood loss causes iron deficiency anemia. Iron deficiency anemia due to bleeding occurs more quickly in young, growing animals that are rapidly producing erythrocytes and using iron stores.

Time after onset of blood loss greatly affects the pattern of laboratory results. Indicators of the erythroid mass in the body (Hct, Hgb concentration, RBC count) may even increase during the first few hours after blood loss. This is most prominent in horses with very contractile spleens but can be seen in dogs during controlled experimental situations.[4] The spleen holds about 20% of the erythrocyte mass and splenic contraction can mask an anemia for the first 1–2 hours after blood loss.

The rapidity of fluid replacement and restoration of normal vascular volume after bleeding affects how rapidly remaining erythrocytes and plasma protein in the vascular system are diluted. It may take 1–2 days for the Hct to reflect the true severity of the anemia (Fig. 24.5). Withholding access to water can delay decreases in the Hct. Aggressive fluid therapy can reduce the Hct rapidly and even cause hemodilution.

Time affects the expected number of reticulocytes. Blood loss anemia is regenerative, but no increase in reticulocytes is expected for the first day or two during which it is termed a pre-regenerative anemia. Peak reticulocytosis is expected 4–8 days after onset (Fig. 24.5).[6] Reticulocyte numbers decrease by 2 weeks after onset, but macrocytic hypochromic erythrocytes remain in circulation to give evidence of prior regeneration.

Blood loss anemia (Table 24.5) becomes less regenerative with time due to loss of nutrients like iron and protein. Chronic, severe blood loss causes iron deficiency anemia, which becomes progressively more non-regenerative (see Chapter 26). About half of iron deficiency anemia cases still have enough reticulocytosis to be called regenerative.

TABLE 24.3 Erythrocyte Shape Changes Associated With Selected Diseases or Conditions

Spherocyte	
Immune-mediated hemolytic anemias	Dog
Transfused blood	Dog
Blood parasite infections	Several species
Anaplasmosis	Cattle
Hereditary spherocytosis	Goat, cattle, dog
Zinc toxicity	Dog
Snake venom (coral snake, European viper)	Dog
Hypophosphatemia	Dog
Keratocyte/Shizocyte	
DIC	Dog, cat, cattle, horse
Congestive heart failure	Dog
Glomerulonephritis	Dog
Myelofibrosis	Dog
Hemangiosarcoma	Dog
Chronic doxorubicin toxicosis	Dog
Acanthocyte/Budding Fragmentation	
DIC	Dog
Hemangiosarcoma	Dog
Portosystemic shunts	Dog
Chronic liver disease	Dog, cat
Lymphosarcoma	Dog
Glomerulonephritis	Dog
Echinocyte	
Crenation artifact	Dog, cat, cattle, horse
Lymphosarcoma	Dog
Glomerulonephritis	Dog
Doxorubicin toxicity	Dog
Electrolyte depletion	Horse, dog
Heinz Bodies	
Onion, leek, garlic ingestion	Dog, cat, cow, horse, sheep
Vitamin K (mainly K_3)	Dog
Acetaminophen treatment	Cat
Phenothiazine treatment	Horse
Red maple leaf ingestion	Horse
Methylene blue treatment	Dog, cat
Phenazopyridine treatment	Cat
Propylene glycol in food	Dog, cat
Brassica spp. ingestion	Cattle
Selenium deficiency	Cattle
Copper toxicity	Sheep
Zinc toxicity	Dog
Eccentrocytes/Pyknocyte	
Vitamin K treatment	Dog
Onion ingestion	Dog
Acetylphenylhydrazine	Dog
Hydrogen peroxide intravenously	Cattle
Glucose-6-phosphate dehydrogenase enzyme deficiency	Horse
Hypochromasia	
Iron deficiency	Dog, cat, cattle, horse, pig, llama, goats, birds
Inflammation	Birds
Lead toxicity	Birds
Macrocytosis	
Regenerative anemia	Many species
Poodle macrocytosis	Dog
Stomatocytosis	Dog
Feline leukemia virus infection	Cat
Myelodysplasia	Cat
Anticonvulsant (antifolate) drugs	Dog
Prolonged storage of blood	Many species
Hypernatremia	Cat, dog
Microcytosis	
Iron deficiency	Dog, cat, cow, horse, pig
Hepatic porto-systemic shunt	Dog
Hyponatremia	Dog
Normal breed characteristic	Dog (Akita, Shibas)

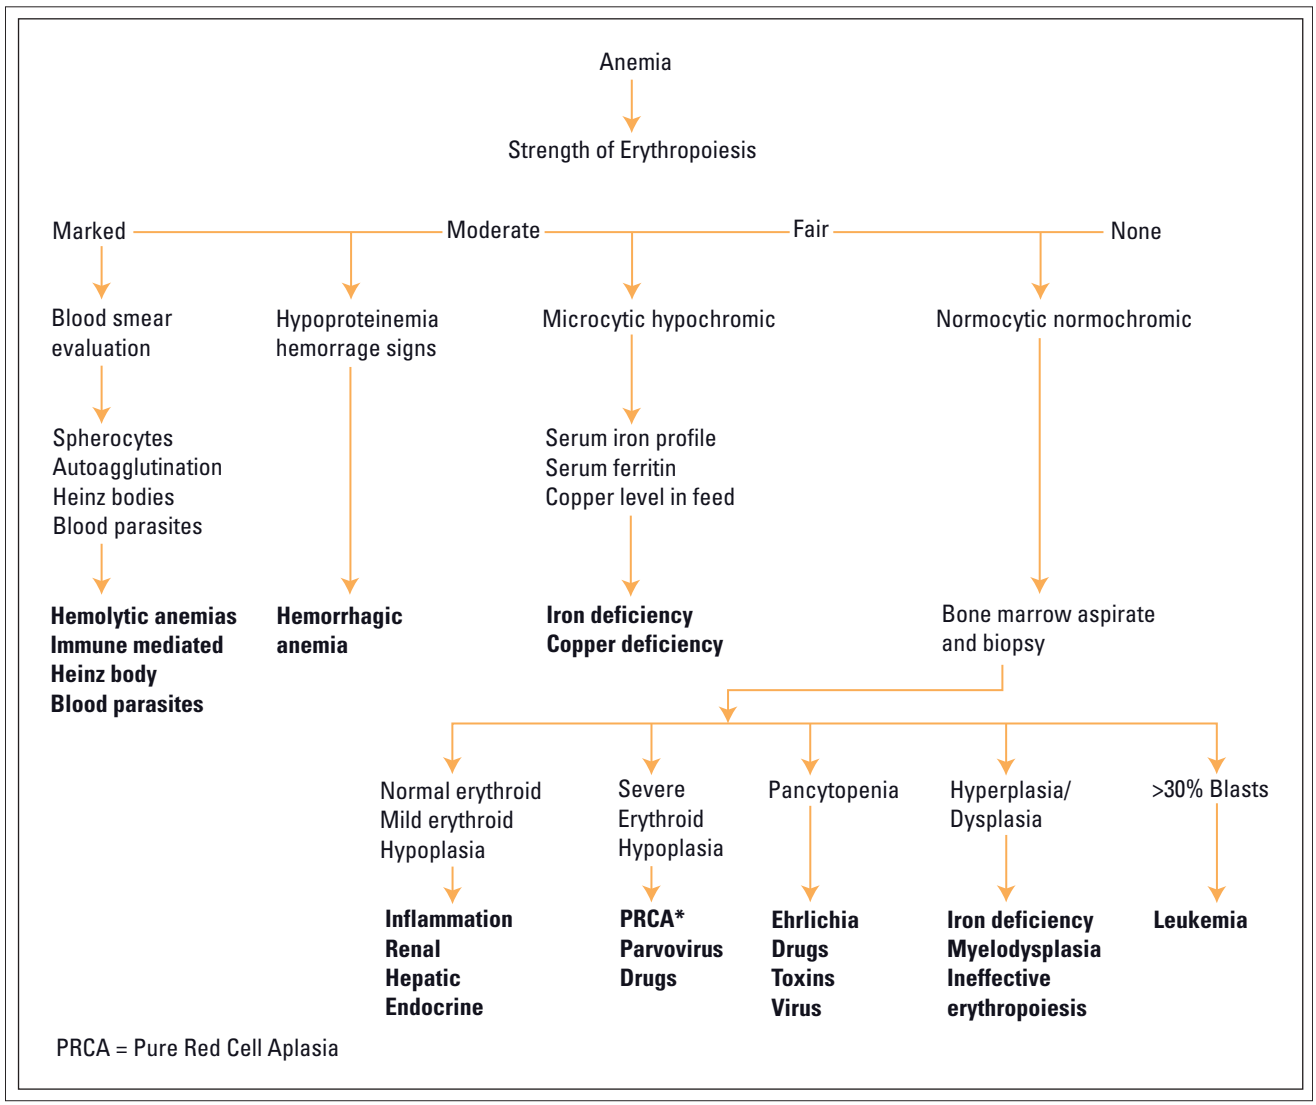

FIGURE 24.4 Algorithm for diagnosis of anemia. Anemia is documented and evaluated for severity. The strength of erythropoiesis is determined usually by reticulocyte evaluation. The marked to moderately regenerative anemias are usually hemolytic and hemorrhagic. Blood smear evaluation frequently identifies the type of hemolytic anemia. Diagnoses are given in bold. Hypoproteinemia and clinical signs indicate hemorrhagic anemia. Microcytic hypochromic anemia indicates iron deficiency that varies from non-regenerative to moderately regenerative. Non-regenerative and inadequately regenerative anemias with normocytic and normochromic RBCs may be diagnosed by bone marrow evaluation.

Confusion has occurred with interpretation of platelet counts during blood loss. A common misconception is that blood loss causes thrombocytopenia. This can mislead diagnosis of actual causes of thrombocytopenia. The platelet count is usually normal to increased after blood loss in dogs (Fig. 24.5B).[2]

NON-REGENERATIVE ANEMIA

The primary causes of secondary-types of mild to moderate non-regenerative anemia, such as inflammation, renal or hepatic disease, endocrine disease, neoplasia, etc., are diagnosed by tests more specific for those problems (e.g. leukogram, clinical chemistry, endocrinology, cytology etc.). The cause of the anemia is usually clinically inferred from the type of disease present (e.g. if renal failure, then anemia of renal disease).

Bone Marrow Evaluation

Bone marrow evaluation is indicated in non-regenerative anemias that have had adequate time (e.g. 3–6 days) to respond, especially if there is a bicytopenia or pancytopenia present. Pancytopenia is a deficiency of cells in all three cell lineages and one should test for *Ehrlichia canis*, other bacteria, virus of that species, and check for exposure to various drugs and toxins.

Bone marrow evaluation is most complete when based on cytologic evaluation of aspirated smears, histologic evaluation of a cortex-to-cortex sections and a

TABLE 24.4 Selective Causes of Hemolytic Anemias

Immune-mediated	Idiopathic, viral (EIA), drugs, blood parasites, neonatal isoerythrolysis, transfusion reaction
Heinz body	Onions, vitamin K_3, phenothiazine, acetaminophen, phenacetin, acetanilide, phenylhydrazine-HCl, benzocaine, red maple, methylene blue, phenazopyridine, copper toxicity, selenium deficiency, *Brassica* sp. ingestion
Toxic hemolysis	Zinc, copper, water in calves, l-sorbose
Hypophosphatemia	Post-parturient hemoglobinuria, refeeding syndrome, diabetes mellitus
Blood parasites	*Anaplasma, Babesia, Haemobartonella, Eperythrozoon, Theileria, Trypanosoma, Sarcocystis, Cytauzoon*
Bacteria	Leptospira, *Clostridium novyi*
Hereditary RBC enzyme deficiencies	Pyruvate kinase, phosphofructokinase, glucose 6-phosphate dehydrogenase

TABLE 24.5 Selected Examples of Hemorrhagic Anemia

Trauma	Hit by car, penetrating wounds, surgical trauma
Bleeding lesions	Intestinal neoplasms, gastrointestinal tract ulceration, burns, infections
	Parasites
	Hookworms, coccidia, *Haemonchus*
	Fleas, lice
	Hemostatic disorders
	Thrombocytopenia, thrombopathy
	Acquired coagulopathy (e.g. warfarin toxicity, hepatic disease)
	Hereditary coagulopathy, von Willebrand's disease
	Disseminated intravascular coagulation

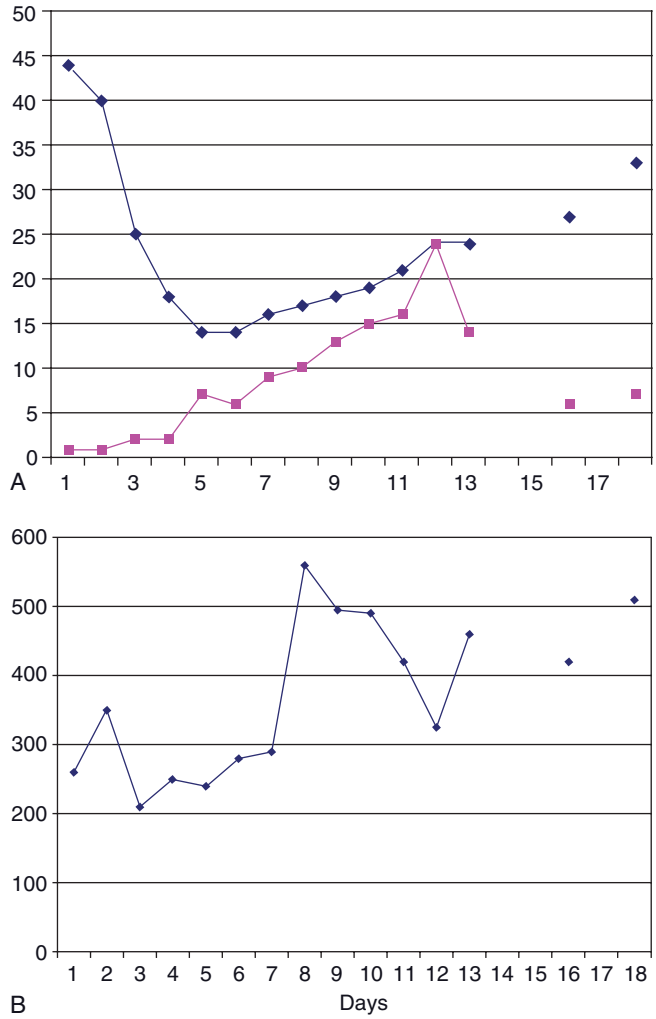

FIGURE 24.5 (**A**) Hematologic changes associated with canine blood loss anemia. A mature, healthy, research Beagle dog had 200–250 mL of blood removed each day for 3 consecutive days. An equal volume of saline and serum were infused intravenously to replace lost blood volume. These are days 2–4 in the figure.[2] Hematocrit (blue line with diamonds) and reticulocyte values (red line with squares) are given in percent on *y*-axis. Days are on the *x*-axis. Day 1 was the control value before bleeding. Note hematocrit does not reach its lowest values until days 5 and 6. The hematocrit was still low (33%) on day 18, which was 14 days after the last bleeding. Reticulocytes peaked at 24% on day 12, which was 8 days after the last bleeding and fell to 6–7% on days 16 and 18. (**B**) Thrombocytosis after canine blood loss. Platelet counts ($\times 10^9$/L) on the *y*-axis are from the same dog in Figure 24.5A. The dog had normal platelet counts before, during bleeding on days 2–4 and 3 days after the last bleeding. It had thrombocytosis on day 8 and higher than baseline platelet counts on days 9–18 which was 5–14 days after the last bleeding.

CBC on blood taken the same day as the bone marrow was obtained. Erythroid hypoplasia, pure red cell aplasia (PRCA), myelofibrosis, aplastic pancytopenia (fatty marrow) and leukemia are the clearest conclusions obtained in non-regenerative anemia.[7] Severe decreases in only the erythroid line is called pure red cell aplasia and may be caused by immune-mediated damage or viruses such as parvovirus in dogs and FeLV in cats (see Chapter 38). Drugs and toxins cause a wide variety of effects on the bone marrow (see Chapters 16 and 17).

Ineffective erythropoiesis is a frequent occurrence. It is identified by finding an adequate to increased number of erythroid cells in the marrow but a non-regenerative anemia in the CBC. Causes of ineffective erythropoiesis include infections, drug reactions, myelodysplastic syndromes, and idiopathic causes. Erythroid hyperplasia and non-regenerative anemia occur in iron deficiency and will be accompanied by a lack of hemosiderin in macrophages.

Myelodysplastic syndromes are indicated by the presence of a hypercellular marrow, cytopenias, and abnormal cell morphology such as megaloblastic rubricytes, dwarf megakaryocytes, binucleated cells, nuclear fragments, and increased blast cells.

Acronyms and Abbreviations

EPO, erythropoietin; P_{50}, the partial pressure of oxygen at which hemoglobin is half-saturated with oxygen; P_aO_2, arterial partial pressure of oxygen; PCV, packed cell volume; RBC, red blood cell; rPDA, reversed patent ductus arteriosus; S_aO_2, arterial hemoglobin oxygen saturation.

Red blood cell (RBC) production typically is in part regulated by the hormone erythropoietin (EPO; see Chapter 6). When oxygen sensors located in the renal cortex become hypoxic, hypoxia-inducible factors are generated and incite EPO gene transcription.[23,43] The resultant EPO then stimulates erythroid precursors in the bone marrow to increase RBC numbers, thereby enhancing the oxygen carrying capacity of the blood.

Erythrocytosis is defined as an increase in peripheral RBC numbers, hemoglobin concentration, and calculated hematocrit or packed cell volume (PCV) above established reference intervals. Often, erythrocytosis is used interchangeably with the term polycythemia. However, in human medicine, polycythemia sometimes denotes not only erythrocytosis, but also concurrent increases in white blood cell and platelet counts.[38] Based on pathogenesis, erythrocytosis can be classified into relative or absolute categories. Absolute erythrocytosis can be further characterized as primary (polycythemia vera) or secondary (Fig. 25.1).

RELATIVE ERYTHROCYTOSIS

Relative erythrocytosis is the most common form of erythrocytosis in dogs and cats. In relative erythrocytosis, the increased PCV is not accompanied by an expanded RBC mass, but rather develops from diminished plasma volume and hemoconcentration due to fluid loss (i.e. severe dehydration associated with vomiting, diarrhea, or polyuria without sufficient water intake). Another cause of relative erythrocytosis in dogs and horses is splenic contraction associated with excitement or anxiety. This catecholamine-mediated release of RBCs from their storage site in the spleen causes transient mild erythrocytosis unassociated with clinical signs.

ABSOLUTE ERYTHROCYTOSIS

Absolute erythrocytosis, defined as a true increase in RBC mass, can develop from primary or secondary causes.

Primary Erythrocytosis (Polycythemia Vera)

Primary erythrocytosis results from autonomous proliferation of erythroid precursors that require little to no EPO for differentiation. The prototypical primary erythrocytosis, also called polycythemia vera, is a chronic myeloproliferative disorder resulting from the clonal expansion of hematopoietic progenitor cells. In humans, polycythemia vera is associated with splenomegaly, leukocytosis, and thrombocytosis, and may progress to myelofibrosis or leukemia.[23,38] However, many of those features are absent in dogs and cats with primary erythrocytosis. It remains unclear whether primary erythrocytosis in companion animals is the same disease as polycythemia vera in humans, or whether it represents a variant with isolated erythrocytosis. Regardless,

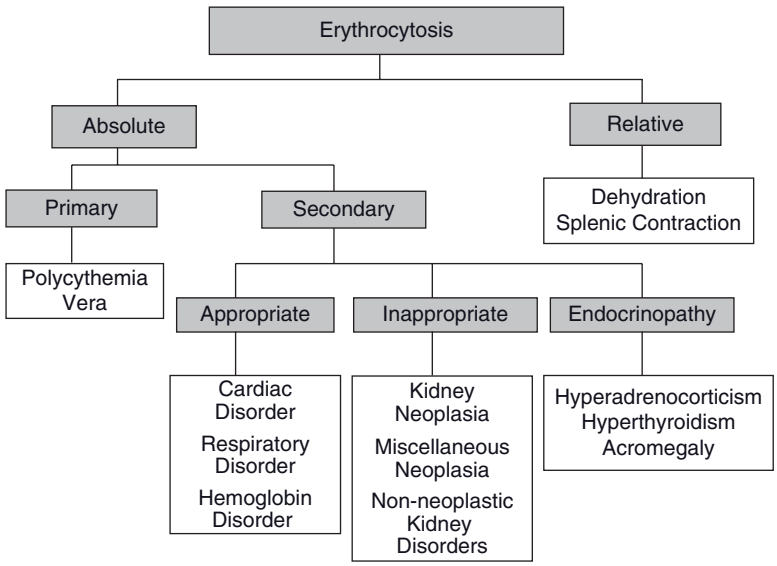

FIGURE 25.1 Flow chart for classification of erythrocytosis.

primary erythrocytosis is a disease of middle-aged (median, 6–7 years) dogs and cats.[49] Dogs with primary erythrocytosis are more frequently female, whereas affected cats are more commonly male.[49]

Secondary Erythrocytosis

Secondary erythrocytosis develops from excessive production of EPO. If EPO is secreted in response to systemic hypoxia, then the resultant erythrocytosis represents an *appropriate* compensatory response. If, on the other hand, the increased EPO secretion is not associated with systemic tissue hypoxia, then the response is *inappropriate* (Fig. 25.1). Endocrinopathy-associated erythrocytosis is another type of secondary erythrocytosis resulting from hormonal (other than solely EPO-mediated) stimulation of erythropoiesis.

Appropriate Secondary Erythrocytosis

In physiologically appropriate erythrocytosis, the EPO-mediated increased RBC mass expands the oxygen carrying capacity of the blood in an attempt to improve inadequate tissue oxygenation. For example, congenital heart anomalies resulting in right-to-left shunting with blood bypassing the lungs (e.g. tetralogy of Fallot, reversed patent ductus arteriosus [rPDA]) cause delivery of poorly oxygenated blood to the systemic circulation with resultant erythrocytosis.[4,5,16,17,24,28,31] Chronic severe pulmonary disease resulting in dyspnea from impaired oxygen transfer also may lead to erythrocytosis.[10,37] Hereditary high-oxygen affinity hemoglobinopathies in humans cause decreased release of oxygen to tissue and consequent erythrocytosis.[15,38] Although this type of hemoglobin disorder has not been described as a cause of pathologic erythrocytosis in companion animals, impaired oxygen transport from chronic methemoglobinemia in dogs and cats with methemoglobin reductase deficiency may cause mild erythrocytosis.[19]

Inappropriate Secondary Erythrocytosis

Excess production of EPO in the absence of systemic hypoxia, termed physiologically inappropriate erythrocytosis, is caused by: (1) EPO-secreting tumors of the kidneys or other organs, or (2) kidney disorders that result in regional hypoxia leading to increased EPO production. In humans, kidney neoplasms, as well as tumors of the liver, adrenal gland, uterus, and cerebellum, have been associated with inappropriate production of EPO and erythrocytosis.[38,43] Tumor-related erythrocytosis has been described with renal carcinoma,[8,36,47,48] renal lymphosarcoma,[4,29] renal fibrosarcoma,[18] nasal fibrosarcoma,[6] cecal leiomyosarcoma,[41] and schwannoma[52] in the dog, and with renal carcinoma[4,22] in the cat. Non-neoplastic kidney abnormalities in humans (e.g. renal cysts, hydronephrosis, glomerulonephritis)[43] and rarely in dogs (e.g. renal cryptococcosis)[48] have been reported as potential causes of erythrocytosis. For two dogs with glomerulonephropathy and erythrocytosis attributed to polycythemia vera, the kidney disorder was speculated to be a consequence, rather than a cause, of the erythrocytosis.[32,39]

Endocrinopathy-Associated Erythrocytosis

Hormones other than EPO, such as cortisol, androgen, thyroxine, and growth hormone, also may stimulate erythropoiesis either directly, or indirectly through increased production of EPO or alternate pathophysiologic mechanisms.[11,38] In dogs, increased cortisol or androgen concentrations associated with adrenal hyperactivity may produce mild erythrocytosis.[11] Similarly, cats with increased thyroxine concentrations from hyperthyroidism may have mildly increased RBC count.[35] Acromegalic cats with excess growth hormone may develop mild erythrocytosis,[35] but similar hematologic findings are usually absent in dogs with acromegaly.[40] The mild erythrocytosis in these endocrine

disorders is insufficient to result in clinical signs, and is usually discovered incidentally during routine diagnostic evaluation for the endocrinopathy.

CLINICAL SIGNS OF ERYTHROCYTOSIS

The clinical signs of both primary and secondary erythrocytosis include erythema (brick-red or ruddy color) of mucous membranes, neurologic disturbances (lethargy, ataxia, weakness, seizures, blindness, behavioral change), bleeding episodes (epistaxis, hematemesis, hematochezia, melena, hematuria), or polyuria and polydipsia. Most of these clinical manifestations are attributed to increased blood viscosity from the expanded RBC mass. In fact, the blood viscosity rises steeply as PCV increases.[3,44] The hyperviscosity slows blood flow, distends capillaries and small vessels, may increase the likelihood of thrombosis and rupture of these vessels, and may impair tissue oxygen delivery.[3,15,43] Vascular changes characteristic of hyperviscosity frequently can be visualized on ophthalmologic examination (i.e. dilated and tortuous retinal vessels, sometimes accompanied by retinal hemorrhage). The polyuria and polydipsia have been attributed to hyperviscosity and increased blood volume leading to impaired vasopressin release.[47]

Laboratory test results may be skewed by extreme erythrocytosis. Hypoglycemia may be noted, and explained by enhanced glucose utilization by the increased number of RBCs in vivo or in vitro. Whole blood samples collected into sodium citrate anticoagulant tubes may result in prolonged prothrombin and activated partial thromboplastin times because of excess citrate concentration for the relatively smaller volume of plasma in patients with profound erythrocytosis.[23]

DIAGNOSTIC APPROACH

Before an extensive diagnostic work-up is started, remember that many sighthound breeds, such as the Greyhound, normally have mild erythrocytosis when their PCV is compared to standard canine reference intervals.

In most animals, the first step in determining the reason for erythrocytosis is to exclude relative causes. Relative erythrocytosis usually results in a mild increase in PCV, rarely exceeding 60–65%.[20,49] However, the PCV may be as high as 70–80% in some dogs with the hemorrhagic gastroenteritis syndrome due to rapid fluid loss into the gut. This observation emphasizes that the magnitude of increase in PCV does not necessarily differentiate between relative and absolute erythrocytosis. The dehydration and hemoconcentration of relative polycythemia usually are identified by clinical findings (e.g. dry mucous membranes, reduced skin turgor), laboratory variables (e.g. hyperproteinemia, pre-renal azotemia), and response to rehydration with intravenous fluid therapy. Excitable or anxious dogs with mild erythrocytosis suspected to be caused by splenic contraction should have another blood sample collected under less stressful circumstances. Rarely, animals with repeatable mild increases in PCV and no obvious evidence of fluid loss may require direct measurement of RBC mass with radioisotope-labeled autologous RBCs to differentiate relative from absolute causes. However, these studies seldom are performed in clinical practice.

Once relative erythrocytosis is excluded, the next step is to differentiate primary and secondary causes of absolute erythrocytosis. Traditionally, serum EPO determinations have been recommended to distinguish these two types. In secondary erythrocytosis, increased EPO activity would be expected, whereas such activity should be low in primary erythrocytosis. However, recent studies have demonstrated considerable overlap in EPO activity among normal animals, animals with primary erythrocytosis, and animals with secondary erythrocytosis.[4,21] Fluctuations in EPO secretion, production of another hematopoietic growth factor not detected by the EPO assays, or renal hypoxia secondary to hyperviscosity may explain these findings.[4,25] Repeat EPO determinations, even following phlebotomy, have been suggested in problematic cases.[2,14,15,23,43] Even though most dogs and cats with primary erythrocytosis have low to low-normal EPO activity, and many animals with secondary erythrocytosis have higher EPO values, results outside of these expected ranges have been encountered.[2,4,14,21] For that reason, EPO determinations should complement rather than supplant a thorough diagnostic evaluation of animals with erythrocytosis. Furthermore, current availability of validated EPO assays for dogs and cats is limited. Additional efforts to match diagnostic features of polycythemia vera in humans with primary erythrocytosis in companion animals have been unrewarding. Routine examination of bone marrow in affected dogs and cats cannot diagnose or differentiate primary and secondary erythrocytosis because both conditions are characterized by erythroid hyperplasia. Therefore, a diagnosis of primary erythrocytosis typically is made by excluding common secondary causes.

Arterial blood gas analysis including determination of partial pressure of oxygen (P_aO_2) and hemoglobin oxygen saturation (S_aO_2) is useful in assessing tissue oxygenation. A P_aO_2 less than 80 mmHg indicates hypoxemia and S_aO_2 less than 95% reflects tissue hypoxia, both values warranting consideration of appropriate secondary erythrocytosis. If initial collection of arterial blood is thwarted by hyperviscosity, sampling may be repeated following cautious phlebotomy.[20] Alternatively, capillary S_aO_2 may be measured non-invasively with a pulse oximeter. Examination of cardiac and pulmonary systems by thoracic auscultation, thoracic radiographs, electrocardiography, and echocardiography may help determine the cause of appropriate erythrocytosis. Studies to confirm a right-to-left cardiac shunt include selective angiography and contrast echoaortography.[12,17] In dogs with rPDA, cyanosis of the vulvar or preputial (but not the oral) mucous membranes may be detected

at rest or following exercise; similarly, lower P_aO_2 values may be identified at the tail or hindlimbs compared to head or forelimbs.[12] This differential hypoxia in rPDA develops because deoxygenated blood shunts from the pulmonary artery into the aorta distal to the left subclavian artery and brachycephalic trunk, allowing more oxygenated blood to travel to the head and forelimbs. Abnormal hemoglobin variants with increased oxygen affinity in humans can be recognized by demonstrating normal P_aO_2 and S_aO_2 values, but reduced partial pressure of oxygen when hemoglobin is half-saturated with oxygen (P_{50}).[20,43] These hemoglobinopathies have yet to be confirmed as a cause of pathologic polycythemia in companion animals. However, some investigators have proposed that the higher PCV (and lower hemoglobin P_{50}) in Greyhounds may indicate that the hemoglobin of this breed has a greater affinity for oxygen.[45]

Once systemic hypoxia is excluded as the cause of erythrocytosis, conditions causing inappropriate EPO production should be considered. To locate the source of EPO in these disorders, results of physical and neurologic examinations, abdominal ultrasonography, intravenous urography, and computed tomography or magnetic resonance imaging should be helpful.

TREATMENT

With relative erythrocytosis due to dehydration, fluid therapy should be administered and the underlying disorder should be addressed. The PCV will usually normalize with successful management. For relative erythrocytosis resulting from splenic contraction, no treatment is necessary.

In primary erythrocytosis, the goal of therapy is to reduce and maintain the PCV within reference intervals, thereby alleviating clinical signs and preventing any potential thrombotic and hemorrhagic complications. The optimal treatment, however, is unknown. In dogs and cats, the disease has been managed with phlebotomy alone[13,26,27] or in combination with other modalities, leeching[30], radioactive phosphorous[26,42,51], or chemotherapeutic agents such as doxorubicin[32] and busulfan[26]. Phlebotomy and leeching must be repeated on a regular basis to maintain the PCV within reference intervals and can lead to iron deficiency and hypoproteinemia. Radioactive phosphorus induces prolonged remission and reduces morbidity, but is not readily available and may increase the risk of leukemia in treated humans.[23,38] Some of the chemotherapeutic drugs used to treat humans with polycythemia vera also may be leukemogenic.[23,38] However, it remains unknown whether leukemic transformation in these instances represents complications of treatment or natural progression of this chronic myeloproliferative disease.[23,38] The infrequent development of leukemia in dogs and cats with primary erythrocytosis may be further proof that it is indeed distinct from polycythemia vera in humans, or may merely reflect the prolonged time (10–15 years) needed for leukemic transformation in humans.[23]

Hydroxyurea, an anti-neoplastic drug, is most commonly used to manage primary polycythemia in dogs and cats. Side effects of hydroxyurea include anorexia, vomiting, bone marrow hypoplasia, mild alopecia, and sloughing of the nails.[34] Cats also may develop methemoglobinemia and hemolytic anemia with Heinz bodies, especially with high doses.[50] The effects of hydroxyurea are enhanced by reducing the PCV to approximately 50–60% with phlebotomy (10–20 mL/kg) and simultaneous fluid replacement.[33,34] Then, hydroxyurea is given at a loading dose of 30 mg/kg PO daily for 7–10 days, followed by 15 mg/kg PO daily in single or divided doses.[33,34,46] Alternate dosing schedules for cats have been reported.[7,9,50] Complete blood and platelet counts should be monitored at 7–14 day intervals until the PCV has normalized, then every 1–3 months. If leukopenia, thrombocytopenia, or anemia develops, hydroxyurea should be discontinued until the blood count returns to normal, and then resumed at a lower maintenance dosage or dose frequency.[33,34]

In inappropriate secondary erythrocytosis, treatment should be directed toward the underlying cause, when feasible. Erythropoietin-secreting tumors should be surgically removed if practical, or managed with chemotherapy and/or radiation therapy. Pre-operative phlebotomy to normalize the PCV may help reduce morbidity and mortality.

In appropriate erythrocytosis secondary to systemic hypoxia, as in some cardiac diseases, treatment of the underlying problem is recommended, if possible. Unfortunately, the two most common types of congenital heart defects associated with polycythemia in pets are not easily amenable to surgical correction: rPDA cannot be corrected surgically because of the attendant pulmonary hypertension, and mortality is high for attempted surgical correction of tetralogy of Fallot.[16] If correction is not possible, then long-term maintenance of the desired PCV can be accomplished with cautious phlebotomy (5–10 mL/kg) and hydroxyurea therapy as outlined for primary erythrocytosis: alternate protocols using hydroxyurea also have been successful.[28] However, because the erythrocytosis in these cases represents a compensatory response to tissue hypoxia, the PCV should be maintained between 55% and 60% rather than attempting normalization.[2] This degree of erythrocytosis seemingly is sufficient to minimize clinical signs associated with the systemic hypoxia as well as the polycythemia-associated hyperviscosity. Other investigators have recommended maintaining the PCV at even higher values (62–68%), or simply relieving clinical signs without concern about attaining a specific PCV.[1,5,38] Regardless, phlebotomy and drug administration in these patients should be performed with careful monitoring.

Acronyms and Abbreviations

MCHC, mean cell hemoglobin concentration; MCV, mean cell volume; RBC, red blood cell; RDW, red blood cell distribution width; TIBC, total iron binding capacity.

Iron is an essential component of all living organisms, playing a role in many metabolic processes particularly those involving electron transfer. Copper is a component of several metalloproteins including cytochrome c oxidase, superoxide dismutase, urate oxidase, dopamine β-hydroxylase, ascorbic acid oxidase, and tyrosine oxidase. Iron absorption, metabolism, and utilization in erythropoiesis are discussed in Chapter 20. In this chapter disorders of iron and copper metabolism will be discussed.

TESTS FOR EVALUATION OF IRON DISORDERS

Erythrocyte Indices

Iron is required for hemoglobin synthesis (see Chapter 20). Both true and functional iron deficiency result in deficient hemoglobin synthesis. Because hemoglobin concentration signals cessation of cell division, iron deficient cells undergo one or two more cell divisions resulting in formation of microcytes.[28] Red blood cells may also be hypochromic. Both MCV and MCHC tend to be decreased in iron deficiency but in some cases MCHC may be normal when the MCV is mildly decreased.

Many flow cytometer-based hematology analyzers can determine and plot the volume and hemoglobin content of individual RBCs (see Chapter 135). This technology can detect low numbers of microcytic or hypochromic RBCs when the MCV and MCHC are within reference intervals. These cells can be detected by inspection of cytograms. The percentage of microcytes or hypochromic or hyperchromic RBCs can be quantified for both mature RBCs and reticulocytes. Because reticulocytes have been recently produced, they most accurately reflect the current iron status.[27]

Serum Iron

Serum iron assesses the transport compartment (see Chapter 147). Serum iron is typically low in iron deficiency and in inflammatory diseases.[10,31] Serum iron may also be low during accelerated erythropoiesis particularly when exogenous erythropoietin is administered without iron supplementation.[2] Serum iron concentration is also decreased by glucocorticoid administration to ruminants.[29] Serum iron is typically increased in hemolytic anemias, dyserythropoiesis, hypoplastic anemia, aplastic anemia, iron overload, and in dogs and horses given glucocorticoids.[11,25,34]

Serum Total Iron Binding Capacity

The total iron binding capacity (TIBC) is a measure of the total serum transferrin concentration (see Chapter 146). TIBC is increased in iron deficiency in humans, horses, cattle, and pigs, but does not appear to be increased in clinical iron deficiency in dogs.[10] TIBC is decreased or in the low-normal range in inflammatory diseases.[3]

Serum Ferritin

Despite being an acute phase protein, serum ferritin correlates with tissue iron stores in domestic animals.[26] Increased serum ferritin occurs in animals with increased iron stores associated with chronic hemolytic anemias, and repeated blood transfusions. Other causes of very high serum ferritin concentrations include benign hemophagocytic disorders and malignant histiocytosis. Serum ferritin is also transiently increased in horses by intense exercise. Serum ferritin is decreased in animals with iron deficiency.

Bone Marrow Iron

Bone marrow aspirates or core biopsies can be stained with Prussian blue stains to detect hemosiderin. Hemosiderin is a tissue storage form of iron and stains blue when the Prussian blue stain is applied. Bone marrow aspirates used for Prussian blue staining should contain several unit particles so adequate material is present for assessment of marrow iron. Hemosiderin is stored within macrophages. Animals with iron deficiency lack stainable iron in bone marrow; however, lack of stainable iron is not necessarily predictive of iron deficiency.[5] Healthy non-iron deficient cats and some cattle lack stainable iron in bone marrow.[8]

Erythrocyte Zinc Protoporphyrin

Heme is formed by the addition of reduced iron to protoporphyrin IX. The reaction is catalyzed by ferrochelatase. When iron availability is reduced, zinc becomes a substrate for ferrochelatase leading to the formation of zinc protoporphyrin. Zinc protoporphyrin is stable and remains in RBCs throughout their lifespan. Zinc protoporphyrin can be measured in washed RBCs using a hematofluorometer. Due to the long lifespan of erythrocytes, iron deficiency must exist for an extended period to permit zinc protoporphyrin concentrations to exceed the reference interval.[18] RBC zinc protoporphyrin concentrations are high in iron deficiency and in chronic inflammatory diseases. In inflammatory diseases iron is sequestered in the mononuclear phagocyte system and is, therefore, unavailable for erythropoiesis.[4] RBC zinc protoporphyrin concentration also increases in lead poisoning.[18]

IRON DEFICIENCY

Causes

True iron deficiency is caused by insufficient gastrointestinal iron absorption or by hemorrhage. Iron deficiency due to decreased intake is rare except in neonatal animals that are nursing. Milk contains low concentrations of iron; therefore, nursing animals can easily become iron deficient as they grow.[15] Piglets reared without access to soil are highly susceptible to iron deficiency. Concurrent infestations with bloodsucking parasites can result in severe iron deficiency. Iron deficiency in piglets can be prevented by allowing them to eat soil or by intramuscular iron dextran injections.

Iron deficiency is a relatively common finding in ruminants and dogs in temperate regions where bloodsucking parasite infestations are severe.[10] Other causes of chronic blood loss include gastrointestinal ulcers, gastrointestinal neoplasia, hemorrhagic colitis, urinary bladder neoplasia, thrombocytopenia, and inherited hemostatic disorders. Iron deficiency is rarely seen in adult horses or cats.[24]

Clinical Features

Iron deficiency has been classified into three stages: iron deficiency, iron-deficient erythropoiesis, and iron deficiency anemia.[13] In iron deficiency, bone marrow iron and serum ferritin are low but serum iron, transferrin saturation, zinc protoporphyrin, and complete blood count values are normal. In iron-deficient erythropoiesis, bone marrow iron and serum ferritin and serum iron transferrin saturation are low, zinc protoporphyrin is high, but complete blood count values remain within the reference intervals. In iron deficiency anemia, bone marrow iron and serum ferritin and serum iron transferrin saturation are low, zinc protoporphyrin is high, and complete blood count values, including hemoglobin, MCV, and MCHC, are altered.

Iron deficiency is usually not identified until a microcytic anemia is present. Clinical signs associated with iron deficiency vary somewhat depending on the cause of the iron deficiency and the presence of other concomitant disorders. Clinical signs that may be present include pale mucous membranes, lethargy, weakness, loss of weight, retarded growth, hematuria, dermatitis, hematochezia, and melena. These signs appear to arise not only from the associated anemia but from deficiency of other iron-containing molecules including cyto-

chrome c, cytochrome oxidase, succinic dehydrogenase, aconitase, xanthine oxidase, and myoglobin.[15] Iron-deficient animals have increased susceptibility to infection; however, the mechanism involved is poorly understood.[15]

Laboratory Features

The anemia in iron deficiency is complex, usually resulting primarily from a combination of hemorrhage and impaired erythropoiesis. However, RBCs produced in an iron-deficient environment also have a reduced lifespan.[14] In acute iron deficiency anemia, the anemia is normocytic and normochromic. The MCV drops below the reference interval only after weeks to months of iron deficiency. In iron deficient animals, a decrease in MCV usually precedes a decrease in MCHC. A low MCHC is frequently present in chronic iron deficiency in ruminants and dogs but is rarely present in iron deficient horses or adult cats. The RBC distribution width (RDW) is frequently increased because of the coexistence of microcytes and normocytes in the blood. Acute iron deficiency is under diagnosed because in many cases the anemia is normocytic and normochromic. However, careful evaluation of RBC cytograms and reticulocyte indices, as well as determination of the percentage of microcytes, provides much earlier indicators of iron deficiency anemia (see Chapter 135). This technology can detect low numbers of microcytic or hypochromic RBCs when the MCV and MCHC are within the reference range. Because reticulocytes are recently produced, reticulocyte indices (MCV_{retic}, CH_{retic}) most accurately reflect the current iron status.[27]

Alteration in RBC morphology in blood smears is most prominent in dogs and ruminants. In these species hypochromic RBCs have a narrow rim of lightly stained hemoglobin and a larger than normal area of central pallor (Fig. 26.1; see Chapter 23). Because of the increased diameter-to-volume of these cells they tend to flatten on the slide and therefore may not appear small when viewed on the stained blood film. Hypochromasia is less apparent in blood films from cats and horses. Further, electronic cell counters may not count microcytic RBCs due to their small size. This results in a spuriously increased MCV. Poikilocytosis, including keratocytes and schistocytes, is frequently present in iron deficiency. The mechanism responsible for these shape alterations is uncertain.

When iron deficiency anemia is the result of hemorrhage, reticulocytosis is frequently present in the early stages. As iron depletion becomes more severe erythropoiesis is compromised and the reticulocytosis is abrogated. Moderate to marked thrombocytosis is a frequent finding in iron deficiency. The mechanism is not clearly defined.

FUNCTIONAL IRON DEFICIENCY

In functional iron deficiency, total body iron stores are normal or increased but iron is relatively unavailable for heme synthesis. Functional iron deficiency has been associated with the anemia of inflammatory and neoplastic diseases (see Chapter 37) and portosystemic shunts.

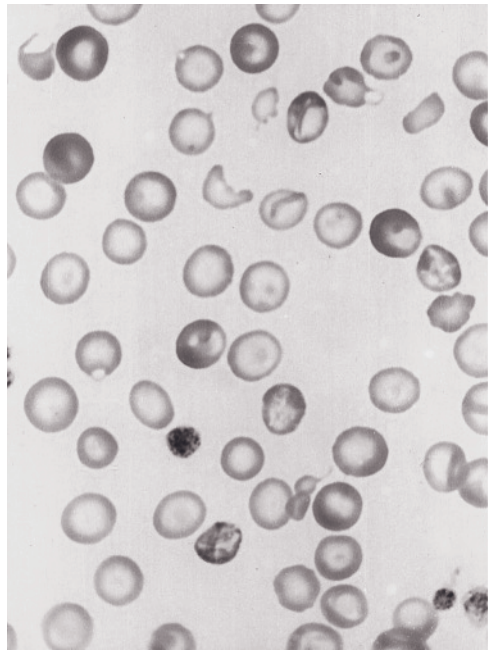

FIGURE 26.1 Hypochromasia and poikilocytosis in a blood smear from a dog with chronic iron deficiency anemia. Wright-Giemsa stain.

Portosystemic Shunts

Portosystemic shunts are vascular connections between the portal and systemic circulation that divert blood around the liver. These vessels may occur congenitally or arise secondary to portal hypertension associated with chronic hepatic disease. Most affected dogs have mild microcytosis and hypochromasia but are not anemic.[19] Poikilocytosis, including codocytes, keratocytes, and elliptocytes, are frequent findings. Approximately half of the affected dogs have hypoferremia but serum ferritin is high.[19]

OTHER MICROCYTIC OR HYPOCHROMIC ANEMIAS

Microcytic or hypochromic anemias have been associated with sideroblastic anemia and refractory anemia with ringed sideroblasts. Refractory anemia with ringed sideroblasts is a type of myelodysplastic syndrome (see Chapter 66).[6]

Sideroblastic Anemias

Sideroblastic anemias result from disorders of heme synthesis which result in accumulation of excess iron in mitochondria of erythroid cells. The hallmark of sideroblastic anemias is the present of large numbers of iron aggregates within RBCs (i.e. sideriocytes) or erythroid precursors (sideroblasts) or the presence of iron

distributed in a ring around the nucleus of erythroid precursor cells (i.e. ringed sideroblasts). Naturally occurring pyridoxine deficiency in humans and experimental pyridoxine deficiency in pigs results in sideroblastic anemia.[7] Pyridoxine is required for the first step in heme synthesis. Several causes of sideroblastic anemia have been reported in dogs. Drugs and chemicals associated with sideroblastic anemia include chloramphenicol, hydroxyzine, zinc, and lead.[9,12] Sideroblastic anemia associated with clinical disease has primarily been seen in dogs with inflammatory diseases.[30] The hemogram in these dogs is characterized by moderate to severe non-regenerative anemia that is frequently hypochromic and the presence of dysplastic features in bone marrow that is most prominent in the erythroid lineage. Siderocytes and sideroblasts and variable numbers of ringed sideroblasts are a prominent feature of this condition.[32]

COPPER DEFICIENCY

Copper deficiency can develop in ruminants eating forage from copper deficient soils. Secondary copper deficiency can occur when copper intake is adequate but use is impaired by high dietary molybdenum or sulfate. Affected animals generally have a microcytic hypochromic anemia; however, normocytic anemias have been reported in experimental copper deficiency in dogs.[1] Microcytosis and hypochromasia is the result of functional iron deficiency. Functional iron deficiency results from a decrease in production of the copper-containing proteins ceruloplasmin, hephaestin, and cytochrome oxidase that are required for iron transport.[16] Hephaestin is involved in release of iron from intestinal enterocytes. Ceruloplasmin facilitates mobilization of iron from the liver and tissues other than enterocytes.[33] Pigs with acute experimental copper deficiency have low serum iron but pigs with chronic experimental copper deficiency develop increased serum iron concentration and have many sideroblasts present.[16] This may be due to a deficiency of the copper-containing enzyme cytochrome oxidase in erythroid precursor cells. Cytochrome oxidase is involved in reducing ferric to ferrous iron in mitochondria for use in heme synthesis.

IRON OVERLOAD

Iron overload can result from acute iron toxicity or chronic accumulation that results in hemosiderosis or hemochromatosis. Iron accumulates in the liver and other tissues when transferrin saturation is high. Although most iron is stored as ferritin, some is likely available to catalyze the formation of reactive oxygen species.[22]

Acute Iron Toxicity

Acute iron toxicity usually results from administration of large doses of iron to animals. Parenteral administration of large amounts of iron to ruminants results in respiratory distress, icterus, and central nervous system signs.[23] Oral intake of a large amount of iron results in respiratory distress, icterus, central nervous system signs, vomiting, bloody diarrhea, and hypovolemic shock. Hepatotoxicity has been documented in neonatal foals after ingestion of a nutritional supplement containing ferrous fumarate iron at a concentration lower than that required to induce acute iron toxicity in adult horses.[20]

Hemosiderosis and Hemochromatosis

Hemochromatosis refers to accumulation of iron in tissue with associated organ injury and dysfunction, while hemosiderosis refers to accumulation of iron within tissues without evidence of organ injury or dysfunction. Hemosiderosis occurs locally within tissues at sites where hemorrhage has occurred. Hemochromatosis has been classified as primary (inherited), secondary, and idiopathic.[17]

Primary Hemochromatosis

Most types of hereditary hemochromatosis in humans result from a mutation in the hepcidin gene. Hemochromatosis has also been described in related Salers cattle.[21] Affected cattle had a history of stunted growth, poor hair coat, and weight loss. These cattle had iron accumulation in multiple tissues and histopathologic lesions consisting of periportal fibrosis, periosteal dysplasia, and osteopenia.

Secondary Hemochromatosis

Secondary hemochromatosis is most frequently associated with hemolytic anemias, repeated blood transfusions, parenteral iron administration, or dietary iron overload. Dietary iron overload does not appear to be a problem in animals except in a few wild animal species housed in captivity.[17] Hemolytic anemias are associated with increased iron absorption. When the hemolysis is chronic, increased intestinal absorption results in iron accumulation within hepatocytes as well as within macrophages. Liver fibrosis eventually develops.

Iron overload associated with blood transfusions is rarely a problem in animals. In general, large numbers of transfusions can be given before hepatocellular degeneration or fibrosis is detected.

Acronyms and Abbreviations

ADP, ALA-D porphyria; AIP, acute intermittent porphyria; ALA-syn, δ-aminolevulinic synthetase; ALA-D, ALA-dehydrase; CEP, congenital erythropoietic porphyria; DHC, dihydrocollidine; EPP, erythropoietic protoporphyria; FER-Ch, protoporphyrin IX by ferrochelatase; GGT, γ-glutamyltransferase; HCB, hexachlorobenzene; HCP, hereditary coproporphyria; HEP, hepatoerythropoietic porphyria; NRBC, nucleated erythrocytes; 5′NT, pyrimidine-5′-nucleotidase; PCT, porphyria cutanea tarda; RPI, reticulocyte production index; TCDD, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin; UV, ultraviolet.

The diseases associated with the accumulation of porphyrin compounds in cells, tissues, and body fluids are classified as the porphyrias or the porphyrinurias. The porphyrias are those inherited enzyme defects of the metabolic pathway leading to the synthesis of porphyrins and their metal complexes, the hemoglobins, other heme proteins and the heme enzymes.[1] The porphyrinurias are those acquired defects due to chemical and metal toxicities of the same pathway of porphyrin synthesis. The heme proteins are found widespread in nature. The photosynthetic pigment of plants, chlorophyll, is a magnesium-porphyrin. The heme proteins of animals include the hemoglobins, myoglobins and heme enzymes such as catalase, peroxidase and cytochromes. As such, the heme compounds are vital to the capture and delivery of oxygen to tissues and to the subsequent generation of chemical energy to sustain life. This chapter will focus on hereditary and acquired events in which toxic porphyrin compounds accumulate amid failures to synthesize the precise porphyrin structures required for their incorporation into functional heme proteins.

PORPHYRIN SYNTHESIS: THE PORPHYRIAS AND THE PORPHYRINURIAS

The biochemical pathway for the synthesis of porphyrin and the heme of hemoglobin is summarized in Chapter 20 and are outlined in Fig. 27.1 and Table 27.1.[10] The synthesis of porphyrins and heme can occur only in respiring cells with a full complement of mitochondrial and cytosolic enzymes. The Krebs cycle is an aerobic cycle, so oxygen would be required in order to supply the succinyl-CoA. The predominant tissues that synthesize heme are the bone marrow for production of

hemoglobin and the liver for the heme-containing enzymes. Thus, these are the two tissues that are central to the pathogenesis of the porphyrias and the porphyrinurias.

DIAGNOSIS OF THE PORPHYRIAS AND THE PORPHYRINURIAS

Clinical Observations

Clinically, the detection of the porphyrins is based upon their reddish-brown color, their characteristic red fluorescence when exposed to ultraviolet (UV) light and the lesions of photosensitivity due to the photosensitizing nature of the porphyrin compounds. Because they are present in all body cells, tissues and fluids, the porphyrins stain all tissues. This is particularly noticeable in the reddish-orange staining of the teeth and dentine, hence the name "pink tooth" is colloquially used for congenital erythropoietic porphyria (CEP). In well vacularized tissues (e.g. mucous membranes) a muddy color is readily detected. Porphyrins in the body fluids are readily excreted in the urine and in saliva, sweat, tears, and mucous secretions. The reddish-orange discoloration of the urine is readily visible and is often the presenting complaint. When UV light of the Soret band (405 nm) or a Wood's lamp is shone on the teeth or urine, an intense reddish fluorescence is seen. This is virtually pathognomonic of porphyria but this red fluorescence should not be confused with the yellow-green fluorescence of tetracycline drugs. The third major clinical observation is photodermatitis, which is evident on light colored areas of the skin. This may be accompanied by photophobia. When exposed to UV light, the porphyrins in the skin absorb UV light energy and are raised to an unstable higher level energy state. The excitation energy can be emitted as fluorescence or transferred to molecular oxygen to form singlet oxygen. Singlet oxygen is a powerful oxidant for many forms of biologically important compounds including the peroxidation of membrane lipids, membrane and cellular proteins, cell enzymes and cell organelles. Peroxidation is the primary event in the photosensitivity and photodermatitis seen in the porphyrias.[16]

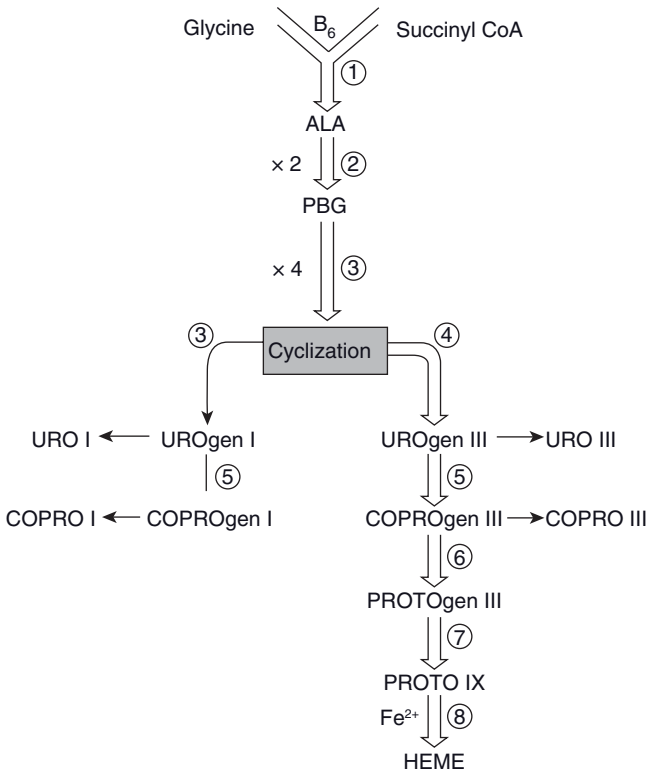

FIGURE 27.1 Alternate pathways for porphyrin synthesis. Normally, enzymes 3 and 4 function together in a coordinated manner to form heme. In the absence of enzyme 4, the alternate and terminal pathway to form the I isomers is taken. The circled numbers correspond to the enzymes listed in Table 27.1.

Laboratory Detection

The principal method now employed for the detection of porphyrins in biological materials in the clinical laboratory is also based upon the characteristic red fluorescence observed when acidic solutions of the porphyrins are exposed to UV light.

Fluorescence does not differentiate the uroporphyrins from the coproporphyrins so these are separated on the basis of their solubilities in organic solvents prior to exposure. Various screening and chemical procedures are described in detail for urine, fecal and blood

TABLE 27.1 Nomenclature for Enzymes of Porphyrin and Heme Synthesis and their Synonyms

No. in Figure 27.1	Abbreviation	Nomenclature
1	ALA-Syn	δ-Aminolevulinate synthase (synthetase)
2	ALA-D	δ-Aminolevulinate dehydrase (dehydratase), porphobilinogen synthase
3	UROgenI-Syn	Uroporphyrinogen I synthase (synthetase), porphobilinogen deaminase
4	UROgenIII-Cosyn	Uroporphyrinogen III cosynthase (cosynthetase)
5	UROgen-D	Uroporphyrinogen decarboxylase
6	COPROgenIII-Ox	Coproporphyringen III oxidase
7	PROTOgen-Ox	Protoporphyrinogen oxidase
8	FER-Ch	Ferrochelatase, heme synthase (synthetase)

TABLE 27.2 Classification of the Porphyrias

Porphyria Type	Inheritance[a]	Enzyme Deficiency[b]
Erythropoietic porphyrias		
Congenital erythropoietic porphyria	AR	UROgenIII-Cosyn
Erythropoietic protoporphyria	AD	FER-Ch
Hepatic porphyrias		
ALA-D deficiency porphyria	AR	ALA-D
Acute intermittant porphyria	AD	UROgenI-Syn (PBG-D)
Porphyria cutanea tarda	AD	UROgen-D
Hepatoerythropoietic porphyria	AR	UROgen-D
Harderoporphyria	AR	COPROgenIII-Ox
Hereditary coproporphyria	AD	COPROgenIII-Ox
Variegate porphyria	AD	PROTOgen-Ox

[b]See Table 27.1 for enzyme abbreviations.

porphyrins as well as for urinary porphobilinogen.[10] High pressure liquid chromatography is now regarded as the best chemical method for detection of porphyrins in feces and in urine.[27,28]

CLASSIFICATION

The porphyrias are those porphyrin diseases that are inherited. There have been many classification systems for the porphyrias. Most are based on the defect in the tissue of origin, the erythropoietic system or the liver.[22,23] A useful system of classification is given in Table 27.2. The porphyrinurias are acquired porphyrin diseases and are generally due to toxins. Coproporphyrin is the main excretory product and the porphyrinurias are seen in a wide variety of conditions including infections, hemolytic anemias, liver disease, and lead poisoning. There are other systems of classification of the porphyrias and while there is general agreement on the eythropoietic forms, there is still some confusion with the classification of the hepatic forms.

ERYTHROPOIETIC PORPHYRIAS

Bovine Congenital Erythropoietic Porphyria

Clinical Observations

The most characteristic finding in bovine CEP is a reddish brown discoloration of the teeth and bones. The disease is seen primarily in Holsteins with a few cases in Shorthorns and Jamaican cattle. Bovine CEP is inherited as an autosomal recessive trait. The condition is present at birth and severely affected calves must be protected from sunlight if they are to survive.

While the predominant clinical manifestations are of teeth, urine discoloration and photosensitization are readily apparent in severely affected animals; these signs vary widely with the degree of the enzyme deficiency, age, time of year, amount of white hair coat, and exposure to sunlight. Marked variations in the urinary excretion of the porphyrins also occur so that the urine color varies.

Laboratory Detection

Normally, free porphyrins are found in very low concentrations in cells, tissues and body fluids. Thus, the finding of porphyrins in any detectable amounts is always significant. Porphyrin excretion in urine varies, ranging for uroporphyrins between 6.3 and 3,900 µg/dL (0.076–46.96 µmol/L) and coproporphyrins between 2.1 and 8,300 µg/dL (0.032–126.74 µmol/L). At concentrations of 100 µg/dL (1.53 µmol/L) or more, a reddish discoloration is discernible. At 1,000 µg/dL (15.27 µmol/L) or more, an intense red fluorescence of the urine is readily observed when examined with a Wood's light. The principal porphyrins excreted are URO I and COPRO I and the amount of each is also variable.

Bovine fecal porphyrins may be derived from two sources: the bile and from chlorophyll in food. The porphyrins derived from chlorophyll are excluded by the usual analytical method. Essentially, the only porphyrin found in the bile and feces of CEP cattle is COPRO I, and its concentration varies over wide limits. Fecal coproporphyrin varies between 1.9 and 11,800 µg/g (0.003–18.0 µmol/g) and biliary coproporphyrin between 320 and 13,600 µg/dL (4.88–207.67 µmol/L). Only small amounts of COPRO III have been observed in feces.

Only traces of free porphyrins are normally present in the plasma and in the erythrocytes. In bovine CEP plasma variable amounts of URO I (1–27 µg/dL; 0.012–0.33 µmol/L) and COPRO I (4.2–25 µg/dL; 0.064–0.38 µmol/L) are present. A striking difference as compared to the human disease is the high level of free PROTO IX in the erythrocytes of the CEP cow. Excess PROTO IX is commonly found in iron deficiency, hemolytic anemia and in lead poisoning.

The hematologic picture in CEP is one of a responsive hemolytic anemia, with the degree of response directly related to the severity of the anemia. The anemia

in mild cases of bovine CEP is normocytic and in the more severe cases is macrocytic accompanied by reticulocytosis, polychromasia, anisocytosis, basophilic stippling and an increase in nucleated RBC. There is a markedly decreased myeloid:erythroid (M:E) ratio in the bone marrow indicating a marked erythroid hyperplasia.

The presence of porphyrins in the nucleated RBCs is clearly evident by examination of unfixed and unstained bone marrow smears with a fluorescent microscope. These fluorescent RBCs have been called fluorocytes. The fluorescence is seen only in morphologically abnormal nucleated RBCs which contain abnormal nuclear inclusions.

The hematology of newborn CEP calves is strikingly different from that of older CEP calves and cows.[11] There is an intense erythrogenic response in the neonatal CEP calf that persists for the first 3 weeks of life. Nucleated RBC counts during the first 24 hours of life range from 5,000 to 63,500/μL. Reticulocyte counts are lower than expected (6.4%) and increase to a peak of only 12.5% at 4 days of life.[11] Survival time of these reticulocytes in the peripheral circulation is extended beyond their normal one day.

Erythrocyte lifespan is shortened in bovine and in human CEP, which is inversely correlated with RBC coproporphyrin concentration.[13] The shortest RBC survival time of 27 days (normal = 150 days) was associated with the highest RBC coproporphyrin concentration. The porphyrins through their lipid solubility are presumed to damage the RBC membrane, leading to the hemolysis. Upon exposure of surface capillaries to sunlight, photohemolysis further aggravates the hemolysis. In vivo ^{59}Fe metabolic studies were compatible with a hemolytic type of anemia and ineffective erythropoiesis.[12] Plasma iron turnover and transfer rates, RBC iron uptake and organ uptakes were increased as expected in a hemolytic process.

The biochemical defect in the bovine CEP reticulocyte in vitro is expressed as an increase in porphyrin synthesis, a marked decrease in heme synthesis, and a delay in the maturation time of reticulocytes.[24] The $T_{1/2}$ for the maturation of the reticulocyte is 50 hours compared to a normal value of 3–10 hours. This delay in reticulocyte maturation is thought to be the direct result of the defect in heme synthesis since the rate of heme synthesis controls the rate of maturation of the reticulocyte.

A similar delay in the maturation of the metarubricyte to the reticulocyte was observed in the bone marrow cells of CEP cows[20] but there was no effect on earlier nucleated erythroid cells. Ultimately, the accumulation of porphyrins in these cells, whether in bone marrow or in blood, induces delayed maturation or hemolysis.

Detection of the Carrier State

The activity of UROgenIII-Cosyn is considerably less in homozygous CEP cattle as compared to normals[14] and the heterozygotes have UROgenIII-Cosyn activities intermediate between porphyrics and normals.[19] Similarly low UROgenIII-Cosyn activity is found in human CEP. The genetic aspects of all forms of hereditary porphyrias have been reviewed.[18]

Normally in heme synthesis, the combined action of UROgenI-Syn and UROgenIII-Cosyn catalyzes the formation of the normal type III porphyrin isomer, UROgenIII, which ultimately leads to heme formation. In a deficiency of UROgenIII-Cosyn, the type I isomers, UROgenI and COPROgenI are formed, the amounts of which are governed by the relative activities of these enzymes. The type I isomers which are formed cannot be converted into a PROTOgenI so there is no type I heme. This is because COPROgenIII-Ox is specific only for the type III isomer and there is no specific coproporphyrinogen I oxidase. The UROgenI and COPROgenI isomers are readily oxidized to their corresponding free and toxic uroporphyrins and coproporphyrins. These oxidized free porphyrins accumulate in the erythropoietic tissues, developing erythroid cells and in mature RBCs where they induce the hemolysis characteristic of CEP.

Total deficiency of UROgenIII-Cosyn is obviously incompatible with life so that surviving cases of CEP have only a partial deficiency of UROgeIII-Cosyn. The central theme for the metabolic basis for bovine CEP is the genetically controlled deficiency of UROgenIII-Cosyn with the accumulation of the resultant type I porphyrins. These type I porphyrins are the ultimate cause of the clinical and pathophysiological manifestations of CEP.

Bovine Erythropoietic Protoporphyria

Erythropoietic protoporphyria (EPP) is well recognized in humans in which it is inherited as a dominant autosomal trait.[18] Patients do not have the major signs of CEP such as anemia, porphyrinuria or discolored teeth. Photosensitivity of the skin is the only significant clinical manifestation of the disease and this is associated with a high plasma protoporphyrin concentration. The most striking laboratory finding is the high concentration of PROTO IX in the erythrocytes and feces.

In cattle, EPP has a pattern of recessive inheritance and may be sex-linked because to date it has only been documented in females. The photosensitivity also seems to diminish in adults animals. Affected cattle do not have anemia, porphyrinuria, or discoloration of the teeth. RBC and fecal protoporphyrins are very high in comparison to normal cows.[21] The fundamental enzymatic defect in bovine EPP is a deficiency of FER-Ch with a resulting accumulation of PROTO IX. Low FER-Ch was found in all tissues of EPP calves so that the defect is a total body defect.

Porphyria of Swine

Porphyria in swine is inherited as a dominant trait. Except for the very severe cases, there appears to be little or no effect upon the general health of the pig. Photosensitivity is not seen even in white pigs. The

predominant feature in affected pigs is a characteristic reddish discoloration of teeth that fluoresces upon exposure to UV light. Porphyrin deposition in teeth of newborn pigs is virtually pathognomonic of porhyria in swine. The porphyrins are principally URO I.

The urine of affected pigs is discolored only in more severely affected pigs. The 24 hour urinary excretion of uroporphyrins ranges between 100 and 10,000 µg and for coproporphyrin, is only 50 µg. PBG is absent in the urine. Close similarities in this pattern of porphyrin excretion to that found in bovine CEP are apparent but the localization of the defect in the erythropoietic tissue has not been established. This disease has not been seen in pigs since its original description.

Porphyria of Cats

The first cases of feline porphyria had the typical discoloration of teeth that fluoresced under UV light. Their urine was also discolored and qualitatively positive for uroporphyrin, coproporphyrin, and porphobilinogen. However, there was no evidence of anemia or photosensitization. The porphyria appeared to be inherited as a simple Mendelian autosomal dominant trait analogous to that seen in swine.

Excessive accumulation of URO I, COPRO I, and PROTO IX was observed in the RBCs, urine, feces, and tissues in a family of Siamese cats.[8] These cats had photosensitivity, severe anemia, and severe renal disease. The principal defect in these cats appeared to be a deficiency of UROgenIII-Cosyn similar to CEP of humans and cows.

Normal Porphyrias

All fox squirrels (*Sciurus niger*) have red bones and this is due to the accumulation of URO I and COPRO I.[5] Fox squirrel porphyria resembles CEP of humans, cows, and cats by having a deficiency of UROgenIII-Cosyn and accumulation of type I porphyrins in their urine and feces, discolored bones, teeth, and tissues which fluoresce upon exposure to UV light. There is increased erythropoiesis but no apparent hemolytic anemia, no photosensitivity or any other deleterious effects. These relatively benign effects are most likely due to their thick hair coats and nocturnal living habits. It is interesting that an enzyme deficiency with serious health effects in other animals should have evolved as a "normal" characteristic in the fox squirrel. This is understandable when one appreciates that CEP cattle that are always kept indoors and protected from sunlight, thrive and reproduce normally.

The UROgenIII-Cosyn deficiency is found only in the fox squirrel and not in the closely related gray squirrel (*Sciurus carolinensis*). Urine porphyrin excretion in the fox squirrel is 10-fold greater than in the gray squirrel and is further increased when erythropoiesis is stimulated by bleeding. The UROgenIII-Cosyn of fox squirrel erythrocytes is very heat sensitive and this may indicate that its CEP is additionally due to an increased lability of the enzyme.

In the feathers of certain brightly colored birds, e.g. Touracos, and in certain lower animals and microorganisms, porphyrins accumulate but these appear to be normal phenomena.

HEPATIC PORPHYRIAS

This group of porphyrias has been seen only in humans in whom they are the most common group of porphyrias (Table 27.2). The predominant site of the metabolic defect is in the liver and the group is further subdivided on the basis of their principal clinical manifestations. Specific enzyme deficiencies have been identified for all forms of hepatic porphyrias.

δ-Amino-levulinic Acid Dehydratase Porphyria

This rare hepatic form of porphyria has a marked deficiency of the enzyme ALA-D in the homozygous state[3] and is called ALA-D porphyria (ADP). It is inherited as an autosomal recessive trait and is characterized by neurologic symptoms without skin photosensitivity.

Acute Intermittent Porphyria

Acute intermittent porphyria (AIP) is the major autosomal dominant form of hepatic porphyria seen in humans and is characterized by acute abdominal attacks and neurological symptoms. Photosensitivity is not a feature of this form. Most patients are not clinically affected unless some form of aggravating factor is present. Attacks are precipitated by several causative factors including barbiturates, sulfonamides, estrogens, and alcohol. The principal urinary finding is the excretion of large amounts of ALA and PBG. The deficient enzyme in this porphyria is UROgenI-Syn.

Porphyria Cutanea Tarda

Porphyria cutanea tarda (PCT) is caused by a deficiency of UROgen-D and presents as both a sporadic form and a familial form. The sporadic form is acquired and the familial form is inherited as an autosomal dominant. The characteristic clinical signs of PCT are the photosensitivity. The disease occurs in mid to late adult life and common precipitating causes of this disease are alcohol and estrogens. The disease can be successfully treated by avoidance of these substances. There is a decrease in hepatic UROgen-D in both forms but the enzyme deficiency is found in extra-hepatic tissues only in the familial form[17]. In the sporadic form, RBC UROgen-D activity is normal whereas in the familial form, RBC UROgen-D is less than 50% of normal.[15] Sporadic PCT has a significant increase in GGT whereas the familial form has normal GGT activity.[18] Furthermore, the ratio of fecal COPRO III:COPRO I when combined with the plasma GGT was found to give an even more accurate differentiation of the sporadic form from the familial form.[2]

Hepatoerythropoietic Porphyria

Hepatoerythropoietic porphyria (HEP) is a form that clinically resembles CEP but there is a marked deficiency of UROgen-D as in PCT. It is thought to be the homozygous form of familial PCT. HEP is characterized by a very severe photosensitivity but there is no liver involvement.

Harderoporphyria

This is a rare form of porphyria in which the propionate group on the A ring only is converted to a vinyl group. The normal next step of B ring conversion is somehow disrupted. There is a deficiency of COPROgenIII-Ox but the mechanism explaining why the groups on both rings are not oxidized is unknown.

Hereditary Coproporphyria

Hereditary coproporphyria (HCP) is clinically similar to PCT with a mild cutaneous photosensitivity and it may also have neurologic symptoms as in AIP. Like AIP, HCP is commonly precipitated by drugs and alcohol. As in harderoporphyria, COPROgenIII-Ox is the deficient enzyme.

Variegate Porphyria

The symptoms of variegate porphyria (VP) are generally more variable than the other forms but in most cases, acute abdominal attacks and photosensitivity are seen. Variegate porphyria is most common among the South African white population and is inherited as an autosomal dominant. There is a deficiency of PROTOgenIII-Ox, which can be observed in cultured fibroblasts and in leukocytes of VP patients.[9]

ACQUIRED TOXIC PORPHYRIAS: THE PORPHYRINURIAS

Chemical Porphyrias

The two major forms of the acquired toxic porphyrias are those due to organic chemical intoxication and to heavy metal poisonings, mainly lead. Experimentally, hexachlorobenzene (HCB), 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), allylisopropylacetylcarbamide (Sedormid), or dihydrocollidine (DHC) have been used to produce the hepatic forms of porphyria.

Lead Poisoning

Lead poisoning occurs in all domestic animals and is a significant clinical problem, particularly in the dog and in children. The principal clinical features are related to the gastrointestinal and nervous systems (see Chapter 17). Anemia is usually seen only in long standing chronic lead toxicities. The anemia has certain features that are suggestive of lead poisoning but these are not diagnostic. A non-responsive mild to moderate normocytic normochromic anemia with basophilic stippling and nucleated RBCs (NRBCs) out of proportion to the degree of anemia may be seen. More than 15 stippled cells per 10,000 RBCs is suggestive of lead poisoning in dogs and >40 stippled cells per 10,000 erythrocytes is reported to be diagnostic.[25] Stippling is thought to represent aggregates of ribosomal RNA that have not been degraded to their nucleotides and subsequently dephosphorylated by pyrimidine-5′-nucleotidase (5′NT). Lead has been shown to decrease the activity of 5′NT in humans[26] and in calves.[7]

Lead is known to have widespread toxic effects on sufhydryl-, carboxyl-, and imidazole-containing proteins that would include enzymes, cell proteins, globins, and membrane proteins. However, only a few are altered in a way that is of diagnostic value. Hemoglobin synthesis is disrupted and this is the major mechanism of the anemia of lead poisoning. The anemia, however, occurs late in chronic lead poisoning and its nonspecific nature makes it of less diagnostic importance than is usually attributed to it.

Several of the enzyme systems of heme synthesis are very sensitive in early exposure to small quantities of lead. The most sensitive are ALA-D and FER-Ch, and these enzymes and their accumulated substrates are widely used as screening tests for lead exposure. Erythrocyte ALA-D is strongly inhibited by lead and as a result, ALA increases in plasma and is excreted in the urine. Measurement of ALA is difficult and the result lacks sensitivity for low-level lead exposure. Therefore, erythrocyte ALA-D is more commonly assayed. The ratio of ALA-D activity assayed at two different pH values demonstrates ALA-D inhibition at low blood lead concentrations of 10–15 µg/dL (0.50–0.70 µmol/L). This is thought to be a more sensitive and reliable index of the blood lead concentration.[4]

FER-Ch is the second major enzyme that is strongly inhibited by lead and as a result, PROTO IX accumulates in the RBCs. RBC ZnPROTO IX increases when blood lead concentrations are at 15–18 µg/dL (0.75–0.85 µmol/L). This is well below the blood lead concentration of >30 µg/dL (1.45 µmol/L) that is currently regarded as diagnostic for lead poisoning in children. Marked elevations in RBC PROTO IX are also found in experimental lead poisoning in calves.[6] Modern fluorometers specifically designed to measure porphyrins have greatly simplified the assay. For these reasons, the current test of choice to monitor lead exposure is the blood ZnPROTO IX concentration.

The final diagnosis of lead poisoning ultimately rests upon the measurement of blood lead concentration and this is best done using atomic absorption spectrophotometry. It is clear that the heme synthetic pathway is affected by blood lead concentrations well below those that are considered normal. The reported reference interval for blood lead in the dog is 10–50 µg/dL (0.48–2.41 µmol/L) and a blood lead concentration of >60 µg/dL (2.90 µmol/L) is diagnostic of lead poisoning.[25] In the light of current knowledge, a blood level of 30 µg/dL (1.45 µmol/L) should be considered diagnostic of

lead poisoning in the dog as well as in all veterinary species.

Acronyms and Abbreviations

ADP, adenosine diphosphate; ATP, adenosine triphosphate; BFU-E, burst forming units-erythroid; CFU-E, colony forming unit-erythroid; DNA, deoxyribonucleic acid; DPG, diphosphoglycerate; EDTA, ethylenediaminetetraacetic acid; G6PD, glucose-6-phosphate dehydrogenase; L-M-P-PFK, liver, muscle, platelet phosphofructokinase; L-M1/M2-R-PK, liver, muscle, red blood cell pyruvate kinase; PFK, phosphofructokinase; PK, pyruvate kinase; RBC, red blood cell.

As the committed erythroid precursor cells proliferate and develop into mature red blood cells (RBCs) in the bone marrow, their cellular metabolism undergoes many changes. While the burst forming units-erythroid (BFU-E) and colony forming unit-erythroid (CFU-E) cells are geared to massively expand the erythroid cell line, which is under the control of erythropoietin, major metabolic and structural shifts occur, particularly during the later erythroid stages, to achieve the highly specialized functions of mature RBCs (see Chapters 6, 20, and 21).[40] To that end, during rubricyte and metarubricyte (also known as normoblasts) stages until the reticulocyte stage, heme and alpha- and beta-globin syntheses are in full force to produce hemoglobin, reaching one-third of a mature RBC's mass. Heme synthesis occurs in both mitochondria and cytoplasm involving several enzymatic steps. Hereditary enzymatic defects in heme synthesis, also known as porphyrias, cause tissue (bone and teeth) accumulation and urinary as well as fecal excretion of varied porphyrins, and can lead to hematological, neurological, gastrointestinal, and cutaneous signs. Porphyrias and their classification and characterization to the molecular level in cats, pigs, sheep, and cattle are described in Chapter 27. While sickle cell disease and thalassemia are the most common RBC disorders in humans, interestingly, no hemoglobinopathies causing anemia have thus far been documented in domestic animals. However, hereditary methemoglobinemias, either due to a cytochrome b5 (methemoglobin) reductase deficiency or a yet unknown mechanism, have been observed in dogs, cats, and even a Rhesus monkey, and are typically associated with cyanosis and erythrocytosis rather than anemia (see Primary erythrocytosis in Chapter 25).[22,32,34,39] Glucose-6-phosphate dehydrogenase (G6PD) of the hexose-monophosphate shunt is the most common hereditary (and only x-chromosomal) RBC enzyme deficiency in humans (Fig. 28.1); these patients are generally not anemic, but can develop hemolytic crises with oxidative stress (drugs, infections, flava beans [flavism]).[2] While in a large canine survey only a single Weimeraner dog was found to have a reduced G6PD activity without any hematological abnormalities,[71] an American saddlebred colt with G6PD had anemia with eccentrocytosis.[39,59] Furthermore, horses with RBC flavin adenine dinucleotide deficiency have both eccentrocytosis (attributable to severe deficiency in glutathione reductase activity) and methemoglobinemia (attributable to cytochrome b5 reductase deficiency); the dual enzyme deficiency occurs because flavin adenine dinucleotide is a required cofactor for both enzymes.[29] Although various erythrocytic membrane defects have also been described affecting cytoskeletal proteins, such as spectrin and band 4.1, others remain undefined and may involve enzymatic pumps to maintain electrolyte and calcium homeostasis as suspected for stomatocytosis in the Alsaka Malamute and Miniature and Middle Schnauzer (see Chapter 29).[76]

Devoid of a nucleus and mitochondria the metabolism of the mature mammalian RBC is fairly restricted, and its energy is solely generated by anaerobic glycolysis, also known as the Embden-Meyerhof pathway (Fig. 28.1; see Chapter 21).[40] Metabolism of one molecule of glucose to two molecules of lactate leads to the net

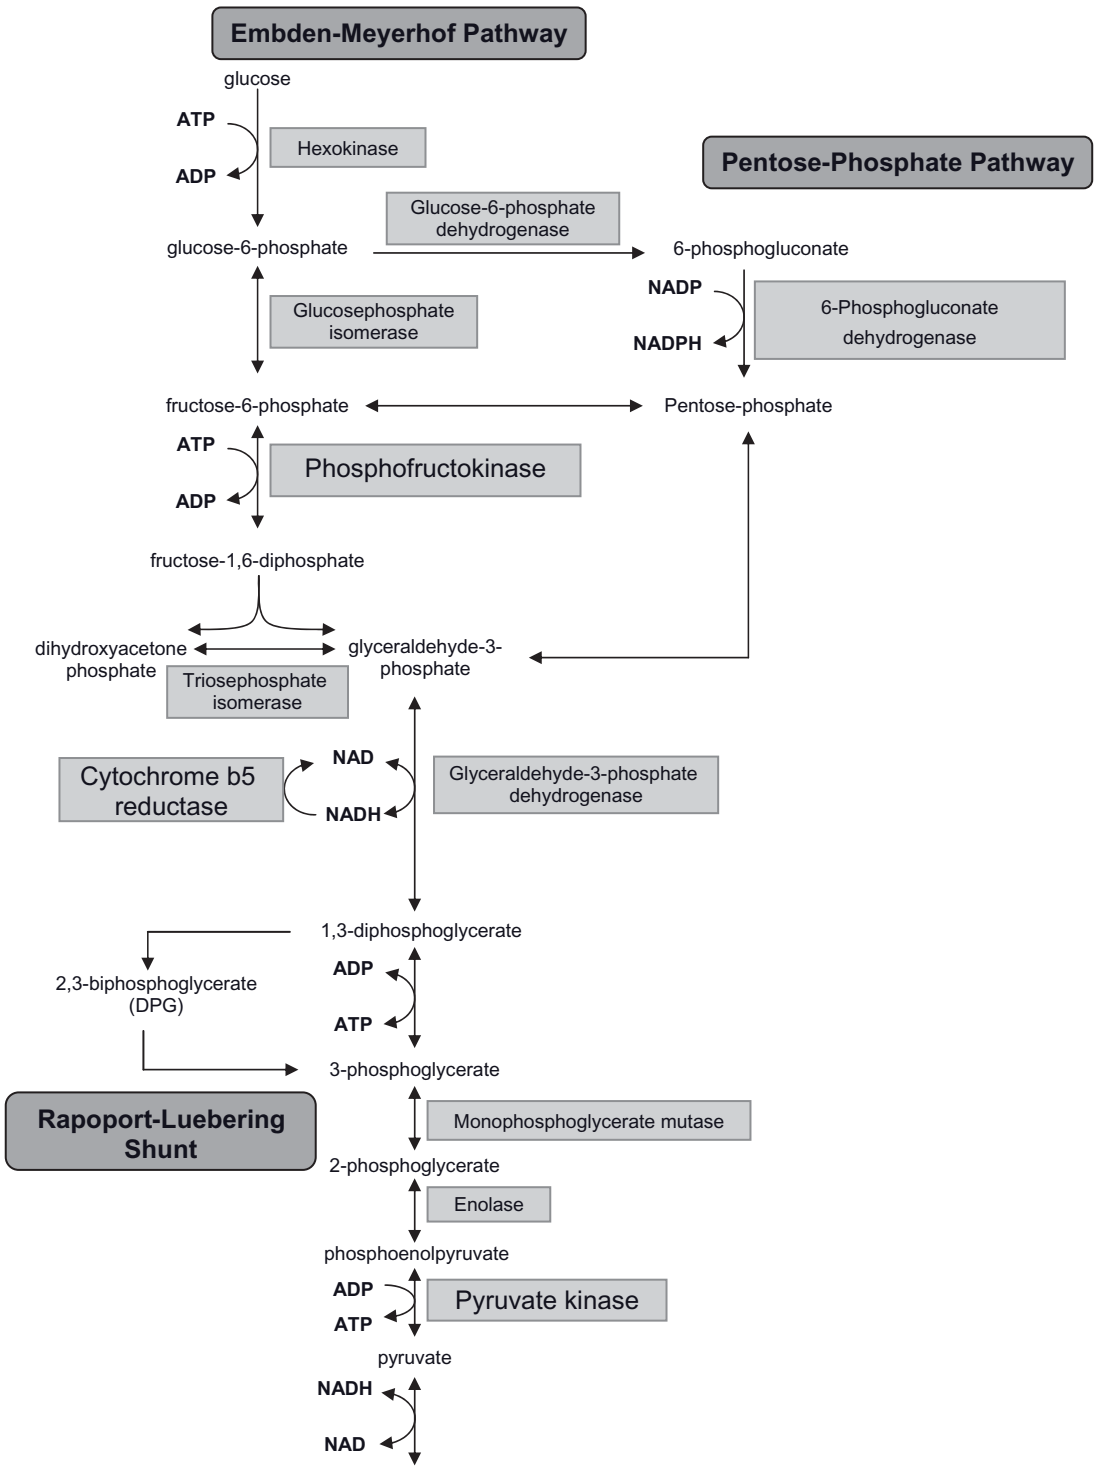

FIGURE 28.1 Embden-Meyerhof (anaerobic glycolytic) pathway with hexose-monophosphate and Rapoport-Luebering shunt in RBCs (simplified). ATP, adenosine triphosphate; ADP, adenosine diphosphate.

production of two molecules of ATP. The rate of glycolysis depends on the need for ATP of RBCs to maintain the shape, deformability, membrane transport, and metabolic functions such as phosphorylation and synthesis of purines, pyrimidines, and glutathione. Over a dozen enzymes are involved in glycolysis, which are associated with the two ancillary pathways, unique to RBCs, the pentose-phosphate (hexose-monophosphate) pathway and Rapoport-Luebering shunts. Some of these enzymes exist in different isoforms allowing for cell and tissue specific expression and regulation. The key regulatory enzyme of anaerobic glycolysis is

phosphofructokinase (PFK). Whereas ATP is the most important inhibitor of PFK activity, inorganic phosphate, AMP and ADP action is stimulatory. In addition, glucose-1,6-biphosphate and fructose-2,6-biphosphate are activators. Under maximally activating conditions for the enzyme PFK, an enzyme distal in glycolysis, pyruvate kinase (PK), becomes rate-limiting (Fig. 28.1).

It is, therefore not surprising that a deficiency of either PFK or PK activity will lead to RBC malfunction and premature RBC destruction, thereby causing hemolytic anemia. Although both erythroenzymopathies impair the same metabolic pathway, their metabolic and hematological abnormalities and clinical presentations are distinctly different and can vary between species. Subsequently, both erythroenzymopathies will be reviewed separately and contrasting features between the two disorders as well as affected species will be highlighted.

PHOSPHOFRUCTOKINASE DEFICIENCY

Phosphofructokinase (PFK; EC 2.7.1.11) catalyzes the regulatory phosphorylation step of fructose-6-phosphate to fructose-1,6-biphosphate. There are three isoforms of PFK, referred to as muscle (M-PFK), liver (L-PFK), and platelet (P-PFK) that are encoded by three different genes.[78] The active PFK enzyme is a homo- or heterotetramer composed of one or more isoforms; each of these combinations provides unique enzyme kinetic properties. Their expression is cell and tissue specific and developmentally regulated. Skeletal muscle contains exclusively M-PFK homotetramers.[54] Human RBCs express equal amounts of M- and L-PFK, whereas in canine RBCs, the M-PFK isoform predominates in a ratio of 86:14 over P-PFK.[78] Furthermore, during myogenesis[7] and erythropoiesis as well as postnatal development,[30] the isoform composition in these cells changes from L-PFK to M- and P-PFK. Deficiency of M-PFK has been associated with hemolysis and myopathy in humans and dogs, whereas in horses and Holstein calves PFK deficiency apparently did not cause any hematologic abnormalities[75] and will, therefore, not be discussed here.

Muscle-type PFK deficiency, also known as Tarui-Layzer syndrome, is a rare genetic disorder in humans characterized by metabolic myopathy and a well-compensated hemolytic disorder.[25,62] PFK-deficient humans exhibit exercise intolerance, muscle weakness, and muscle cramping on exertion. Because of the residual half-normal PFK activity in affected RBCs, contributed by L-PFK isozymes and lack of alkaline fragility of human RBCs, overt clinical signs of hemolysis occur rarely. In fact, human patients can over-compensate their hemolytic component, and develop a mild erythrocytosis, because PFK-deficient erythrocytes do not readily release oxygen from hemoglobin. The ensuing tissue hypoxia accelerates erythropoiesis. Several mutations in the M-PFK gene have been described in human patients.[55]

Canine Phosphofructokinase Deficiency

Canine M-PFK deficiency was first described as an autosomal recessive trait in English Springer Spaniels in 1985 and was the first defect characterized at the molecular level for a common inborn error in dogs.[9,10,12,13,23,68] PFK-deficient dogs have a nonsense mutation in the last exon of the M-PFK gene.[69,70] The resulting change from a tryptophan codon to a stop codon causes truncation of the M-PFK protein by 40 amino acids, leading to rapid degradation and complete deficiency of the M-PFK enzyme.[53,70] Affected dogs completely lack PFK activity in muscle and have 8–22% of control PFK activity in RBCs due to residual P- and L-PFK expression (other tissues appear less affected as they express higher levels of other PFK isoforms).[15,30,33,36,78] The metabolic block at the PFK step results in deficiency of ATP and DPG in RBCs, reduced blood lactate production, and accumulation of sugar phosphates and glycogen in muscle; hence also the term glycogenosis or glycogen storage disease type VII.[10,11,15] This metabolic pattern is also known as a metabolic crossover, indicating the specific metabolic block in a pathway.

In erythroenzymopathies, the mechanism of accelerated lysis is generally not known, but it is assumed to be caused by energy depletion. In dogs, the compensated hemolytic disorder of PFK deficiency is accentuated by life-threatening hemolytic crises. A unique mechanism has been documented to be responsible for intravascular lysis, namely an increased alkaline-induced hemolysis.[9] Although incompletely understood and possibly related to an aberrant RBC calcium homeostasis, canine RBCs are more alkaline fragile than cells from other species.[41,79] RBC calcium homeostasis is disturbed in PFK deficiency, which results in an energy imbalance that accelerates adenine nucleotide pool depletion. Ca^{2+}-calmodulin activation of RBC AMP deaminase contributes to this metabolic dysregulation and limits ATP, thereby likely contributing to increased RBC lysis.[63] In vivo, the intracellular pH of RBCs is determined by organic phosphate and chloride anions. Because PFK-deficient RBCs have markedly decreased DPG concentrations, chloride ions move in and increase RBC pH.[9,11,29] Thus, PFK-deficient RBCs start lysing at about pH 7.4 (Fig. 28.2A). Consequently, even minor systemic alkalemia or hyperthermia can induce intravascular hemolysis. Alkalemia is associated with any form of hyperventilation.[9,13]

The low DPG content of PFK-deficient RBCs markedly increases oxygen affinity and this is reflected in a left shift of the hemoglobin-oxygen dissociation curve.[9,10] The relative tissue hypoxia impairs, for instance, muscle and other tissue metabolism and stimulates renal erythropoietin synthesis and erythropoiesis. Therefore, aside from the occasional hemolytic crises associated with anemia, the chronic hemolytic disorder can be fully compensated with a robust regenerative response even at normal hematocrit. However, erythrocytosis as seen in PFK-deficient humans does not occur in affected dogs.

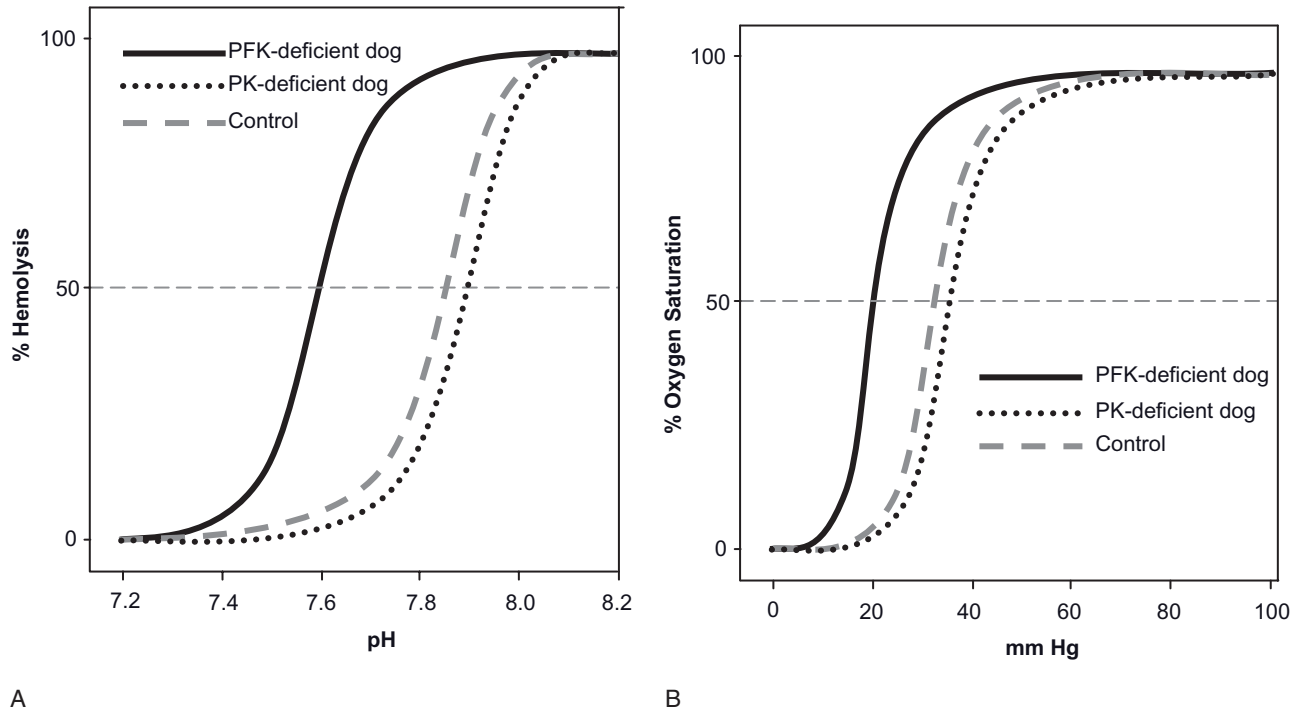

FIGURE 28.2 (**A**) Alkaline fragility of RBCs from a phosphofructokinase (PFK)-deficient English Springer Spaniel and pyruvate kinase (PK)-deficient Beagle compared to a healthy control dog. RBCs were incubated at various pH values for 1 hour at 37 °C 24 hours after collecting the blood samples. Note that RBCs from PFK-deficient dog are very alkaline fragile, while those from PK-deficient dogs behave like controls. (**B**) Hemoglobin-oxygen dissociation curve of RBCs from phosphofructokinase (PFK)-deficient English Springer Spaniel and pyruvate kinase (PK)-deficient Beagle. Note the severe left shift of the curve of the PFK-deficient cells (higher hemoglobin-oxygen affinity, P_{50} = 17 mmHg), while pyruvate kinase (PK)-deficient canine RBCs are slightly right-shifted (lower hemoglobin-oxygen affinity, P_{50} = 32 mmHg) compared to canine control blood (28 mmHg).

Sporadic intravascular hemolytic crises associated with pigmenturia, anemia, or jaundice are the hematological hallmark findings of PFK deficiency in dogs.[9,13,35] These episodes are induced by hyperventilation-associated events such as excessive panting and barking, strenuous exercise and high environmental temperatures. Thus, guests or a new pet at the patient's home, a visit to the veterinary clinic, boarding, and training for field trialing can precipitate hemolysis. These crises can be first observed at a few months of age, although some animals may not experience any problems until several years of age, or they may be completely missed until the owner looks for them. During these episodes, which generally last one to several days, affected animals can have pale to severely icteric mucous membranes, are lethargic, inappetent, and often febrile, and splenomegaly may be noted. Thus, PFK deficiency can readily be confused with immune-mediated and other acquired hemolytic anemias. Pigmenturia is characterized by hemoglobinuria during crises, whereas hyperbilirubinuria is persistently strong. The anemia may become life-threatening with hematocrits as low as 5%, but is always macrocytic, hypochromic and strongly regenerative with corrected and absolute reticulocyte counts of 4–25% and 200,000–1,200,000/μL, respectively. The apparent half-life of chromium-labeled PFK-deficient RBCs is 16 days compared to 20–28 days for normal canine cells. Beside polychromasia, marked anisocytosis and normoblastosis (but no poikilocytosis) are observed on microscopic examination of a blood smear. Yet unexplained, leukocytosis and hyperglobulinemia also may be present. The plasma may be discolored because of hemoglobinemia and bilirubinemia. Transient hyperkalemia is due to lysis of high potassium containing reticulocytes and young RBCs.[9,13]

The debilitating exertional metabolic myopathy typically seen in human PFK-deficient patients is less commonly observed and frequently milder in affected dogs. PFK-deficient dogs may develop muscle signs on exertion, even only for a short distance.[3,14,15,51,52] In fact, muscle cramping in one of the limbs even after mild exercise is the most dramatic presentation.[14] Affected dogs may suddenly refuse to run and have high serum creatine kinase activity. Despite a complete lack of PFK activity in muscle, clinical signs of myopathy in deficient dogs are generally mild and rare, presumably due to the high oxidative rate of canine skeletal muscle.[72] Nevertheless, major impairments in oxidative and anaerobic muscle metabolism have been demonstrated experimentally.[3,51,52] Aside from the acute signs of cramping, affected dogs may only show clinically mild exercise intolerance and intermittent muscle wasting. The serum creatine kinase activity is normal to slightly increased. PFK-deficient skeletal muscle accumulates

slightly more glycogen and occasionally amylopectin, an abnormal glycogen.[14,31] Interestingly a couple of Whippets with PFK deficiency also showed clinical signs of a cardiomyopathy probably resulting from the M-PFK isozyme deficiency in heart muscle.[8]

PFK deficiency is an autosomal recessive trait[10] and occurs commonly in the English Springer Spaniel breed.[20,44] Since the first description in 1985,[9] over 200 cases have been documented, but the gene frequency remains unknown. A randomized survey of American Kennel Club (AKC)-registered championed and bred English Springer Spaniels in 1998 revealed that 4% of field trial and and 2.7% of show (bench) English Springer Spaniels were still carriers. Based on extensive pedigree analyses, a common ancestor goes at least back to the 1960s, if not earlier. PFK deficiency also has been reported in American Cocker Spaniels,[19] and several mixed breed dogs and Whippets.[8] As they all had the same disease-causing DNA mutation, these animals must have a common ancestor.

PFK deficiency may be suspected based upon signalment, family history, typical clinical signs, and suggestive laboratory test abnormalities. While the pigmenturia is generally marked (i.e. orange to black), it may not be noted by the owners, particularly with a female dog, and other signs may be mild unless the dog is rigorously exercised. A definitive diagnosis requires proof of the PFK mutation or reduced RBC PFK enzyme activity. A simple polymerase-chain reaction (PCR)-based DNA test accurately identifies PFK-deficient dogs (homozygotes, affected; two mutant alleles) and carriers (heterozygotes; one mutant and one normal allele) in the English Springer Spaniel, American Cocker Spaniel, and Whippet as well as the mixed breeds.[8,18,19,70] EDTA-anticoagulated blood, but also a drop of blood dried on special filter paper (Guthry paper), a buccal swab with a cytobrush, and even semen from a semen bank or formalized tissues can be suitable sources for DNA extraction and PCR testing. Whereas the PCR test and differentiation either by sequencing or restriction-enzyme digest are simple and permit a diagnosis of deficient, carrier, and normal animals from the first day of life, the PFK enzyme activity test is cumbersome and not accurate until two months of age. Normal and affected neonatal dogs express large quantities of L-PFK in RBCs, which increases the overall PFK activity.[30] As the PCR-based test is mutation-specific, the measurement of PFK enzyme activity may, however, be indicated in other breeds and species, where the same disease is suspected. The PCR-based PFK test is recommended for use as a screening test for English Springer Spaniels (1) with suspicious clinical signs, (2) related to affected or carrier dogs, (3) used for breeding, and (4) prior to training for field trialing. In Whippets and American Cocker Spaniels, PFK deficiency seems to be more isolated and thus general screening is not recommended.

PFK-deficient dogs can have a normal life expectancy, if crises-inducing situations are avoided.[13] Dogs experiencing a hemolytic crisis are provided supportive care including, if needed, type-matched blood transfusions and in case of repeat transfusions cross-matched blood. Fever and excessive panting or barking should be avoided whenever possible. Diamox, a carbonic anhydrase inhibitor, may acidify the blood, and aspirin and dipyrone may counter the fever accompanying hemolysis, thereby preventing further intravascular lysis during an acute crisis; however, they have not been proven effective in clinical practice. Similarly, because of disturbed purine metabolism, adenine could be considered as treatment, but efficacy and safety data are lacking.[63] Despite massive intravascular hemolysis, hemoprotein-induced acute nephropathy has not been observed. Nevertheless, hemolytic dogs should be well hydrated. Affected dogs recover from these crises within days. The management of the cardiomyopathy seen in PFK deficient Whippets may represent one of the breed-specific complications limiting their life expectancy.[8]

Finally, experimental bone marrow transplantation has successfully corrected the hematological abnormalities and abolished the hemolytic crises. Moreover, the corrected RBCs also normalized the hemoglobin-oxygen affinity and, thereby, positively affected oxygenation of muscle and aerobic muscle function.[51,52] Because of the morbidity and mortality associated bone marrow transplantations even when a dog leukocyte antigen (DLA)-matched donor (PFK carrier or normal) sibling is available and the relatively mild signs, when preventative measures are instituted, bone marrow transplantation cannot be recommended for this inborn error of metabolism.

PYRUVATE KINASE DEFICIENCY

Pyruvate kinase (PK; EC 2.7.1.40) catalyzes the ATP-generating conversion of phosphenolpyruvate to pyruvate and is, therefore, an important regulator in the terminal glycolytic pathway. There are two different genes coding by alternative splicing a total of four developmentally dependent and tissue-specific PK isoforms.[42,50,57,58] The PKLR gene encodes RBC (R-PK) and liver (L-PK) isoenzymes, whereas the PKM gene generates the muscle (M1-PK and M2-PK) isoforms. R-PK is expressed almost exclusively in mature RBCs and has a different first exon making the amino-terminal sequence longer when compared to that of L-PK. In contrast, erythroid precursors express M2-PK and switch to R-PK isoforms during differentiation to mature RBCs.[50] Erythrocytic PK deficiency causing hemolytic anemia has been described in humans, dogs, cats, and mice.[43,55,56,73]

Pyruvate kinase deficiency is the most prevalent hereditary non-spherocytic hemolytic anemia caused by a glycolytic enzymopathy.[55,74] Many mutations in the PKLR gene have been found to cause R-PK deficiency in human patient; some of them are common in certain ethnic (Amish) and geographical regions.[5,55] Most of the patients, however, are compound heterozygotes with two different mutant alleles. Clinical signs in PK-deficient humans are very variable, ranging from a mild compensated hemolytic disorder to severely anemic

patients who become transfusion-dependent, may develop iron overload (particularly when receiving regular transfusions), and die during early childhood. Splenectomy has been shown to be helpful in some human patients with severe anemia; iron chelation and bone marrow transplantation are other options.[25,74]

Canine Pyruvate Kinase Deficiency

In 1971, erythrocytic PK deficiency was first recognized in Basenji dogs.[64] It served as the classic example of an inborn error of metabolism in veterinary medicine, despite the fact that the biochemical derangements turned out to be more complex, making a clinical diagnosis more difficult. R-PK deficiency occurred most frequently in Basenjis,[17,64,65] but has also been reported in Beagles,[16,28,60] West Highland White[4,67] and Cairn Terriers,[64] Miniature Poodles, Dachshunds,[45] Chihuahuas, and American Eskimo Toy dogs. In Basenjis, a single base-pair deletion in exon 5 of the R-PK gene has been identified causing a frameshift and severe truncation of the protein.[81,82] In contrast, a six base insertion ambiguously positioned at the 3′-end of exon 10 in the R-PK sequence was found in West Highland White Terriers.[67] This insertion results in the in-frame addition of two amino acids, threonine and lysine, and is likely also the causative mutation in Cairn Terriers,[63] a related breed. In the Beagle, an exon 1 mutation has been found while in the other breeds a disease-causing mutation has yet to be confirmed. Despite the varied mutations in R-PK, the biochemical changes and clinicopathologic manifestations of PK deficiency in any of the reported canine breeds appear identical.

The R-PK deficiency in RBCs of affected dogs can be demonstrated by agarose gel electrophoresis, immunoblotting, and, immunoprecipitation studies.[17,37,38] However, all affected dogs express M2-PK in RBCs, which increases total RBC PK activity of affected dogs, and, therefore, is misleading. For instance, the Miniature Poodles with non-spherocytic anemia and osteosclerosis may well have had R-PK deficiency,[61] despite high RBC PK activity in vitro. In contrast M2-PK expression is rarely observed in human patients. This M2-PK isozyme, which is normally present in erythroid precursor cells, appears to be heat-labile and dysfunctional in vivo, because affected RBCs show a severe metabolic block at the PK step.[17] Beside the accumulation of proximal glycolytic metabolites in RBCs, the DPG content is also increased. The resulting right shift of the hemoglobin-oxygen dissociation curve allows for improved oxygen delivery, thereby ameliorating the clinical signs of severe anemia in PK-deficient dogs.

PK-deficient dogs frequently present for evaluation at a few months to a couple of years of age because of intermittent weakness and exercise intolerance. They appear to adapt very well to the anemia, presumably due to the favorable tissue oxygenation. The hematocrit ranges between 12% and 28%; the anemia is highly regenerative with reticulocyte counts of 10–90%. Ecchinocytes have been documented.[64] In contrast, canine PK-deficient RBCs have normal alkaline fragility and readily release oxygen compared to canine PFK-deficient RBCs (Fig. 28.2). The erythrocyte half-life is only 5.8 days compared to 19–28 days in normal dogs.[17] Hepatosplenomegaly, due to extramedulary erythropoiesis and hemosiderin deposition, may also be noted. Affected dogs die because of anemia or hepatic failure between 1 and 9 years of age, with Basenjis having a more severe form than Beagles and West Highland White Terriers. Interestingly, all PK-deficient dogs develop a progressive myelofibrosis and osteosclerosis that remain unexplained and do not occur in other species with PK deficiency.[4,16,17,28,45,63,64,66] The osteosclerosis may be identified by radiography of long bones at 1 year of age and completely obstructs the marrow cavities by 3 years in Basenjis, but occurs later in other breeds.

A diagnosis of PK deficiency is strongly suggested by the concurrent occurrence of a highly regenerative severe anemia and osteosclerosis in a dog. Generally, routine screening tests rule out or are not supportive of acquired anemias and the anemia is persistent and appears well-tolerated. PCR-based PK tests are available for the Basenji,[80,81] Beagles, and West Highland White Terrier breeds.[67] These DNA tests are accurate to detect affected and carrier dogs in these breeds. However, because they are mutation-specific, they cannot be used for other breeds. In other breeds, cumbersome PK enzyme activity assays using agarose gel electrophoresis, immunologic, and heat-lability methods specific for R-PK are required due to M-PK expression. PK carriers do not express M-PK and, therefore, have intermediate (~50% of normal) RBC PK activity. Unfortunately, the PK activity assays are not very accurate in detecting carriers, as the carrier and normal ranges overlap.[17] PK deficiency has most commonly been reported in the Basenji, West Highland White Terrier, and Beagle breeds, but the PK mutation frequency remains unknown in all canine breeds.

Affected dogs are managed symptomatically in clinical practice. Because of the excellent DPG-facilitated oxygen release from hemoglobin, PK-deficient dogs adapt well despite severe anemia. They rarely need transfusions except for their terminal stage. Bone marrow transplantation, performed experimentally,[80] corrects the hemolytic anemia and halts the osteosclerosis and hemosiderin deposition, whereas splenectomy has not been shown to be effective in slowing the hemolysis and anemia.

Feline Pyruvate Kinase Deficiency

In the early 1990s, erythrocytic pyruvate kinase deficiency was identified and characterized in the Abyssinian, Somali and Domestic Shorthair cats.[6,21] A 13 base-pair deletion at the 3′-end of exon 5 in the R-PK cDNA, but not the genomic sequence is caused by a splicing defect and results in a severe reduction in RBC PK enzyme activity. In cats there is no anomalous M2-PK expression in RBCs and no osteosclerosis, which are observed in all PK-deficient dogs. Since the original observations of the PK-deficient Abyssinian

and Somali cats, over 3,000 have been screened; approximately 12% are affected and 24% are carriers, making this one of the most frequent causes of anemia in these breeds. Since then, PK-deficient Abyssinian and Somali cats have been reported from Europe[26,27,47,48,77] and Australia.[1,49] In addition, a few Domestic Shorthair cats have also been found with the same mutation in the United States. Interestingly, a specific pathogen-free research colony of domestic cats also carries this same PK mutation and is responsible for an unexplained mild to moderate intermittent anemia.

Affected cats have chronic intermittent hemolytic anemia that might not first be recognized until advanced age. The anemia is intermittent, mild to severe with PCV ranging from 5 to 35%. It is slightly macrocytic-hypochromic and slightly to strongly regenerative (reticulocyte count 45,000–290,000/μL).[24,47,48] Moreover, PK-deficient cats frequently have a marked lymphocytosis and hyperglobulinemia. Many of these features are similar to cats with increased RBC osmotic fragility with splenomegaly in the same breeds.[46] However, PK-deficient cats typically have a greater regenerative response and only mild splenomegaly and mild osmotic fragility (Fig. 28.3) Extrahepatic biliary obstruction due to bilirubin calculi is seen in affected cats.[8,27] It should be noted that many deficient cats remain completely asymptomatic for years and the associated anemia may not be the primary reason for a PK-deficient cat's illness.

PK-deficient cats frequently do not require treatment, just like PK- and PFK-deficient dogs. However, during a crisis, deficient cats may need to be transfused with AB blood-type compatible blood. In case of severe splenomegaly or persistently severe anemia, splenectomy appears to reduce the severity of the hemolytic crises.[24]

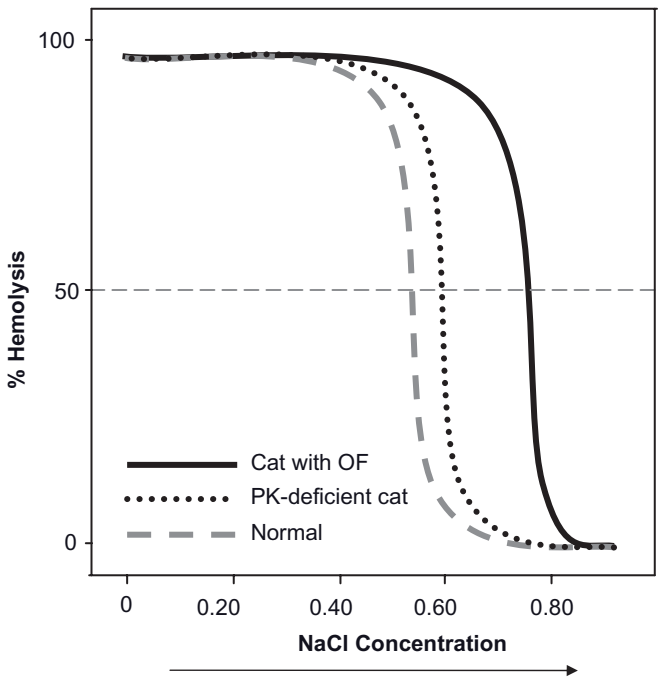

FIGURE 28.3 Erythrocyte osmotic fragility (OF) curve from a PK-deficient Abyssinian cat and an Abyssinian with increased OF and splenomegaly. RBCs were exposed in vitro to different saline concentrations from 0% (water) to 0.85% (physiological saline) at room temperature for 30 min.

CHAPTER 29

Erythrocyte Membrane Defects

MUTSUMI INABA and JOANNE B. MESSICK

Hemolytic Anemias Caused by Hereditary Red Cell Membrane Defects
Hereditary Spherocytosis
Hereditary Band 3 Deficiency in Cattle (Band 3$^{Bov.Yamagata}$)
Spectrin and Ankyrin Deficiencies in Animals
Hereditary Elliptocytosis
Hereditary Protein 4.1 Deficiency in Dogs
Spectrin Anomaly with Elliptocytosis in a Dog
Hereditary Stomatocytosis
Hereditary Stomatocytosis in Dogs and Cats
HSt in Miniature and Standard Schnauzers
HSt in chondrodysplastic Alaskan Malamute dwarf dogs
Familial stomatocytosis-hypertrophic gastritis in dogs
Hemolytic anemia with increased erythrocyte osmotic fragility in cats
Diagnostic Approaches to Erythrocyte Membrane Defects
Membrane Transport Defects
Amino Acid Transport Deficiency in Animals
High Membrane Na,K-ATPase Activity in Dogs

Acronyms and Abbreviations

DHS, dehydrated hereditary stomatocytosis; HE, hereditary elliptocytosis; HPP, hereditary pyropoikilocytosis; HS, hereditary spherocytosis; HSt, hereditary stomatocytosis; OHS, overhydrated hereditary stomatocytosis; PCR-RFLP, polymerase chain reaction-restriction fragment length polymorphism; PCR-SSCP, PCR-single strand conformation polymorphism; RBC, red blood cell; SDS-PAGE, sodium dodecyl sulfate-polyacrylamide gel electrophoresis.

Red blood cells (RBCs) must be very durable and flexible to undergo marked deformation under high shear stress condition so that they can survive during repeated passages through the microcirculation. These important properties are determined by three major elements of their membranes: a lipid bilayer, integral or transmembrane proteins, and a membrane skeletal network (Fig. 29.1). A lipid bilayer provides a permeability barrier between the cytosol and the external environment. Major constituents of the membrane skeleton mechanically support the plasma membrane and are organized into a lattice-like meshwork that is linked with both integral membrane components and cytoskeletal elements. Some of the transmembrane proteins embedded within the lipid bilayer ensure selective permeability to maintain RBC homeostasis. Accelerated destruction of erythrocytes (hemolytic anemia) may occur when these properties of the RBC membrane are affected or deficient by some genetic defects. This chapter reviews the current progress in the investigation of inherited red cell membrane disorders in animals.

HEMOLYTIC ANEMIAS CAUSED BY HEREDITARY RED CELL MEMBRANE DEFECTS

The membrane protein-protein and protein-lipid interactions are the critical determinants of red cell morphology and mechanical stability, as evidenced by the numerous hereditary RBC disorders in humans attributed to mutations of the membrane.[2,51–53,73,74] These interactions are divided into two categories (Fig. 29.1): (1) vertical interactions involving the band 3-ankyrin-spectrin and glycophorin C-protein 4.1-spectrin binding, which attach the spectrin-actin network to the plasma membrane and stabilize the lipid bilayer, and (2) horizontal interactions involving spectrin dimer-dimer association (tetramer formation), and contact of the distal ends of spectrin with F-actin by the aid of protein 4.1 and adducin within the junctional complex. In general, the loss of vertical linkage between membrane skeleton and lipid bilayer causes decreased membrane cohesion leading to membrane loss (e.g. hereditary spherocytosis). Weakening of horizontal linkages

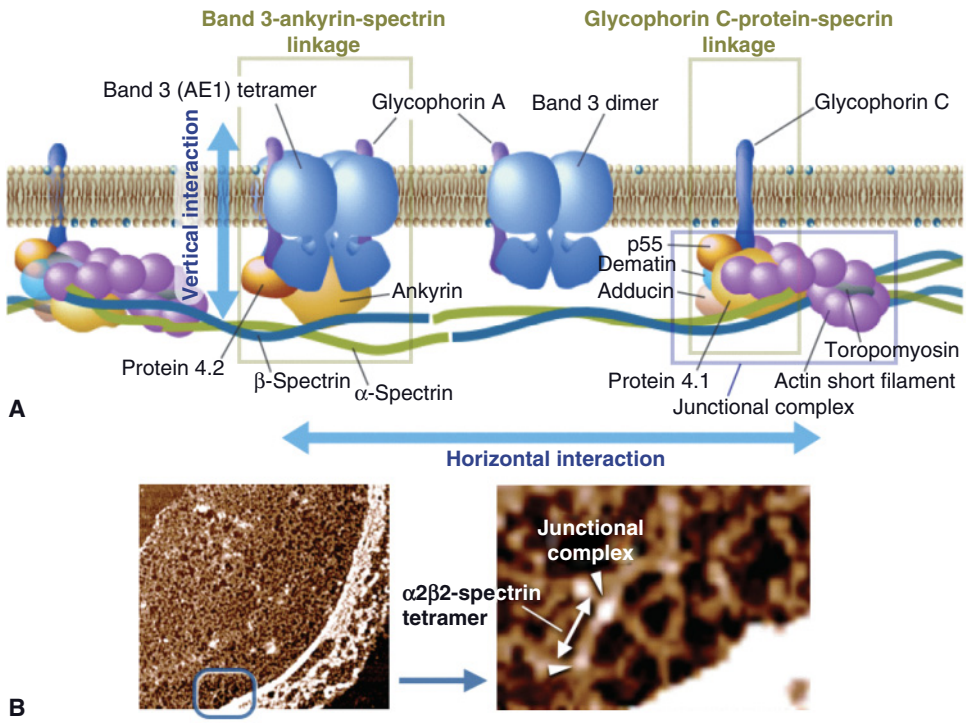

FIGURE 29.1 A schematic diagram illustrating structural and functional organization of RBC membrane proteins. Membrane protein-protein associations are divided into two categories: (1) vertical interactions involving band 3-ankyrin-spectrin linkage and glycophorin C-protein 4.1 (P4.1)-spectrin linkage, and (2) horizontal interactions involving the spectrin heterodimer contact (tetramer formation) and association of spectrin tetramer at the distal ends with F-actin at the junctional complex consisting of actin, P4.1, and adducin. In general, a defect of vertical interactions leads to hereditary spherocytosis, whereas a defect of horizontal interactions causes hereditary elliptocytosis and pyropoikilocytosis.

between skeletal proteins results in decreased membrane mechanical stability leading to membrane loss (e.g. hereditary elliptocytosis).[1,51] The severity of the anemia is directly related to the extent of the membrane surface area loss in both of these defects; loss of membrane not only compromises the ability of the RBC to deliver oxygen to the tissues, but also results in premature removal from the circulation by the spleen. In human patients, splenectomy results in correction of the anemia.[1] The reader is directed to Chapter 20 for details of the structural organization of the normal RBC membrane.

HEREDITARY SPHEROCYTOSIS

The cardinal features of hereditary spherocytosis (HS) are hemolytic anemia of varying severity, spherocytosis, increased RBC osmotic fragility, and splenomegaly.[59] Pathophysiology of HS involves two major factors: intrinsic membrane defect, and selective sequestration of HS cells in the normal spleen. Hence, anemia can be corrected by splenectomy in human HS patients. Typical forms of HS need to be distinguished from other hemolytic anemias manifesting moderate to small numbers of spherocytes, such as autoimmune hemolytic anemia by Coombs' test as well as unstable hemoglobin and oxidative damage by Heinz body screening. HS is now considered to be a disorder of vertical interactions of the membrane proteins, although the primary molecular defects are heterogeneous including deficiencies or dysfunctions of spectrin, ankyrin, band 3, and protein 4.2. Consequently, the lipid bilayer is destabilized, leading to membrane and surface area loss, and spherocyte formation.[25,53,74]

Hereditary Band 3 Deficiency in Cattle (Band $3^{Bov.Yamagata}$)

Band 3 (anion exchanger 1, AE1) is the most abundant transmembrane protein in mammalian RBCs.[56] Hereditary band 3 deficiency in Japanese black cattle (band $3^{Bov.Yamagata}$) is associated with HS and is inherited by an autosomal dominant trait. Homozygous affected animals totally lack band 3 due to a nonsense mutation Arg664 → Stop (R664X) of the *AE1* gene (*SLC4A1*)29 and show mild to moderate, chronic hemolytic anemia (hematocrit, 25–35%); slight acidosis; and growth retardation. Carrier cattle heterozygous for the R664X mutation also have abnormal RBC morphology and impaired anion transport activity due to partial deficiency of RBC band 3 (about 30%). However, spherocytosis in heterozygotes is mild, and the hemolysis is well compensated. In heterozygous animals, mutant band 3 is rapidly degraded in the endoplasmic reticulum without

translocation to the plasma membrane and there is selective reduction of mutant band 3 mRNA.[30,31]

Genotypes for R664X mutation are easily determined using genomic DNA as the template by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP)[29,30] or PCR-single strand conformation polymorphism (PCR-SSCP) techniques. A protocol to determine the genotype for band $3^{Bov.Yamagata}$ and the sex of embryos before embryo tranfer has been developed.[37] The ancestral origin of this genetic defect has not yet been identified.

Band 3 has two major functions:[34,56,71,72] (1) it mediates a rapid Cl^-/HCO_3^- exchange across the plasma membrane to increase five-fold the capacity of the blood to carry CO_2 from tissues to lungs and maintains blood acid-base homeostasis together with the renal band 3 function; and (2) it may also participate in maintaining mechanical properties of RBC membranes by forming the band 3-ankyrin-spectrin complex. Various mutations leading to disorders and partial deficiency of RBC 3 associated with abnormal RBC morphology (spherocytosis and ovalocytosis) have been reported in humans,[32,35,53] but none of them exhibited complete lack of the protein or its function.

The most surprising finding, therefore, is that cattle with total lack of band 3 survived to and thrived in adulthood. They suffer from extremely severe hemolytic anemia shortly after birth and exhibit jaundice and splenomegaly. The mortality rate is high during this period, particularly in the first week after birth. Once they overcome this neonatal crisis, jaundice subsides and hemolysis becomes modest. Until 1998, a half dozen homozygous affected cattle older than 3 years of age had been found. One of three affected females had two normal parturitions. The studies on bovine hereditary band 3 deficiency have demonstrated the importance of band 3 in RBC morphology and homeostasis.

Red blood cells from homozygotes of band $3^{Bov.Yamagata}$ are also deficient in spectrin, ankyrin, actin (by 20–50%), and protein 4.2, resulting in a distorted and disrupted membrane skeletal network (Fig. 29.2). Their RBC membranes are extremely unstable and demonstrate the spontaneous loss of surface area by invagination, vesiculation, extrusion of microvesicles, and fragmentation, thereby leading to the formation of spherocytes with irregular contours, gouging, and pitting (Fig. 29.3). RBCs from homozygous and heterozygous cattle constantly show considerably increased osmotic fragility with 50% hemolysis at 0.75% and 0.65–0.70% NaCl, respectively (normal, 0.45–0.55% NaCl), demonstrating that the surface area/volume ratios of RBCs from both homozygotes and heterozygotes are remarkably reduced due to the mechanical instability of their RBC membranes (Fig. 29.4). Despite these severe changes, the affected animals show no reticulocytosis and no noticeable intravascular hemolysis. However, the protein 4.1a/4.1b ratio, which is a good marker of RBC aging,[24,27,28] is remarkably reduced and paralleled by increased erythropoiesis. These findings demonstrate the functional importance of band 3-ankyrin-spectrin association in maintaining mechanical stability of the membrane[41] but not in assembly of the membrane skeletal architecture; they also indicate that accelerated and continual destruction of RBCs occurs in homozygous cattle and also in heterozygotes though it is less severe.

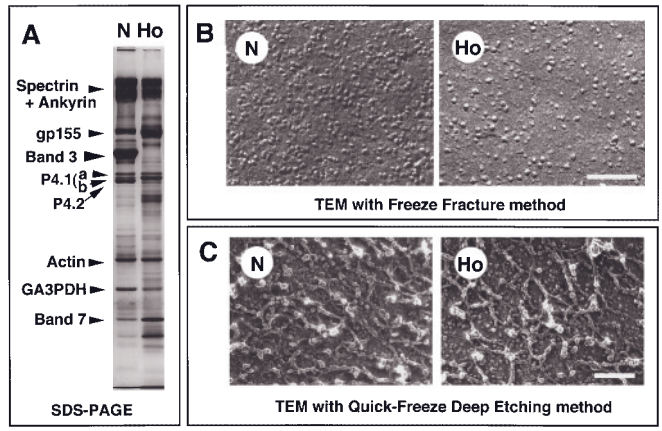

FIGURE 29.2 Abnormal RBC membrane structures in bovine band 3 deficiency (band $3^{Bov.Yamagata}$). (**A**) SDS-PAGE profiles of RBC membrane proteins from the normal (N) and the homozygote for R664X mutation (Ho). Note that spectrin (+ankyrin) and actin levels are reduced compared to protein 4.1. Protein 4.2 is almost missing. A 66-kDa protein only found in the homozygote was albumin. gp155 indicates a transmembrane protein characteristic to ruminant RBCs.[65] (**B**) Markedly reduced number of intramembrane particles in homozygous RBCs (Ho) compared to normal RBC on electron micrographs by the freeze fracture method. (**C**) Disrupted membrane skeletal network in band-3–deficient RBCs visualized by the quick-freeze deep etching method. The membrane skeletons in band-3-deficient RBCs (Ho) are disrupted and distorted with filaments of uneven length and width compared with the well-organized normal RBCs (N). Scale bars = 0.1 µm.

Total deficiency of band 3 also results in defective Cl^-/HCO_3^- exchange. The Cl^- influx into the RBCs from homozygotes requires approximately 2 hours to reach transmembranous equilibrium even at 37°C. Band 3 deficiency causes mild acidosis with decreases in the HCO_3^- concentration and total CO_2 in the blood. However, these values remain in the normal range. As CO_2 in blood rarely reaches saturation, it is suggested that the additional CO_2 carrying capacity facilitated by band 3 is probably not as critical as has been believed previously,[33,70] except under high stress conditions such as vigorous exercise or high altitude.

Transgenic mice with complete band 3 deficiency have similar RBC features.[57,68] These studies demonstrate that band 3 indeed contributes to RBC membrane organization, CO_2 transport, and acid-base homeostasis. In band 3 knockout mice, glycolytic enzymes that normally exist as multienzyme complexes on the inner surface of RBC membranes, are not membrane-associated but distributed throughout the cytoplasm. The assembly of glycolytic enzymes on the membrane is likely a general phenomenon of mammalian RBCs and stability of these interactions depends primarily on band 3.[6]

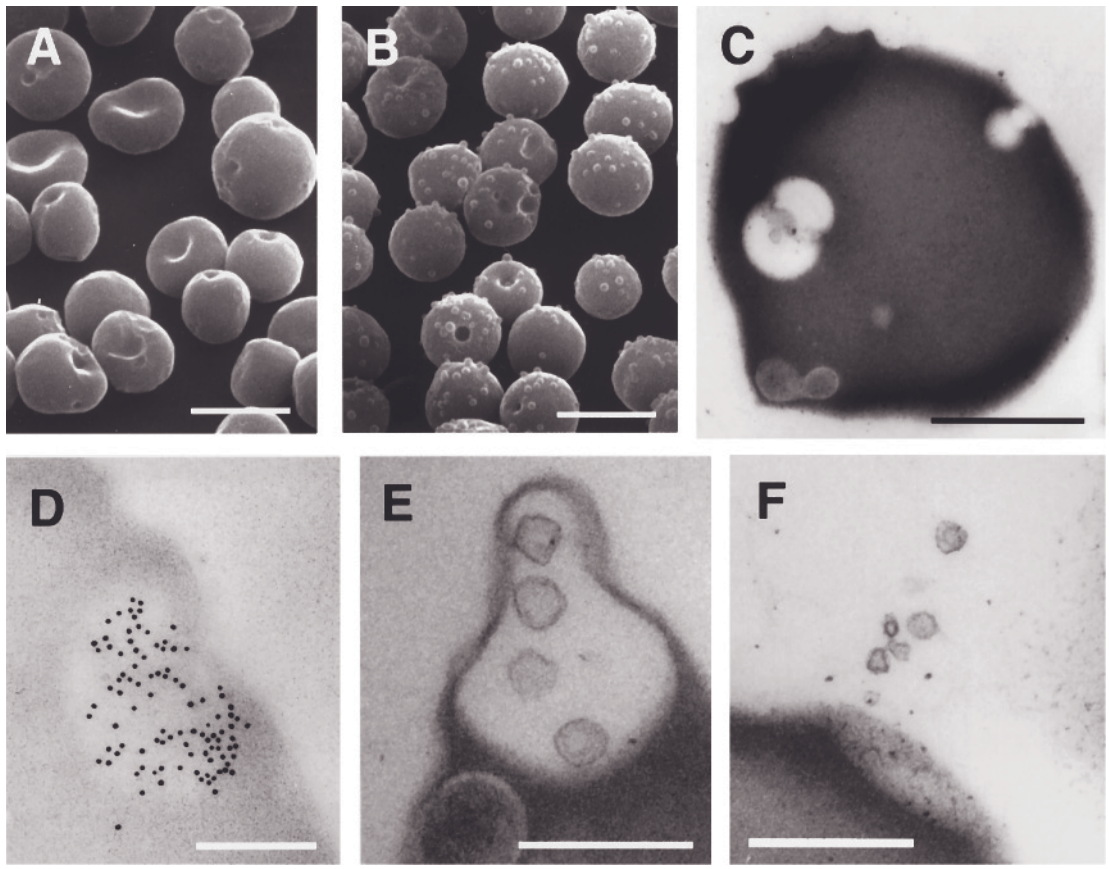

FIGURE 29.3 Morphologic anomaly in bovine band 3 deficiency. Scanning (A, B) and transmission (C–F) electron micrographs of RBCs from a homozygous animal of band $3^{Bov.Yamagata}$. (**A**) The proband RBCs look like potatoes and greatly vary in size, principally being spherocytic and stomatocytic with irregular contours. (**B**) When blood is allowed to stand for several hours at ambient temperature, numerous small globules are observed on the surface. (**C**–**F**) Marked endocytosis-like invagination, exocytosis-like projections, fusion of vesicles inside the cell, and extrusion of microvesicles. The vesicles in the cytoplasm contain plasma proteins as determined by immunoelectron micrography using anti-bovine albumin antibodies (D). Scale bars = 5μm (A and B), 1μm (C), and 0.2μm (D–F).

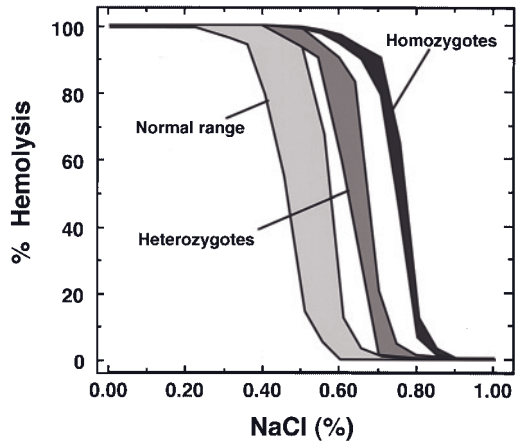

FIGURE 29.4 Increased RBC osmotic fragility in bovine band 3 deficiency. Data for normal cattle (n = 15) as well as homozygotes (n = 4) and heterozygotes (n = 8) of band 3 deficiency.

Spectrin and Ankyrin Deficiencies in Animals

Several mutations that affect components of the RBC membrane skeleton have also been reported in mice.[3,79] These include spectrin deficiencies in house[21,42] and deer mice[63] as well as ankyrin deficiency in nb mice[79] with moderate to life-threatening hemolytic anemia and fragile short-lived spherocytes.

A quantitative spectrin deficiency with an autosomal dominant inheritance was reported in Dutch Golden Retrievers.[66] The affected dogs had markedly reduced RBC spectrin concentration that was 50–65% of unaffected dogs and exhibited increased RBC osmotic fragility. However, the disorder was not associated with either spherocytosis or elliptocytosis. The exact mechanism for this occult spectrin deficiency without morphological anomaly remains to be clarified.

Bovine α– and β-spectrin genes possess polymorphisms leading to generation of spectrin proteins with different amino acid sequences. One of these genotypes appears to cause mild reduction in RBC spectrin contents without morphological lesions and

probably has a modulatory role in severity of RBC phenotypes in band $3^{Bov.Yamagata}$ (M. Inaba, unpublished observation).

HEREDITARY ELLIPTOCYTOSIS

The principal lesion of human hereditary elliptocytosis (HE) involves heterogeneous defects in horizontal membrane protein interactions (Fig. 29.1) resulting in a mechanically unstable membrane (e.g. abnormal spectrin structure affecting the spectrin heterodimer contacts, deficiency or dysfunction of protein 4.1).[51,53,74] Common HE is morphologically characterized by elliptocytes and rod-shaped RBCs in some patients. In severe cases, aberrant disruption of the horizontal interactions results in fragmentation of RBCs, leading to hereditary pyropoikilocytosis (HPP). Ovalocytosis, spherocytic HE, is a rare condition in which both round oval RBCs lacking central concavity and spherocytes are present on the blood film. It is likely that elliptocytes and poikilocytes are permanently stabilized in their abnormal shape. The weakened horizontal connections facilitate reorganization of skeleton, which follows axial deformation of cells by a prolonged shear stress.[51,53,74] Although camelid RBCs are elliptocytic by nature, the molecular basis and physiologic importance of this unique feature remains unknown.

Hereditary Protein 4.1 Deficiency in Dogs (HE in Dogs)

Canine HE was discovered by Smith et al.[67] The proband exhibited elliptocytosis, membrane fragmentation, microcytosis, and poikilocytosis without anemia (Fig. 29.5). RBC mechanical stability was markedly decreased, and osmotic fragility was remarkably increased. The proband RBC membranes were deficient in protein 4.1 (4.1a and 4.1b). The parents of the proband had decreased amounts (approximately 50% of normal) of protein 4.1 and some elliptocytes.

Protein 4.1 forms a tertiary complex with spectrin and actin within the junctional complex. This spectrin-actin binding region was mapped to the 10-kDa domain[9] containing amino acid sequences encoded by a 21-amino acid alternative exon and a 59-amino acid constitutive exon.[7] Immunoblotting of RBC membrane proteins from the proband showed the presence of a small amount of 76-kDa polypeptide lacking the 21 amino acid segment and a very faint band of normal protein 4.1. RT-PCR analysis and sequencing of cloned reticulocyte protein 4.1 cDNA consistently showed that mRNA with a deletion of the alternative exon encoding 21 amino acid peptide was the predominant form with only a small quantity of normal mRNA. Therefore, the functional defect in the HE dog is likely due to the combined influences of two factors: a quantitative deficiency of protein 4.1 and a failure to activate efficiently expression of an alternatively spliced exon encoding 21 amino acids in the spectrin-actin binding region during erythropoiesis.[8] The primary cause leading to inefficient RBC-specific alternative splicing has not been defined.

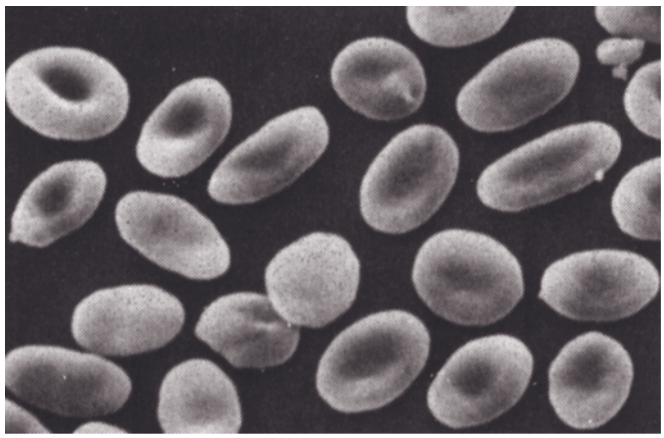

FIGURE 29.5 Scanning electron micrograph of RBCs from the proband with hereditary elliptocytosis. The proband RBCs reveal biconcave elliptocytes. (Reproduced from Smith JE, Moore K, Arens M, Rinderknecht GA, Ledet A. Hereditary elliptocytosis with protein band 4.1 deficiency in the dog. Blood 1983;61:373–377, with permission.) Scale bar = 5μm.

Spectrin Anomaly with Elliptocytosis in a Dog

An elliptocytosis was recently reported in a mixed-breed dog.[11] Although the elliptocytosis was asymptomatic and was not associated with hemolytic anemia, the dog's RBCs had decreased deformability and stability when subjected to shear stress. This is consistent with non-hemolytic HE in humans due to structural abnormality in either the α– or β-spectrin. Molecular analysis revealed that the elliptocytosis was probably due to a β-spectrin mutation in codon 2110 (T2110M), a region of spectrin that is critical for the self-association of spectrin dimmers. This would be expected to result in reduced formation or reduced stability of tetramers.

HEREDITARY STOMATOCYTOSIS

Stomatocytes are uniconcave or bowl-shaped RBCs in suspension but have a slit-like appearance, an artifact on dried blood films (Fig. 29.6). Two distinct phenotypes having abnormalities in membrane cation permeability leading to changes in changes in RBC volume have been identified in humans: dehydrated hereditary stomatocytosis (DHS) and overhydrated hereditary stomatocytosis (OHS).[1,51] DHS is associated with a well-compensated hemolytic anemia with less than 10% stomatocytes usually seen on blood smears. In contrast, stomatocytes are a major feature of RBC morphology in OHS. An important characteristic of these stomatocytosis patients is a marked predisposition to thrombocytosis and development of hypercoagulability after splenectomy.[1]

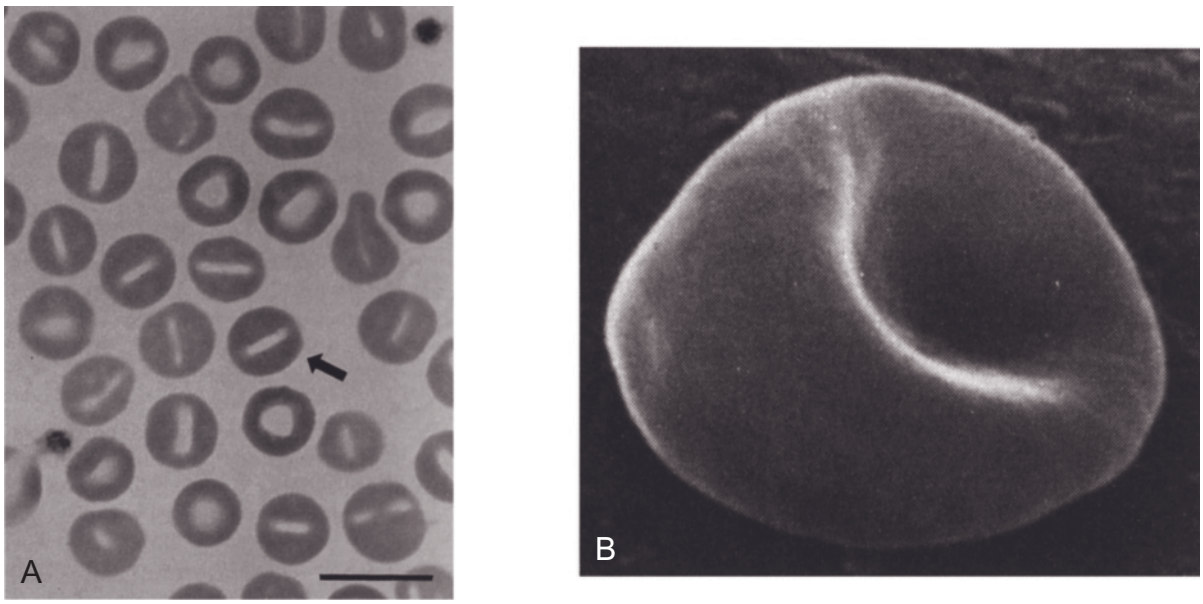

FIGURE 29.6 Erythrocyte morphology of canine hereditary stomatocytosis (hydrocytosis). (**A**) Numerous stomatocytes (arrow) with a slit-like appearance are present on a Wright-Giemsa-stained blood smear from a Miniature Schnauzer. (Reproduced from Brown DE, Weiser MG, Thrall MA, Giger U, Just CA. Erythrocyte indices and volume distribution in a dog with stomatocytosis. Vet Pathol 1994;31:247–250, with permission.) (**B**) Scanning electron micrograph of a typical stomatocyte from an affected Alaskan Malamute. (Reproduced from Pinkerton PH, Fletch SM, Brueckner PJ, Miller DR. Hereditary stomatocytosis with hemolytic anemia in the dog. Blood 1974;44:557–567, with permission.) Scale bar = 10 µm. (Courtesy of Mitsumi Inaba and Joanne B. Messick.)

OHS (hydrocytosis) is a heterogeneous group of disorders in humans characterized by moderate to severe hemolytic anemia with stomatocytes, an elevated mean corpuscular volume, and a reduced mean corpuscular hemoglobin concentration. The principal lesion involves a remarkable increase of Na^+ influx into RBCs, resulting in a marked increase of intracellular Na^+ and water content and a corresponding decrease of K^+.[50,86] The molecular basis of this permeability defect is unknown. Human OHS is frequently associated with reduced contents of a 31-kDa integral membrane protein 7.2b (stomatin), which may function in regulation of cation transport and a stretch- or pressure-sensitive system, in the RBC membrane from OHS patients.[16,40,69] It is reported that stomatin-actin association is necessary for maintaining the structure and modulating the function of stomatin in RBCs.[80]

Hereditary Somatocytosis in Dogs and Cats

Hereditary stomatocytosis (HSt) is recognized in dogs and cats with undefined etiologies. All disorders appear to be transmitted as autosomal recessive traits.

HSt in Miniature and Standard Schnauzers

Stomatocytosis inherited by autosomal recessive trait has been reported in Miniature and Standard Schnauzers (Fig. 29.6A) without clinical signs of disease.[4,5,20] Hereditary stomatocytosis in Schnauzers is characterized by macrocytosis, relatively high packed cell volume, remarkably decreased mean corpuscular hemoglobin concentration, and increased osmotic fragility. Erythrocyte survival is only slightly shortened. Affected Miniature Schnauzers are of normal stature. Stomatin is not deficient from the erythrocyte membrane in affected Standard Schnauzers.[54]

HSt in Chondrodysplastic Alaskan Malamute Dwarf Dogs

In Alaskan Malamutes, chondrodysplasia (short-limbed dwarfism) occurs along with stomatocytosis[14,15] (Fig. 29.6B). The affected Malamutes have macrocytosis, decreased mean corpuscular hemoglobin concentration, increased osmotic fragility, shortened RBC survival, reticulocytosis, erythroid hyperplasia, and increased iron turnover.[58] Although heterozygous carriers have minor changes in their RBCs, they have a normal RBC lifespan and no dwarfism. RBC Na^+ concentration and water content are increased in affected dogs.

The pathogenesis of stomatocyte formation in Malamutes and Schnauzers is attributed to an increase in monovalent cation and, consequently, increased water content of RBCs as is reported in human HSt. However, the exact nature of membrane defects leading to the changes in RBC indices in these breeds is obscure.

Familial Stomatocytosis-Hypertrophic Gastritis in Dogs

Familial stomatocytosis-hypertrophic gastritis is a multiorgan disease with hemolytic anemia, HSt, and hyper-

trophic gastritis described in the Drentse Partrijshond breed.[64,65] The main clinical signs are diarrhea, jaundice, and ataxia and paresis of the pelvic limbs. Pathologic findings involve hypertrophic gastritis, progressive liver disease, renal cysts in aged subjects, and polyneuropathy.[64]

Erythrocytes from affected dogs show increased osmotic fragility. In contrast to Malamutes and Schnauzers with stomatocytosis, RBCs from affected Partrijshonds have normal mean corpuscular volume, slightly increased cell water with basically normal content, and fluxes of Na and K, suggesting a different mechanism for stomatocyte formation.[65] Affected dogs have normal RBC membrane protein profile, but a decrease of phosphatidylcholine with altered fatty acid composition and simultaneous increase of sphingomyelin in both RBCs and plasma. It is suggested that this polysystemic disease is a disorder of lipid metabolism in which defective membrane function and RBC shape change are induced by abnormal phospholipid composition of the plasma. This is supported by a shortened half-life of RBCs from normal dogs after transfusion into dogs with this syndrome. Stomatocytic shape change may be attributed to membrane surface loss, presumably due to abnormal phospholipid composition of the bilayer. The exact relation between anomaly in phospholipid and hypertrophic gastritis and the primary cause of this syndrome are unknown.

Hemolytic Anemia with Increased Erythrocyte Osmotic Fragility in Cats

A hereditary RBC defect is suspected in Abyssinian and Somali cats with Coombs' negative hemolytic anemia.[38,39] The affected cats exhibited recurrent anemia (hematocrit, 15–25%); severe splenomegaly with extra medullary hemopoiesis, hemosiderosis, congestion, and lymphoid hyperplasia; loss of body mass; macrocytosis; and a few stomatocytes. The anemia was variably regenerative. The osmotic fragility of their RBCs was markedly increased. Splenectomy partially corrected the anemia and prevented hemolytic crises, but long-term survival remains unknown.

DIAGNOSTIC APPROACHES TO ERYTHROCYTE MEMBRANE DEFECTS

Genetic aberrations of RBC membranes described above are feasibly surveyed by evaluating RBC morphology, osmotic fragility, and RBC parameters. The osmotic fragility test is a simplified means to estimate the surface area/volume ratio of RBCs. It is most valuable in the diagnosis of HS but is also useful in evaluation of most forms of HE and overhydrated HSt (hydrocytosis). Several laboratory tests, such as Coombs' test and Heinz body screening, may be required to eliminate a possibility that hemolytic anemia and abnormal RBC shapes result from extrinsic factors. As exemplified for bovine HS in Figure 29.2A, SDS-PAGE analysis followed by some immunochemical, biochemical, and biophysical techniques often provides insights into primary defects of membrane skeletal and integral proteins resulting in HS, HE, and HPP.

MEMBRANE TRANSPORT DEFECTS

Deficiency and dysfunction of membrane transport systems may affect RBC homeostasis. Particularly, defects in transport of amino acids involved in glutathione metabolism have been reported to generate hemolytic anemia when RBCs are exposed to extrinsic factors including oxidants.

Amino Acid Transport Deficiency in Animals

Red blood cell glutathione deficiency, inherited as an autosomal recessive trait, occurs in Finnish Landrace sheep.[75] Affected animals are not anemic but have shortened RBC lifespan.[76] This is possibly caused by increased oxidant sensitivity as exemplified by Heinz bodies. Affected sheep are more likely to become anemic after the administration of oxidants in vivo.[78] RBCs from the affected animals are defective in the transport system for various amino acids including cysteine.[84,85] Consequently, cysteine uptake and glutathione synthesis are limited, and glutathione concentrations in RBCs are decreased to approximately 30% of normal. The transport deficiency appears to develop during reticulocyte maturation.[77]

A similar defect of amino acid transport is found in about 30% of thoroughbred horses[13] but seems to cause no clinical signs. The lesion appears to result in increased amino acid levels and glutathione deficiency in some cases.

High Membrane Na,K-ATPase Activity in Dogs

Although canine reticulocytes have a considerable amount of membrane Na,K-ATPase (Na/K-pump) activity, its activity is rapidly lost during maturation into mature RBCs.[46] Proteolytic degradation[23] and extrusion of vesicles (exosomes)[36] are likely involved in this process. As a consequence, dogs usually have RBCs with low K^+ and high Na^+ concentrations (LK RBCs).[55] However, some Japanese Shiba and mongrel dogs have HK RBCs with high K^+ and low Na^+ concentrations, because the Na,K-ATPase protein and its activity are retained in mature RBCs.[23,41,45] This HK phenotype representing immaturity of erythroid precursor cells[26,47] is inherited in an autosomal recessive manner and has also been found in Japanese Akita[10] and several breeds of Korean dogs.[18,49] Although dogs with HK RBCs are not anemic, their RBCs have shortened lifespans,[47] increased osmotic fragility, increased mean corpuscular volume, and normal mean corpuscular hemoglobin values, suggesting an increase in RBC water.[45] The molecular basis for RBC HK and LK phenotypes is unknown. Due to the leak of K^+ from RBCs, blood from HK dogs may cause pseudohyperkalemia in vitro after storage or on delaying plasma or serum separation.[10]

Thus, care should be taken, particularly when stored blood from HK dogs is used for transfusion.

Canine RBCs possess a high-affinity Na^+-dependent transport system for glutamate and aspartate[12,22] which resembles the kinetic and pharmacologic properties of the transporter in the brain.[60–62] The increased concentration gradients of Na^+ and K^+ across the membrane produced by the presence of Na,K-ATPase with high activity accelerates transport of glutamate and aspartate into HK RBCs.[23] The concentration of reduced glutathione is increased 5–7 times that of normal because the feedback inhibition of γ-glutamylcysteine synthetase by glutathione is released by glutamate accumulated in these cells at about 90 times that in normal RBCs.[44] Some variant dogs of HK phenotype that lack the increase of RBC glutathione have been reported,[17,19] suggesting that several independent mutations have emerged in these breeds.[61]

The accumulation of glutathione in the canine HK RBCs only provides improved protection against oxidative damage induced by acetylphenylhydrazine, but these RBCs are more susceptible to oxidative damage induced by 4-aminophenyl disulfide,[48] onions,[43,81] and sodium n-propylthiosulfate,[83] one of the hemolytic thiosulfate compounds isolated from onions.[82] The increased glutathione concentration accelerates the generation of superoxide through its redox reaction with the aromatic disulfide,[48] but the exact mechanism by which HK RBCs are more sensitive to the thiosulfates remains to be clarified.

CHAPTER 30

Congenital Dyserythropoiesis

DOUGLAS J. WEISS

Poodle Macrocytosis
Inherited Selective Malabsorption of Cobalamin Clinical Condition
Congenital Dyserythropoiesis, Polymyopathy, and Cardiac Disease in English Springer Spaniels
Hereditary Stomatocytosis in Alaskin Malmutes (see Chapter 29)
Congenital Anemia, Dyskeratosis, and Progressive Alopecia in Polled Hereford Calves

Acronyms and Abbreviations

RBC, red blood cell; RDW, RBC distribution width.

Congenital conditions associated with dysplastic features in red blood cells (RBCs) and bone marrow include Poodle macrocytosis,[2,8] inherited selective malabsorption of cobalamin,[4,5,7] congenital dyserythropoiesis, polymyopathy, and cardiac disease in English Springer Spaniels,[6] hereditary stomatocytosis in Alaskan Malamutes (see Chapter 29), and congenital anemia, dyskeratosis, and progressive alopecia in polled Hereford calves.[9,10] In general, these conditions are characterized by dysplastic changes in RBCs or erythroid precursor cells associated with ineffective erythropoiesis.[11] The mechanisms associated with accelerated intra-marrow cell death are discussed in Chapter 64.

POODLE MACROCYTOSIS

Poodle macrocytosis is a familial condition that occurs mostly in Toy and Miniature Poodles.[2,8] The abnormality affects both sexes. Affected dogs do not have associated clinical signs, are not anemic, and do not have reticulocytosis. The most distinctive feature in the blood is marked macrocytosis with mean cell volumes varying between 85 and 105 fL.[2,8] Metarubricytosis is a frequent finding and some of these cells show nuclear-cytoplasmic asynchrony. Additionally, Howell-Jolly bodies are increased in number and tend to be large and multiple (Fig. 30.1). Bone marrow is characterized by marked dyserythropoiesis and the morphologic changes resemble those associated with vitamin B_{12} deficiency. Features of dyserythropoiesis include megaloblasts, binucleation, multinucleation, irregular nuclear shapes, nuclear fragmentation, nuclear-cytoplasmic asynchrony, and nuclear bridging (Fig. 30.2).[2] Nuclear bridging is a unique feature seen in Poodle macrocytosis that is rarely seen in other congenital or acquired types of dyserythropoiesis or in myelodysplastic syndromes (Fig 30.3). Mitotic figures are increased in number.

The nature of the hematopoietic defect has not been investigated. Bone marrow cytologic abnormalities in Poodle macrocytosis have some similarity to those seen in congenital dyserythropoietic anemia type I of children as well as those in Hereford cattle with congenital anemia, dyskeratosis, and progressive alopecia.[5,9,10]

INHERITED SELECTIVE MALABSORPTION OF COBALAMIN

An inherited selective malabsorption of cobalamin (vitamin B_{12}) has been identified in Giant Schnauzers and has been reported in Border Collies, and in a Beagle and a cat.[3,4,7] Cobalamin is obtained in all species by absorption from the intestinal tract. Cobalamin can be produced by microorganisms in the gastrointestinal tract of ruminants but must be liberated from digestion of foodstuffs by other species. Cobalamin is essential as a cofactor for the activity of the enzymes methylmalonic-CoA mutase and methionine synthase.[1] Deficiency of methylmalonic-CoA mutase results in methylmalonic acidemia and aciduria.[1] Deficiency of methionine syn-

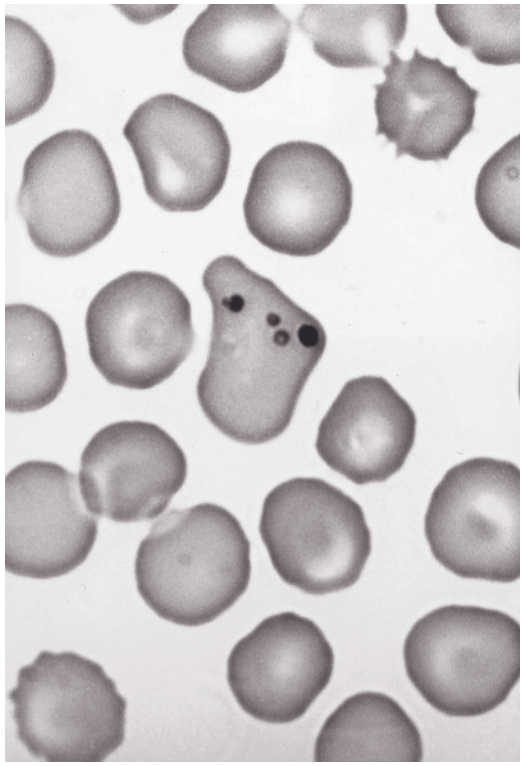

FIGURE 30.1 Blood from a dog with poodle macrocytosis. Notice the presence of an RBC with multiple large Howell-Jolly bodies.

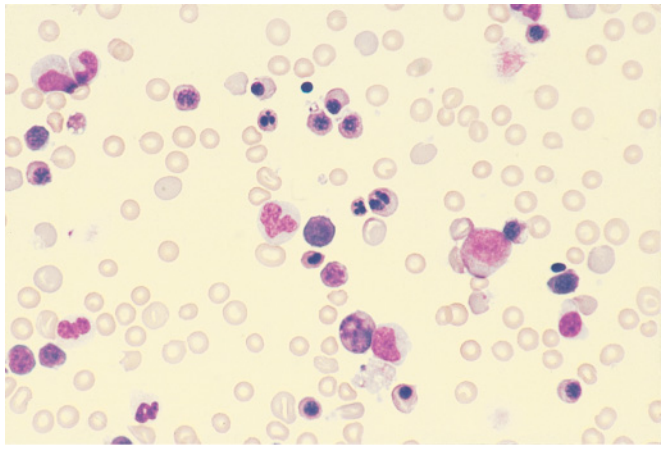

FIGURE 30.2 Erythroid precursor cells in bone marrow from a dog with Poodle macrocytosis. Notice the presence of misshapen and fragmented nuclei in rubricytes.

thase causes homocysteinemia and inhibits conversion of 5-methyl-tetrahydrahydrofolate to tetrahydrahydrofolate.[1] Tetrahydrahydrofolate is an essential cofactor for enzymes of purine and pyrimidine synthesis.[1] Resultant inhibition of nucleic acid synthesis is most noticeable as inhibition of hematopoiesis in adult animals.[3,4] Inhibition of nuclear maturation typically results in a non-regenerative anemia, with megaloblastosis, neutropenia, and hypersegmented neutrophils.[3,4] Although humans and non-human primates develop a

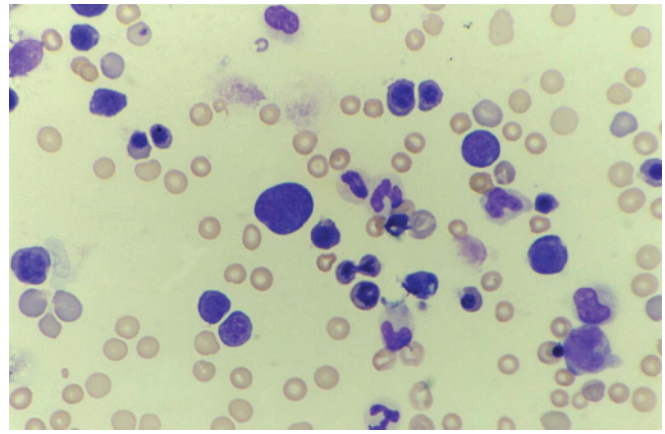

FIGURE 30.3 Bone marrow aspirate from a dog with Poodle macrocytosis. Notice the presence of a rubricyte with nuclear bridging (center of photo).

macrocytic anemia with cobalamin deficiency, the anemia in dogs, rodents, horses, pigs, and ruminants is normocytic and normochromic.[3,4] In dogs, both large and small RBCs are present in the blood with cobalamin deficiency.[3,4] This results in an increase in red cell distribution width (RDW) but the mean cell volume remains within the reference interval.

Clinical Condition

Inherited selective malabsorption of cobalamin in Giant Schnauzers is an autosomal recessive condition caused by lack of a receptor for intrinsic factor-cobalamin complex (i.e. cubilin) on the brush border of the small intestine and renal tubular epithelial cells.[3,4] Affected dogs develop anorexia, lethargy, and cachexia by 2–3 months of age. Blood cell morphology is characterized initially by a mild neutropenia followed by development of a chronic non-regenerative normocytic normochromic anemia, acanthocytosis, and increased RDW.[3,4] RBC morphology is characterized by many small RBCs, ovalocytes, and occasional megaloblasts (Fig. 30.4). Occasional hypersegmented neutrophils and giant platelets are also present. Bone marrow granulocytes are characterized by hypersegmented neutrophils and giant bands and metamyelocytes. Erythroid cells in marrow are characterized by nuclear-cytoplasmic asynchrony and abnormal nuclear chromatin clumping.

Diagnosis of cobalamin deficiency is best made by determining serum cobalamin concentrations.[3,4] Low serum cobalamin concentration appears to be the earliest indicator of cobalamin deficiency. Increased serum methylmalonic acid and serum total homocysteine concentrations can also be measured.

Affected dogs respond well to daily injections of vitamin B_{12}.[3,4] Alternatively, one megadose of 1 mg of vitamin B_{12} is sufficient to maintain an affected dog in remission for 1 month. Complete resolution of hematologic signs and growth retardation occurs with parenteral administration of cyanocobalamin.

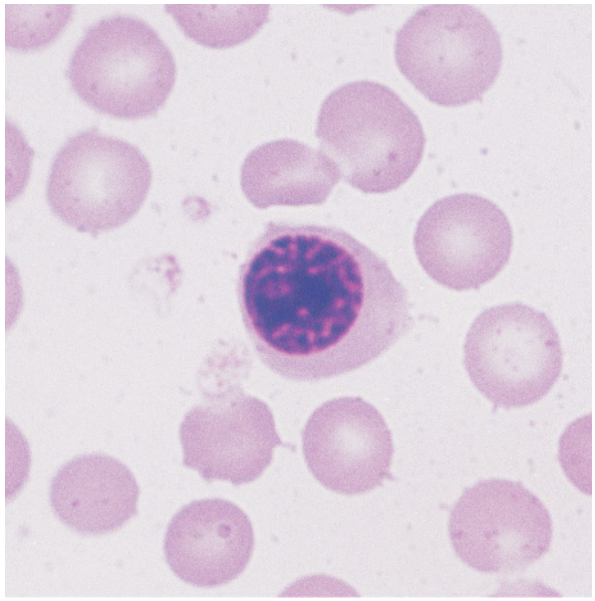

FIGURE 30.4 Blood from a dog with selective malabsorption of cobalamin. Notice the presence of a megaloblast exhibiting an immature nucleus and a fully hemaglobinized cytoplasm.

CONGENITAL DYSERYTHROPOIESIS, POLYMYOPATHY, AND CARDIAC DISEASE IN ENGLISH SPRINGER SPANIELS

Congenital dyserythropoiesis, polymyopathy, and cardiac disease has been described in three related English Springer Spaniels.[6] Clinical signs include regurgitation, stunted growth, stiff gait, skeletal muscle wasting, cardiomegaly, megaesophagus, and generalized muscle atrophy that is most pronounced in temporal muscles. All dogs have a mild to moderate microcytic normochromic non-regenerative anemia with marked metarubricytosis. Alterations in RBC morphology included spherocytes, schistocytes, dacryocytes, codocytes, and vacuolated RBCs. Bone marrow is characterized by erythroid hyperplasia and dyserythropoiesis. Features of dyserythropoiesis include lobulated nuclei, marked binucleation, arrested mitotic figures, and cytoplasmic vacuolization. The hematologic condition remain stable but the polymyopathy is slowly progressive.

CONGENITAL ANEMIA, DYSKERATOSIS, AND PROGRESSIVE ALOPECIA IN POLLED HEREFORD CALVES

Hereford calves with congenital anemia, dyskeratosis, and progressive alopecia have a congenital syndrome characterized by dyserythropoiesis and progressive alopecia associated with dyskeratotic hyperkeratosis.[9,10] A familial pattern has been demonstrated which is consistent with a simple autosomal recessive mode of inheritance.

Clinically, the condition is slowly progressive but is frequently fatal.[9] Iron, cobalamin, and folate deficiencies were ruled out as causes and viral agents were not identified in affected calves. Affected calves have a macrocytic normochromic anemia with a mild reticulocytosis. Dyserythropoiesis in bone marrow is characterized by multinuclearity, nuclear bridging, irregular nuclear shapes, and irregular chromatin patterns. These dysplastic changes resemble those associated with Poodle macrocytosis and congenital dyserythropoiesis type I in humans.[2,5]

Acronyms and Abbreviations

APBT, American Pit Bull Terrier; CME, canine monocytic ehrlichiosis; CNS, central nervous system; EDTA, ethylenediaminetetraacetic acid; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; HGE, human granulocytic ehrlichiosis; PCR, polymerase chain reaction; PCV, packed cell volume; RBC, red blood cell.

A seemingly ever-increasing number of rickettsial, mycoplasmal and protozoal agents are being recognized as the cause of anemia in veterinary species.[2] The anemia is frequently hemolytic in nature; however, with some organisms the anemia is non-regenerative resulting either from cytokine suppression of hematopoiesis or bone marrow pathology. Of importance to the veterinary hematologist is that many of these organisms can be visualized on blood films, providing a definitive diagnosis.

RICKETTSIA

The order *Rickettsiales* contains many organisms that cause significant hematologic disease in veterinary species. Many of the genera in this order have undergone reclassification. The order now contains two families, *Anaplasmataceae* and *Rickettsiaceae*. The *Anaplasmataceae* are intracellular parasites that grow within a cytoplasmic vacuole in the host cell as opposed to the *Rickettsiaceae* that infect the host cell cytoplasm or nucleus and are not bounded by a vacuole.

Ehrlichiosis

Canine Monocytic Ehrlichiosis (CME)

Ehrlichia canis is the most significant cause of canine monocytic ehrlichiosis worldwide. Transmission is by tick vectors (primarily *Rhipicephalus sanguineous*) and direct blood inoculation. Organisms replicate in cells of

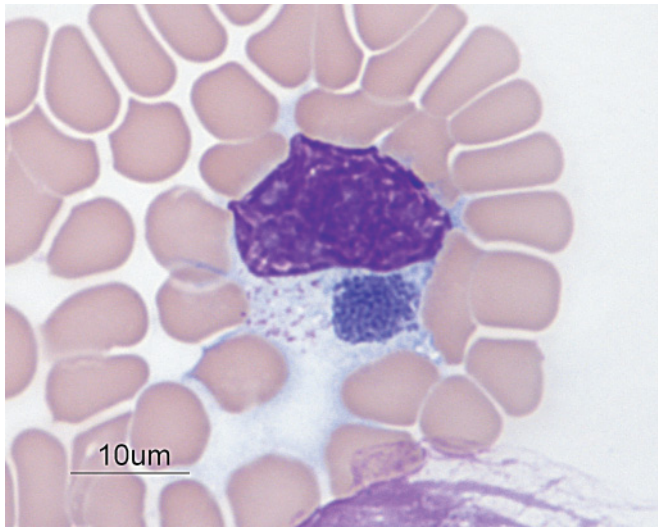

FIGURE 31.1 Blood film from a dog with *E. canis* infection. A morula is present in a disrupted large granular lymphocyte. The morula has the distinctive punctuate, granular appearance. Romanowsky stain.

the mononuclear phagocyte system and can be seen in lymphocytes, monocytes or macrophages.[42] Within mononuclear cells, organisms multiply by binary fission in a cytoplasmic vacuole. They appear by light microscopy as round, variably-sized, basophilic cytoplasmic inclusions termed morulae that have a punctate, granular appearance (Fig. 31.1). Parasitemia in peripheral blood is low and transient following initial infection. Diagnosis is generally made by serology or PCR, rather than visualization of organisms.

Hematologic findings depend on the stage of infection. Acute infection is associated with thrombocytopenia, that may be marked, and non-regenerative anemia. Leukopenia and neutropenia are less consistent. After acute infection, there is a subclinical phase during which anemia typically resolves but thrombocytopenia may be persistent. Dogs that develop the severe chronic phase typically have profound pancytopenia. Bone marrow aspirates obtained in these animals are hypocellular with marked reductions of all hematopoiectic cell lines (see Chapter 19).[8]

Canine Granulocytic Ehrlichiosis

The causative agent of granulocytic ehrlichiosis is *E. ewingii*.[1] Transmitted by *Amblyomma americanum*, *E. ewingii* has been reported from the southern and southeastern United States.[21] Polyarthritis is a common clinical manifestation of infection.[21] Clinical disease is considerably milder than that caused by *E. canis*. Hematologic findings include thrombocytopenia and a mild to moderate non-regenerative anemia.[21] *E. ewingii* infection is not associated with a chronic-phase pancytopenia.

Morulae of *E. ewingii* are found predominantly in neutrophils and rarely in eosinophils. Morulae are similar in appearance to those of *E. canis*, although they sometimes have a "packeted" appearance rather than fine punctate granulation typical of *E. canis*. Organisms are seen in the blood transiently during acute infection, but parasitemia is frequently high enough to allow diagnosis by microscopy.[21] Organisms may be identified in neutrophils of synovial fluid samples in dogs with polyarthritis. No specific serologic test exists for *E. ewingii*, but there is cross-reaction with *E. canis* serology. Infection can also be confirmed by PCR.[21]

Anaplasmosis

Historically, members of the genus *Anaplasma* infected red blood cells (RBCs) of ruminants causing hemolytic anemia. However, with the reclassification of several *Ehrlichia* spp. as *Anaplasma* spp., members of this genus may infect RBCs (*A. marginale*), granulocytes (*A. phagocytophilum*) or platelets (*A. platys*). Anemia is not a main feature of *A. platys* infection.

Granulocytic Anaplasmosis (*A. phagocytophilum*)

Anaplasma phagocytophilum now includes the organisms previously described as *Ehrlichia phagocytophila, Ehrlichia equi*, and the human granulocytic ehrlichiosis (HGE) agent.

Granulocytic Anaplasmosis in Dogs *A. phagocytophilum* infection in dogs is widespread. In the United States, it occurs most commonly in the upper Midwest and along the Pacific coast.[22] Clinical signs are non-specific and include fever, anorexia, depression, lymphadenopathy, and splenomegaly.[22] Some dogs may manifest either a neutrophilic polyarthritis or acute CNS signs, including seizures. Thrombocytopenia, mild to severe, is the most frequent hematologic abnormality and occurs in the majority of cases.[22] Mild to moderate non-regenerative anemia may also occur.[22] Morulae are similar to those of *E. ewingii* and can be seen in neutrophils at a fairly high parasitemia during the acute phase of infection.

Granulocytic Anaplasmosis in Horses *A. phagocytophilum* infection in horses has been reported from many states in the USA as well as Canada, Brazil, and Europe.[32] It causes a febrile illness characterized by anorexia, limb edema, mild petechiation, and reluctance to move. The predominant hematologic finding is a profound thrombocytopenia, variable neutropenia, and mild anemia may be present.[18] The parasitemia may be high with morulae readily seen in blood neutrophils during acute infection.

Granulocytic Anaplasmosis in Ruminants *Anaplasma phagocytophilum* is associated with abortion in cattle and increased susceptibility to other infections in lambs throughout Europe. Thrombocytopenia and leukopenia

are common hematologic findings, but anemia is not a prominent feature.

Erythrocytic Anaplasmosis in Ruminants

Anaplasmosis is a significant cause of disease in cattle.[29] Two species are described: *Anaplasma marginale* is widespread and *Anaplasma centrale* occurs in South America and South Africa. Wild ruminants are reservoirs, but do not usually manifest disease. *A. marginale* infection causes fever and mild to marked hemolytic anemia. Numerous tick species serve as vectors and mechanical transmission may also occur. The hemolysis is primarily extravascular; hemoglobinuria is not seen. Disease is most pronounced in older animals; calves 6–9 months old are relatively resistant and disease is mild. *Anaplasma centrale* is generally less pathogenic than *A. marginale.*

Organisms are visible in erythrocytes during acute infection. They are round, 0.5–1 µm, basophilic bodies frequently present on the periphery of RBCs (Fig. 31.2). They resemble Howell-Jolly bodies, from which they must be differentiated. *Anaplasma centrale* organisms are similar, but not peripherally located in RBCs. Although long thought to occur only in RBCs, *A. marginale* has been shown to invade microvascular endothelial cells both in vivo and in vitro.[11]

After infection, parasitemia increases until the hemolytic crisis, frequently with more than 50% of RBCs infected.[29] After development of the anemia, parasite numbers decline due to removal of infected RBCs. Cattle that survive acute infection become chronic carriers and act as reservoirs.

Anaplasma ovis causes anaplasmosis in sheep and goats. The disease occurs in tropical and subtropical regions throughout the world. Morphologically, *A. ovis* is similar to *A. marginale*.

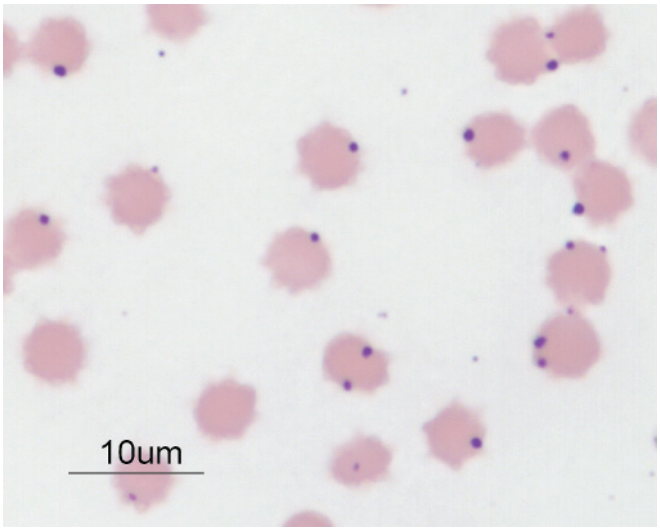

FIGURE 31.2 Blood film from a steer experimentally infected with *A. marginale*. Marked parasitemia with more than 50% of RBCs containing inclusions. Note the marginal position of most organisms. Romanowsky stain.

HEMOTROPHIC MYCOPLASMAS (HEMOPLASMAS)

Epierythrocytic parasites previously known as *Haemobartonella* and *Eperythrozoon* have been reclassified to the genus *Mycoplasma* and renamed, some with the designation *Candidatus* indicating they are incompletely described. As a group, these hemoplasmas have worldwide distribution, infect a wide variety of vertebrate animals, and share similar characteristics and morphologic features.[38] On routine blood films they are small basophilic round, rod, or ring-shaped organisms that appear on RBCs individually or in chains. Electron microscopy has shown them to have a single limiting membrane and lack nuclei or distinct organelles (Fig. 31.3). Organisms are typically found in depressions and invaginations in RBC membranes and appear connected to the membrane by delicate fibrils (Fig. 31.4).[57]

Hemoplasmas vary in their ability to cause clinically apparent disease, but infected animals may remain carriers despite antibiotic therapy; parasitemia may reemerge in times of stress. Hypoglycemia secondary to glucose consumption by the bacteria has been reported in heavily parasitized pigs, sheep, llamas, and calves; however, rapid bacterial glycolysis in vitro may also cause artifactually decreased blood glucose concentrations.[9] Historically, diagnosis has relied on detection of hemoplasmas on blood films. Organisms are generally found associated with the RBC membrane, but sometimes are free in the plasma (Fig. 31.5). Hemoplasmas

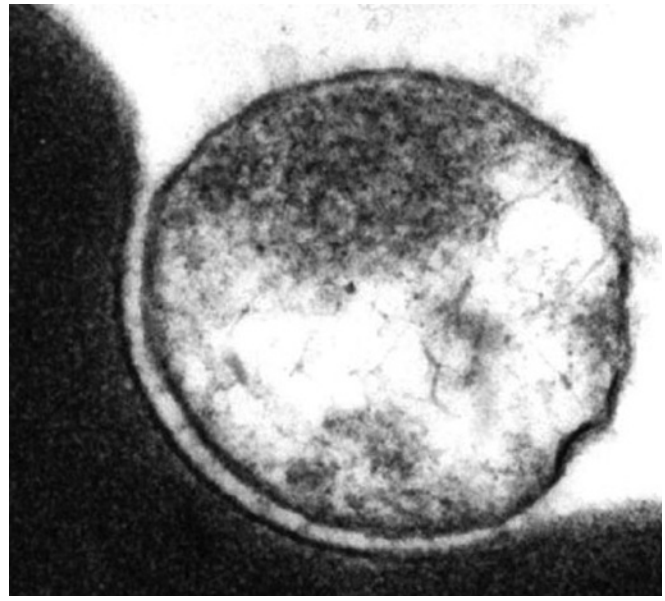

FIGURE 31.3 Transmission electron micrograph of a hemoplasma parasite (*M. haemofelis*) illustrating a single limiting membrane separating the cytoplasm of the organism from the host RBC. Delicate fibrils attach the organism to the host cell. (Reprinted from Messick JB. Hemotrophic mycoplasmas (hemoplasmas): a review and new insights into pathogenic potential. Vet Clin Pathol 2004;33:2–13, with permission.)

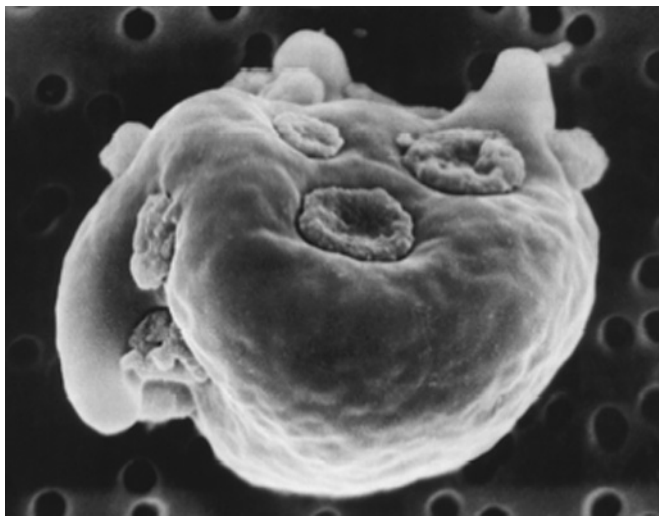

FIGURE 31.4 Scanning electron micrograph of several hemoplasma parasites (*M. suis*) within shallow depressions on the surface of an RBC. (Reprinted from Messick JB. Hemotrophic mycoplasmas (hemoplasmas): a review and new insights into pathogenic potential. Vet Clin Pathol 2004;33:2–13, with permission.)

dissociate from RBCs and die after a variable amounts of time in EDTA.[43] In aged samples, dead organisms can appear as pale pink clumped granular material in the background of the blood film (Fig. 31.6). Development of sensitive PCR assays capable of discriminating between various hemoplasmas has greatly enhanced diagnosis of these parasites, and has led to the identification of several new *Mycoplasma* species.

Canine Hemotrophic Mycoplasmas

Two hemoplasmas, *Mycoplasma haemocanis* (previously *Haemobartonella canis*) and "*Candidatus* Mycoplasma haematoparvum", infect domestic canines. *M. haemocanis* causes acute hemolytic anemia in dogs that are splenectomized, immunocompromised, or have concurrent infections.[39] These dogs usually have sufficient circulating parasites for them to be easily demonstrated on blood films. Anemia may be severe; spherocytes may be observed and Coombs' test results may be positive. By contrast, healthy dogs typically develop chronic, asymptomatic infections with sporadic, low-grade parasitemia.[39] Transmission is presumed to occur via arthropod vectors and has been experimentally demonstrated with the brown dog tick, *Rhipicephalus sanguineus*. Transmission of organisms may also occur via blood transfusion from asymptomatic carriers, but the recipient must be splenectomized or otherwise severely compromised for hemolytic disease to occur.[39]

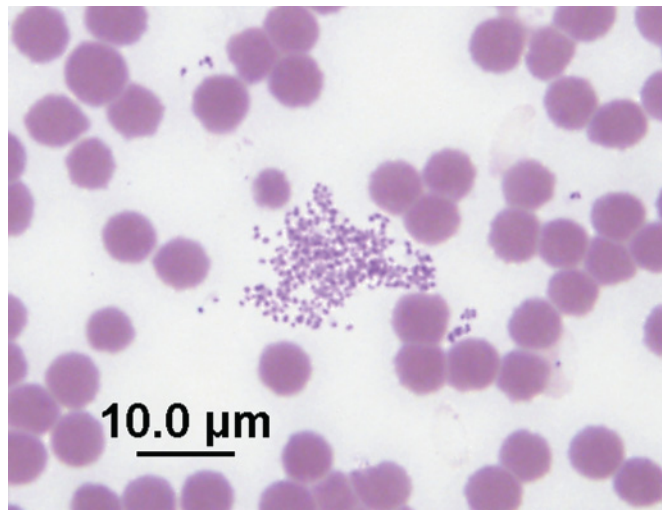

FIGURE 31.6 Blood film from a cat with *M. haemofelis* infection prepared from aged blood. Organisms have detached from RBCs and are degenerating, appearing as clumps of pink granular material in the background. Romanowsky stain.

On routine blood films *M. haemocanis* organisms are quite pleomorphic, but have a tendency to form long chains across the surface of RBCs, sometimes with "violin bow" morphology. Individual organisms are 1–3 µm and can appear round, rod-shaped, or in ring form (Fig. 31.7).[57]

"*Candidatus* Mycoplasma haematoparvum" was recently identified in a California dog with a T cell lymphoproliferative disease that had undergone splenectomy and blood transfusions.[51] Molecular characterization found the organism to be most similar to "*Candidatus* Mycoplasma haemominutum" in cats. These organisms are smaller than *M. haemocanis* or *M. haemofelis* (<0.3 µm) and, therefore are more difficult to appreciate on blood films. Knowledge about the pathogenic potential of "*Candidatus* M. haematoparvum" awaits further studies.

Feline Hemotrophic Mycoplasmas

Three hemoplasmas, *Mycoplasma haemofelis* (previously *Haemobartonella felis*), "*Candidatus* Mycoplasma haemo-

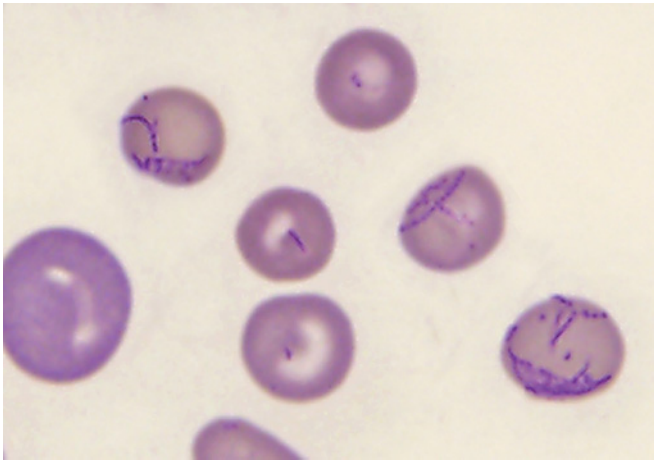

FIGURE 31.7 Blood film from a dog with *M. haemocanis* infection. Organisms are visible as chains of cocci on the surface of RBCs. Romanowsky stain; 1,000×.

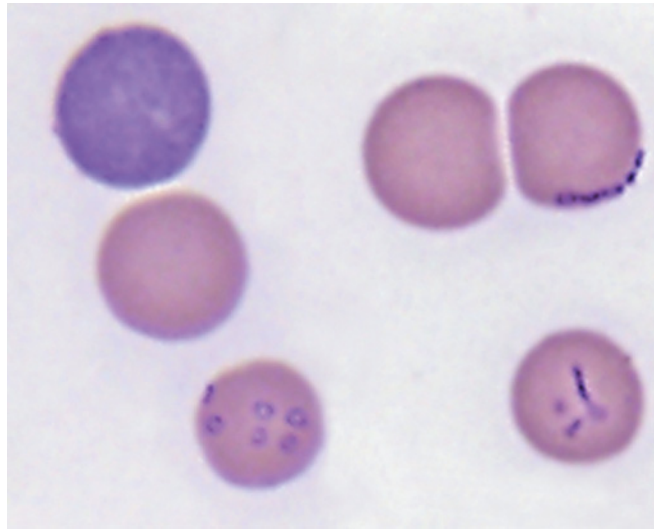

FIGURE 31.8 Blood film from a cat with *M. haemofelis* infection. Organisms are visible as chains of cocci and individual ring forms on the surface of RBCs. Romanowsky stain; 1,000×.

minutum", and "*Candidatus* Mycoplasma turicensis", are currently known to infect domestic cats. *M. haemofelis* was previously described as the large variant or Ohio strain to differentiate it from the small variant or California strain that was later named "*Candidatus* M. haemominutum".[38]

Mycoplasma haemofelis causes an acute hemolytic anemia characterized by variable numbers of circulating RBC parasites. Unlike *M. haemocanis*, disease occurs in immunocompetent hosts; however, retrovirus infection (FeLV or FIV) may be a predisposing factor in some cases. Hemolysis is primarily extravascular and results in a regenerative anemia that may be severe. RBC agglutination may be present and Coombs' test results are frequently positive. Parasitemia is cyclic, with a gradual increase in parasite numbers over a period of days followed by a sudden decline; infected RBCs may disappear from circulation in as little as 2 hours.[24] Cats that recover remain carriers despite treatment, with variable low-grade parasitemia.

Transmission is presumed to occur by arthropod vectors such as fleas, but experimental evidence of such transmission is lacking. Transmission has been accomplished by blood transfer. Iatrogenic transmission via blood transfusions is thus a concern, prompting recommendations for screening of potential blood donors using PCR-based DNA tests.[23] Vertical transmission from queens to kittens may also occur.

Morphology of *M. haemofelis* on routine blood films is similar to that described for *M. haemocanis*, with round (<0.8 µm), rod (up to 1.5 µm), and ring forms observed singly, in clusters, and short chains (Fig. 31.8).

"*Candidatus* Mycoplasma haemominutum" is reported to be about half the size of *M. haemofelis*, hindering visualization on blood films. Prevalence investigations utilizing PCR-based DNA tests indicate there is substantial subclinical infection in domestic cats, supporting the experimental evidence that "*Candidatus* M. haemominutum" is less pathogenic than *M. haemofelis*.[52] However, there is evidence that immunosuppressed cats or those coinfected with *M. haemofelis*, FIV, or FeLV may develop clinically significant anemia. Additionally, evidence is starting to emerge that "*Candidatus* M. haemominutum" may act as a primary pathogen in some cats, causing PCVs as low as 8%.[47]

"*Candidatus* Mycoplasma turicensis" was recently identified in a Swiss cat with severe hemolytic anemia.[59] Several studies indicate this organism is relatively common, widely distributed, and frequently associated with "*Candidatus* M. haemominutum" coinfection.[52] To date, this organism has been detected only by molecular methods. Limited experimental work suggests this organism is capable of causing severe anemia in immunocompromised cats, and mild anemia in healthy cats.[59]

Swine Hemotrophic Mycoplasmas

Two hemoplasmas, *Mycoplasma suis* (previously *Eperythrozoon suis*) and *Eperythrozoon parvum* are known to infect swine. *M. suis* has a worldwide distribution and causes hemolytic anemia accompanied by icterus in neonatal pigs, feeder pigs, and pregnant sows. Splenectomy of latently infected animals results in a marked increase in parasitemia, as does immunosuppressive therapy. On routine blood films *M. suis* may appear as small (approximately 1 µm) cocci, rods, or ring forms occurring individually, in chains, or clusters. Similar to *M. haemofelis*, parasitemia is frequently transient. Newer PCR based DNA tests are proving sensitive and specific for the diagnosis of *M. suis* in the absence of demonstrable parasitemia.[25]

Eperythrozoon parvum was originally described as coccoid or ring-shaped organisms on RBCs of splenectomized pigs.[49] This organism was approximately half the size of *M. suis*, and despite heavy parasitemia few clinical signs were observed. Recently, a hemoplasma believed to be *E. parvum* was identified in the blood of

pigs using a PCR protocol designed to detect the feline parasite "*Candidatus* M. haemominutum".[40] This organism will likely be reclassified as a mycoplasma, and renamed.

Ruminant Hemotrophic Mycoplasmas

Two hemoplasmas are currently known to infect ruminants. *Mycoplasma wenyonii* (previously *Eperythrozoon wenyonii*) infects cattle, and *Mycoplasma ovis* (previously *Eperythrozoon ovis*) infects sheep and goats. *M wenyonii* occurs worldwide and is typically thought of as an opportunistic pathogen, resulting in clinical anemia in splenectomized or otherwise compromised cattle. Parasitemia without anemia has been reported associated with fever and mammary, scrotal, or hind limb edema.[41,48] The mode of transmission for *M. wenyonii* is unknown, but presumed to occur via vectors such as lice, flies, ticks, and mosquitoes. Iatrogenic infection from blood transfer by contaminated needles and equipment may also occur. On blood films, *M. wenyonii* organisms are small and pleomorphic but frequently coccoid or ring-shaped, and may be found free in the background in large numbers.[48] Parasitemia is transient, however, and PCR-based DNA tests may be more sensitive than microscopy for detection of latent infections.[56]

M. ovis affects sheep and goats worldwide. While frequently considered relatively non-pathogenic, the severity of hemolytic anemia with acute infection is variable depending on age, nutrition status, concurrent worm burden, and possibly *M. ovis* strain differences.[38] Fatal disease occurs more often in lambs than in adults. Natural transmission may occur via arthropod vectors such as mosquitoes and ticks, and iatrogenically by blood transfer. On blood films, *M. ovis* organisms are coccoid, rod, or ring shaped, 0.5–1.0 µm in diameter, and are frequently seen free in the background.

Camelid Hemotrophic Mycoplasmas

"*Candidatus* Mycoplasma haemolamae", originally described as an eperythrozoon-like parasite, affects llamas and alpacas. Anemia varies from mild to severe, with more severe clinical signs found in younger animals that are stressed or have other concurrent diseases; adults may be asymptomatic. Heavy parasitemia has been identified in crias as young as 1 day of age, suggesting vertical transmission in utero. On blood films, "*Candidatus* M. haemolamae" organisms are coccoid to ring shaped, 0.5–1.0 µm in diameter, and are often free in the background (Fig. 31.9).[46] Asymptomatic carriers have been identified using a DNA-based PCR assay.[53]

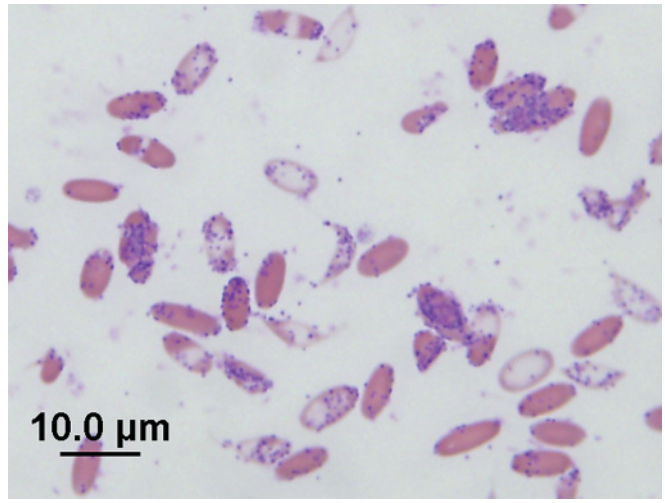

FIGURE 31.9 Blood film from a llama with "*Candidatus M.* haemolamae" infection and iron deficiency. Large numbers of coccoid organisms are present on the surface of RBCs and free in the background. Romanowsky stain.

PROTOZOA

Members of two groups of apicomplexan protozoal erythroparasites, the *Babesias* and *Theilerias*, will likely eventually undergo reorganization subsequent to genetic sequencing and phylogenetic studies. Historically, morphology and features of their life cycles defined them. Neither genera form pigment in the parasitized cell (as opposed to *Plasmodium* and *Hemoproteus*). Both are transmitted by ixodid ticks, but transovarial tick transmission occurs with *Babesia* species and not with *Theileria* species.[36] Additionally, *Babesia* sporozoites directly invade erythrocytes, while *Theileria* sporozoites first invade lymphocytes or macrophages to form schizonts.[36]

Theileriosis

Ruminants

There are multiple *Theileria* species that affect domestic and wild ruminants, primarily in Africa, Europe, Australia, and Asia. The life cycle of these parasites involves a schizont stage, typically within lymphocytes, in addition to piroplasms within RBCs.[36] An interesting feature of the life cycle of some *Theileria* is the reversible transformation and clonal expansion of lymphocytes that occurs as a direct result of infection.[16]

Theileria parva is the most economically important organism, causing the rapidly fatal bovine disease East Coast Fever in Africa.[6] The schizont stage of *T. parva* is the major cause of pathology. Anemia is typically mild and non-regenerative, but may become severe as erythroid precursors in bone marrow are infected. *Theileria annulata* causes tropical theileriosis in cattle from the Mediterranean to Asia.[6] Both the schizont stages and erythrocytic piroplasms are pathogenic, with severe hemolytic anemia and icterus a common occurrence. *Theileria hirci* (also known as *T. lestoquardi*) causes a similar hemolytic disease is sheep and goats in Asia and Africa. Many other *Theileria* species have been described, including *T. mutans*, *T. sergenti*, *T. orientalis* in cattle and *T. cervi* in deer and elk, but seem to be less pathogenic under most circumstances. *Theileria buffeli* has recently

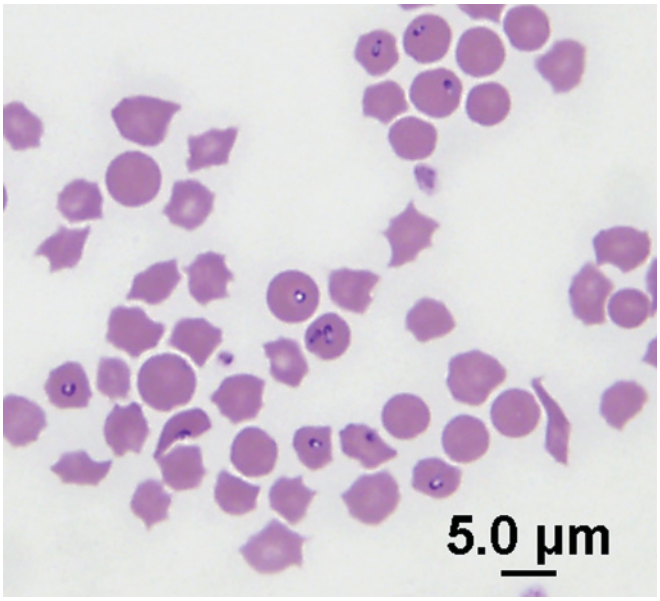

FIGURE 31.10 Blood film from a white-tailed deer with *T. cervi* infection. Small round to oval "signet-ring" piroplasms are present within RBCs. Romanowsky stain.

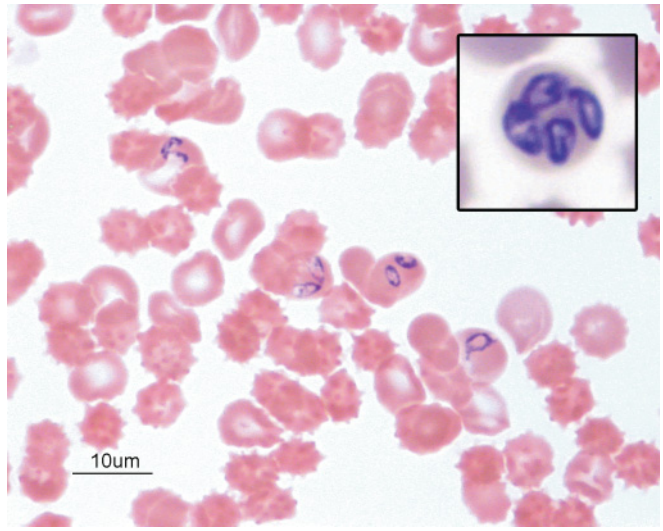

FIGURE 31.11 Blood film from a dog with *B. canis* infection. This animal did not have evidence of hemolysis (note lack of polychromasia) and probably represents a recurrent parasitemia in a chronically infected dog with subsequent immunosuppression from concurrent illness. Note the characteristic paired, piriform organism in erythrocytes. Inset: RBC containing four organisms. Romanowsky stain.

been recognized as a cause of hemolytic disease in cattle in the United States; however, asymptomatic infections were also detected.[50]

On routine blood films theilerial piroplasms are pleomorphic, occurring as round, rod, comma, piriform, signet-ring, and racquet shapes, with occasional tetrad (Maltese-cross) formation (Fig. 31.10). The particular species cannot be determined based on morphology. Schizonts may be identified in lymphocytes in lymph node biopsies or aspirates.

Equines

The small piroplasm formerly described as *Babesia equi* has been renamed *Theileria equi*.[35] *T. equi* causes fever, hemolytic anemia, and icterus in horses in tropical and subtropical regions of the world. It is not yet a problem in the USA, despite the presence of appropriate tick vectors. The anemia varies from mild to severe, and subclinical infections may be detected by serology. *T. equi* piroplasms are small (1–2 µm) round to oval signet-ring structures within RBCs. Dividing stages may appear piriform in Maltese-cross arrangement.[35]

Canines

Small signet-ring piroplasms have been identified in RBCs from Spanish dogs with fever and hemolytic anemia.[61] This organism has been provisionally named *Theileria annae*. *Babesia conradae*, a small piroplasm identified in California dogs with hemolytic anemia, has been shown to be more similar to *Theileria* species than to other *Babesia* species based on genetic studies. Thus, the specific nomenclature for many of these small piroplasms will likely be revised.

Babesiosis

In contrast to *Theileria* species, pathogens of the genus *Babesia* are limited to RBCs within the host. Sporozoites injected into the host directly attach to, penetrate, and multiply within RBCs.[60] They are classified morphologically as large (>3 µm) or small (<3 µm). Organisms exit by rupturing the host RBC and then invade new RBCs. Hematologic findings are primarily hemolytic anemia, although thrombocytopenia is common with many *Babesia* infections.

Canines

Large Canine Babesia Large canine *Babesia* has historically been called *Babesia canis*. The organism appears as large (up to 5 µm), single or paired piriform bodies (Fig. 31.11). Differences in clinical syndromes, vectors, serologic tests and cross-immunity have led to the designation of three subspecies or strains: *B. canis canis*, *B. canis vogeli* and *B. canis rossi*.

B. canis vogeli is the large *Babesia* found in the USA and also occurs in Africa, Europe, Asia, and Australia. It causes relatively mild disease and is endemic in many populations of kenneled Greyhound dogs.[7] Infections are often subclinical with clinical disease most common in pups. Hematologic manifestations include a hemolytic anemia and thrombocytopenia. Parasites are rarely seen in the peripheral blood of subclinically affected animals and diagnosis generally is made by serology.

B. canis rossi is the most virulent strain and is found in Africa. It causes a severe, hemolytic anemia that can be both intra- and extravascular. Thrombocytopenia is also common. This parasite can induce a wide spectrum

of disease manifestations unrelated to hemolysis, referred to as "complicated" babesiosis.[26]

B. canis canis is found in Europe and is of moderate pathogenicity. Recently a fourth, genetically distinct, large *Babesia* causing hemolytic anemia has been identified in several dogs from North Carolina.[30]

Small Canine Babesia *Babesia gibsoni* has long been recognized as a problem of dogs in Asia, Africa, and Europe and has recently been identified as an emerging infection of dogs in the USA.[5] In the United States, the majority of the affected dogs are American Pit Bull Terriers (APBT) or dogs that have been bitten by Pit Bulls.[31] Acutely, the organism causes a hemolytic anemia and thrombocytopenia.[5,37] Surviving dogs remain subclinical carriers and the incidence of such carriers is quite high in certain populations of APBTs.[31] *B. gibsoni* can be transmitted between dogs by tick vectors, direct blood inoculation or transplacental transmission.[20,37] In most endemic areas, *B. gibsoni* is transmitted by *Hemophysalis* ticks.[5] It is not known if there is a competent tick vector in the United States. Clinical signs are non-specific and generally relate to hemolytic anemia. The anemia is regenerative; spherocytosis and positive direct Coombs' test results suggest an immune-mediated component. Marked thrombocytopenia is a frequent finding and may occur before and last longer than parasitemia and/or anemia.[37] Parasitemia is detectable in the acute phase of infection, but is generally low. Parasites are small (1–2.5 µm) and pleomorphic.[31] The most common shape is a signet ring, although elongated forms are also seen (Fig. 31.12). Splenectomized animals show more severe clinical signs, more profound anemia, and a greater parasitemia than animals with an intact spleen.[37] Serologic tests and PCR are useful for detecting chronically infected animals and have been used in prevalence studies.[4]

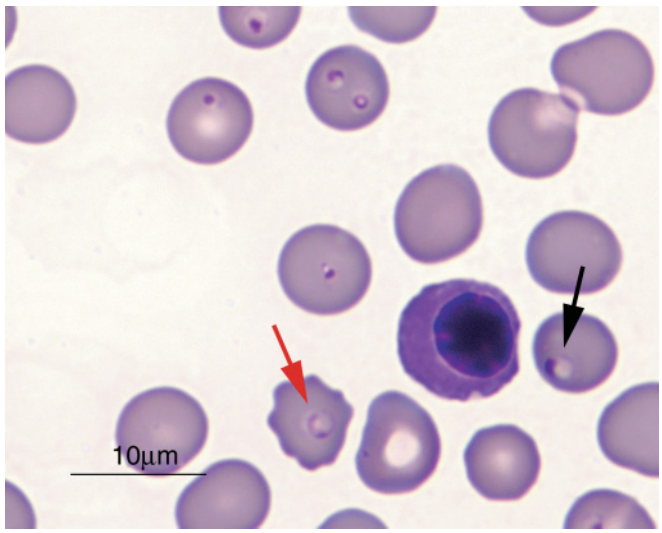

FIGURE 31.12 Blood film from an American Pit Bull Terrier with *B. gibsoni* infection. This dog suffered an acute hemolytic crisis after splenectomy for removal of a splenic tumor. Note the varying sized organisms, many of which have the classic signet-ring appearance. In some, the nuclear material is punctate (black arrow) while in others the nuclear material is spread along the periphery of the ring (red arrow). Romanowsky stain.

A small *Babesia* causing hemolytic anemia and thrombocytopenia in dogs from California was originally assumed to be *B. gibsoni* based on morphology and host.[13] It was later shown to be genetically distinct and was renamed *Babesia conradae*.[28], This organism is associated with a higher parasitemia and more profound anemia than *B. gibsoni*.

Ruminants

There are four widely recognized species of *Babesia* in cattle: *B. bovis*, *B. bigemina*, *B. divergans* and *B. major*, *B. divergans* and *B. major* are reported in cattle in Europe.[54] *B. bovis* and *B. bigemina* are the most widespread and of most economic significance. *Boophilus* and *Rhipicephalus* ticks serve as vectors, although iatrogenic transmission by direct blood transfer also occurs.

B. bigemina is a large piroplasm often appearing as the classical pair of piriform organisms. *B. bovis* is a small piroplasm frequently seen as a single round body. Both organisms cause an acute febrile illness and hemolytic episode. Calves infected at less than 8 months of age often develop subclinical disease due to innate resistance.[14] Release of replicating parasites from RBCs causes intravascular hemolysis with resultant hemoglobinemia and hemoglobinuria. Increased osmotic fragility of all RBCs may result in massive terminal hemolysis despite reduced parasitemia.[14] Marked accumulation of *B. bovis* parasitized RBCs in small cerebral capillaries can result in ischemia. The associated CNS signs are termed "cerebral babesiosis".

Two species, *B. ovis* and *B. motasi*, cause disease in sheep and goats in Africa, Asia, and Europe.[54] *B. ovis* is a small oval piroplasm, while *B motasi* is larger and is commonly seen as paired, piriform organisms.

Equines

Babesia caballi is the only true equine *Babesia* species since *B. equi* has been properly reclassified as *T. equi*. It is a large, piriform organism typically appearing in pairs with an acute angle. It is tick transmitted, and transovarial transmission may occur through several generations of ticks. The distribution of *B. caballi* includes Africa, the Americas, Asia, and Europe. Despite the presence of potential tick vectors, it is not a significant disease in the USA. Disease induced by *B. caballi* is generally much less severe than that of *T equi*. Pronounced clinical signs and severe anemia are uncommon. Hemoglobinuria is not typical. The parasitemia is generally extremely low, even in splenectomized animals.[15] Foals are immune for the first 6–9 months of life from passive immunity and innate factors.

Felines

Babesia felis is a small piroplasm reported regularly in cats from coastal regions of South Africa.[45] No vector

has been identified although it is assumed to be tick borne. It is most common in young adult cats, which may have severe regenerative anemia, hyperbilirubinemia and agglutination. The parasitemia is variable, and may be extremely high.

Feline Cytauxzoonosis

Cytauxzoon felis is a hemoparasite of wild and domestic cats that is common in the south central and southeastern USA. The disease is tick borne with bobcats, and possibly other wild felids, serving as a reservoir host.[27]

Cytauxzoon piroplasms are found in RBCs and schizogony occurs in macrophages of various tissues. The schizogonous phase is responsible for the marked clinical disease with parasitized intravascular macrophages becoming greatly enlarged and obstructing the lumen of vessels. Clinical signs include profound depression, dehydration, marked fever and icterus. Anemia, generally non-regenerative, is a common finding that develops relatively late in the course of disease. Leukopenia and thrombocytopenia are also common. Diagnosis is usually confirmed by identification of piroplasms on peripheral blood films. The characteristic shape most easily differentiated from artifact is the signet-ring. This is a small ring (~1–3 µm) with a round or linear thickening of nuclear material at one point of the ring (Fig. 31.13).[58] Schizont-containing macrophages can be identified in impression smears of many tissues including lung, spleen, liver, lymph nodes and bone marrow, and may also be observed on peripheral blood films late in the disease course. Parasitized macrophages become greatly enlarged and have a large, prominent nucleolus (Fig. 31.14). The prognosis for cats with cytauxzoonosis has been grave with mortality rates of nearly 100%. Survival of cats unrelated to treatment has been reported and may suggest the presence of less virulent strains.

Trypanosomiasis

Trypanosomes are flagellated protozoal organisms. They are not a significant cause of anemia in animals in North America.

Trypanasoma cruzi, etiologic agent of Chagas' disease, has been reported in dogs in several states.[3] The organisms may be found in the peripheral blood in the acute stages of infection; however, anemia is not a significant finding. Organisms are fusiform, approximately 15–20 µm in length, with a centrally located nucleus and small basophilic subterminal kinetoplast. (Fig. 31.15)

Trypanasoma theileri is a larger organism (up to 100 µm in length) that occurs in cattle worldwide. This organism is fairly prevalent, but is considered nonpathogenic.[17]

Anemia in animals is caused by a variety of African trypanosomes including *T. congolense* and *T. vivax* in cattle; *T. brucei and T. congolense* in goats and sheep; *T. brucei* in horses and donkeys; and *T. brucei and T. congolense in dogs*.[12] The pathogenesis of anemia is

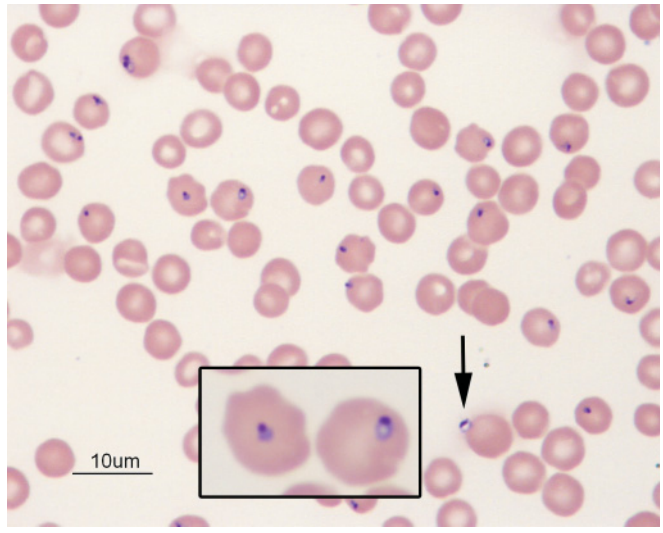

FIGURE 31.13 Blood film from a cat in with terminal cytauxzoonosis. In fatal cases, parasitemia typically progressively increases with time. Organisms are variably sized and somewhat pleomorphic. Only some demonstrate the characteristic signet-ring shape. One extracellular piroplasm is present (arrow). Inset: Higher magnification of two piroplasms. In the larger one on the right, the inner portion of the ring can be seen to be lighter than the RBC. Romanowsky stain.

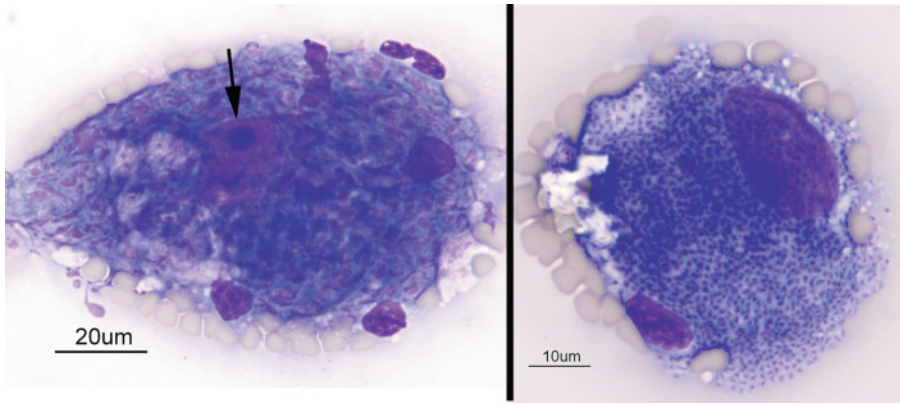

FIGURE 31.14 Large mononuclear cells with *C. felis* schizonts from the feathered edge of a blood film of a cat with cytauxzoonosis. The schizont on the left is less mature. Nuclear material is visible as variably sized, amorphous purple areas within the basophilic schizont. The schizont on the right, from the same blood film, is more mature. Nuclear material has transformed to fine punctuate inclusions of developing merozoites. Romanowsky stain.

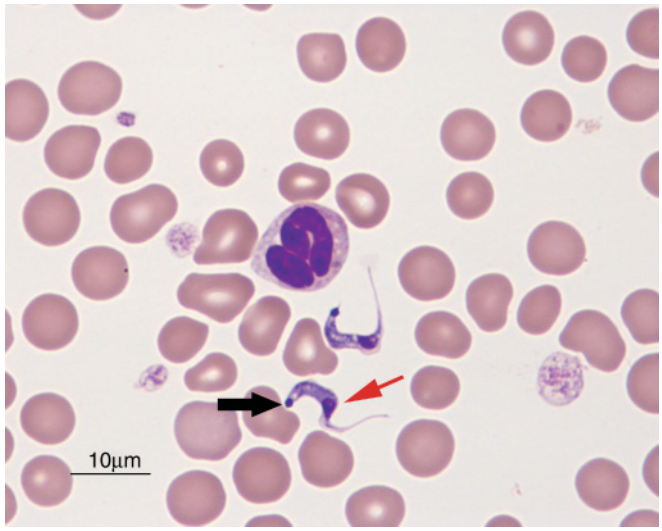

FIGURE 31.15 Blood film from a dog with *T. cruzi* infection. This dog was treated with multiple immunosuppressive agents for immune-mediated hemolytic anemia. Organisms were visible on follow-up blood films after resolution of anemia. Note the dark, subterminal kinetoplast (black arrow) and larger purple nucleus (red arrow). Romanowsky stain.

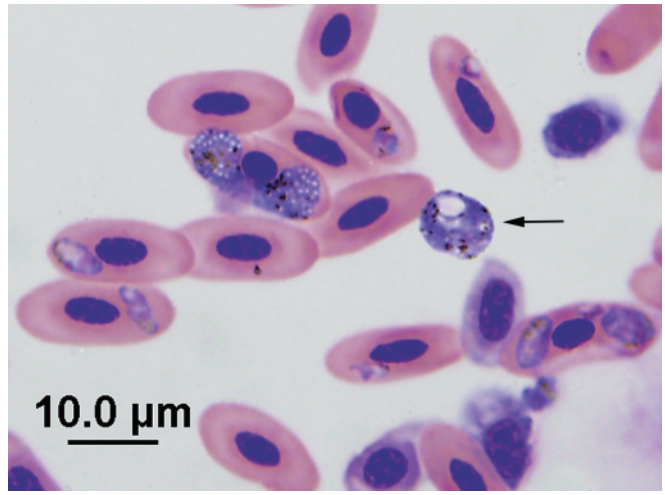

FIGURE 31.16 Blood film from an owl with *Haemoproteus* infection. Several different stages of intracellular gametocytes containing yellow-brown hemozoin pigment are visible, which surround but do not displace the nucleus. One extracellular form is present (arrow). Wright's stain.

complex. In acute disease, RBC membranes are damaged directly by hemolysins released from trypanosomes. Extravascular RBC removal also occurs in the spleen, bone marrow and lungs secondary to coating of RBCs with trypanasomal antigens.[12]

Sarcocystosis

Several different species of *Sarcocystis* have been reported to cause anemia in ruminants including cattle, sheep, and goats. However, there is no parasitic stage of *Sarcocystis* that infects RBCs; thus there are no specific hematologic findings. Anemia related to sarcocystosis is thought to be due to hemolysis. In experimental infections, it reaches a nadir at about 1 month post-inoculation. Second generation meronts are maturing in endothelium at that time, suggesting that microangiopathy due to vasculitis may play a role in the anemia. Calves inoculated with *S. cruzi*, the most pathogenic species for cattle, develop a severe anemia attributed to extravascular immune-mediated hemolysis, and have evidence of a consumptive coagulopathy attributed to endothelial cell damage and disseminated intravascular coagulopathy.[19] The anemia is reportedly minimally regenerative, possibly due to superimposed anemia of inflammatory disease.[33]

Haemoproteus

Many different species of *Haemoproteus* can affect birds and reptiles. In general they are considered relatively non-pathogenic, although co-infection with other hemoparasites may have detrimental effects in wild populations. Clinical disease seems to be associated with the tissue stages of parasite development, rather than the RBC stages. Anemia may develop in parasitized animals that are ill, injured, or immunocompromised, with a few reports of mortality associated with anemia occurring in young quail and pigeons. Parasitemia is frequently observed in raptors undergoing rehabilitation for illness or injury, and the magnitude of parasitemia frequently decreases as birds recover.[44]

Haemoproteus gametocytes are generally present in RBCs, although extra-erythrocytic forms may occasionally be seen on blood films (Fig. 31.16). Gametocytes vary in appearance depending on their stage of development, and may be round, oval, or elongated.[10,34] Large forms typically encircle the RBC nucleus without displacing it. Gametocytes usually contain refractile yellow to brown iron pigment (hemozoin), a result of hemoglobin digestion ("malarial pigment").

Plasmodium

Parasites of the genus *Plasmodium* are the cause of malaria in humans and many animal species. Numerous different *Plasmodium* species have been identified. In veterinary medicine, malarial parasites are most often encountered in birds and reptiles. Some species of birds seem more susceptible to clinical disease (canaries, penguins, ducks, pigeons, raptors, domestic poultry), while others may be asymptomatic carriers. Reported disease manifestations include hemolytic anemia, leukocytosis, lymphocytosis, hepatomegaly, splenomegaly, and death.[10]

Gametocytes contain yellow-brown iron pigment (hemozoin), similar to that found in *Haemoproteus* gametocytes. Gametocytes may be elongated or round depending on the particular species; round forms tend to displace the host cell nucleus, unlike *Haemoproteus* (Fig. 31.17). Schizonts may be found in peripheral blood RBCs, thrombocytes, and leukocytes. They have

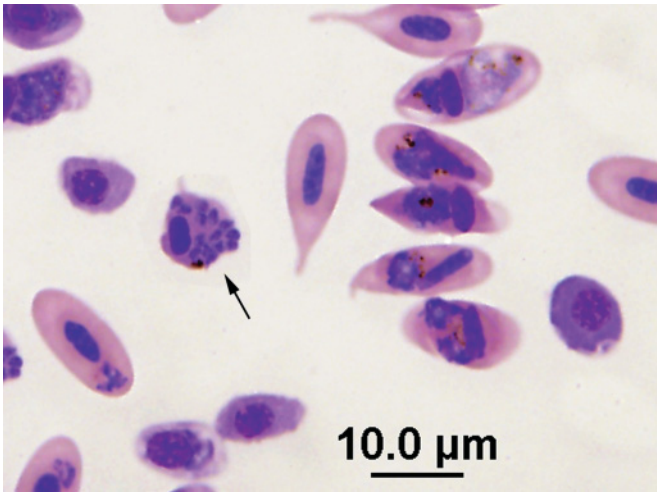

FIGURE 31.17 Blood film from a golden eagle with *Plasmodium* infection. Developing gametocytes containing yellow-brown hemozoin pigment displace RBC nuclei. One erythrocyte contains developing merozoites (arrow). Wright's stain.

a variable appearance depending upon the stages of the developing merozoites, which may appear fused or as distinct basophilic structures. Trophozoites are round to oval with an eccentric nucleus, resulting in a signet-ring appearance. Features of *Plasmodium* useful to differentiate it from *Haemoproteus* are presence of schizonts in peripheral blood, developing parasite stages within leukocytes and thrombocytes in addition to RBCs, and displacement of the host cell nucleus.[10] However, there are significant differences in the appearance of these parasites in blood cells; depending upon the particular *Plasmodium* species observed, schizonts may only be observed within RBCs, and the host cell nucleus may or may not be displaced. Those interested in detailed morphologic descriptions of avian haemosporidia are referred to the comprehensive monograph by Valkiunas.[55] Recently developed DNA-based PCR assays should prove helpful to better understand and classify the various morphologic variants.

CHAPTER 32

Anemia Associated with Bacteria and Viral Infections

CASEY M. RIEGEL and STEVEN L. STOCKHAM

Yellow Lamb Disease by (Enterotoxemic Jaundice, Yellows) Caused by *Clostridium perfringens* type A
Bacillary Hemoglobinuria, Red Water Disease, or Nevada Red Water Caused by *Clostridium haemolyticum* (or *C. novyi* type D)
Corynebacteriosis Caused by *Corynebacterium pseudotuberculosis*
Leptospirosis Caused by *Leptospira interrogans* serovars *pomona* and *icterohaemorrhagiae*
Equine Infectious Anemia Caused by Equine Infectious Anemia Virus

Acronyms and Abbreviations

AGID, agar gel immunodiffusion; CBC, complete blood count; CELISA, competitive enzyme-linked immunosorbent assay; EIA, equine infectious anemia; EIAV, equine infectious anemia virus; ELISA, enzyme-linked immunosorbent assay; IgM, immunoglobulin M; RBC, red blood cell; WBC, white blood cell.

Many bacterial and viral infections can directly or indirectly cause anemia. This chapter's primary topics are the anemias associated with infections by *Clostridium*, *Corynebacterium*, *Leptospira*, and equine infectious anemia virus (Table 32.1). Anemias caused by feline viruses (i.e. feline leukemia virus and feline immunodeficiency virus), rickettsial bacteria (e.g. *Rickettsia*, *Ehrlichia, Anaplasma*) or mycoplasmal bacteria (e.g. *Mycoplasma haemocanis*, *Mycoplasma haemofelis*) are described in Chapters 19, 31, 55, and 62, respectively.

Most anemias associated with bacterial and viral infections are caused by the inflammatory reaction (i.e. anemia of inflammatory disease, see Chapter 37). Infections may cause more severe anemias if they result in hemorrhage (vascular damage, thrombocytopenia), red blood cell (RBC) fragmentation (vasculopathy, coagulopathy), or generalized bone marrow damage (marrow necrosis or replacement, see Chapters 17 and 18).

Infectious agents, their products, or the animal's specific response to the agent may cause an anemia via three major processes: (1) damaged circulating RBCs causing intravascular or extravascular hemolysis, (2) damaged erythroid precursors causing erythroid hypoplasia, (3) damaged hematopoietic or supportive stromal cells causing general marrow hypoplasia.

YELLOW LAMB DISEASE (ENTEROTOXEMIC JAUNDICE, YELLOWS) CAUSED BY *CLOSTRIDIUM PERFRINGENS* TYPE A (BASONYM *CLOSTRIDIUM WELCHII*)

Yellow lamb disease occurs in spring nursing lambs of northern California and Oregon[22] and in lambs and calves in Canada, Australia, New Zealand, and South Africa.[28] *Clostridium perfringens* infections in two horses were associated with intravascular hemolytic anemias that were considered immune-mediated.[38] Hemolytic anemias are not described in most enteric diseases caused by *C. perfringens* type A.

Clinical signs include depression, fever, weakness, pale mucous membranes, anemia, hemoglobinuria, icterus, and diarrhea. Death may occur within 6–12 hours of onset of illness especially if icterus and hemoglobinuria are present.[22,28] Changes in blood are consistent with massive intravascular hemolysis.[6,28,38]

An α toxin, a phospholipase C, which is produced by *C. perfringens* type A, causes the RBC damage.[20] The α toxin causes hydrolysis of membrane phospholipids (Fig. 32.1) and resultant lysis of red blood cells (RBCs), white blood cells (WBCs), platelets, endothelial cells, and myocytes.[33]

TABLE 32.1 Bacterial and Viral Infections that Cause Anemia[a]

Organism	Disease	Susceptible Animals
Clostridium perfringens type A	Yellow lamb disease, enterotoxemic jaundice, or yellows	Lambs, calves, captive Siberian ibex, horses
Clostridium haemolyticum (or *C. novyi* type D)	Bacillary hemoglobinuria, red water disease, or Nevada Red Water	Cattle, sheep
Corynebacterium pseudotuberculosis	(Experimental infection)	Sheep
Leptospira interrogans serogroups	Leptospirosis	Calves, lambs, pigs, perhaps rhinoceros, possibly dogs
Equine infectious anemia virus	Equine infectious anemia, swamp fever, equine malarial fever, mountain fever, slow fever	Horses, ponies, donkeys, mules

[a]Feline leukemia virus, feline immunodeficiency virus, rickettsial bacteria (e.g. *Rickettisa, Ehrlichia, Anaplasma*), and mycoplasmal bacteria (*Mycoplasma haemocanis, Mycoplasma haemofelis*) not included.

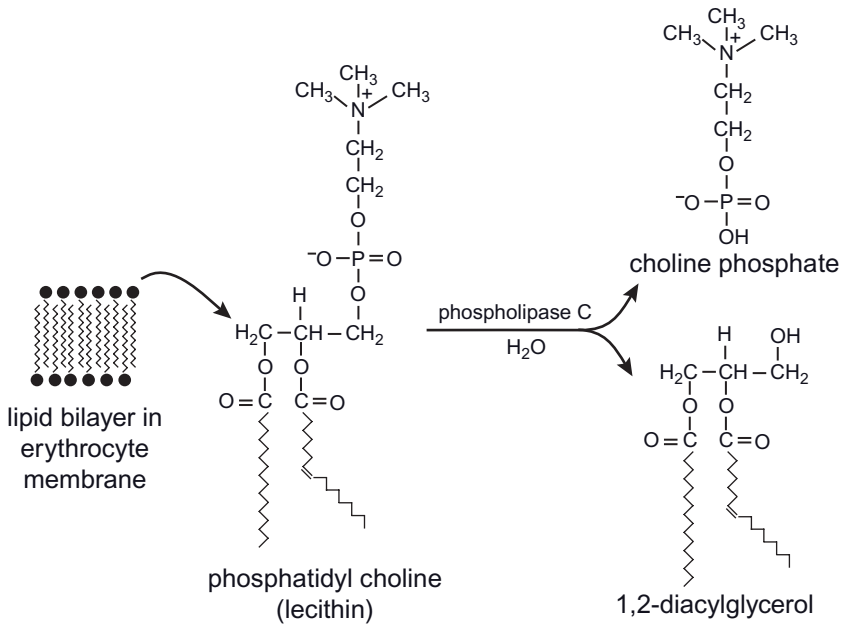

FIGURE 32.1 Action of phospholipase C on the RBC membrane. Phospholipase C catalyzes the hydrolysis of two RBC membrane lipids – phosphatidylcholine and sphingomyelin – that are the predominant phospholipids in the outer hemileaflet of the RBC membrane. The reaction shows hydrolysis of phosphatidylcholine into its hydrophilic portion (choline phosphate) and hydrophobic portion (1,2-diacylglycerol). In a similar reaction, phospholipase C catalyzes the hydrolysis of sphingomyelin to ceramide and sphingosine 1-phosphate (not shown).

Clostridium perfringens type A is a part of intestinal microbiota in animals, but increased bacterial growth has been associated with highly proteinaceous diets,[36] overfeeding,[34] and starchy foods.[31] After production by the bacteria, α toxin is absorbed by intestinal mucosa, enters the blood, and damages cell membranes. Major postmortem findings include evidence of massive intravascular hemolysis, renal hemoglobin casts, destruction of capillary walls leading to intestinal mucosal necrosis, centrolobular hepatic necrosis, and serosal, petechial and ecchymotic hemorrhages. In calves, abomasal hemorrhage and ulceration may be present. Small intestine may be hyperemic but rapid autolysis may obliterate the lesions; large, Gram-positive bacilli may be found in the mucosa and submucosa.[27]

A diagnosis of yellow lamb disease is confirmed by detecting α toxin in intestinal contents or blood from fresh carcasses via serum-neutralization tests in mice and guinea pigs.[5] Polymerase chain reaction assays can detect the α toxin gene (also known as cpa gene) of *C. perfringens* type A.[10]

BACILLARY HEMOGLOBINURIA, RED WATER DISEASE, OR NEVADA RED WATER CAUSED BY *CLOSTRIDIUM HAEMOLYTICUM* (OR *C. NOVYI* TYPE D)

Bacillary hemoglobinuria is a fatal disease that occurs naturally in cattle and experimentally in sheep. It can be a seasonal disease (summer and early fall) and is associated with liver fluke migration. It is endemic in poorly drained or swampy areas of the Gulf coast states, western United States, South America, Wales, eastern Europe, and New Zealand.[34,36]

Bacillary hemoglobinuria is rarely recognized antemortem because the severe hemolysis causes acute death. When seen, clinical signs include malaise, reluctance to move, arched back, bloody diarrhea, fever, rapid and shallow breathing, and blood-tinged froth from nostrils. The classic port-wine urine of hemoglobinuria is uncommon.[32] If the affected animal survives the initial crisis, icterus and a regenerative anemia can develop.[4] In experimental infections, severe anemia and death is seen within 3 days of inoculation. Calves and ewes develop fever, a gradual to precipitous drop in hematocrit values, mild to moderate leukocytosis, and increased aspartate transaminase activity (either due to RBC or hepatocyte damage).[25]

RBC damage is caused primarily by a β toxin, a phospholipase C (lecithinase), that hydrolyzes phosphatidylcholine and sphingomyelin (Fig. 32.1). The β toxin is not related serologically to the phospholipase of other clostridial species.[30] The β toxin is produced by two clostridial organisms, *C. haemolyticum* and *C. novyi* type D. Other minor hemolysins are reported as products of *C. haemolyticum*.[21]

After spores are ingested, organisms cross the intestinal mucosa and are transported to liver and other organs in macrophages. Spores may persist in Kupffer cells for a long time. Anaerobic conditions, such as those induced by hepatic biopsy and the presence of liver parasites stimulate growth of organisms and production of toxins.[25] Absorption of β toxin into blood leads rapidly to intravascular hemolysis, damaged endothelial cells, icterus, hemoglobinuria, and death.[32]

Necropsy findings may include pale and icteric mucous membranes, petechial and ecchymotic subcutaneous hemorrhages, copious amounts of red-tinged abdominal and thoracic fluid, hemoglobinuria, renal hemoglobin casts, congested or hemorrhagic lymph nodes, extensive edema, and bloody intestinal contents. Characteristic liver lesions are foci of hepatic necrosis surrounded by a reddened reaction zone.[34]

Diagnosis is usually made from the combination of a sudden death and postmortem findings. Numerous Gram-positive bacilli may be found in liver, spleen, blood, and abdominal fluid but their presence must be interpreted with caution. Fluorescent antibody tests for detection of the organism in fresh liver tissue can be performed.[17] In addition, phospholipase C activity (β toxin) can be detected in tissues.

CORYNEBACTERIOSIS CAUSED BY *CORYNEBACTERIUM PSEUDOTUBERCULOSIS*

Corynebacterium pseudotuberculosis produces an exotoxin that has sphingomyelin-specific phospholipase D activity. When given intravenously in sheep, the exotoxin causes an acute, severe intravascular hemolytic anemia.[14] The exotoxin causes alterations in the phospholipid composition of RBC membranes leading to spherostomatocyte formation and pitting of RBC membranes.[2] *C. pseudotuberculosis* causes caseous lymphadenitis in sheep and goats and other forms of abscessation; anemia in these animals is probably the anemia of inflammatory disease. Natural infections with *C. pseudotuberculosis* may not cause a hemolytic anemia due to the production of anti-toxin against the phospholipase D during early stages of the disease.

LEPTOSPIROSIS CAUSED BY *LEPTOSPIRA INTERROGANS* SEROVARS *POMONA* AND *ICTEROHAEMORRHAGIAE*

Leptospirae are saprophytic spirochetes that live in moist habitats throughout the world and infect humans, most domestic animals, and many wild animals.[16] However, in domestic animals, the hemolytic state of leptospirosis is seen primarily in calves, lambs, and pigs.[3,35] A leptospiral infection may be a cause of acute hemolytic anemias of black rhinoceros.[13] Many serovars of leptospira are reported to cause anemia in dogs, but the mechanism for the anemia is not understood.[15]

When the hemolytic state is present, the clinical signs and clinicopathologic abnormalities can include fever, depression, anorexia, anemia, hemoglobinemia, hemoglobinuria, icterus, neutrophilia, and petechial or ecchymotic hemorrhages. In experimental infections in calves, RBC fragility was increased.[26] Several explanations for the hemolytic process have been proposed; experimental evidence in lambs indicates involvement of an immunoglobulin M (IgM) cold agglutinin.[1,12]

In lambs, major necropsy lesions include hemoglobinuria, icteric membranes and tissues, severe renal tubular necrosis with casts, and periacinar hepatocellular necrosis.[11] A hemolytic anemia caused by leptospirosis is confirmed by finding leptospiral spirochetes in urine or other fluids by direct dark-field microscopic examination, culture of organisms with specific media, animal inoculation, and by serologic testing. Either enzyme-linked immunosorbent assay (ELISA) or agglutination tests can detect IgM agglutinins within 7–9 days of onset of disease.[35] Diagnosis should be based on finding at least a four-fold increase in titer to either *pomona* or *icterohaemorrhagiae* serogroups over the course of infection.

EQUINE INFECTIOUS ANEMIA (EIA) CAUSED BY THE EIA VIRUS (EIAV)

Equine infectious anemia virus occurs worldwide but infections are more prevalent in lowland swamps; thus the common name of swamp fever (see Chapters 19 and 35). The EIAV infection can produce clinical illness in horses, ponies, donkeys, and mules.

The EIAV enters the horse via insect vectors or fomites and infects cells of the mononuclear phagocyte system. The persistent viral replication in macrophages and the animal's response to the infection creates the clinical manifestations that have been put into four stages (Table 32.2).[18] When clinically ill, CBC results may detect anemia, thrombocytopenia, and either a

TABLE 32.2 Stages of Equine Infectious Anemia Infection

Stage	Clinical Signs
Acute	Acute illness may last 3–5 days, sudden fever, weakness, anemia, tachypnea, anorexia, petechial hemorrhages, thrombocytopenia, dependent edema
Subacute	Febrile episodes of several days' duration occur almost monthly[a]
Chronic	Febrile episodes at intervals of 5 months or longer; weight loss, hypergammaglobulinemia[a]
Carrier	Asymptomatic

[a]See clinical signs of acute stage when febrile.

neutropenia or neutrophilia. In the acute stage, thrombocytopenia is the most consistent hematologic abnormality and is due to both decreased platelet survival and production.[8] Either binding of complement or immune-complexes to circulating platelets causes their removal from blood by macrophages.[29] Also, concentrations of tumor necrosis factor-α, transforming growth factor-β, and interferon-α increase before the onset of the EIA thrombocytopenia, and these cytokines can suppress megakaryocytopoiesis.[37]

The EIAV infection causes anemia by decreasing RBC lifespan and decreasing RBC production.[7] During an acute stage, a horse's anemia may be accompanied by a hemoglobinemia reflecting intravascular hemolysis. The association of EIAV envelope glycoprotein with RBC membranes activates complement and causes a C3-fraction coating of RBCs and resultant hemolysis.[9] Antibody binding may be necessary for the coating of RBCs with C3;[24] infected horses may be Coombs'-positive. Morphologic changes in RBCs may include anisocytosis due to macrocytosis, Heinz bodies,[23] spherocytes (difficult to detect in equine blood), and sideroleukocytes (Fig. 32.2). The pathogenesis of the progressive non-regenerative anemia of chronic EIA is similar to the anemia of inflammatory disease (see Chapter 37).

If a horse dies during the acute stage, findings may include hemorrhages in a variety of tissues, splenomegaly, enlarged lymph nodes, subcutaneous edema, and evidence of anemia. Bone marrow and lymph node hyperplasia, hepatomegaly with hemosiderosis and necrosis, and a proliferative glomerulonephritis are reported in chronically infected horses.

The diagnosis of EIA is confirmed by finding serologic evidence of the EIAV infection. The standard test has been an agar gel immunodiffusion (AGID) assay (Coggins test) that detects precipitating antibody against the EIAV's group-specific core protein, p26. A horse may produce detectable EIAV antibodies within 12–25 days post-inoculation.[19] A competitive enzyme-linked immunosorbent assay (CELISA) is also available. Immunoblot assays for antibodies against three major EIAV antigens can be used to clarify discrepancies in either AGID or CELISA results.[19]

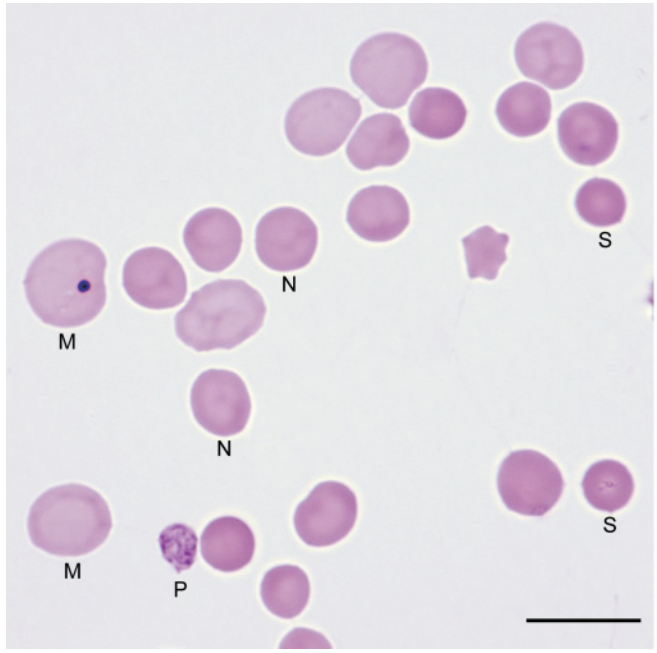

FIGURE 32.2 Blood film from a horse with acute hemolytic anemia due to EIA. The blood film contains macrocytes (M; one contains a Howell-Jolly body), two possible spherocytes (S), normocytes (N); and a platelet (P). Modified Wright stain; bar, 10μm.

Acronyms and Abbreviations

AIHA, autoimmune hemolytic anemia; ANA, antinuclear antibody; APC, antigen-presenting cell; C3, third component of complement; CD, cluster of differentiation; DAT, direct antiglobulin test; DEA, dog erythrocyte antigen; DELAT, direct enzyme-linked antiglobulin test; DIC, disseminated intravascular coagulation; Ig, immunoglobulin; IL, interleukin; IMHA, immune-mediated hemolytic anemia; IMN, immune-mediated neutropenia; IMT, immune-mediated thrombocytopenia; MHC, major histocompatibility complex; NOD, non-obese diabetic mouse; NRIMHA, nonregenerative immune-mediated hemolytic anemia; NZB, New Zealand black mouse; PCV, packed cell volume; PRCA, pure red cell aplasia; RBC, red blood cell; SLE, systemic lupus erythematosus; TNF, tumor necrosis factor.

DEFINITION AND PATHOGENESIS

Definitions

An immune-mediated hemolytic anemia (IMHA) arises when red blood cells (RBCs) (or bone marrow erythroid precursors) are destroyed via the mechanism of type II hypersensitivity, following the attachment of immunoglobulin to the cell membrane (Fig. 33.1). Antibody binding may activate the classical pathway of the complement system and result in deposition of complement components on the erythrocyte surface. If complement activation proceeds through the terminal pathway to the formation of transmembrane channels (membrane attack complexes), the RBC may be destroyed by osmotic lysis in the circulation (intravascular hemolysis). Alternatively, the surface immunoglobulin and complement may interact with Fc and complement receptors expressed by phagocytic cells (chiefly macrophages), resulting in damage to, or removal of, coated erythrocytes in extravascular sites such as the spleen or liver (extravascular hemolysis).

The terminology describing these effects must be used with care. An IMHA may be primary or secondary in nature. Secondary IMHA occurs when there is an underlying reason for the attachment of immunoglobulin to RBCs. For example, IMHA may occur as a secondary phenomenon in neoplastic disease or when antibody has specificity for an infectious agent or drug that is associated with the RBC surface. In these latter cases, the RBC destruction is due to "bystander hemolysis" as the causative antibody is not specific for the RBC itself.

By contrast, in primary idiopathic IMHA there is no underlying disease or evidence of recent drug or vaccine administration, and the antibody is considered to be a true autoantibody with specificity for a self-antigen of the RBC membrane.[16] Only this form of disease is true autoimmune hemolytic anemia (AIHA); thus, the terms IMHA and AIHA should not be used interchangeably. AIHA may occur as a single clinical entity, or may be recognized concurrently with primary autoimmune immune-mediated thrombocytopenia (IMT; the combined disease is Evans' syndrome), primary autoimmune immune-mediated neutropenia (IMN) or be part of the multisystemic autoimmune disease systemic lupus erythematosus (SLE). In some cases, the autoimmune response is directed against bone marrow

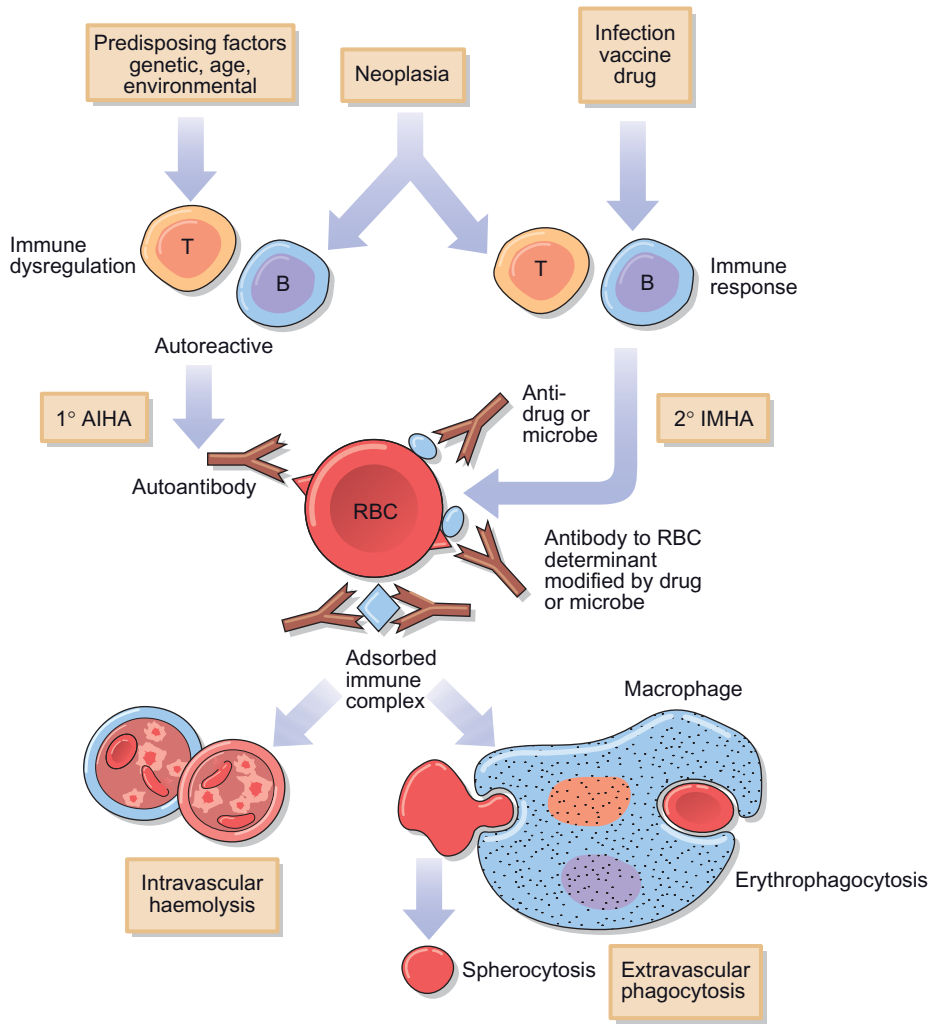

FIGURE 33.1 Pathogenesis of immune-mediated hemolytic anemia. Immune-mediated hemolytic anemia (IMHA) may be primary (autoimmune, AIHA) or secondary to a defined underlying cause. In AIHA, a series of predisposing factors interact to allow activation of self-reactive T and B cells and production of autoantibody specific for an antigen of the RBC membrane. In secondary IMHA, the erythrocyte becomes an "innocent bystander" in an immune response that is directed towards infectious agent or drug associated with the RBC membrane, or that generates immune complexes that non-specifically adsorb to the RBC surface. In either case, the RBC may be destroyed following complement fixation and formation of the "membrane attack complex" (intravascular hemolysis), or interact with phagocytic cells that express surface Fc and complement receptors. In this case the RBC may be entirely removed by erythrophagocytosis, or suffer partial loss of its cell membrane to form a spherocyte. These processes occur in the spleen or liver (extravascular hemolysis).

erythroid precursors resulting in the spectrum of change that includes both nonregenerative IMHA (NRIMHA) and acquired pure red cell aplasia (PRCA). In this group of diseases, there may or may not be autoantibodies that react with circulating RBCs in addition to the precursor population. In AIHA or NRIMHA/PRCA, erythrocyte-specific autoantibody is thought rarely to be found free in the circulation as most is bound to RBCs or precursors. The reactions to blood group antigens (blood transfusion reactions, neonatal isoerythrolysis) and the uncommon cold agglutinin disease may be considered as forms of IMHA, but these disorders are not considered in this chapter.

IMHA is one of the most common immune-mediated disorders of the dog and the majority of cases (at least in North America, Northern Europe and Australia) are currently considered to be primary AIHA.

Immunopathogenesis of AIHA

Factors underlying the development of a true autoimmune response are complex, and even now, not entirely understood. Briefly, the expression of any autoimmune disease requires that a combination of predisposing factors permits the development of an immunological alteration resulting in the observed autoimmune pathology. Such immunological alterations have been experimentally investigated using murine models of AIHA. For example, AIHA may be induced in particular inbred strains of mice that are immunized with rat RBCs,[12] or that are transgenic for high expression of interleukin (IL)-4,[22] or expression of an RBC autoantibody.[42] IL-2 deficient mice, created by targeted disruption of the IL-2 gene, develop a lymphoproliferative syndrome with multisystemic autoimmunity including Coombs'

positive hemolytic anemia.[47] New Zealand black (NZB) mice spontaneously develop autoimmunity including AIHA or a SLE-like disease characterized by immune complex glomerulonephritis and serum antinuclear antibody (ANA). The AIHA is mediated by $CD4^+$ Th1 lymphocytes that are first activated in very young mice before the appearance of autoantibodies and anemia.[51] A strain of non-obese diabetic (NOD) mice that develop autoimmune destruction of pancreatic beta cells mediated by T cells, culminating in insulin-dependent diabetes mellitus, may also develop Coombs'-positive hemolytic anemia late in life. However, the immune mediated anemia in the NOD strain may occur in both diabetic and non-diabetic mice.[4]

Activation of autoreactive lymphocytes is generally considered to reflect a failure of natural regulation (suppression) of such cells. A variety of mechanisms is involved in the control of self-reactive lymphocytes including: (1) central deletion of T cells with such specificity as part of intra-thymic development and of autoreactive B cells during development in the bone marrow, (2) peripheral deletion of self-reactive T cells upon exposure to autoantigenic peptide outside of the thymus, (3) the induction of anergy by exposure to autoantigen in the absence of delivery of co-stimulatory signals, (4) immunological ignorance due to failure to present autoantigen to the autoreactive populations, and (5) active suppression by regulatory lymphocytes. Particular advances have been made recently with respect to understanding of the last component. A population of "natural suppressor" T cells defined by expression of CD4 and CD25 is thought to be constitutively present within the immune system in order to prevent the activation of pathogenic T cells specific for autoantigen or allergen. These "Treg" cells are further defined by expression of specific genes (e.g. Foxp3, GITR) and although they secrete the immunoregulatory cytokine IL-10 are thought to require direct contact ("cognate interaction") with the target cells they intend to regulate. Treg cells have now been identified in the dog[7] and it is likely that suboptimal function of this population occurs in canine autoimmunity. Other T cell types also are known to have suppressive function. Overall, T regulatory cells are involved in dampening an immune response after they have successfully tackled invading organisms as well as keeping in check immune responses that may potentially attack one's own tissues.

It is now also believed that microbial infection is of particular importance in the induction of autoimmune diseases. Clinically normal individuals have circulating lymphocytes that are programmed to recognise self-antigens, but these cells are normally incapable of responding to autoantigens (self-tolerance). The altered immunoregulation that follows infection may permit loss of self-tolerance and the subsequent expression of autoimmune disease. For example, mice infected with a particular substrain of the lymphocytic choriomeningitis virus develop transient AIHA. In this instance the anemia is not caused by antibodies that react with a shared epitope on the virus and RBC, but by true erythrocyte-specific autoantibodies.[36] The induction of this autoimmune response is thought to be due to inappropriate activation of autoreactive T cells by virally-derived peptides that are "molecular mimics" of erythrocyte-derived peptides; these peptides would normally not be presented by the antigen presenting cells (APCs) of the immune system and thus, autoreactive T cells are maintained in a state of "immunological ignorance".

Factors Predisposing to Canine AIHA

A number of factors predisposing to the development of AIHA are defined in the dog. There is a strong genetic influence suggested by the greater prevalence of the disease in particular breeds (e.g. Old English Sheepdog, Cocker Spaniel, Border Collie, Poodle, English Springer Spaniel, Irish Setter, Miniature Schnauzer) and within particular pedigrees.[13,18,19,58] Recent investigations have revealed associations with allotypes and haplotypes of genes of the major histocompatibility complex (MHC), which are strongest when specific breed groups (e.g. Cocker and English Springer Spaniels) are considered.[31] Some MHC haplotypes increase susceptibility to IMHA, whereas others appear to confer protection. Current studies are investigating broader genomic associations in dogs of these breeds (LJ Kennedy and MJ Day, unpublished data). One report has suggested that expression of the blood group antigen DEA7 in Cocker Spaniel dogs reduces susceptibility to IMHA.[40]

Canine AIHA is generally a disease of middle age (6–8 years). Although there is no clear gender predisposition, the disease can be precipitated in bitches by the stress of whelping or oestrus. A seasonal incidence also has been proposed for canine AIHA; however, this is not consistent between different studies and may in fact be related to the prevalence of underlying infections, or timing of vaccinations (Fig. 33.2).[21,32,58]

Immunopathogenesis of Canine AIHA

A series of investigations has revealed many parallels between canine AIHA and the disease in humans and experimental rodent models. The autoantibodies that characterize the canine disease are heterogeneous in their class and specificity, suggesting that a range of different underlying mechanisms may be involved in triggering the disease. Both IgM and IgG autoantibodies are found, and particular subclasses (IgG1 and IgG4) dominate the IgG response.[14] Significant quantities of IgA may also be associated with the erythrocyte membrane in AIHA, but the presence of this immunoglobulin is of questionable relevance. The specificity of the IgG autoantibodies has been characterized by eluting them from the surface of patient RBCs and incubating them with biotin-labeled normal canine RBC in the technique of immunoprecipitation.[2,15] These autoantibodies are directed against various components including erythrocyte membrane glycophorins, the anion exchange molecule (band 3) and the cytoskeletal molecule spectrin (Fig. 33.3).

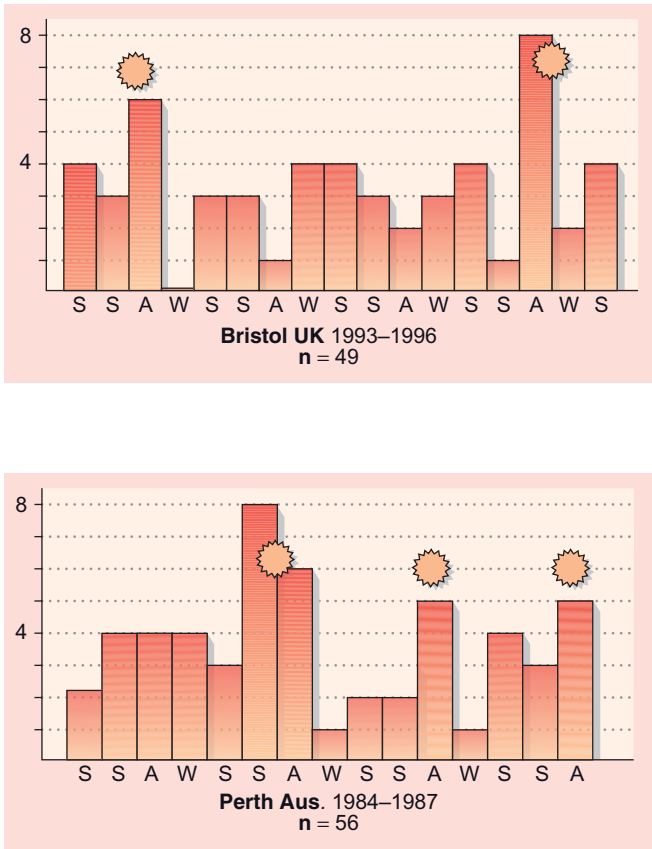

FIGURE 33.2 Seasonal distribution of cases of canine IMHA. Data are presented from the Northern (United Kingdom) and Southern (Australia) Hemispheres. The number of cases in each season (Spring, Summer, Autumn, Winter; SSAW) over a 3-year period are shown. Although there is a spread of cases, peaks (stars) are noted in some autumn periods and one Southern Hemisphere summer. Interpretation of such data is difficult, but may reflect seasonal infections or annual cycles of administration of vaccines.

T cell reactivity in canine AIHA has also been examined. Like other species, clinically normal dogs harbour RBC-reactive lymphocytes that can be induced to proliferate in vitro when challenged with RBC-derived antigens. Such cells have a greater degree of reactivity when they are obtained from dogs recovered from AIHA (memory lymphocytes) or from normal dogs that are closely related to AIHA cases.[11] The latter observation suggests an immunological mechanism for genetic susceptibility to AIHA in dogs. It is important to further investigate the fine specificity of such autoimmune responses, as this knowledge will form the basis for developing novel immunotherapeutic agents in future years.

Secondary IMHA in the Dog

There are numerous triggers for secondary IMHA in dogs. Before considering a diagnosis of AIHA, attempts should be made to rule out underlying disorders that are known to precipitate secondary IMHA.

Neoplastic disease is one such trigger, and associations between IMHA and lymphoma, myeloproliferative disease, anaplastic sarcoma, and hemangiosarcoma are well documented.[30,37] The immunological mechanisms whereby neoplasia might trigger the production of RBC-reactive antibodies are not understood.

A trigger for IMHA of increasing importance is infectious disease. In particular, the canine arthropod-transmitted infectious diseases (babesiosis, ehrlichiosis, leishmaniosis, rickettsioses, and possibly anaplasmosis and bartonellosis) may all include IMHA as one part of their complex pathogenesis.[6,26,50] These organisms establish a unique interaction with the host immune system that may result in a range of secondary immune-mediated phenomena not directly associated with the infection per se.[50] Although IMHA triggered by such

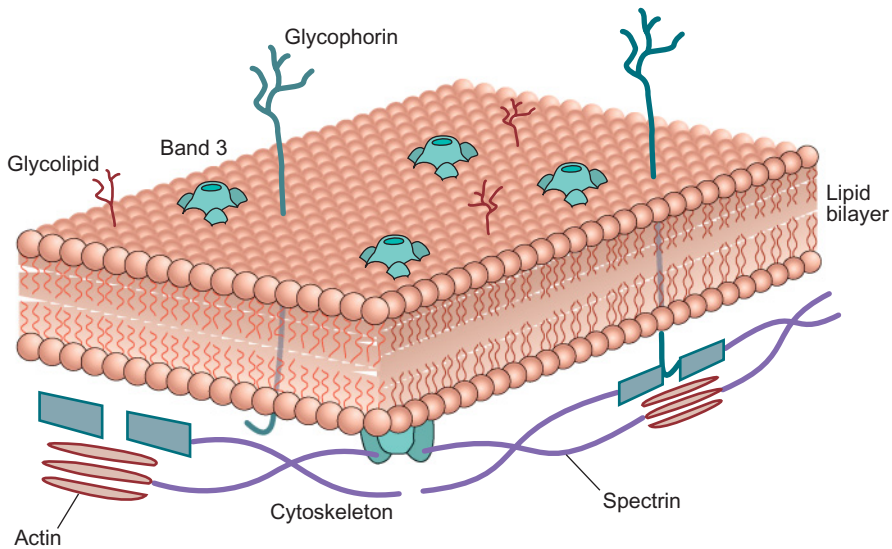

FIGURE 33.3 A schematic diagram of the RBC membrane showing the major target autoantigens in canine AIHA: the glycophorins, the anion exchange molecule (band 3) and the cytoskeletal molecule spectrin. There is conservation of some of these autoantigens across species. Band 3 may be recognized in dogs and humans with AIHA, and is the target of the autoimmune response in some experimental mouse models of the disease.

infection has been long recognized in traditionally endemic areas, recent increases in international pet animal movement, together with the background of climate change, means that these infectious diseases must now be considered in non-endemic geographical regions. The travel history of any dog presenting with anemia must be considered, and practitioners should remain updated on the progressive spread of these organisms and their vectors. There are now a number of documented instances of geographical extension of the canine arthropod-borne infections, for example the spread of leishmaniasis throughout the North American foxhound population,[20] and spread of babesiosis into northern European countries.[5,34] Recent interest has been expressed in the potential for hemoplasmas to trigger IMHA in the dog.[28,62] A single, small study of dogs with IMHA failed to detect bacteremia by blood culture as a potential trigger for the disease.[40]

A further well-documented trigger for canine IMHA is drug therapy. Classically the potentiated sulphonamide drugs are incriminated in a wide range of breeds[55] and one experimental instance of cephalosporin-associated immune cytopenia has been documented.[8] A single case study of carprofen-associated immune-mediated blood dyscrasia is reported.[38]

The most controversial association is that proposed between the development of canine IMHA and vaccination in the immediately preceding 4-week period.[17] Anecdotal evidence for this association has been available for some time;[18] however, a pivotal study by Duval and Giger[21] provided evidence for a temporal relationship of vaccine-associated IMHA in the dog. A large epidemiologic survey that was subsequently conducted in the United Kingdom failed to support these findings. In this study, there was no clear evidence that dogs with Coombs'-positive AIHA were more likely to have been recently vaccinated.[1]

Overall, it appears that vaccine-associated IMHA does occur in dogs but with low incidence. The report of the United Kingdom Veterinary Products Committee provided specific data from a pharmacovigilence database which suggested that vaccine-associated IMHA was a relatively rare occurrence (incidence of 0.001 per 10,000 doses of vaccine sold).[24] The immunological mechanisms by which these reactions develop are not understood and no particular vaccine has been implicated.

Nonregenerative IMHA in the Dog

The immune response in dogs with IMHA may sometimes target the bone marrow erythroid precursors instead of, or in addition to, circulating RBCs. In this instance the bone marrow will fail to develop a regenerative response. Examination of the bone marrow becomes an essential component of the diagnostic work-up in animals with IMHA that do not have reticulocytosis after 5 days. A spectrum of such change is recognized and classified in different ways. Some reports distinguish the situation where there is impaired erythropoiesis but erythroid precursors are present (NRIMHA), to that where there is virtual absence of erythropoiesis (acquired PRCA; see Chapter 38).[53] In NRIMHA the erythroid lineage may display either hyperplasia or maturation arrest at a specific point of the developmental lineage.[25]

The diagnostic process in PRCA is similar to that described below, but affected dogs may be Coombs'-negative if the causative antibody that targets marrow precursors does not cross-react with antigens expressed by mature RBCs. In a retrospective study investigating nonregenerative IMHA in the dog, the Coombs' test was positive in 57%; 23% of these patients also tested positive for ANA.[53] There is no diagnostic test for the detection of precursor-associated antibody or complement, although the serum of such dogs has been shown to contain antibody that can inhibit erythropoiesis in vitro.[59]

A range of bone marrow pathology has recently been described in dogs with PRCA, suggesting that the hemopoietic impairment involves changes in addition to antibody-mediated inhibition of erythropoiesis.[60] These reported changes include: dysmyelopoiesis, myelonecrosis, myelofibrosis, interstitial edema, hemorrhage, acute inflammation, hemophagocytic syndrome, lymphoid aggregation or plasma cell hyperplasia. These changes were more often present in the marrow of animals with NRIMHA with erythroid hyperplasia, than those with NRIMHA with maturation arrest, or in PRCA. The former subgroup of dogs also had reduced survival time compared with the two latter subgroups.

CLINICAL PRESENTATION

There are two main clinical presentations of canine IMHA. That most commonly recognized has a chronic onset (days to weeks) and is characterized by signs referable to anemia, erythrophagocytosis and immunological activity:

- weakness
- lethargy, exercise intolerance
- anorexia
- pyrexia
- pallor of mucous membranes
- tachypnoea, tachycardia
- hepatosplenomegaly
- lymphadenomegaly.

Acute onset (1–2 days) IMHA is less commonly recorded and is associated with:

- severe intravascular hemolysis with jaundice, hemoglobinemia and hemoglobinuria
- pyrexia
- vomiting.

A proportion of dogs with IMHA will subsequently develop disseminated intravascular coagulopathy (DIC) or dyspnea due to pulmonary thromboembolism.[29,33] Thromboembolic disease may affect the spleen, kidneys, heart and lymph nodes in addition to the

lung.[58] Risk factors for development of these complications are reported as hyperbilirubinemia, a negative Coombs' test, elevated serum alkaline phosphatase, hypoalbuminaemia, cage confinement, recumbency and the presence of indwelling catheters.[10,29,58] These complications arise following development of venous stasis, endothelial damage and a hypercoagulable state. It has been suggested that this effect may in part be associated with the presence of an anti-phospholipid antibody that enhances platelet aggregation and depresses regulation of the coagulation pathways.[52] However, in a recent case series only two of 20 dogs had evidence of anti-phospholipid activity.[49]

DIAGNOSIS

The diagnosis of IMHA proceeds through a series of laboratory tests after identification of compatible clinical history and presenting signs. An EDTA-anticoagulated blood sample should be collected for hematological examination. This should be examined for the phenomenon of autoagglutination that may be observed by rotating the collection tube, or by placing a drop of blood on a microscope slide. Autoagglutination may only occur at 4 °C, so blood should be refrigerated before making this assessment. True autoagglutination may be grossly distinguished from rouleaux formation by adding an equal volume of saline to the drop of blood. Rouleaux will be dispersed by this procedure but agglutination will persist. It is often said that a positive "in-saline slide autoagglutination test" provides definitive evidence for IMHA and precludes the need for a Coombs' test. However, as described below, the Coombs' test can provide additional valuable information and should always be requested where possible.

Standard hematological examination will demonstrate the features of anemia. Canine IMHA is often a severe disease with a packed cell volume (PCV) of less than 20%. The anemia is classically regenerative (see nonregenerative disease below) with reticulocytosis, polychromasia, anisocytosis, and nucleated RBCs as consistent features (Fig. 33.4). The absence of a regenerative response after 5 days suggests the possibility of bone marrow disease and warrants collection of a bone marrow aspirate and core biopsy. Microscopic evidence of autoagglutination may be found and the presence of significant numbers of spherocytes is strongly suggestive of immune-mediated RBC damage. IMHA is often accompanied by pronounced neutrophilia and left shift. The mechanism by which this arises is thought to involve tissue necrosis and the effect of pro-inflammatory cytokine (e.g. IL-1, IL-6 and TNF-α) production by activated macrophages on granulopoiesis. Platelet numbers will be adequate in primary AIHA, but significant reduction in platelet count may indicate concurrent IMT, thromboembolism or DIC. Dogs with IMHA may have a range of hemostatic abnormalities including prolonged prothrombin time and activated partial thromboplastin time, elevation of fibrin degradation products, elevation in D-dimer, and decrease in anti-thrombin activity.[10,49] Activation of circulating platelets as assessed by increased expression of membrane P-selectin is also reported.[61]

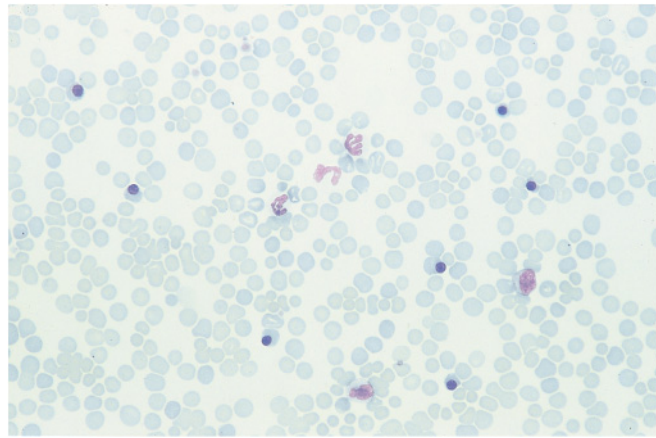

FIGURE 33.4 Blood smear from a dog with AIHA demonstrating the features of anisocytosis, polychromasia, spherocytosis and the presence of nucleated RBCs.

In the presence of clinical and hematological evidence for IMHA, the definitive diagnostic procedure is the Coombs' test (direct antiglobulin test, DAT) (Fig. 33.5). This test will demonstrate the presence of erythrocyte-bound immunoglobulin and/or complement, but does not distinguish between AIHA and secondary IMHA. The Coombs' test is performed with EDTA blood and there will be variation in the methodology used by different laboratories (see Chapter 140). A full Coombs' test will be performed using a polyvalent Coombs' reagent (that recognizes IgG, IgM and complement C3), but also with antisera specific for each of these immunoreactants alone. The read-out for the test is erythrocyte agglutination, and the titer of each positive reaction should be determined. The incidence of false negative reactions is greatly reduced when the full test is performed in this manner. Recent studies have shown that when the test is only performed using polyvalent reagent at 37 °C a proportion of dogs with IMHA will be falsely Coombs' negative.[43,57]

In general terms, two broad patterns of Coombs' reactivity are identified and these have some correlation with clinical presentation.[57] The most commonly recorded pattern involves an IgG antibody that may be present with IgM and/or C3, and that reacts equally at 4 °C and 37 °C. This pattern frequently correlates with disease of chronic onset and is compatible with extravascular RBC removal. Occasionally, a cold-reactive IgM antibody is identified that may fix complement and occurs in the absence of IgG. Such cold-agglutinating IgM antibodies generally elute from the surface of the RBCs at physiological temperature. The clinical significance of these antibodies is often debated, but this pattern of Coombs' reactivity is more often associated with sample autoagglutination, intravascular hemolysis and acute onset, severe clinical disease. A recent study also suggests that cold-reactive IgM antibodies may more frequently associate with secondary IMHA.[57]

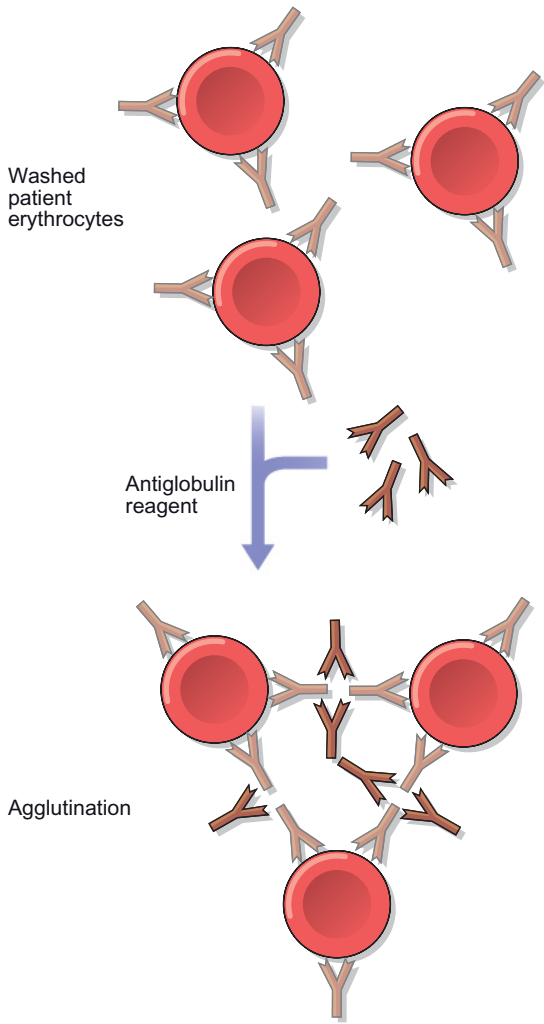

FIGURE 33.5 Principle of the Coombs' test. A suspension of washed patient RBCs with membrane immunoglobulin or complement attached in vivo, is incubated with an antiglobulin reagent that cross-links these immunoreactants, forming a lattice that appears grossly as an agglutinate of RBCs.

Such cold agglutinins may be pathogenic, rather than simply an in vitro phenomenon, if their thermal reactivity extends to the sub-physiological range. The clear example of clinical relevance of these antibodies is in the relatively rare "cold agglutinin disease", where IgM hemagglutinins result in the formation of microthrombi that occlude peripheral capillaries in the skin of the ear and tail tip. Predisposed patients will therefore develop necrosis of these sites when inadvertently exposed to freezing temperatures. There is no clear association between the titer of RBC-bound antibody and disease severity. Although low-titers or the presence of complement alone on the RBC surface are often thought to be more consistent with secondary IMHA than AIHA, a recent study has not confirmed this.[57]

The Coombs' test remains the "gold standard" for diagnosis of IMHA; however, other tests are reported. The indirect Coombs' test (for detection of circulating autoantibody by incubation with normal erythrocytes) is not considered valid for use in veterinary species due to the low prevalence of non cell-bound autoantibody.[56] A cell-ELISA based method (DELAT) has been described, but is a time consuming procedure and is largely used as a research tool.[3] Recent studies have demonstrated the utility of flow cytometry for detection of RBC-bound antibody. Flow cytometric testing has good sensitivity and specificity when compared to the Coombs' test, but is limited by availability of this equipment.[45,63]

A recent innovation is the development of a tube-based test designed for in-practice use.[56] This rapid assay involves the use of polyvalent reagent and gives a simple positive or negative outcome, and validation studies show good agreement with the more definitive Coombs' test (MJ Day, unpublished data).

Other immunodiagnostic procedures may be positive in dogs with IMHA. Some cases are reported to have significant serum titers of ANAs. In the series presented by Weinkle et al.[58] 39% of dogs with IMHA had a serum ANA titer >80. In the presence of concurrent thrombocytopenia, tests for platelet autoantibody should be requested, although this is not routinely possible in many areas of the world. Adjunct immunodiagnostic tests such as determination of serum complement concentration (decreased levels of C3 or C4 may reflect deposition on RBC membranes) or serum IgA concentration (IgA deficiency may be associated with canine autoimmunity) may be requested.[54,56]

THERAPY

Management of canine IMHA is dependent on whether the disease is primary or secondary in nature, the latter necessitating appropriate therapy for any underlying infectious or neoplastic trigger. The first line approach to therapy for canine idiopathic IMHA involves the use of tapered immunosuppressive doses of glucocorticoids (e.g. prednisolone commencing at 2–4 mg/kg daily). In dogs with severe, acute-onset intravascular hemolysis, or with nonregenerative IMHA, or with anemia that is non-responsive to glucocorticoid, the addition of cytotoxic agents (e.g. cyclophosphamide 50 mg/m^2 orally for the first 4 days of each week for 4–5 months only; azathioprine commencing at 2 mg/kg daily) to the regime is indicated. Recent studies have questioned the efficacy of adjunctive cyclophosphamide in therapy for AIHA and suggested that in fact this combination may worsen disease outcome. For this reason cyclophosphamide adjunct therapy has now largely fallen out of favour.[9,27,35] Where a standard combination immunosuppressive protocol of prednisolone and azathioprine was used in one large case series, effective control was reported with 3 months duration of treatment in the majority of dogs.[44]

In severely anemic dogs (PCV < 10%), supportive therapy in the form of cross-matched whole blood or packed RBC transfusion may be required. The benefits

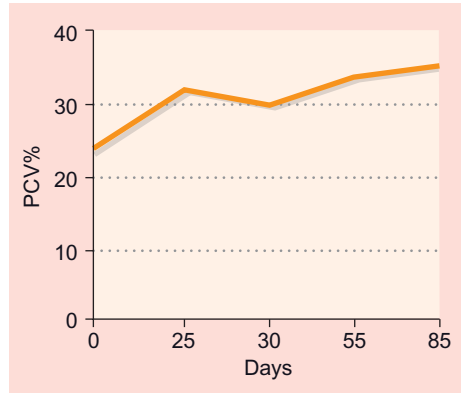
of transfusion in providing short-term oxygen carrying capacity outweigh any possibility of enhancing hemolysis by providing greater antigenic load. The use of polymerized bovine hemoglobin has also been investigated but some studies suggest this may contribute to poor clinical outcome[27] although this finding is not corroborated by others.[58] A number of other adjuncts to glucocorticotherapy are documented. The use of danazol (5 mg/kg orally twice daily) is controversial as recent studies have suggested that this drug may have little beneficial effect.[27,39] Similarly, combination therapy with glucocorticoid and ciclosporin (5 mg/kg daily) appears to provide no greater benefit than glucocorticoid monotherapy.[27] The use of intravenous human gammaglobulin (0.5–1.5 g/kg given over 4 hours), to block macrophage Fc receptors or bind circulating autoantibody, is of documented benefit, but an expensive undertaking.[48] There is no consistent evidence that splenectomy (to remove a major site of extravascular hemolysis and autoantibody production) has any beneficial effect, although occasional early reports proposed this procedure.[23] In dogs with acute, severe AIHA the use of prophylactic heparin or ultra-low dose aspirin treatment to prevent the complications of DIC or pulmonary thromboembolism is advocated. A number of such prophylactic regimes are described.[58]

OUTCOME

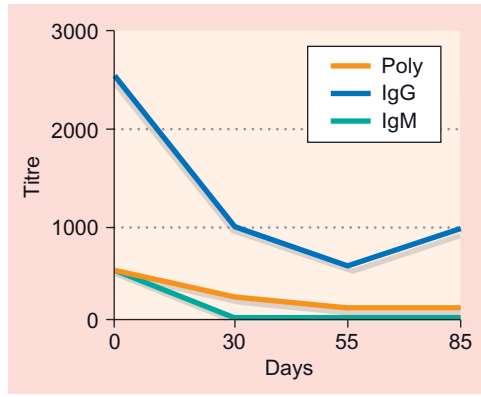
Recent studies have evaluated clinical outcome in canine IMHA.[44,46,58] It is clear that canine IMHA must be regarded as a severe disease, as in the referral setting, around 50% of animals will die during initial hospitalization. Death is more likely to occur in patients with secondary or acute onset disease.[41,57] Factors associated with reduced survival in the large case series of Weinkle et al.[58] included:

- autoagglutination
- high serum bilirubin (>15.0 µmol/L)
- left shift neutrophilia (bands ≥3.0 × 10^9/L)
- thrombocytopenia (platelets <150 × 10^9/L)
- hypoalbuminaemia (serum albumin <30.0 g/L)
- hypokalemia (serum potassium <3.5 mmol/L)
- elevated serum creatine kinase (>250 U/L).

By contrast, some dogs with IMHA may make excellent recovery with appropriate supportive and immunosuppressive therapy, but remain at risk for disease relapse. There is often very rapid clinical and hematological response to therapy in such patients; however, serial monitoring of the Coombs' test has revealed striking persistence (for many months) of RBC-bound autoantibody in many cases (Fig. 33.6).[15] Relapses may occur months or years after the initial episode, and are often more severe, resulting in death. The median survival time in most studies is just over 1 year, but in one large case series, approximately 25% of patients had excellent long-term survival.[58] Other manifestations of autoimmunity may surface in dogs recovered from



A



B

FIGURE 33.6 Serial monitoring of IMHA in a dog with IMHA. The dog was treated with prednisolone at an initial dose of 2 mg/kg daily that was gradually tapered and withdrawn on day 76. Despite the rise and plateau in packed cell volume (**A**), the dog remained Coombs'-positive throughout the period of monitoring (**B**). In **B**, serial titres obtained using polyvalent canine Coombs' reagent, anti-dog IgG and anti-dog IgM are shown. (Adapted from Day MJ. Serial monitoring of clinical, haematological and immunological parameters in canine autoimmune haemolytic anaemia. J Small Anim Pract 1996;37:523–534, with permission).

IMHA, sometimes several years later. For example, dogs may present with IMT (and no anemia) subsequent to IMHA (without thrombocytopenia). SLE and immune-mediated skin disease are also reported sequels.

Therefore, recovery from IMHA necessitates regular monitoring for the life of the patient. Hematological monitoring is the most cost-effective means; it is recommended that a PCV be performed every 2 weeks throughout the course of treatment, extending for 6–12 months after withdrawal of therapy. In dogs recovered from IMHA associated with vaccination, care should be taken with administration of subsequent booster vaccines. A risk-benefit analysis should be conducted in consultation with the client. Measurement of serum antibody titre to core virus components may be performed to support any decision not to re-vaccinate, but

where re-vaccination is required, use of a product from a different manufacturer and a product with the longest possible duration of immunity is advised. There is, however, little clear evidence that booster vaccination induces relapse of disease or disease of greater severity; such studies remain to be performed.

Acronyms and Abbreviations

C3, complement component 3; Fc, fragment crystallizable region of the immunoglobulin heavy; chain FeLV, feline leukemia virus; Hct, hematocrit; IFN-γ, interferon-γ; IgG, immunoglobulin G; IL-10, interleukin 10; IgM, immunoglobulin M; IMHA, immune-mediated hemolytic anemia; MHC, major histocompatibility; PRCA, pure red cell aplasia; PTU, propylthiouracil; RBC, red blood cell; T, T helper cell; Tr, regulatory T helper cell.

Immune-mediated hemolytic anemia (IMHA) is an uncommon hematological disorder in cats. IMHA is usually caused by the binding of antibodies to mature red blood cell (RBC) membranes, causing their accelerated and premature removal from the circulation by mononuclear phagocytes. In some cases, the immune attack is thought to be directed against erythroid progenitors in the marrow, resulting in a nonregenerative anemia from ineffective erythropoiesis or pure red cell aplasia (PRCA).[46,51] If the initiating cause of IMHA is unknown, the disease is called primary or idiopathic (this condition has also been termed autoimmune hemolytic anemia; see Chapter 33). When IMHA is initiated by an underlying disease (e.g. infectious agents, neoplasia) or drugs, it is called secondary IMHA. Hemolytic transfusion reactions and neonatal isoerythrolysis are also immune-mediated conditions, caused by blood group incompatibilities.

Pathogenesis

IMHA is considered a type II immune complex hypersensitivity reaction, in which there is a failure of self-tolerance.[5] Antibodies, usually IgM or IgG, react with antigens in the RBC membrane. Once the antibodies bind to RBCs in the circulation, they can activate complement. RBCs are then destroyed through Fc- and complement-receptor-mediated phagocytosis by macrophages in the spleen (primarily), liver and bone marrow (i.e. extravascular hemolysis) and/or through direct complement-mediated lysis (i.e. intravascular hemolysis) (Fig. 34.1). In cats, hemolysis is primarily extravascular, with many cats displaying autoagglutination of RBCs.[32,44,56] Intravascular hemolysis, with hemoglobinemia and hemoglobinuria, is rare and usually secondary to exposure to incompatible RBC blood types.[4,24]

Substantial progress has been made in the understanding of the basic pathogenesis of classic IgG-mediated IMHA from studies in humans and genetically-modified mice. Antibody production in IgG-mediated IMHA is a T helper (specifically Th1) cell-dependent phenomenon. It is now thought that IMHA results from the proliferation of auto-reactive Th1 cells (perhaps through unmasking of a cryptic antigen or more efficient processing and presentation of RBC antigens by dendritic cells) combined with suppression of T regulatory cells (Tr), which normally inhibit auto-reactive Th1 cells (Fig. 34.1).[5] The underlying mechanisms responsible for altered antigen processing or unmasking of cryptic antigens are unknown. Antigens that induce IMHA can be intrinsic to the RBC ("self" antigens) or can be foreign proteins (e.g. drugs or infectious agents) that bind to or modify RBCs, rendering them antigenic, or that potentially express similar antigenic determinants to RBCs. Specific RBC antigens responsible for IMHA in cats have not been identified.

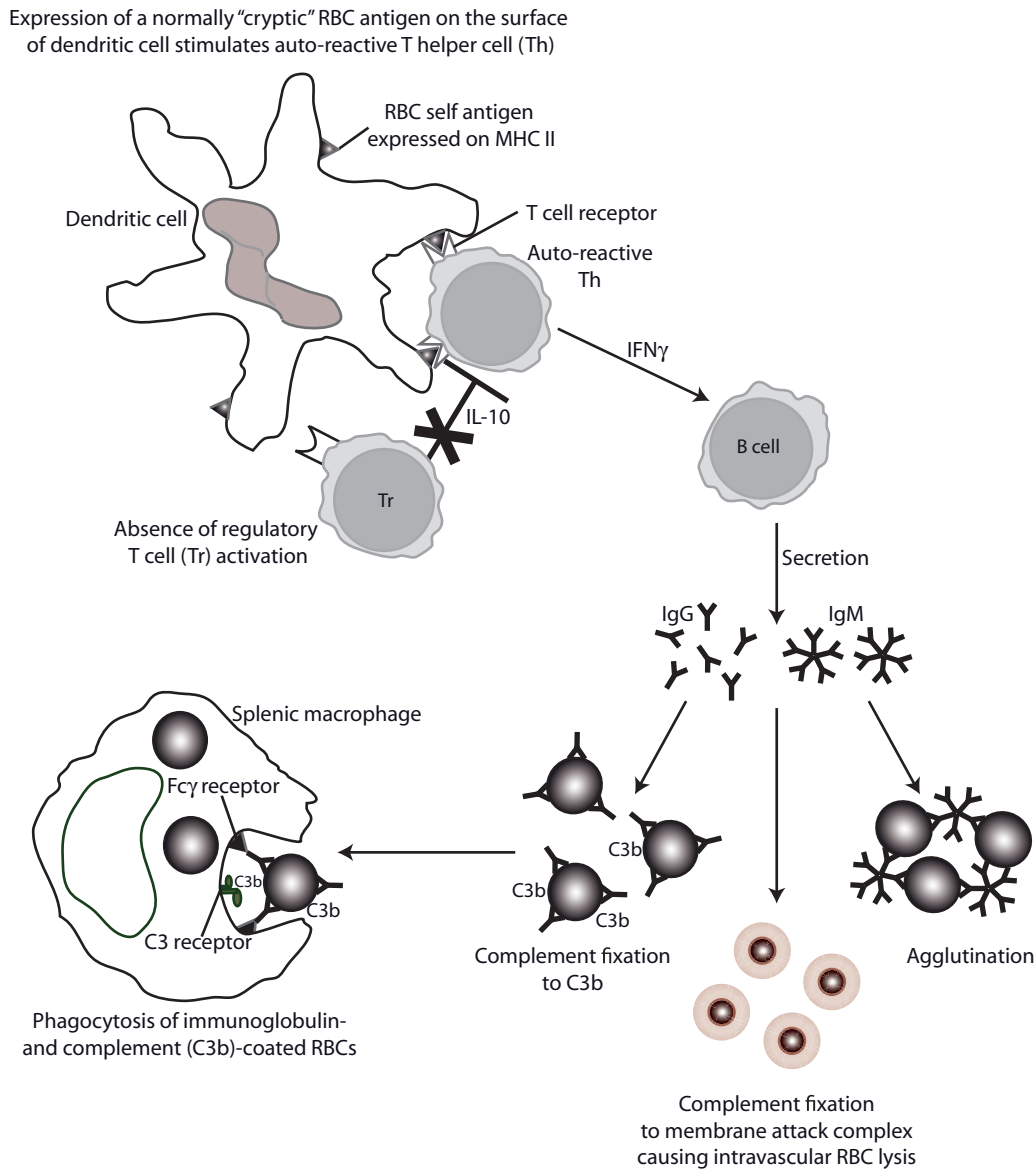

FIGURE 34.1 A self-RBC antigen (which is normally inefficiently or not processed) is expressed on the surface of a dendritic cell or other antigen-presenting cells in conjunction with major histocompatibility type II (MHC II) proteins. The self-RBC antigen and MHC II (not shown) are recognized by T cells and co-stimulatory receptors (not shown) on auto-reactive T helper cells. Concurrently, regulatory T cells (which normally keep the immune system in check through secretion of interleukin-10 [IL-10]) are suppressed, leading to uncontrolled proliferation of auto-reactive T helper cells. These T helper cells activate B cells, via a Th1-driven response (through secretion of IFNγ). B cells secrete immunoglobulins (IgM and/or IgG) that specifically recognize the RBC self-antigen. Activation of complement (by IgM or certain classes of IgG), through the classical pathway, leads to the binding of C3b on RBCs. Macrophages in the spleen, liver and bone marrow recognize the Fc portion of immunoglobulin and bound C3b through specific receptors and remove the immunoglobulin- and C3b-coated RBCs prematurely from the circulation. Efficient complement-fixing antibodies can result in the formation of the membrane attack complex of complement (C6-9) on RBCs, causing them to lyse intravascularly. Alternative mechanisms by which Th1 cells can be activated are processing of a foreign peptide that cross-reacts with RBC antigens or microbial superantigens that cause hyper-stimulation of the immune system.

T cell dysregulation also likely underlies nonregenerative variants of IMHA, including PRCA,[21] although there is no definitive proof for this in cats. In nonregenerative IMHA, the inciting RBC antigen is expressed exclusively or concurrently on RBC progenitor cells,[12,22] resulting in their intramedullary destruction. Also, antibodies that target erythropoietin can result in PRCA.[18,21] Although the focus on IMHA pathogenesis has been on antibody-mediated destruction of RBCs, cell-mediated immune mechanisms may also be operative, particularly in nonregenerative forms of IMHA, such as PRCA.[21] Cytotoxic T and natural killer cells (granular lymphocytes) can directly kill (in an antibody-dependent or -independent fashon) RBC progenitor cells through direct lysis or apoptosis. Indeed, cell-mediated cytotoxicity is thought to be responsible for some cases

of acquired PRCA in humans associated with neoplastic or non-neoplastic expansions of these lymphocytes.[21] Alternatively, activated T cells or macrophages can suppress rubriblast proliferation through secretion of inhibitory cytokines, such as interferon-γ (IFNγ) and tumor necrosis factor-α.[17,21]

Clinical Signs

Clinical signs in cats with primary and secondary IMHA are primarily attributable to the anemia and consist mostly of lethargy and inappetence. Some cats also suffer from vomition, pica, constipation or obstipation, and polydipsia.[32,44,46,56] On physical examination, cats have mucous membrane pallor and are usually afebrile, with heart murmurs secondary to anemia. Some cats have mild organomegaly (mostly affecting the spleen) or icterus.[32,44] Cats with secondary IMHA may display additional clinical signs related to the underlying primary disease.

Diagnosis

Because clinical signs and physical examination findings are not specific, the diagnosis of IMHA (primary or secondary) relies on confirming an immune-mediated pathogenesis for the anemia. This is accomplished by identifying autoagglutination, documenting positive immunologic testing (specifically a positive direct Coombs' test), or a favorable response to immunosuppressive therapy. Spherocytes, which are sensitive indicators of IMHA in dogs,[16,49] are difficult to identify in cats, due to their small RBCs which normally lack central pallor.

Autoagglutination of whole blood is seen in many cats with IMHA.[32,44,51,56] However, RBC rouleaux formation (secondary to increased fibrinogen and/or immunoglobulins) can mimic agglutination and it is important to confirm grossly visible agglutination on diluted whole blood or washed RBCs. Typically a 1:4 dilution of whole blood with isotonic or phosphate-buffered saline or washing of RBCs should disperse rouleaux, whereas agglutination persists.[56] However, weak avidity antibodies may be eluted from RBCs during dilution, resulting in a false negative agglutination reaction. Agglutination should ideally be confirmed by microscopic examination of the sample, where agglutinated clumps of RBCs can usually be distinguished from rouleaux. Agglutination is typically considered prima facie evidence of IMHA; however, it can rarely be observed as an artifact secondary to EDTA-associated binding of a non-pathogenic antibody to RBCs.[42]

Because most pathogenic antibodies are warm-reacting IgG, a direct Coombs' test (performed at 37 °C) is frequently positive in cats with primary or secondary IMHA.[13,32,35,40,44,51,56] However, if low numbers or weak avidity antibodies are attached to RBCs or antibodies only recognize epitopes expressed on RBC progenitor cells, the direct Coombs' test may be negative, as reported for up to 50% of cats with nonregenerative IMHA.[2,46] Direct Coombs' testing at 4 °C is not recommended, since RBCs from healthy cats can yield a positive reaction due to the existence of non-pathogenic cold-reactive antibodies.[20,29]

In the absence of autoagglutination or a positive direct Coombs' test, the diagnosis of IMHA depends on a positive response to immunosuppressive therapy. This approach has been used to diagnose cases of primary and secondary IMHA in cats.[33,46,57]

Treatment

Primary IMHA is treated with immunosuppressive drugs, typically corticosteroids. Other immunosuppressive agents (e.g. cyclosporin, intravenous IgG) may be added if the anemia remains non-responsive. Adjunctive supportive therapy, including blood transfusions and gastroprotective drugs, is often required. Most cats develop a regenerative response (increase in aggregate reticulocytes or increases in hematocrit [Hct]) within 1 month of treatment. Relapses can occur when immunosuppressive therapy is tapered, particularly if done abruptly or rapidly. The prognosis with primary IMHA is good, with >60% of cats surviving for several months to years after diagnosis. The regeneration status does not appear to influence the response to treatment.[2,31,32,46,57] Cats with secondary IMHA should be treated for the underlying disease. This alone (particularly in the case of drug-induced IMHA) may result in resolution of the hemolytic process and the anemia; however, additional corticosteroid therapy may be required.[3,8,18,40,41,44]

PRIMARY IMHA

Primary IMHA is defined as an immune-mediated anemia of unknown cause; therefore, it is a diagnosis of exclusion. It is an uncommon disease in cats, with only three published retrospective case series of 9–57 affected cats in a 6–10 year period,[32,46,51] and two abstracts of 25–36 affected cats over a 10–18 year period.[2,31] In three of these studies,[31,32,51] the diagnosis of IMHA was made on the basis of autoagglutination and/or a positive direct Coombs' test without evidence of underlying disease in anemic cats. In one study on PRCA, the diagnosis was primarily based on response to immunosuppressive therapy.[46] Two other retrospective studies of 7 and 21 cats consisted mostly of cats with secondary IMHA, with only 14–28% likely having primary IMHA.[44,56] The diagnosis in these latter two studies was accomplished by direct Coombs' testing or autoagglutination. Although the occurrence of primary IMHA may be quite low as indicated by the paucity of reports, the reliance on a positive direct Coombs' test or autoagglutination for diagnosis may cause the true disease incidence to be underestimated. Since these tests are not 100% sensitive for IMHA in other species,[49] it is unlikely that all cases of feline primary IMHA will have positive results, particularly the nonregenerative variants.

Primary IMHA is typically considered to result in a regenerative hemolytic anemia (with concurrent

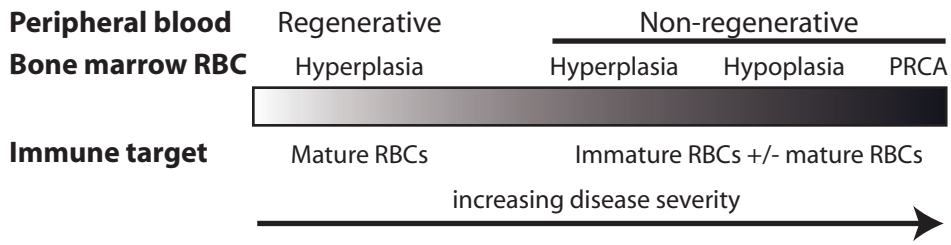

FIGURE 34.2 IMHA forms a continuous spectrum of disease, ranging from the classical presentation of a regenerative anemia with erythroid hyperplasia in the bone marrow to the most severe clinical manifestation, a nonregenerative anemia due to the lack of RBC progenitors in the bone marrow (i.e. pure red cell aplasia). IMHA can also present between these two extremes as either a weakly regenerative anemia or a nonregenerative anemia associated with bone marrow erythroid hyperplasia or hypoplasia.

erythroid hyperplasia in the bone marrow); however, the anemia may be nonregenerative.[2,32,36,46,51,57] In one study, the anemia was nonregenerative in 58% of 19 cats with primary IMHA.[32] Lack of regeneration may be due to duration, disease severity, presence of concomitant disease, or antigen specificity (Fig. 34.2). If the bone marrow has had sufficient time to respond (i.e. the anemia has been present for >5 days), the absence of regeneration has been attributed to ineffective erythropoiesis or PRCA (see below).[46,51] These two bone marrow conditions appear to occur with similar frequency in cats with nonregenerative IMHA.[2,51] Since bone marrow aspirates were not done in the 19 cats of one report[32] and some cats had been sick for <5 days, the cause of the nonregenerative nature of the anemia in these cats is uncertain.

Regardless of the form of primary IMHA (regenerative or nonregenerative), the disorder occurs mostly in young (<3 years), domestic shorthair cats of both sexes. The anemia is usually normocytic, normochromic, and severe (Hct < 20%).[2,32,36,46,51,57] Leukocyte and differential cell counts are usually within reference limits, although some cats can have a concurrent neutropenia or lymphocytosis.[2,31,32,51] Thrombocytopenia has been identified in several cats.[2,31,32,51,57] Thrombocytopenia and neutropenia are more frequently seen in cats affected with ineffective erythropoiesis than those with PRCA.[46,51] Some cats (30% of 10 tested cats) in one study had prolonged screening coagulation times and were suspected or clinically diagnosed with disseminated intravascular coagulopathy;[32] however, clinical thrombosis is rarely recognized.[38] Cats can have a mild hyperbilirubinemia (supporting an extravascular hemolytic process),[31,32] although this is uncommon in PRCA.[46] There is also evidence of hypoxic liver injury in about half of the cats.[32,46] Hyperferremia with normal total iron binding capacity is a consistent finding in cats with PRCA.[46]

In cats with nonregenerative anemia, bone marrow aspirates are required to distinguish between ineffective erythropoiesis and PRCA and to help exclude other causes, including primary or infiltrative bone marrow neoplasia, reactive histiocytic disorders, and myelodysplastic syndromes. In one study, 60-day survival rates were lower in cats with ineffective erythropoiesis compared to PRCA (although treatment details were not provided),[51] highlighting the importance of bone marrow aspirates in these cats. Ineffective erythropoiesis is characterized by erythroid hyperplasia in a typically hyperplastic marrow. Erythroid maturation may be left-shifted (with more immature than mature precursor cells) or incomplete. Incomplete maturation has also been called "maturation arrest", a term which should be avoided, because there is no evidence that the absence of late stage erythroid precursors is due to a true arrest in maturation. There is minimal evidence of dysplasia in cats with incomplete maturation of erythroid precursors.[51] PRCA is defined as <5% erythroid progenitor cells in the bone marrow. A consistent bone marrow finding in cats with ineffective erythropoiesis and PRCA (86–100% of cats) is a lymphocytosis of small lymphocytes (15–55% of total cells), found diffusely or in aggregates.[46,51] Based on one study, these lymphocytes appear to be mostly B cells (identified by CD19 immunostaining).[52] However, this marker has not been validated in cats[37] and only four cats were evaluated in this study; therefore these results should be verified by immunophenotyping additional cases with accepted feline B cell markers.[37] Such bone marrow lymphoid aggregates are also not specific for primary IMHA, because they can be seen in cats with various infectious and non-infectious diseases.[9,15,52] Unlike dogs,[47] myelofibrosis is quite rare. In one study, only 4% of 57 cats with IMHA had evidence of collagen fibrosis.[51] Ineffective erythropoiesis and PRCA likely represent extreme variations on a common theme, rather than separate entities. Indeed, animals whose bone marrow findings are not consistent with the above two categories (e.g. those with erythroid hypoplasia) likely fall between these two extremes (Fig. 34.2).

The main differential diagnoses for ineffective erythropoiesis are secondary IMHA (induced by drugs, infectious disease, or underlying neoplasia) and myelodysplastic syndromes (also called primary myelodysplasia), a clonal disorder of hematopoiesis (see Chapter 64).[7,28] Secondary IMHA can be distinguished by testing for underlying disorders (including PCR-based tests for hemotrophic mycoplasma) and historical details. Cats with myelodysplastic syndromes typically have prominent dysplastic features in one or more hematopoietic cell lines, more frequent myelofibrosis, and iron is often evident in mature (siderocytes) and immature (sideroblasts) erythroid cells.[6,7] Individual cases of ineffective erythropoiesis due to nonregenerative IMHA may have mild dysplastic features in hematopoietic cells[51] which

can make distinction difficult. In these cases, confirmation of a diagnosis of nonregenerative IMHA may depend on a favorable response to immunosuppressive therapy and negative test results for feline leukemia virus (FeLV), which may be positive in myelodysplastic syndromes.[7] PRCA can also occur secondary to drugs, specifically recombinant erythropoietin,[18,41] and FeLV infection.[34,45] These causes can potentially be distinguished by historical details and FeLV testing. Furthermore, FeLV-induced PRCA is mostly an experimental disease (see below).[45]

SECONDARY IMHA

The diagnosis of secondary IMHA is based on the same criteria as primary IMHA (i.e. positive Coombs' test, autoagglutination, and favorable response to immunosuppressive therapy); however, an underlying disease is identified in affected cats or they have been given an incriminating drug.[32,40,41,44,56] The most frequent diseases associated with secondary IMHA are infectious agents (e.g. FeLV and *Mycoplasma hemofelis*) and neoplasia.[32,44,56] Animals with secondary IMHA often respond to immunosuppressive therapy, along with treatment directed at the primary disease or drug withdrawal. It should be noted that the presence of IgG bound to RBCs or a positive Coombs' test (particularly if weakly positive) does not always mean that the pathogenesis of an anemia is immune-mediated. For example, cats with anticoagulant rodenticide toxicity and inflammatory disease (e.g. cholangiohepatitis, pancreatitis) can have a positive direct Coombs' test.[20,32] RBCs from cats with induced sterile abscesses show enhanced binding of IgG (particularly on older RBC fractions), which may be secondary to neutrophil-induced RBC oxidant injury.[53,55] Although IgG-mediated extravascular hemolysis may decrease RBC survival and contribute to the early mild decrease in Hct (average 8% decrease within 3–7 days of abscess induction) in these cats,[54] immunosuppressive therapy is not warranted.

Infectious Agents

FeLV infection was the most common underlying disease in two retrospective studies of cats with IMHA, being identified in 42–71% of 7 and 21 cats, respectively.[44,56] A regenerative anemia occurs in cats experimentally infected with FeLV subgroups A and B.[34] A positive direct Coombs' test (at 37 °C) was identified in 83% of 12 anemic FeLV-positive cats in another study.[20] However, in most affected cats the anemia was attributed to primary myelodysplasia rather than IMHA. It is likely that the anemia in some FeLV-infected cats is immune-mediated, because the anemia can resolve with immunosuppressive therapy.[44] Experimental infection with FeLV subgroup C virus can induce PRCA in cats;[34] however, this does not appear to be immune-mediated and has been attributed to inhibition of early erythroid progenitor cells.[1] FeLV subgroup C is rarely isolated from naturally FeLV-infected cats with PRCA.[45] In fact, all reported cases of immune-mediated PRCA in cats were FeLV negative,[36,46,51,57] indicating that FeLV is likely not involved in the pathogenesis of the majority of feline PRCA cases.

IMHA can occur in cats experimentally or naturally infected with *Mycoplasma hemofelis*,[35,56,58] and corticosteroids are common adjunctive therapy in infected cats.[27] A nonregenerative anemia that responded to doxycycline and corticosteroid therapy occurred in two cats with *Ehrlichia* infections.[8] A positive RBC agglutination test has been documented in 16% of cats naturally infected with *Babesia felis*.[43] Taken together, these findings suggest that an immune-mediated component may contribute to the anemia in cats with various infectious diseases.

Neoplasia

Hematopoietic neoplasia (lymphoma, myelodysplastic syndromes, and acute myeloid leukemia) has been associated with positive direct Coombs' test results or secondary IMHA.[20,32,44,56] However, because most affected cats in these reports had concurrent FeLV infection, it is unclear if the neoplasia was directly responsible for the secondary IMHA. In humans, PRCA can be a paraneoplastic response associated with lymphoid and other solid neoplasms (e.g. thymoma).[21] However, this has not been reported in the cat.

Drugs

Various mechanisms have been proposed as causes of drug-induced IMHA (Table 34.1).[19,39] Although any drug has the potential to cause secondary IMHA (regenerative or nonregenerative), such reactions have been reported infrequently in cats. Drug-induced IMHA has been identified in cats treated primarily with propylthiouracil (PTU) for hyperthyroidism and recombinant erythropoietin for anemia of renal failure (see Chapter

TABLE 34.1 Mechanisms of Drug-Induced Secondary Immune-mediated Hemolytic Anemia

Hapten	
	Antibodies primarily recognize the drug, which is bound to RBC proteins. The RBC is subsequently destroyed as an innocent bystander
Immune complex	
	Antibodies (usually IgM) primarily recognize the drug-RBC protein complex
Autoimmune	
	Anti-RBC or anti-erythropoietin antibodies are induced by the drug (due to probable cross-reactivity). Hemolysis can proceed in the absence of the inciting drug
Adsorption	
	Drugs can induce the non-specific binding of immunoglobulins, complement components and other proteins to RBC membranes. Although this can result in a positive direct Coombs' test, RBC survival is usually unaffected

16).[3,18,40,41,48] A severe anemia and thrombocytopenia developed in 9% of 105 hyperthyroid cats administered PTU. In all seven tested cats, the direct Coombs' test was positive. The anemia resolved with drug withdrawal and corticosteroid therapy.[40] PTU induced a regenerative hemolytic anemia, which was direct Coombs' test positive, within 3–8 weeks after initiation of PTU therapy in 40% of healthy cats. The anemia resolved and the Coombs' test became negative within 1–4 weeks after drug withdrawal and did not recur when a non-sulfated derivative of the drug was administered.[3] PRCA develops in some cats treated with recombinant erythropoietin, of both human and feline origin, presumably due to anti-erythropoietin antibody production.[18,41,48] This unexpected reaction with recombinant feline erythropoietin may be due to allelic and amino acid differences in natural and recombinant feline erythropoietin.[41]

Miscellaneous

Other immune-mediated conditions that have been associated with secondary IMHA include presumptive graft versus host disease in a cat after bone marrow transplantation[13] and systemic lupus erythematosis.[33]

COLD AGGLUTININ DISEASE

Cold agglutinin disease is really a hemolytic anemia induced by antibodies whose thermal reactivity is below 37 °C. In human patients, the antibody is usually a monoclonal IgM, produced in association with non-Hodgkin's lymphoma. The antibody binds to RBC in the extremities (28–31 °C) and fixes complement. Although this may result in mild intravascular hemolysis, usually the IgM elutes off RBCs at warmer core temperatures. However, the fixed complement (usually C3b) remains attached causing a chronic extravascular hemolytic anemia. In some cases, the monoclonal IgM may agglutinate RBCs in vessels in the extremities, causing ischemic necrosis. Cold hemolytic anemia can also occur as a transient disease with viral and bacterial (*Mycoplasma pneumonia*) infections in people. In these cases, the antibody is usually polyclonal.[19,23,39]

Cold hemolytic anemia is poorly recognized in the cat. IgM cold agglutinins have been identified in cats with experimental *Mycoplasma hemofelis* infections and were suspected to contribute to the anemia in these cats.[58] Cold agglutination was suspected (on the basis of a positive slide agglutination reaction in blood diluted 1:1 in saline) in a cat with tail and ear tip necrosis. However, the clinical signs in the cat resolved with removal of a lead foreign body.[25] Tail tip necrosis in kittens with suspected neonatal isoerythrolysis was also attributed to cold agglutination.[10] Autoagglutination or a low titer direct Coombs' test that is only positive at 4 °C should be interpreted with caution, since both humans and cats can have non-pathogenic cold-reactive antibodies that can cause these reactions.[19,20,23,29,39]

RBC BLOOD GROUP INCOMPATIBILITIES

Three main blood types are present in cats: A, B and AB (see Chapter 92).[11,26] Recently, a fourth blood type, *Mik*, was identified.[50] Immune-mediated destruction of RBCs through intra- and extravascular hemolysis occurs in cats exposed to incompatible blood types through transfusions or in utero during pregnancy (neonatal isoerythrolysis).[4,11,14,24,30] This hemolytic reaction does not require prior sensitization, because cats contain naturally occurring antibodies against RBC antigens.[11,24,50] These reactions are most severe in type B cats exposed to type A or AB blood, due the presence of strong agglutinins and hemolysins in these cats (see Chapter 100).[11,24]

Acronyms and Abbreviations

AGID, agar gel immunodiffusion test; AIHA, autoimmune hemolytic anemia; CR1, complement receptor 1; CR3, complement receptor 3; EIA, equine infectious anemia; EIAV, equine infectious anemia virus; ELISA, enzyme linked immunosorbent assay; Fcγ receptor, fragment crystallizable gamma receptor; Hgb, hemoglobin; IgA, immunoglobulin A; IgG, immunoglobulin G; IgM, immunoglobulin M; JFA, jaundiced foal agglutination (test); MAC, membrane-attack complex; NI, neonatal isoerythrolysis; PCV, packed cell volume; RBC, red blood cell; USDA, United States Department of Agriculture.

Immune-mediated hemolytic anemia (IMHA) is an accelerated destruction of red blood cells (RBCs) caused by antibody bound to erythrocytes. In comparison with dogs and cats, IMHA in horses and ruminants appears to have no breed or gender predilection and occurs less frequently, but is still an important cause of anemia.[16,23,39] IMHA may be primary or secondary in nature. Primary IMHA occurs when antibodies are formed against the normal RBC surface antigens. This can occur with incompatible blood transfusions, in neonatal isoerythrolysis, or with idiopathic autoimmune hemolytic anemia. Secondary IMHA occurs when antibodies are formed against substances that abnormally coat the RBC.[23,35] Reported cases of IMHA in horses are most commonly secondary (Table 35.1) rather than primary, with 15–26% associated with clostridial infections.[39] IMHA is a rare cause of anemia in cattle, with nine reported cases. Most affected cattle were young animals. This chapter provides an overview of the major causes of immune mediated anemia in ruminants and horses, focusing on immune mediated hemolytic diseases, neonatal isoerythrolysis and equine infectious anemia.

IMMUNE-MEDIATED HEMOLYTIC ANEMIA

Primary IMHA (i.e. AIHA) resulting from an idiopathic loss of self-tolerance to RBC surface antigens, is a rare condition in large animals.[1,17] Secondary IMHA in horses and ruminants is associated with infection, neoplasia, and exposure to drugs or toxins. Drug-induced hemolytic anemia is a Type II hypersensitivity reaction in which destruction of RBC occurs by one of three mechanisms: (1) the drug and antibodies combine to activate complement and destroy bystander RBC; (2) the drug acts as a hapten, a molecule that is not

	Purpura hemorrhagica[10]	

inherently immunogenic but binds to a carrier protein and covalently binds to RBC; or (3) the drug modifies the RBC membrane such that antibody coats the RBC (see Chapters 14 and 16).[36] There have been a number of equine cases of IMHA associated with penicillin acting as a hapten.

RBC destruction secondary to infectious disease is also a Type II hypersensitivity reaction. Lipopolysaccarides of bacteria and hemagglutinin subunits of equine infectious anemia virus (EIAV), for example, bind to RBCs resulting in antibody coating and binding of C3 complement (see Chapter 32).[20,36] Direct RBC membrane injury by bacterial toxin is thought to be a potential mechanism of *Clostridium* induced IMHA in horses.[39]

Pathogenesis of Immune Mediated Hemolytic Anemia

Regardless of whether the process was primary or secondary in nature, destruction of RBCs in IMHA is due to the removal of the antibody-coated RBCs by macrophages, primarily in the spleen and liver (extravascular hemolysis) or less frequently mediated by complement (intravascular hemolysis). Specifically, RBC bound with IgG is cleared from circulation via cells of the fixed mononuclear phagocytic system expressing a specific Fcγ receptor and most predominantly in the spleen. Immunoglobulin-coated RBC can fix C3 and are cleared by macrophages with CR1 and CR3. Alternatively, some immunoglobulin bound to RBCs activates the entire complement cascade with formation of the membrane-attack complex (MAC) and resultant RBC intravascular lysis.[17]

IgA antibody has not yet been identified in horses as an agglutinin in IMHA due to limited ability to identify surface-bound IgA of horses. IgA is involved in the development of purpura hemorrhagica.[10,40]

Autoantibodies are further classified as warm or cold reactive. Warm RBC autoantibodies react strongly at 37 °C, are associated with severe anemia and are predominantly IgG. Cold RBC autoantibodies react strongly at 4 °C and tend to be IgM class.[1] A special subset of cold autoantibodies that are active at 30 °C are thought to cause a cryopathic or cold hemagglutinin disease, in which the IgM agglutinates in the peripheral circulation of the extremities (distal limbs, ears, etc.) and causes ischemic necrosis and gangrene. This form of IMHA has been reported in the Freisian heifers as a consequence of *Salmonella dublin* infection.[12] Cold RBC autoantibodies that react only at 10–15 °C appear not to cause pathology as they have been demonstrated in the serum of healthy animals.

Clinical Features of Immune Mediated Hemolytic Anemia

Primary and secondary IMHA are clinically indistinguishable. Onset of hemolytic disease is variable depending on the rate of destruction, severity of anemia, and underlying disease process. Common signs include fever, depression, icterus, and hemoglobinuria. With severe, profound hemolysis (PCV < 15%) clinical signs reported include: tachycardia, tachypnea, cold extremities, pale mucous membranes, muscle weakness, and heart murmur. Some animals may have an apparent splenomegaly based on ultrasound and rectal palpation findings.

Diagnosis of Immune Mediated Hemolytic Anemia

Diagnosis of IMHA is based upon demonstration of multiple clinicopathologic criteria: (1) RBC morphology changes consistent with RBC destruction; (2) anemia; (3) autoagglutination; (4) a positive direct antiglobulin

result (i.e. Coombs' test) in a test validated for use with the horse or ruminant; and (5) elimination of other underlying causes of anemia.

Red blood cell morphology changes that have been described include marked poikilocytosis and echinocytes (type III > type II). Spheroechinocytes were described in a *Clostridium perfringens* type A-induced IMHA in a Warmblood gelding. *Clostridium perfringens* type A produces α-toxin, a phospholipase that alters RBC membrane phospholipids.[39]

Anemia of IMHA is usually quite severe with PCVs of less than 20%, but is typically regenerative as erythropoesis is not affected. Unlike blood-loss anemia, horses with hemolytic anemia may develop very low levels of reticulocytosis. Low levels were detected in one horse at 13 days after the onset of anemia with the use of an automated reticulocyte count using chromagen Oxazin 750 staining of RBC.[39]

Microscopic evaluation of a blood smear may also reveal autoagglutination with IMHA. In horses, in which RBCs are characterized by rouleaux formation, true autoagglutination is difficult to appreciate. Persistent agglutination, after washing or dilution in saline, differentiates autoagglutination from rouleaux formation.[1,23]

Confirmation of anti-RBC antibody is done by use of a direct antiglobulin (Coombs') test (see Chapter 140). The patient's washed RBCs are incubated with antiserum to equine IgG, IgM, and complement. Specific identification of antibody-coated RBCs can be done with direct immunofluorescence using flow cytometry. The direct immunofluorescence assay detected low levels of cell-bound antibody and is valuable in monitoring the response to therapy in regards to monitoring reduction of RBC-bound and platelet-bound IgG in horses.[38,40]

Additional hematologic changes in IMHA include leukocytosis with neutrophilia, hyperfibrinogenemia, and hyperbilirubinemia associated with pigmenturia. Urinalysis may indicate hemoglobinuria.

Further work-up should focus on the identification of the underlying disease process. Rectal palpation, abdominocentesis, ultrasound examination should be conducted for the detection of intra-abdominal abscesses and neoplasia. Auscultation, thoracic radiographs, and ultrasonography of the chest should be done to determine lower respiratory disease or thoracic masses. Transtracheal washes and/or thoracocentesis may be needed. Endoscopy of the upper airways and guttural pouches is recommended to look for potential *Streptococcus* spp., and lymphadenopathy. Additional laboratory tests include serology for various infectious diseases, particularly for equine infectious anemia (EIA), blood culture for bacteremia, and culture of abscesses.

Differential diagnoses for anemia in adult horses include EIA, ehrlichiosis, babesiosis, blood loss, chronic disease, leptospirosis, and neoplasia. Anaplasmosis, eperythrozoonosis, theileriasis, and bacillary hemoglobinuria, are included in the differential list for ruminants. Lymphosarcoma has been associated with IMHA in horses, dogs, and humans, but no association has been documented with cattle.[28]

Treatment of Immune Mediated Hemolytic Anemia

Once an animal is diagnosed, therapy should include discontinuation of any drugs associated with IMHA. If a primary disease process or infection is involved, antimicrobial therapy may necessitate switching of the class of antibiotic drug being used. Additional appropriate treatments of the underlying disease process should be instituted.

Immunosupressive doses of corticosteroids are indicated with the purpose of stabilizing RBCs, decreasing production of antibody, decreasing the avidity of the antibody for RBC, and decreasing the rate of clearance of antibody-coated RBC. It is important to keep in mind that corticosteroids may be less effective for treating IMHA with intravascular hemolysis mediated by IgM and complement.[36] Additionally, in horses chronically infected with EIA, steroid immunosuppression may result in recrudescence of the virus.[20,23] Horses with suspected IMHA should test negative for EIA before initiation of therapy. Dexamethasone (0.1 mg/kg [range 0.05–0.8 mg/kg IV or IM once or twice daily) is the most commonly used corticosteroid in horses. Once the PCV stabilizes at greater than 20%, tapering of the steroid dose to 0.01–0.02 mg/kg daily can be initiated. Alternatively, prednisolone (1 mg/kg IM twice daily) may be used. Monitoring of the PCV should be continued. Treatment may be necessary for several weeks. In cases that were non-responsive to corticosteroids, cyclophosphamide, azathioprine, or vincristine has been used.[21,39] Blood transfusion is indicated if anemia becomes life threatening; however, compatible blood donors may be difficult to find and transfusion may exacerbate the hemolytic process. Plasmapheresis was utilized in the treatment of IMHA in one horse with a *Clostridium perfringens* infection.[39] Splenectomy is utilized as a treatment modality in refractive cases of IMHA in dogs, but has not been described in large animals.

Blood transfusion in cattle is difficult and not commonly used because blood groups are complex and difficult to match (see Chapters 98 and 139). The B blood group system in cattle contains more than 60 antigens and is inherited in combinations of phenogroups.[36] Successful blood transfusion and treatment of a year old Holstein heifer with IMHA has been described.[11]

Prognosis for Immune Mediated Hemolytic Anemia

The overall prognosis for horses with IMHA is dependent on the underlying disease process. Horses that have multiple recurrences of hemolysis are a high risk for having neoplasia and should be carefully examined. Reports of IMHA in cattle are too limited to make a reliable estimation of prognosis.

NEONATAL ISOERYTHROLYSIS

Neonatal isoerythrolysis (NI) is an important cause of anemia in newborn foals and mules. The prevalence of NI varies among different breeds but has been reported to be 1% in Thoroughbreds and 2% in Standardbred horses.[9] In mules (donkey sire/horse dam), the case rate is higher at 8–10% due to a unique donkey RBC antigen.[18] In severe cases, NI can be life-threatening. Neonatal isoerythrolysis is rare in ruminants, but can occur in cattle vaccinated against anaplasmosis or babesiosis.[24,34]

Pathogenesis of Neonatal Isoerythrolysis

Neonatal isoerythrolysis is caused by maternal alloantibodies directed against specific surface blood-group antigens on the affected foal's RBCs. Alloantibodies are produced after sensitization of the dam with incompatible blood group RBCs (i.e. leakage of blood across the placenta during pregnancy or at delivery, transfusion of mismatched blood). Alloantibody production in the mare may persist for years. Within the eight equine blood groups, 32 blood group antigens are present on RBCs. Although alloantibodies can occur with any blood group, Aa and Qa account for the majority of NI cases. Factors Ab, Ac, Db, Pa, Pb, Qc, and Ua also have been associated with NI in horses. Interestingly, anti-Ca antibody may be protective for NI as it is commonly present, but not associated with the occurrence of clinical disease.[4,9,31] A recent publication described NI in two Friesian foals due to a non-specific hemolytic alloantibody acting as a heterophil antibody (an antibody that arises in response to a cross-reactive epitope originating from the environment such as food or bacteria), but further research is needed to substantiate this.[9]

Neonatal isoerythrolysis is an acquired immunologic hemolytic disease. IgG alloantibodies do not cross the placenta but are acquired by ingesting colostrum and are absorbed intact into the foal's circulation during the first hours after birth. If the foal inherits the RBC antigens (from the sire) that its mare lacks, the foal is at risk of developing NI. The maternal alloantibodies bind to neonatal RBC, causing primarily hemolysis and also hemagglutination with subsequent extravascular or intravascular hemolysis.[4] Thrombocytopenia, presumably due to antiplatelet alloantibodies, has been reported in mule foals.[4,18]

In cows, sensitization occurs with vaccination for anaplasmosis and babesiosis. These vaccines contain large quantities of RBCs obtained from infected calves and induce antibodies against the A and F blood systems. If the sensitized cow is mated to a sire with these blood groups, the calf may be at risk of developing NI.[24,30,36]

Clinical Features of Neonatal Isoerythrolysis

Typically, foals and calves are normal at birth with signs developing as early as 5 hours after birth, but usually at 12–48 hours of age. Signs vary from subacute to peracute depending on the degree of anemia and rate of RBC destruction. Foals may present with lethargy, weakness, tachypnea, tachycardia, pale mucous membrane, icterus, pigmenturia, and hemodynamic shock. Death may occur if hemolysis is severe. Additionally, hypoxemia and tissue hypoxia may induce neurologic disorders, metabolic acidosis, and multiple organ failure.[31] Extreme elevations of unconjugated bilirubin can lead to bilirubin encephalopathy or kernicterus in foals.[13] Fulminant hemolysis in calves can trigger fatal disseminated intravascular coagulopathy[36] Mule foals may develop concurrent thrombocytopenic purpura.[4,31]

Diagnosis of Neonatal Isoerythrolysis

Neonatal isoerythrolysis should be considered in a newborn foal or calf presenting with weakness and icterus in the first few days of its life. It should be considered in a multiparous mare or mare with a previous history of foals with NI, but should also be considered even in a maiden mare. It should be considered in a cow vaccinated for anaplasma or babesia.

Anemia is the primary clinicopathologic finding in neonatal foals or calves with NI, with the PCV typically <20%. A decrease in the normal 3:1 ratio of PCV to hemoglobin may be noted due to the presence of free hemoglobin (Hgb) in serum. Other clinicopathologic findings include: hemoglobinemia and hemoglobinuria due to intravascular hemolysis and hyperbilirubinemia (20–40 mg/dL). If toxic hepatopathy occurs, liver enzymes, bile acids, and blood ammonia levels may be elevated.[4,23] In a recent retrospective study of NI, four out of 15 foals with NI had failure of passive transfer.[4]

Diagnosis of NI requires demonstration of maternal alloantibody binding to foal RBCs. Lytic assays are considered more accurate as alloantibodies act more strongly as hemolysins. Agglutination tests may be hindered by rouleaux formation of equine blood. Hemolytic assays involve the mare's serum mixed with foal RBCs and complement (pooled rabbit serum). If the serum contains alloantibodies, hemolysis results in pink/red supernatant and decreased RBC mass after centrifugation.[1,23] Similar hemolytic assays with appropriate bovine reagents can be performed in calves.[36]

The jaundiced foal agglutination (JFA) test consists of serial dilutions of the mare's colostrum in the presence of 5% RBC suspension from the foal. Agglutination is the end-point of a positive test result (agglutination at dilutions of 1:16 or greater are considered significant). The JFA test is reported to correlate well with the hemolytic test and does not require an exogenous source of complement.[31] The Coombs' test can be used to demonstrate the presence of antibodies or complement bound to foal RBC, but is not specific for the diagnosis of NI.

Differential diagnosis of NI in foals presenting with weakness and icterus include septicemia, hypoxic-ischemic encephalopathy, equine herpesvirus-1, and leptospirosis. Potential causes of anemia in neonates include hemothorax, rib fracture, umbilical bleeding, and external hemorrhage.

Prevention and Treatment of Neonatal Isoerythrolysis

Prevention of NI is twofold: (1) determining whether the foal is at risk, and (2) protecting the foal from exposure to alloantibody. Determination of risk requires blood typing of the mare before parturition. Mares that test negative for Aa, Qa, Ua, or Pa should be considered at risk for making alloantibodies when exposed to antigen. Stallions bred to Qa/Aa negative mares can also be blood typed to determine if they are Qa/Aa positive. Alternatively, the mare's serum can be screened for the presence of anti-RBC antibodies within 30 days before parturition using a panel of blood-typed RBCs or tested against the sire's RBCs. Before the foal is allowed to nurse, either a hemolytic test or JFA test should be performed.[4,23,31] In calves, screening of serum and colostrum of vaccinated cows with a saline agglutination test has been reported to be helpful in predicting the occurrence of NI.[14]

If the mare's colostrum has been determined to contain alloantibodies and the foal is positive for the specific antigen, the foal should be muzzled and not allowed to nurse for the first 30–48 hours postpartum. The mare's udder should be stripped regularly during this time to remove all colostrum and maintain milk production. Colostrum from an alternative source should be administered to the foal.

Foals that are diagnosed with NI should be immediately prevented from further exposure. Foals with mild anemia may only require exercise restriction to prevent clinical signs of NI. Use of corticosteroids to reduce the rate of clearance of sensitized RBCs may be beneficial. Broad-spectrum antibiotics are recommended, particularly with the use of corticosteroids for the prevention of secondary sepsis. In foals with clinical signs of NI, supportive therapy with oxygen insufflation and/or oxyglobin therapy may improve oxygen saturation. Weak and recumbent foals need supplemental nutrition, intravenous fluid therapy, and nursing care.[4,31]

In cases of severe anemia a blood transfusion is needed. In addition to clinical signs (weakness, acidosis, tachypnea), parameters indicative of blood transfusion include a PCV of <10–15%, RBC count $<3 \times 10^6$ cells/μL, and Hgb concentration ≤5 g/dL. The choice of donor is critical as the donor RBCs must be free of the specific reactive antigen. Donor whole blood should be from an Aa/Qa negative universal blood donor. Suitable donors should be crossmatched (donor RBCs with mare or foal serum). The optimal choice for donor is the mare, but the mare's RBCs need to be washed to remove alloantibody-containing plasma. The foal's sire is the least desirable donor as it has the same RBC antigenic factors as the foal. In the case of mule foals, because the offending antigen is the unique donkey antigen, RBCs from any horse could potentially be used for transfusion. Transfused RBCs have a 2–4 day lifespan in circulation. One to four liters of whole or washed RBCs is sufficient to induce clinical improvement. Depending on the foal's bone marrow response to anemia or continued hemolysis, additional transfusions may be needed.[1,4,31]

Prognosis of Neonatal Isoerythrolysis

Prognosis for NI depends on the degree of alloantibody antigenicity. Cases with acute anemia, hypoxemia, and onset of seizures have a guarded prognosis. Foals that continue to have hemolysis after transfusion develop secondary degenerative hepathopathy, or signs of kernicterus have a grave prognosis.

EQUINE INFECTIOUS ANEMIA

Equine infectious anemia (EIA) is an important and reportable disease of horses and is characterized by IMHA. Horses of all ages and breeds are susceptible to infection with equine infectious anemia virus (EIAV). Despite the development of a sensitive and specific Federal regulatory test (Coggins test) and institution of regulatory guidelines for infected horses, EIA is still present in the United States, with outbreaks occurring sporadically throughout the country, but is most prevalent in the southeast.[20]

Pathogenesis of Equine Infectious Anemia

Equine infectious anemia is caused by a non-oncogenic retrovirus of the *Lentivirus* genus that infects macrophages. Natural infection occurs from the transmission of infected blood through the interrupted feeding of hematophagous arthropods (primarily *Tabanus* spp. and *Chrysops* spp.). Upon infection, the virus multiplies in the host macrophages, incorporates into the genome, and persistently infects the host. Viral replication has been found to occur at all times even during subclinical phases at reduced rates.[20]

Clinical Features of Equine Infectious Anemia

Three clinical forms of EIAV disease have been described in and include: acute, subacute to chronic, and chronic inapparent (carrier). In acute infection, the virus invades the host macrophages and undergoes massive replication. Clinical signs of acute EIA are seen within 7–30 days after exposure and manifests as fever, depression, anorexia, and mucosal petechiae. Thrombocytopenia is common during initial infection and leucopenia with lymphocytosis and monocytosis also may occur. Anemia is not seen in this stage.[20,23]

In the subacute to chronic form of EIA disease, horses infected for longer than 30 days develop signs of weight loss, edema of the limbs and ventral abdomen, cyclical fevers, anemia, and icterus. Horses also can develop ataxia, abortion, colic, liver disease, and renal disease associated with viral infection. During the subacute and chronic form of disease, the PCV, RBC count, and Hgb levels decrease with hemolysis. Hemolysis is thought to occur from immune mediated processes wherein the hemagglutinin subunit of EIA virus binds to RBCs, causing the coating of RBC with antibody and subsequent binding of C3 complement.[20] The Coombs' test is positive during these periods. Increased liver enzymes

and proteinuria also may be seen. With infection of host macrophages, viral proteins induce strong humoral and cell-mediated immune responses, with most horses developing detectable serologic responses by 16–42 days post-infection. Continued viral production results in lymphoreticular hyperplasia and hypergammaglobinemia.

Horses may succumb to infection either in the acute or subacute to chronic stages of disease, but most recover. Some horses have periodic recrudescence of the virus during periods of stress or treatment with corticosteroids, but a majority of horses remain clinically inapparent carriers of EIAV. No hematological abnormalities are detected in these horses.

Diagnosis of Equine Infectious Anemia

The Coggins test is still primarily utilized to diagnose EIA. The Coggins test is an agar gel immunodiffusion (AGID) test and detects serum antibodies against the EIAV gag p26 protein. The test is sensitive and specific but may provide false-negative results during the acute stage of EIA infection. Foals that have ingested colostrum from infected dams may have a false positive test. Repeat testing of suspected horses after 10–14 days and of suspected foals after 6 months of age (as maternal antibody levels decrease) is advocated. Three other tests have been approved by the USDA. These tests provide for more rapid testing and are more sensitive than the AGID, but are less specific and should be confirmed with the AGID.[20]

Treatment and Prevention of Equine Infectious Anemia

There is no treatment for EIAV infection. Individual states and federal government require the humane destruction and/or quarantine of EIAV infected horses. State regulatory guidelines vary, but a physical quarantine of a 200-yard distance between affected horses and non-infected horses is required.

Red blood cells (RBCs) are highly specialized cells that perform the critical function as an oxygen carrier in a wide range of environments. They are continuously exposed to oxidant stress under both physiologic and pathologic conditions. Because circulating mature RBCs cannot synthesize new proteins or replace cellular components de novo, they are limited in their ability to respond to these stresses and may become irreversibly damaged. The most common consequence of oxidant injury to the red blood cell is the formation of Heinz bodies (HBs), eccentrocytes, and methemoglobin.

In 1890, Heinz first described round structures protruding from the surface of RBCs of humans and animals exposed to certain types of coal-tar drugs. These structures, which were associated with RBC destruction, were subsequently called Heinz bodies (HBs) and can be found on the surface of RBCs in several species secondary to oxidative injury. Heinz bodies are formed by denatured clumps of precipitated hemoglobin on the inner surface of the RBC (Fig. 36.1). These structures can more easily be seen with new methylene blue (NMB) staining (Fig. 36.2).

Eccentrocytes (sometimes called erythrocyte hemighosts) are erythrocytes characterized by the concentration of hemoglobin on one side of the cell leaving a pale or clear portion on the other side (see Chapter 23).[11] Eccentrocytes are probably formed as a result of direct damage to the RBC membrane with adhesion of the opposing faces of the membrane[5] (Fig. 36.3).

Methemoglobin is formed by the oxidation of ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}) in the heme groups and can be seen in combination with HBs and eccentrocytes (see Chapter 21).

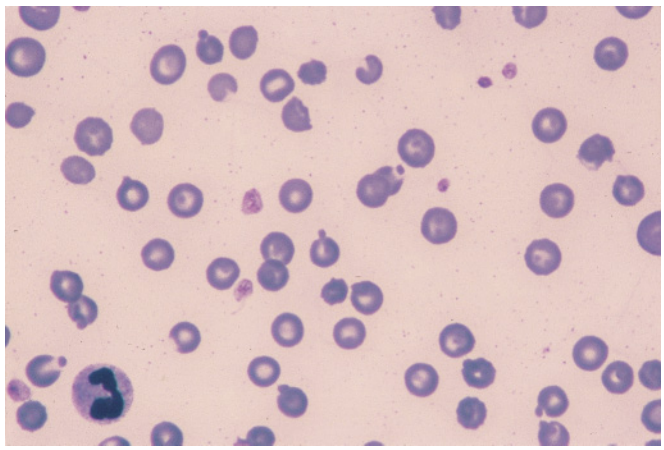

FIGURE 36.1 Heinz bodies with modified Wright-Giemsa stain: Heinz bodies are protuberances on the surface of RBCs. Original magnification 500×.

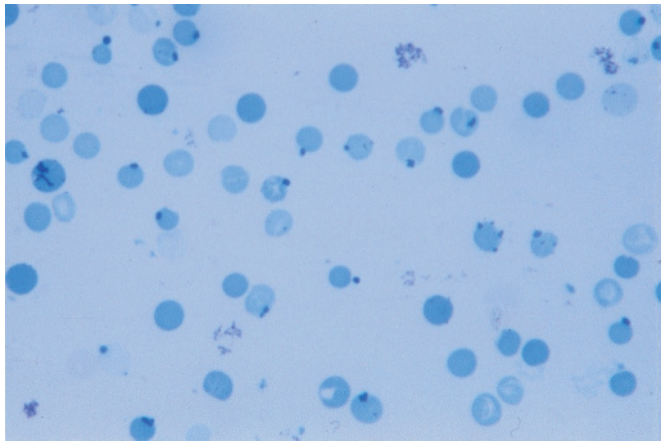

FIGURE 36.2 Heinz bodies with new methylene blue stain: Heinz bodies are dark round protuberances on the surface of erythrocytes. Original magnification 500×.

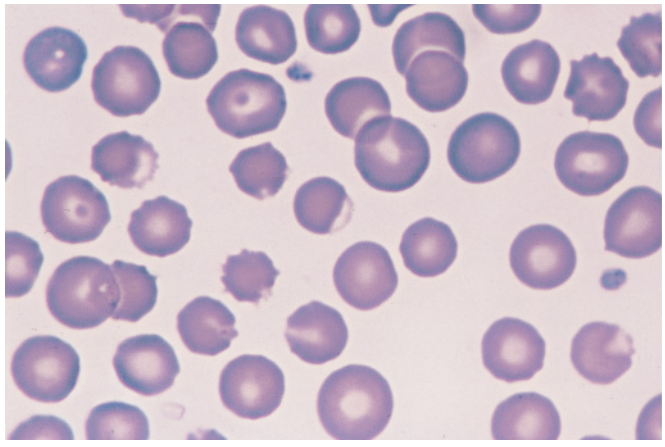

FIGURE 36.3 One eccentrocyte is present in the center and is characterized by hemoglobin concentrated on one side of the RBC, leaving a pale area at the other extremity. Modified Wright-Giemsa stain. Original magnification 500×.

PATHOPHYSIOLOGY OF OXIDATIVE INJURY

Oxygen carried by the RBC is a strong oxidant since it can generate highly reactive derivatives such as superoxide free radical (O_2^-), hydrogen peroxide (H_2O_2) and, by reacting with iron, it forms hydroxyl radical ($OH^•$). These oxidants are constantly produced and RBCs have several mechanisms to prevent oxidation and damage to the hemoglobin (see Chapter 21). The enzymes superoxide dismutase (SOD), glutathione reductase (GR), glutathione peroxidase (GPx) and reduced glutathione (GSH) protect RBCs against oxidative damage.[17] When these systems are overwhelmed, HB or eccentrocyte formation occurs: oxidation of the sulfhydryl groups on globin chains results in formation of HB whereas direct oxidative damage of the RBC membrane results in eccentrocyte formation.

INCREASED SUSCEPTIBILITY OF FELINE HEMOGLOBIN

Feline hemoglobin is more susceptible to oxidative damage than that of other mammalian species: this is due to the presence of eight reactive and fragile sulfhydryl groups on the molecule (instead of two strong ones in other species) and the easy dissociation of hemoglobin from a tetramer to a dimer form.[7]

The feline spleen is non-sinusoidal and inefficient at removing HBs from RBCs because of the large pores in splenic pulp venules which allow RBCs to enter without deformation. This explains why low numbers of HBs may be present in normal cats.[7]

Because RBCs may circulate relatively unimpeded in the spleen, splenic destruction of RBCs is not the major mechanism for the development of anemia in cases of oxidative stress in cats. Thus, other mechanisms must be present, such as increased rigidity of the RBC membrane, abnormal surface charge distribution and protease-activated HB removal, resulting in decreased RBC survival.[7] Binding of globin to cytoskeletal proteins may result in loss of membrane integrity, increased membrane proteolysis, and subsequent RBC lysis.

CAUSES OF OXIDATIVE INJURY IN DOMESTIC SPECIES

Feline Species

Acetaminophen (Paracetamol)

In most mammalian species, acetaminophen (paracetamol in Europe) is primarily transformed to nontoxic products by the liver via conjugation with glucuronic acid and, to a lesser degree, sulfates, followed by elimination by the kidneys. In humans, most cases of acetaminophen intoxication involve hepatotoxicity.[22] Dogs and cats are unique because they tend to develop methemoglobinemia and oxidative hemolytic anemia with signs of cyanosis, depression, facial edema, dyspnea

and vomiting occurring 2–4 hours post-intoxication.[22] Oxidative hemolytic anemia is usually seen 48–72 hours post-intoxication whereas methemoglobinemia can occur as soon as 2–4 hours after ingestion.[22]

In most species, acetaminophen is metabolized in the liver through sulfation and glucuronidation. A small percentage of acetaminophen is oxidized by cytochrome P450 to *N*-acetyl-*para*-benzoquinoneimine (NAPQI).[2] However, at toxic doses, both the sulfation and glucuronidation pathways become saturated and NAPQI production increases.[22] If GSH is depleted to less than 20% of normal concentrations, NAPQI binds to cysteine groups on hepatocellular proteins, resulting in cellular death and centrolobular necrosis.[2]

Until recently, it was believed that a similar mechanism was also responsible for oxidative injury to RBCs, with NAPQI being the culprit. For instance, it was thought that cats produce more NAPQI than other species because they have limited acetaminophen glucuronidation;[9] however, feline acetaminophen metabolism is primarily by sulfation, with glucuronidation playing a minimal role (less than 1.5%).[22] Moreover, NAPQI is not likely produced by RBCs since they lack cytochrome P450 enzymes and NAPQI is not released in circulation by hepatocytes.[22] Finally, NAPQI does not chemically react with oxyhemoglobin in a redox cycle.[22]

Recently, it has been found that a minor acetaminophen metabolite, *para*-aminophenol (PAP) can react with oxyhemoglobin in a redox fashion.[22] PAP is produced by deacetylation of acetaminophen by hepatic microsomal carboxyesterases.[22] In most species, *N*-acetylation of drugs is catalyzed by two enzymes: *N*-acetyltransferase-1 and *N*-acetyltransferase-2. However, cats have only *N*-acetyltransferase-1 and dogs have no *N*-acetyltransferase enzymes. Therefore, dogs and cats are deficient in *N*-acetylation activity. This may result in greater quantities of PAP released into the circulation by the liver, with PAP reacting in a redox fashion with oxyhemoglobin. Moreover, canine and feline RBCs have low methemoglobin reductase activity[22] and this limits the ability to efficiently reduce the methemoglobin produced by co-oxidation.[22] Both mechanisms are probably responsible for the sensitivity of RBCs to acetaminophen in canine and feline species.

There is no safe dose of acetaminophen for cats. Toxic doses as low as 10 mg/kg of body weight have resulted in death in cats.

Diabetes Mellitus

Oxygen-radical mediated damage has been recognized in both humans and animals with diabetes mellitus. Oxidative damage is caused by the formation of radicals secondary to glucose autooxidation, compromised antioxidant systems, oxidized plasma lipoproteins, alterations in inflammatory mediators as well as changes in antioxidant nutrient status.[8] Cats with ketoacidosis can have significantly more HBs than nonketotic animals.[8] The percentage of HBs in diabetic cats seems to be directly correlated with levels of plasma ß-hydroxybutyrate and inversely correlated with RBC glutathione concentrations.[8]

Cats with diabetes mellitus may become severely hypophosphatemic. Hypophosphatemia may impair phosphorylation of glucose to glucose-6-phosphate, preventing glucose entry into the pentose monophosphate shunt and thus impair formation of GSH: decreased GSH could result in increased HB formation.[1]

Propylene Glycol

Propylene glycol (PG) itself is non-toxic to RBCs and a toxic metabolic intermediate may be required.[7] Propylene glycol at a concentration varying between 6% and 13% was used several years ago in semi-moist food. Propylene glycol resulted in the formation of HBs, reticulocytosis, and decreased RBC lifespan. Despite formation of HBs and decreased RBC half-life, anemia is either not present or is minimal.[18] Despite the absence of anemia in the majority of cats, the presence of oxidative injury to RBCs pushed the Food and Drug Administration's (FDA's) Center for Veterinary Medicine to prohibit the use of PG in cat food.

Hyperthyroidism

To our knowledge, only one study has looked at the association between hyperthyroidism and development of HBs in cats.[6] In this study 15 out of 21 cats with hyperthyroidism had an increased percentage of HBs and their presence usually did not result in overt anemia.

Lymphoma

One study investigated the relationship between lymphoma and HB formation.[6] In this study, 15 out of 17 cats with lymphoma had increased numbers of HBs. Mechanisms for HB formation are unclear but oxidative stress on bone marrow precursor cells may result in abnormal or damaged hemoglobin increasing the risk of HB formation.

Phenazopyridine

In cats, use of phenazopyridine (Pyridium®), a medication used for the treatment of urinary tract infections in humans,[13] alone or in combination with other drugs, is contraindicated because of the high risk of dose-related methemoglobinemia and HB formation.[15]

Methylene Blue

Methylene blue (MB) is used in veterinary medicine either as a treatment for methemoglobinemia or less commonly as a urinary antiseptic.[33] In the treatment of methemoglobinemia, MB reacts with methemoglobin and reduces it to hemoglobin.[32] Recent studies demonstrated that intravenous administration of single or limited doses of MB to treat methemoglobinemia did

not result in anemia despite an increase in the number of HB-containing RBCs.[32]

Benzocaine

Benzocaine is an ethyl ester of *p*-aminobenzoic acid that is used as a local anesthetic in several over-the-counter medications (ex: Lanacane®). To our knowledge, only one case of benzocaine intoxication has been reported in cats.[37]

Onions

Onions (*Allium cepa)* are considered to cause oxidative damage through thiosulfate compounds that form disulfide bonds with hemoglobin or GSH.[39] Onion intoxication is far less common in cats than dogs, probably due to the finicky eating nature of cats. However, baby food, commonly used in sick anorexic cats, may contain onion powder causing HB formation and sometimes anemia. The rate and degree of HB formation varies depending on the concentration of onion powder in the baby food.[30]

Canine Species

Onions/Garlic/Chinese Chive

All types of onions (i.e. raw, cooked, or dehydrated) can be toxic to dogs.[19] In onions, *n*–propyl disulfide, sodium *n*-propyl thiosulfate, sodium *trans*-1-propenyl thiosulfate and sodium *cis*-1-propenyl thiosulfate are thought to be the agents responsible for oxidative injury.[38,40] Ingestion of garlic (*Allium sativum)* and Chinese chive (*Allium tuberosum)* can also result in oxidative injury.[40] The oxidative agent present in garlic is sodium 2-propenyl thiosulfate.[40] In cases of natural intoxication with garlic and/or Chinese chive, eccentrocytosis seems a more prominent feature of anemia than HB formation.[40] In dogs, there seems to be a correlation between the animal's weight and the development of HB in cases of onion/garlic/Chinese chive intoxication, as HB anemia is mostly seen in small breeds. So-called high potassium (HK) breeds (e.g. Akitas, Japanese mongrels, Shibas, Jindos, and Chinese Shar-Peis) are more susceptible to onion-induced oxidative damage than non-HK dogs.[38]

Acetaminophen (Paracetamol)

Acetaminophen is a very popular over-the-counter analgesic and antipyretic drug and can result in both hepatic damage (zone-3 hepatocellular necrosis) and oxidative injury (eccentrocytes, HBs, and methemoglobinemia) in dogs. The recommended dose of acetaminophen is 15 mg/kg body weight per os q8 hours. Toxic dosage in dogs is around 200 mg/kg body weight.[34] Clinical signs may include tachycardia, tachypnea, blue-gray or pale brown mucous membranes, facial edema as well as brown urine and blood.[25] The mechanisms for RBC oxidative damage are discussed in the feline section.

Skunk Musk

Spraying with skunk musk is a rare cause of HB anemia and methemoglobinemia in dogs.[41] Skunk spray contains thiols which may potentially react with oxyhemoglobin, forming methemoglobin thiol radicals and hydrogen peroxide.[41] Both thiol radicals and hydrogen peroxide are highly reactive substances that may react with sulfhydryl groups on hemoglobin, resulting in the formation of HBs.

Zinc

Most cases of hemolytic anemia associated with acute or subacute exposure to zinc are related to ingestion of zinc-containing material, with the three most common sources being skin ointment (more than 100 products, including Desenex®), pennies minted in the USA after 1982, and metallic objects such as toys or nuts coated with zinc, which may be present in carrying cages.[14,19] American pennies are composed of 98% zinc, each penny containing approximately 2,440 mg of elemental zinc.[14,18] Most dogs with zinc intoxication are young (less than 2 years of age), since younger animals are more likely to ingest foreign objects than older animals. In one study,[14] smaller dogs (mean weight 6 kg) were more likely to be intoxicated than larger dogs: smaller dogs have smaller pylori, making it more difficult for objects to pass from the stomach and allowing more time for erosion by gastric acid, freeing more zinc for absorption. A dose-related effect may also be involved.[14] The pathophysiology of zinc-induced hemolysis in veterinary medicine is not completely understood but inhibition of GR and enzymes of the hexose-monophosphate pathway probably plays a role. Not all dogs with zinc intoxication develop RBC oxidative injury with formation of HBs or eccentrocytes.[14]

Naphthalene

Naphthalene, derived from coal tar, is one of two ingredients that can be found in mothballs, the other one being paradichlorobenzene (PDB).[10] Naphthalene can also be found in other products, such as driveway sealants and toilet bowl deodorizers. Presently, PDB is more common than naphthalene in mothballs. Naphthalene is metabolized by the liver to α-naphthol, ß-naphthol, α-naphthol-quinone and ß-naphtholquinone.[10] The metabolite responsible for the hemolytic crisis and HB anemia is α-naphtol.

Naphthalene intoxication seems relatively common in human medicine but, to our knowledge, is rare in veterinary medicine with only one case reported in a dog.[10]

Diabetes Mellitus

Pathophysiology and mechanisms for oxidative injury to RBCs in dogs with diabetes mellitus are similar to those in cats. Similar to cats, dogs with ketoacidotic

diabetes mellitus are at greater risk for oxidative damage than non-ketoacidotic animals.[5]

T Cell Lymphoma

In a retrospective study, several dogs with T cell lymphoma had evidence of eccentrocytes indicative of oxidative injury to RBCs. This is similar to cats, where several animals with lymphoma developed HBs.[6] The mechanism for oxidative injury is unclear.[5]

Vitamin K and Vitamin K Antagonists

Both vitamin K administration and vitamin K antagonist intoxication have been reported as causes of oxidative injury in dogs.[5,11] In cases of vitamin K administration, both vitamin K_3 and vitamin K_1 may result in HB formation, with vitamin K_3 being more toxic than vitamin K_1.[11] Vitamin K_3 reacts with hemoglobin and oxidizes oxyhemoglobin to methemoglobin with production of an intermediate, the semiquinone radical.[11] Semiquinone can combine with O_2 to produce H_2O_2 and contribute to RBC membrane damage. In the study of Caldin et al.,[5] more dogs that were intoxicated with vitamin K antagonists had eccentrocytosis than dogs with vitamin K administration. It is therefore possible that HBs present in dogs treated with vitamin K were present prior to vitamin K administration. Different explanations are possible for oxidative injury in cases of vitamin K antagonist intoxication: vitamin K antagonists themselves may have oxidative potential. It is also possible that an additive to the drug has oxidant properties. Finally, pathological abnormalities caused by vitamin K antagonism (for example, acidosis caused by blood loss) may lead to oxidative damage.[5] In conclusion, both vitamin K administration and vitamin K antagonist intoxication can cause oxidative damage to RBCs, resulting in the formation of HBs and/or eccentrocytes.

Benzocaine

Benzocaine is a local anesthetic that can be used as a topical anesthetic. Rare cases of HB anemia/hemoglobinemia have been reported in dogs secondary to benzocaine-containing products.[16,19]

Equine Species

Red Maple Leaves

Dried red maple (*Acer rubrum*) leaves can induce toxicosis with oxidative injury to the RBC membrane and hemoglobin, resulting in hemolytic anemia characterized by HBs, eccentrocytes, and/or methemoglobinemia.[3] There does not seem to be a sex, breed, or age predisposition for this condition and most cases seem to occur either during the summer or fall.[3] Clinical signs may include tachypnea, tachycardia, icterus, cyanosis, scleral petechiation, and brownish discoloration of urine and blood. Signs appear as soon as 24 hours after ingestion with a peak 72 hours after ingestion.[12]

Leaves are toxic at a dosage of 1.5 g/kg of body weight or more.[12] Gallic acid, present in red maple leaves, is often implicated in the oxidative damage of equine hemoglobin but experiments suggest that another still unidentified agent in red maple leaves must be present in combination with gallic acid to enhance methemoglobin formation.[3] These toxins are not destroyed by prolonged storage or freezing.[12] In one study, looking at 32 horses with red maple leaf intoxication, HBs or eccentrocytes were noted in only 33% of affected animals.[3]

Garlic

Garlic can be used as an antifungal ingredient in livestock feed in order to prevent mycotoxin contamination.[26] Horses fed freeze dried garlic at a dosage of 0.2 g/kg of body weight or more showed signs of oxidative injury to RBCs with decreased RBC parameters and presence of HBs: these changes occurred 4 days after initial feeding and were associated with sweating.[26] Complete recovery occurred within 5 weeks after cessation of garlic supplementation.

Phenothiazine

Phenothiazine was one of the first broad-spectrum veterinary anthelmintics. Presently it is used only in horses but is not recommended for use in pregnant mares because it can result in abortion. Its principal use is in mixtures with piperazine and in small daily doses to inhibit egg-laying by resident intestinal parasites.[4] Phenothiazine is degraded in the gastrointestinal tract to phenothiazine disulfide, an oxidative metabolite.[23] Clinical signs associated with intoxication may include tachycardia, anorexia, dullness, pale mucous membranes and opaque brown urine. The toxic dosage seems to be 30 g or more. Anemia usually develops over a period of 6–13 days after administration.

Lymphoma

Anemia caused by oxidative injury is an uncommon sequela of lymphoma in horses. In a recent review of equine lymphoma, none of the anemic horses had evidence of oxidative injury but the majority had evidence of agglutination, suggesting an immune-mediated component.[21] To our knowledge, there is only one case report of HB anemia associated with lymphoma in a Quarter Horse filly.[31]

Bovine/Ovine Species

Selenium/Copper Deficiency

Selenium deficiency with or without concurrent copper deficiency can be seen in cattle and sheep.[24,35] In cattle, selenium deficiency can lead to a marked decrease in the selenium-containing enzyme GPx, whereas copper deficiency may result in HB anemia because superoxide

dismutase (SOD) is a cupro-enzyme. SOD protects RBCs from oxidative damage caused by accumulation of superoxide.[36] If both deficiencies are present at the same time, a cumulative effect may be present because both enzymes are required to detoxify superoxide free radicals.

Chronic Copper Intoxication

In sheep, copper toxicosis may also result in hemolytic anemia due to oxidative damage. Sheep are more susceptible to copper intoxication than other species because hepatocytes store copper and biliary excretion is limited. When liver copper increases there is increased hepatocyte turnover enhancing both cell division and apoptosis.[20] When the rate of hepatocyte apoptosis and loss exceed replacement, copper is released into circulation, resulting in intravascular hemolysis. Copper intoxication is also possible in cattle, but is less common than in sheep.[36]

Brassica

Forage brassicas (cabbage, kale, forage rape) constitute a feed with high nutritional value, allowing a reduction in the purchase of concentrates.[28] However, brassicas contain sulfur compounds such as *S*-methylcysteine sulfoxide (SMCO) which is first converted in the rumen to thiosulfonate. Thiosulfonate is further metabolized to n-propyl disulfides, dipropyl disulfides and dipropenyl disulfides. All three disulfides are oxidizing agents, with dipropenyl disulfides being the most powerful.

When cattle are fed brassica-type plants, HB numbers peak at 10 days to more than 4 weeks after the initiation of feeding. In extreme cases, the hematocrit may fall to 30–50% of initial values.[28] The severity and rapidity at which the anemia develops is proportional to the amount of *Brassica* in the diet. Total recovery is achieved when animals are completely removed from *Brassica* feeding. RBC parameters return to reference intervals 3–4 weeks after complete removal of the plants.

Onions

Onions, garlic and other plants of the *Allium* family contain SMCO. Cattle are less susceptible to onion toxicity than dogs and cats but are more susceptible than sheep and goats.[29] Ruminal fermentation of SMCO leads to the formation of oxidative metabolites.[29] A study looking at onion feeding in cattle showed that feeding up to 25% cull onions on a dry-matter basis resulted in mild decreases in RBCs, hemoglobin, and packed cell volume as well as appearance of HBs in RBCs but did not result in clinical anemia.

Oak Leaves and Shrubs

Oak trees and shrubs are present in most countries, and ingestion of immature leaves or freshly fallen acorns is the most common source of intoxication. Immature leaves and acorns are rich in tannic acid that is metabolized to pyrogallol and resorcinol.[27] Pyrogallol can trigger oxidation of hemoglobin to methemoglobin[27], resulting in oxidative damage to RBCs.

CHAPTER 37

Anemia of Inflammatory, Neoplastic, Renal, and Endocrine Diseases

MICHAEL M. FRY

Inflammation
Neoplasia
Renal Disease
Endocrine Disease

Acronyms and Abbreviations

CRF, chronic renal failure; DIC, disseminated intravascular coagulopathy; DM, diabetes mellitus; EPO, erythropoietin; ESA, erythropoiesis-stimulating agent; HSA, hemangiosarcoma; IL, interleukin; IMHA, immune-mediated hemolytic anemia; LEAP-1, liver-expressed antimicrobial peptide; RBC, red blood cell; rcEPO, recombinant canine erythropoietin; rfEPO, recombinant feline erythropoietin; rhEPO, recombinant human erythropoietin.

Many pathologic conditions may cause secondary anemia. This chapter will focus on inflammation, neoplasia, renal disease, and endocrine disease as causes of anemia. These categories are not mutually exclusive. Anemia in patients with these conditions is usually, but not necessarily, nonregenerative.

INFLAMMATION

For many years physicians and veterinarians have recognized that patients with infectious or inflammatory disease frequently develop anemia, and that this phenomenon is associated with altered iron homeostasis.[13-16] The condition has been termed "anemia of chronic disease" or "anemia of inflammation" – the terminology is not consistent even in the contemporary literature. For the purposes of this chapter, it will be called "anemia of inflammation". Affected individuals have some laboratory features of iron deficiency (hypoferremia and decreased total iron binding capacity), but increased iron stores in the mononuclear phagocyte system – seemingly paradoxical findings that are consistent with functional iron deficiency. In contrast to patients with classical iron deficiency anemia, which in advanced cases is microcytic and hypochromic (see Chapter 26), patients with anemia of inflammation typically have normocytic, normochromic, nonregenerative anemia. This pattern is recognized in domestic animals in both research and clinical contexts. Experimentally induced sterile inflammation in dogs and cats resulted in normocytic, normochromic anemia, hypoferremia, and decreased total iron binding capacity.[15,16,46] Experimental ehrlichial infection studies in dogs resulted in similar findings.[5] Experimental infection of calves with *Psoroptes ovis* resulted in bone marrow myeloid hyperplasia, increased plasma fibrinogen concentration, and moderate nonregenerative anemia.[40]

The veterinary clinical literature contains many references to anemia of chronic disease or anemia of inflammation, and it is generally accepted to be a common clinical entity.[34] However, the relationship between inflammation and anemia in animals with naturally occurring disease has received little attention.

A proposed evolutionary rationale for anemia of inflammation is that it results from an immunologic adaptation to limit microbial access to iron.[13,17] The past decade has seen breakthroughs in the understanding of molecular mechanisms of anemia of inflammation. Many of the new insights involve hepcidin, a hormone now generally accepted as the key mediator of anemia of inflammation.[17] Initially recognized as an antimicrobial peptide and referred to as liver-expressed antimicrobial peptide (LEAP-1), hepcidin was subsequently identified as an acute phase protein and a key inhibitory regulator of iron metabolism.[17,22,33] It is synthesized mainly by hepatocytes – hence the name hepcidin – intimating both its tissue of origin and its direct antimicrobial effects. The bioactive form is a 25-amino acid

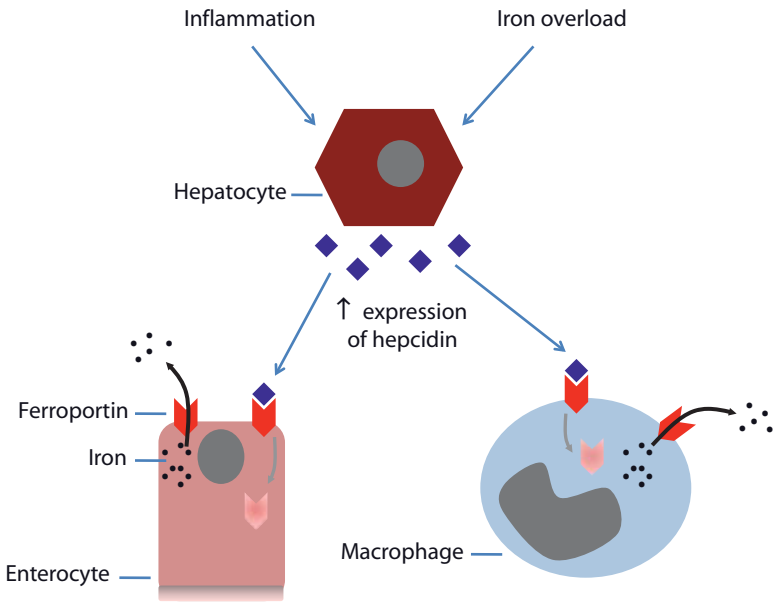

FIGURE 37.1 Hepcidin expression is increased by inflammation and iron overload. Hepcidin binds to ferroportin and causes its internalization and degradation, thus inhibiting efflux of iron into the plasma.

peptide that exerts its effects by binding to the cell surface iron efflux protein, ferroportin, and inducing its internalization and degradation.[17] The effect of this interaction is to inhibit both absorption of dietary iron from intestinal epithelium and export of iron from macrophages and hepatocytes. Overexpression of hepcidin (for example by hepcidin-secreting tumors) results in iron deficiency anemia, while deficiency of hepcidin is a feature of most recognized forms of hereditary hemochromatosis.[18]

Hepcidin expression increases in response to inflammation and iron overload (Fig. 37.1).[32] While interleukin-6 (IL-6) plays a central role in increasing hepcidin production, other cytokines, including interleukin-1 (IL-1), are also likely involved. Conversely, hepcidin expression decreases in response to anemia caused by hemorrhage or hemolysis, and in conditions associated with hypoxia, and iron deficiency.[4,17]

Inflammation can contribute to anemia via mechanisms other than hepcidin-mediated disruption of normal iron handling. Studies have implicated inflammatory cytokines as inhibitors of erythropoiesis via direct toxic effects on erythroid precursors (e.g. via free radical formation or induction of apoptosis), decreased expression of hematopoietic factors including erythropoietin (EPO) and stem cell factor, and decreased expression of EPO receptors. Inflammation has also been shown to cause decreased red blood cell (RBC) survival in some species.[45,46] These findings may not be equally applicable to all species: calves treated with endotoxin had a mean RBC lifespan slightly shorter than that of control animals, but the difference was not statistically significant.[42] Some investigators have suggested that oxidants produced by activated neutrophils alter RBC surface antigenicity, which could in turn lead to accelerated destruction of RBCs by immune-mediated mechanisms (see Chapter 22).[44]

NEOPLASIA

Anemia is common in humans with cancer, especially in cases of hematologic malignancies, and is recognized to have a negative impact on quality of life, prognosis, and response to chemoradiotherapy.[19] Recognized causes of anemia in people with cancer include both disease- and treatment-related factors.[19] Disease-related factors include acute or chronic hemorrhage, secondary immune-mediated hemolysis, impaired renal function resulting in decreased EPO production, nutritional deficiencies (folate, vitamin B_{12}, iron), and neoplastic infiltration of bone marrow. When not attributable to one of these causes, anemia in people with cancer is most likely anemia of inflammation, as described above.[19] There is a high incidence of anemia as a complication of myelosuppressive chemotherapy in humans with cancer.[19] Hemolytic anemia has also been reported secondary to anti-neoplastic therapy.[19]

The prevalence of anemia in the general population of animals with cancer is not well-characterized, but anemia certainly is recognized as a complication of cancer in veterinary medicine and is documented to be common in some types of cancer.[1,10,29] The deleterious effects of anemia on quality of life in veterinary cancer patients have received little attention and need further investigation. As in people, recognized causes of anemia in animals with cancer include both disease- and treatment-related factors.[25] Disease-related mechanisms of anemia include hemorrhage, hemolysis, and decreased or ineffective erythropoiesis. Bleeding may occur directly from a neoplastic lesion, or distant sites due to defective hemostasis. Hemolysis may occur via phagocytosis of RBCs by neoplastic cells, secondary immune-mediated destruction, oxidative insult, or as mechanical damage (e.g. microangiopathic hemolysis). Decreased erythropoiesis may occur due to inflammation, space

occupation of the bone marrow by neoplastic infiltrates or fibrosis; elaboration of myelotoxic factors (e.g. estrogen); or increased apoptosis. Frequently the cause of anemia in animals with cancer is multifactorial. In principle, anemia can occur as a complication of virtually any type of neoplasia, but the risk is higher in certain types of malignancies. While most of the examples listed below are in dogs, the pathologic principles are not species-specific.

Primary or metastatic bone marrow neoplasia in animals can cause anemia by displacing normal hematopoietic tissue, inciting secondary myelofibrosis, and causing ineffective hematopoiesis due to increased apoptosis of hematopoietic cells.[3,43]

Anemia due to hemorrhage is a frequent finding in some types of neoplasia in animals. For example, hemoperitoneum is a frequent complication of splenic hemangiosarcoma (HSA) in dogs.[20] Bleeding may be caused by rupture of the primary tumor, but exacerbated by other tumor-related pathology. Thrombocytopenia occurs in the majority of these cases and disseminated intravascular coagulopathy (DIC) is a frequent complication.[20] Anemia and clinical evidence of bleeding are frequent in dogs with gastrointestinal sarcomas and renal neoplasia. Hyperestrogenism-induced bone marrow hypoplasia is a recognized complication of canine Sertoli cell neoplasia.[39]

Neoplasia can also cause anemia by hemolytic mechanisms. Canine hemophagocytic histiocytic sarcoma (see Chapter 73), as its name implies, is characterized by malignant histiocytes that are erythrophagic.[29] The large majority of affected dogs have Coombs'-negative regenerative anemia, and thrombocytopenia. Erythrophagocytosis is the major cause of anemia. Although bleeding is not a clinical characteristic of this disease, thrombocytopenia and other laboratory evidence suggest that hemorrhage may also play a role.

Neoplasia may cause immune-mediated or oxidative destruction of RBCs. Underlying neoplasia is a frequent differential diagnosis for immune-mediated hemolytic anemia (IMHA) in animals.[25] In a retrospective study on equine lymphoma, the majority of affected animals were anemic, and autoagglutination was a frequent finding.[28] Other mechanisms that may have contributed to the anemia in these horses include decreased erythropoiesis due to tumor myelophthisis or anemia of inflammation. Hemorrhage was not described in these horses; however, thrombocytopenia was noted in greater than one-third of cases. Lymphoma is also a frequent differential diagnosis in small animals with IMHA.[30] However, a causative relationship between anti-RBC antibodies and anemia has not been clearly shown.

An association between lymphoma and oxidative damage to RBCs, with or without anemia, has been documented in cats and dogs. A study in cats found Heinz bodies to occur significantly more often in animals with lymphoma (15 of 17 cases) than in a healthy control group.[8] However, anemia was not a consistent finding in affected individuals. A recent retrospective study of canine eccentrocytosis found the prevalence of the condition was only 1.4% (60 of 4,251 dogs), but every animal with T-cell lymphoma (5 of 5) had eccentrocytosis; however, information about the prevalence of anemia in these dogs was not provided.[6]

Many anti-neoplastic therapies are known to cause myelosuppression in humans and animals, and such treatment is likely to be a contributing factor to anemia in affected individuals. However, the impact of myelosupression on RBCs is less severe than on other blood cell types because of the long RBC lifespan, and monitoring of hematologic toxicity of chemotherapy or radiotherapy typically focuses on neutrophils and platelets.[25] In the opinion of at least some veterinary oncologists, chemotherapy is more likely to cause treatment-limiting anemia as a result of gastrointestinal hemorrhage than as a result of myelosuppression (A LeBlanc, personal communication).

RENAL DISEASE

Nonregenerative anemia is an expected complication of chronic renal failure (CRF) in humans and in domestic animals, and is recognized to contribute to overall morbidity.[11] The major cause of anemia in patients with CRF is decreased production of EPO. Other contributing factors recognized in people include inflammation, hemorrhage, iron deficiency, decreased RBC survival due to metabolic insult or mechanical damage, and the anti-proliferative effects of uremic toxins.[31] Concurrent disease may increase the risk of anemia in patients with renal disease (e.g. diabetes mellitus is a risk factor for development of anemia in human beings with impaired renal function).

The frequent occurrence of nonregenerative anemia in patients with CRF is well documented in the veterinary literature.[12] A recent report of juvenile nephropathy in 37 Boxer dogs found anemia to be a frequent finding (44% of cases), but did not characterize the anemia as regenerative or nonregenerative.[7] Animals with CRF typically have inappropriately low plasma EPO concentrations. In a study of plasma EPO concentrations in dogs and cats, anemic animals without CRF had significantly increased plasma EPO concentrations compared to healthy controls, while a similar increase was not present in animals with CRF.[37] In cats there was no overlap in EPO concentrations between anemic animals with and without CRF; however, in dogs there was considerable overlap between these two disease groups. In a study of anemia of CRF in dogs, 12 of 17 patients had nonregenerative anemia, and there was a direct correlation between severity of azotemia and anemia.[21] It is not clear how frequently or to what degree factors besides decreased EPO production contribute to development of anemia in animals with renal disease.

Recombinant EPO has been used extensively to treat anemia associated with CRF in humans and has been used to a lesser extent in dogs and cats. However, the use of such "erythropoiesis-stimulating agents" (ESAs)

is not without risk, as has been documented in the human literature, and the Food and Drug Administration recently ordered changes in the labeling of ESAs (http://www.fda.gov/cder/drug/infopage/RHE/default.htm; accessed September 2, 2008). Demonstrated or potential major risks of ESA therapy in humans include thromboembolism, promotion of tumor growth, and decreased survival. ESA therapy in people has also been shown to result in transient functional iron deficiency due to an imbalance between supply (available iron) and demand (increased erythropoiesis), a situation that can be remedied with intravenous iron therapy.

A potential side-effect of using recombinant human EPO (rhEPO) in animals is marked erythroid hypoplasia, the most severe manifestation being pure red cell aplasia (see Chapter 38). This is presumed to occur due to induction of antibodies that not only neutralize the recombinant EPO but are cross-reactive with the patient's endogenous EPO. This complication has been recognized in dogs, cats, and horses treated with rhEPO.[38] Species-specific recombinant canine (rcEPO) and feline EPO (rfEPO) have been developed; however, rfEPO resulted in development of red cell aplasia in some cats.[38] Neither rfEPO nor rcEPO is commercially available at the time of this writing.

ENDOCRINE DISEASE

Endocrinopathies are recognized to cause anemia in humans and animals. This section will focus on the relationship between anemia and several endocrine diseases that are well characterized in veterinary medicine: diabetes mellitus (DM), hypothyroidism, hyperthyroidism, and hypoadrenocorticism. Some of these conditions are associated with polyuria, and decreased plasma volume may mask the severity of anemia.[24]

The etiology is multifactorial, but development of anemia in patients with DM is closely linked with renal disease. In humans with DM, anemia occurs with secondary renal disease and functional EPO deficiency. Various other factors may also contribute to the anemia.[26,41]

Diabetes mellitus has been shown to cause increased Heinz body formation in cats, but it is not clear exactly how this relates to development of anemia (see Chapter 36). One study found Heinz bodies to occur significantly more often in cats with DM (19 of 21 cases) than in a healthy control group.[8] Evidence presented in this study suggested a causal relationship to anemia. A subsequent study found that cats with diabetic ketoacidosis had more Heinz bodies than non-ketotic diabetic cats. However, a significant association between percentage of Heinz bodies and degree of anemia was not found.[9] Heinz bodies were also detected in five cats with DM and hemolytic anemia associated with hypophosphatemia, but the hemolysis in these cats was presumed to be caused by hypophosphatemia.[2]

Nonregenerative anemia is a recognized complication of hypothyroidism in humans and animals, occurring in approximately one-third of cases in dogs.[35,36] Anemia develops primarily as a result of decreased erythropoiesis, with possible mechanisms including decreased EPO production, decreased responsiveness of developing erythroid cells to EPO, and direct effects of thyroid hormone on hematopoietic stem cells and erythroid progenitor cells.[36]

Despite thyroid hormone effects in promoting erythrocyte production, anemia occurs in approximately 10–25% of people with hyperthyroidism.[23] Decreased erythrocyte survival and ineffective erythropoiesis have been suggested to play a role in development of anemia in humans with hyperthyroidism. A study in cats found Heinz bodies to occur significantly more frequently in animals with hyperthyroidism (15 of 21 cases) than in a healthy control group, but not all affected animals were anemic and the study did not demonstrate a causal relationship between Heinz bodies and increased erythrocyte destruction.[8]

Humans and animals with hypoadrenocorticism are frequently anemic, but the anemia may be masked by decreased plasma volume.[24,27] The pathophysiology of anemia in hypoadrenocorticism is not well understood, but most likely involves decreased erythropoiesis, because glucocorticoids have been shown to interact with EPO and stem cell factor to promote erythropoiesis.[23] In a retrospective study of 225 dogs with hypoadrenocorticism, the prevalence of anemia was between 18% and 27%, depending on whether PCV or hemoglobin concentration, respectively, was used as an index of RBC mass. Blood loss, especially gastrointestinal hemorrhage, may also contribute to development of anemia in dogs with hypoadrenocorticism.[27]

Acronyms and Abbreviations

BFU-E, burst-forming unit-erythroid; CFU-E, colony-forming unit-erythroid; DNA, deoxyribonucleic acid; FeLV, feline leukemia virus; IgG, immunoglobulin G; IgM, immunoglobulin M; IMHA, immune-mediated hemolytic anemia; PCV, packed cell volume; PRCA, pure red cell aplasia; RBC, red blood cell.

Pure red cell aplasia (PRCA) defines a condition characterized by selective failure of erythropoiesis.[10,17,18,21] The cardinal findings include severe anemia, reticulocytopenia, and absence or extreme depletion of erythroid precursors in bone marrow (Fig. 38.1).[17,18,21] The anemia is normocytic and normochromic, and granulopoiesis and thrombopoiesis are unaffected. Pure red cell aplasia must be differentiated from aplastic anemia which, although the term has the same meaning, has been used to specifically denote panhypoplasia of the bone marrow (see Chapter 39).[5]

Pure red cell aplasia occurs in both dogs and cats, and most frequently results from an acquired immune response that attacks early erythroid precursor cells in the bone marrow. This can occur as a primary immune-mediated disease process or as a sequela of treatment with recombinant erythropoietin.[19,20,29] Selective erythroid cell destruction or altered replication also can occur secondary to viral infections or modified live virus vaccination.[2–4,8]

PURE RED CELL APLASIA IN DOGS

Immune-Mediated Pure Red Cell Aplasia

Definition and Incidence

Immune-mediated PRCA is considered to be a type of nonregenerative immune-mediated hemolytic anemia (IMHA).[18,28] Other types of nonregenerative IMHA include IMHA with arrested maturation and IMHA

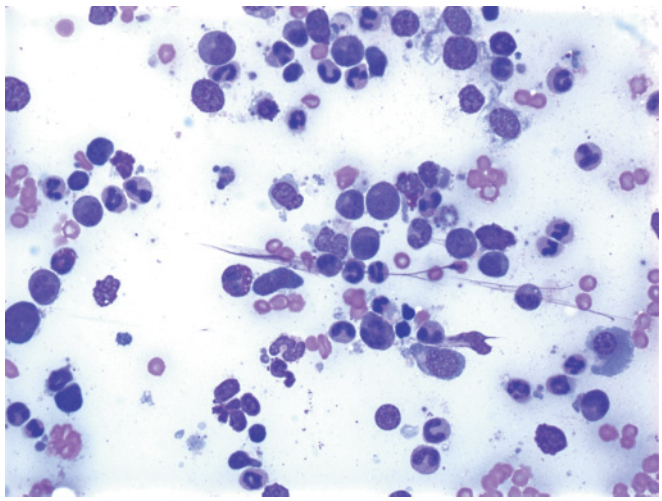

FIGURE 38.1 Bone marrow aspiration smear from a dog with immune-mediated pure red cell aplasia. Notice the presence of a normal population of granulocyte precursors but absence of erythroid precursor cells. Wright-Giemsa stain.

with erythroid hyperplasia (see Chapter 33). In one study of 82 dogs with primary nonregenerative IMHA, 33% had PRCA, 46% had nonregenerative IMHA with bone marrow erythroid hyperplasia, and 21% had nonregenerative IMHA with erythroid maturation arrest.[28] In another study, of 43 cases, 95% had maturation arrest or erythroid hyperplasia and only 5% had PRCA.[18] The overall incidence of PRCA is unknown but PRCA was diagnosed in 3.4% of dog bone marrows in a retrospective study of clinical bone marrow reports at a veterinary teaching hospital.[25]

The inclusion of PRCA as a subtype of nonregenerative IMHA is based on several observations. These include detection of serum antibodies that inhibit erythroid colony formation in vitro, positive direct Coombs' test results, and spherocytosis in some dogs.[18,20,29] Additionally, most affected dogs respond to immunosuppressive therapy.[18,20,29] T cell-mediated PRCA, that accounts for a large portion of primary PRCA in people, has not been documented in dogs.[6] Human T cell-mediated PRCA has been associated with thymoma, large granular lymphoma, chronic lymphocytic leukemia, other lymphoid malignancies, Epstein-Barr virus infection, and T cell leukemia virus 1 infection.[9,12] Lymphocytes from patients with these disorders suppress erythropoiesis in colony assays.

Clinical Features

Affected dogs tend to be middle-aged with a greater incidence in females but no known breed predisposition.[21] Presenting signs include lethargy, collapse, weakness, anorexia, ataxia, weight loss, pica, and seizures. Physical examination findings include mucous membrane pallor, systolic cardiac murmur (due to anemia), tachycardia, and tachypnea.[21]

Laboratory Features

Anemia is severe (median PCV = 10%), reticulocytopenia is profound, and total leukocyte and platelet counts are usually within the reference interval. Spherocytes, microcytes, or nucleated RBCs are observed in less than 20% of affected dogs. Direct Coombs' test results are infrequently positive.[21] Serum chemistry profiles are generally unremarkable. Bone marrow cellularity is normal or increased with normal numbers of granulocytes and megakaryocytes. Most affected dogs have virtually no erythroid cells in bone marrow aspirates but some have low numbers of rubriblasts and prorubricytes (Fig. 38.1). Increased numbers of plasma cells are present in most affected dogs and small lymphocyte are increased in some dogs.

Differential Diagnosis

Immune-mediated PRCA must be differentiated from other types of nonregenerative IMHA, PRCA associated with parvovirus infection or modified-live parvovirus vaccination, *Ehrlichia canis* infection, myelodysplastic syndromes, or anemias associated with chronic renal failure, and myelofibrosis.[3,8,13,18,21] Each of these conditions should be considered and appropriate diagnostic tests chosen. The presence of dysplastic features in bone marrow aspiration smears points to myelodysplasia as a cause of the anemia.[23] Dogs not vaccinated or recently vaccinated against parvovirus should be tested by measuring IgG and IgM levels and by testing for parvovirus DNA. Additionally, bone marrow could be evaluated for viral particles. Although chronic ehrlichiosis has not been definitively proven to cause PRCA, testing may be indicated in endemic areas.[13]

Therapy, Course, and Prognosis

Most affected dogs initially require packed RBC transfusions (see Chapter 95). Because response to immunosuppressive therapy is frequently delayed, repeated transfusions may be necessary.

All affected dogs should be treated with immunosuppressive doses of prednisone (1–3 mg/kg PO, q12 hours).[18] Nonsteroidal immunosuppressive agents that may be used in addition to prednisone include azathioprine and cyclophosphamide. The risk of thrombosis appears to be relatively low in PRCA; therefore aspirin or heparin therapy has not been used.[21] Recombinant erythropoietin therapy has not been extensively used in immune-mediated PRCA.

Response to immunosuppressive therapy is frequently delayed. In one study, median initial response time was 38 days and time required for the PCV to return to the reference interval was 118 days.[21] Complete hematologic recovery has been reported in 77% of dogs treated with immunosuppressive therapy, and partial recovery was reported in 8%.[21] In another report, response rate to immunosuppressive therapy was

reported as: complete response 61%, partial response 13% and poor response 26%.[18]

Parvovirus Infection- or Vaccination-associated Pure Red Cell Aplasia

Parvovirus infection or vaccination has been incriminated as a possible cause of canine PRCA (see Chapter 19).[8] Parvovirus B19 infection is a cause of PRCA in humans.[30] Parvovirus readily infects hemic precursor cells of dogs and causes acute aplastic anemia.[3,8] However, severe erythroid and megakaryocytic aplasia has been reported 1–3 weeks after vaccination of dogs with modified live parvovirus vaccine.[8] A causal relationship has been hypothesized.[8] In some dogs the aplasia was irreversible and led to death, whereas in other cases the dogs recovered.

Pure Red Cell Aplasia Associated with an Immune Response to Recombinant Human Erythropoietin

Dogs frequently develop PRCA 4–16 weeks after initiation of treatment with recombinant human erythropoietin.[19] The anemia occurs because dogs develop an immune response to the recombinant protein. These antibodies cross-neutralize endogenous canine erythropoietin resulting in profound anemia. The onset of anemia is typically 2–3 months after initiation of therapy and dogs usually recover spontaneously 3–11 weeks after discontinuing treatment.

Congenital Red Cell Aplasia

An inherited PRCA, termed Diamond-Blackfan anemia, has been described in children.[11] Congenital PRCA is not established as a diagnosis in dogs. However, one 3-month-old Samoyed was reported to have PRCA and have some features of the human condition.[14] Unlike Diamond-Blackfan syndrome, this dog had a mild thrombocytopenia, had no evidence of illness before 3 months of age, and had no congenital anatomical abnormalities that are seen in Diamond-Blackfan syndrome. Further, vaccination history was not discussed and parvovirus infection was not eliminated as a possible cause of the anemia. Therefore, a congenital origin for this condition remains in question.

PURE RED CELL APLASIA IN CATS

Immune-mediated Pure Red Cell Aplasia

Definition and Incidence

An immune-mediated etiology for PRCA is cats is based on positive direct Coombs' test results in some cats, response to immunosuppressive therapy, and the presence of mature lymphocytosis in bone marrow.[17,28] In a relatively recent retrospective study of clinical bone marrow reports at a veterinary teaching hospital, PRCA was diagnosed in 25 of 203 reports (12.6%).[24] Only one of these cats tested positive for feline leukemia virus. Another retrospective study conducted at a veterinary teaching hospital identified nine cats with immune-mediated PRCA during a 9 year period.[17] Therefore, reports vary regarding the relative incidence of PRCA in cats.[6,13]

Clinical Features

Affected cats are usually less than 3 years old.[17] Clinical signs include anorexia, lethargy, and behavioral changes. Physical examination findings include severe pallor of mucous membranes and systolic heart murmur (due to anemia).

Laboratory Features

All affected cats have a severe normocytic normochromic nonregenerative anemia (median hematocrit ~7%), with total leukocyte and platelet counts within or above reference intervals.[17,28] Bone marrow contains few or no erythroid cells; however, rare rubriblasts and prorubricytes are present in some cats. Dysplastic changes are not a feature of immune-mediated PRCA. The percentage of small lymphocytes is increased in more than 90% of cases and can exceed 50% of all nucleated cells in bone marrow.[28] Lymphoid aggregates are frequently seen in bone marrow core biopsy sections.[22,28] This benign lymphocytosis can be confused with a lymphoid malignancy. Unlike dogs, few cats have plasma cell hyperplasia in bone marrow.[24]

Differential Diagnosis

Immune-mediated PRCA must be differentiated from other types of nonregenerative IMHA, parvovirus infection, myelodysplastic syndromes, and anemias associated with chronic renal failure, and myelofibrosis.[26–28] Each of these conditions should be considered and appropriate diagnostic tests chosen. As in dogs, the presence of dysplastic features in bone marrow aspiration smears points to a myelodysplastic syndrome as a cause of the anemia. Cats not vaccinated should be tested for parvovirus infection.

Therapy, Course, and Prognosis

Most affected cats initially require one or more transfusions of packed RBCs (see Chapter 95). Immunosuppressive doses of prednisone (3.5–5.5 mg/kg PO, daily in divided doses) are routinely used for treatment of immune-mediated PRCA.[17] Cyclophosphamide (2.5 mg/kg PO q24 h for 4 days each week) is also frequently used in addition to prednisone.[17] Recombinant human erythropoietin therapy has been used but its benefit is uncertain. Long term use is contraindicated because cats may develop anti-erythropoietin antibodies.

Most cats respond to immunosuppressive therapy. The 60 day survival was reported to be 88% in one study.[28] Initial increases in reticulocyte count or hematocrit usually occur within 2–4 weeks after initiation of treatment and hematocrits return to the reference interval within 5 weeks.[17] Despite this rapid response, many cats require prolonged treatment with immunosuppressive drugs to manage this disorder. Some cats relapse when immunosuppressive therapy is withdrawn while other cats do not.

Feline-Leukemia Virus-induced Pure Red Cell Aplasia

Definition and Pathogenesis

Feline leukemia is currently classified into subgroups A, B, and C.[7] Subgroup C arises de novo from subgroup A through mutation or recombination with endogenous FeLV sequences. Studies with cloned FeLV have shown that FeLV subgroup C uniquely produces PRCA and results in a fatal anemia.[7] The genetic determinant of PRCA codes for the *N*-terminal 241 amino acids of an envelope gp70.[7,15] Anemogenesis may be mediated by an interaction of viral gp70 with a receptor on erythroid progenitor cells. However, the anemogenic activity of FeLV subgroup C is not dependent on unique tropism. Both FeLV subgroup C and FeLV subgroup A infect all three cell lineages in feline bone marrow; however, only subgroup C selectively eliminates erythroid precursor cells.[7] Erythroid burst-forming units (BFU-E) appear to be uniquely sensitive to FeLV subgroup C suppression. Erythroid colony-forming units (CFU-E) disappear 2–3 weeks before the onset of anemia in cats experimentally infected with FeLV subgroup C/Sarma while BFU-E and granulocyte-macrophage colony-forming units persist.[1] These data indicate that the gp70 of FeLV subgroup C/Sarma interferes with differentiation of BFU-E to CFU-E. The mechanism by which BFU-E fails to differentiate into CFU-E is incompletely understood. BFU-E fails to respond to hematopoietic growth factors and has an abnormal complement sensitivity.[2]

Clinical Features

Although FeLV-induced PRCA has been repeatedly induced experimentally, the clinical importance of the virus as a cause of PRCA is uncertain. Under experimental conditions, susceptibility to FeLV is age-related. Neonatal kittens are most sensitive with older kittens developing significant natural resistance by 4 weeks of age. Kittens inoculated with FeLV-KT became anemic in 3–8 weeks, whereas immunosuppressed cats inoculated with FeLV subgroup C became anemic after 9–45 weeks.[2,4]

Laboratory Features

Cats experimentally infected with FeLV subgroup C have a profound anemia (hematocrit < 10%), reticulocytopenia, and an absence of identifiable erythroid precursor cells in bone marrow.[16] Granulocyte and megakaryocyte precursors are usually normal. Extramedullary hematopoiesis is absent in the disorder. Some cats develop osteosclerosis or myelofibrosis with associated pancytopenia (see Chapter 18).

Course and Prognosis

FeLV-associated PRCA does not respond to immunosuppressive therapy or other known therapies. The anemia is unrelenting and disease progression is rapid despite therapeutic efforts.[16] Blood transfusions offer short term relief from the anemia. At present the prognosis is grave.

Pure Red Cell Aplasia Associated with an Immune Response to Recombinant Human Erythropoietin

As in dogs, cats can develop PRCA after treatment with recombinant human erythropoietin. Unlike dogs, cats can also develop PRCA after treatment with recombinant feline erythropoietin. The anemia results from an immune response to the recombinant protein that cross-neutralizes endogenous feline erythropoietin and results in profound anemia. Cats usually recover spontaneously after treatment is discontinued.

Acronyms and Abbreviations

FeLV; feline leukemia virus; RBC, red blood cell.

Aplastic anemia (also termed aplastic pancytopenia) is a clinical syndrome characterized by bicytopenia or pancytopenia in the blood and replacement of bone marrow by adipose tissue (Fig. 39.1).[4,22] Hematopoietic cells are nearly absent and the low number of cells that remain usually consist of lymphocytes and plasma cells. Excluded from this are pancytopenias associated with myelophthisic disorders, such as secondary myelofibrosis, and leukemias, hypoplastic myelodysplastic syndromes, pure red cell aplasia, hemophagocytic syndrome, myelonecrosis, and inflammatory disorders of bone marrow.[4]

Aplastic anemia can occur in acute and chronic forms. If the bone marrow suppression occurs acutely, as is seen in some types of drug- or virus-induced aplasia, neutropenia typically develops within 1 week followed by thrombocytopenia at 9–14 days.[28] Anemia does not develop for an extended period of time, because of the long lifespan of red blood cells (RBCs). Therefore, acute aplastic anemia is typically characterized by a neutropenia and thrombocytopenia. Acute aplastic anemia is most frequently associated with destruction of rapidly dividing progenitor or proliferative cells in bone marrow. In chronic aplastic anemia, the hematologic dyscrasia develops more slowly and is characterized by moderate to severe normocytic normochromic nonregenerative anemia, neutropenia, and thrombocytopenia.[22,14] Chronic aplastic anemia is most frequently associated with stem cell destruction.[22]

PATHOGENESIS

A large variety of etiologic agents have been incriminated in aplastic anemia. These include infectious agents, chemical/physical agents, drugs, toxins, and immune-mediated causes. The end result of each of these insults is decreased blood cell formation.[22,28] Although several mechanisms could lead to decreased hematopoiesis, direct toxic injury to stem cells or progenitor cells appears to be the primary mechanism involved in clinical aplastic anemia.[17,18] Other possible mechanisms include an altered stromal microenvironment resulting in failure to hematopoiesis, impaired production of hematopoietic growth factors, genetic mutations that decrease the proliferative capacity of stem cells, and immune-mediated suppression of hematopoiesis.[22] There is little experimental evidence to support defects in hematopoietic growth factors, the stromal microenvironment, or genetic mutations. T cell immunosuppression has been incriminated in the pathogenesis of idiopathic aplastic anemia in humans.[32] The role of autoreactive T cells in human aplastic anemia is supported by coculture studies in which marrow lymphocytes from affected patients suppressed hematopoietic colony formation of normal marrow.[19] Cytokines with inhibitory effects on hematopoiesis, including interferon-gamma, interleukin-2, and tumor necrosis factor-alpha, are increased in the marrow of patients with idiopathic aplastic anemia.[16] Therefore,

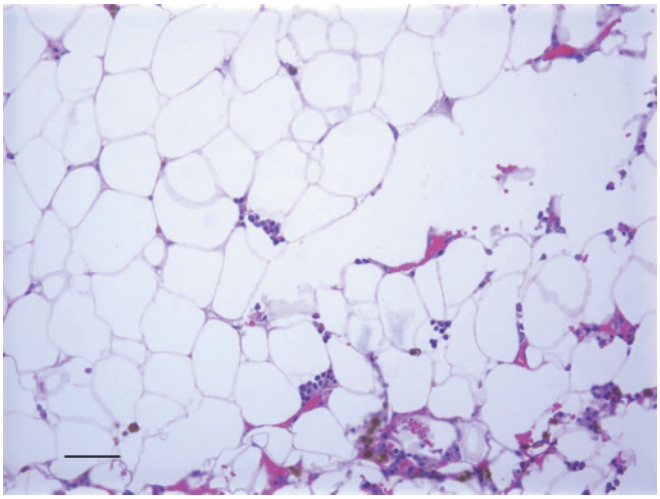

FIGURE 39.1 Bone marrow core biopsy section from a dog with idiopathic aplastic anemia. Cells present are mostly small lymphocytes and plasma cells. Hematoxylin & Eosin stain; bar = 200 µm.

immune inhibition in human idiopathic aplastic anemia is mediated in part by inhibitory cytokines released by cytotoxic T cells.[16] The autoreactive T cell etiology for idiopathic aplastic anemia is further supported by clinical trials in which anti-lymphocyte globulin has been used as an effective therapy for aplastic anemia.[22] Additionally, certain genetic mutations appear to predispose people to aplastic anemia.[24]

DIAGNOSIS

Inclusion criteria for a diagnosis of aplastic anemia in humans are well defined. They include: hemoglobin concentration <10 g/dL, reticulocytopenia, platelet count $<50 \times 10^3/\mu L$, a neutrophil count $<1.5 \times 10^3/\mu L$, and hypocellular bone marrow aspirates and core biopsies as well a battery of ancillary diagnostic tests including cytogenetic analysis of the peripheral blood and bone marrow, fetal hemoglobin percentage in children, flow cytometry for phosphatidylinositol glycan-anchored proteins, liver function tests, vitamin B_{12} and folate concentrations, viral studies, testing for immune-mediated diseases, and diagnostic imaging.[14] Diagnostic recommendations for aplastic anemia in veterinary patients are not well defined and currently minimally include evaluation of a complete blood count, bone marrow aspiration smear, and core biopsy specimen.[4,28] Fat content of bone marrow depends on location and depth of core biopsy. The bone marrow collection sites should be carefully chosen as fatty marrow samples can be obtained in healthy animals if an improper collection site is selected.[30] Ancillary diagnostic tests should be chosen based on the species and case history. Animals should be evaluated for drug, chemical, and toxin exposure, exposure to specific infectious agents and the presence of associated diseases such as chronic renal failure.[4]

Infectious agents in the dog include *Ehrlichia canis* and parvovirus infection, in the cat include feline leukemia virus and parvovirus infection, and in horses include equine infectious anemia infection.[4,26,28]

MODELS OF APLASTIC ANEMIA

A variety of in vivo and ex vivo animal models of aplastic anemia have been described.[5] A mouse model has been used to study benzene-induced aplastic anemia. Use of this model has enabled investigators to identify a benzene-induced defect in the capacity of bone marrow stromal cells to process cytokines. A mouse model of busulfan-induced aplastic anemia has been extensively studied.[5] Busulfan treatment results in hematopoietic stem cell depletion with pancytopenia and bone marrow aplasia developing up to a year after treatment. Other studies suggest the presence of a qualitative defect in hematopoietic stem cells or hematopoietic stromal cells. Radiation injury has also been studied in several species.[6] Exposure of mice to 4 Gy ionizing radiation resulted in significant reduction in hematopoietic stem cells.

Immune-mediated aplastic anemia has been reproduced in mice by sublethally irradiating them and injecting them with heterologous lymphocytes.[5] Total body irradiation with 6 Gy and injection of 10 million lymph node cells produced a fatal pancytopenia within 2–3 weeks. Aplasia was shown to be dependent on the presence of T cells in the infused lymphocyte population.

APLASTIC ANEMIA IN DOGS

Aplastic anemia was identified in 2.4% of clinical bone marrow specimens evaluated at a veterinary teaching hospital.[28] Of these, the majority (1.7%) were idiopathic.[4] Other causes of aplastic anemia included infectious causes, drugs, toxins, and radiation.

Infectious Causes

Infectious agents that cause aplastic anemia include parvovirus and *Ehrlichia canis* (see Chapters 19 and 31). Puppies with parvovirus infection develop erythroid and myeloid hypoplasia.[3] This is not a true aplastic anemia because the hypoplasia is accompanied by degenerative changes including myelonecrosis, edema, and hemorrhage (see Chapter 17).[3] These could be caused by the cytotoxic effects of the virus or more likely the effects of secondary bacterial sepsis or endotoxemia on the marrow microvasculature. Parvovirus invades rapidly dividing myeloid and erythroid progenitor cells. Hematopoietic stem cells are not infected. Therefore, bone marrow rapidly regenerates if puppies survive the acute stage of the disease. Dogs with chronic *Ehrlichia canis* infections develop hypoplastic bone marrows.[10] Rarely aplastic anemia may occur.

Drug-associated Causes

Drugs that induce hematologic dyscrasias are discussed in Chapter 16. In this chapter, some general comments about drug-induced aplastic anemia are presented. The mechanism by which the drug induces suppression of hematopoiesis is important to clinical finding and outcome. Drugs that target progenitor or proliferative cells in marrow, such as anti-neoplastic drugs and sulfadiazine, result in acute aplastic anemia.[29] In some cases these drugs are directly cytotoxic to rapidly proliferating hematopoietic cells, whereas other drugs act indirectly by inducing immune-mediated hematopoietic cell destruction. Affected dogs are typically neutropenic and thrombocytopenic but not anemic, and frequently undergo prompt hematologic recovery when the drug is withdrawn.[29] Drugs that target stem cells, such as estradiol and phenylbutazone, frequently cause chronic aplastic anemia that is characterized by pancytopenia.[29] Recovery is uncertain and when it occurs it may be delayed for months.

Canine bone marrow is uniquely susceptible to estrogen-induced suppression (see Chapter 16).[29] In dogs, a single large dose of estradiol, repeated therapeutic doses, and elevated endogenous estrogen levels associated with cystic ovarian follicles, ovarian granulosa cell tumors, or Sertoli cell tumors, result in hematologic dyscrasias.[23] Dogs with endogenous estrogen toxicity typically present with pancytopenia but some are bicytopenic.[23] Bone marrow is usually characterized by panhypoplasia; however, in the early stage, some dogs have granulocyte hyperplasia. Administration of a single large dose of estradiol to dogs results in a consistent transient aplastic anemia.[22] Individual dogs appear to be uniquely sensitive to the effects of estrogen and develop severe aplastic anemia. This appears to be the result of hematopoietic stem cell destruction The prognosis for these dogs is poor but recovery after weeks to months of supportive care has been documented.[29]

Idiopathic Aplastic Anemia

Idiopathic aplastic anemia was observed in 1.7% of clinical bone marrow specimens examined at a veterinary teaching hospital.[4] Affected dogs tend to be young adult with no sex or breed predisposition. The history usually indicates a chronic onset of illness with nonspecific signs including lethargy, anorexia, and exercise intolerance. Fever, petechiae, and epistaxis may also be observed. The anemia varies from mild to severe and is normocytic and normochromic. Neutropenia is usually severe with leukocytes consisting mostly of small lymphocytes. Thrombocytopenia varies from moderate to severe. Bone marrow aspirates and core biopsy specimens are markedly hypocellular. In some dogs, small lymphocytes or plasma cells are increased in number.

Treatment of canine idiopathic aplastic anemia is not well defined and is mostly supportive. Whole blood, packed RBC, or platelet transfusions are frequently needed. Broad-spectrum antibiotics are indicated to prevent opportunistic infections. Because of the clear connection with the human disease, a primary immune-mediated destruction of hematopoietic precursor cells has been suspected in canine idiopathic aplastic anemia. However, the author has found that administration of immunosuppressive doses of prednisone is ineffective as a treatment. This is not surprising because idiopathic aplastic anemia in humans only responds to intensive immunosuppressive therapy that includes anti-thymocyte globulin and steroidal and non-steroidal immunosuppressive drugs.[22]

Outcome of idiopathic aplastic anemia is variable. In one study of seven affected dogs, two dogs had complete hematologic recovery with symptomatic therapy and were alive more than 5 years after diagnosis.[4] Therefore, although the prognosis is guarded to poor, some have complete clinical recoveries.

APLASTIC ANEMIA IN CATS

Aplastic anemia has been observed in 10% of feline clinical bone marrow specimens at a veterinary teaching hospital.[31] Conditions associated with aplastic anemia include chronic renal disease, feline leukemia virus (FeLV) infection, prolonged anorexia/starvation, and adverse drug reactions including griseofulvin, chemotherapeutic agents, propylthiouracil, and methamizole.[27] Chronic renal disease is typically associated with nonregenerative anemia, and aplastic anemia is an infrequent finding. Some cats with aplastic anemia associated with chronic renal disease have serous atrophy of fat in bone marrow (see Chapter 18).[27] Serous atrophy of fat is usually associated with starvation. Starvation has been implicated in the pathogenesis of the marrow failure in people and other species.

FeLV infection has been associated with a variety of bone marrow disorders including aplastic anemia.[7,27] Cats usually have a severe normocytic normochromic anemia(hematocrit <10%), severe leukopenia, and thrombocytopenia. Affected cats frequently have secondary bacterial infections as a result of the neutropenia. Bone marrow is aplastic; however, the pathogenesis of the aplasia is unclear. Survival time for FeLV-associated aplastic anemia is usually short.

In one study of aplastic anemia in cats, 30% were classified as idiopathic.[27] However, most cats had associated disease conditions. The most frequent diseases included oral and gastrointestinal ulcers. Many affected cats had a history of prolonged partial or complete anorexia with associated cachexia.[27] One case had serous atrophy of fat and gelatinous transformation in bone marrow. Therefore, starvation may have played a role in the development of the aplasia in these cats.

Although not recognized as a clinical disorder, cat bone marrow appears to be uniquely sensitive to mycotoxins. Mycotoxin exposure results from ingestion of grain that becomes damp during storage permitting growth of fungi. In a search for an experimental model

for T-2 mycotoxicosis, sequiterpene T-2 mycotoxin was administered to rats, mice, guinea pigs, rabbits, dogs, pigs, sheep, poultry, cattle, horses, and cats.[13] Only cats developed signs of hematotoxicity. This was characterized by pancytopenia and bone marrow was characterized by hypocellularity, hemorrhage, inflammation, and multinucleated giant cells. Although this is consistent with acute toxic injury rather than aplastic anemia, the bone marrow may become aplastic at a later stage of the disease.

APLASTIC ANEMIA IN HORSES

Several reports of equine aplastic anemia have been published. These reports appear to present distinct types of bone marrow aplasia including idiopathic, drug-associated, possible toxin-associated, genetic, and hypoplastic myelodysplastic syndrome. A case of idiopathic aplastic anemia was reported in a 2-year-old Quarter Horse.[2] This horse had severe pancytopenia and bone marrow aplasia typical of aplastic anemia and had no history of exposure to drugs, toxins, or infectious agents. The horse died from hemorrhage as a result of the bone marrow biopsy procedure.

Several suspected drug-induced aplastic anemia cases have been reported. Phenylbutazone has been incriminated as a cause of aplastic anemia.[8] A 4-year-old Quarter Horse developed aplastic anemia after treatment with penicillin, trimethoprim-sulfadiazine, oxytetracycline, phenylbutazone, dipyrone, flunixin meglumine, and isoxsuprine.[11] This horse was also direct Coombs' test positive and had a transient increase in the blood of large immature basophilic cells resembling lymphoblasts. Therefore, it is difficult to incriminate any one drug as the cause of the aplasia, but penicillin and sulfadiazine are known to induce immune-mediated hematologic disorders. The horse had prompt and complete clinical and hematologic recovery after discontinuation of treatment.

Aplastic anemia in a 9-week-old Clydesdale foal was associated with biliary hyperplasia and portal fibrosis.[15] Because of this combination of findings, an in utero or neonatal toxicity was suspected. A panhypoplasia of bone marrow has been reported in eight Standardbred horses sired by the same stallion.[9]

Finally a severe nonregenerative anemia and leukopenia that initially had an aplastic bone marrow was reported in a 17-year-old Thoroughbred gelding.[25] Unusual features of this case were marked anisocytosis in the blood, normal numbers of megakaryocytes in bone marrow, and an increase in blast cells in bone marrow. Re-evaluation of bone marrow several months later revealed a hypercellular marrow with an increase in lymphocytes and blasts cells. This is suggestive of hypoplastic myelodysplastic syndrome (see Chapter 66).

Based on these sparse and varied reports, aplastic anemia appears to occur infrequently in horses. Drug-induced causes should be considered in all horses. In older horses leukemia and myelodysplastic syndromes may induce pancytopenia.

APLASTIC ANEMIA IN RUMINANTS

Drug-Associated Causes

A case of aplastic anemia in a 14-day-old Holstein heifer was associated with prior administration of sulfamethazine, trimethoprim, and sulfadoxine for treatment of bloody diarrhea.[1] Detection of aplastic bone marrow 8 days after initiation of sulfa therapy fits with a drug-induced aplastic anemia.

Bracken Fern Ingestion

Bracken fern (*Pteridium aquilinum*) is typically eaten by ruminants when pastures are overgrazed. After repeatedly ingesting bracken fern, cattle, horses, sheep, and pigs develop aplastic anemia.[19] The major toxin is a thiaminase called ptaquiloside.[31] Thiamine depletion in cattle is thought to be involved in the pathogenesis of aplastic anemia. Other species are more likely to develop neurological signs related to polioencephalomalacia.[31] Development of urinary bladder neoplasia (i.e. chronic enzootic haematuria) is also linked to prolonged ingestion of bracken fern.[19]

Trichloroethylene-extracted Soybean Oil Ingestion

Many cases of fatal aplastic anemia and renal injury in cattle in the 1950s were traced to feeding of trichloroethylene-extracted soybean oil meal.[12,21] Although trichloroethylene is no longer used to extract soybean oil, it and related compounds are widely used as solvents. The toxic factor was identified as *S*-(1-2-dichlorovinyl)-l-cysteine. Administration of a single dose of this compound intravenously at 4 mg/kg or 0.4 mg/kg per day intravenously for 10 days reproduces the aplastic anemia and renal injury.

Mycotoxin Ingestion

A variety of mycotoxins produce aplastic anemia in ruminants. Mycotoxin exposure occurs with ingestion of grain that is contaminated with fungi as a result of becoming damp during storage. Aplastic anemia has been documented in cattle and sheep ingesting feed contaminated with *Stachybotrys* spp.[20] Many other mycotoxins, including T-2 mycotoxin, trichothecene mycotoxin, trichothecene vomitoxin, diacetoxyscirpenol, ochratoxin, and zearalenone, appear to be directly cytotoxic to a variety of cells including hematopoietic precursor cells and lymphocytes.[6] As a result, many mycotoxins cause bone marrow hypoplasia/aplasia and lymphocyte depletion.[6] Initial changes in bone marrow consist of individual cell necrosis or apoptosis; however, by the time affected animals are evaluated

clinically the bone marrow frequently appears aplastic.[6] Depletion of primary and secondary lymphoid tissue may also be seen.

Acronyms and Abbreviations

BMAP, bovine myeloid antimicrobial peptide; BPI, bactericidal/permeability-increasing protein; eCATH, equine cathelicidin; e-NAP, equine neutrophil antimicrobial peptide; FMLP, formyl-methionyl-leucyl-phenylalanine; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; hCAP, human cathelicidin protein; K9CATH, canine cathelicidin; LAMP, lysosome-associated membrane protein; MPO, myeloperoxidase; NADPH, nicotinamide adenine dinucleotide phosphate; Nramp1, natural resistance-associated macrophage protein 1; PMAP, porcine myeloid antimicrobial peptide; SNARE, soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor.

Neutrophils provide the first line of defense against invading microorganisms, tissue trauma, or any inciting inflammatory signal.[1] The capacity of neutrophils to systematically engulf and fight bacteria depends on the presence of numerous membrane receptors and subsequent cell signaling along with specific cytoplasmic constituents within granules. The goal of this chapter is to provide a detailed overview of the constituents of cytoplasmic granules and associated membrane receptors and their functions. An attempt will also be made to provide comparative species differences whenever possible. For additional information on neutrophils, readers are referred to Chapters 4, 7, 41–43, and Section IX.

NEUTROPHIL ULTRASTRUCTURE

Mature, segmented neutrophils are approximately 10–12 µm in diameter.[5] Scanning electron microscopy shows that their surface contains numerous small pseudopodia (Fig. 40.1). This increases the surface area of the neutrophil, which is crucial to phagocytic function.[21] Mature neutrophils have a lobulated nucleus composed mostly of heterochromatin with a thin strand of euchromatin in the center. A nucleolus is only rarely observed, and few nuclear pores are present.[4] With the exception of numerous granules, neutrophil cytoplasm contains few organelles (mitochondria, Golgi apparatus, endoplasmic reticulum) and a variable number of glycogen particles. A thin rim at the periphery of neutrophils typically contains a small area free of organelles and inclusions but with numerous cytoskeletal proteins.[4]

NEUTROPHIL GRANULE TYPES

Neutrophils contain a variety of granules that contribute to the first-line host defense against bacteria, fungi, protozoa, and some viruses. These granules contain many proteins including antimicrobial proteins, proteases, and components of the respiratory burst, as well as receptors for endothelial adhesion molecules, extracellular matrix proteins, bacterial products, and soluble mediators of inflammation.[12] These proteins must be properly packaged and exocytosed in order to prevent widespread damage to host tissue.[24] The granule types and contents have been best characterized in humans; therefore this section focuses predominantly on what is known regarding human neutrophils with any identified species differences being noted.

In humans, there are three main granule types present in mature neutrophils: primary (azurophil or myeloperoxidase-positive), secondary (specific), and tertiary

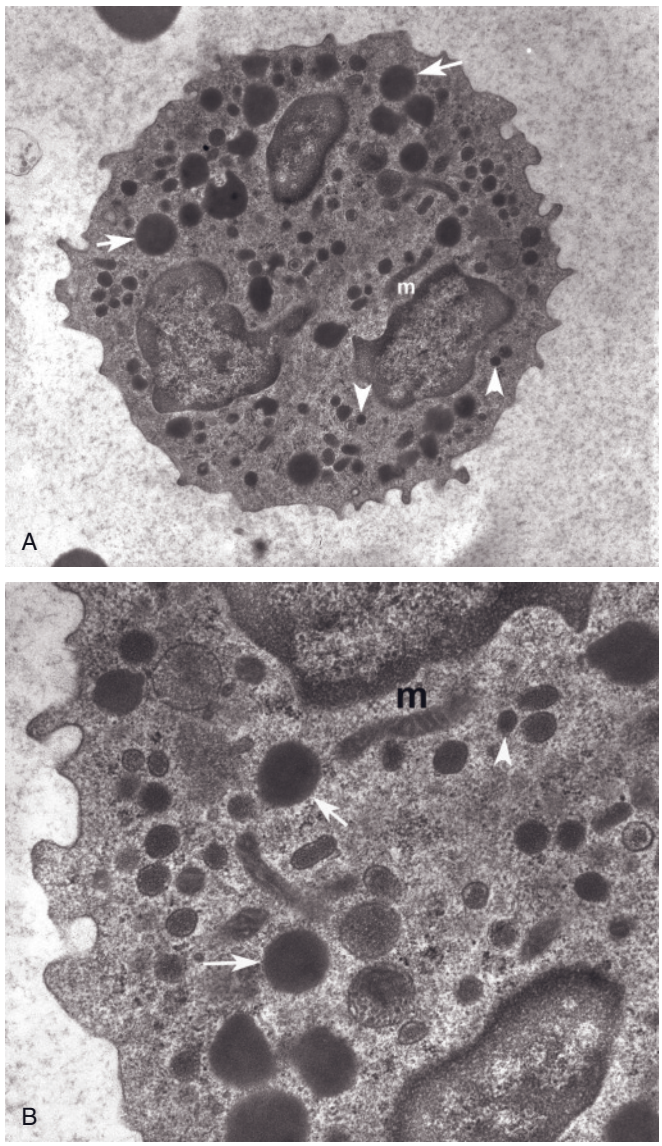

FIGURE 40.1 (**A**, **B**) Transmission electron micrographs of a segmented canine neutrophil. The neutrophil contains numerous variably-sized round to oval primary (arrows) and secondary (arrowheads) secretory granules. Several nuclear lobes are visible with marginated heterochromatin and central euchromatin. Few organelles, including rare mitochondria (m), are present in a cytosol replete with electron-dense glycogen granules. Stained with uranyl acetate and lead citrate. (**A**) ×8400 and (**B**) ×20,000. (Courtesy of Dr. Craig Thompson, Purdue University, College of Veterinary Medicine.)

(gelatinase) granules. Secondary and tertiary granules are both peroxidase-negative. Other similar structures present are secretory vesicles and multilaminar and multivesicular bodies. Secretory vesicles, which contain plasma proteins, are likely formed by endocytosis;[6] therefore they are classified as endocytic vesicles rather than true granules. Multilaminar and multivesicular bodies may be precursors to "housekeeping" lysosomes. Typical dense, mature lysosomes found in most other cells have not been identified in neutrophils.[8] Until fairly recently, primary granules were thought to be primary lysosomes. Like lysosomes, their membrane contains CD63 (lysosomal membrane-associated protein-3; LAMP-3) and CD68, but they do not have LAMP-1 or LAMP-2.[11] They, along with the other granules, may therefore be more accurately referred to as regulated secretory granules or lysosome-related organelles.[8,11]

Granules are, for the most part, formed sequentially during neutrophil maturation (Fig. 40.2). Primary granules are the first to be formed in the promyelocyte stage, while secondary granules are formed during the myelocyte and metamyelocyte stages.[2] Tertiary granules and secretory vesicles both appear to be formed in the band and segmented neutrophil stages.[6] Mature neutrophils therefore contain a mixture of granules and vesicles.

NEUTROPHIL GRANULE STRUCTURE

Neutrophil granules have a phospholipid bilayer membrane surrounding an intragranular matrix that contains proteins for either exocytosis into the environment or fusion with a phagosome. In most species, primary granules are the largest and most dense of the granules based on subcellular fractionation in a density gradient.[4] Primary granules can have great heterogeneity in size and shape.[6] Secondary granules are smaller, less dense, and more numerous than primary granules (Fig. 40.1).[4] They can be round, oval, elongated, or dumbbell shape.[6] Tertiary granules are slightly smaller than secondary granules. Secretory vesicles range from 100 to 200 nm in size and are widely distributed within the cytosol similarly to granules.[26] They do not have defining ultrastructural characteristics and have been identified on electron microscopy by double-labeling with anti-albumin and either anti-CD11b/CD18 (Mac 1) or anti-cytochrome b_{558} antibodies.[26]

The bulk of evidence supports the hypothesis that granule proteins are predominantly segregated into their respective granule by a "targeted-by-timing" expression of proteins rather than an active sorting mechanism.[12,15] In the targeted-by-timing theory, the proteins are produced by the endoplasmic reticulum in response to regulated expression of transcription factors present at specific stages of neutrophil development (e.g. PU.1, AML-1, C/EBPε).[7] Therefore, whichever proteins are being synthesized at the time a particular granule is produced will be incorporated into that granule.[10,12] For example, primary granules are formed during the promyelocyte stage, when myeloperoxidase is expressed.[6] However, not all protein differences among the granules can be explained by timing of their synthesis, because defensins are produced in both early and later stages, but are not incorporated into secondary and tertiary granules.[3,12,15]

GRANULE FUNCTION

The separation of proteins into different granules/compartments serves two major purposes. First, it separates

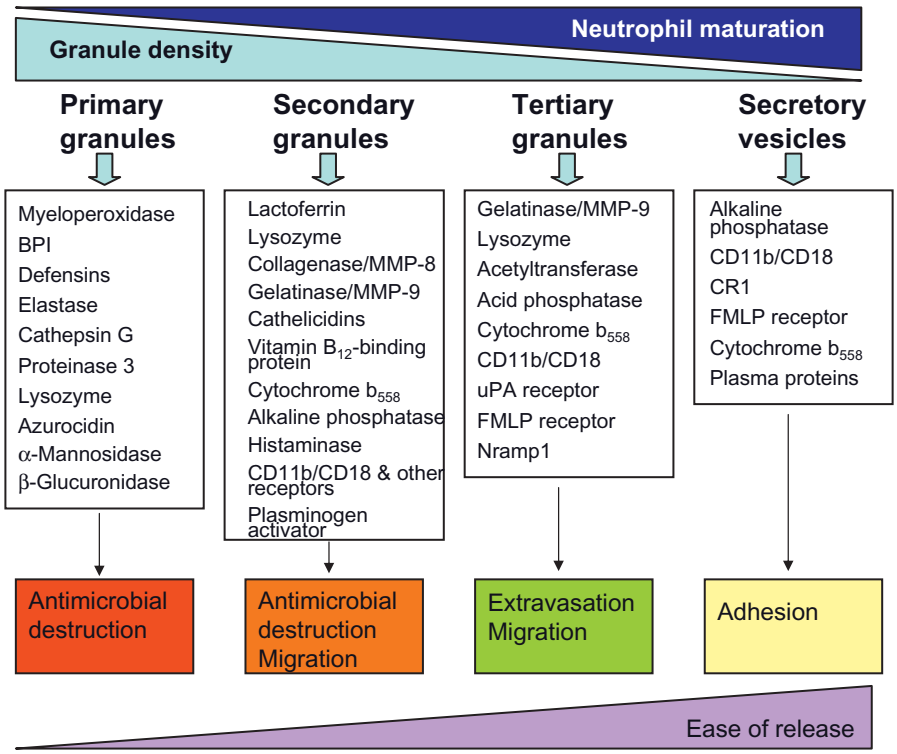

FIGURE 40.2 Neutrophil granules, contents, and their functions. Neutrophils contain primary, secondary, and tertiary granules and secretory vesicles that contain many proteins involved in neutrophil-mediated attack on microorganisms. The granules and their contents are sequentially formed during neutrophil maturation. The above figure contains a partial listing of granule contents. Although the granules have many overlapping functions, a simplified summary of the primary role of each granule is shown at the bottom of the figure. (Adapted from Gullberg U, et al. Processing and targeting of granule proteins in human neutrophils. J Immunol Methods 1999;232:201–210, with permission.)

proteins that cannot coexist together without the risk of activation of enzymes, protein degradation or cellular danage. Second, it allows for differential exocytosis of proteins based on varying degrees of neutrophil stimulation. This fulfills the need to have proteins available for use at different times and in different contexts to perform the multiple functions of the cell.

Granule release is dependent on receptor-mediated neutrophil stimulation by a variety of molecules. One of the frequently used activators studied in vitro is formyl-methionyl-leucyl-phenylalanine (FMLP), a bacterial peptide. This peptide illustrates the marked variation across species seen in neutrophil activation responses. For instance, neutrophils of humans, nonhuman primates, rabbits, guinea pigs, and mice are all activated by FMLP. However, neutrophils of cattle, pigs, dogs, and cats have no FMLP response presumably due to a lack of FMLP receptors.[28]

When granules are released, their contents can either be released into phagosomes (e.g. primary granules) or they can be released into the extracellular environment (e.g. secondary and tertiary granules).[19] During exocytosis, the granule or vesicle membrane becomes incorporated into the phagosome or neutrophil membrane, respectively. This concept of membrane fusion is crucial, as the granule/vesicle membranes contain many different receptors necessary for neutrophil extravasation, chemotaxis, migration, and immunomodulation.

There is significant overlap in protein content and function of these granules; however, it is useful to consider the general classes of enzymes and proteins present in each granule in order to highlight their primary function (Fig. 40.2). In general, their ease of exocytosis is inversely related to the order of the formation of the granules.[6,20] Secretory vesicles are the first to be released upon neutrophil stimulation, and they are rapidly and completely mobilized early during neutrophil-endothelial interactions. At the same time, L-selectin is shed from the neutrophil surface.[12,26] Secretory vesicle membranes contain adhesion proteins (e.g. CD11b/CD18), chemoattractant receptors, and complement receptors that are incorporated into the neutrophil cell membrane after exocytosis.[26] These receptors permit the neutrophil to establish firm adhesion with the endothelium, and aid in subsequent diapedesis and chemotaxis.[6] Tertiary granules are the next most readily released. They contain matrix-degrading enzymes (e.g. gelatinase) and membrane receptors that aid in neutrophil extravasation and migration.[12] Next to be mobilized are secondary granules, which contain many antimicrobial substances but also contain some matrix-degrading metalloproteinases. Secondary

granules, along with the primary granules, participate mainly in microbial destruction. The primary granules require the greatest stimulus in order to be released (Fig. 40.2).[6]

Granule Contents

Despite a large degree of overlap in the protein content among granules, there are several important proteins characteristic of certain granules. By definition, primary granules contain myeloperoxidase (MPO), a potent microbicidal hemoprotein involved in the oxygen-dependent destruction of microorganisms.[6,20] Other typical proteins found within primary granules include alpha-defensins, bactericidal/permeability-increasing protein (BPI) and the serine proteases such as elastase, cathepsin G, and proteinase 3. Recently, granzyme B has been identified in primary granules of human neutrophils.[29]

Defensins are powerful pore-forming antimicrobial peptides that are produced during the late promyelocyte and myelocyte stage. Primary granules can, therefore be divided into two types: early-appearing, defensin-poor primary granules and late-appearing, defensin-rich primary granules.[12] Bactericidal/permeability-increasing protein binds lipopolysaccharide of Gram-negative bacteria, inducing growth inhibition and membrane damage. It also mediates phagocytosis of bacteria.[12] The serine proteases can degrade extracellular matrix, aid in microbial death, and regulate the immune response.[16] Many of the proteins present in the primary granules are synthesized as proforms but the propeptides are removed during granule maturation, and they are therefore stored in their active conformation.[12]

Secondary granules also contain large amounts of antimicrobial substances, particularly lactoferrin, which is their main defining protein. Other antimicrobial proteins present in secondary granules include hCAP-18 (a cathelicidin), alkaline phosphatase, and lysozyme.[12] Secondary granules also contain several matrix-degrading enzymes such as collagenase and a small amount of gelatinase. The membrane of secondary granules is an important source of cytochrome b_{558}, a component of NADPH oxidase.[6] Enzymes in secondary granules are stored as inactive latent proforms and are activated upon exocytosis.

Tertiary granules have a large amount of gelatinase and only a small amount of lactoferrin. They also contain many other enzymes, including lysozyme. Tertiary granule membranes contain many important receptors and proteins, including natural resistance-associated macrophage protein 1 (Nramp1), which may help deprive microorganisms of divalent cations.[12]

Secretory vesicle membranes contain many receptors important in extravasation and phagocytosis (CD11b/CD18, CR1, FMLP-receptor, CD14) in addition to alkaline phosphatase. Their matrix contains plasma proteins, including albumin, while antimicrobial enzymes are absent.[26] A partial listing of granule contents is given in Fig. 40.2.

Neutrophil granules also contain anti-inflammatory proteins, and a recent study found the acute phase protein $alpha_1$-acid glycoprotein in bovine neutrophil granules.[23] $Alpha_1$-acid glycoprotein modulates the expression of anti-inflammatory cytokines by macrophages and decreases neutrophil chemotaxis, among other anti-inflammatory functions. This may provide a feedback mechanism whereby neutrophils can modulate their responses locally, limiting host tissue damage.[23]

Species Differences

There is a large degree of interspecies variability in the quantitative presence and activity of each granule element, and species-specific distribution of granule constituents may affect the pathogenicity of microorganisms in different species.[21,26,27] However, species-specific distribution of granule constituents is not well defined. Only a limited number of enzymes and proteins have been evaluated in species other than humans. To complicate comparison among those species that have been studied, most studies of neutrophil physiology and function use cells from a single species and use different collection, isolation, and processing techniques.[28]

Despite the relative lack of information regarding species differences in neutrophil granules, some conclusions can be made. First, it appears that most species studied contain primary and secondary granules, and the most frequent enzymes evaluated within these granules appear to be similarly distributed across species. Second, many species (cattle, sheep, goats, dogs, cats, rabbits, rats, guinea pigs, and horses) appear to have a third granule type that may or may not correlate in function with tertiary granules in humans.[4,13,27]

The third neutrophil granule in cattle has been the most characterized of the above species, and the third granule of sheep and goats appears similar. In cattle, these granules are large, dense, and peroxidase-negative and are referred to as "large" or "dense" granules.[14,30] They do not appear to be equivalent to the tertiary granules of humans. Ultrastructurally, they are the largest (0.4–0.5 μm) and most numerous granules in mature bovine neutrophils, and they contain pale homogeneous matrix material.[14] They are readily mobilized and are responsible for the majority of antimicrobial protein activity in bovine neutrophils, containing lactoferrin, bactenecins (members of the cathelicidin family), and beta-defensins.[30] They are the only neutrophil granule known to contain defensins in the bovine, in contrast to humans, where defensins are localized to primary granules.[30]

Regarding enzyme content, there is marked variation in neutrophil enzyme activity among species, which could be explained by an actual difference in neutrophil content of the enzyme, differences in the biochemistry and detection of the enzyme by the assay employed, or the presence of the enzyme in its inactive form.[25] Most information is based on studies that evaluate activity within the entire neutrophil rather than activity within individual granules.

In these studies, beta-glucuronidase and MPO were present to some degree in neutrophils of all species evaluated except chickens and geese. However, MPO activity was typically lower in animals compared to humans except for dogs and non-human primates.[25,28] A relatively recent study found that chicken heterophils contain MPO activity, contrary to the earlier studies showing a lack of MPO activity in avian heterophils.[17] Neutrophil lysozyme was deficient in monkeys, cattle, goats, sheep, cats, and hamsters, and only a small amount of activity was detected in horses, dogs, rats, and guinea pigs.[25,28] Alkaline phosphatase was undetectable in rhesus monkeys, cats, some mouse strains, chickens and geese, and was low in dogs.[25] A small degree of elastase activity was present in horse and pig neutrophils versus a large amount present in the rabbit.[28] Bovine neutrophils contained high levels of arylsulfatase, and both bovine and porcine neutrophils contained low levels of beta-glucuronidase.[28]

Alpha-defensins have been identified in neutrophils of humans, rabbits, guinea pigs, and hamsters, but not in mice, cattle, pigs, and birds. Beta-defensins have been identified in neutrophil dense granules of cattle and in avian heterophils, but not in neutrophils of sheep.[18] Theta-defensins are a newly described class of defensins that are present in granulocytes of rhesus macaques and other Old World monkeys and orangutans but not in great apes, humans, and New World monkeys.[18] Horse neutrophils contain only trace amounts of defensins but they do contain significant amounts of equinins (e-NAP1 and e-NAP2). These novel proteinase inhibitors have antibacterial and antiviral activities and are structurally different from defensins.[9,22] Cathelicidins are present in neutrophils of dogs (K9CATH), horses (eCATH), cattle (bactenecins, BMAPs), sheep, pigs (protegrins, prophenins, PMAPs), rabbits, guinea pigs, rats, mice, and birds.[18]

ARDS, acute respiratory distress syndrome; BPI, bacteria permeability-enhancing factor; C, γ subfamily of chemokines; CC, β subfamily of chemokines; CXC, α subfamily of chemokines; CX_3C, δ subfamily of chemokines; CXCL8, interleukin-8; DC, dendritic cell; MODS, multiple organ dysfunction syndrome; IFN-γ, interferon-gamma; ICAM, intercellular adhesion molecule; IL, interleukin; kDa, kilodalton; LBT, leukotriene; lymphocyte function-associated antigen (LFA-1)]; MOF, multiple organ failure; NETs, neutrophil extracellular traps; PSGL-1, P-selectin glycoprotein ligand-1; TNF-α, tumor necrosis factor-alpha; VCAM-1, vascular cell adhesion molecule-1.

Neutrophils circulate in the blood for only a few hours, existing either in a circulating or marginated pool. In healthy animals, neutrophils randomly leave the circulation, primarily migrating into the gut, lungs, and skin. This process is essential in preventing bacterial infection. When neutrophil numbers in the blood reach a critically low level (usually <500 segmented neutrophils/μL) animals are highly susceptible to bacterial infection. Neutrophils also are recruited from the blood to sites of infection. When they encounter a microorganism, they phagocytize and attempt to kill the pathogen. This chapter provides an overview of the mechanisms of neutrophil adherence, chemotaxis, phagocytosis, and organism killing.

ADHERENCE

The recruitment of neutrophils to sites of tissue injury and infection is a hallmark of the acute inflammatory response. Neutrophils leave the flowing bloodstream by first tethering and then rolling on inflamed endothelium. In the systemic circulation, this occurs primarily in post-capillary venules and collecting venules.[24] With the appropriate chemoattractants, rolling neutrophils will become firmly adherent to the endothelial surface and migrate across the endothelium, with transmigration being completed in less than 2 minutes.[2] Neutrophil transendothelial migration can occur through distinct routes, either paracellular (between endothelial cells) or transcellular (through endothelial cells).

Selectins

Selectins mediate the initial interactions between neutrophils and endothelium, resulting in their attachment and rolling. Rapid on and off bonding events between selectins and their ligands cause leukocytes attached to endothelium to roll under blood flow conditions (Fig. 41.1). There are three known selectins, each with a highly specific pattern of cellular expression. L-Selectin (CD62L) is expressed by leukocytes, E-selectin (CD62E)

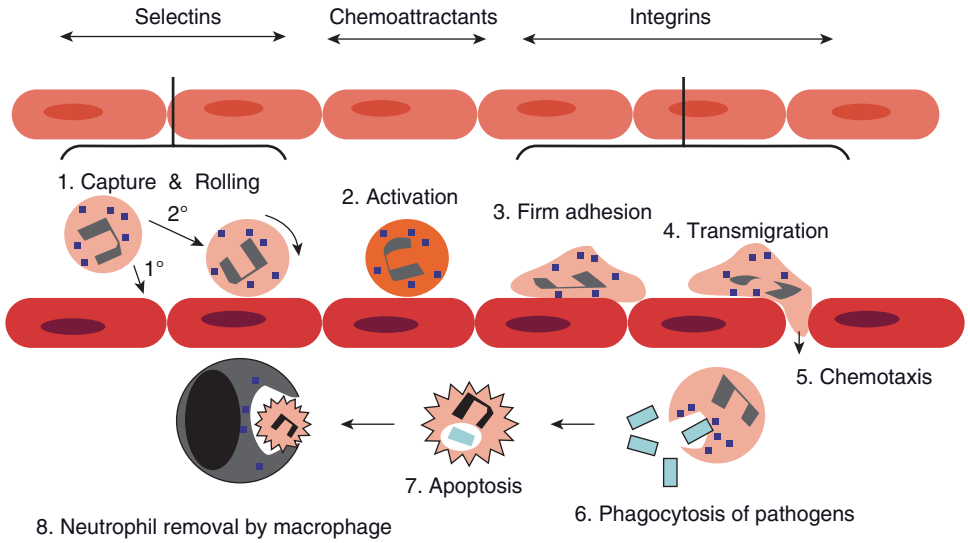

FIGURE 41.1 Antimicrobial activity of neutrophils is a multistep process. Neutrophils in flowing blood accumulate first by direct capture. The tethered neutrophils then roll and become activated by chemoattractants. This leads to firm adhesion and transendothelial migration. Upon entering the tissues, neutrophils migrate toward chemotatic gradients and phagocytize and kill bacterial pathogens. Phagocytosis induces programmed cell death (apoptosis) with resultant phagocytosis by macrophages.

is expressed by endothelial cells, and P-selectin (CD62P) is expressed by platelets and endothelial cells.

The selectins are type I integral membrane proteins composed of distinct tandem protein domains. Neutrophils uniformly and constitutively express L-selectin which plays a broad role in neutrophil recruitment. L-Selectin is tightly regulated. For instance, neutrophils down-regulate L-selectin expression by ectodomain proteolysis (shedding) in a very efficient and rapid manner upon their stimulation by cytokines and chemoattractants.[28] Studies performed in vitro and in vivo indicate that L-selectin shedding affects leukocyte adhesiveness and recruitment.[28] L-Selectin shedding maintains high levels of soluble L-selectin in the serum,[11] which can diminish leukocyte-endothelium interactions. Soluble L-selectin may serve as an adhesion buffer to suppress neutrophil accumulation below a certain inflammatory threshold. Interestingly, a reduced level of serum L-selectin correlates with susceptibility to inflammatory disease.

The selectin family of adhesion proteins are highly selective lectins that recognize specific glycan structures displayed in most cases on an appropriate protein backbone. P-Selectin glycoprotein ligand-1 (PSGL-1) is the main glycoprotein ligand on neutrophils for P-selectin. PSGL-1 also serves as the primary ligand on endothelium for L-selectin.[28]

Integrins

Integrins mediate firm adhesion of neutrophils and locomotion by interacting with ligands on cells and in the extracellular matrix (Fig. 41.1). Integrins consist of noncovalent heterodimers (α and β subunits) of type 1 transmembrane glycoproteins, and are made up of subfamilies that are organized around a particular subunit.[10]

The β_2 (CD18) subfamily is expressed on all cells of hematopoietic origin and plays a critical role in neutrophil transendothelial cell migration and in phagocytosis and apoptosis. CD18 integrins exist in an inactive state on circulating leukocytes, but undergo rapid affinity and valency changes required for optimal integrin function when stimulated with various chemoattractants. There are four known α (CD11) subunits that can combine with the CD18 subunit to form unique receptors. The α-subunits are defined as CD11a, b, c, and d. The α and β subunits are expressed from different genes and can be independently expressed on different cell types.

CD11b/CD18 ($\alpha_M\beta_2$ or Mac-1) is constitutively expressed by neutrophils, monocytes, and macrophages. Mac-1 is stored in secretory vesicles in neutrophils that are translocated to the surface following certain types of activation, allowing increased Mac-1 cell membrane expression. Mac-1, like LFA-1, is less active on resting cells than activated cells. Mac-1 interacts with intercellular adhesion molecules (ICAMs) and a growing list of other ligands. ICAMs are type I transmembrane glycoproteins and belong to the immunoglobulin superfamily.[12] ICAM-1 is expressed on resting endothelium and is induced on many cell types by inflammatory cytokines. Mac-1 participates in a number of adhesion reactions where the nature of the ligand is not known, such as adhesion of neutrophils to plastic or glass surfaces and binding to a variety of denatured proteins, suggesting a scavenger receptor-like function. Of particular importance is that Mac-1, also referred to as complement receptor 3, binds to C3bi. This complement fragment bonds to surfaces when triggered by immunoglobulin or microbial surfaces (opsonization), and particles coated with C3bi are readily phagocytized by neutrophils.

CD11a/CD18 ($\alpha_L\beta_2$ or lymphocyte function-associated antigen; LFA-1) is the most broadly expressed leukocyte integrin. It is expressed on early hematopoietic progenitor cells and on all mature leukocytes. LFA-1 interacts with ICAM-1, and ICAM-2, which are mainly expressed on endothelium, and ICAM-3 which is mainly expressed on leukocytes.

CD11c/CD18 ($\alpha_X\beta_2$ or P150,95) is highly homologous to Mac-1, but is expressed at lower levels on neutrophils. Like Mac-1, CD11c/CD18 binds to some of the same ligands, including C3bi, fibrinogen, a variety of denatured proteins, as well as binding to many pathogens.[12]

CD11d/CD18 ($\alpha_D\beta_2$) is the most recently defined member of the leukocyte integrin family and is expressed on tissue macrophages, dendritic cells, and eosinophils and binds to ICAM-3 and vascular cell adhesion molecule-1 (VCAM-1).[5] The latter binding interaction may contribute to recruitment of eosinophils to inflamed airways.

CHEMOTAXIS

Chemotaxis is accomplished by binding of chemokines to neutrophil receptors. This chemokine system is complex involving greater than 50 distinct chemokines and 20 G-protein-coupled chemokine receptors.[6,9,21] These chemokines are produced either constitutively or in response to inflammatory stimuli and regulate hematopoiesis, leukocyte trafficking, angiopoiesis, tissue architecture, and organogenesis. This diverse response of cells to chemoattractants is largely due to the cells' capacity to express a unique combination of chemokines receptors and the complex network of intracellular signaling that can result from receptor stimulation.

Chemokines are a superfamily of 8- to 15-kDa polypeptide molecules.[6,9,21] The chemokines are clearly distinct from other chemoattractants, such as complement components C3a and C5a and platelet-activating factor and leukotriene B4. Based on the presence of a cysteine at the amino terminal, chemokines have been classified into four subfamilies. The α subfamily has two cysteines separated by a single amino acid and so is designated the CXC subfamily. The δ subfamily has two cysteines and is designated the CC subfamily. The γ subfamily has one cysteine and is designated the C subfamily. The δ subfamily has two cysteines separated by three amino acids and is designated the CX_3C superfamily. To unify chemokine nomenclature, chemokines in each subfamily are named with the letter L (to denote ligand) and given a number (e.g. CXCL8 is the new name for IL-8). Although it had been thought that CXC chemokines target neutrophils and CC chemokines target mononuclear cells, more recent data indicate that subfamilies are not target cell-specific. Chemokines are produced by a wide variety of cells in the body. Each family of chemokines interacts with a reciprocal family of heterotrimeric, 7-transmembrane, G protein-coupled receptors that are expressed on leukocytes. In addition to leukocytes, other cells, including endothelial cells, epithelial cells, and muscle cells express chemokines and their receptors.[24] Chemokine receptor expression varies depending on the stage of leukocyte differentiation and exposure to activation stimuli.[24] Chemokines bind to receptors on leukocytes causing activation of a variety of cell signaling pathways. This signaling from the chemokine receptor results in polarization, and locomotion, in part through the activation of the integrin adhesion molecules. Leukocyte locomotion towards higher concentrations of a chemoattractant is termed chemotaxis and this can occur in a hierarchal manner. For instance, neutrophils become less sensitive to an initially encountered chemoattractant gradient, allowing them to then respond to a newly encountered chemoattractant.[8] This process allows neutrophils to find their ultimate target through a complex stimulant environment. Different classes of chemoattractants include chemokines, lipid mediators, complement factors, and other peptides.

PHAGOCYTOSIS

Neutrophils ingest bacteria and other particulate material by receptor mediated phagocytosis.[22] This process forms a vesicle around the organism and internalizes it. After internalization, the vesicle containing the organism undergoes a stepwise process of maturation in which the vesicle fuses predominately with primary granules and to a lesser extent with secondary granules. Within the phagolysosome, organisms are digested by proteolytic enzymes and reactive oxygen radicals. The process of phagosome fusion with primary granules and subsequent organism killing is complex and incompletely understood.

BACTERICIDAL MECHANISMS

Antimicrobial mechanisms within the mature phagosome have generally been divided into oxygen-dependent and oxygen-independent mechanisms.[13] Although these mechanisms interact in complex ways, they will be discussed separately.

Oxygen-Dependent Mechanisms

Oxygen-dependent mechanisms are located within primary granules.[1] These mechanisms are initiated by the process of phagocytosis or by perturbation of the cell membrane and are dependent on a membrane-bound nicotinamide-adenine dinucleotide phosphate (NADPH) oxidase. NADPH oxidase consists of five essential protein components. The membrane-associated component is a flavocytochrome b_{558}. Flavocytochrome b_{558} is distributed in the cell membrane and in the membrane of the granules and is incorporated into the wall of phagocytic vacuoles. The cytosolic components consist of a 40-kDa protein (p40-*phox*), a 47-kDa protein (p47-*phox*) and a 67-kDa

component (p67-*phox*). When stimulated, the cytosolic components are translocated to the membrane. Both assembly of the NADPH oxidase complex and electron flow are dependent on the influence of 3 GTP-binding proteins. The NADPH oxidase complex catalyzes the reduction of molecular oxygen to superoxide anion ($NADPH + O_2 \rightarrow NADP^+ + H^+ + O^{2-}$). The associated rapid consumption of oxygen has been termed the "respiratory burst." Superoxide anions are rapidly dismutated to hydrogen peroxide (H_2O_2). Superoxide anions also can be converted to hydroxyl radicals ($OH^\bullet$)in the presence of catalytic metals such as iron according to the Haber-Weiss reaction ($Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + OH^\bullet + O_2$). Myeloperoxidase catalyzes the conversion of H_2O_2 and halide ions to hypohalous acids with hypochlorous acid being the primary acid produced. Finally, H_2O_2 interacts with hypohalous acids to produce singlet oxygen ($^1O_2$). Singlet oxygen is a high energy form of oxygen that can attack double bonds. These reactive oxygen intermediates interact with unsaturated lipids, carbon bonds, sulfhydryl and amino groups, nucleic acids, pyrimidine nucleotides, and enzymes within organisms.

Products of the respiratory burst are toxic to cells as well as invading organisms. A variety of antioxidant systems exist to protect cells from the harmful effect of these oxidants.[27] These systems include cytosolic superoxide dismutase, glutathione peroxidase, glutathione reductase, and catalase, all of which convert oxygen radicals to water. Other compounds with oxygen radical scavenging potential include vitamin E, vitamin C, selenium, transferrin, and cysteine.[27] The glutathione needed for the reaction is maintained in the reduced state by reduced NADPH that is supplied by the pentose phosphate pathway.

Oxygen-Independent Mechanisms

Non-oxidative mechanisms may be more important in killing microorganisms than oxidative mechanisms. Some investigators hypothesize that the major role of the NADPH oxidase system is to adjust phagosomal pH and to pump electrons into the phagocytic vacuole.[25] This movement of ions across the phagosome membrane produces conditions that are conducive to oxygen-independent organism killing. For example, $gp91^{phox}$ of NADPH oxidase functions as a proton channel. This proton pump appears to be critical in shuttling hydrogen ion and several other ions across the phagosomal membrane. An influx of potassium appears to be important in liberating proteases such as elastase and cathepsins from their acidic proteoglycan matrix within granules. NADPH oxidase also is thought to induce depolarization that inhibits calcium influx into neutrophils.

Oxygen-independent bacterial killing mechanisms are present within primary, secondary, and tertiary granules. Contents of these granules are discussed in Chapter 40.

Defensins are a family of low-relative-molecular-mass antimicrobial peptides that have been isolated from neutrophils and heterophils of humans, rats, guinea pigs, and rabbits.[7] They contain six invariant cysteine residues and are arginine rich. The cysteine residues form disulfide bonds, and pairing of the first and sixth residues creates a cyclic structure. Defensin-like peptides have been isolated from cow and horse neutrophils and chicken heterophils. These peptides have a broad spectrum of antimicrobial activity, being active against both Gram-positive and Gram-negative bacteria, as well as some fungi, enveloped viruses, protozoa, and cells.

Bacteria permeability-enhancing factor (BPI) is a large, lysine-rich protein that is active against *Escherichia coli* and *Salmonella typhimurium* but lacks antimicrobial activity against Gram-positive bacteria and fungi. Bacteria permeability-enhancing factor appears to bind to the outer membrane of susceptible Gram-negative bacteria and increases membrane permeability to hydrophobic molecules.

Granulocytes also contain a variety of proteases and acid hydrolases, the most notable of which are cathepsin G, elastase, collagenase, lysozyme, acid phosphatase, aryl sulfatase, neuramidase, and nuclease. Cathepsin G has microbicidal activity against Gram-positive and Gram-negative bacteria as well as some fungal organisms. Cathepsin G also inhibits bacterial respiration and energy dependent transport systems, as well as protein, DNA, and RNA biosynthesis. Elastase degrades bacterial cell wall proteins and potentiates the lytic activity of lysozyme and the microbicidal activity of cathepsin G. Lysozyme is a cationic protein that hydrolyzes bacterial cell walls by attacking the β1–4 glycosidic linkage that joins *N*-acetyl muramic acid and *N*-acetyl glucosamine of peptidoglycan. Lactoferrin has bacteriostatic activity that is associated with its capacity to sequester iron. However, lactoferrin also exerts a bactericidal effect independent of its bacteriostatic effects.[16]

Neutrophils also appear to trap and kill pathogens in what has been termed neutrophil extracellular traps (NETs).[29] Neutrophil extracellular traps form from activated neutrophils and consist of neutrophil-derived DNA embedded with enzymes and antimicrobial peptides. Neutrophil extracellular traps provide a high local concentration of antimicrobial molecules that kill microbes effectively. The process of cell death that results in NET formation is dependent on generation of reactive oxygen species by NADPH oxidase. NETs have been described in cattle.[17] Formation of NETs is not inhibited by milk; therefore NETs may play an important role in defense against mastitis.

NEUTROPHIL-MEDIATED AMPLIFICATION OF INFLAMMATION

Neutrophils secrete a variety of proinflammatory mediators that amplify the inflammatory process. These include leukotrienes, prostaglandins, cytokines, and chemokines. Arachidonic acid and other C20 polyunsaturated fatty acids are the immediate precursors of prostaglandins and leukotrienes (LBTs). They are

released from phospholipids by the action of phospholipase A, phospholipase C, and diacylglycerol lipase. Neutrophils, monocytes, macrophages, eosinophils, and mast cells are major producers of LTB. Separate pathways synthesize LTB4 and sulfidopeptide leukotrienes (LTC4, LTD4, LTE4). Neutrophils synthesize mostly LTB4. LTB4 has both priming and direct activating effects on neutrophils. It is a potent chemotatic and chemokinetic agent for neutrophils, monocytes, and eosinophils. It also stimulates neutrophil aggregation, superoxide production, and integrin expression.

Neutrophils secrete a broad spectrum of cytokines that are mostly involved in the innate immune response.[26] Activated neutrophils release tumor necrosis factor-α (TNF-α), IL-1β, and IL-6. At sites of inflammation, release of these cytokines amplifies the inflammatory process. Neutrophils also produce interferon-gamma (IFN-γ), IL-12, and transforming growth factor-β, known to affect adaptive immunity.

Neutrophils secrete both CC and CXC chemokines. CC chemokines include macrophage inflammatory protein-1α and -1β. CXC chemokines include CXCL8 (IL-8) and CXCL10 (IFN-γ-inducible protein-10). Therefore, neutrophils amplify the inflammatory response by attracting more inflammatory cells to the site.

ROLE OF NEUTROPHILS IN THE ADAPTIVE IMMUNE RESPONSE

Although neutrophils are key players of the innate immune response that provide a first line of defense against invading pathogens, there is increasing evidence for their role in modulating the adaptive immune response as well. Neutrophils play an immunoregulatory role and are able to signal other members of the immune system. Through release of chemokines such as MIP-1α, neutrophils recruit immune cells including T cells, monocytes, macrophages, and dendritic cells (DCs). In addition, antimicrobial peptides produced by neutrophils (e.g. alpha-defensins) can attract T cells and immature DCs. Conversely, regulatory T cells can secrete cytokines (e.g. IL-17) that attract neutrophils. Further, a recent report has demonstrated that regulated cellular interactions between neutrophils and immature DCs contribute to neutrophil-induced adaptive responses. Together, these chemokines, cytokines, and cellular interactions indicate the role of neutrophils is in passing information on to other players of the adaptive immune response.

Consistent with these observations are studies that suggest that, in addition to DCs, neutrophils may shuttle particulate antigens and microbes from the periphery to lymphoid tissue. It is unknown how neutrophils that gain access to lymphoid tissue affect the ensuing immune response. It is important to note that most of this information is derived from human and mouse studies and functional differences between neutrophils of human, murine, and veterinary species may limit direct extrapolation of these results.

NEUTROPHIL-MEDIATED TISSUE INJURY

Neutrophils have the capacity to injure host tissues by the same mechanisms as are used to kill invading organisms.[14,15] This injury can vary from local tissue injury at a site of inflammation to a systemic inflammatory response syndrome. Several experimental models of neutrophil-mediated tissue injury have been developed. These include neutrophil-mediated rat lung injury induced by thermal injury to skin, ischemia-reperfusion-induced injury to several organs, endotoxin-induced lung injury, and injury of isolated perfused organs. Neutrophils have been incriminated in local injury at sites of inflammation and in ischemia-reperfusion injury. Systemic disease states in which neutrophil-mediated tissue injury has been incriminated have variously been termed systemic inflammatory response syndrome, acute respiratory distress syndrome (ARDS), endotoxic shock, septic shock, and multiple organ dysfunction syndrome (MODS).[14,15] The lungs are particularly sensitive to neutrophil-mediated injury both because of their extensive capillary network and a unique sensitivity of their capillary endothelium to neutrophil-mediated injury. However, other organs, including heart, liver, and kidneys, can be damaged and undergo functional compromise.

Neutrophil-Mediated Injury at Sites of Inflammation

The most studied localized neutrophil-mediated organ injury in veterinary medicine is lung injury associated with shipping fever in cattle. Invasion of the causative organism, *Mannheimia haemolytica*, results in rapid recruitment of neutrophils into the lungs within the first 2 hours. These changes are characterized histopathologically by a fibrinopurulent pneumonia and by endothelial disruption and alveolar epithelial swelling.[35] The endothelial and alveolar epithelial damage occurs immediately beneath sites of neutrophil attachment. Activation of neutrophils while they are attached to endothelium may cause vascular injury and resultant increased permeability, resulting in flooding of alveoli with plasma.[18] Neutrophil depletion before experimental inoculation of *Mannheimia haemolytica* organisms into the lungs of calves markedly attenuates alveolar capillary endothelial injury in the first 6–8 hours after inoculation of the organism.

Ischemia/Reperfusion Injury

Prolonged ischemia results in metabolic and ultrastructural changes within cells. Ischemia decreases cellular oxidative phosphorylation resulting in failure to resynthesize high energy phosphate compounds such as adenosine 5′-triphosphate. Adenosine 5′-triphosphate catabolism during ischemia results in accumulation of hypoxanthine. Upon reperfusion of hypoxic tissue, hypoxanthine is converted to oxygen radicals. Ischemia also promotes expression of leukocyte and platelet adhesion receptors on the cell surface, promotes expres-

sion of proinflammatory cytokines, and bioactive agents, and suppresses anti-inflammatory and antithrombotic gene products, including nitric oxide, nitric oxide synthase, thrombomodulin, and prostacyclin. Reperfusion injury is primarily directed at the endothelial cells lining the microvasculature and is manifest as accelerated production of a variety of bioactive agents and expression of adhesion molecules for neutrophils.[4] Neutrophils become activated while attached to endothelium, releasing oxygen radicals and granule contents directly onto the endothelial surface. Superoxide is also generated from hypoxanthine within endothelial cells and by mast cells and macrophages.

Neutrophils may also contribute to tissue hypoperfusion after blood flow is reestablished. Activated neutrophils are rigid and tend to lodge in capillaries. Neutrophil-neutrophil aggregates and platelet-neutrophil aggregates may plug capillaries, resulting in prolonged maldistribution of blood flow. Platelet-neutrophil aggregates may also contribute to microthrombus formation.

Neutrophil-Mediated Injury at Distant Sites

Neutrophils can become activated within the circulation during a variety of physiologic and pathologic conditions in domestic animals. Circulating activated neutrophils have been documented during strenuous exercise, inflammatory disease, equine colic, and equine laminitis. The extent to which these activated neutrophils induce organ injury/failure is uncertain but there is evidence to suggest that these activated neutrophils may contribute to the pathogenesis of organ injury in some disease processes.

Exercise

Strenuous exercise has been associated with up-regulation of neutrophil surface-associated integrin receptors in dogs undergoing short duration sled-pulling activity.[20] Additionally, decreased neutrophil granularity was observed post-exercise. Because CD11b/CD18 is stored in neutrophil granules and is transported to the cell surface when neutrophils degranulate, the combination of increased cell surface integrin concentration and decreased granularity post-race is consistent with exercise-associated neutrophil degranulation.

Inflammatory Disease

Neutrophils circulate in an activated state in a variety of inflammatory conditions. Dogs with naturally occurring septic and non-septic inflammatory diseases had increased cell surface expression of CD11b.[34] Neutrophils from dogs with septic inflammatory diseases and those with evidence of multiple organ dysfunction also had decreased neutrophil granularity and increased neutrophil size. However, leukocytes may have decreased bactericidal activity. Monocytes and lymphocytes from dogs with septic and non-septic inflammation and multiple organ dysfunction had decreased expression of major histocompatability factor class-II, suggesting impaired immune responsiveness.[34]

Leukocyte deformability, neutrophil CD11b expression, and neutrophil size were evaluated in calves experimentally inoculated intrabronchially with *Mannheimia haemolytica* organisms.[19] Infected calves had decreased leukocyte deformability and increased neutrophil size by 1 hour and increased CD11b expression by 6 hours after organism inoculation. Decreased neutrophil deformability and increased size may contribute to sequestration of neutrophils in alveolar capillary beds during sepsis.

Equine Laminitis

Neutrophils may become activated in the prodromal stages of equine laminitis. At various times during the first 12 hours after induction of black walnut-induced laminitis, horse neutrophils had increased oxygen radical production and some horses had increased phagocytosis of bacteria.[3] These changes were associated with neutropenia and were presumed to be due to a systemic inflammatory response resulting from absorption of inflammatory mediators from the intestine. These activated neutrophils have been incriminated in the pathogenesis of the laminar injury.[3]

Equine Colic

Activated neutrophils were not detected in healthy horses or horses with impaction or gas colic.[30] Conversely, horses with inflammatory bowel disease consistently had increased neutrophil cell membrane CD11/CD18 expression, increased neutrophil size, and decreased neutrophil granularity consistent with circulating activated and degranulated neutrophils. These horses also had decreased leukocyte deformability, indicating that neutrophils were rigid. Horses with strangulating colic had variable results. Among horses with strangulating colic, changes in leukocyte deformability, neutrophil size, and neutrophil granularity correlated directly with adverse outcome.

Acute Respiratory Distress Syndrome and Multiple Organ Failure

Activated neutrophils are central to the pathogenesis of ARDS and MODS associated with sepsis and endotoxemia.[15] In these conditions microvascular injury is the major site of organ injury. The lungs are particularly sensitive to neutrophil-induced vascular injury. The process of neutrophil sequestration in the lungs differs from that of other tissues. In other tissues, neutrophil sequestration occurs predominately in post-capillary venules and is dependent on selectin and integrin adhesion molecules. By contrast, neutrophil sequestration in the lungs occurs primarily in pulmonary capillaries and is largely independent of adhesion molecules. Sequestration is thought to be the result of rigid activated neutrophils lodging in the extensive capillary beds within lung tissue.

Limited neutrophil activation while in contact with the endothelium is part of the normal adhesion and emigration process. However, excessive activation of neutrophils while attached to endothelium can result in direct release of oxygen radicals and granule contents onto the endothelial surface. Mediators implicated in various experimental models of ARDS include oxygen radicals, activated complement factors, nitric oxide, proteolytic enzymes, and metalloproteinases.[14] Consequences of this endothelial injury include: (1) massive leakage of plasma into alveoli, (2) vasodysregulation leading to maldistribution of blood flow, and (3) disturbances of oxygen transport and utilization. All of these lead to dypsnea and hypoxemia.

Neutrophils have been incriminated in the pathogenesis in acute inflammatory liver disease.[23] Neutrophils can be activated in the circulation by a variety of factors including cytokines, chemokines, and complement. After activation they accumulate in the hepatic microvasculature and transmigrate into the hepatic parenchyma. Neutrophils can directly adhere to hepatocytes and kill them through oxidative and non-oxidative mechanisms.[23]

Role of Neutrophils in Microvascular Thrombosis

Local and disseminated activation of coagulation frequently accompanies sepsis and endotoxemia.[33] The mechanism responsible for this sepsis-induced procoagulant effect is complex. The role of neutrophils in microvascular thrombosis appears to be in their capacity to induce endothelial injury and to bind and activate platelets. Endothelial injury results in conversion of the endothelial cell surface from an anticoagulant surface to a procoagulant surface. Destruction of endothelial cells activates the intrinsic clotting system through exposure of subendothelial collagen and activates the extrinsic coagulation system (i.e. tissue factor pathway) through contact with tissue factor.

Platelets frequently become activated during sepsis and endotoxemia. Both activated neutrophils and activated endothelial cells express platelet-activating factor that is a potent platelet agonist. When activated platelets degranulate, P-selectin is transported from alpha granules to the cell membrane. P-Selectin interacts with PSGL-1 on the neutrophil surface forming platelet-neutrophil aggregates. Platelet-neutrophil aggregates are rigid and, therefore lodge in capillary beds and initiate microvascular inflammatory and thrombotic events. Platelet-neutrophil aggregates have been detected in horses undergoing near-maximal treadmill exercise and in horses and ponies with carbohydrate overload-induced laminitis.[31,32]

CHAPTER 42

Neutrophil Function Disorders

DOUGLAS J. WEISS

Congenital Neutrophil Function Defects
- Leukocyte Adhesion Deficiency
  - Bovine leukocyte adhesion deficiency
  - Canine leukocyte adhesion deficiency
- Granule Alterations
  - Chédiak-Higashi syndrome
  - Birman cat neutrophil granulation anomaly
  - Mucopolysaccharidosis
- Defects in Oxidative Metabolism
  - Chronic granulomatous disease in Doberman pinschers
  - Myeloperoxidase deficiency in cyclic hematopoiesis of gray collies
  - Altered chemiluminescence in Weimaraners
- Other Defects
  - Cyclic hematopoiesis in gray collies
  - Pelger-Huët anomaly

Acquired Neutrophil Function Defects
- Neutrophil Dysfunction in Periparturient Dairy Cattle
- Neutrophil Dysfunction in Neonatal Animals
- Neutrophil Dysfunction Associated with Viral Infection
- Neutrophil Dysfunction Associated with Parasitic Diseases
- Effects of Stress on Neutrophil Function
- Effects of Nutrition on Neutrophil Function

Acronyms and Abbreviations

BLAD, bovine leukocyte adhesion deficiency; BVDV, bovine viral diarrhea virus; CD, cluster of differentiation; CLAD, canine leukocyte adhesion deficiency; IBRV, infectious bovine rhinotracheitis virus; Ig, immunoglobulin; LAD, leukocyte adhesion deficiency; MPS, mucopolysaccharide; MSP, mucopolysaccharidosis.

CONGENITAL NEUTROPHIL FUNCTION DEFECTS

Leukocyte Adhesion Deficiency

Leukocyte adhesion deficiency (LAD) syndromes (LAD-1, LAD-1 variants, and LAD-2) result in impaired extravasation of neutrophils into sites of inflammation due to dysfunctional selectin- or integrin-mediated adhesion events.[2] The LAD syndromes are relatively uncommon; however, the clinical consequences are often severe and lethal, and include recurrent or unresolved localized infections, systemic sepsis, and impaired wound surveillance and repair.

Classical leukocyte adhesion deficiency type 1 (LAD-1) is an autosomal recessive disorder arising from germ line mutations in the gene encoding CD18 and thus affects all CD18 subfamilies.[2] LAD-1 has been described in humans, Holstein cattle, dogs, and mice.[2,19] In humans, the CD18-integrin subunit is either not synthesized or unable to associate with the respective CD11 subunits, and the resulting LAD can be characterized as severe to moderate.

Bovine Leukocyte Adhesion Deficiency

Bovine leukocyte adhesion deficiency (BLAD) has been extensively investigated.[1] The molecular basis of BLAD is a single point mutation that results in an aspartic acid to glycine substitution at amino acid 128 of the CD18 polypeptide. Interestingly, expression of L-selectin on neutrophils from BLAD calves appears to be reduced as well. Neutrophil adhesion is markedly impaired and chemotatic responses are diminished. The hallmark clinical findings in BLAD include recurrent or chronic diarrhea, chronic pneumonia, ulcerative stomatitis, gingivitis, chronic dermatitis, stunted growth, and impaired wound healing. Persistent and severe neutrophilia is the most prominent hematologic finding; however, neutrophil morphology is normal. Pathologic lesions are primarily located in lungs and intestinal tract. Neutrophils are present in lung lesions but not in

intestinal ulcers or lesions in other tissues. Therefore, neutrophils can enter the lungs by integrin-independent processes.[1]

Canine Leukocyte Adhesion Deficiency

Canine leukocyte adhesion deficiency (CLAD) occurs in Irish Setter and Irish Setter-cross-bred dogs.[17,19,39] As with BLAD, the molecular basis of CLAD is due to a single point mutation; however, in the dog, a cysteine at amino acid 36 is substituted for a serine. This cysteine is a highly conserved residue in the extracellular domain of CD18, and the structural defect results in a failure to express the CD11/CD18 complex on the leukocyte surface. Affected dogs develop severe bacterial infections shortly after birth and usually die or are euthanized.

Granule Alterations

Chédiak-Higashi Syndrome

Defective phagosome maturation occurs in Chédiak-Higashi syndrome which is inherited in an autosomal recessive manner. Chédiak-Higashi syndrome has been described in human beings, Hereford, Brangus, and Japanese black cattle, Persian cats, beige mice, Arctic foxes, mink, and a killer whale.[3,11] These species have abnormal lysosomal granule formation and altered degranulation. This appears to result from a defect in lysosomal docking proteins. Granule membrane fusion is defective and discharge of granule contents into the phagosome is delayed.[31] Additionally, in some species altered microtubule formation results in decreased chemotaxis. A hallmark of the condition is fusion of granules in neutrophils, eosinophils, epithelial cells, renal tubular cells, and Kupffer cells. Resultant pink- to magenta-staining granules are seen in all species (Fig. 42.1). Neutrophil function abnormalities vary somewhat between species. Cattle and mice appear to have increased susceptibility to bacterial infection as a result of impaired neutrophil function.[33,44] Neutrophil function appears to be less severely affected in cats.[11] Most species have platelet-related bleeding due to platelet granule defects.[33] Humans and animals have partial oculocutaneous albinism due to altered distribution of melanin granules. Typical of the pigmentation alterations are the beige mouse, the Aleutian mink, and the smoke blue Persian cat with yellow-green irises. Diagnosis of Chédiak-Higashi syndrome is based on the presence of altered pigmentation, presence of giant granules, hemorrhagic tendencies, and possible susceptibility to infection.

Birman Cat Neutrophil Granulation Anomaly

A granulation alteration in neutrophils is inherited as an autosomal recessive trait in Birman cats.[23] The anomaly is characterized by fine eosinophilic-stained granules in Romanowsky-stained blood smears (Fig. 42.2). In bone marrow, affected granules stain similar to granules present in progranulocytes. These granules do not stain metachromatically with toluidine blue dye as do granules in animals affected with mucopolysaccharidosis. No alterations in neutrophil ultrastructure have been reported. Additionally, no defects in neutrophil cytochemistry, phagocytosis, oxidative metabolism, or bactericidal activity have been observed. Affected cats do not appear to be predisposed to infections; however, the granules need to be differentiated from toxic granulation and mucopolysaccharidosis types VI and VII.

Mucopolysaccharidosis

Mucopolysaccharidosis (MSP) is characterized by large intensely stained azurophilic granules in neutrophils and bone and cartilage defects.[21] These granules stain metachromatically when stained with toluidine blue dye. The defect involves enzyme deficiencies in mucopolysaccharide (glycosaminoglycan) catabolism. This results in accumulation of metabolic byproducts within

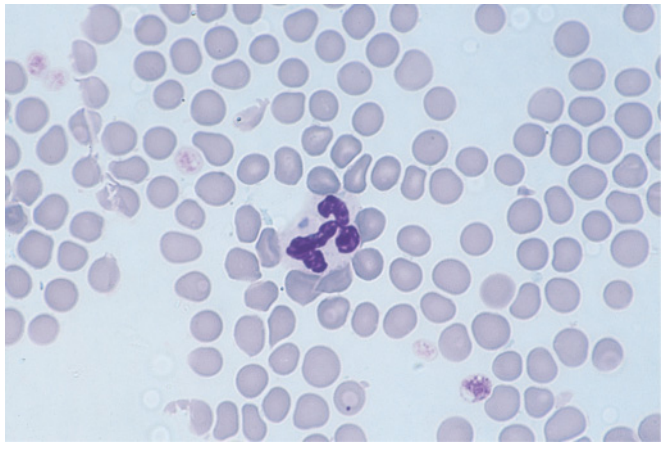

FIGURE 42.1 Giant lysosomes in the neutrophil cytoplasm of a cat that has Chédiak-Higashi.

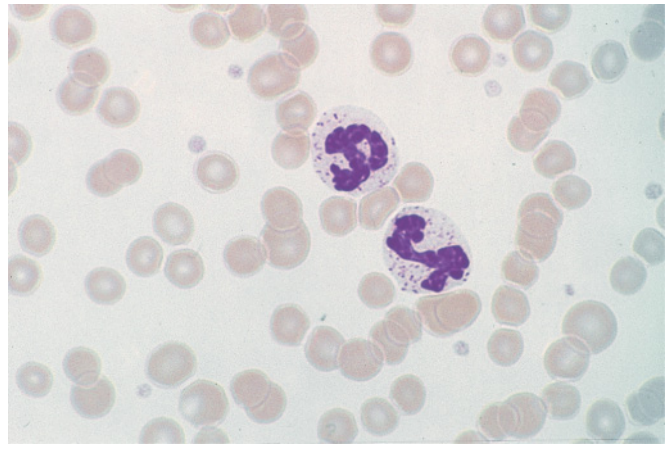

FIGURE 42.2 Birman cat neutrophil granulation anomaly with azurophilic cytoplasmic granules. (Courtesy of Dr. K.S. Latimer, University of Georgia, Athens, Georgia.)

leukocyte granules. Several genetic forms of MSP have been described in cats and dogs including MSP I (Hurler's syndrome), MSP II (Hunter syndrome), MSP III (Sanfilippo syndrome), MSP IV (Morquio syndrome), and MSP VI (Maroteaux-Lamy syndrome), and MSP VII (beta-glucuronidase deficiency). Although neutrophils from affected animals do not appear to have functional defects, the presence of prominent granulation in some cells must be differentiated from other causes of prominent granulation. Differential diagnoses include, Chédiak-Higashi syndrome, Birman cat neutrophil granulation anomaly, and toxic granulation.

Defects in Oxidative Metabolism

Chronic Granulomatous Disease in Doberman Pinschers

Several defects in the capacity of neutrophils to generate oxygen radicals have been described in humans. These include chronic granulomatous disease, glutathione peroxidase deficiency, glucose-6-phosphatase deficiency, and myeloperoxidase deficiency.[28] Chronic granulomatous disease is caused by mutations in genes encoding components of NADPH oxidase. In excess of 40 specific mutations have been reported. Chronic granulomatous disease is characterized by recurrent severe, but usually not fatal, bacterial and fungal infections beginning in early childhood.[28] Neutrophils have an inability to mount a respiratory burst due to inability to activate the NADPH oxidase system. A neutrophil bactericidal dysfunction with decreased capacity to mount a respiratory burst has been described in eight closely related Doberman pinschers.[5] These dogs all had a history of chronic bacterial pneumonia that improved with antibiotic treatment but relapsed when antibiotics were discontinued. Both Gram-positive and Gram-negative bacteria were cultured from a transtracheal aspirate of one dog. The neutrophils phagocytized bacteria normally but had a defect in oxygen radical generation. This defect was not as severe as seen in humans with chronic granulomatous disease and it is not clear if the defect was in NADPH oxidase or in another pathway such as myeloperoxidase.

Myeloperoxidase Deficiency in Cyclic Hematopoiesis of Gray Collies

Myeloperoxidase deficiency is the most common of the inherited neutrophil defects in humans.[28] However, the condition produces few clinical signs. Although killing of bacterial organisms is delayed, killing is eventually complete. Myeloperoxidase deficiency has been described in cyclic hematopoiesis of gray collie dogs.[24] Affected dogs have defective bactericidal activity.

Altered Chemiluminescence in Weimaraners

Abnormal neutrophil chemiluminescence responses have been described in a group of Weimaraner puppies. These dogs had a history that included recurrent fevers, diarrhea, pneumonia, pyoderma, lymphadenopathy, stomatitis, and osteomyelitis.[12] Decreased chemiluminescence in response to phorbol esters was the major neutrophil function alteration noted in these dogs. Although these dogs had lower serum IgG and IgM concentrations, no defects in humoral or cellular immune responses were detected.

Other Defects

Cyclic Hematopoiesis in Gray Collies

Cyclic hematopoiesis is an autosomal recessive disorder characterized by severe cyclic neutropenia, platelet-related bleeding, recurrent bacterial infections, and coat color dilution.[10] Although the human condition results from a mutation in neutrophil elastase, dogs have a mutation of the β subunit of adaptor protein complex 3 (AP3).[24] The specific defect is an insertion of an adenine nucleotide residue in exon 20 leading to a frameshift with premature termination and absence of mRNA. An equivalent mutation causes Hermansky-Pudlak syndrome type 2 in humans, pearl mice, and ruby *Drosophilia*.[24] This rare syndrome is characterized by cutaneous and retinal hypopigmentation and platelet-related bleeding that is associated with abnormal platelet dense granules.

AP3 is a membrane cargo transport protein that is specifically responsible for routing proteins from the Golgi network to lysosomes. AP3 may be a carrier protein for neutrophil elastase. If true, the canine defect would result in mistrafficking of neutrophil elastase.[24] If all types of cyclic neutropenia are associated with increased elastase on neutrophil membranes, signaling through elastase may explain the periodicity observed in cyclic neutropenia.[15] Arrest of hematopoiesis occurs at regular 11–14 day intervals. Because neutrophils have the shortest half-life, neutropenia is the most prominent feature in the blood. Neutropenia lasts 3–4 days and is followed by a neutrophilia. Clinically, affected puppies typically die at birth or during the first few weeks of life and rarely live longer than one year. Dogs that survive the neonatal period may be stunted and typically develop recurrent bacterial infections during periods of neutropenia.[27] They also develop amyloidosis in multiple tissues with resultant renal disease and coagulopathies. Diagnosis is based on coat color, cyclic variation in neutrophil count, increased susceptibility to bacterial infections, and decreased myeloperoxidase activity in neutrophils.[24] Canine G-CSF can be administered to eliminate the cyclic neutropenia.[27] Bone marrow transplantation eliminates the cyclic hematopoiesis and is curative.

Pelger-Huët Anomaly

Pelger-Huët anomaly is an inherited condition identified in dogs, cats, horses, rabbits, and humans and is characterized by failure of mature granulocyte nuclei

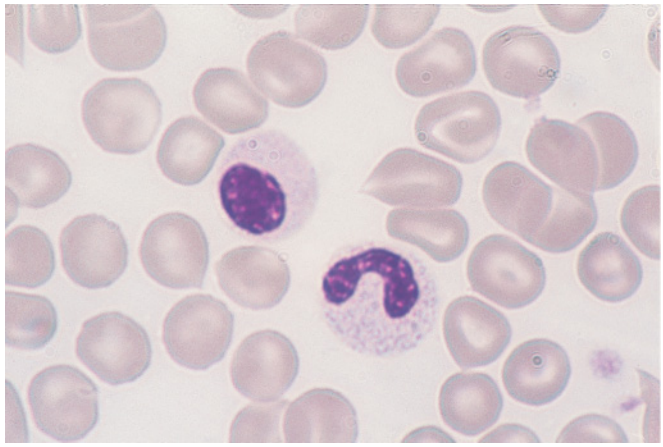

FIGURE 42.3 Band and myelocyte neutrophils from a border collie that has Pelger-Huët anomaly. (Courtesy of Dr. K.S. Latimer, University of Georgia, Athens, Georgia.)

to lobulate (Fig. 42.3).[18] Megakaryocytes are also hyposegmented suggesting that this is a stem cell defect. The condition appears to be inherited in most species as an autosomal dominant trait. The human and mouse mutation is caused by a mutation in the gene encoding for lamin B receptor.[42] Apparently nuclear lamins are involved in segmentation of granulocyte nuclei.

Heterozygote dogs do not have signs of disease and the condition is usually an incidental laboratory finding. Granulocytes are hyposegmented but the chromatin is condensed. It is important to differentiate this condition from a left shift associated with inflammatory disease. Pelger-Huët anomaly must also be differentiated from pseudo-Pelger-Huët anomaly which refers to an acquired hyposegmentation of granulocytes secondary to infections, myelodysplastic syndromes, or drug treatments. The main difference is that the chromatin is more clumped in Pelger-Huët anomaly. Although some initial reports indicated decreased neutrophil chemotaxis, more recent reports indicate no alteration in neutrophil function in Pelger-Huët anomaly. Many breeds are affected. The homozygous condition, described in rabbits and a kitten, is associated with skeletal deformities and increased susceptibility to infection and is usually lethal.

ACQUIRED NEUTROPHIL FUNCTION DEFECTS

Neutrophil Dysfunction in Periparturient Dairy Cattle

A variety of studies have documented neutrophil dysfunction in periparturient dairy cattle. In one study, significantly decreased random migration, iodination, and chemiluminescence of neutrophils was observed 1 week after parturition.[25] In another study, decreased neutrophil oxidative burst activity was observed between 1 and 3 weeks after calving.[14]

The cause of periparturient neutrophil dysfunction is incompletely understood. Selenium and glucocorticoid concentrations in periparturient cattle may be a significant factor in predicting neutrophil function. Neutrophils from post-parturient dairy cows with relatively high blood selenium concentrations had greater superoxide production and greater potential to kill bacteria when compared to cows with relatively low selenium concentrations.[9] Similar neutrophil function alterations have been reported in periparturient cattle and in glucocorticoid-treated cattle.[8] This suggests that high glucocorticoid concentration in periparturient cattle may be responsible for the neutrophil function defects.

Altered recruitment of neutrophil to the mammary gland and altered neutrophil function in the mammary gland have been incriminated as factors in increased incidence of mastitis during the periparturient period.[25,34] In general, neutrophils in milk are less effective than blood neutrophils in phagocytizing and killing bacteria.[34] This has been attributed to the lower energy reserve of milk neutrophils and phagocytosis of milk fat globules and casein. Milk has been reported to reduce the capacity of neutrophils to phagocytize bacteria 3-fold.[35] Neutrophil recruitment appears to be a critical determinant of resistance to mastitis. Post-parturient cows have a reduced capacity to recruit neutrophils into the mammary gland during coliform mastitis.[43]

Genetic markers have also been associated with susceptibility to bovine mastitis. Cows with allelic variation in CXCR2 (i.e. the IL-8 receptor) had increased susceptibility to mastitis.[38] Cows with a CC or GC at CXCR2 + 777 had decreased neutrophil migration in response to IL-8 when compared to cows expressing the GG genotype. Additionally, decreased upregulation of cell surface CD18 was observed on neutrophils after stimulation with IL-8. The results of these studies support a genetic predisposition to mastitis and further emphasize the importance of rapid mobilization of neutrophils into the mammary gland in prevention of infection.

Neutrophil Dysfunction in Neonatal Animals

Neutrophil dysfunction appears to contribute to the susceptibility of newborn calves and foals to septicemia, endotoxemia, pneumonia, and enteritis. Reports of neutrophil dysfunction in foals are inconsistent. When compared to horses, some reports indicate that foals have no difference in phagocytic activity; others report decreased phagocytosis when organisms are opsonized with autologous serum but not when opsonized with adult serum, while yet others report that phagocytosis of *Staphlococcus aureus* is decreased when opsonized with either autologous or adult serum.[30] Bacterial killing has been reported to be reduced in some studies and similar to that of adult horses in other studies.[45] Other neutrophil function alterations reported in foals include increased random migration, increased CD18 expression, decreased chemotaxis, decreased iodination, and the presence of an unidentified serum factor that suppresses oxidative burst activity.

Reports concerning neutrophil dysfunction in calves also tend to be inconsistent. This is in part due to variation in the age of the calves, the colostrum status, and the techniques used to evaluate neutrophil function. Both increased and decreased respiratory burst activity have been reported in neonatal calves when compared to cows.[13,22] However, this appears to be agonist-dependent. This suggests that age-related alterations in cell membrane receptors or intracellular signal transduction may be involved in neonatal respiratory burst activity.[22] Other functional alterations in neonatal neutrophils include decreased myeloperoxidase and increased alkaline phosphatase activities, decreased concanavalin A capping, increased chemotaxis, decreased Fc receptor number, increased aggregation, and increased shape change.[47]

Neutrophil Dysfunction Associated with Viral Infection

Viral infections have been incriminated as predisposing food animals to bacterial infections. This effect may, in part, be mediated by virus-induced neutrophil dysfunction. The bovine viral diarrhea virus (BVDV) is a classic example of a virus that induces neutrophil dysfunction.[7] Neutrophils from cows experimentally infected with either noncytopathogenic or cytopathogenic strains of BVDV develop marked impairment of iodination capacity. However, other measures of oxygen radical generation are not altered. Even cattle given modified-live BVDV vaccines have altered neutrophil function.[40] Cattle that are persistently infected with BVDV have multiple alterations in neutrophil function, including decreased random migration, decreased phagocytosis of *Staphylococcus aureus*, decreased iodination, decreased reduction of cytochrome c, decreased antibody-independent cell-mediated cytotoxicity, decreased cytoplasmic calcium flux, and decreased oxygen radical production.

Another virus incriminated as predisposing cattle to bacterial pneumonia is infectious bovine rhinotracheitis virus (IBRV).[6,29] In one study, calves were exposed to IBRV 5 days before exposure to *Mannheimia haemolytica*.[6,29] IBRV-exposed calves had decreased neutrophil recruitment to the lungs. Neutrophils from IBRV-exposed calves had decreased random migration and chemotatic responses. Further, alveolar macrophages had decreased capacity to produce chemotatic factors. The results of this study indicate that IBRV infection may predispose cattle to secondary bacterial infections.

Other bovine virus infections associated with altered neutrophil function include parainfluenza 3 virus, bovine herpes virus 1, and bovine immunodeficiency-like virus.[6,16] Infection of cattle with parainfluenza 3 virus results in decreased iodination and oxidative metabolism in neutrophils. Infection with bovine herpes virus 1 results in reduced neutrophil random migration but enhanced bacterial ingestion. Infection with bovine immunodeficiency-like virus is associated with decreased neutrophil antibody-independent cell-mediated cytotoxicity and iodination activities.

Neutrophil function has also been investigated in cats infected with feline leukemia virus.[26] Neutrophil chemotaxis was evaluated in vitro by use of a modified Boyden chamber apparatus. Cats that were viremic and clinically ill had decreased chemotatic and chemiluminescence responses.

Neutrophil Dysfunction Associated with Parasitic Diseases

Infection of cattle with coccidia and infection of a dog with *Prototheca zopfii* resulted in suppressed neutrophil function.[37,41] Cattle infected with *Eimeria* sp. had decreased neutrophil oxidative metabolism and iodination activity, and had increased susceptibility to bacterial pneumonia.[41] Serum from a dog infected with *Prototheca zopfii* suppressed neutrophil chemotatic activity.[37]

Effects of Stress on Neutrophil Function

The effects of environmental, transportation, and exercise stress on neutrophil function have been evaluated. The effect of 4 hours of transportation was evaluated on four 4–6 month old Holstein calves.[32] After transportation, calves had a neutrophilia, enhanced neutrophil superoxide production, suppressed lymphocyte blastogenesis and increased plasma cortisol concentrations. These data suggest that neutrophils became activated during transportation despite the potentially suppressive effects of cortisol on neutrophil function.

The effects of cold stress on neutrophil function have been evaluated in bovine neonates.[46] Exposure of neonatal calves to temperatures of 1 °C for 3 days had no effect on bactericidal activity of neutrophils.

The effects of exercise on equine neutrophil function have been evaluated.[36] When untrained horses were subjected to moderately intense exercise, an increase in neutrophil oxidative burst activity and neutrophil phagocytosis was observed. However, high intensity exercise was associated with transient impairment of oxidative burst activity and phagocytosis. After 17 weeks of exercise training, neutrophil oxidative burst activity and neutrophil phagocytosis were decreased when compared to neutrophil function test results at 0 and 10 weeks. These data suggest that high intensity exercise training and long duration training have a general suppressive effect on equine neutrophil function.

Effects of Nutrition on Neutrophil Function

Selenium and vitamin E appear to be important nutrients in maintaining neutrophil function. Neutrophils from post-parturient dairy cows with relatively high blood selenium concentrations have greater superoxide production and greater capacity to kill bacteria than those from cows with relatively low blood selenium concentrations.[9] Injection of selenium-vitamin E into cows has been reported to increased the capacity of

neutrophils to kill bacteria.[20] Because selenium is required for glutathione metabolism, selenium deficiency probably causes a defect in the oxygen-dependent pathway of bacterial killing.

Copper deficiency may also adversely affect neutrophil function. Neutrophils from cattle made copper deficient by feeding diets low in copper and high in molybdenum or iron were reported to have decreased capacity to kill *Candida albicans* organisms.[4]

Acronyms and Abbreviations

CLCP, Charcot-Leyden crystal protein; EBP, eosinophilic bronchopneumopathy; ECF-A, eosinophil chemotactic factor of anaphylaxis; ECP, eosinophil cationic protein; EDN, eosinophil-derived neurotoxin; EoSV, eosinophil sombrero vesicle; EPO, eosinophil peroxidase; HES, hypereosinophilic syndrome; HETE, hydroxyeicosatetraenoic acid; HHT, hydroxyheptadecatrienoic acid; GI, gastrointestinal; IFN, interferon; IL, interleukin; MBP, major basic protein; MCP-3, monocyte chemotactic peptide-3; MIP-1a, macrophage inflammatory protein-1a; PAF, platelet-activating factor; PGE, prostaglandin E; RER, rough endoplasmic reticulum; Siglec, sialic acid-binding Ig-like lectin; SNARE, soluble *N*-ethylmaleimide-sensitive factor attachment receptor; TGF, transforming growth factor; WBC, white blood cell.

The eosinophil was named by Ehrlich based on its affinity for anionic dyes, such as eosin.[27] This cell defends against helminthic parasites, is a bidirectional partner in basophil- or mast cell-mediated inflammation, and has the potential to damage host tissues. Eosinophils also are important in innate, acquired, and adaptive immunity, tissue remodeling, and developmental biology. No longer regarded simply as an end-stage effector cell, the eosinophil is a pleotrophic multifunctional cell that serves complex physiologic roles. This chapter emphasizes structure–function relationships to explicate the eosinophil's varying roles in many complex processes. The reader is referred to several recent comprehensive reviews.[22,28,31,37,38,56]

REGULATION, PRODUCTION, AND RELEASE

Eosinophils develop in bone marrow and to a lesser extent in thymus, spleen, lung, lymph nodes in some laboratory species (see Chapter 7).[17,29,65] Type 2 helper T (TH_2) cells, which secrete IL-5 and IL-13, are important regulators of all aspects of eosinophil development and function, including increased production by bone marrow, mediated by IL-5 and recruitment to tissues by eotaxins, regulated by IL-13.

Eosinophils differentiate and mature in bone marrow over 2–6 days, depending on the species. They comprise less than 10% of bone marrow nucleated cells, and the marrow-to-blood eosinophil ratio varies between 300:1 in guinea pigs to 3.4:1 in humans. Generation and emergence times are shortened in animals that have *Trichinella* infections. In rats, eosinophils travel to the spleen to complete maturation. In healthy individuals, the half-life of eosinophils in circulation varies from less than 1 hour in the dog to 18–24 hours in people. Eosinophils migrate into tissues, especially the gastrointestinal (GI) tract and lungs, where they live for about 2 days unless anti-apoptotic factors, such as IL-5, prolong their survival for up to 2 weeks. Under pathologic conditions, it is possible for eosinophils to re-enter circulation.[13]

TISSUE DISTRIBUTION AND METABOLISM

Eosinophils are tissue-dwelling cells, residing predominantly in the skin, respiratory tract, and GI tract. The location and number of eosinophils vary with species, stage of estrous cycle, diet, and histamine content of the tissue; however, the major population of eosinophils is found in the GI tract where they are recruited by the chemokine eotaxin-1 (CCL11).[42,45]

STRUCTURE AND MORPHOLOGY

Eosinophils are polymorphonuclear leukocytes that become recognizable morphologically with the appearance of specific, or secondary, granules at the progranulocyte stage (Fig. 43.1). Myelocytes have numerous immature specific granules, as well as an extensive Golgi complex and abundant rough endoplasmic reticulum (RER). The nucleus undergoes characteristic segmentation, and granules continue to mature in the band and segmented forms. Eosinophils contain three types of granules, specific granules, primary granules, and small dense granules, as well as sombrero vesicles (EoSVs),[44] lipid bodies, mitochondria, free ribosomes, sparse RER, a small Golgi, and glycogen.[2,15]

Specific granules contain potent cytotoxic proteins and comprise the majority of the granule population in eosinophils. They have a bicompartmental structure in many species, including humans, rhesus monkeys, cats, goats, rabbits, opossum, guinea pigs, rats, and mice,[2,32,43] with a distinctive electron-dense core, or crystalloid, that is characterized by both longitudinal and cross-sectional periodicity and is surrounded by a more lucent matrix (Fig. 43.2 A–D). Cores vary in density, size, and shape among species, and there is especially wide variation in cats. Approximately 10% of canine granules have distinct cores.[30] Equine eosinophil granules contain dense cores that lack crystalline patterns, are often located eccentrically, and are surrounded by a less dense matrix.[55] Homogeneous granules are found in eosinophils from cattle, mink, and gorillas.[32,43] Features of the four major proteins are described in Table 43.1.

Major basic protein (MBP), located in the core, comprises >50% of the granule protein content. Deposits of MBP can be found in tissues at sites of eosinophilic inflammation. The other proteins are found in the matrix. Eosinophil peroxidase (EPO) can be found in progranulocytes and myelocytes in the RER, perinuclear cisterna, Golgi, and specific granules. Thereafter, EPO is located solely in specific granules.[2,15] Eosinophil peroxidase is distinct from and more potent than myeloperoxidase.[2] Different sources conclude that EPO is involved in bacterial killing as well as having activities against parasites and viruses.[50,60] This enzyme has been widely reported to be absent from feline eosinophils; however, protein peaks separated from feline eosinophil granules are most compatible with EPO, eosinophil cationic protein (ECP), and MBP.[20] Further characterization is still needed. ECP constitutes ~30% of the granule protein and damages membranes by a colloid osmotic process, causing formation of transmembrane non-ion-selective pores. Eosinophil cationic protein promotes mast cell degranulation and is bactericidal. Two isoforms have been identified by chromatography.[22] Eosinophil-derived neurotoxin (EDN) is also expressed in mononuclear cells and possibly neutrophils. This protein damages myelinated nerve fibers and is implicated in antiviral activity against respiratory viruses.[50] Other granule constituents include catalase, peroxisomal lipid B oxidation enzymes (enoyl-CoA hydratase, 3-ketoacyl-CoA thiolase), flavoprotein (acyl-CoA oxidase), β-glucuronidase, cathepsin D, serine:pyruvate aminotransferase, and zinc.[15,32] Acid phosphatase and arylsulfatase activities may be

Wright's stain; 1,000×.

unmasked in the matrix when eosinophils are activated.[15] Four basic proteins have been isolated from equine eosinophils but could not be correlated definitively to human proteins, although one is likely the analogue of human MBP.[48]

Membrane-bound primary granules are most numerous in the progranulocyte, but can be found in all stages of eosinophils in some species (Fig. 43.2D). Their lysophospholipase activity has been reported to reside in the Charcot-Leyden crystal protein (CLCP) but may be due to other eosinophil lysophospholipases.[28] CLCP comprises 7–10% of total eosinophil protein.[15,16] This protein polymerizes to form hexagonal crystals deposited in tissues at sites of eosinophilic inflammation even when intact eosinophils are no longer visible. The function of CLCP remains obscure.[28] Lysophospholipase dampens inflammation by impeding generation of arachidonic acid metabolites and may inactivate cell-damaging lysophosphatides produced during degranulation.[22] A third type of eosinophil granule, the small dense granule, contains acid phosphatase, arylsulfatase, and perhaps ECP, catalase, and peroxidase.

Lipid bodies store arachidonic acid, chiefly in esterified forms, used in the generation of lipid mediators such as leukotrienes and prostaglandins.[15] Eosinophils also synthesize cytokines, proteoglycans, vitamin B-binding proteins, and numerous enzymes, including collagenase, histaminase, phospholipase D, and nonspecific esterases. At least 35 cytokines, chemokines, and growth factors are produced by eosinophils.[28] Eosinophils are the chief producers of cytokines such as TGF-β in a variety of eosinophil-associated diseases such as asthma.

The plasma membrane contains nicotinamide adenine dinucleotide phosphate (NADPH) oxidase to generate an oxidative burst and alkaline phosphatase in some species (cattle, horses, dogs, and cats).[32] Eosinophils lack the bactericidal agents lysozyme, lactoferrin, and phagocytin.[14]

SURFACE MOLECULES

The surface of eosinophils, as visualized by scanning electron microscopy, has short blunt processes and sparse microvilli. Eosinophils have many cell surface receptors including receptors for cytokines, chemokines, complement proteins, immunoglobulins (Ig), adhesion molecules, lipid mediators, enzymes, and signaling and apoptotic factors.[68] Adhesion receptors link

TABLE 43.1 Summary of Major Preformed Proteins Released from Eosinophil Specific Granules

	Location	Characteristics	Actions
Major basic protein (MBP)	Specific granule core (also found in basophils)	Cationic protein, 14 kDa, pI 10.9, 117 amino acid (aa) single polypeptide rich in arginine; pre-molecule (207 aa) has a pI of 6.2 owing to a 90 aa acidic portion thought to protect cell from toxic effects of MBP during transport	Cytotoxic to parasites, protozoa, bacteria, normal mammalian epithelial cells, murine tumor cells; stimulates signaling pathways and mediator release from mast cells, neutrophils, and basophils; neutralizes heparin; activates platelets, basophils, mast cells, neutrophils; induces bronchospasm; activates complement via classical and alternative pathways; activates remodeling factors from epithelial cells; increases cutaneous vasopermeability; adversely affects smooth muscle contraction responses; implicated in regulating peripheral nerve plasticity by inhibiting apoptosis; no enzymatic activity
Eosinophil peroxidase (EPO)	Specific granule matrix	Heavy (58 kDa) and light (14 kDa) subunits; pI 10.8; genetically and biochemically distinct from myeloperoxidase	In presence of H_2O_2 and halide, generates oxygen radicals toxic to helminths, bacteria, mycoplasmas, fungi, protozoa, viruses, tumor cells; in absence of H_2O_2 acts as cationic toxin; toxic to host respiratory epithelium; induces release of granules, histamine from mast cells; inactivates leukotrienes
Eosinophil cationic protein (ECP)	Specific granule matrix	Cationic protein, 18–21 kDa, pI 10.8, 133 aa; secreted and stored forms differ; ribonuclease gene superfamily; 66% sequence homology with EDN	Toxic to helminths, protozoa, bacteria, tracheal epithelium; neurotoxic; neutralizes heparin; promotes mast cell degranulation
Eosinophil-derived neurotoxin (EDN, protein X, EPX)	Specific granule matrix	Cationic protein, 18–19 kDa, pI 8.9, 134 aa; ribonuclease gene superfamily; 66% sequence homology with ECP	Toxic to myelinated nerve fibers; significant ribonuclease activity; antiviral activity in respiratory infection

eosinophils with endothelial cells or extracellular matrix components, allowing them to leave the circulation and directing their movement in tissues and extracellular spaces. Chemotactic factors and chemokines recruit eosinophils to sites of inflammation. Many factors, including lipid mediators, immunoglobulins, and complement components, act through receptors to activate eosinophils to perform effector functions and to connect them with their targets.[32,37,38]

More recently, surface molecules previously associated with other cell types have been identified on eosinophils and include Toll-like receptors and inhibitory receptors, such as sialic acid-binding Ig-like lectin (Siglec-8).[38,51] Activation of inhibitory receptors suppresses eosinophil activation and induces negative signaling in murine eosinophils; cross-binding Siglec-8 induces apoptosis of eosinophils.[28]

SIGNS OF ACTIVATION

Activation of eosinophils results in various changes in morphology, cell surface characteristics, and functional activities.[5,15,37] These changes generally are acquired after leaving the circulation, but may be found in circulating eosinophils of patients with allergic disease and hypereosinophilic syndrome. Activated eosinophils are typically hypodense, have fewer specific granules, and have increased numbers of lipid bodies (Fig. 43.2E) and vesiculotubular structures. Lipid bodies are repositories of arachidonate-containing lipids for oxidative metabolism and synthesis of lipid mediators, and vesiculotubular structures, now termed eosinophil sombrero vesicles (EoSVs), store and transport granule products. Upon activation, EoSVs move to the plasma membrane and fuse with it to rapidly release mediators. In a canine model of asthma, eosinophils found in bronchoalveolar lavage fluid have either a typical polymorphonuclear appearance or the appearance of a globule leukocyte. Other changes noted in human eosinophils are increased primary granules (containing CLCP) and small dense granules. Functionally, cytotoxicity to parasites and mammalian cells is increased, there is enhanced generation of reactive oxygen species, and enzymes, such as acid phosphatase, are activated.

INVOLVEMENT IN HOMEOSTASIS AND THE IMMUNE SYSTEM

In addition to their involvement in inflammation, eosinophils are important to homeostatic and immune

functions, especially mucosal immunity in the GI tract. Under homeostatic conditions, eosinophils traffic into the thymus, mammary gland, uterus, and, most prominently, the GI tract.[51] They are recruited to the thymus during the neonatal period by eotaxin-1 and are associated with thymocyte deletion.[57] They participate in T cell-mediated immunity through recognition and presentation of microbial, viral, and parasitic antigens, as well as superantigens. The immunologic roles of eosinophils may be related to their location at surfaces in contact with the outside environment, their capacity to respond to particulate antigens (e.g. inhaled, ingested, or granuloma-encapsulated antigens) and their expression of Fc receptors for IgG, IgE, and IgA.[63] Eosinophils can also regulate T-cell polarization and proliferation of effector T cells.[51] In several reproductive processes, including development of the post-pubertal mammary gland, onset of estrus cycling, and blastocyst implantation, eosinophils appear to play regulatory roles.[23,49,51]

TRAFFICKING IN EOSINOPHILIC INFLAMMATION

Trafficking of eosinophils into inflammatory sites is directed by TH_2 and endothelial-derived cytokines, including IL-4, IL-5, and IL-13, adhesion molecules (β1-, β2-, and β7-integrins), chemokines (CCL5, and the eotaxins), and many other molecules, including acidic mammalian chitinase.[66] Eotaxin-1 was identified in 1994;[34] subsequently CCL24 and CCL26 (eotaxins 2 and 3) were discovered, but their sequences are not closely related to CCL11.[54] In human hypersensitivity disorders, these chemokines are produced by respiratory epithelium and skin fibroblasts; CCL11 appears at the earliest stages, followed by CCL24 and then CCL26.[28]

The following sequence of events describes the path leading the circulating eosinophil to participate in inflammatory processes:

1. Quiescent eosinophils in the circulation express L-selectin which binds reversibly and with weak affinity to carbohydrate ligands on postcapillary venule endothelium, permitting the eosinophil to roll along the vessel wall.[37,38]
2. The eosinophil meets a priming stimulus, released from perivascular immune cells, endothelial cells, and the local inflammatory site. Eosinophil primers include IL-3, GM-CSF, IL-5, IgG, and IgA.[36] IL-4 mediates ε isotype switching and brisk production of IgE.[21] IL-5 initiates signal transduction in eosinophils resulting in expression of genes for surface receptors, structural and secreted proteins, and transcription factors.[36,58] Priming leads to adhesion, chemotaxis, degranulation, release of lipid mediators, and oxidative burst.
3. One of the priming functions of IL-5 is to increase the number of eosinophils that respond.[11,47] The primed eosinophils express β1 (very late activation [VLA]-4), β2 (Mac-1 and leukocyte function-associated antigen [LFA]-1), and β7 integrins that mediate secure adhesion to the endothelial ligands vascular cell-adhesion molecule (VCAM)-1 and intercellular-adhesion molecule (ICAM)-1, induced by IL-1.[4,5] Although the latter pathway is also used by neutrophils, the VLA-4/VCAM-1 pathway is selective for eosinophils and basophils.[4] Expression of tissue factor by eosinophils also may play a role in migration from blood.[46] Adhesion further primes the eosinophil to respond to chemoattractants and lipid mediators.
4. Recruited by various chemotactic factors, the primed eosinophil flattens against the endothelium and migrates between cells into the interstitial space. Depending on the target organ, eosinophils cross the endothelium into tissues by a regulated process involving coordinated interaction between networks involving the chemokine CCL11, eosinophil adhesion molecules (α4β1, α4β7, αmβ2, αLβ2), and adhesion receptors on the endothelium (MAdCAM-1, VCAM-1, and ICAM-1).
5. The eosinophil approaches its final destination, guided by interactions with adhesion molecules in the extracellular matrix (fibronectin, laminin, and fibrinogen) and a concentration gradient of chemoattractants, including C5a, *N*-formyl-methionyl peptides, leukotrienes, platelet-activating factor (PAF), hydroxyeicosatetraenoic acids (HETEs), hydroxyheptadecatrienoic acids (HHTs), monocyte chemotactic peptide-3 (MCP-3), macrophage inflammatory protein-1a (MIP-1a), eosinophil chemotactic factor of anaphylaxis (ECF-A), histamine, parasite-derived factors, and chemokines like CCL5.[37,38]
6. Along the way, the eosinophil is activated by cytokines, lipid mediators, chemoattractants, and immunoglobulins to release granule proteins, lipid mediators, and oxygen radicals.
7. Eosinophil survival is enhanced through exposure to inflammatory cytokines, such as IL-5.[26]
8. Eosinophils may contribute to wound healing, or sclerosis, by secretion of TGFβ, procoagulation through activation of factor XII by ECP, and fibrinolysis by activation of plasminogen.[7,12,59,61]

The predominance of eosinophils in certain disorders, such as parasitic disease and asthma, is likely mediated by several eosinophil-selective molecules, including adhesion molecules, primers, chemoattractants, and anti-apoptotic agents. Finally, a major consequence of chronic eosinophilic inflammation is tissue damage. The injury to airway epithelium and other cells mediated by MBP appears to be reversible, but myocardial fibrosis, perhaps induced by granule proteins or TGF, is permanent in hypereosinophilic syndrome.[5,22,38]

EFFECTOR FUNCTIONS

Defense Against Helminthic Parasites

Although eosinophils are capable of phagocytosis, helminths are too large for this approach; therefore they

secrete mediators directly onto the target rather than engulfing them. Eosinophils, working in concert with T cell-derived perforins, bind to larvae opsonized with IgG, IgE, or complement, flatten against the integument; release a barrage of basic toxins and hydrolytic enzymes directly onto the target; and migrate under the damaged larval skin.[6,8,37,43] The oxidative burst in eosinophils may contribute to anti-helminthic action, but the cytotoxic effect of MBP to schistosomula of *Schistosoma mansoni* occurs independently of oxygen metabolites.[38] Eosinophils may also contribute to host defense by decreasing the number of infectious agents, dampening immediate pathologic responses, or participating in tissue remodeling and immunomodulation. IL-5 may play a role in the effectiveness of parasite vaccines in mice.[41]

The role of eosinophils in helminthic cytotoxity in vivo remains uncertain. Some human studies suggest a role for eosinophils in preventing reinfection rather than clearing an initial infection.[24] Experimental models using transgenic mice that overproduce IL-5 or mice that are deficient in IL-5, eotaxin or the eotaxin receptor have yielded conflicting results about the role of eosinophils and their mediators in helminthic infections. Parasitized mice in which eosinophil and IgE responses were ablated by administering anti-IL-5 antibody had no changes in parasite burden or resistance to infection compared with mice that had intact eosinophil responses.[33,53] Difficulties in interpreting results arise from use of parasites for which the mouse is not the natural host, from equating murine and human eosinophils, which have functional differences, and from the lack of ability to ascertain that eosinophils are degranulating in response to parasitic infection. After all these years, the beneficial role of eosinophils in control of parasite infection remains to be fully understood.

Effector Cells in Asthma and Allergic Disease

Although eosinophils are thought to play a central role in the pathologic changes that characterize hypersensitivity disorders their definitive contributions are still being determined. Asthma is characterized by inflammation, hyperresponsiveness, mucus secretion, and remodeling with smooth muscle hyperplasia, collagen deposition, neovascularization, and metaplasia of goblet cells.[3,7] Studies in animals and people suggest an important role for eosinophils in airway remodeling and in acute exacerbations in asthma, but many uncertainties remain.

Eosinophils promote damage and dysfunction through elaboration of proinflammatory mediators, such as leukotriene C4, PAF, and eicosanoids, and release of granule proteins.[67] Eosinophils are recruited into tissues by cytokines. In an amplification loop, eosinophils themselves may recruit CD4+ cells into tissues by releasing IL-16. IgE-mediated mast cell degranulation, induced upon re-exposure to allergens and parasite antigens, also plays a role in eosinophil recruitment in hypersensitivity disorders.[37] Eosinophil granule products, reactive oxygen species, and lipid mediators cause damage to airway mucosa and nerves and also cause bronchoconstriction. Major basic protein in particular is toxic to airway epithelium and triggers degranulation of mast cells and basophils.[51] Eosinophils from patients with asthma are hyperadhesive and have increased collagen receptor expression. TGF-β from eosinophils may play an important role in airway remodeling. Leukotrienes secreted by eosinophils mediate vascular permeability, secretion of mucus, and constriction of smooth muscle. In addition, cytokines involved in recruitment also enhance effector functions and prolong survival of eosinophils by delaying apoptosis.

Modulation of Inflammation

Eosinophils suppress immediate hypersensitivity reactions.[37] Specifically, eosinophils phagocytose immune complexes, peroxidize mast cell granule debris, and release histaminase to neutralize histamine, phospholipase B to inactivate mast cell PAF, MBP to inactivate mast cell heparin, plasminogen to reduce local thrombin activity, aryl-sulfatase B and hypochlorous acid to inactivate leukotrienes, prostaglandin E1 (PGE1) and PGE2 to inhibit degranulation of basophils and mast cells, and lysophospholipase to prevent generation of arachidonic acid metabolites.

Phagocytosis

Eosinophils have the capacity to phagocytose immune complexes, antibody-coated RBCs, mast cell granules, inert particles, yeast, and bacteria, including *Mycoplasma*. They are less efficient at killing bacteria than neutrophils despite having higher levels of peroxidase activity, oxidative responses, and H_2O_2 production.[14,32] Eosinophils lack several bactericidal substances and have a lower density of complement receptors than neutrophils.

Antitumor Effect

Eosinophils and their products are cytotoxic to or induce apoptosis of tumor cells in vitro,[33] and antitumor roles for IL-5 and eosinophils are suggested in murine models of increased expression of IL-5 and eotaxin deficiency, respectively. In some neoplasms, local infiltration by eosinophils in the absence of peripheral eosinophilia improves prognosis.[40] In human colorectal carcinomas, improved prognosis associated with eosinophil infiltration was independent of staging, vascularization, p53 expression, and histologic grade.[19] However, in other studies eosinophilic infiltrates in tumors have been associated with a poorer prognosis or had no impact on prognosis.[1,39]

MECHANISMS OF EOSINOPHIL EFFECTOR FUNCTION

Release of Granule Proteins

Granule products are released through exocytosis, piecemeal degranulation, or cell lysis.[44,52] In piecemeal degranulation, granule products are carried to the plasma membrane by transport vesicles with resultant disassembling (Fig. 43.2B–D) and emptying of granules. Unique to eosinophils is a dynamic system of vesicular compartments, termed eosinophil sombrero vesicles (EoSVs), generated by the specific granules themselves. Using electron tomography, which permits three-dimensional imaging of subcellular structures, EoSVs are demonstrated to be highly pleomorphic curved tubular structures that may be round, C-shaped, or elongate (Fig. 43.2C,D). They can change shape to accommodate transport of membrane-bound proteins over long distances in the cell and store certain proteins for quick release upon stimulation.[44] EoSV "dock" and then fuse with the plasma membrane, releasing proteins. The docking complex consists of soluble *N*-ethylmaleimide-sensitive factor attachment receptors (SNARE) located on the plasma membrane and the vesicle. When eosinophils are activated, EoSVs move to the plasma membrane to permit rapid release of mediators. Piecemeal degranulation is selective and tightly regulated so that only specific proteins are released after receiving a distinctive stimulus. For example, IgE induces release of EPO and IgA binding can cause release of ECP and EPO, whereas IgG binding results in release of ECP and EDN.[35,37,43] Equine eosinophils degranulate through a complex process of compound exocytosis and cumulative fusion in which multiple granules fuse with one another after fusion of one granule with the plasma membrane, resulting in a degranulation sac and focal release of granule proteins.[52]

Release of Lipid Mediators

Eosinophils not only respond to PAF, they produce and secrete it on activation. Platelet-activating factor enhances many eosinophil activities including adherence to endothelium, chemotaxis, binding of IgE, production and release of oxygen radicals, release of granule proteins, and synthesis of prostanoids. Other lipid mediators released by eosinophils include leukotrienes (e.g. LTB4 and LTC4), thromboxane A2, and prostaglandins.[37,38] With the exception of PGE, which may down-regulate eosinophil effector functions, lipid mediators contribute to host dysfunction, such as bronchial hyperreactivity.[38]

Cytokine Release

Eosinophils exhibit paracrine regulation of other inflammatory cells, endothelial cells, and fibroblasts through release of IL-1, IL-2, TNFα, TNFβ, IL-4, IL-5, IL-6, IL-8, IL-10, IL-12, IL-13, IL-16, IL-18, TGFα/β, eotaxin, and CCL5. Autocrine control results from elaboration of IL-3, IL-5, and GM-CSF by eosinophils.[5,63]

MECHANISMS OF EOSINOPHILIA AND EOSINOPENIA

Factors influencing the number of eosinophils in the circulation include: diurnal variation related to cortisol levels, age, exercise, and exposure to environmental stimuli. Eosinophils are enumerated in several ways. The least accurate is the differential white blood cell (WBC) count performed on a stained blood film, but this method is useful in most situations. Eosinophil counting chambers also can be used, but automated methods that stain peroxidase provide the most accurate counts. Eosinophil peroxidase is not detected by this method in all animal species, especially cats. The reference interval for eosinophils varies among species and geographic regions. Eosinophilia is not always present in the face of eosinophilic inflammation in tissues where eosinophil survival is increased. Specific causes of eosinophilia and eosinopenia are discussed in Chapters 46–50.

Eosinophilia

The pathway to eosinophilia in most causes of eosinophilic inflammation is the elaboration of eosinophilopoietic factors, principally IL-5, by T cells sensitized by parasite antigens or allergens.[25] IL-5 derived from mast cells and eosinophils probably plays a local role in priming eosinophils, enhancing their function, and prolonging their survival.[64] Eosinophilia associated with parasitism is more likely to occur when parasites are located in tissues rather than in the intestinal lumen. In eosinophilic bronchopneumopathy (EBP), previously termed pulmonary infiltrates with eosinophilia (PIE), eosinophilic infiltrates are found in the bronchial mucosa and interstitium,[9,10] and hypersensitivity in this syndrome may be initiated by heartworm infection, migration of larval parasites, exogenous proteins, and antigens associated with chronic infections. Chronic eosinophilia is associated with inflammatory disorders of mast cell-rich organs, namely skin, lung, GI tract, and uterus. Other conditions include eosinophilic granuloma complex and eosinophilic inflammatory bowel disease in cats and eosinophilic myositis, eosinophilic panosteitis, and eosinophilic gastroenteritis in dogs. Paraneoplastic eosinophilia is caused by a variety of tumors, such as lymphoma, mast cell tumor, and solid tumors, in which IL-5 and other cytokines are elaborated.[18] Eosinophilic leukemia is a rare disease, and the diagnosis depends on ruling out other causes and measuring serum IgE levels (see Chapter 63). In hypereosinophilic syndrome (HES), characterized by persistent eosinophilia of unknown origin, increased survival of eosinophils in circulation, tissue infiltrates, and organ dysfunction, a proposed mechanism of eosinophilia is

clonal expansion of T cells generating eosinophilopoietic factors.[62] Increased levels of IL-5 in some of these patients may override the apoptotic effects of corticosteroids, resulting in steroid resistance. In a subset of people with HES, constitutive expression of tyrosine kinases leads to production of eosinophils independent of growth factors.[51] Eosinophilia is sometimes recognized in animals with hypoadrenocorticism owing to decreased or absent cortisol.

Eosinopenia

Detection of low numbers of eosinophils, especially on a routine differential WBC count, has limited significance, and some healthy animals have no eosinophils detected in a complete blood count. However, there are several known associations with eosinopenia, although the underlying mechanisms are unclear. For example, corticosteroids cause eosinopenia, perhaps by neutralization of circulating histamine and inhibition of mast cell degranulation. The lympholytic effect of corticosteroids may attract eosinophils into lymphoid tissues after release of cytokines; alternatively, production of cytokines promoting growth and function of eosinophils may be diminished. Corticosteroids also inhibit cytokine-dependent eosinophil survival. Thus, eosinopenia may occur in some animals with hyperadrenocorticism or following exogenous administration of corticosteroids. Other inducers of eosinopenia include catecholamines. This may occur through a β-adrenergic effect, as the effect is eliminated by β-blockers. Eosinopenia may be present in acute inflammation or infection, in part owing to release of corticosteroids and catecholamines.

THERAPEUTIC APPROACHES

Understanding the molecular and cellular mechanisms of eosinophilic inflammation has opened the door to novel therapeutic interventions that may transform medical management of patients with eosinophilic inflammation.[5,28,38,51] Glucocorticoids have been the therapeutic mainstay and act by destabilizing eotaxin mRNA, suppressing transcription of IL-4, IL-5, and eotaxin genes, and inhibiting survival of eosinophils. However, not all patients respond or maintain a response to glucocorticoids, possibly owing to loss of receptors or alterations in regulatory proteins. Other approaches include reduction of eosinophil production by myelosuppressive drugs, such as hydroxyurea, inhibition of eosinophil degranulation and effector functions by IFN-α, and interference with transcription of cytokines, such as IL-5 and GM-CSF by cyclosporin A. Novel approaches include anti-IL-5 antibodies; antagonists to leukotrienes, such as cysteinyl leukotrienes, or their receptors; tyrosine kinase inhibitors, such as imatinib, that may be effective in patients with HES caused by constitutive production of tyrosine kinases; lidocaine, recently demonstrated to shorten eosinophil survival; third generation anti-histamines; blockers of eosinophil adhesion; inhibitors of the eotaxin/CCR3 pathway; anti-human IL-13 antibody; and induction of eosinophil apoptosis by antibody cross-linking of Siglec-8.

Acronyms and Abbreviations

AP-1, activation protein-1; bFGF, basic fibroblast growth factor; CD, cluster of differentiation; C3biR, inhibitory receptor for C3b; CTAP-III, connective tissue-activating protein III; ELAM, endothelial-leukocyte adhesion molecule; ERK, extracellular receptor-activated kinase; Fc, fragment crystallizable; FIC, fibroblast induced cytokine; GM-CSF, granulocyte-macrophage colony stimulating factor; ICAM, intercellular adhesion molecule; H&E, hematoxylin & eosin IFN-γ, interferon-gamma; Ig, immunoglobulin; IgA, immunoglobulin A; IgE, immunoglobulin E; IgG, immunoglobulin G; LFA, lymphocyte function-associated antigen; IGF, insulin-like growth factor; IL, interleukin; IFN, interferon; LT, leukotriene; LTC_4, leukotriene C_4; LTD_4, leukotriene D_4; LTE_4, leukotriene E_4; MAC-1, macrophage-1 antigen; MAP, mitogen-activated protein; MCP-1, monocyte chemotactic protein 1; MIP-1a, macrophage inflammatory protein-1a; MC_T, mast cell subset with tryptase; MC_{TC}, mast cell subset with tryptase and chymase; NGF, nerve growth factor; NK, natural killer; NFAT, nuclear factor of activated T-cells; NF-κB, nuclear factor κB; PAF, platelet-activating factor; PGD_2, prostaglandin D_2; PECAM, platelet/endothelial cell adhesion molecule; Pgp-1, phosphoglycoprotein-1; PLA_2, phospholipase A_2; RANTES, regulated on activation normal T cell expressed and secreted; SCF, stem cell factor; TGF-β, transforming growth factor beta; Th1, T-helper lymphocyte type 1; Th2, T-helper lymphocyte type 2; TLR, toll-like receptor; TNF, tumor necrosis factor; TxB_2, thromboxane B_2; VCAM, vascular cell adhesion molecule; VEGF, vascular endothelial growth factor; VLA, very late antigen; VNR, vitronectin receptor.

Because basophils and mast cells are alike in chemical composition and function, they are typically referred to as sister cells. However, these cells function independently[30,33] and are immunophenotypically distinct from each other as well as from other hematopoietic cells.[9] Also in the few reported cases of defective basopoiesis or basophil function, patients had no concurrent mast cell defect.[15]

PRODUCTION AND TISSUE DISTRIBUTION

Basophils

Basophils, are terminally differentiated granulocytes that originate from CD34+, Fcg, c-kit– cells in the bone marrow (see Chapter 7).[19] They are the least numerous blood granulocyte in domestic mammals constituting

about 0.5% of blood leukocytes in health. Basophilic myelocytes can be identified in the bone marrow using routine hematologic stains. Normally, the process of maturation takes about 2.5 days and is completed in the bone marrow.[12] Once in the peripheral blood, they circulate briefly (half-life is approximately 6 hours) but may live as long as 2 weeks in the tissue.[17] Basophils may be recruited into tissue during an immunologic or inflammatory response. Once there, basophils retain their unique morphologic features, but are not routinely identified in hematoxylin and eosin-stained tissue sections.

IL-3 is the major basophil growth factor and cytokine effector of basophil function. It promotes the production, differentiation and survival of basophils in vitro, and results in upregulation of essentially all basophil responses.[27] IL-3 is especially important for bone marrow basophil hyperplasia and blood basophilia in conjunction with Th2 immunologic responses. Other growth factors that contribute to basophil production and differentiation are GM-CSF, IL-5, SCF, IL-4 and other cytokines (Table 44.1). These cytokines generally either induce mediator release from basophils or augment release of mediators stimulated by other agonists. In addition to directing basophils to inflammatory sites, chemotactic cytokines (Table 44.1) also produce or enhance basophil release functions.[3] Further, TGF-β, in the presence of IL-3, curbs eosinophil differentiation and augments basophil production, providing evidence for reciprocal control of the maturation of pluripotent progenitor cells into basophils or eosinophils.[26]

Basophils accumulate at sites of inflammation. To do so, basophils must emigrate from the blood into and through tissues in response to chemotactic agents (Table 44.1).[3,24,31] After stimulation, basophils release cytokines, including TNF-α and IL-4, that increase expression of adhesion molecules on endothelial cells, thereby initiating the first step of emigration. Rolling of basophils along endothelium is mediated by basophil selectins, which act to tether the cells loosely to their carbohydrate counter ligands on endothelial cells. Adherence of basophils to the vascular endothelium involves ICAM-1, ELAM-1 and VCAM-1 that are expressed on the cell surface of activated endothelial cells. Basophils express integrins as receptors for these molecules and these integrins and members of the immunoglobulin superfamily then act to establish firm adhesion. Transendothelial migration and movement through the extracellular matrix also are mediated by similar mechanisms.

Mast Cells

Mast cells originate in the bone marrow from agranular, CD34+, pluripotent, hematopoietic stem cells, that differentiate into a separate and distinct lineage from monocytes/macrophages and from granulocytic precursors.[2,4,8,13,18] Researchers have identified the CD34+, c-kit+, and CD13– precursor cells that, in the presence of specific growth factors, will differentiate into mast cells. Mast cell survival, growth, and differentiation are promoted by SCF (a mast cell hemopoietin that is produced by endothelial cells, epithelial cells, fibroblasts and other cell lines in culture) and inhibited by GM-CSF, IFN-γ and TGF-β.

Normal interactions between SCF and c-kit and the resulting molecular signaling that follows are critical for the development of normal mast cells.[21] Mast cells deprived of SCF undergo apoptosis, whereas mutations in c-kit that result in increased expression of the c-kit proto-oncogene can cause mastocytosis and mast cell neoplasia (see Chapter 68).[21]

Primed by SCF and other growth factors (Table 44.1), committed mast cell precursors leave the bone marrow early in their development, and in normal mammals, circulate as agranular, c-kit+, CD34+, CD13+ mononuclear cells.[12] Mast cell precursors eventually migrate into connective tissue or the lamina propria of the mucosa to proliferate, differentiate, mature, and accumulate their characteristic cytoplasmic granules under the influence of a variety of interleukins such as IL-3, IL-4, IL-9 and IL-10.[18,29]

BIOLOGIC FUNCTIONS

Basophils

Basophils have an important role in the late-phase of the type-1 (immediate-type) hypersensitivity reaction,[9,20] as well as during the early phase of the cell-mediated delayed-type hypersensitivity response. Circulating basophils enter tissues at sites of inflammation during the late phase of the IgE-mediated immediate hypersensitivity reaction where, like mast cells, they have deleterious, rather than protective effects.[26] Their important role as mediators of an allergic response is illustrated in genetically engineered mast cell deficient mice that are capable of mounting an IgE-mediated anaphylactic response.[16] Extensive evidence exists supporting the role of basophils in allergic conditions such as allergic rhinitis, hives, or urticaria, asthma, allergic conjunctivitis, allergic gastritis, and drug-induced or insect-bite-induced anaphylaxis.[7,16]

Even though the phagocytic potential of basophils is minimal, one of their protective functions involves the defense against helminths.[26] This is achieved by the stimulation of T cells to produce a Th2 response. In fact, in the absence of basophils, Th2 cytokine production by T cells is minimal or absent.

Basophils have been reported to have a critical function in the development of IgE-mediated chronic allergic inflammation, where they are necessary for recruitment of inflammatory cells including neutrophils and eosinophils.[25] Basophils may also antagonize or promote hemostasis by means of the anticoagulant actions of secreted heparin and the procoagulant effects of kallikrein. They may promote lipolysis by activation of lipoprotein lipase through secretion of heparin.

TABLE 44.1 Major Properties of Basophils and Mast Cells[a]

Characteristic	Basophils	Mast Cells
Pluripotential stem cell	CD34+	CD34+
Origin of precursor cells	Bone marrow	Bone marrow
Site of differentiation and maturation	Bone marrow	Connective tissue (a few in marrow)
Nucleus	Long ribbon-like, variably segmented	Round to oval
Recruitment of mature cells into tissue	Yes (in inflammation)	No
Mature cells normally present in connective tissue	No	Yes (located perivascularily, around nerves and beneath the epithelium)
Circulation of mature cell in blood	Yes, but low numbers	Rare
Proliferative ability of mature cells	None reported	Yes
Lifespan	Days (similar to other granulocytes)	Weeks to months
Major growth factors mediating differentiation and proliferation	IL-3	SCF, IL-3, IL-6, CCL11, CCL24, CCL26, NGF
Surface structures		
TLRs	TLR1 (mouse), TLR2 and TLR4 (human and mouse), TLR6 (mouse)	TLR1, TLR2, TLR3, TLR4, TLR6, TLR7, TLR9
Immunoglobulin receptors	FcεRI, FcεRII (CDw32)	FcεRI, FcεRII
Expression of FcγRI	High	High
Cytokine/growth factor receptors	IL-1R, IL-2R (CD25), IL-3R, IL-4R, and IL-8R, chemokine and interferon receptors, +/– SCFR (c-kit) (CD117)	SCFR (c-kit) (CD117)
Cell adhesion structures	P24 (CD9), LFA-1 chain (CD11a), C3biR, Mac-1 (CD11b), LFA-1 chain (CD18 and CD29), PECAM (CD31), leukosialin (CD43), Pgp-1 (CD44), VLA-4 (CD49d), VLA-5 (CD49e), ICAM-3 (CD50), ICAM-1 (CD54), LFA-3 (CD58), ICAM-2 (CD102)	CD9, CD29, CD43, CD44, CD49d, CD49e, CD50, VNR,CD51, CD54, CD58, LFA-1, chain, CD61, CD102
Major cell products		
Stored preformed in cytoplasmic granules		
Biogenic amines	Histamine, adenosine, serotonin (rats and mice)	Histamine, serotonin (rats and mice)
Enzymes	Neutral proteases with bradykinin-generating activity, elastase, β-glucuronidase, cathepsin G-like enzyme	Tryptase, chymase (M_{TC}), carboxypeptidase (M_{TC}), cathepsin G (M_{TC}), acid hydrolases, phospholoiase A_2, aminopeptidase, hexosaminodase, chitinases
Proteoglycans	Chondroitin sulfate, heparin, dermatan sulfate	Heparin and/or chondroitin sulfate
Other	Major basic protein	
Mediators synthesized de novo		
Arachidonic acid products	LTC_4	PGD_2, LTC_4, LTB_4, LTE_4, TxB_2, PGE_2
Cytokines	IL-4, IL-8, IL-13, TNF-α, CCL3	SCF, TNF-α, IL-1, IL-3, IL-4, IL-5, IL-6, IL-8, IL-10, IL-13, IL-16, GM-CSF, MCP-1, CCL3, CCL4, bFGF, CCL4, endothelin, lymphotactin, VEGF, NGF
Other	PAF	PAF
Agonists		
Cytokines	IL-1, IL-2, IL-3, IL-4, IL-5, IL-8, CD40 ligand, GM-CSF, IFNγ, IGF-I and II, TGF-β, NGF, chemokines	IL-3, IL-4, IL-9, IL-10, NGF, GM-CSF, SCF, endothelins
Chemokines	CCL1, CCL3, CCL4, CCL6, CCL7, CCL24, CCL26	IL-8, CCL2, CCL3, CCL5
Chemotaxins	IL-3, GM-CSF, IL-5, IL-8, PAF, C5a and chemokines	
Complement proteins	C1, C3, C4, C5a	C3a, C5a
Metachromatic staining with basic dyes		
At acid pH	Yes	Yes
At neutral pH	No	Yes
Cytochemical staining		
Chloracetate activity	Negative usually (except cats)	Positive
Tryptase activity	Negative	Positive

[a]Species variations exist.

Mast Cells

Mast cells function to promote hypersensitivity reactions characterized by vasodilation, increased vascular permeability, bronchoconstriction, mucus secretion, and nerve stimulation; they modulate the immune response by stimulating T cells; they play a role in host defense against tissue parasites; and they promote acute and chronic inflammatory responses by stimulating leukocyte migration, endothelial-leukocyte adhesion, angiogenesis, fibrin deposition, fibroblast proliferation, and fibrosis.[23]

Mast cells have long been recognized as tissue cells with critical roles in type 1 hypersensitivity reactions. More recently, mast cells have been established as tissue leukocytes with key functions in host defense, inflammation, tissue remodeling and fibrosis, as well as coagulation.[28] Research is currently being conducted on the role of mast cells in asthma, atherosclerosis, myocardial infarction, human immunodeficiency virus, cocaine abuse, fibrotic disorders, and rheumatological disorders (Table 44.1).

BINDING OF IgE TO BASOPHILS AND MAST CELLS

Both basophils and mast cells express the $\alpha\beta\gamma_2$ form of the high-affinity, surface Fc receptor for IgE, known as FcεRI. FcεRI is specific for ε-heavy-chains. In healthy people and animals, these IgE molecules vary significantly in antigen specificity.[32] Conversely, in atopic patients, many of the IgE molecules that are bound to mast cells and basophils are specific for one or only a few different antigens.[32] This lack of IgE variablilty, upon exposure to the specific antigens, results in cross-linking of the Fc receptors, which results in rapid cell activation and degranulation. Activation and degranulation of tissue mast cells then triggers an immediate hypersensitivity reaction (Fig. 44.1), as well as sequential recruitment of basophils to tissue sites, thereby expanding the spectrum of the inflammatory process.[5]

ACTIVATION, DEGRANULATION, AND PRODUCTION OF MEDIATORS BY BASOPHILS AND MAST CELLS

There are numerous initiators of mast cell and basophil activation such as cross-linking of IgE by antigen, cytokines, chemokines, chemical agents (e.g. radiocontrast solutions), physical stimuli (e.g. cold), peptides (e.g. neutrophil lysosomal proteins, insect and animal venoms, bacteria, and bacterial products), viruses, calcium ionophors, narcotics, and muscle relaxants. IgE-mediated activation and degranulation is the most well understood of these phenomena so it will be the focus of the discussion.

When antigen binds to two adjacent IgE molecules, it induces aggregation of the IgE molecules and associated FcεRI receptors (Fig. 44.1).[18] This event initiates a signaling cascade resulting in three types of biological responses: (1) secretion of the preformed contents of the granules (including histamine), (2) synthesis and secretion of lipid mediators, and (3) synthesis and secretion of cytokines (Table 44.1), all of which work together to initiate a local inflammatory response.[1]

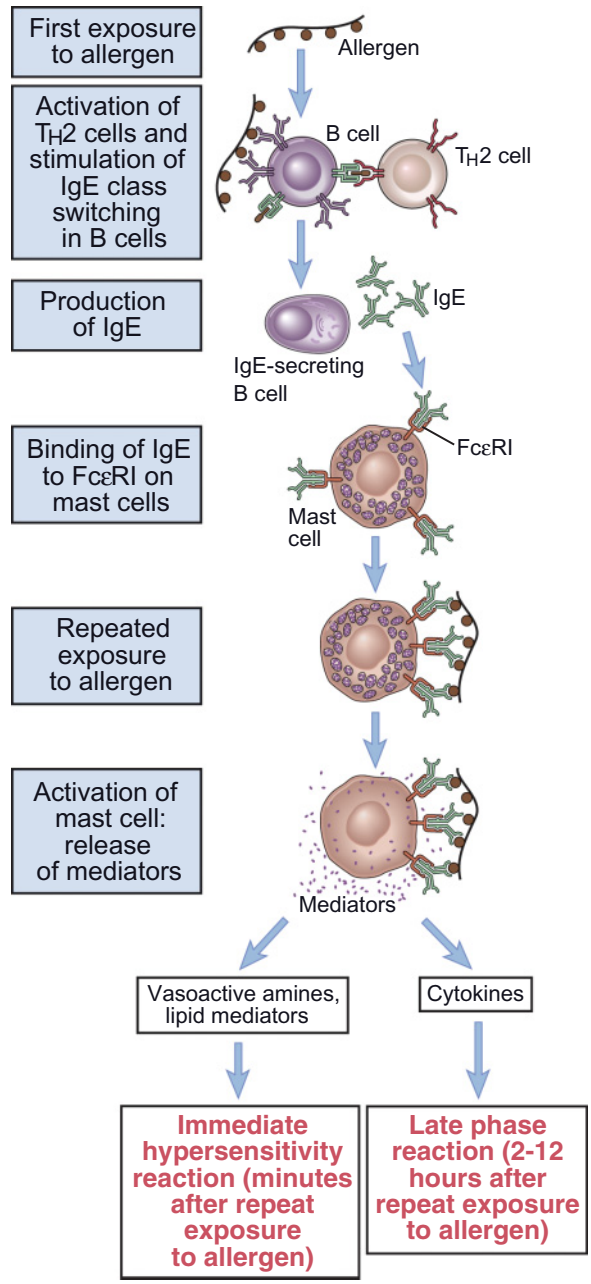

FIGURE 44.1 Order of events in type 1 (immediate-type) hypersensitivity. Type 1 hypersensitivity diseases begin with exposure to an allergen. On first exposure, the allergen stimulates a Th2-type response and production of IgE. IgE binds to FcεRI receptors on mast cells and results in sensitization. With subsequent exposure to the allergen mast cells are activated to secrete mediators that are responsible for the pathologic effects of type 1 hypersensitivity. (Adapted with permission from Abbas AK, Lichtman AH, Pillai S, Immediate hypersensitivity, Chapter 19, In: Cellular and Molecular Immunology, 6th ed. Philadelphia: Saunders, 2007. ©Elsevier.)

Histamine is a short-lived vasoactive amine that causes an immediate increase in local blood flow and vessel permeability. Enzymes, such as chymase, tryptase, and serine esterases, activate matrix metalloproteases. Matrix metalloproteases in turn, cause tissue destruction by breaking down tissue matrix proteins.

Synthesis and secretion of lipid mediators is induced via the activation of the cytoplasmic enzyme phospholipase A_2 (PLA_2). This is activated by two signals: (1) increased cytoplasmic calcium and (2) phosphorylation catalyzed by mitogen-activated protein (MAP) kinases such as extracellular-regulated kinase (ERK). Activation of PLA_2 results in hydrolysis of mast cell membrane phospholipids and the production of arachidonic acid, which is converted by cyclooxygenase or lipoxygenase to subsequently produce prostaglandin and leukotrienes respectively.[2] Protein kinases also act on genes coding for cyclooxygenases and lipoxygenases to promote transcription and increased expression.[1] The major arachidonic acid-derived mediators produced by mast cells are PGD_2 LTC_4, LTD_4 and LTE_4. Basophils produce predominantly LTC_4.[1] PAF causes bronchoconstriction, retraction of endothelial cells, and relaxation of vascular smooth muscle.[1]

IgE-mediated synthesis and secretion of cytokines occurs as a result of activation of protein kinases, which in turn results in the induction of gene transcription factors such as NFAT, and NF-κB, as well as activation of AP-1. These transcription factors stimulate transcription of IL-4, IL-5, IL-6, IL-13, and TNF, among others.[2] Both mast cells and basophils also express Fc receptors for IgG1 that can be activated by cross-linking bound IgG1 (Fig. 44.2). IgE is, however, the major antibody involved in mast cell and basophil activation.[1]

Mast cell degranulation is also controlled by surface catecholamine receptors (α- and β-adrenoceptors) that have opposing effects. Mast cell degranulation is augmented by molecules that stimulate α-receptors (e.g. norepinephrin and phenylephrin) or block β-receptors (e.g. propranolol). Conversely, mast cell degranulation is inhibited by molecules that stimulate β-receptors or block α-receptors. β-Stimulants are widely used in the treatment of allergies and include isoproterenol, epinephrine and salbutamol. β-Blockade, resulting in increased mast cell degranulation and tissue inflammation, can be caused by some respiratory pathogens such as *Bordetella pertussis*, or *Haemophilus influenza*.[32] Animals with these infections also have an increased predisposition to development of respiratory allergies.[32]

Activation of mast cells and basophils is regulated by a variety of inhibitory receptors. Of these, one of the most important is FcγRIIb (Fig. 44.2). Experiments in

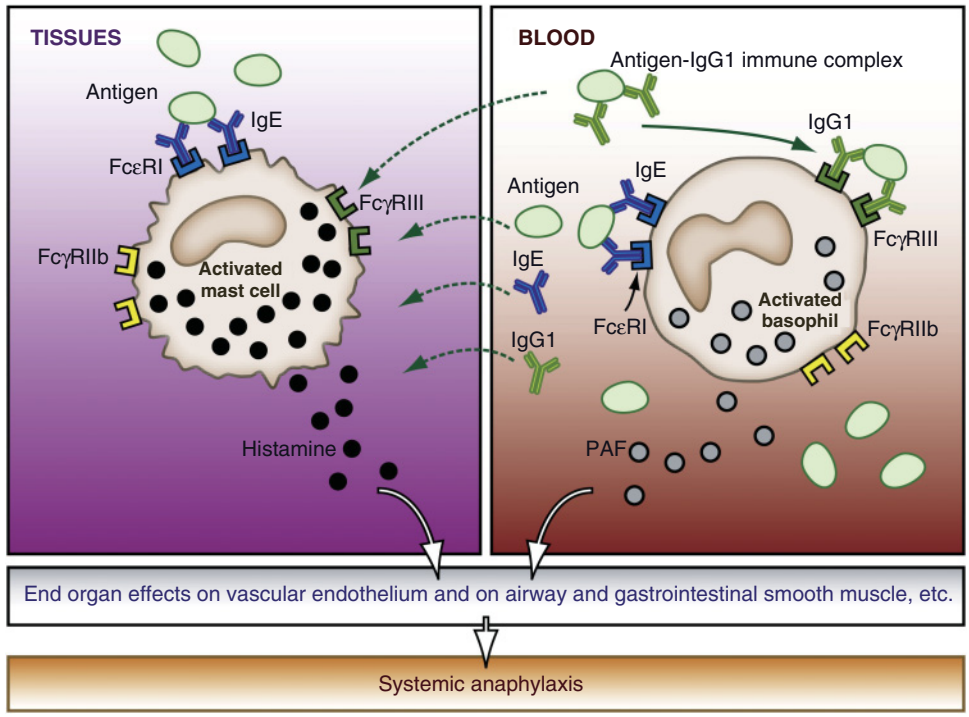

FIGURE 44.2 Contributions of mast cells and basophils to systemic anaphylaxis. Intravenous injection of antigen in sensitized mice is recognized by basophils that have bound antigen-specific IgG1 antibodies. Antigen and circulating IgE and IgG1 complexes can gain access to mast cells by diffusion through vascular endothelium and tissues especially in the face of increased vascular permeability. Antigen-specific IgE and IgG1 are also produced in tissues. When surface FcεRI is aggregated by the binding of FcεRI-bound IgE to bi- or multivalent antigen, basophils and mast cells are activated to secrete mediators. Both cell types also can be activated when surface FcεRIII binds IgG1 immune complexes and specific antigen. If antigen bound to IgG1 antibodies colligates FcεIII or FcεRI and the inhibitory receptor, FcεRIIb, mast cell and basophil activation is repressed. Basophil-derived PAF is a major mediator of IgG1-dependent systemic anaphylaxis. (Reproduced from Galli SJ, Franco CB, Basophils are back! Immunity 2008;28:495–497, with permission. ©Elsevier.)

mice show that FcγRIIb can regulate mast cell activation in vivo.[1] Pharmacologic inhibitors of mast cell and basophil activation include corticosteroids, cyclosporine A, and theophylline.[17]

MAJOR PRODUCTS OF MAST CELLS AND BASOPHILS

The primary substances stored in mast cell and basophil granules include biogenic amines, enzymes, proteoglycans, and, in basophils, major basic protein (Table 44.1).[9] The secondary products that are synthesized de novo subsequent to activation include lipid-derived mediators and cytokines. IL-4, that recruits eosinophils and helps drive immunoglobulin class switching and IgE production, is the major cytokine synthesized by basophils. Degranulated mast cells and basophils will regenerate their granules.[32]

ROLE OF MAST CELLS AND BASOPHILS IN ALLERGIC DISEASE

Mast cells and basophils are the central components and major effector cells of immediate hypersensitivity reactions and allergic diseases. The cytoplasmic granules of both cells contain the major mediators of hypersensitivity reactions (Table 44.1).[1] Type 1 hypersensitivity is a form of inflammation that primarily involves cross-linking of FcεRI by antigen on mast cells and basophils, which results in abrupt release of inflammatory mediators (Fig. 44.2). The clinical and pathologic manifestations depend on the tissue location and the number of effector cells responding. The number of effector cells responding depends on: (1) the degree to which the animal has been previously sensitized, (2) the quantity of antigen to which the animal is exposed, (3) the route of antigen administration, and (4) the chronicity of the resulting inflammatory process.[1,32]

Exposure to environmental antigens is a part of daily life. There is no obvious clinical consequence in most animals because they respond by producing IgG or IgA antibodies. However, some animals produce excessive amounts of IgE antibody, which is the result of an exaggerated Th2 response (Fig. 44.1).[32] Basophils are believed to be key players in this exaggerated Th2 response because they alter lymphocyte responses and promote the Th2 response by providing the initial IL-4 required to activate the CD4+ T cells. In vitro studies have also shown that basophils induce switching of isotype to IgE.

INTERACTIONS OF BASOPHILS AND MAST CELLS WITH EOSINOPHILS

Mast cells, basophils, and eosinophils frequently interact in inflammation, with each having both protective and pathologic effects.[32] Mast cells produce IL-5 and CCL11, CCL24 and CCL26 that stimulate the release of eosinophils from the bone marrow.[32] Also, molecules such as CCL11, CCL24 and CCL26, histamine, LTB_4, 5-hydroxytryptamine, and PAF attract eosinophils to the sites of inflammation.[32] Basophil influx occurs in the late-phase of the allergic response. Eosinophil degranulation releases major basic protein and PAF causing more mast cells and basophils to degranulate. This effect is augmented by mast cells, which further synthesize and secrete IL-3, IL-5 and GM-CSF, thereby enhancing eosinophil and basophil growth, differentiation, and activation.[32]

MAST CELLS AND BASOPHILS IN INFLAMMATION AND HOST DEFENSE

Most of our knowledge of mast cell and basophil-mediated responses comes from the analysis of hypersensitivity diseases. Even though mast cells and basophils have traditionally been thought of in terms of their association with the allergic response, studies indicate that these cells also provide protective functions with roles in innate immunity, host defense and inflammation.[1] Hosts must be able to mobilize defenses and direct them to the site(s) of pathogen growth when organisms cross epithelial barriers and attempt to establish foci of infection. Activation of mast cells, which are sentinel cells, is one mechanism by which this is achieved.[32]

The location of mast cells near body surfaces allows them to recruit both specific and nonspecific effector elements to sites where infectious agents are most likely to enter the body.[32] In response to microbial invasion, tissue damage, bacteria and bacterial products, and inflammatory mediators, including defensins, neuropeptides, adenosine, and endothelins, mast cells and basophils release potent inflammatory mediators, such as histamine, proteases, chemotactic factors, cytokines and metabolites of arachidonic acid.[29] Collectively, these act on the vasculature, smooth muscle, connective tissue, and mucous glands, and attract inflammatory cells to the lesion. This release is carefully regulated to ensure that the severity of inflammation is appropriate to the body's immediate needs. Therefore, in a healthy inflammatory response, release of inflammatory mediators occurs relatively slowly (Table 44.1).

Activation of mast cells and basophils results in increased flow of lymph from sites of antigen deposition to regional lymph nodes, where naïve lymphocytes are first activated. IgE-mediated mast cell and basophil responses are critical in defense against parasite infection.[1] IgE-dependent mast cell activation in the gastrointestinal tract and lungs has also been shown to promote the physical expulsion of parasites by initiating an outpouring of mucus and triggering muscular contractions, thereby increasing peristalsis in the gut.[1] IgE-mediated mast cell and basophil responses are also protective against blood-sucking ticks. On first exposure, skin at the site of a tick bite contains degranulated mast cells, basophils, and eosinophils. However, with subsequent tick-feedings, resistance to the tick bite

typically develops. In dogs and cats, heartworm infection frequently induces an increase in basophils both in the tissues and in the blood.

Mast cells also have an important protective role in the innate immune response to invading bacteria; the mediators they release during these responses are critical for clearing the infection. Moreover, studies in mice indicate that during an acute bacterial infection, mast cells are activated by IgE-independent mechanisms.[1]

Mast cells are present in significant numbers in heart tissue of many species including amphibians, mice, rats, dogs, and humans. They release many inflammatory mediators at the site of ischemia that are important in both the proinflammatory phase and the proliferative/fibrosis phase of infarct healing.[14]

LABORATORY EVALUATION OF BASOPHILS

Microscopic Appearance

When seen on blood films, normal mammalian basophils are larger than neutrophils, with a diameter similar to that of eosinophils. Like other granulocytes in domestic species, the nuclei of basophils are mildly segmented and have mostly condensed chromatin. The nuclei of canine and feline basophils frequently extend to the margins of the cell and may be described as long and ribbon-like with twisting and folding, but with less segmentation and chromatin clumping than mature neutrophils, and fewer nuclear filaments. The cytoplasmic granules of mammalian basophils are variably sized, round to oval and typically stain metachromatically with basic dyes such as Alcian blue and toluidine blue at low pH. The amount of granulation varies between species (see Section IX).

Basophil Histamine Release Assays

Basophils contain most of the histamine in blood. Therefore, in an attempt to assess hypersensitivity states in several species, including horses and sheep, assays for basophil histamine release have been developed.[22]

Basophil Counts

Automated methods for counting basophils are usually based on the resistance of human basophils to lyse in fluids that lyse other leukocytes. This method does not appear to work for the dog and cat. For example, The Technicon H1®, Advia 2120®, Sysmex XT 2000 iV®, and Lasercyte® all failed to accurately detect basophils when basophils were present in large numbers in canine cases, (Dr. Harold Tvedten, personal communication).[33] The Sysmex XT 2000 iV® did not detect basophilia in feline cases, but some feline cases with increased mast cells had cells detected as basophils, suggesting that mast cells are not lysed in the basophil reagent. The Technicon H1®, Advia 2120®, and Sysmex XT 2000 iV® have indicated the presence of basophilia when basophilia were not detected by blood smear inspection.[33] Thus an increase in automated basophil counts in the dog and cat should be considered an error. Accuracy of automated basophil counts in other species has not been validated (Dr. Harold Tvedten, personal communication). Alternatively, 100-cell differential counts are imprecise for evaluating basophils, because basophils usually account for less than 2% of the leukocytes in most species. One must count thousands of cells, or use direct counting methods with a hemocytometer and basophil stain to obtain precise counts.

Basophilia

Basophilia in mammals is relatively rare. In healthy animals, basophils are so infrequently seen that they are rarely included in the 100-cell differential cell count. For domestic mammals, only marked or persistent increases in basophil concentrations should be considered abnormal. Typically, when seen, basophilia in domestic mammals is typically associated with an IgE-mediated disorder, and it is usually accompanied by an eosinophilia. Therefore, primary considerations should be given to allergic diseases and parasitism. Causes of basophilia include drugs, foods, inhalants, and parasite stings or bites. Parasites documented to cause basophil recruitment and the accumulation of tissue basophils include ectoparasites such as fleas and ticks, gastrointestinal parasites such as nematodes, and vascular parasites such as *Dirofilaria immitis* and *Dipetalonema reconditum*.[10]

If parasites and allergy are ruled out, other inflammatory or neoplastic conditions should be considered. Basophilic leukemia is rare but has been reported in dogs and cats (see Chapter 63). Basophilias may also occur with mast cell neoplasia with or without mastocythemia and in dogs that have lymphomatoid granulomatosis.[11] Potentially, basophilia also may occur with other forms of cancer.

Frequently, hyperlipidemia has been mentioned as a cause of basophilia, but there is no good evidence to support this. Basophilia without eosinophilia may indicate that endogenous or exogenous corticosteroids have depressed eosinophil concentrations more than basophil concentrations.

Basopenia

With the reference interval including 0 cells/μL, basophils are rarely observed in the blood and bone marrow of healthy animals. Therefore, in most species, basopenia is not recognized. Nevertheless, using more sensitive enumeration techniques, decreased numbers of circulating basophils have been reported in several disorders. Disorders associated with decreased circulating basophil concentrations include urticaria and anaphylaxis, some inflammatory and immunologic conditions, corticosteroid administration, neoplasia, and hemorrhage.

LABORATORY EVALUATION OF MAST CELLS

Structure, Morphology, and Staining Characteristics

When stained with most Romanowsky-type stains, mast cells are identified by their characteristic fine-to-coarse deep purple cytoplasmic granules. However, approximately 15% of the time mast cell granules may stain poorly or not at all when manual quick stains are used. The lack of staining may be associated with dissolution of mast cell granules by these largely aqueous stains if fixation is inadequate. Therefore, leaving the slide in the fixative for at least 5 minutes before staining the slide may improve granule staining.

With Romanowsky-type stains, mast cells are round cells with round to slightly oval, usually central or slightly off-center nuclei. They have variable quantities of cytoplasm that contain varying shades of red to deep purple, variably sized, yet often very coarse granules. If the cytoplasm is not packed with granules, it can appear clear, pale pink, or blue. Nuclei are frequently obscured by the granules, but when seen the chromatin patterns range from coarsely granular to finely stippled, depending on cell maturity. Mast cell nuclei frequently absorb less stain than the granules and thus appear as pale blue circles amongst the abundant mass of deep purple granules. Prominent nucleoli are not typically seen in normal mast cells but may be seen in mast cell neoplasia. In some species, highly granulated basophils can be confused with mast cells.

Mastocythemia and Marrow Mastocytosis

Because mast cells are normal residents of many tissues, occasional mast cells are seen in many tissues including bone marrow and lymph nodes.[6] Mastocytosis or mastocythemia (also called mastocytemia) may represent either a reactive or a neoplastic state (see Chapter 68 for mast cell neoplasia).

Finding mast cells in the blood of dogs, for many years, was considered highly suggestive of mast cell neoplasia; however, mastocythemia may be seen in animals with inflammatory diseases, regenerative anemia, tissue injury, neoplasia other than mast cell tumors, and necrosis.[30] In a study of 19 dogs with mastocythemia, 18 of 19 had acute inflammatory leukograms with associated toxic neutrophils. Mastocythemia also has been associated with inflammatory skin disease in dogs.

Acronyms and Abbreviations

DNA, deoxyribonucleic acid; FIV, feline immunodeficiency virus; IL, interleukin; MAP, *Mycobacterium avium* subsp. *paratuberculosis*; MHC, major histocompatibility antigen; NF-κB, nuclear factor-kappaB; Nramp1, natural resistance-associated macrophage protein-1; TGF-β, transforming growth factor-beta;TNF-α, tumor necrosis factor-alpha, TLR, Toll-like receptor; VLA, very late activation antigen.

Monocytes and free and fixed tissue macrophages and their progenitor cells in bone marrow make up the mononuclear phagocyte system.[13] Dendritic cells are a distinct subset of bone marrow-derived cells that are morphologically and functionally related to macrophages.[3] That being said, dendritic cells have been shown to differentiate from monocytes and macrophages in vitro under appropriate cytokine stimulation.[3]

Monocytes continuously emigrate from the blood into peripheral tissues.[13,19,36] Depending on the tissue or the inflammatory process encountered, monocytes differentiate into a variety of subtypes of fixed tissue and free, and inflammatory macrophages. Tissue macrophages include Kupffer cells, alveolar macrophages, microglial cells, and osteoclasts (Table 45.1).[34] Macrophages in various tissues have specialized functions. For example, alveolar, peritoneal, and pleural

TABLE 45.1 Phenotypic Heterogeneity of Mononuclear Phagocytes Associated With Site-Specific Differentiation In Vivo

Cell Type	Phenotype
Peripheral monocytes	F4/80^{low}, CD11b^{+}, CD68^{+}, Dectin-1^{+}, CD14^{+}
Inflammatory monocyte	CCR2^{+}, CD62L^{+}, Ly6C^{+}, CD14^{+}
Bone marrow stromal Mθ/Kupffer cells	F4/80^{+}, Sialoadhesin^{+}, CD68^{+}, CD11b$^{low/-}$
Splenic red pulp Mθ	F4/80^{+}, CD68^{+}, CD11b$^{low/-}$, Sialoadhesin^{low}, MR^{+}, Dectin-2^{+}
Splenic white pulp Mθ	CD68^{+}
Dendritic cells	CD11c^{+}, MHCII^{+}, CD68^{low}
Langerhans cells	F4/80^{-}, CD11b^{+}, CD68^{+}, Langerin^{+}, MCHII^{+}, Dectin-2^{+}
Inflammatory elicited Mθ	F4/80^{+}, CD11b^{+}, CD68^{+}, MR^{+}, Dectin-1^{+}
Resident peritoneal Mθ	F4/80^{high}, CD11b^{high}, CD68^{+}, Dectin-1^{+}, DIGNR1^{+}
Microglia	F4/80^{+}, CD11b^{+}, CD68^{+}
Alveolar Mθ	F4/80^{low}, CD68^{+}, Sialoadhesin^{+}, MR^{+}, Dectin-1^{+}

macrophages have enhanced bactericidal activity, whereas splenic macrophages and Kupffer cells are specialized for phagocytosis of senescent erythrocytes and for iron storage.[34] Inflammatory macrophages include epithelioid cells and multinucleate giant cells. Pulmonary intravascular macrophages are a unique part of the mononuclear phagocyte system of several species, including ruminants, pigs, horses, cats, mice, and rats.[21] These cells localize circulating foreign particles in the lungs.

STRUCTURE AND BIOCHEMISTRY

Ultrastructure

As monocytes develop into macrophages, the cells enlarge, the number of mitochondria and lysosomal granules increase, the size of the Golgi complex increases, and the acid hydrolases content of lysosomes increase (Fig. 45.1). Macrophages are highly dynamic cells usually containing large numbers of cell surface microvilli. These cells are constantly engaged in uptake of fluid through pinocytosis and have variable numbers of small clear vacuoles in their cytoplasm. Phagolysosomes may also be present that contain ingested material. The number and size of mitochondria vary with the phagocytic activity of the cell.

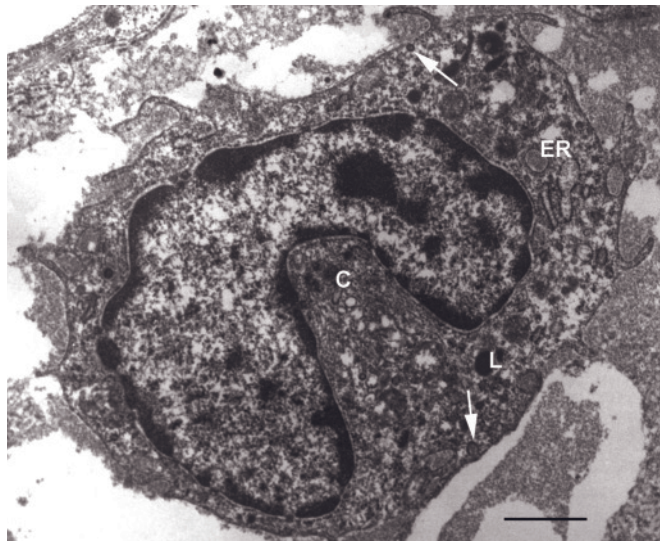

FIGURE 45.1 Porcine tissue macrophage from the skin. Endoplasmic reticulum (ER), primary lysosomes (L), clathrin-coated pits (arrows). Bar, 2 µm. (Courtesy of W.L. Steffens III, University of Georgia.)

Metabolism

Mononuclear phagocytes derive their basal metabolic energy primarily from glycolysis. Alternatively, oxidative phosphorylation contributes substantially to the generation of adenosine triphosphate in alveolar macrophages. Phagocytosis is accompanied by a marked increase in oxygen consumption which is part of the antimicrobial response. As with neutrophils, macrophages contain the multicomponent NADPH oxidase system that is responsible for the respiratory burst (see Chapter 41). Additional fluids, that may contain nutrients, are continually endocytosed into macrophages by a process of pinocytosis.[15] Fluid uptake occurs through macropinosomes (vesicles larger than 0.2 µm), clathrin-coated vesicles, and small uncoated vesicles.

Secretion

Macrophages contain a variety of secretory products, most of which are produced after exposure to various stimuli.[28] When activated by a variety of agonists, monocytes and macrophages produce proinflammatory cytokines (e.g. interleukin [IL]-1, IL-6, tumor necrosis factor-alpha [TNF-α]), anti-inflammatory cytokines (e.g. IL-10), growth factors (e.g. granulocyte-monocyte colony-stimulating factor, granulocyte colony-stimulating factor, platelet-derived growth factor, and transforming growth factor-β), various enzymes (e.g. collagenase, elastase, acid hydroliases, and

plasminogen activator), alternative and classic complement pathway factors, and prostaglandins and lipoxygenase products.

Cell Surface Receptors

As phagocytes, monocytes and macrophages have a complex array of cell membrane receptors that vary somewhat depending on the tissue of origin and the activation status (Table 45.2).[13,36] These can be grouped into various functional categories, including adhesion receptors, phagocytosis receptors, growth receptors, differentiation receptors, activation receptors, migration receptors, and function receptors (Table 45.2). However, individual receptors frequently have more than one function. Major receptor groups include Fc receptors, complement receptors, Toll-like receptors (TLRs), major histocompatibility receptors, cytokine receptors, chemokine receptors, and scavenger receptors.[36]

Fc Receptors

Fc receptors are expressed on the cell surface of monocytes, macrophages, granulocytes, and platelets.[36] Three distinct subclasses of Fc receptors have been identified in human cells that interact with various types of monomeric IgG, complexed IgG, or with immune complexes. Human and mouse Fc receptors function to bind the Fc portion of immunoglobulin and function in phagocytosis, cell activation, and in antibody-dependent cellular cytotoxicity. Fc receptors in animal species have been less well investigated but early studies indicate that these receptors may function differently from human Fc receptors. Bovine Fc receptors may function to secrete IgG onto mucosal surfaces. However, Fc receptors do appear to be involved in the activation of bovine neutrophils.[16,27]

Complement Receptors

Four receptors are present on monocytes and macrophages that bind fragments of C3.[45] Complement receptor 1 (CD35) binds to C3bi.[46] The other three complement receptors are members of the integrin family and include CD11a/CD18, CD11b/CD18, and CD11c/CD18. Interaction of complement receptors with complement fragments primarily initiates phagocytosis and to a lesser extent initiates cell activation.

TABLE 45.2 Macrophage Receptors and Their Ligands

Macrophage Receptor	Ligand
Transmembrane receptor	
TLR1:TLR2 heterodimer	Peptidoglycans, lipoproteins, lipoarabinomannan, GPI, zymosan
TLR3	dsRNA
TLR4/CD14/MD2 complex	Lipopolysaccharide (Gram negative bacteria), lipoteichoic acids (Gram positive bacteria)
TLR5	Flagellin from bacteria
TLR7	ssRNA
TLR8	G-rich oligonucleotides
TLR9	Unmethylated CpG DNA from bacteria
TLR11	Propellin
MARCO (macrophage receptor with collagenous structure)	Unopsonized inert particles and bacteria
Scavenge receptors	Unopsonized inert particles and bacteria
Dectin-1	Several types of carbohydrates
DC-SIGN (dendritic cells)	ICAM-2, ICAM-3, lipopolysaccharide
FPR (formyl peptide receptor)	*N*-formylated peptide of bacteria
MR (mannose receptor)	Mannose, lipopolysaccharide
Cytosolic receptor	
Naip5 (neuronal apoptosis-inhibiting protein 5)	Flagellin
Ipaf	Flagellin?
Nod1 and Nod2 (nucleotide oligomerization domains 1 and 2)	Peptidoglycan
RIG-1 (retinoic acid-inducible gene 1)	dsRNA, dsDNA?
Extracellular receptor	
SP-A and SP-D (surfactant proteins A and D)	ssRNA, lipopolysaccharide, lipoteichoic acids
LPB (lipopolysaccharide-binding protein)	Lipopolysaccharide
CD14	Lipopolysaccharide
MD-2	Lipopolysaccharide
PTX3 (pentraxin 3)	Complement proteins, zymosan
MBL (mannose-binding lectin)	Mannosylated moieties
CRP (C-reactive protein)	Phosphocholine
Complement	Microbial surfaces

Integrin Receptors

The leukocyte integrin subfamily of adhesion molecules consists of a group of four heterodimeric glycoproteins.[9] All share a common β_2-subunit designated CD18 but have variable α-subunits designated CD11a, CD11b, CD11c, and CD11d. CD11a is expressed on all leukocytes; CD11b is present on monocytes, macrophages, and granulocytes; CD11c is primarily present on monocytes, and macrophages; and CD11d is expressed by some macrophages and T cells.[26] Several β_1 integrins are also expressed by monocytes and macrophages; these include very late activation antigen (VLA)-4, VLA-5, and VLA-6. These are fibronectin receptors. Integrins along with L-selectins play a central role in cell adhe-

sion to endothelium and extracellular matrix proteins and migration through tissues (see Chapter 41).

Toll-Like Receptors

Mammalian Toll-like (TLR) receptors are a family of proteins that are localized on the cell phagosomal membrane of macrophages and dendritic cells.[1] The major function of these molecules is to detect and bind pathogen-associated molecular patterns and to initiate signal transduction leading to activation of macrophages and dendritic cells. Each of the 11 TLRs detects a different set of microbial components. For example, TLR2 recognizes triacylpeptides; TLR4 in combination with CD14 recognizes lypopolysaccharide, and TLR9 recognizes bacterial DNA.[1]

Mannose Receptors

The mannose receptor interacts with linear or branched chain mannosyl and fucosyl residues.[36] This permits the mannose receptor to bind a wide variety of bacteria, yeast, and parasitic organisms. The primary result of binding to mannose receptors is phagocytosis; however, some cell signaling via these receptors has been documented.

Scavenger Receptors

Scavenger receptors recognize negatively charged macromolecules.[31] They have not been extensively studied in animal species. In humans, they have been shown to play a role in uptake of cholesterol from low-density lipoproteins, to recognize pathogens, and to remove apoptotic cells.[31] Scavenger receptors have been identified in cattle. These scavenger receptors, designated WC1, are transmembrane glycoproteins expressed on gamma delta T cells.[4] The subpopulation of gamma delta T cells expressing WC1 appear to be inflammatory-type cells, whereas WC1-negative gamma delta T cells appear to be regulatory-type cells.[4]

FUNCTION

A major function of macrophages is to restrict replication of intracellular microorganisms.[36] As such, these cells play a key role in defense against a variety of organisms including *Mycobacterium*, *Leishmania*, *Rhodococcus*, *Toxoplasma*, *Listeria*, *Brucella*, *Salmonella*, *Yersinia*, *Shegellia*, *Rickettsia*, *Legionella*, and *Theileria*. Other macrophage functional activities include processing and regulating immune responses through presentation of antigens to the immune system and secretion of cytokines (e.g. IL-10, IL-12, transforming growth factor[TGF]-β), modulation of inflammatory responses through secretion of hematopoietic growth factors (e.g. granulocyte-monocyte colony-stimulating factor, granulocyte colony-stimulating factor), initiation of inflammation (e.g. IL-1, IL6, TNF-α), and inhibition of inflammation (e.g. IL-10, TGF-β), production of cytokines, and chemokines (e.g. CXCL8, CXCL10, CCL5), regulation of iron metabolism, removal of dead and damaged tissue, and interaction with tumor cells (Table 45.3).

Macrophage Activation

When macrophages are activated, they mount specific functional responses that depend on the activating stimuli.[23] When activated by classical inflammatory stimuli like interferon-gamma and lipopolysaccharide, macrophages are proinflammatory and have been termed M1 macrophages (Fig. 45.2). M1 macrophages secrete proinflammatory cytokines, have increased major histocompatibility antigens and costimulatory molecules on their surface, have enhanced endocytic functions, and enhanced capacity to kill organisms. M2 macrophages are alternatively activated macrophages and have anti-inflammatory activity. They have been divided into M2a (activated by IL-4 or IL-13), M2b (activated by immune complexes in combination with IL-1β or lipopolysaccharide), and M2c (activated by IL-10, TGF-β, or glucocorticoids). M1 macrophages support development of a Th1-type immune response through secretion of IL-12, while M2 macrophages support development of a Th2-type immune response through secretion of IL-10 (see Chapter 51). M2 macrophages are thought to be important in the resolution of inflammation and in tissue repair.[23]

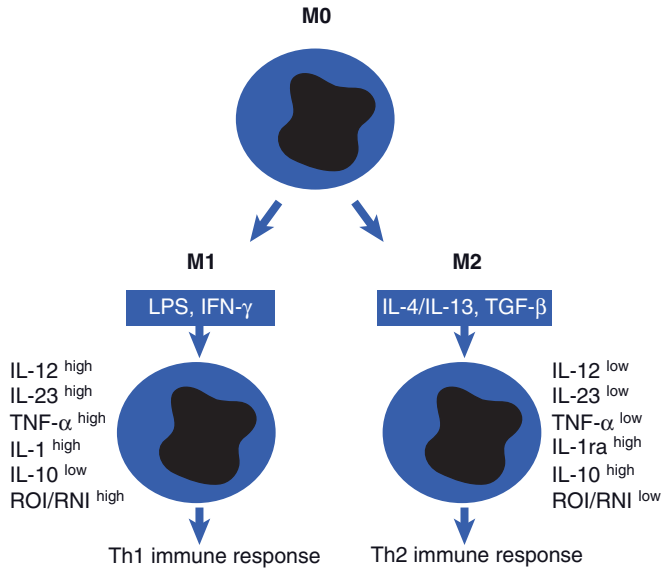

FIGURE 45.2 Macrophage functional activity is dependent on the activating stimulus. Macrophages activated by classical inflammatory stimuli (M1 macrophages) secrete proinflammatory cytokines, induce a Th1-type immune response, and have enhanced antimicrobial activity. Macrophages stimulated by anti-inflammatory stimuli (M2 macrophage) have anti-inflammatory activity, stimulate a Th2-type immune response, and have reduced antimicrobial response. IL, interleukin; RNI, reactive nitrogen intermediates; ROI, reactive oxygen intermediates; TNF-α, tumor necrosis factor-α.

TABLE 45.3 Major Cytokines Expressed by Macrophages

Cytokine	Receptor(s)	Target cell(s)	Major biological function(s)
TNF-α	TNF-R1/R2	Multiple cell and tissues	Proinflammatory; induces apoptosis, cellular proliferation; inhibitory effects on tumorigenesis and viral replication
IL-1	IL 1RI and IL1RI-Acp	Macrophages, T lymphocytes, B lymphocytes, endothelial cells, etc.	Proinflammatory cytokine; promotes costimulation and secretion of cytokines and other acute-phase proteins
IL-6	IL6Rα	B lymphocytes, T lymphocytes, thymocytes, myeloid cells, etc.	Proinflammatory and costimulatory action; induces proliferation and differentiation; synergizes with TGF-β to drive Th17 responses
IL-10	IL10R1 and IL10R2	Macrophages, Th1/2 cells, dendritic cells	Immune suppression; down-regulation of MHC class II expression; down-regulates inflammatory responses regulated by Th1and Th17 cells
IL-12	IL12Rβ1 and IL12Rβ2	T lymphocytes, NK cells, macrophages	Differentiation and proliferation of T cells; promotes Th1 responses and macrophage activation
IL-18	IL18R and IL18-R-AcP	Th1 cells, NK cells, B lymphocytes	Differentiation and proliferation of Th1 cells; induction of IFN-γ production, enhances NK cell toxicity
IL-19	Same as IL-20	Macrophages, Th1/2 cells, dendritic cells	Biological functions under investigation
IL-20	IL-20R1 and IL-20R2		Regulates proliferation and differentiation of keratinocytes during inflammation; promotes cell expansion of multipotential hematopoietic progenitor cells
IL-23	IL23R and IL23Rβ1	T lymphocytes	Inflammatory; promotes proliferation of Th1 and Th17 cells; macrophage activation
IL-27	WSX-1/gp130	T lymphocytes	Induction of early Th1 differentiation by stimulating expression of T-BET transcription factor; inhibition of effector Th17 cell response by inducing STAT-1-dependent blockade of IL-17 production
IL-28	IL28R1/IL10R2	Virus infected cells	Role in immune defense against viruses
IL-33	ST2/IL1R-AcP	T-lymphocytes, mast cells, others?	Costimulation; promotes Th2 cytokine production

Antimicrobial Mechanisms

Our understanding of macrophage antimicrobial mechanisms have developed from study of the interaction of macrophages with several intracellular organisms, the most prominent of which are *Mycobacterium*, *Leishmania*, and *Toxoplasma*.[36] These studies have unraveled both the mechanisms by which macrophages kill organisms and mechanisms by which pathogens circumvent these antimicrobial mechanisms. Within veterinary species, most research has focused on the interaction of *Mycobacterium avium* subsp. *paratuberculosis* (MAP, the cause of Johne's disease) with ruminant monocytes and macrophages. Initial studies established that bovine monocyte-derived macrophages lacked the capacity to kill MAP organisms.[42] Results of more recent studies indicate that cellular responses are initiated when MAP interacts with host cell-membrane receptors.[44] A major signaling receptor incriminated in susceptibility to MAP infection is TLR2. TLR2 has been shown to activate two key cell signaling pathways, the mitogen-activate protein kinase-p38 pathway and the NF-κB pathway.[44] Both pathways initiate transcription of IL-10. Early production of IL-10 appears to suppress macrophage activation and inhibit initiation of a Th1-type immune response. In addition to failing to initiate inflammatory and immune responses, phagosomes containing MAP fail to acidify and fuse with lysosomes.[35] Preincubation of bovine monocyte-derived macrophages with anti-IL-10, anti-TLR2, or an inhibitor of the mitogen-activate protein kinase-p38 pathway resulted in increased phagosome acidification, phagolysosome fusion, and killing of MAP organisms.[44]

Antigen Processing

Once phagocytized, macrophages and dendritic cells degrade complex proteins, attach them to major histocompatibility antigen (MHC) class-II molecules, and transport them to the cell surface for presentation to the immune system. Many virulent organisms interfere with this process, thus attenuating the immune response. Virulent mycobacteria interfere with antigen presentation by inhibiting phagolysosome fusion, preventing activation of proteolytic enzymes in the phagosome, and altering expression and distribution of MHC class-I, MHC class-II, and co-regulatory molecules.[29]

Regulation of Iron in Phagosomes

The overall role of macrophages in iron metabolism and recycling of red blood cell (RBC) iron is discussed in Chapter 20, and sequestration of iron in the macrophages during inflammatory disease states is discussed in Chapter 37. Here, the role of macrophages in regulating iron within phagosomes will be discussed. Natural resistance-associated macrophage protein-1 (Nramp1, also called SLC11A1) was originally identified in mice and was shown to control resistance to *M. bovis*, *Salmonella typhimurium*, and *Leishmania donovani*.[38] Later studies have shown that Nramp1 codes for a 12 transmembrane domain integral membrane phosphoglycoprotein that is expressed by macrophages and neutrophils. Nramp-1 is constitutively expressed, is interferon-γ-inducible, and is rapidly recruited to the phagosome membrane through fusion with Nramp1-containing vesicles.[7] Nramp1 appears to function by pumping protons and divalent metals out of the phagosome, thereby enhancing phagosome acidification and depleting iron and other divalent metals needed for bacterial growth. Mycobacteria prevent phagosome acidification in part by inhibiting delivery of Nramp1 to the phagosome.

Removal of Dead Cells and Damaged Tissue

Macrophages play a central role in removal of senescent RBCs (see Chapter 22), and in resolution of damaged tissue. Macrophages are essential to wound healing and are attracted to the site of injury by chemotatic signals generated by damaged cells. Lysophosphatidylcholine and other substances released by apoptotic and necrotic cells serve as chemotactic signals for macrophages. At sites of injury, macrophages phagocytize cellular debris and apoptotic cells, recruit inflammatory cells by releasing hematopoietic cytokines and chemokines, and recruit myelofibroblasts.[18] Macrophages also regulate neovascularization, and induce fibrosis.[18] Depletion of macrophages in a mouse model of myocardial injury has been shown to impair wound healing.[37]

Interaction with Tumor Cells

Many tumors are infiltrated with macrophages. The relationship between macrophages and tumor cells is complex.[22] M1-type macrophages can inhibit tumor growth through release of cytotoxic substances such as TNF-α, oxygen radicals, or nitric oxide. Alternatively, M2-type macrophages enhance tumor growth by promoting angiogenesis and tissue repair. Whether macrophages oppose or support tumor growth depends on the activation signals they receive.

DISTRIBUTION AND FATE

The circulating half-life of monocytes varies from 70 hours in humans to 18 hours in mice, to 20–23 hours in cattle. Once released into the blood, monocytes are distributed in a circulating pool, a marginal pool, and in some species, exist as pulmonary intravascular macrophages. In humans, the ratio of the circulating to marginated pool is 1:3.5. Rabbits have a large marginated pool and approximately 60% of mouse monocytes are marginated.[12] Because of this, stimuli such as infectious diseases may cause monocytosis due to redistribution of the marginated pool into the circulating pool. It is not known if a marginated pool of monocytes exists in other domestic animals; however, monocytosis has been observed after glucocorticoid administration to dogs suggesting that a marginated pool exists in this species.

Monocytes appear to leave the circulation in a random manner. In response to inflammation, monocytes accumulate at the lesion site. This is dependent on integrin and selectin adhesion molecule interaction with receptors expressed on endothelium and chemokines released at the site of inflammation.[30] Although macrophages at sites of inflammation have the capacity to divide, less than 5% of the resident macrophage population arise de novo. Free macrophages, found at sites of inflammation, have the capacity to migrate to other tissues and to reenter the circulation.

The exact lifespan of macrophages is unknown but it appears that tissue macrophages are long lived. In human bone marrow transplant recipients, autologous macrophage populations are replaced with donor-derived cells over approximately 100 days.[12] In contrast, studies in mice indicate that mouse macrophages may live for more than 1 year.[12] Unlike tissue macrophages, monocytes and macrophages responding to inflammatory stimuli appear to be short lived cells.

MONOCYTE DISORDERS

Monocytopenia

Cats, horses, and ruminants typically have less than 1,000 monocytes/μL and dogs typically have less than 1,500 monocytes/μL in the blood. Because of these relatively low numbers, little significance has been attached to monocytopenia. Due to the long lifespan of tissue macrophages and their capacity to replicate de novo, even prolonged suppression of monocytopoiesis is relatively inconsequential. Monocytopenia is observed in aplastic anemia associated with a variety of causes including estrogen toxicity, chemotherapy, and parvovirus infection (see Chapter 39). Because monocytes are produced in 3 days from bone marrow progenitor cells, whereas neutrophils require 6 days to develop, recovery from the monocytopenia occurs before recovery from a neutropenia. Therefore, monitoring the monocyte count may be useful in predicting recovery from bone marrow suppression.

Monocyte Dysfunction

Viral Infection

Several viruses infect monocytes and macrophages, and can alter cell function without altering cell numbers.

Many lentiviruses have a tropism for mononuclear phagocytes. Lesions produced are generally attributable to altered cytokine secretion and defective anti-inflammatory activities. Feline immunodeficiency virus infects monocytes and macrophages as well as CD4+ T cells.[20] Peritoneal macrophages from feline immunodeficiency virus-infected cats produced less IL-1, suggesting that they have altered function.

Infection of monocytes and macrophages has also been described with the sheep (Maedi-Visna virus), goat (caprine arthritis encephalitis virus), cattle (bovine immunodeficiency virus), and horse (equine infectious anemia) lentiviruses.[5,24,33] Although various cell types are susceptible to infection with the sheep lentivirus, only macrophages are permissive for viral replication.[5] Infection by the goat lentivirus alters expression of cytokines by infected macrophages.[17] Blood monocytes are susceptible to infection with equine infectious anemia virus (see Chapters 19, 32, and 35). Little effect on monocyte function has been observed in experimental infections of cattle with bovine immunodeficiency virus, but this may reflect the low levels of infection achieved.[33]

Several other viruses infect macrophages, including many herpesviruses. This infection results in recurrent inflammatory lesions that may result from aberrant inflammatory cytokine production. Infection of cat macrophages with feline leukemia virus subgroup C results in increased production of TNF-α that has been shown to suppress erythropoiesis in vitro.[16] Therefore macrophage infection may contribute to the erythroid hypoplasia/aplasia associated with feline leukemia virus infection (see Chapter 38).

Anti-Inflammatory Response

Monocytes and lymphocytes in many humans and dogs with septic and non-septic inflammatory diseases have decreased function, as determined by detecting decreased MHC class II expression, suggesting impaired immune responsiveness.[45] When stimulated with various agonists, these monocytes tend to produce predominately anti-inflammatory cytokines. This state is thought to represent a compensatory anti-inflammatory response. The purpose of this anti-inflammatory response is to prevent an uncontrolled systemic inflammatory response that could lead to respiratory distress syndrome and multiple organ dysfunction.

Monocytosis

Monocytosis can result from a reactive (i.e. benign) condition or a malignant condition. Malignant proliferations of monocytic cells, including acute and chronic monocytic leukemia and acute myelomonocytic leukemia, are discussed in Chapters 65 and 67. Reactive monocytosis generally results in a modest increase in monocyte numbers with monocyte counts rarely exceeding 10,000/μL. In dogs, the most frequent cause of monocytosis is excess endogenous or exogenous corticosteroids.[47] Alternatively, monocytopenia occurs in humans and laboratory animals in response to corticosteroids; cats, horses, and cow monocytes have a variable responses to corticosteroids.[19] Other causes of reactive monocytosis include infections and necrosis. Infectious causes include acute and chronic bacterial infections, rickettsial infections, fungal infections, and protozoal infections. Monocytosis is not seen as consistently as is neutrophilia in infectious diseases. Monocytosis has been documented in dogs with bacterial endocarditis, chronic mycobacteriosis, and ehrlichiosis.[8,47] Necrotic disorders associated with monocytosis include hemorrhage, hemolysis, malignant neoplasia, infarction, and trauma. In necrotic conditions, monocytes/macrophages are needed to phagocytize necrotic debris and initiate wound healing. Morphologic alterations may be seen in blood monocytes in reactive monocytosis. Typically, reactive monocytes have highly vacuolated cytoplasms (Fig. 45.3)

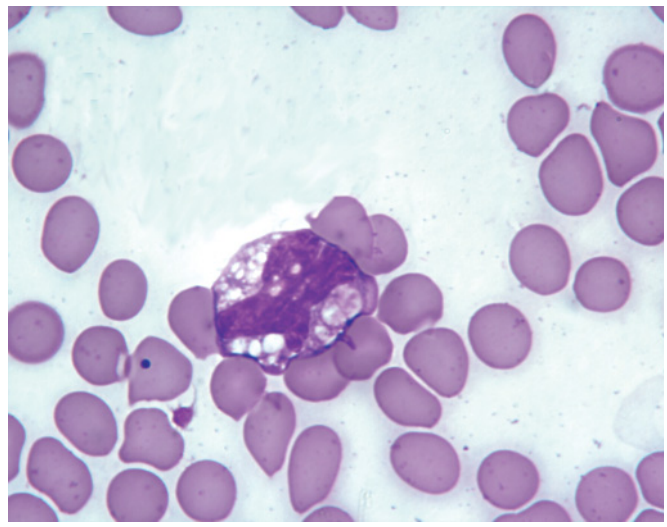

FIGURE 45.3 Reactive monocyte from a dog with bacteremia. Monocytes comprised 22% of the differential WBC count. The cytoplasm of all monocytes was highly vacuolated and the nuclei were convoluted. Wright's stain. (Courtesy of Dorothy Bienzle, University of Guelph.)

MACROPHAGE DISORDERS

Classification of macrophage disorders is problematic. Benign macrophage proliferation can result from macrophage activation syndrome (i.e. hemophagocytic syndrome), lipid storage disorders, or occur secondary to several chronic infectious diseases. An idiopathic systemic granulomatous disease has also been described in horses and cattle.[2,32] Malignant processes are difficult to differentiate from reactive processes and include histiocytoma, and localized and systemic histiocytic sarcoma (see Chapter 73).[11] Other histiocytic conditions, including cutaneous/systemic histiocytosis, and hemophagocytic histiocytosis are more difficult to categorize as to whether they are malignant or benign conditions (see Chapter 73).

Hemophagocytic Syndrome

Hemophagocytic syndrome is a benign proliferative disorder of activated macrophages that is associated with multiple cytopenias in the blood.[39,41] The pathogenesis of hemophagocytic syndrome remains elusive. Cytopenias associated with hemophagocytic syndrome are thought to result from phagocytosis of hemic cells because bone marrow is usually hypercellular. Among human patients, hemophagocytic syndrome is divided into two subcategories: primary hemophagocytic lymphohistiocytosis and macrophage activation syndrome.[14] Primary hemophagocytic lymphohistiocytosis is a group of autosomal recessive immune disorders in which approximately one-third of patients have a mutation in the gene encoding perforin,[14] a protein that mediates the cytotoxic activity of natural killer cells and cytotoxic T cells. This suppresses natural killer activity and results in lack of control of cellular immune responses. Over secretion of Th1-type cytokines may cause activation and proliferation of macrophages. Resultant secretion of proinflammatory cytokines, including TNF-α, IL-1, and IL-6, further amplifies the inflammatory process. Although natural killer and cytotoxic T cells have been incriminated in macrophage activation syndrome as well, the mechanism is poorly understood.[14]

Hemophagocytic syndrome has been documented in dogs and cats.[41] In a retrospective study, 3.9% of canine clinical bone marrow specimens, evaluated at a veterinary teaching hospital, had evidence of hemophagocytic syndrome.[41] Alternatively, hemophagocytic syndrome appears to be a relatively rare condition in cats. Clinical signs associated with canine hemophagocytic syndrome include fever, icterus, splenomegaly, hepatomegaly, and diarrhea. In dogs, hemophagocytic syndrome is associated with immune-mediated, infectious, and neoplastic/myelodysplastic conditions, and also occurs as an idiopathic condition. Overall, dogs with infection-associated hemophagocytic syndrome appear to have a better survival rate than dogs with immune-associated and idiopathic hemophagocytic syndrome.

Hemophagocytic syndrome is difficult to diagnose both clinically and cytologically. Because the condition frequently occurs secondary to other diseases and clinical signs resemble those associated with bacterial sepsis and the systemic inflammatory response syndrome, the condition may be underdiagnosed.[39,41] Further, cytopenias may be attributed to excessive demand for neutrophils in tissues or consumption of platelets due to disseminated intravascular coagulopathy. Therefore, it is important to determine which cases need bone marrow evaluation for detection of hemophagocytic syndrome. In human medicine, serum ferritin concentration has been used as a screening test for detection of hemophagocytic syndrome and malignant histiocytosis. Serum ferritin has been evaluated as a diagnostic test in dogs.[10] Moderate hyperferritinemia was observed in hemolymphatic neoplasia, and hepatic disease. Marked hyperferritinemia was observed in malignant histiocytosis and in immune-mediated hemolytic disease. Therefore, serum ferritin concentration appears to be very high in several pathologic conditions in dogs.

Pathologic conditions that can be confused with hemophagocytic syndrome include malignant histiocytosis, necrosis, granulomatous inflammation, and monocytic and myelomonocytic leukemias.[6,40,43] Malignant histiocytosis (also termed disseminated histiocytic sarcoma) is a malignant proliferation of myeloid dendritic cells.[6] Features of malignant histiocytosis that are useful in differentiating it from hemophagocytic syndrome include highly anaplastic features, large cell size, multinucleate giant cells, and greater than 3% histiocytic cells in cellular bone marrow aspirates. Additional tests to differentiate hemophagocytic macrophages from malignant dendritic cells include evaluation of flow cytometric scatter plots and immunophenotyping.[41]

Chronic Infectious Disease

Several chronic systemic infectious diseases result in proliferation of inflammatory macrophages with or without multinucleate giant cells or epithelioid cells in tissues. In some cases activated macrophages and epithelioid cells can be mistaken for a malignant process. Conditions frequently associated with macrophage proliferations include mycobacterial infections, deep fungal infections (e.g. *Blastomyces*, *Histoplasma*), and other systemic fungal infections.

Idiopathic Systemic Granulomatous Inflammation in Horses and Cattle

Idiopathic systemic granulomatous inflammation is characterized by perivascular infiltrates of macrophages, lymphocytes, plasma cells, and giant cells in multiple organs.[2,32] Typically nodules are spread throughout the body. Bacterial, viral and fungal causes have been ruled out and an immune-mediated cause is suspected.

Lysosomal Storage Disorders

A variety of inherited lysosomal storage disorders have been described in animals. These disorders are classified into broad groups based on the type of macromolecule that accumulates within lysosomes.[25] Although progressive neurological disease is the major clinical disease in most of these disorders, hematologic alterations may be encountered associated with splenomegaly, cytopenias, and the accumulation of swollen foamy macrophages in various tissues. Hereditary disorders include GM1 and GM2 gangliosidosis, glucocerebrosidosis (Gaucher disease), sphingomylinosis (Neimann-Pick disease), galactosialidosis, galactocerebrosidosis (globoid cell leukodystrophy, Krabbe disease), α- and β-mannosidosis, and α-L-fucosidosis.

In addition to the inherited lysosomal storage disorders, several acquired lysosomal storage disorders have

been described. Swainsonine is a toxic agent in several species of plants. This indolizidine alkaloid is a potent inhibitor of lysosomal α-mannosidase. Therefore, prolonged ingestion of these plants by ruminants results in a disease process very similar the hereditary form of α-mannosidosis. Similarly, ingestion of *Trachyandra divaricata*, *Phalaris* sp. or *Solanum* has been associated with lysosomal storage disorders.

Basophilia and Basopenia
Lymphocytosis and Lymphopenia
Monocytosis and Monocytopenia
Camelid Leukocyte Responses

Acronyms and Abbreviations

BLAD, bovine leukocyte adhesion deficiency; BLV, bovine leukemia virus; BVDV, bovine viral diarrhea virus; JLIDS, juvenile llama immunodeficiency syndrome; N:L, neutrophil to lymphocyte ratio; WBC, white blood cell.

Interpretation of ruminant white blood cell (WBC) responses, like that of other species, can be an essential component of diagnosis, monitoring, and prognosis of disease, though a single leukogram is rarely diagnostic for a specific condition. In some respects ruminant WBC responses are similar to those in other species, but they also have some distinct features.

Cattle normally have the lowest neutrophil to lymphocyte ratio (N:L)of the domestic species with a ratio of about 0.5 in adult cattle.[94] Sheep have a similar N:L to cattle. Adult goats 3 years of age and older have an N:L of approximately 1.0, though younger goats may have an N:L like that of cattle and sheep.[35] These ratios frequently change in a number of physiologic and pathologic conditions.

Ruminants mobilize bone marrow stem cell reserves more slowly than, for example, dogs though production time for neutrophils is approximately 1 week in both calves and dogs.[101] This contributes to the unique ruminant early leukogram response to acute inflammation. Cattle, sheep, and goats also typically have a lower peak level of leukocytosis in the face of acute inflammation than do other domestic animals.[101] For cattle, a WBC count of 20,000–30,000/μL is considered extreme leukocytosis.[40] Inflammatory conditions in goats can result in a leukocytosis of 22,000–27,000/μL.[40]

CHANGES IN LEUKOCYTE MORPHOLOGY

Morphologic changes in neutrophils may occur when cells develop in the bone marrow in the face of acute, severe inflammation. These changes, characterized as toxic, include increased cytoplasmic basophilia from retained ribosomes, azurophilic ("toxic") granules that are retained primary granules, and cytoplasmic vacuolation (Figs. 46.1 and 46.2).[41] Döhle bodies, which are retained rough endoplasmic reticulum, appear as distinct bluish cytoplasmic structures in some toxic neutrophils.

Pseudo Pelger-Huët anomaly is another morphologic change that can occur transiently in ruminants with inflammatory disease. This is an infrequent consequence of impaired granulopoiesis in which granulocyte nuclei do not segment normally. This results in band-shaped to round nuclei that have mature-appearing chromatin.[70]

Large, abnormal-appearing granules appear in neutrophils, eosinophils, and basophils of cattle with Chediak-Higashi syndrome (see Chapter 42). The number of abnormal granules appears variable from one animal to the next on Wright-Giemsa-stained blood smears.[8] However, staining with Sudan black B or peroxidase shows more uniform granule abnormalities in

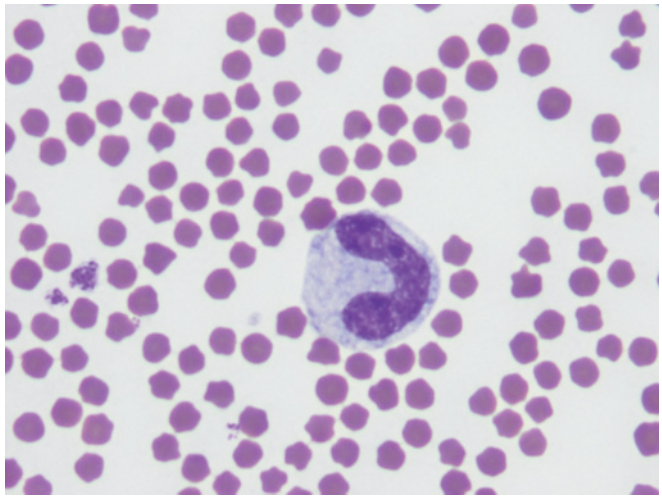

FIGURE 46.1 Toxic band, caprine blood. Wright-Giemsa stain.

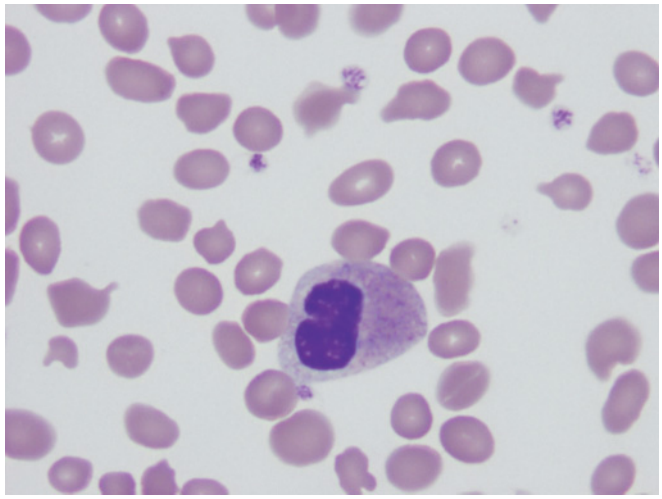

FIGURE 46.2 Toxic metamyelocyte, calf blood. Wright-Giemsa stain.

affected animals.[68] The abnormal granules are defective lysosomal granules that have decreased function.[72] This inherited disorder has been reported in Japanese Black, Brangus, and Hereford cattle.

PHYSIOLOGIC EFFECTS ON THE LEUKOGRAM

Age-Related Leukogram Changes

Some studies report that neonatal calves have total leukocyte counts that are higher than adult reference intervals, but others report mean WBC counts in neonates are within adult reference intervals.[20,50,65,97] The difference may reflect marked variability between individual calves. Calves have a N:L ratio greater than 1.0 at birth, with a rapid decrease in neutrophils and more modest increase in lymphocytes resulting in an N:L ratio similar to that of adults by a week of age.[40,41,96] This rapid shift may be related to the stress of birth and release of cortisol, as it is not seen in calves delivered by cesarean section.[40] A gradual decrease in lymphocyte numbers is then seen as cattle age.[65,104] Eosinophil percentages are relatively low at birth, show increases by 3 weeks of age and reach adult levels by 2 years of age.[20,105]

Age-related changes in lambs are reported to be similar to those in calves, with a rapid decline in neutrophil numbers and an increase in lymphocyte numbers reversing the N:L of greater than 1.0 that is present at the time of birth.[98]

Young goats experience an increase in total WBC numbers from birth to a peak at 3 months that reflects both significant increase in lymphocyte numbers and a smaller increase in neutrophil numbers that peak at 1 month of age.[35] The N:L ratio which is greater than 1.0 at the time of birth, reaches a nadir of 0.3 in 3 month-old kids, but then increases back to about 1.0 in adults.[88] Some studies show a gradual increase in eosinophil counts from young kids to adult goats.[87]

Stress and Excitement-Related Leukogram Changes

A stress leukogram is frequently present in ruminants that are exposed to endogenous or exogenous glucocorticoids. Leukogram changes include a mild mature neutrophilia, lymphopenia, eosinopenia, and variable monocytosis.[3,52] In cattle, the N:L ratio is frequently reversed to greater than 1.0. Several studies have shown that certain subpopulations of circulating lymphocytes are disproportionately reduced in experimentally induced stress. The percentage of γδ T cells have been shown to decrease in cattle given immunosuppressive doses of dexamethasone with more variable effects on B cells and other T cell populations.[3,64] Decreased proliferative capability of lymphocytes is observed in cattle treated with dexamethasone.[3,64] The mechanisms for corticosteroid-induced neutrophilia are postulated to include increased release of neutrophils from the marginated pool, accelerated movement of neutrophils from the bone marrow to the blood, and decreased diapedesis of neutrophils from the blood to tissues.[40] Studies of the effects of dexamethasone on expression of neutrophil adhesion molecules and other proteins have begun to clarify these mechanisms.[7] For example, shedding of neutrophil surface L-selectin and CD18 adhesion receptors occurs in response to injection of dexamethasone.[71] However, there may be differences in naturally-induced stress and dexamethasone-induced effects on neutrophils.[55] Transportation stress in goats and cattle has been shown to result in neutrophilia, lymphopenia and a marked increase in the N:L ratio like that seen in dexamethasone-induced stress. The changes have been reported as transient, but persisting for up to 24 hours following transport.[43,57]

Physiologic leukocytosis is a transient increase in neutrophils and lymphocytes caused by epinephrine released in the face of excitement or fear. The neutrophils are mature and the changes are present for a short period of time on the order of 30 minutes following the stimulus.[40]

Parturition

In the periparturient period, cows typically have a stress leukogram characterized by a neutrophilia, lymphopenia, eosinopenia, and monocytosis. Several studies have shown shifts in proportions of different lymphocyte populations at the time of parturition. These changes may be partly related to nutritional status and other health parameters, but pregnancy and lactation appear to have the primary effect.[63,102] Decreased in vitro function of neutrophils and lymphocytes from periparturient cows contribute to an immune-suppressed state that predisposes cows to infectious diseases at this time (see Chapter 42).[46] These functional deficiencies reach a nadir during the first week post-partum.

Sheep and goats also experience leukocytosis associated with marked mature neutrophilia, lymphopenia, and mild eosinopenia at the time of parturition.[4,62] In sheep, these changes resolve to pre-partum levels by the 14th day post-partum.[4]

PATHOLOGIC EFFECTS ON THE LEUKOGRAM

Inflammation

The early leukogram changes in acute inflammation are probably the most distinctive feature of ruminant WBC responses. In the first 24–48 hours of acute, severe inflammation, a marked neutropenia occurs due to recruitment of neutrophils from the blood to the site of inflammation and slower mobilization of the marrow stem cell pool compared to other species.[58,101] The effect of stress-induced corticosteroids may also contribute to an overall leukopenia with a decrease in lymphocyte numbers. The relatively larger decrease in neutrophil numbers compared to lymphocytes, results in a lowered N:L ratio. At about 24 hours following the onset of the inflammatory insult, immature neutrophils including bands, metamyelocytes, and sometimes myelocytes begin to appear in the blood and may show signs of toxicity (Fig. 46.3). This left shift in the face of neutropenia, suggests a poor prognosis in most species. However, ruminants can rebound with an increase in neutrophil numbers in about 3–5 days. This increase includes both immature and mature neutrophils at this time, and eventually, bone marrow production of mature neutrophils is increased enough to result in a mature neutrophilia in the peripheral blood. Neutropenia with a left shift that persists beyond several days indicates failure of the bone marrow to respond normally.[40]

Inflammation that becomes chronic may be associated with neutrophilia or normal neutrophil numbers. The lack of a predictable neutrophilia in chronic inflammation and in acute inflammation that is less severe, makes plasma hyperfibrinogenemia a better indicator of these conditions in ruminants. Cattle and sheep may have increases in plasma fibrinogen of up to 1.5 g/dL or higher, while the response is less in goats.[40] Monocytosis may be seen in either acute or chronic inflammation in ruminants, but it is not a consistent change.

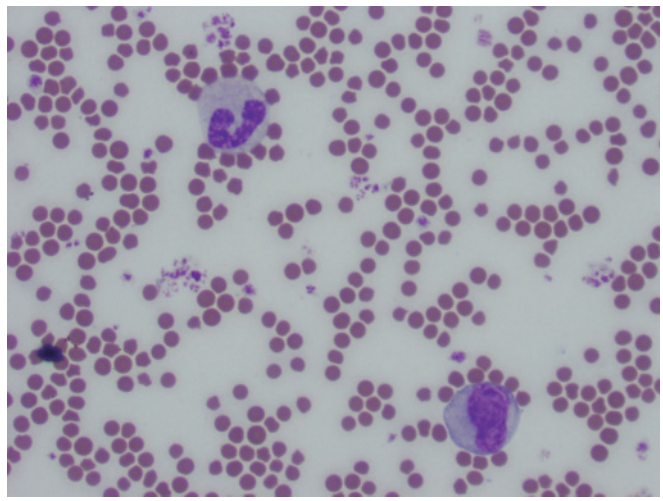

FIGURE 46.3 Left shift, caprine blood, band and metamyelocyte. Wright-Giemsa stain.

Leukocyte Organisms

Anaplasma phagocytophilum is an obligate intracellular bacterium formerly known as *Ehrlichia phagocytophila*.[106,108] It infects neutrophils, eosinophils, and monocytes of cattle, sheep, and goats as well as other mammals.[92] The organism appears as small dark-blue to purple cocci in the cytoplasm of infected WBCs in blood smears. Microcolonies form morulae that may also be seen in the cytoplasm of WBCs.[76] Organisms are carried by ticks. Clinical signs of infection may include transient fever, lameness, abortion, and reduced milk yield in dairy cattle. Infection may also cause immune suppression by avoiding killing by neutrophils and decreasing neutrophil and lymphocyte function; thus secondary infections may be seen. At peak bacteremia, more than 50% of the host's granulocytes may be infected.[107] Sheep infected with *A. phagocytophilum* are frequently severely leukopenic, due to both neutropenia and prolonged lymphopenia. Lymphocyte subsets are differentially affected, with early reductions in CD4+ T cells and γδ T cells and a relative increase in CD8+ T cells.[104,105] The organism has multiple effects on neutrophil function, including inhibition of phagosome-lysosome fusion, suppression of the respiratory burst and delay of neutrophil apoptosis, which effectively allows the organism to finish replication in a cell which normally has a short lifespan.[107]

NEUTROPHILIA AND NEUTROPENIA

Neutrophilia in ruminants is frequent in mild or moderate inflammation and following the acute stage of more severe inflammation as the bone marrow increases neutrophil production. In chronic inflammation, either a neutrophilia or normal neutrophil count may be

observed.[19,74] Neutrophilia associated with inflammation may or may not include a left shift, toxic changes, and hyperfibrinogenemia. Inflammatory neutrophilia has been reported in bacterial, viral, fungal, protozoal, and parasitic infections of cattle, goats, and sheep.[1,6,60,82,84,93,96] Sites of infection in these reports include mammary gland, liver, central nervous system, heart, gastrointestinal tract, respiratory tract and urinary tract[5,19,30,54,74,96]

Neutrophilia is also variably reported in cases of neoplasia,[49] abomasal displacement,[79] toxicosis,[15] immune-mediated anemia,[51] acute respiratory distress syndrome associated with hypersensitivity,[99] and in cattle treated with somatotropin.[22]

Bovine leukocyte adhesion deficiency (BLAD) is an inherited disorder of cattle that results from defective expression of β2 integrins on leukocytes (see Chapter 42).[67] The defective adhesion molecules result in a primary immunodeficiency characterized by decreased neutrophil function. Affected cattle have multiple recurrent or chronic infections as well as delayed wound healing. The condition is associated with a persistent moderate to marked neutrophilia with no evidence of morphologic abnormalities in neutrophils.[47,67] A left shift or toxic changes in neutrophils might be seen due to secondary infections.

Physiologic causes of neutrophilia are frequent: the effects of stress and excitement were described in a previous section.

Neutropenia is frequently seen in ruminants with peracute and acute severe inflammatory diseases including Gram-negative sepsis,[81] mastitis, peritonitis, metritis, pneumonia, and gastrointestinal disease. The neutropenia usually begins to resolve after 48 hours as bone marrow releases immature and eventually mature neutrophils. Neutropenia that continues beyond 3–4 days indicates that granulopoiesis is suppressed or is inadequate to meet the demand for neutrophils.[40]

Several viral infections of ruminants cause neutropenia. These include bovine viral diarrhea virus (BVDV), border disease virus, and bluetongue virus.[36,48,59,89] The neutropenia is transient in most viral infections. The mechanism of neutropenia in high virulence and low virulence isolates of a noncytopathic type 2 BVDV was studied. While both induced neutropenia, the high virulence isolate caused a more prolonged neutropenia with evidence of delayed myelopoiesis. In vitro studies showed that the high virulence isolate significantly decreased the proliferative capacity of bone marrow progenitor cells.[48] Additional mechanisms of neutropenia may include direct infection of progenitor cells as well as loss of neutrophils into inflamed organs.[89]

Organisms in the Anaplasmataceae family include *Anaplasma phagocytophilum* and *Ehrlichia* (formerly *Cowdria*) *ruminantium*, the agent of heartwater disease of ruminants. Neutropenia is a consistent feature of acute infection with these agents, as it is with other ehrlichiae.[38,56,76] Although neutrophils are one of the target cells for *A. phagocytophilum*, this is not the case for *Ehrlichia ruminatium*, which infects endothelial cells.

Neutropenia also has been reported in cases of theileriosis,[69] experimental mycoplasmosis,[77] *Psoroptes ovis* infestation,[91] and trypanosomiasis.[1] In experimentally-induced trypanosomiasis in calves, neutropenia was severe for 14 weeks following infection. This was associated with a reduction in myeloid precursers in bone marrow.[100]

Bone marrow necrosis, fibrosis, or suppression will lead to neutropenia in association with other cytopenias. These have been reported in association with toxins such as bracken fern,[73] dioxin,[25] furazolidine,[83] hydroxyurea,[86] and the tropical plant *Ipomoea carnae*[95] and may also be idiopathic.[2,104]

EOSINOPHILIA AND EOSINOPENIA

Eosinophils are crucial cells in host response to parasitic infections and in allergic reactions. Eosinophilia has been reported in a variety of endoparasitic infections in goats,[30,33,53,80,109] cattle,[14] and sheep.[80] Eosinophilia is not always present in parasitic infections even when there is an eosinophil response in tissues.[44] Ectoparasites can elict an eosinophilia as well,[39] though one study showed that cattle experimentally infested with ticks did not have increased peripheral eosinophil numbers when compared to controls.[10]

Eosinopenia may be a component of a stress response in ruminants. Extreme eosinopenia has also been reported in *Theileria parva* and *Theileria annulata* infections in cattle.[62,69] Toxins and other causes of bone marrow necrosis, fibrosis, or suppression may result in pancytopenia that includes eosinopenia.

BASOPHILIA AND BASOPENIA

In general, basophils react similarly to eosinophils, that is, they tend to increase in response to parasitic infections and hypersensitivity; however, significant differences in the basophil count are not frequently reported in ruminants. Basophilia has been reported in cattle with tick infestations[10,107] and in goats experimentally infected with nematodes.[75] Cattle infected with flukes showed no increase in basophil numbers[14] and sheep appear to be less likely to display basophilia than some other species.[78] Basophil numbers are normally so low in the circulation that basopenia is infrequently reported.

LYMPHOCYTOSIS AND LYMPHOPENIA

In general, lymphocytosis is not common in ruminants, though it may occur in chronic viral infections, chronic trypanosomiasis, and in other causes of chronic inflammation as well as epinephrine release and lymphocytic leukemia.

The bovine leukemia virus (BLV) causes a persistent lymphocytosis in approximately one-third of infected cattle (see Chapter 62).[29,42] Approximately 3–4% of infected cattle eventually develop leukemia. In contrast, sheep experimentally infected with BLV do not develop

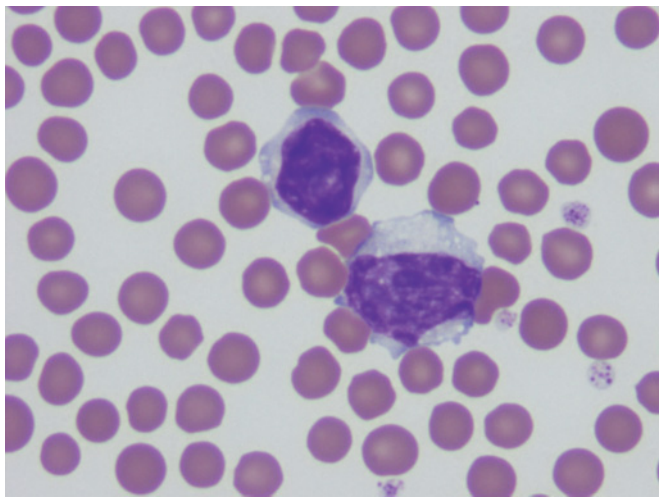

FIGURE 46.4 Circulating lymphoblast, bovine leukemia virus-positive cow. Wright-Giemsa stain.

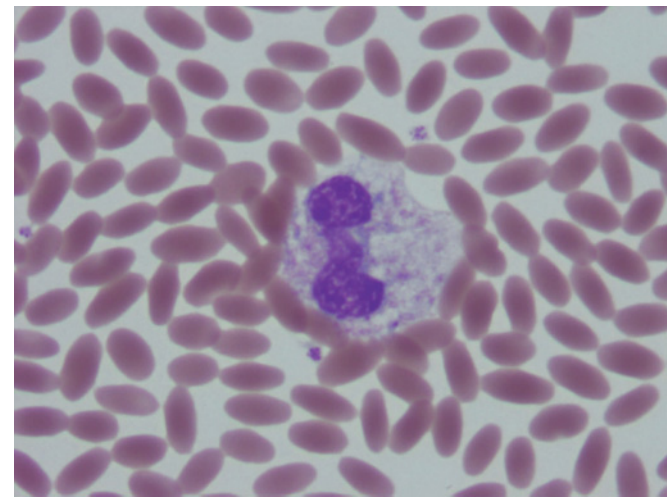

FIGURE 46.5 Toxic band, llama blood. Wright-Giemsa stain.

persistent lymphocytosis and nearly 100% develop leukemia (Fig. 46.4).[24] Other species have been infected with the virus, but none have been shown to develop a persistent lymphocytosis or leukemia. The lymphocytosis in BLV-infected cattle is characterized by the accumulation of a polyclonal population of B cells which predominantly express IgM and are CD5+ and CD11b+.[17,23,61] In cattle, lymphocytosis results from decreased B cell apoptosis.[17] In contrast to BLV infected cattle, leukemia in sheep develops from increased monoclonal B cell proliferation.[16,18]

The most frequent cause of lymphopenia in ruminants is the corticosteroid-induced stress response. Lymphopenia may also occur in the acute phase of viral, ehrlichial, mycoplasmal or other bacterial infection and septicemia.[11,45]

MONOCYTOSIS AND MONOCYTOPENIA

Monocytosis is sometimes seen as part of a stress response in ruminants, but not as frequently as in other species. It may also be noted in several inflammatory conditions.[105] Monocytopenia may be associated with endotoxemia and other peracute and acute inflammation.[40]

CAMELID LEUKOCYTE RESPONSES

The Camelidae, which include llamas, alpacas, guanacos, vicunas, and the Old World camels, are sometimes considered to be modified ruminants. Hematologically, they are different from the ruminants in several ways. Reference intervals for total WBC numbers and for eosinophils are higher for healthy adult camelids than they are for cattle, sheep, and goats.[26,103] The N:L ratio in camelids is reported to vary, with an average of about 1.5 which is more similar to horses than to cattle and sheep.[21,26,27,32,103] The differences in the reported ratios have been attributed to epinephrine release causing a transient increase in neutrophils at the time of capture and sampling. The typical features of a stress leukogram including mature neutrophilia and lymphopenia are seen in camelids, and epinephrine-induced or physiologic neutrophilia and lymphocytosis are also seen to varying degrees.[26,103]

Camelids with inflammatory conditions most frequently have a neutrophilia that may or may not be accompanied by a left shift and hyperfibrinogenemia.[34] Neutrophilia may be higher than that seen in ruminants. In experimental infection of alpacas with *Corynebacterium pseudotuberculosis*, total WBC counts reached as high as 30,000/μL, mainly due to increased numbers of neutrophils.[9] An initial neutropenia may be seen in acute inflammation, particularly in endotoxemic and septic camelids; this tends to rebound to a left shift and neutrophilia in 12–24 hours (Fig. 46.5).[28]

A left shift was a consistent leukogram finding in 10 cases of lymphosarcoma in llamas and alpacas.[12] A case of acute myeloid leukemia in an alpaca was characterized by a neutropenia with a left shift and toxic changes in the neutrophils.[90] Myelodysplasia in an alpaca was accompanied by a severe leukopenia that was primarily due to lymphopenia.[66]

In a series of cases of llamas with juvenile llama immunodeficiency syndrome (JLIDS), affected animals had leukograms that varied from severe, left-shifted neutropenia to mature neutrophila.[37,85] It was suggested that the variability reflected the degree of secondary inflammation and disease at the time of JLIDS diagnosis. Interestingly, lymphopenia is not a feature of the syndrome.[37]

Eosinophil numbers tend to be higher in normal camelids than in other domestic species. This has not been proven to be related to external or internal parasitism. Parasite infections may be associated with eosinophilia in camelids.[34] However, eosinopenia was actually a very frequent finding in a series of llamas and alpacas with the intestinal coccidian parasite *Eimeria*

macusaniensis.[13] In addition to eosinopenia, most of the camelids had neutrophilia, a frequent left shift, and monocytosis. It may be that animals with clinical signs associated with *Eimeria macusaniensis*, are stressed, and thus immune-compromised. Leukogram findings then represent both inflammation and stress. Leukocytosis due to lymphocytosis and monocytosis has been reported in trypanosomiasis in camels, with no accompanying eosinophilia.[31]

Benefit of serial leukograms

Acronyms and Abbreviations

CBC, complete blood count; EDTA, ethylenediaminetetraacetic acid; IgG, immunoglobulin G; IgM, immunoglobulin M; IL, interleukin; RNA, ribonucleic acid; WBC, white blood cell.

White blood cell (WBC) function, production, and kinetics in horses are similar to those described in other species. Equine neutrophils circulate for approximately 10.5 hours and are equally distributed in the circulating and marginated neutrophil pools.[7]

GENERAL CONSIDERATIONS IN EQUINE LEUKOGRAM INTERPRETATION

Samples for complete blood counts (CBC) in horses should be handled with similar care as in other species. The preferred sample is EDTA-anticoagulated whole blood. Heparin anticoagulation is sufficient, but morphologic features and staining of cells are altered.[41] Morphology of leukocytes is best if smears are made from EDTA-anticoagulated blood soon after collection. Refrigerated EDTA-anticoagulated blood samples maintain morphologic integrity fairly well for approximately 24 hours, but there are frequently clear cytoplasmic vacuoles, membrane irregularity, and ruptured neutrophils seen on blood smears.[17] If samples are processed after refrigeration of 48 hours or more, WBCs are typically severely smudged or unidentifiable on a stained blood smear. Analysis of equine blood by use of an Advia 120® hematology instrument found that artifactual leukocyte morphologic changes in blood stored for 24–48 hours included misclassification of granulocytes as mononuclear cells on the basophil channel. These changes were more pronounced in samples stored at 4°C compared with samples stored at 24°C.[10]

Neutrophil hypersegmentation (≥5 nuclear lobes) is an infrequent finding on equine blood smears, but can be seen in situations were there is delayed emigration of neutrophils from the vasculature into tissues (e.g. increased endogenous or exogenously administered corticosteroids). Neutrophil hyposegmentation is seen in band neutrophils in inflammatory conditions and in congenital Pelger-Huët anomaly, which has been reported in two Arabian horses (see Chapter 42).[14,16,21]

If the WBC count is increased, 14,000–20,000 leukocytes per/μL is considered moderate leukocytosis,

20,000–30,000 leukocytes/μL is considered marked leukocytosis, and >30,000 leukocytes/μL is considered extreme leukocytosis.[17]

Leukopenia is a significant finding and usually results from neutropenia because neutrophils are the predominant circulating WBC in healthy horses. Diseases that cause neutropenia are generally acute and severe. Neutropenia places the patient at increased risk for secondary bacterial infection.

Reference intervals determined by most laboratories are fairly wide because values from horses of different breeds, ages, and sexes are included.[24] Reference intervals for a specific breed of horse may have a much tighter interval. Differences between sexes are insignificant, but some age-related differences are important.

CELL MORPHOLOGY

The expected appearance of equine WBCs in Romanowsky-stained blood smears is described in Chapter 106.[22] Segmented neutrophils have nearly colorless cytoplasm with a jagged, ribbon-shaped nucleus (Fig. 47.1). Band neutrophils frequently are slightly larger and have nearly parallel nuclear margins. The cytoplasm is colorless to pale blue.

Toxic neutrophils are typically large. Toxic changes affect the neutrophil nucleus and cytoplasm. They are caused by accelerated production and maturation during bone marrow development under the influences of various inflammatory mediators, cytokines, and products from infectious agents.[15] Toxic changes of the cell and nucleus include overall cell swelling, nuclear swelling, reduced lobulation, and less condensation of chromatin. Toxic changes of the cytoplasm include increased basophilia (increased staining of RNA), vacuolization (from burst granules), Dohle bodies (lamellar stacks or whirls of rough endoplasmic reticulum that appear blue-gray), and toxic granulation (primary granules with increased permeability to stains that appear acidophilic to purple, Fig. 47.2).

Horses that have *Anaplasma phagocytophilum* (previous name *Ehrlichia equi*) infection may have neutrophils that contain morulae or mulberry-like inclusions in the cytoplasm (Fig. 47.3).[27] In contrast, inclusions have not been observed in WBCs from horses infected with *Ehrlichia risticii* (monocytic ehrlichiosis, Potomac horse fever, ehrlichial colitis).[44] Eosinophils are larger than neutrophils and have a lobulated nucleus with less condensed chromatin than neutrophils. Described as raspberry-like, eosinophils contain multiple, large, fairly uniformly sized, round, bright, red-orange granules (Fig. 47.4).

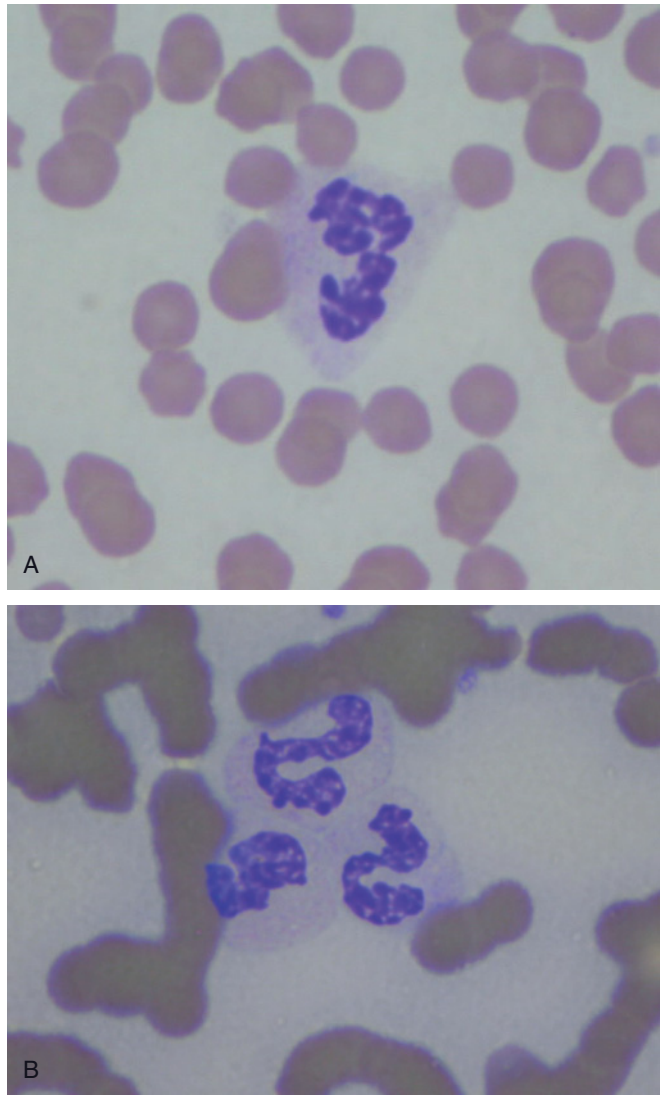

FIGURE 47.1 (**A**) Equine segmented neutrophil with distinct nuclear lobulation. (**B**) Three neutrophils that show typical jagged nuclear margins unlike the distinct nuclear lobulation in other species.

AGE, GENDER, AND EXERCISE RELATED LEUKOGRAM CHANGES

At birth, healthy foals have approximately 2.5 times more neutrophils than lymphocytes, variable numbers of monocytes, and an absence of eosinophils.[17] Absolute neutrophil counts frequently exceed the reference interval for adult horses for several months, whereas lymphocyte counts are slightly less than the reference interval for adults. By 3–4 months of age, these WBC values reach adult reference intervals. Eosinophils gradually increase in number over several months, probably in response to intestinal parasite exposure. Premature foals have significantly lower neutrophil counts than term foals for the first several hours of life.[9] Premature foals that survive may have nearly equal neutrophil and lymphocyte counts at birth, with the neutrophil proportion increasing rapidly within the first 18 hours of life. In contrast, the neutrophil-to-lymphocyte ratio does not increase significantly in

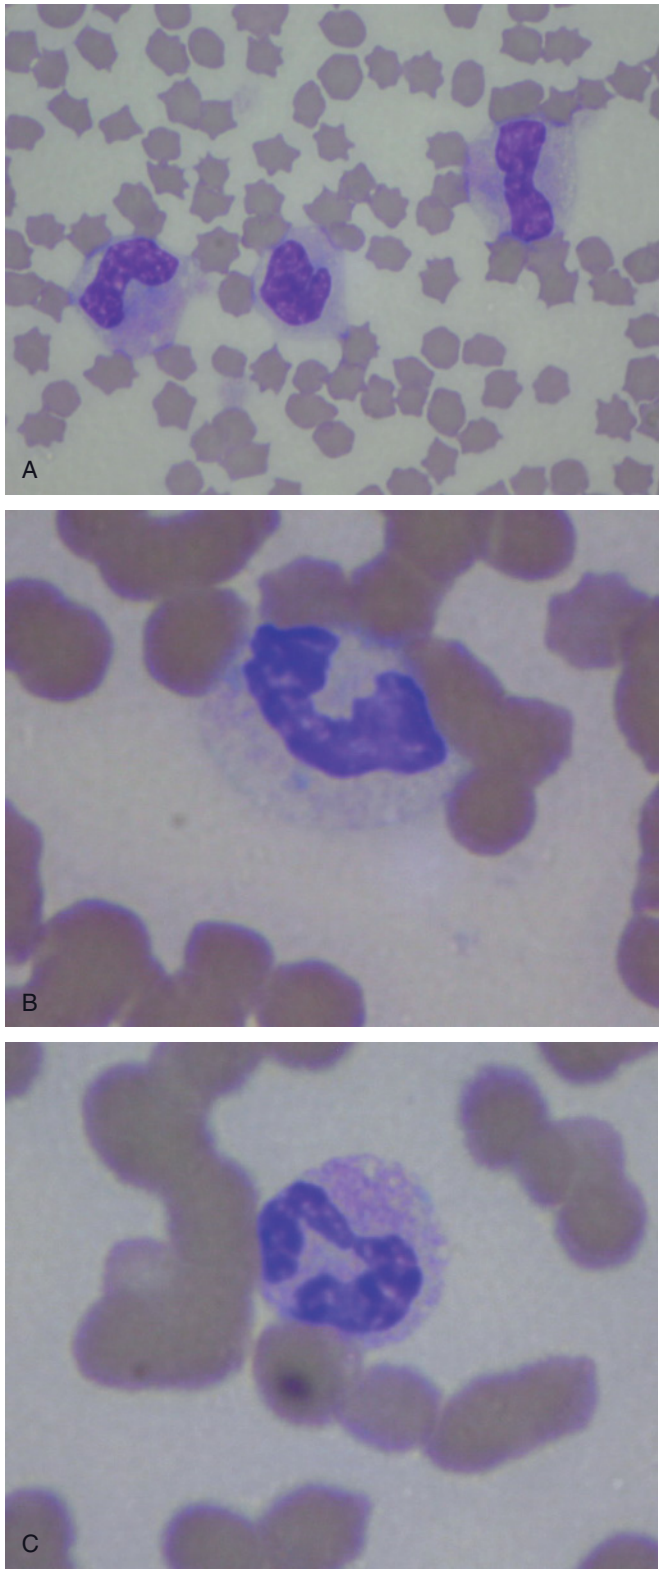

FIGURE 47.2 (**A**) Equine toxic neutrophils showing slightly swollen cells, swollen nuclei with hypolobulation, cytoplasmic basophilia, and cytoplasmic vacuolization. (**B**) Toxic band neutrophil showing cytoplasmic basophilia and a Dohle body. (**C**) Band neutrophil showing toxic granulation.

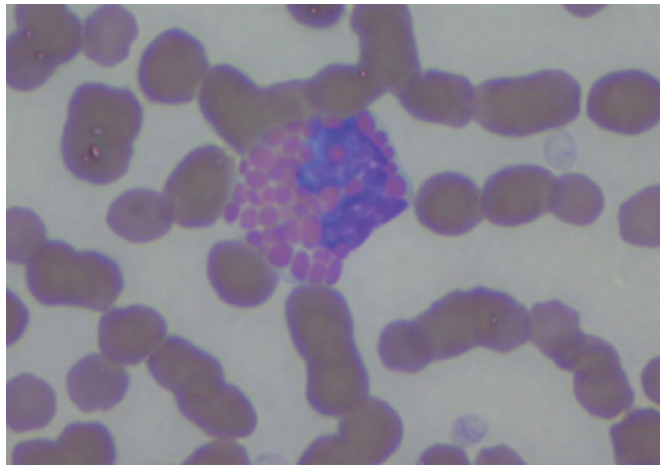

FIGURE 47.4 Equine eosinophil.

nonsurviving premature foals. However, these findings may not be evident before 35 hours after birth.

Total and differential WBC counts are similar in mares in the follicular and luteal phases of estrus.[36] Total WBC count is significantly decreased (but all values are within the typical reference intervals) in mares during pregnancy compared with postpartum samples owing to decreased T-helper and T-cytotoxic lymphocytes.[1]

Granulocytes increase in circulation after prolonged strenuous exercise (e.g. endurance races and 3 day event competitions).[2,37] Neutrophils are activated during intense exercise which results in degranulation.[2] Owing partially to increased levels of endogenous corticosteroids, neutrophil function is decreased for up to 3 days after prolonged strenuous activity (e.g. 80 km endurance race).[37]

LEUKOGRAM RESPONSE PATTERNS

Although WBC types are kinetically independent and respond differently to various stimuli, they collectively demonstrate certain distinct response patterns.

Leukograms Characterized by Leukocytosis

Physiologic Leukocytosis

Physiologic leukocytosis[39] is a transient (20–30 minutes) but moderate increase in total WBC count, frequently reaching 12,000–25,000 cells/μL. Typically, a modest mature neutrophilia exists in the absence of a left shift or toxic change. Lymphocytosis (6,000–14,000 lymphocytes/μL) is frequently observed and may be proportionately greater than the increase in neutrophils.[7] In frightening, painful, or exciting conditions, or after vigorous exercise activity, catecholamines increase cardiac output, hydrostatic blood pressure, and muscular activity. Neutrophils subsequently are swept from the marginated pool into the circulating pool, transiently increasing the numbers of cells enumerated by the WBC count. The causes of lymphocytosis are not as well documented; however, muscular activity may force cells in lymphatics into circulation and catecholamines may alter receptors on postcapillary venular endothelial cells and lymphocytes, blocking normal lymphocyte recirculating patterns.[7] Horses have a marginated pool of neutrophils at least as large as the circulating pool; therefore, total cell counts may double with excitement. Physiologic leukocytosis is observed frequently in horses because they are easily excited, especially young hot-blooded horses and most horses that are unaccustomed to being handled.

Stress and Corticosteroid Effects

Stress and corticosteroid leukograms are characterized by a moderate neutrophilia, usually no left shift, lymphopenia, eosinopenia, and variable monocyte counts.[7,8,33] This response is mediated by glucocorticoids of either endogenous or exogenous origin. Neutrophilia is caused predominately by early release of neutrophils from the bone marrow storage pool and to a lesser extent by decreased margination and emigration from the blood, causing neutrophils to circulate longer. Hypersegmented neutrophils may be observed on blood smears of some horses. Lymphopenia is caused by temporary sequestration of cells in lymphoid tissues. Lymphocytes and eosinophils generally are not killed at the concentrations of glucocorticoids obtained physiologically or achieved through most therapeutic uses of corticosteroids in horses. This response pattern may be seen in horses secondary to endogenous corticosteroid release in acute and severe diseases, with pituitary adenoma, or after administration of exogenous corticosteroids.

Inflammation/Infection-Associated Effects

Inflammatory changes in the leukogram have variable appearances depending on the severity and duration of the inciting agent, lesion, or condition.[38] A left shift is the hallmark of inflammation. Typically, these are band neutrophils, but less mature precursor cells also may be present. A significant left shift is present if there are greater than 300 bands/μL, and the total WBC is within or greater than the reference interval. In the presence of neutropenia, a significant left shift exists if bands comprise at least 10% of the neutrophil population. If a neutropenia exists or the total WBC is within the reference interval and the number of immature neutrophils exceeds the number of mature segmented neutrophils, a degenerative left shift exists. Immature neutrophils and neutrophils demonstrating toxic changes have decreased functional ability compared with mature neutrophils.[40] Therefore, toxic bands or metamyelocytes may have significantly decreased functional capabilities compared with mature segmented neutrophils.

Toxic changes are graded on a subjective scale from +1 to +4 in most laboratories; the greater the number, the more severe the toxic change. If the cause of the condition is eliminated, the toxic changes disappear within 12–24 hours. The decrease or disappearance of toxic changes in neutrophils and an increasing neutrophil count are favorable prognostic signs.[27]

Leukograms indicative of acute inflammation usually have a significant left shift with or without toxic changes in the neutrophils. Established or chronic inflammation may be difficult to recognize. Typically, leukocytosis is accompanied by mature neutrophilia because increased granulopoiesis over sufficient time (at least a week or more) has replenished the bone marrow storage pool such that only mature neutrophils are released into circulation and production has exceeded tissue usage. Additional information may be helpful for leukogram interpretation, including physical examination, history, previous leukogram data, and acute phase reactant levels. Serum acute phase reactant concentrations are useful mostly for assessment of inflammation, especially when the leukogram shows no or minimal indication of inflammation. Although rather insensitive, an increased concentration of fibrinogen or low (<10) plasma protein-to-fibrinogen ratio (which allows adjustments for alterations that are present because of dehydration and hemoconcentration) is indicative of inflammation. Another indicator of inflammation, that can be easily measured by automated instrumentation, is serum iron concentration. Hypoferremia is a more sensitive test than is increased fibrinogen concentration or low plasma protein-to-fibrinogen ratio.[4] There is only one report of true iron deficiency anemia in horses; therefore, hypoferremia can be used as an indicator of inflammation.[5]

Eosinophilia

Eosinophilia is uncommon in horses and may be subtle when present. It usually is related to parasite or allergen

exposure;[28] however, some horses that have heavy intestinal parasite burdens have normal to low eosinophil counts.[17] This may be related to the stress of disease inducing endogenous corticosteroid release. Horses may have significant tissue infiltration by eosinophils without a concurrent eosinophilia because of the short blood transit time and relatively long lifespan of eosinophils in tissues.[34] Cutaneous eosinophilic granulomas, either idiopathic or associated with parasite infection, may be accompanied by eosinophilia. Hypereosinophilic syndromes involving the gastrointestinal tract and pancreas or multiple organs have been reported intermittently in horses.[23] Cases of lymphoid leukemia or lymphosarcoma in horses have been reported with concurrent hypereosinophilic syndrome.[20] Such observations are similar to paraneoplastic syndromes in human patients in whom production of interleukin-5 (IL-5) by neoplastic T cells causes selective differentiation and activation of eosinophils.

Lymphocytosis

Lymphocytosis is a component of physiologic leukocytosis. Lymphocytosis may be observed infrequently after antigenic exposure and frequently accompanies lymphoid neoplasia.

Leukemias

Hematopoietic neoplasia that originates in the bone marrow is called leukemia (see Section V). Leukemias are rare in horses, but lymphocytic, granulocytic, monocytic, eosinophilic, and myelomonocytic leukemias have been reported.[3,6,27,30,31] Lymphocytic leukemia is the most frequent leukemia in horses, followed by myelomonocytic leukemia. Total and differential leukocyte counts of the affected cell lines can be below, within, or above reference intervals. Abnormal or immature cells (blast cells) are frequently observed in stained blood smears. A preponderance of these cells is apparent in Romanowsky-stained bone marrow smears and aspirates or biopsies of other tissues and organs. Lymphoid leukemia has been reported as a primary disorder;[2] however, a leukemic blood picture also may occur with malignant lymphoma.[26] Lymphocyte counts may be with in the reference interval, but abnormal cells may be observed on blood smears.[42] Chronic lymphocytic leukemia has been diagnosed in two aged horses: one was a T cell type and the other was a B cell type with a monoclonal gammopathy (IgG) and light chain proteinuria.[11]

Leukograms Characterized by Cytopenias

Lymphopenia

Lymphopenia is a predictable component of the stress-corticosteroid-associated leukogram pattern. In addition, lymphopenia may be observed with acute, severe inflammatory disorders and infections. In such conditions, endogenous corticosteroid release is one cause. Furthermore, antigen-induced sequestration and trapping of cells in lymphoid tissues and organs occurs in response to infectious agents. In horses, lymphopenia is rarely caused by loss of lymphocyte-rich lymph into the thorax. Chylothorax has been diagnosed rarely in horses, but it has not been associated with lymphopenia. Combined immunodeficiency in Arabian and Arabian-cross foals is characterized by severe lymphopenia (<1000/mL) and lack of IgM production (see Chapter 57).[25,35] A deficiency of both T and B cells exists. Hypoplasia of lymph nodes may be apparent in biopsy specimens. Alternatively, the presence of hypoplasia in other lymphoid tissues and organs can be documented more extensively during postmortem examination.

Monocytopenia, Eosinopenia, and Basopenia

Monocytopenia, if present, is not clinically significant. Eosinopenia may be part of a stress and corticosteroid leukogram. Basopenia is not clinically significant, if recognized at all.

Neutropenia

Neutropenia has significant clinical significance because it predisposes the patient to infection. Neutropenia can result from three major mechanisms. First, lack of or ineffective production of neutrophils may occur. Information from a group of eight related young Standardbred horses with significant neutropenia and intermittent thrombocytopenia has been reported.[19] Bone marrow cultures from these horses revealed myeloid precursor cells were present and capable of responding to growth factors. Therefore, the investigators concluded that the cytopenias were caused by a familial bone marrow microenvironmental defect or a growth factor defect. Seven of the eight horses either died or were euthanized. Defective neutrophil production also has been associated with crowding of the marrow space (i.e. myelophthesis) by neoplastic cells (e.g. malignant lymphoma).[32] Second, neutrophils can be rapidly redistributed from the circulation to the marginated pool after endotoxin exposure.[13] Endotoxin causes an up-regulation of cell adhesion molecules on both neutrophils and endothelial cells.[43] If endotoxin exposure is terminated, a rebound neutrophilia occurs within 24 hours. However, if exposure is continued, prolonged neutropenia is the result of increased peripheral usage of cells. Third, increased peripheral usage or reduced survival of neutrophils may occur. In this most common cause of neutropenia, tissue demand for neutrophils exceeds the bone marrow's capacity to supply them. The transit time from bone marrow release to migration into tissues is usually shortened. Horses have approximately a 5 day supply of mature neutrophils in the bone marrow storage compartment in health, but this reserve can be rapidly depleted by demands of acute, severe infectious disease. Continued neutropenia with a left shift and toxic changes over several days in

TABLE 47.1 Serial Inflammatory Leukogram Findings and Their Interpretation

Leukogram Finding	Favorable Prognostic Sign	Unfavorable Prognostic Sign
Neutropenia	Increase in absolute neutrophil count	Continued neutropenia Development of greater left shift Development of toxic changes
Degenerative left shift	Increase in segmented neutrophils Decrease or lack of band neutrophils	Continued degenerative left shift
Toxic changes	Resolution of toxic changes	Continued toxic changes
Concurrent lymphopenia	Increase in absolute lymphocyte count	Continued lymphopenia

the face of appropriate therapy suggests a poor to grave prognosis.

Leukograms observed in foals or adult horses that have suspected septicemia or endotoxemia can have a variable appearance and must be interpreted in conjunction with other information collected from the patient. A moderate to marked leukopenia with left shift and toxic changes are leukogram findings highly consistent with septicemia or endotoxemia and are observed in most cases.[18,29] At the time of admission to a hospital, foals with Gram-negative bacteremia are more likely to have lower total WBC and lymphocyte counts than foals with Gram-positive bacteremia. This may be helpful in the selection of antibiotics before obtaining bacterial culture results. Even with adequate passive transfer of immunoglobulin, most neonatal foals that have severe disease have leukopenia, neutropenia, and significant left shift with toxic changes in the neutrophils within 24 hours after hospital admission.[12]

Benefit of Serial Leukograms

Performance and interpretation of leukograms for two or more days are valuable in determination of the response to therapy, clinical prognosis, or confirmation of a diagnosis.[18,27] Favorable and unfavorable prognostic signs related to data derived from serial leukograms are presented in Table 47.1.

Acronyms and Abbreviations

ACTH, adrenocorticotropic hormone; EDTA, ethylenediaminetetraacetic acid; G-CSF, granulocyte colony-stimulating factor; WBC, white blood cell.

The total white blood cell (WBC) count in healthy dogs varies from 5,000 to 14,100 cells/μL of blood.[39] The neutrophil is the most commonly encountered leukocyte in the blood of healthy dogs. The half-life of circulating blood neutrophils is approximately 7.4 hours. Lymphocytes are less numerous than neutrophils. Monocytes and eosinophils are seen less frequently than neutrophils or lymphocytes, whereas basophils are seen rarely.

Total WBC counts are highest in puppies, and the counts gradually decrease throughout life. Both neutrophils and lymphocytes decrease in number with advancing age. Eosinophils also decrease in number but have minimal effect on the total leukocyte count. Monocytes tend to increase slightly with advancing age.[31]

Diurnal variation in the total leukocyte count and absolute numbers of neutrophils, lymphocytes, and eosinophils can be detected in conditioned dogs kept under controlled light, feeding, and activity. The total WBC and absolute neutrophil counts reach maximum values in the late afternoon (7 pm). Lymphocyte counts are highest in late evening (11 pm) and lowest in the early morning (7 am). Eosinophil counts reach a zenith in late evening (11 pm) with the nadir at midday (12 pm). Although statistically different, diurnal variation has minimal effect on cell counts. Therefore, these daily cellular fluctuations would be unlikely to cause

problems in interpretation of clinical data from patients in which comparison is made to standard reference intervals.[42]

CLASSICAL CANINE LEUKOGRAM PATTERNS

Physiologic Leukocytosis

Dogs that experience fear, excitement, or engage in brief periods of strenuous exercise may develop physiologic leukocytosis. This reaction is more common in puppies and is seldom seen in the adult dog. The leukogram is characterized by mild, mature neutrophilia and lymphocytosis. The monocyte and eosinophil counts may remain within the reference intervals or increase slightly. The magnitude of lymphocytosis may exceed that of the neutrophilia. Physiologic leukocytosis is transient, occurs within minutes of the stimulus, and usually resolves within 30 minutes. The mechanism of neutrophilia involves an epinephrine-mediated demargination of neutrophils from the marginal pool into the circulating pool, where they can be quantitated by the WBC count. Because the total number of neutrophils in the blood (sum of the marginal and circulating pools) does not change, this reaction is frequently termed pseudoneutrophilia. The lymphocytosis is believed to be caused by epinephrine-mediated blockade of lymphocytes entering lymphoid tissues or by mobilization of lymphocytes from the thoracic duct.[31,40]

Corticosteroid-Induced Leukocytosis

Endogenous release of glucocorticoids because of severe stress or hyperadrenocorticism (Cushing's syndrome), and due to administration of exogenous glucocorticoids or adrenocorticotropic hormone may cause corticosteroid-induced leukocytosis in the dog. Total WBC counts usually range from 15,000 to 25,000/μL of blood, but may occasionally reach 40,000/μL of blood. The leukogram is characterized by mature neutrophilia, lymphopenia, monocytosis, and eosinopenia. Rarely, a mild left shift can occur if the bone marrow storage pool is depleted at the time of stimulation by corticosteroids. The leukogram alterations occur within 4–8 hours after a single administration of glucocorticoids and usually resolve within 24 hours. Leukograms from dogs given long-term corticosteroid therapy (>10 days) may require 2–3 days to return to baseline values after treatment ceases. The neutrophilia usually resolves before resolution of the lymphopenia. The mature neutrophilia is the result of several factors, including: decreased emigration of neutrophils from blood into tissues, increased release of mature neutrophils from the bone marrow storage pool, and decreased margination of neutrophils. The lymphopenia is attributed to redistribution of circulating lymphocytes. Long-term use of corticosteroids may cause lympholysis. The monocytosis may be the result of mobilization of marginated cells within the blood vasculature. Eosinopenia occurs because of inhibition of eosinophil release from the bone marrow and sequestration of eosinophils within tissues.[31,40]

Inflammatory Leukocytosis

The leukogram is an excellent method by which to monitor inflammation in the dog. Infections caused by bacteria, rickettsia, viruses, fungi, or parasites cause alterations in the leukogram. Immune-mediated diseases, tissue necrosis, and neoplasia also elicit inflammatory reactions. Because neutrophils respond within hours to various chemotactic stimuli during inflammation, the time of phlebotomy relative to initial inflammatory stimulus is important in interpretation of the leukogram.

Peracute Inflammation

Sudden onset of an overwhelming infection or other inflammatory reaction can cause leukopenia characterized by neutropenia. Transient neutropenia can be detected within 1–3 hours after exposure to endotoxin. Overwhelming sepsis caused by infection of the lungs, thorax, uterus, or peritoneum by Gram-negative bacteria may cause similar responses. The neutropenia, which usually persists for 2–3 hours, is caused by endotoxin-mediated neutrophil margination within the vasculature, shortened neutrophil half-life, and increased cell emigration into tissues.[31,40]

Acute Inflammation

Within 6–8 hours after an initial inflammatory stimulus, the bone marrow compensates by accelerated release of neutrophils, which results in neutrophilia. The acute inflammatory leukogram in the dog is characterized by leukocytosis. Total WBC counts usually range from 20,000 to 30,000/μL of blood and are characterized by neutrophilia with a left shift (>450 bands, metamyelocytes, or myelocytes/μL of blood). The neutrophilia and left shift occur because the production and early release of neutrophils by the bone marrow exceed the tissue demand for neutrophils. The left shift is usually orderly in that number of bands > metamyelocytes > myelocytes. Toxic changes may be observed in neutrophils. Concurrent lymphopenia and eosinopenia are typical owing to release of endogenous corticosteroids. Monocytosis is an inconsistent observation but may be present, particularly if a stress response is superimposed on the inflammatory leukogram.[31,40]

Chronic Inflammation

Established inflammation of days to weeks duration can result in characteristic alterations in bone marrow, including expansion of the proliferative, maturation and, storage pools of neutrophils to meet tissue demand

TABLE 48.1 Causes of Leukemoid Reactions and Extreme Neutrophilia in Dogs

Infections/infectious agents	Chronic active peritonitis, *Hepatazoon canis* infection, internal abscesses, pyometra, salmon disease (lymphoid and monocytoid reaction)
Neoplasia	Metastatic fibrosarcoma, pulmonary adenocarcinoma, rectal adenomatous polyp, renal tubular carcinoma, renal tubular adenocarcinoma
Immune mediated	Immune-mediated hemolytic anemia
Other	Canine leukocyte adhesion deficiency (leukocyte glycoprotein CD11/CD18 deficiency), extreme eosinophilia from non-neoplastic causes (idiopathic hypereosinophilic syndrome)

for these cells. The leukogram is characterized by leukocytosis with neutrophilia; a left shift may be mild or absent. Alterations in the numbers of other leukocytes may be variable.

Leukemoid Reactions and Extreme Neutrophilia

The term leukemoid refers to a leukogram that resembles granulocytic leukemia in cell numbers and differential WBC counts but is caused by benign processes (Table 48.1). Typical leukemoid reactions are characterized by marked neutrophilic leukocytosis ranging from 50,000 to 100,000 cells/μL of blood with a concurrent, orderly left shift that may extend to myelocytes or promyelocytes. Toxic change in neutrophils may or may not be present. Rarely, leukemoid reactions involve significant lymphocytosis or eosinophilia.[1,33] Causes include chronic localized infections (e.g. pyometra, peritonitis), immune-mediated hemolytic anemia, CD11/CD18 neutrophil protein adhesion deficiency (canine granulocytopathy syndrome, canine leukocyte adhesion deficiency),[20] *Hepatozoon canis* infection, and paraneoplastic syndromes (e.g. renal tubular carcinoma,[35] metastatic fibrosarcoma,[9] metastatic pulmonary adenocarcinoma,[59] and rectal adenomatous polyp[58]). Terminology used by clinical pathologists for leukemoid reactions of extreme degree may vary. Leukograms characterized by neutrophilic leukocytosis (>100,000/μL of blood) with a left shift and no evidence of hemopoietic neoplasia are sometimes refered to as extreme neutrophilic leukocytoses. The term leukoerythroblastic response has been used to describe a typical leukemoid reaction that is accompanied by metarubricytosis.[46] Differentiation of benign leukemoid reactions from chronic myelogenous leukemia can be challenging and frequently requires serial complete blood counts and bone marrow examinations. The diagnosis of chronic myelogenous leukemia is made by exclusion of causes of inflammation, presence of a disorderly left shift, or observation of abnormal granulocyte morphology in blood or bone marrow smears.

NEUTROPHILIA AND NEUTROPENIA

Causes and Mechanisms of Neutrophilia

Canine neutrophils have 2–5 nuclear lobes that are separated by constrictions. The nuclear outline is slightly irregular, and the chromatin is tightly condensed. The cytoplasm is moderate in amount and is filled with a myriad of granules that appear faintly pink in Romanowsky-stained blood films. The number of neutrophils in the blood of dogs depends on several factors, including rate of release from bone marrow, shifting of neutrophils between marginal pool and circulating pools in the blood, and emigration rate of neutrophils from blood into tissues.[40]

Neutrophilia, defined as >12,000 neutrophils/μL of blood, is a frequent observation in canine blood films (Table 48.2).[40] The more frequent causes of neutrophilia in dogs include physiologic leukocytosis, corticosteroid-induced leukocytosis, and inflammation. Additional causes of neutrophilia in dogs include hemolysis, hemorrhage, genetic defects in leukocyte adhesion molecules, and immune-mediated diseases. Several benign and malignant neoplastic conditions cause paraneoplastic syndromes that can result in neutrophilia. Thrombosis, infarction, burns, and uremia also can cause neutrophilia.[31,40]

Inflammation is the most frequent cause of neutrophilia. The intensity of the underlying disease process has a direct effect on the magnitude of the total neutrophil response.[31] Localized purulent lesions, like abscesses, induce greater neutrophilia than do more generalized diseases, such as septicemia. Neutrophilia with a left shift is the hallmark of acute inflammatory reactions. The degree of the left shift is considered a direct indication of severity of disease.[31] Left shifts of great magnitude may occur in dogs that have pleuritis, peritonitis, pyoderma, or pyometra. Release of myelocytes and metamyeolcytes from bone marrow is related to the increased tissue demand in purulent inflammation. However, in some diseases, inflammation is too mild to induce a left shift. Left shifts may be mild or nonexistent in seborrheic dermatitits, catarrhal enteritis, or hemorrhagic cystitis, conditions in which tissue demand for neutrophils is minimal.[31]

Causes and Mechanisms of Neutropenia

Neutropenia, defined as >2,900 neutrophils/μL of blood, occurs less frequently than neutrophilia in dogs. Because neutrophils are the primary line of defense against microorgansims, neutropenia results in increased risk of infection. The more severe the degree of neutropenia, the greater the risk of infection. Three frequent mechanisms of neutropenia include decreased production of neutrophils in bone marrow, cellular shifting from the circulating to the marginal pool, and increased tissue emigration in excess of bone marrow release of neutrophils (Table 48.2).[40] Decreased production of neutrophils occurs from a variety of causes including dogs treated with total-body ionizing

TABLE 48.2 Causes of Neutrophilia and Neutropenia in Dogs

Neutrophilia	
Chemical and drug toxicity	Estrogen (acute phase only), recombinant granulocyte-CSF
Corticosteroid-induced leukocytosis	
Genetic adhesion molecule (CD11/CD18) deficiency	Canine leukocyte adhesion deficiency
Hemolysis	
Hemorrhage	
Immune-mediated diseases	Hemolytic anemia, systemic lupus erythematosus, polymyositis, polyserositis, rheumatoid arthritis, systemic necrotizing vasculitis
Infection	Bacteria (many species), viruses (canine distemper virus), fungi (many organisms), parasites (many species), rickettsia (Rocky Mountain spotted fever)
Inflammatory leukocytosis	Acute, chronic, or leukemoid responses
Leukemia	Several types, acute or chronic
Necrosis	Thrombosis, infarction, burns
Physiologic leukocytosis	
Tissue neoplasia/paraneoplastic syndromes	Several benign and malignant tumors
Toxemia	Endotoxemia, uremia
Neutropenia	
Decreased production of neutrophils in bone marrow	
Bone marrow necrosis	
Cyclic hematopoiesis	Gray collies (congenital), cyclophosphamide administration
Drug administration	
Predictable	Estrogen toxicity (late), chemotherapeutic agents
Idiosyncratic	Cephalosporins, phenylbutazone, thiacetarsamide, Noxema ingestion
Malabsorption of vitamin B_{12}	Giant Schnauzers (congenital)
Myelofibrosis and osteopetrosis	
Myeloproliferative and lymphoproliferative diseases	Several types of leukemia and lymphosarcoma
Radiation	
Cellular shifting from the circulating to the marginal pool	
Anaphylaxis	
Endotoxemia	
Increased tissue emigration in excess of bone marrow release	
Infection	Bacteria (many), rickettsia (ehrlichiosis), viruses (parvoviral enteritis, canine distemper virus), parasites (*Babesia canis*)
Immune-mediated disease	

irradiation, certain chemotherapeutic agents, and estrogen toxicosis (see Chapters 16–19, and 39). These conditions kill hemopoietic stem cells or progenitor cells or inhibit their replication. Significant neutropenia results from a single treatment of 12 Gy in dogs that have total-body irradiation (see Chapter 39). Bone marrow transplantation or infusion of hemopoietic stem cells is necessary to repopulate the bone marrow and prevent death. Predictable neutropenia occurs in dogs treated with certain chemotherapeutic agents (see Chapter 16).[31] The onset of neutropenia occurs within several days. Male dogs that have Sertoli cell tumors and those treated with estrogen for perianal gland tumors or prostatic hyperplasia may develop estrogen toxicosis (see Chapter 39).[57] Female dogs given diethylstilbestrol or estradiol cyclopentylpropionate for urinary incontinence, infertility, or mismating may also develop estrogen-induced bone marrow suppression (see Chapter 39).[19,57] Idiosyncratic drug reactions (e.g. phenylbutazone, cephalosporin antibiotics, trimethoprim-sulfadiazine, thiacetarsamide, phenobarbital) may cause neutropenia and pancytopenia in dogs (see Chapter 16).

The neutropenia and leukopenia of canine parvoviral enteritis can be attributed to several mechanisms (see Chapter 19). The virus is cytotoxic for hemopoietic stem cells. Endotoxemia resulting from gastrointestinal necrosis causes depletion of the maturation and storage pools of neutrophils in the bone marrow. Endotoxemia may cause increased margination of neutrophils in the vasculature as well as toxic injury to bone marrow.[49]

Decreased production of neutrophils occurs in <30% of dogs that have chronic ehrlichiosis[11,55] and in some Giant Schnauzer dogs that have inherited malabsorption of vitamin B_{12} (see Chapters 30 and 31).[17] Because of decreased hemopoietic space, bone marrow necrosis, myelofibrosis, and osteopetrosis result in neutropenia in dogs (see Chapters 17 and 18).[27,64] Infrequently, disseminated granulomatous disease secondary to histoplasmosis[10] and myelophthisis secondary to proliferation

of neoplastic cells within the marrow causes neutropenia in dogs (see Chapter 18).[13,54] Myelophthisis has been associated with various leukemias and metastatic neoplasia in the bone marrow.

Cyclic hemopoiesis is an autosomal recessive disease of gray-collie dogs that has been attributed to mutation of the AP3B1 gene and altered intracellular transport of neutrophil elastase (see Chapter 42).[29] This stem-cell defect results in profound cyclic neutropenia. Untreated the disease is fatal within 3 years. Repeated endotoxin injections and administration of lithium carbonate control the neutropenia.[7] Parenteral administration of recombinant granulocyte colony-stimulating factor (G-CSF) and lentivrus-mediated administration of G-CSF have also been used to treat this condition.[67] Long-term control of the disease requires bone marrow transplantation. Similar cyclic hemopoietic disease has been reported in cocker spaniels and Pomeranian dogs. Administration of cyclophosphamide also results in cyclic neutropenia.

A second mechanism of neutropenia is cellular shifting from the circulating to marginal pool. Rapid margination of neutrophils occurs with anaphylaxis and endotoxemia in dogs.

The third major mechanism of neutropenia is increased tissue emigration in excess of bone marrow release of neutrophils. Rapid use of neutrophils occurs with infections by pyogenic bacteria. Intense, acute, purulent infection of the lungs, uterus, gastrointestinal tract, or body cavities may cause moderate to significant neutropenia. A degenerative left shift, which occurs when the number of immature neutrophils is greater than that of mature neutrophils, may be seen in these conditions.[40] The total number of blood neutrophils may be normal or decreased.

While not a frequent finding, evidence for immune-mediated destruction of neutrophils in dogs is growing steadily. Weiss and colleagues have developed an indirect immunofluorescence assay to detect IgG binding to canine neutrophils and documented increasing neutrophil counts in affected dogs treated with immunosuppressive therapy.[63,65]

Morphologic Alterations in Neutrophils

Nuclear Alterations in Neutrophils

Asynchronous Nuclear Maturation An indication of dysplasia, asynchronous nuclear maturation is characterized by a lobulated nucleus with an immature chromatin pattern. The neutrophil can appear slightly swollen and have some degree of toxic change. Nuclear lobes can be enlarged or coiled in unusual configurations, and the chromatin can appear dispersed. This uncommon nuclear alteration occurs in dogs that have significant resurgent neutrophilia, myeloid leukemia, and myelodysplastic or preleukemic syndromes.

Nuclear Hypersegmentation Neutrophils with >5 nuclear lobes are seldom observed in the blood of dogs (Fig. 48.1). Hypersegmented neutrophils are associated with prolonged transit times in the vasculature and occur secondary to severe stress (endogenous corticosteroid release), hyperadrenocorticism, and exogenous corticosteroid administration. Few normal to slightly larger, hypersegmented neutrophils are reported in toy and miniature Poodles that have congenital erythrocytic macrocytosis. Giant hypersegmented neutrophils have been observed in myelodysplastic syndromes and in granulocytic leukemia.[31,39]

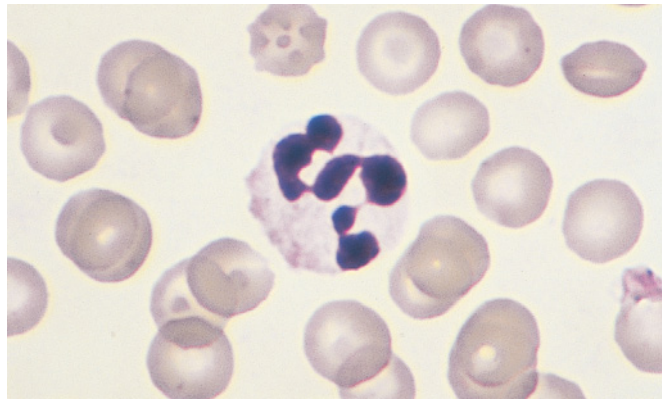

FIGURE 48.1 Hypersegmented neutrophil from a dog that had hyperadrenocorticism. Wright's stain.

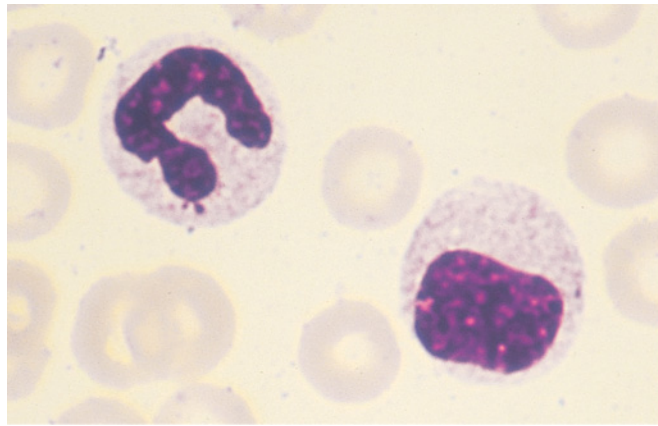

FIGURE 48.2 Late-band and metamyelocyte neutrophils from a dog that had inflammation. Wright's stain.

Nuclear Hyposegmentation Hyposegmentation of the neutrophil nucleus can be associated with the left shift of inflammation or infection, Pelger-Huët anomaly, or pseudo-Pelger-Huët anomaly. The key to differentiation between neutrophil immaturity (Fig. 48.2) and Pelger-Huët anomaly is assessment of the maturity of nuclear chromatin and observation of other immature neutrophilic cells in the blood smear that support a left shift. The chromatin in bands and metamyelocytes is progressively less condensed than that of neutrophils in Pelger-Huët anomaly in which there is a failure of the nucleus to segment.[32,39]

Pelger-Huët Anomaly Reported in several breeds of dogs, Pelger-Huët anomaly is a benign condition

FIGURE 48.3 Neutrophil from dog with Pelger-Huët anomaly. Notice coarse mature chromatin pattern and hyopsegmented nucleus. Wright's stain.

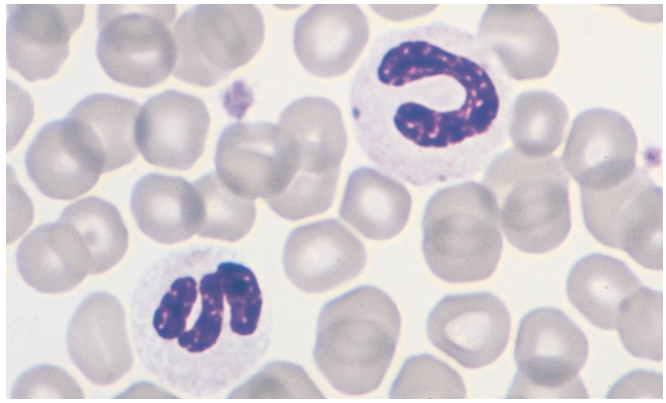

FIGURE 48.4 Canine segmented (left bottom) and band (right top) neutrophils with toxic change, characterized by cytoplasmic basophilia and Döhle bodies. Wright's stain.

(Fig. 48.3). This hereditary disorder of granulocyte development is presumed to be transmitted as an autosomal dominant trait and is characterized by granulocytes and monocytes with hyposegmented nuclei and mature chromatin patterns. The nucleus of neutrophils, eosinophils, and basophils typically has a band or peanut-shaped nucleus with tightly condensed chromatin. Most dogs that have Pelger-Huët anomaly are heterozygous for the condition, and the neutrophils have normal function. Therefore, affected dogs have no predisposition for infection.[5,36–38]

Cytoplasmic Alterations/Inclusions in Neutrophils

Ethylenediaminetetraacetic acid-induced Artifact Ethylenediaminetetraacetic acid (EDTA) induces artifacts in canine neutrophils when there is a delay in smear preparation.[21] When whole blood is collected in EDTA and allowed to incubate at room temperature, neutrophils develop a few, clear vacuoles in the cytoplasm and an irregular distribution of cytoplasmic granules. Cell membranes appear irregular, and mild pyknosis may occur. Cytoplasmic basophilia and foamy vacuolation (i.e. signs of toxic change) are not observed as EDTA-induced artifactual change.

Toxic Change A set of disease-induced morphologic alterations in neutrophils, including cytoplasmic vacuolation, cytoplasmic basophilia, Döhle bodies, or prominently stained primary granules (toxic granulation) is referred to as a toxic change (Fig. 48.4).[39] These cytoplasmic lesions may be seen in cases of intense, localized or systemic infection, sterile inflammation, and drug toxicity.[31]

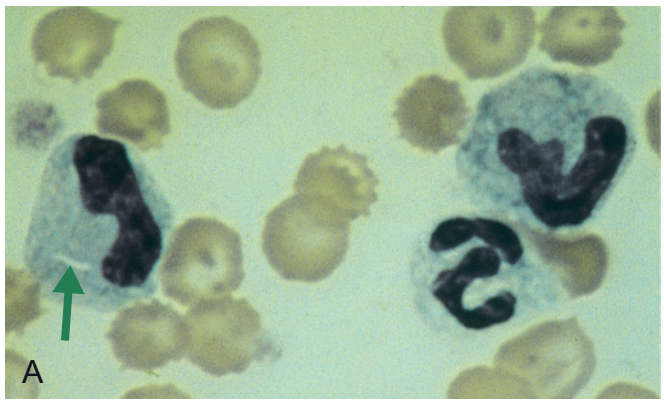
Cytoplasmic vacuolation occurs in neutrophils when bone marrow production of these cells is disrupted, resulting in loss of granule and membrane integrity. Persistent ribosomes impart the cytoplasm with its characteristic basophilia. Döhle bodies are angular, blue-to-gray, cytoplasmic inclusions that stain with variable intensity and measure approximately 0.5–2.0 µm in diameter. They represent lamellar aggregates of retained rough endoplasmic reticulum. Increased permeability of primary granule membranes to Romanowsky stains results in toxic granulation, a seldom seen change in canine neutrophils.[22,23] Resolution of toxic change in neutrophils after appropriate treatment of the underlying disease is a favorable prognostic indicator in the dog.

Infectious Agents Bacterial rods and cocci can be infrequently detected in the cytoplasm of neutrophils and other blood phagocytes during septicemic crises.[60] The bacteria stain positively or negatively in Romanowsky-stained blood films and buffy coat preparations (Fig. 48.5). Although clinical signs and leukograms can provide supportive evidence for bacteremia, the diagnosis is best confirmed by blood culture.

Canine distemper virus inclusion bodies can be infrequently observed in neutrophils from dogs that have naturally occurring viral disease or post-vaccination (Fig. 48.6). The intracytoplasmic inclusions are round to irregularly shaped, homogeneous, magenta to gray-blue structures that may occur in blood cells, including erythrocytes and several types of leukocytes.[31]

Hepatozoon canis and *Hepatozoon americanum* gametocytes can be detected in the cytoplasm of neutrophils or monocytes. Parasitemia varies from high to low levels. It may be necessary to examine several blood films, capillary blood smears, or buffy coat preparations to identify gametocytes (Fig. 48.7). The oval gametocytes measure 5 × 10 µm and are unstained to ice-blue within the cytoplasm of monocytes and neutrophils in Romanowsky-stained blood smears. Infection frequently is associated with neutrophilic leukocytosis.[44]

Histoplasma capsulatum is a yeast-like fungus that can be observed in neutrophils, monocytes, and eosinophils in Romanowsky-stained blood films and buffy coats from dogs that have disseminated disease (Fig. 48.8). The organisms are round, 2–4 µm in diameter, and have thin walls. They have a small round, purple nucleus, and can occur singly or in clusters within the cytoplasm.[10]



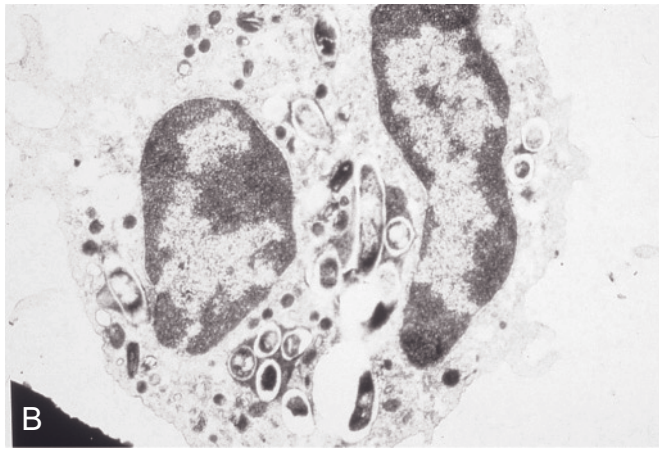


FIGURE 48.5 (**A**) Neutrophil with negatively stained intracellular bacillus (arrow) in blood smear from a dog that has mycobacteriosis, Wright's stain. (**B**) Transmission electron micrograph of a neutrophil from the same dog that has several bacilli. (Courtesy of Dr. Harold W. Tvedten, Michigan State University, East Lansing, MI.)

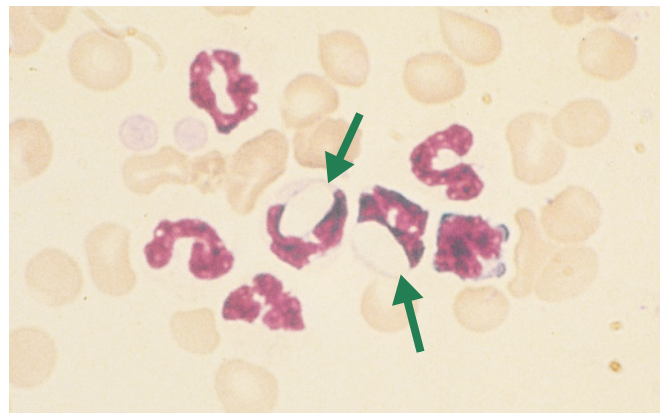

FIGURE 48.7 Two segmented neutrophils with intracytoplasmic, clear to ice-blue *H. canis* gametocytes. Wright's stain. (Courtesy of Dr. Robert Green, Texas A&M University, College Station, TX.)

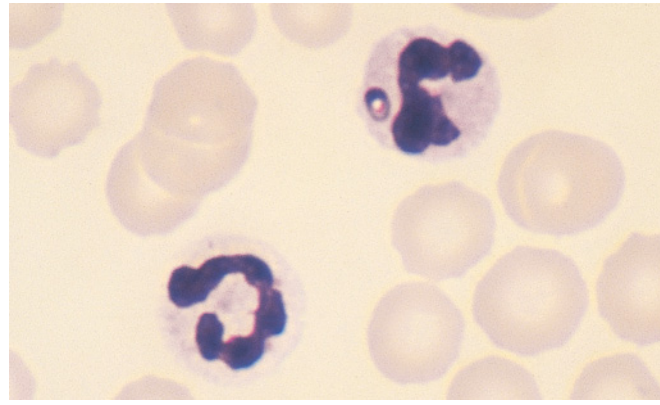

FIGURE 48.8 Segmented neutrophil with intracytoplasmic *Histoplasma capsulatum*. Wright's stain.

Leishmania donovani amastigotes rarely have been identified in neutrophils from dogs that have disseminated leishmaniasis.[53] Leukocytosis with neutrophilic left shift is a frequent finding. The amastigotes are small, round to oval organisms and occur 1–2 organisms per neutrophil. They have an oval nucleus, basophilic ventral kinetoplast, and light blue cytoplasm. Amastigotes have been identified in approximately 3% of circulating neutrophils.

Anaplasma phagocytophilia morulae are identified frequently in neutrophils from infected dogs and *Ehrlichia canis* morulae can be observed infrequently in monocytes.[56] Morulae from the different strains of *Ehrlichia* species appear similar. The *Ehrlichia* morulae vary from magenta to blue-gray in color and resemble a mulberry (Fig. 48.9). The identity of the specific agent can be established by polymerase chain reaction, RNA or DNA sequencing, or by determination of acute and convalescent serum antibody titers.

Miscellaneous Inclusions Hemosiderin granules have been observed in the cytoplasm of occasional neutrophils and monocytes from dogs with immune-mediated hemolytic anemia after transfusion therapy. The brown granules, that stain positive for iron, measured 1–4 µm in diameter (Fig. 48.10). Multiple granules can be observed in some cells. The mechanism of their occurrence in neutrophils is uncertain.[18]

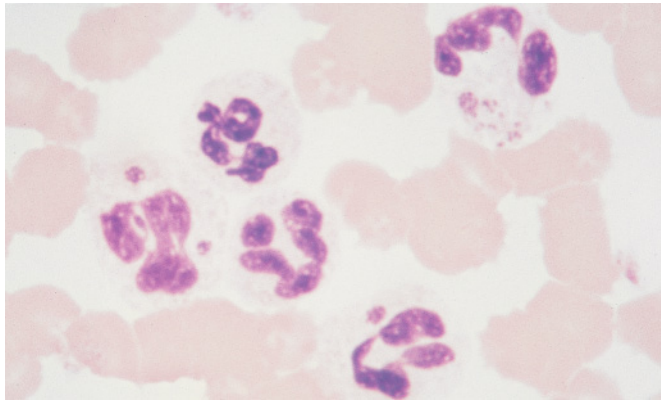

FIGURE 48.9 Three neutrophils containing morulae of *Ehrlichia ewingii*, Wright's stain. (Courtesy of Dr. Steven L. Stockham, Kansas State University, Manhattan, KS.)

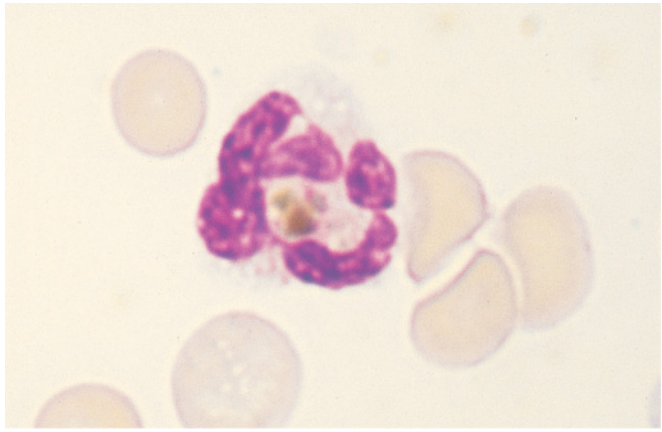

FIGURE 48.10 Segmented neutrophil with hemosiderin crystal from a dog that had immune-mediated hemolytic anemia. Wright's stain. (Courtesy of Dr. Stephen Gaunt, Louisiana State University, Baton Rouge, LA.)

Mucopolysaccharidosisis type VI (arylsulfatase B deficiency) and type VII (β-glucuronidase deficiency) are lysosomal storage diseases that have been reported rarely in the dog. Neutrophils and lymphocytes from affected dogs can have large, pink-to-purple staining inclusions (Alder-Reilly bodies) in the cytoplasm in routine Romanowsky-stained blood films (Fig. 48.11). The inclusions in mucopolysaccharidosis type VII can stain metachromatically with 1% toluidine blue dye. The granules represent intermediate products that accumulate in cells caused by the arylsulfatase B (type VI) or β-glucuronidase deficiency (type VII). Disease inheritance is by means of an autosomal recessive pattern.[26,47]

EOSINOPHILIA AND EOSINOPENIA

Causes and Mechanisms of Eosinophilia

In Romanowsky-stained blood films, canine eosinophils have a bilobed or trilobed nucleus with condensed chromatin and abundant cytoplasm that contains

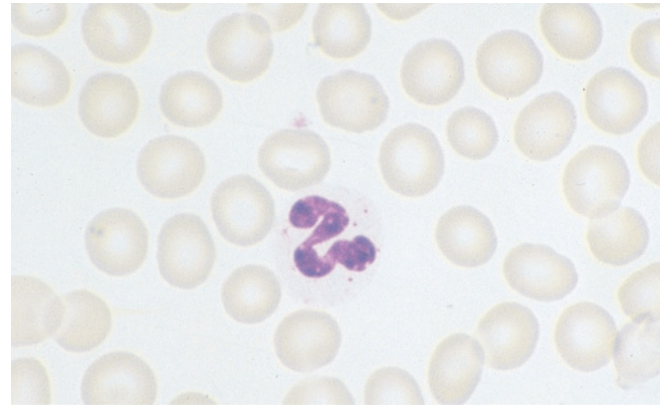

FIGURE 48.11 Segmented neutrophil with Alder-Reilly bodies from a dog that had mucopolysaccharidosis type VII. Wright's stain. (Courtesy of Dr. Mary Anna Thrall, Colorado State University, Ft. Collins, CO and Dr. Mark Haskins, University of Pennsylvania, Philadelphia, PA.)

round, red-orange granules. The granules frequently vary in number and size. In some dogs, eosinophils appear degranulated or vacuolated. The primary functions of eosinophils are to destroy parasites (primarily helminths) and to modulate hypersensitivity reactions (see Chapter 43).

Eosinophilia, defined as >1,300 eosinophils/μL of blood, is a frequent occurrence in dogs (Table 48.3).[39] The most common cause of eosinophilia in dogs is parasitism. Both endoparasites and ectoparasites cause eosinophilia. However, this alteration occurs more often and is of greater magnitude with endoparasites that migrate through body tissues and have prolonged host-tissue contact. Inflammation or local hypersensitivity reactions in the alimentary, respiratory, and genitourinary systems and in skin that are mediated by mast cell degranulation also cause eosinophilia. In some dogs, localized tissue eosinophilia may occur in the presence of normal blood eosinophil counts.[31]

Eosinophilia may occur as a paraneoplastic syndrome in some dogs.[12,43,50] Although many malignant and some benign neoplasms have been reported to cause eosinophilia, disseminated mast cell neoplasia most frequently causes this alteration in dogs. The mechanism of eosinophilia is unknown. However, T lymphocyte-derived cytokine mediators, such as interleukin-2 and -5, are probably involved.[36] Idiopathic hypereosinophilic syndrome occurs rarely in dogs and is characterized by persistent eosinophilia with extensive tissue infiltration and organ dysfunction of unknown cause (see Chapter 43).[2] It may be difficult to differentiate hypereosinophilic syndrome from eosinophilic leukemia. Rarely, eosinophilia is reported after administration of certain drugs in the dog. Eosinophilia has been associated with tetracycline and recombinant interleukin-2 administration.[6,14]

Causes and Mechanisms of Eosinopenia

Eosinophil counts in healthy dogs range from 0 to 1,300 eosinophils/μL of blood.[39] Because many normal dogs

TABLE 48.3 Causes of Eosinophila and Eosinopenia in Dogs

Eosinophilia	
Drug administration	Recombinant interleukin-2 administration, tetracycline
Hypoadrenocorticism	
Hypersensitivity reactions (alimentary, genitourinary, respiratory systems, skin and special senses may be affected)	Oral granuloma, ulcerative/eosinophilic gastroenteritis, gastrointestinal eosinophilic granuloma, pyometra, myositis, panosteitis, pulmonary infiltrates with eosinophilia, canine eosinophilic granuloma, sterile eosinophilic pustulosis
Fungi/yeastlike fungi	*Aspergillus fumigatus, Cryptococcus neoformans, Pythium insidiosum*
Parasites	
Nematodes	*Ancylostoma* sp., *Angiostrongylus vasorum, Ascarids, Dipetalonema reconditum, Dirofilaria immitis, Oslerus* (*Filaroides*) *osleri, Filaroides hirthi, Physaloptera* sp., *Spirocerca lupi, Trichinella spiralis, Trichuris vulpis*
Trematodes	*Heterobilharzia americana, Paragonimus kellicotti, Alaria* sp.
Arthropods	*Dermatobia hominis*, fleas, ticks, *Sarcoptes scabiei* var. *canis*, pentastomes
Protozoa	*Babesia canis, Hepatozoon canis, Pneumocystis carinii, Sarcocystis canis, Haemobatonella canis*
Neoplasia	Idiopathic hypereosinophilic syndrome, myeloid leukemia, paraneoplastic syndromes (fibrosarcoma, lymphomatoid granulomatosis, mammary carcinoma, disseminated mastocytosis, rectal polyp, thymoma, T-cell lymphoma), essential thrombocythemia
Eosinopenia	
Corticosteroids	
Endogenous	Hyperadrenocorticism, stress
Exogenous	Corticosteroid treatment
Acute infection/inflammation	

may routinely have eosinophil counts of 0/μL, true eosinopenia is difficult to document and is of limited clinical significance. Determination of absolute eosinophil counts with a hemocytometer and eosin-based diluent is recommended to confirm suspected cases of eosinopenia and may be valuable in monitoring responses to *o,p'*-DDD (mitotane) treatment in dogs that have hyperadrenocorticism.[31]

Eosinopenia may occur in dogs that have emotional or physical stress, or have inflammatory disease owing to release of adrenocorticosteroids as well, as in hyperadrenocorticism (Cushing's syndrome).[40] It is hypothesized that corticosteroids inhibit histamine release, neutralize circulating histamine, and initiate release of cytokines that mediate alterations in eosinophil distribution. Eosinopenia from a single dose of corticosteroids occurs within 1–6 hours and counts return to normal within 12–24 hours. Long-term use of high-dose corticosteroids depresses eosinophil production by the bone marrow.[40]

BASOPHILIA AND BASOPENIA

Causes and Mechanisms of Basophilia

Basophils are seen infrequently in blood films submitted for hematologic evaluation. These unique cells, which are slightly larger than segmented neutrophils, usually account for <2% of the differential leukocyte count or an absolute count of 0–140 basophils/μL.[39] Basophils have a poorly lobulated nucleus that has been described as a twisted ribbon (see Chapter 104). The blue-gray cytoplasm contains widely scattered, round, metachromatic granules that vary greatly in size and number.

Basophil granules contain preformed mediators, including histamine and heparin (see Chapter 44). When stimulated, these cells synthesize platelet-activating factor; thromboxane A2; and leukotrienes C4, D4, and E4.[32] Basophils are intricately involved in host defense by means of immunoglobulin E (IgE)-mediated inflammatory reactions (see Chapter 44).[25,30]

Basophilia, defined as a prolonged increase in circulating numbers of basophils (>140 basophils/μL of blood), is a rare event. Because numbers of circulating basophils are low in health, the routine differential cell count is a rather insensitive measure of basophil numbers. Only sustained increases in basophil numbers of >3–6% of the differential cell count can be detected on routine blood smears.[36] Usually, basophilia accompanies eosinophilia but can occur independently. The most frequent cause of basophilia in the dog is infection with the canine heartworm, *Dirofilaria immitis* (Table 48.4).[36] Basophilia also is associated with infection with several other parasites and infectious agents. In addition, basophilia is associated with various hypersensitivity or inflammatory conditions, neoplastic diseases, and as an infrequent consequence of the administration of certain drugs.[36,48] Although it has been suggested that basophilia is a result of lipemia associated with chronic liver disease, nephrotic syndrome, and endocrine disturbances, including diabetes mellitus and hyperadrenocorticism, these assertions have not been confirmed in many cases. Basophilia caused by basophilic leukemia is rare.[45]

Causes and Mechanisms of Basopenia

Basophil counts in healthy dogs range from 0 to 140 basophils/μL.[39] Because many normal dogs routinely have basophil counts of 0/μL, basopenia is difficult to document with currently available methods and is considered clinically insignificant at this time.

TABLE 48.4 Causes of Basophilia in Dogs

Drug administration	Heparin, penicillin
Hypersensitivity and/or inflammatory lesions	Allergic respiratory disease, cutaneous eosinophilic granuloma, eosinophilic gastroenteritis, experimental *Candida crusei* and *Candida albicans* administration, osteomyelitis, pulmonary eosinophilic granuloma, pulmonary infiltrates with eosinophilia
Neoplasia	Basophilic leukemia, disseminated mast cell neoplasia, essential thrombocythemia, lymphomatoid granulomatosis, thymoma
Parasitic diseases	*Ancylostoma* and *Uncinaria* sp., *Dirofilaria immitis, Dipetalonema reconditum, Hepatozoon canis, Crenosoma vulpis*

LYMPHOCYTOSIS AND LYMPHOPENIA

Causes and Mechanisms of Lymphocytosis

Canine peripheral blood lymphocytes are predominately small, round mononuclear cells (see Chapter 104). They have a round to oval nucleus with aggregated chromatin and have indistinct nucleoli. The blue cytoplasm is scant and may contain a few azurophilic granules. In healthy dogs, the lymphocyte is the second most frequently encountered WBC. B and T cells appear similar by light microscopic examination of Romanowsky-stained blood films. However, the majority of lymphocytes in the blood are T cells.[39] In general, B cells are short-lived (days to weeks) compared with T cells (months to years). Lymphocytes have the capacity to recirculate and undergo mitosis.[31]

Lymphocytosis, defined as >2,900 lymphocytes/μL of blood, is an uncommon occurrence in the dog (Table 48.5). Physiologic leukocytosis may cause a transient lymphocytosis. Physiologic lymphocytosis does not occur frequently in the adult dog but occurs more frequently in puppies. This form of lymphocytosis can be avoided if animals are not overly excited at time of venipuncture. Examination of a second sample of blood, collected from the calmed or tranquilized dog, can be used to distinguish transient lymphocytosis of

TABLE 48.5 Causes of Lymphocytosis and Lymphopenia in Dogs

Lymphocytosis	
Chronic antigenic stimulation	Aspergillosis, actinomyces, *Babesia canis* infection, blastomycosis, brucellosis, ehrlichiosis, encephalitozoonosis, leishmaniasis, pneumocystis pneumonia, Rocky Mountain spotted fever, *Trypanosoma cruzi gambiense* infection
Hypoadrenocorticism	
Lymphoid neoplasia	Lymphocytic leukemia (acute or chronic), lymphosarcoma, thymoma
Physiologic leukocytosis (not common in the dog)	
Lymphopenia	
Acute systemic bacterial infections	Septicemia, endotoxemia
Corticosteroids	Stress-induced leukocytosis (pain, extremes in body temperature), hyperadrenocorticism (Cushing's syndrome), exogenous corticosteroid therapy or ACTH administration
Disruption of lymph node architecture	Generalized granulomatous disease, multicentric lymphosarcoma
Immunodeficiency syndromes	Combined T- and B-cell deficiency of Basset hounds, combined immunodeficiency of Jack Russell terriers
Immunosuppressive drugs	
Loss of lymphocyte rich fluids	Protein-losing enteropathy (lymphangiectasia), ulcerative enteritis, granulomatous enteritis, chylothorax, chyloperitoneum
Malignant neoplasia	Lymphosarcoma, lymphocytic leukemia
Radiation	
Viral infections (acute stages usually)	Canine distemper, infectious canine hepatitis, coronavirus enteritis, canine parvovirus

physiologic leukocytosis from lymphocytosis of pathologic origin.[36]

Persistent antigenic stimulation in chronic infections or inflammatory reactions may cause lymphocytosis in dogs. Chronic canine ehrlichiosis[11] and Rocky Mountain spotted fever are diseases that result in proliferation of lymphocytes and expansion of the blood lymphocyte pool. Trypanosomiasis,[3] leishmaniasis,[24] and brucellosis[61] also may cause lymphocytosis by a similar mechanism.

Lymphoid neoplasia can cause lymphocytosis.[51] Malignant lymphoma, acute or chronic lymphocytic leukemia, and thymoma have been associated with lymphocytosis (see Chapters 69 and 77). The highest lymphocyte counts usually are associated with chronic lymphocytic leukemia.[41] Malignant lymphoma, a neoplastic proliferation of lymphocytes within tissue, also can produce lymphocytosis in approximately 10% of dogs that have this disease.

Hypoadrenocorticism (Addison's disease) has been reported to cause lymphocytosis in 11–20% of affected dogs.[66] The lack of lymphopenia in a severely stressed dog provides supportive evidence for glucocorticoid deficiency.

Causes and Mechanisms of Lymphopenia

Lymphopenia, defined as <400 lymphocytes/μL blood, is a frequent occurrence in dogs and may result from several mechanisms (Table 48.5).[39] Physical stresses such as extremes in temperature or pain, which result in excess corticosteroid release, cause lymphopenia of transient and predictable nature. Exogenous administration of corticosteroids or ACTH and hyperadrenocorticism also cause lymphopenia. Acute infections can cause lymphopenia by means of stress-induced corticosteroid release and redistribution of lymphocytes.[31,36] Specific antigens can cause lymphocytes to become trapped in lymphoid tissues. Lymphopenia can occur when lymphocytes are recruited to antigenically stimulated lymph nodes and then emigrate into tissues.[36] Inflamed lymph nodes can occlude efferent lymph flow, thus preventing lymphocyte recirculation and compounding lymphopenia.[28] Certain viruses, particularly canine distemper virus and canine parvovirus, cause lymphocyte destruction, atrophy of lymphoid tissues, and depletion of lymphocyte subpopulations.[36]

Some cases of protein-losing enteropathy, lymphangiectasia, ulcerative enteritis, and granulomatous enteritis in dogs cause lymphopenia as a result of loss of lymphocyte-rich fluid into the intestinal lumen.[34] Chylothorax and chyloperitoneum can result in lymphopenia due to sequestration of lymphocyte-rich fluids in body cavities.[16] Repeated centesis and removal of chyle from body cavities may exacerbate lymphopenia. Occlusion of the flow of lymph caused by disseminated granulomatous inflammation or neoplasia also can result in lymphopenia.

Rarely, lymphopenia can be the result of congenital lymphocyte deficiency.[15] Basset hounds that have combined immunodeficiency have lymphopenia and recurrent infections such as mycobacteriosis (see Chapter 57).[8] Autosomal recessive severe combined immunodeficiency of Jack Russell terriers results in puppies with marked lymphopenia and decreases in the concentrations of serum immunoglobulins secondary to hypoplasia of all lymphoid tissues.[4]

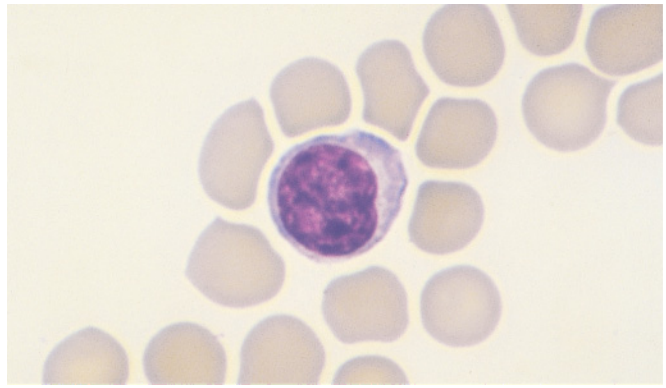

FIGURE 48.12 Reactive lymphocyte in a canine blood smear. Wright's stain.

Morphologic Alterations in Lymphocytes

Reactive Lymphocytes

Reactive lymphocytes (also termed immunocytes and transformed lymphocytes) are antigentically stimulated lymphoid cells that are seen in the blood of dogs (Fig. 48.12). These cells have a deeply basophilic cytoplasm. Reactive lymphocytes vary in size, nuclear chromatin clumping, and number of nucleoli visualized. While some resemble small lymphocytes with a basophilic cytoplasm, others resemble lymphoblasts. The cytoplasm may have a perinuclear Golgi zone and may contain a few vacuoles and resemble plasma cells.[36,39]

Plasma Cells

Plasma cells are rare in the blood of dogs and are usually observed in bone marrow or lymph-node aspirates (Fig. 48.13). They are large cells with intensely basophilic cytoplasm and a prominent, pale-staining, perinuclear Golgi zone. The nucleus is usually eccentrically located and has condensed chromatin.[36,39]

Granular Lymphocytes or Natural Killer Cells

Granular lymphocytes or natural killer cells are null lymphoid cells that are seen infrequently in blood smears (Fig. 48.14). They have a few distinct azurophilic granules that tend to cluster at the nuclear margin or indentation.[36]

Lymphoblasts

Lymphoblasts are large lymphoid cells that are observed frequently in disseminated lymphoma and

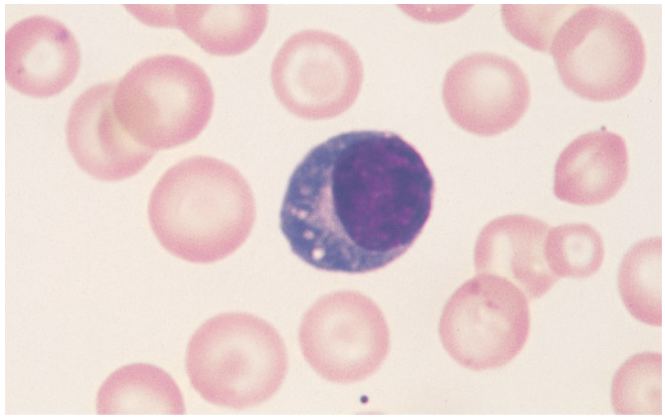

FIGURE 48.13 Plasma cell in canine blood smear. Wright's stain. (Courtesy of Dr. Steven L. Stockham, Kansas State University, Manhattan, KS.)

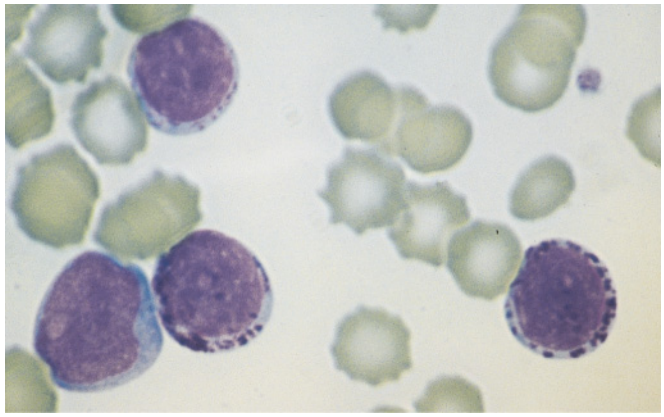

FIGURE 48.14 Large granular lymphocytes in a canine blood smear. Wright's stain. (Courtesy of Dr. Maxey L. Wellman, The Ohio State University, Columbus, OH.)

lymphoblastic leukemia (Fig. 48.15). Lymphoblasts have a large nucleus with vesicular chromatin and prominent nucleoli. The cytoplasm is abundant and has a deep blue hue.[36,39]

Phospholipidosis-Induced Cytoplasmic Vacuoles

Lymphocytes from dogs with drug-induced phospholipidosis may have large clear cytoplasmic vacuoles.[62] These vacuoles occur singly or may be multiple and may push the nucleus eccentrically. Affected lymphocytes are readily visible upon examination of Wright-stained blood smears.[52]

MONOCYTOSIS AND MONOCYTOPENIA

Causes and Mechanisms of Monocytosis

Canine monocytes are large cells with pleomorphic (round, oval, bilobed, or multilobed) nuclei and fine lacy nuclear chromatin patterns (see Chapter 104). Monocytes have large amounts of blue-gray cytoplasm

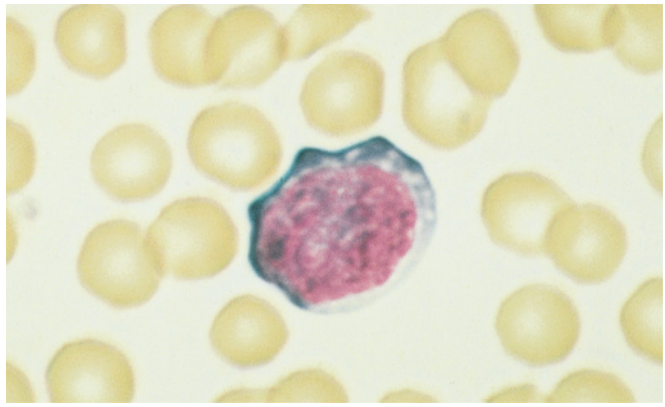

FIGURE 48.15 Lymphoblast in blood smear of a dog that has malignant lymphoma. Notice the prominent nucleoli. Wright's stain. (Courtesy of Dr. Rose Raskin, Purdue University, West Lafayette, IN.)

TABLE 48.6 Causes of Monocytosis in Dogs

Inflammatory lesions (acute or chronic)	Bacteremia/septicemia, bacterial endocarditis, immune-mediated injury (hemolytic anemia), necrosis/suppuration (tissue or body cavities), osteomyelitis, pyogranulomatous disease (several causes)
Miscellaneous causes	Corticosteroid-induced leukocytosis, hemorrhage/hemolysis, rebound neutropenia/cyclic hematopoiesis, recombinant G-CSF administration, trauma
Neoplasia	Benign tumors (rectal polyp), malignant tumors (chondrosarcoma, hemangiosarcoma, lymphosarcoma), malignant histiocytosis, monocytic leukemia, myelomonocytic leukemia
Parasitic diseases	*Hepatozoon canis* infection, *Pneumocystis carinii* pneumonia, *Trypanosoma brucei* infection, *Angiostrongylus vasorum* infection, *Crenosoma vulpis* infection, *Dirofilaria immitis* infection

that may contain numerous small vacuoles and few pink-to-azurophilic granules (lysosomes). Amoeboid or short hairlike processes (pseudopodia) may bulge from the cytoplasmic membrane.[39]

Monocytes occur in low numbers in the blood of healthy dogs. Monocytosis is defined by numbers that exceed 1,400 monocytes/μL of blood.[39] In general, monocytosis occurs with neutrophilia, but rarely it occurs as a single alteration in a leukogram (Table 48.6).[36,39] Monocytosis is a frequent leukogram alteration that is associated with necrosis, suppuration, malignant neoplasia, pyogranulomatous lesions, internal hemorrhage, hemolysis, trauma,[36] and immune-mediated diseases. It is an inconsistent finding in the leukogram of dogs responding to corticosteroids. It may be observed in leukograms of dogs that have bacterial endocarditis or bacteremia. Monocytosis is seen in dogs rebounding from neutropenia such as in cyclic

hemopoiesis of gray-collie dogs.[39] Significant, persistent monocytosis, with counts >50,000/μL of blood, may be detected in monocytic or myelomonocytic leukemia. Abnormal monocyte morphology and numerous blast cells can be detected in the blood or bone marrow during these neoplastic diseases.

Causes and Mechanisms of Monocytopenia

Reference intervals for monocyte counts in the blood from healthy dogs are fairly broad. Therefore, it is difficult to document monocytopenia. Thus, this alteration is of little clinical significance. However, monocytopenia may be detected in some cases of acute pancytopenia due to several causes.[36]

LEUKEMIA

The definition of leukemia is the neoplastic proliferation of hemopoietic cells originating in the bone marrow (see Section V). Leukemias (i.e. myeloproliferative disorders) are classified by cell type and differentiation, time course of disease process (acute or chronic), and presence or absence of neoplastic cells in circulation. Myeloproliferative disorders reported in the dog include granulocytic (myeloid) leukemia, myelomonocytic leukemia, monocytic leukemia, basophilic leukemia, mast cell leukemia, erythremic myelosis, polycythemia vera, megakaryocytic leukemia, and essential thrombocythemia. Lymphoproliferative diseases reported in the dog include lymphocytic leukemia and plasma cell leukemia. Diagnosis of these disorders is facilitated by examination of Romanowsky-stained blood films and bone marrow aspirates. Histologic examination of bone marrow core biopsies may be required in some cases. Use of immunohistochemistry greatly aids diagnosis in poorly differentiated cell types.[31,36,39,40]

Acronyms and Abbreviations

CBC, complete blood count; CNP, circulating neutrophil pool; EDTA, ethylenediaminetetraacetic acid; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; MDS, myelodysplastic syndrome; MPD, myeloproliferative disease; nRBC, nucleated red blood cell; WBC, white blood cell.

The complete blood cell count (CBC) is a vital component of the minimum laboratory database used in the evaluation of feline illnesses. The CBC provides quantitative and qualitative information regarding the status of red blood cells (RBCs), platelets , and white blood cells (WBCs); it is also termed the leukogram. The leukogram includes a total WBC count with absolute and relative quantification of WBC types and comments on WBC morphology. Although some general rules regarding leukogram interpretation may be applied to all species, some unique characteristics must be considered and recognized during evaluation of the feline leukogram.

In normal cats, the total WBC population is composed primarily of mature neutrophils and lesser numbers of lymphocytes. Monocytes, eosinophils, and basophils usually do not contribute significantly to the total WBC count. Chapter 105 offers a detailed review of normal feline WBC morphology.

LEUKOCYTE MORPHOLOGIC ARTIFACTS

Peripheral blood samples that are collected in EDTA anticoagulant and allowed to sit for several hours before a blood smear is made tend to develop artifactual leukocyte nuclear hypersegmentation, pyknosis, or cytoplasmic vacuolization (Fig. 49.1). Once these changes occur, the cells are difficult or impossible to identify. Artifactual cytoplasmic vacuolation also may be confused for toxic changes of neutrophils. When nucleated cells rupture or are stripped of their cytoplasm during

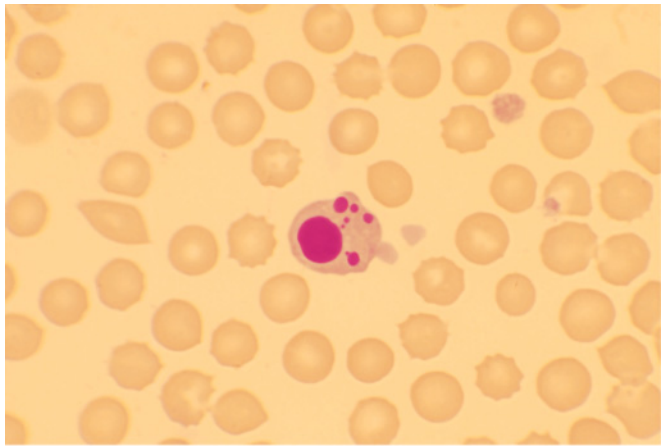

FIGURE 49.1 Improper sample handling has resulted in altered WBC morphology. A WBC shows pyknosis, karyorrhexis and karyolysis. Wright-stained blood smear. (Courtesy of Oklahoma State University, College of Veterinary Medicine teaching files.)

blood smear preparation, the nuclear chromatin spreads out and stains eosinophilic. These eosinophilic masses are referred to as basket cells. Attempts should not be made to identify basket cells. When more than 10% of WBCs are artifactually affected, the WBC differential count is invalid.

NONPATHOLOGIC LEUKOCYTE RESPONSES

Various physiologic and pharmacologic processes can cause changes in the total leukocyte count. Because neutrophils are the predominant blood leukocyte in the cat, alterations in the WBC count frequently parallel alterations in the absolute neutrophil count. Nonpathologic leukogram changes primarily result from shifts in neutrophil populations related to changes in neutrophil kinetics. Granulopoiesis is directed by cytokines primarily secreted from macrophages within the bone marrow. Maturation of neutrophils occurs in approximately 3.5–6 days.[18] Three distinct pools of neutrophils exist. The first pool is the bone marrow pool of developing and mature neutrophils. Neutrophils are released from the bone marrow in an age-ordered fashion. Once in the systemic circulation, they are distributed between the marginated neutrophil pool and the circulating neutrophil pool (CNP). Marginated neutrophils adhere to endothelium of venules and capillaries primarily in the spleen, lungs, and splanchnic vessels, whereas neutrophils of the CNP remain free in the vasculature. Only circulating neutrophils are collected during venipuncture sampling. In the cat, the ratio of the marginated neutrophil pool to circulating neutrophil pool is approximately 3:1.[9] Blood neutrophils remain in a dynamic equilibrium, and many processes can cause a redistribution of neutrophils between these pools. Shifts are dynamic and may occur rapidly, altering circulating neutrophil numbers as reflected by the total WBC and neutrophil counts. Two distinct patterns of nonpathologic leukograms have been identified.

Physiologic Leukocytosis

In physiologic leukocytosis, a mild to moderate leukocytosis characterizes the leukogram. Mild, mature neutrophilia and lymphocytosis exist. The lymphocytosis is frequently of greater magnitude than the neutrophilia.[9,18] Lymphocytosis is probably caused by redistribution of lymphocytes between the blood, lymphatics, and lymphoid organs. The neutrophilia reflects the redistribution of neutrophils from the marginated to the circulating pool due to the effects of epinephrine. This leukogram pattern is generally seen in young, healthy cats that become excited or frightened by environmental stresses (e.g. fear, excitement, restraint, venipuncture). Leukogram changes are immediate but transient, lasting approximately 20–30 minutes. The short duration of the physiologic lymphocytosis helps to distinguish this physiologic state from other pathologic processes that cause a persistent lymphocytosis (e.g. lymphoma and lymphocytic leukemia). Young cats typically have a higher number of circulating lymphocytes than older cats, and a physiologic lymphocytosis rarely exceeds 20,000 lymphocytes/μL of blood.[9]

Stress (Glucocorticoid-Induced) Leukogram

Exogenous glucocorticoids or elevations in endogenous glucocorticoids tend to cause a mild to moderate leukocytosis characterized by a mature neutrophilia, lymphopenia, and eosinopenia. Monocytosis generally is not observed in cats, and an eosinopenia is difficult to document in any species. Glucocorticoids induce neutrophilia primarily by enhancing the release of mature neutrophils from the bone marrow. Secondarily, glucocorticoids promote the shift of marginated neutrophils into the circulating neutrophil pool, decreasing the egress of circulating neutrophils into tissue. The normal blood transit time of circulating neutrophils is approximately 10–12 hours, but this blood transit time is prolonged by glucocorticoid administration. Finally, chronic glucocorticoid excess stimulates granulopoiesis. The lymphopenia is the result of redistribution of circulating lymphocytes; lysis of immature or uncommitted lymphocytes may occur with high dosages of corticosteroids given over prolonged periods. Glucocorticoids also exert a neutralizing effect on histamine, a major chemoattractant for eosinophils.[13] The corticosteroid response is initially seen at approximately 4 hours and peaks 6–8 hours post-stress or after administration of corticosteroids. Neutrophil values return to reference intervals within 24 hours after a single 5 mg dose of prednisolone and within 48–96 hours after cessation of prolonged corticosteroid therapy.[18]

PATHOLOGIC LEUKOCYTE RESPONSES

Because neutrophils are the predominant leukocyte in the cat, alterations in the total WBC count frequently parallel alterations in neutrophil numbers. Many factors, including physiologic, pharmacologic, and

pathologic processes can cause changes in the absolute neutrophil count in blood.

Inflammatory Leukogram

In a normal animal, homeostasis is maintained between production and egress of neutrophils into tissues. Bone marrow production, margination, and tissue demand for neutrophils all can be affected by various disease processes. With an increased tissue demand for neutrophils, the bone marrow responds by increasing the release of mature neutrophils into circulation. In the cat, a significant, mature neutrophilic leukocytosis indicates inflammation. With established inflammation, a sustained neutrophilia indicates that bone marrow release of mature neutrophils exceeds neutrophil emigration into tissues. Bone marrow evaluation usually reveals granulocytic hyperplasia. These findings reflect the bone marrow's capacity to produce enough mature neutrophils to combat the inciting agent and also suggests that the inflammatory process has been present for at least several days. The demand for neutrophils depends on the chronicity and severity of the disease process.

Inflammatory Leukogram With a Left Shift

When the demand for neutrophils exceeds bone marrow reserve capacity, the storage pool of mature neutrophils becomes exhausted. Immature neutrophils are then released into the circulation. An increase in the number of band cells and occasionally earlier precursor cells into the blood is referred to as a left shift. A clinically significant left shift is the hallmark of an inflammatory leukogram. In the cat, a left shift is considered clinically significant when immature neutrophils exceed 500–1000 bands/μL with a normal or elevated total WBC count.[22] A left shift may be categorized as either regenerative or degenerative, which may be useful clinically as a prognostic indicator of disease severity. Additionally, the severity of the left shift can be assessed by evaluating the numbers of immature granulocytes and degree of immaturity of the cells, as an increase in both parameters generally parallels the severity of the condition. A regenerative left shift is defined as a neutrophilic leukocytosis in which the number of immature neutrophils does not exceed the number of segmented neutrophils. A regenerative left shift indicates that the bone marrow is meeting the body's need for neutrophils. In contrast, a degenerative left shift is present when the number of immature neutrophils exceeds the number of segmented neutrophils.[13] The number of segmented neutrophils is typically within the reference interval or decreased. A degenerative left shift indicates that the bone marrow cannot meet the tissue demand for neutrophils, indicating a severe disease process and suggests a guarded to poor prognosis. Degenerative left shifts can occur in conditions such as septicemia, endotoxemia, and severe inflammation of large-surface areas (e.g. peritonitis, pleuritis, pneumonia, gastroenteritis, placentitis). Frequently, a left shift is limited to band neutrophils, but with severe disease, metamyelocytes, myelocytes, and promyelocytes (progranulocytes) can appear in the blood. These immature stages are more likely to be associated with a degenerative left shift than with a regenerative left shift. Giant neutrophils or metamyelocytes are more frequent in the cat than in other species and can be seen as cats recover from severe neutropenia. Toxic neutrophils are frequently seen with inflammatory responses and are discussed later. Occasionally, an inflammatory process may induce an extreme neutrophilia (>50,000 cells/μL) with an associated left shift that may include band, metamyelocyte, myelocyte, and promyelocyte stages. This is termed a leukemoid response and can be difficult to distinguish from granulocytic or myelomonocytic leukemia (see Section V).

NEUTROPHIL RESPONSES

Pathologic Changes in Neutrophil Morphology

Toxic Change

Toxic change occurs in neutrophils during maturation in the bone marrow and primarily affects the myelocytic and metamyelocytic stages of development. Toxic change is a maturational defect caused by toxic substances generated by strong inflammatory conditions including severe bacterial infections (pyothorax, pyoabdomen, sepsis, pneumonia), septicemia, acute inflammatory conditions, and extensive burns. Toxic changes can be seen in both mature and immature neutrophils and generally are associated with a left shift. Toxicity can be observed before quantitative changes in the leukogram, thus serving as a harbinger of disease, and may be the only hematological change evident to indicate an infectious/inflammatory condition.[23] Toxic change can be present with a neutrophilia or a neutropenia and with or without a left shift. Toxicity is most frequently secondary to systemic rather than localized infectious/inflammatory conditions.[26,29]

Although both nuclear and cytoplasmic toxic changes occur, the cytoplasmic changes are more reliable and occur more frequently. Although all cell types are exposed to the same insult, toxic change is evaluated only in neutrophils. The type of toxic change is indicated and semiquantitated as either 1+ to 4+, or as slight, mild, moderate, or severe. Cytoplasmic toxic changes include diffuse cytoplasmic basophilia, cytoplasmic vacuolation, Döhle bodies, and toxic granulation, with the latter change infrequently observed. Diffuse cytoplasmic basophilia occurs when polyribosomes are retained in the cytoplasm. Cytoplasmic vacuolation generally occurs in association with diffuse basophilia (Fig. 49.2). The mechanism of cytoplasmic vacuolization is thought to stem from damage to the cell membrane and subsequent loss of integrity.[26,29] Döhle bodies are intracytoplasmic clumps of endoplasmic reticulum that stain a light blue with most Romanowsky-

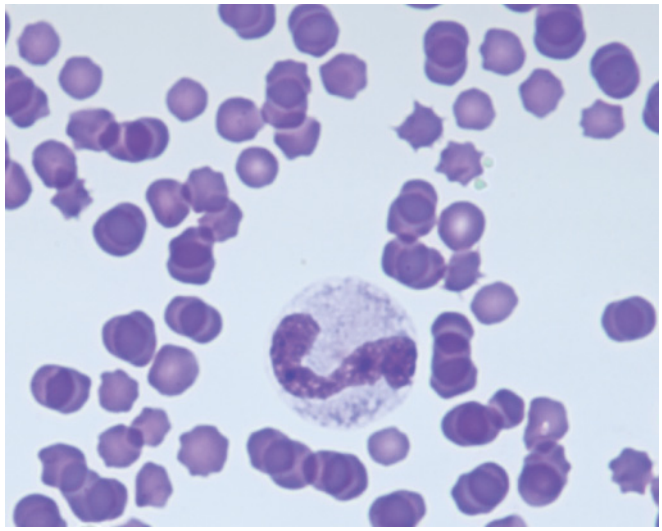

FIGURE 49.2 Feline neutrophil showing toxic change denoted by increased cytoplasmic basophilia, Döhle bodies, and foamy cytoplasm. Wright-stained blood smear. (Courtesy of IDEXX Reference Laboratories teaching files.)

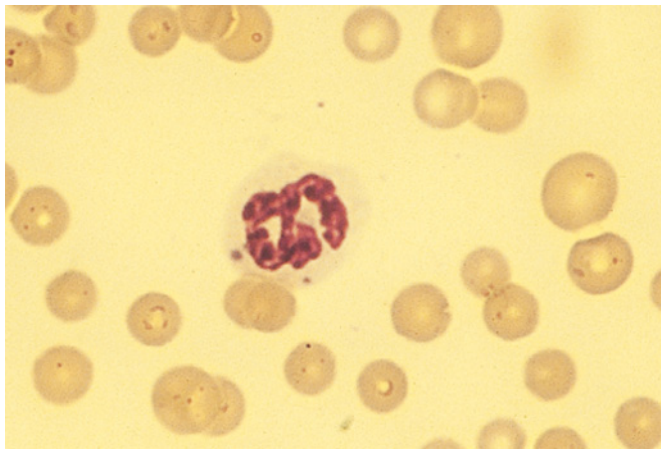

FIGURE 49.3 A feline neutrophil contains Döhle bodies. Wright-stained blood smear. (Courtesy of Oklahoma State University, College of Veterinary Medicine teaching files.)

type stains (Fig 49.3). Döhle bodies occur frequently in cat neutrophils. Regardless of the number of neutrophils containing Döhle bodies, their presence should never be interpreted as indicating anything more than a mild toxic change. Toxic granulation occurs when primary granules within neutrophils retain sufficient amounts of mucopolysaccharide so that these granules stain reddish-purple. Nuclear toxic changes can include: vacuolization, hyposegmentation, ring formation, karyorrhexis, karyolysis and giant neutrophils.[26,29]

Pelger-Huët Anomaly

Pelger-Huët anomaly is an inherited or acquired (pseudo Pelger-Huët) defect in granulocyte nuclear segmentation (see Chapter 42).[19,20,31] In Pelger-Huët anomaly, hyposegmented nuclei characteristically have a mature chromatin pattern, in contrast to nuclear hyposegmentation of infection where band cells have finely granular chromatin (Fig. 49.4). The lack of toxic change in the face of a significant degenerative left shift is also a hint to consider Pelger-Huët anomaly, and to carefully assess the nuclear chromatin pattern of the granulocytes. Neutrophil function is normal in affected cats, and cats with this anomaly are not predisposed to infection.

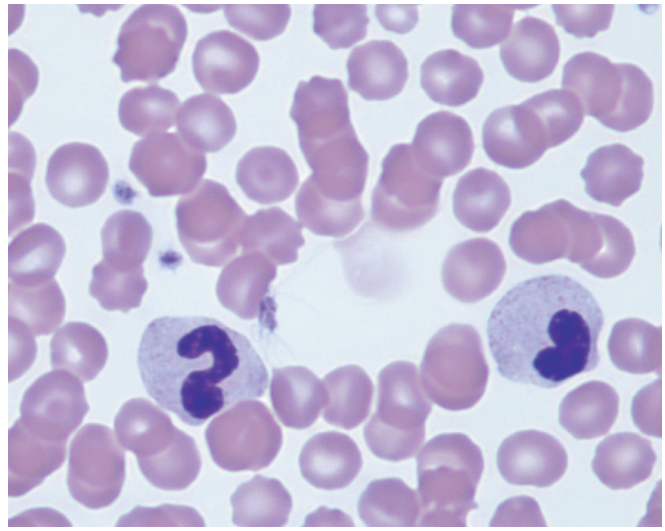

FIGURE 49.4 Pelger-Hüet anomaly. Two neutrophils show mature chromatin patterns and lack of segmentation. Wright-stained blood smear. (Courtesy of IDEXX Reference Laboratories teaching files.)

Hypersegmented Neutrophils

Hypersegmented neutrophils contain ≥5 distinct nuclear lobes. Hypersegmentation can occur as an in vivo aging change caused by prolonged blood transit time. More frequently, hypersegmentation, as well as pyknosis, represents an in vitro artifactual aging change that is seen in smears of EDTA-anticoagulated blood that has been allowed to sit for several hours.

Mucopolysaccharidosis

Mucopolysaccharidosis is a metabolic storage disease caused by inborn errors of mucopolysaccharide (glycosaminoglycan) metabolism.[6,7,10,11] Circulating neutrophils contain few to many coarse, reddish-purple, intracytoplasmic granules on Romanowsky-stained blood smears (Fig. 49.5). Basophilic granules frequently are enlarged and metachromatic.

Chédiak-Higashi Syndrome

This syndrome occurs in Persian cats (see Chapter 42).[15,16] Circulating neutrophils and lymphocytes contain

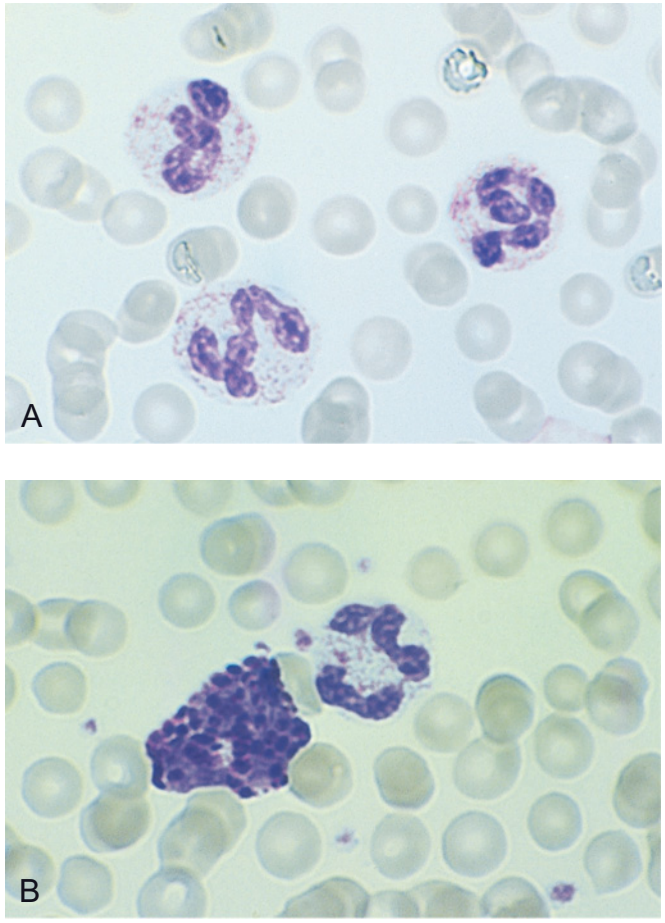

FIGURE 49.5 Blood smear from a cat with mucopolysaccharidosis type VI. (**A**) Three neutrophils contain granular, purple, intracytoplasmic inclusions. (**B**) A neutrophil with intracytoplasmic inclusions and a basophil with dark blue-black granules. Wright stain. single to multiple, pink to reddish, intracytoplasmic granules (Fig. 49.6). Eosinophilic granules also may be enlarged.

Cytoplasmic Vacuolization

Cytoplasmic vacuolization of neutrophils can be observed with drug toxicities including high doses of chloramphenicol or phenylbutazone. Also, cholesteryl ester storage disease is associated with subtle cytoplasmic vacuolation of neutrophils, lymphocytes, and monocytes on fresh blood smears.[28] Neutrophil cytoplasmic granulation is also seen after storage of blood in EDTA.

Neutrophil Granulation Anomaly

A neutrophil granulation anomaly has been identified in Birman cats (see Chapter 42). The anomaly is characterized by the presence of azurophilic cytoplasmic granules that resemble toxic granulation.[11] The anomaly is inherited as an autosomal recessive trait and is innocuous.

Intracellular Infectious Agents

Histoplasma capsulatum yeast can rarely be seen in blood and buffy coat leukocytes in cats with disseminated histoplasmosis (see Chapter 19). These organisms are identified by their small size and round shape. They are 2–4 µm in diameter with a darkly staining, eccentrically located nucleus and a thin clear cell wall that resembles a halo (Fig. 49.7). The presence of intracellular bacteria is uncommon, and could be consistent with contamination of the specimen or with sepsis. Correlation with clinical signs, history, laboratory data, and results of blood culture are necessary to distinguish between these differentials. One or more morulae of *Ehrlichia* spp. are rarely identified in the cytoplasm of circulating neutrophils or monocytes in cats (see Chapter 31). Morulae are found in cytoplasmic vacuoles, are round with an approximate diameter of

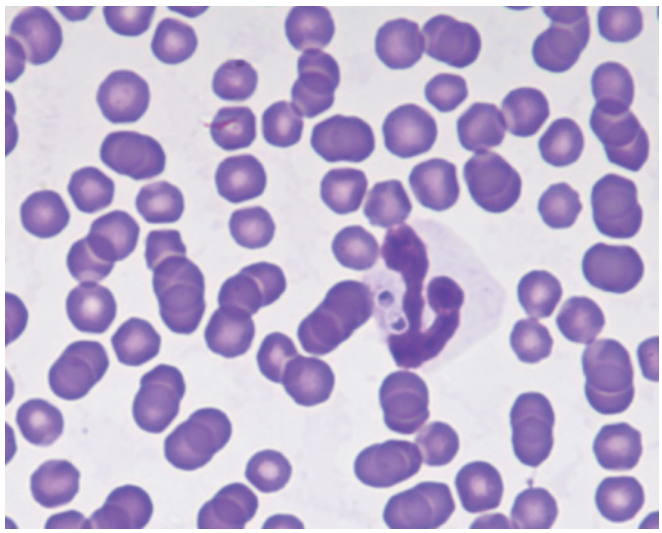

FIGURE 49.7 Feline neutrophil with two intracellular yeast forms of *Histoplasma capsulatum*. Wright-stained blood smear. (Courtesy of IDEXX Reference Laboratories teaching files.)

1.5–4 μm, and are composed of many small intracellular organisms that stain basophilic with Wright stains.

Intracellular Pigment

Rarely in hemolytic anemia, circulating sideroleukocytes can be identified. Sideroleukocytes are neutrophils and occasionally monocytes with intracellular hemosiderin, staining either brown-yellow, or blue-green on Romanowsky-stained blood films. The presence of intracellular hemosiderin can be confirmed with iron stains.

Neutrophilia

As previously stated, blood neutrophil counts may be increased by physiologic leukocytosis, corticosteroid-induced leukocytosis or pathologic mechanisms. Inflammation is the most common cause of a pathologic neutrophilia. Inflammation may stem from infectious or noninfectious origins. Infectious disease processes include bacterial, viral, fungal, and parasitic infections that can be localized or generalized (systemic).[18] The magnitude of the neutrophilia and the presence or absence of a left shift depends on the severity and duration of disease, as well as the competence of the bone marrow to produce and release neutrophils. With prolonged duration, localized inflammatory processes may result in very high neutrophil counts. These cases are frequently associated with a left shift and toxic change of neutrophils. Occasionally, the inflammatory nidus is obscure. In such cases, exudative loss of neutrophils into large-surface areas should be considered. Such sites of loss include the skin, gastrointestinal tract, genitourinary tract, respiratory tract, and joints. Surgical removal of the inciting cause (e.g. abscess) often results in a transient increase in neutrophil numbers due to granulocytic hyperplasia in the bone marrow. Medical treatment involving the administration of glucocorticoids may induce a transient glucocorticoid (stress) leukogram. Generalized or systemic infectious processes also can cause a neutrophilia, but the magnitude of the neutrophilia is generally less severe than localized infectious processes. Some specific examples include feline viral rhinotracheitis and feline infectious peritonitis. These diseases infrequently present with neutropenia.

Various noninfectious causes of tissue necrosis can induce mild to moderate neutrophilia. Any process that leads to tissue necrosis can result in an inflammatory response. As expected, the magnitude of the neutrophilia and the presence of a left shift depend on disease severity and chronicity. A few examples include soft-tissue trauma, immune-mediated diseases (e.g. hemolytic anemia), hemorrhage, and nonleukemic neoplasia.

Neutropenia

Neutropenia (<2500 neutrophils/μL) can result from several causes and various mechanisms.[9] General mechanisms of neutropenia include increased tissue use or destruction in which neutrophil egress or loss exceeds bone marrow production, decreased bone marrow production or release of neutrophils, and redistribution or sequestration of neutrophils. A single cause (e.g. endotoxemia) may act by several different mechanisms to produce neutropenia.

Increased Use or Destruction

When tissue demand for neutrophils exceeds replacement by the bone marrow, neutropenia occurs. Acute inflammatory processes frequently cause massive emigration of neutrophils into tissue. Acute or peracute bacterial infection of highly vascular organs is the most frequent cause of increased tissue use of neutrophils in cats. With time, inflammatory responses secondary to bacterial infections generally progress to a neutrophilic leukocytosis, assuming there is adequate bone marrow response. Endotoxemia, associated with bacterial infections, induces a neutropenia by several mechanisms. Neutrophil circulation time is decreased and egress into tissues is enhanced. Endotoxemia also activates complement and production of complement fragment C5a induces intravascular neutrophil aggregation (leukoagglutination) and subsequent neutrophil destruction. In addition, excessively high body temperature (e.g. heatstroke) may result in the destruction of neutrophils and neutrophil precursors in the bone marrow.

Deficient Production

Decreased bone marrow production of neutrophils can occur secondary to variety of causes. Basic mechanisms include hemopoietic stem cell death, seen with certain infectious agents (e.g. FIV, FeLV and feline parvovirus; see Chapter 19) and some drugs (e.g. chloramphenicol,

cytotoxic drugs; see Chapter 16), as well as myelophthisic diseases (e.g. neoplasia and myelofibrosis) with subsequent loss of hemopoietic space. Although bone marrow suppression usually involves all hemopoietic elements (pancytopenia), the earliest change in the blood is a neutropenia.

Approximately 50% of cats that have FeLV-related illness present with a neutropenia and are leukopenic (see Chapter 60).[9,18,22] Three FeLV-associated leukogram patterns have been described. A mild neutropenia with normal marrow cellularity is the most frequent form. A moderate to severe neutropenia, with concurrent marrow granulocytic hypoplasia is referred to as a panleukopenia-like syndrome. Presentation with a severe, persistent neutropenia and concurrent bone marrow granulocytic hyperplasia with dysplastic changes has been referred to as myelodysplasia (see Chapter 66). Mechanisms of neutropenia include virus-induced stem cell destruction, and retarded maturation, survival, and release of neutrophils from the bone marrow. Cyclic hemopoiesis, characterized by a neutropenia with cycle lengths ranging from 8 to 16 days, has been documented in FeLV-positive cats.[27] Neutropenia has been seen in cats infected with FIV, an immunosuppressive retrovirus (see Chapter 55).

Administration of drugs including chemotherapeutic drugs and chloramphenicol, can induce neutropenia in cats by suppression of bone marrow granulopoiesis (see Chapter 16). Toxic changes, notably Döhle bodies and cytoplasmic vacuolation, can be present in blood neutrophils. Chloramphenicol toxicity is seen with high dosages or with chronic administration of lower dosages.[30]

Neutropenia can be seen with many myelophthisic diseases, including leukemias, certain granulomatous inflammatory conditions (i.e. disseminated histoplasmosis), metastatic neoplasms, myelofibrosis, and osteosclerosis (i.e. bone deposition, see Chapter 18). Myelophthisic diseases frequently affect other hemopoietic cell lines, resulting in a panleukopenia (nonregenerative anemia, thrombocytopenia, and leukopenia). Examination of a bone marrow aspirate and core biopsy may provide a definitive diagnosis when myelophthisic disease is suspected.

Ehrlichiosis in cats is associated with neutropenia, usually with concurrent anemia and thrombocytopenia (see Chapter 19). Intracellular *Ehrlichia* morulae are uncommonly identified in neutrophils and monocytes. Bone marrow findings are consistent with hypoplasia with evidence of dysplasia.[2]

Redistribution and Sequestration

Pathologic processes may cause sequestration or shifts in neutrophil populations. Early endotoxemia enhances margination of circulating neutrophils, and a rapid, marked neutropenia may ensue after initial endotoxin exposure. This effect is transient, and frequently is followed by a neutrophilia within 1–3 hours.[18] Sequestration of neutrophils may be seen post-transfusion or with processes such as hypersplenism.

MONOCYTE RESPONSES

The bone marrow does not contain a storage pool of monocytes. Thus, the bone marrow transit time is short, approximating 1–2.5 days. After monocytes enter the blood, they exit the vasculature randomly. The blood half-life of monocytes is 8.4 hours.

Monocytosis

An absolute monocyte count >850 cells/μL is considered a monocytosis.[9,18] Monocytosis is a nonspecific finding that has been reported to occur in approximately 11% of the leukograms of hospitalized cats.[18] Monocytosis is not a characteristic feature of the stress leukogram in cats as it is in dogs. Monocytosis occurs in many conditions, including both acute and chronic inflammation, tissue destruction, and neutrophilia. Some of the reported causes of a monocytosis include trauma-related injuries, suppuration, necrosis, pyogranulomatous inflammation, hemolysis, hemorrhage, malignancy, and immune-mediated disorders.

Monocytopenia

Persistent monocytopenia is clinically unimportant in cats and is seldom documented, because the low end of the reference interval is zero cells/μL of blood. With severe leukopenia, the clinical focus is on neutropenia and prevention of sepsis; little attention is given to coexisting monocytopenia.

LYMPHOCYTE RESPONSES

Lymphocytes are the second most frequent leukocyte in the blood of healthy cats. Most blood lymphocytes are small-sized, long-lived, T cells that are capable of recirculation. Antigenically-stimulated lymphocytes (e.g. reactive lymphocytes) are larger and have more abundant, dark-blue cytoplasm. Rarely, immune-stimulated lymphocytes may exhibit plasmacytoid differentiation. Such cells have a round, eccentric nucleus with coarse nuclear chromatin; abundant dark-blue cytoplasm; and a pale-staining Golgi zone located between the nucleus and the largest volume of cytoplasm. Granular lymphocytes, that are natural killer cells and in the null cell group, may be observed. These cells are identified by distinctive azurophilic granules, usually in the vicinity of the nuclear indentation. In contrast, lymphoblasts (immature lymphocytes) are large lymphocytes (equal to or larger than neutrophils) with finely stippled nuclear chromatin and multiple, prominent nucleoli. Lymphocyte vacuolation has been associated with cholesteryl ester storage disease of Siamese cats and mannosidosis of Persian cats.[21,28]

Lymphocytes are evaluated by their morphology and absolute number. Blood lymphocyte numbers are influenced by physiologic states, disease, and drug administration, causing changes in lymphocyte

production, distribution, margination, recirculation, sequestration, destruction, or loss.

Lymphocytosis

Lymphocytosis (>7000 lymphocytes/μL) can be secondary to epinephrine-mediated physiologic leukocytosis, hypoadrenocorticism, chronic antigenic stimulation (e.g. FeLV), hyperthyroidism, or lymphoid neoplasia. Young animals also have higher absolute lymphocyte counts compared to middle-aged or old cats.[9] Young, healthy cats (especially those <1 year of age) are especially prone to lymphocytosis secondary to excitement or fear (physiologic leukocytosis). With physiologic leukocytosis, the absolute lymphocyte count is usually less than 20,000 lymphocytes/μL but has been reported to exceed 36,000 lymphocytes/μL.[18] Physiologic lymphocytosis is caused by epinephrine and is short lived. If another blood sample can be collected from the cat after it has been allowed to calm down, the absolute lymphocyte count should be within the reference interval, allowing differentiation from a pathologic cause of lymphocytosis. Lymphocytosis also is present in 20% of cats that have glucocorticoid deficiency (hypoadrenocorticism).[18]

Chronic antigenic stimulation causes lymphocyte proliferation and may result in lymphocytosis. An example of chronic antigenic stimulation is the lymphocytosis seen with FeLV-associated peripheral lymph node hyperplasia. Lymphocytosis also may be seen a few days post-vaccination. Reactive lymphocytes (immunocytes) are a more frequent finding with antigenic stimulation than is lymphocytosis. Reactive lymphocytes, when present, must be differentiated from atypical (immature) lymphocytes that would suggest lymphoid neoplasia.

Lymphopenia

Lymphopenia is recognized by an absolute lymphocyte count of less than 1,500 lymphocytes/μL of blood in adult cats or less than 2,500 lymphocytes/μL of blood in young cats.[9,18] The most frequent cause of lymphopenia is corticosteroid-induced redistribution of lymphocytes. Some other causes include viral infections (e.g. panleukopenia, FeLV, and FIV), septicemia or endotoxemia, lymphocyte-rich thoracic effusions (chylothorax from thoracic duct rupture, cardiovascular disease, nonexfoliating neoplasia, malignant lymphoma, or thymoma), and gastrointestinal disease (e.g. ulcerative enteritis, granulomatous enteritis, malignant lymphoma, and other neoplasias).

EOSINOPHIL RESPONSES

Like neutrophils, the bone marrow has a storage pool of eosinophils. Eosinophils have many functions, including the destruction of parasites, the modulation of hypersensitivity reactions, and a proinflammatory function.

Eosinophilia

The absolute number of eosinophils that constitutes an eosinophilia varies by geographic areas, but it generally represents absolute eosinophil counts in excess of 750–1,500 eosinophils/μL. Some causes of eosinophilia include hypersensitivity or inflammatory lesions (e.g. ulcerative gastroenteritis, food allergy, flea allergy dermatitis, atopy, eosinophilic keratitis, feline eosinophilic granuloma complex, bronchial asthma), parasites (endoparasites and ectoparasites), idiopathic hypereosinophilic syndrome, FeLV-associated eosinophilia, tumor-associated eosinophilia (mast cell neoplasia, carcinomas, malignant lymphoma, myeloproliferative disease)[1,4,17,24] and miscellaneous conditions (e.g. hyperthyroidism and hypoadrenocorticism).[3,4,9,18] Eosinophilic leukemia and idiopathic hypereosinophilic syndrome result in a marked eosinophilia (>50,000 eosinophils/μL).[5]

Eosinopenia

Eosinopenia is difficult to recognize clinically because the lower end of the reference interval for feline eosinophil counts is 0 cells/μL. Eosinopenia usually is associated with exogenous administration or stress-related endogenous release of glucocorticoids. Acute infections are associated with eosinopenia, but this is likely glucocorticoid-induced.

BASOPHIL RESPONSES

Basophils are the least numerous of the blood leukocytes in healthy cats, accounting for less than 2% of the leukocyte differential count.[18]

Basophilia

A basophilia is recognized by an increased absolute basophil count (>200 basophils/μL) and generally occurs with a concomitant eosinophilia. Some causes of basophilia in cats include allergic respiratory conditions, heartworm disease, eosinophilic granuloma complex, basophilic leukemia, myeloid leukemia, mast cell neoplasia and polycythemia vera.[3,9,18]

Basopenia

Basophils are rarely observed in blood smears of cats; basopenia is not a recognized clinical problem.

LEUKEMIAS (MYELOPROLIFERATIVE AND LYMPHOPROLIFERATIVE DISORDERS)

In depth discussion, including pathogenesis, classification, general and detailed features of acute and chronic myeloid and lymphoid leukemias can be found in Section V. Leukemias and myeloproliferative disorders (MPDs) originate in the bone marrow. Most of the MPDs and leukemias in cats are FeLV-associated and

some also have been associated with FIV infection. Myeloproliferative disorders include neoplastic proliferation of granulocytes, monocytes, erythrocytes, and megakaryocytes. The acute MPDs include acute undifferentiated leukemia and the acute myeloid leukemias (French-American-British classification M1–M7).[8] Chronic MPD categories include chronic myeloid leukemias, polycythemia vera, idiopathic myelofibrosis, myeloid metaplasia, and essential thrombocythemia.[8]

Leukemias are encountered less frequently than lymphoma in the cat.[8] Cats that have leukemia generally have vague and variable clinical signs, including anorexia, loss of body mass, and lethargy. Clinical findings often include organomegaly, anemia, fever, emaciation, and petechiae.[18] Leukemia usually is associated with a high total WBC count, but it occasionally may present with a normal WBC count or leukopenia. In chronic leukemias composed of well-differentiated cells, the type of leukemia often can be identified by examination of Wright-stained blood and bone marrow smears. However, in acute leukemias, blast cells can appear similar morphologically.[14] Therefore, immunophenotypic assessment may be needed to identify the neoplastic cell line.[14]

Granulocytic, myelomonocytic, and monocytic leukemias all occur in cats. Granulocytic leukemia must be differentiated from a leukemoid response or extreme neutrophilic leukocytosis secondary to an inflammatory focus (e.g. infection and tumor with a necrotic center).

Eosinophilic leukemia is rare and difficult to differentiate from idiopathic hypereosinophilic syndrome. Basophilic leukemia also is rare and should not be confused with mast cell neoplasia. In cats, mast cell neoplasia usually is associated with splenic enlargement or gastrointestinal involvement and with circulating mast cells.

Lymphoproliferative disease includes acute lymphoblastic leukemia and chronic lymphocytic leukemia. The latter is characterized by many small, well-differentiated lymphocytes, and must be differentiated from a physiologic lymphocytosis and from a reactive lymphocytosis secondary to antigenic stimulation.

MYELODYSPLASTIC SYNDROMES

Hallmarks of myelodysplastic syndromes (MDSs) are: ineffective hematopoiesis leading to peripheral cytopenias and evidence of dysplasia in the peripheral blood or bone bone marrow (Fig. 49.8; see Chapter 66).[32] Some cases of MDS in the cat occur secondary to FeLV infection, resulting in retroviral induced mutations in bone marrow stem cells. MDS in the cat is most frequently associated with a moderate to severe anemia, but bicytopenia and pancytopenia are common.[12] Dysplastic changes observed in peripheral blood neutrophils can include: giant neutrophils, ring-shaped nucleated neutrophils, and hypersegmented neutrophils.[12,25] Transition into acute myeloid leukemia is frequent in some types of MDS.

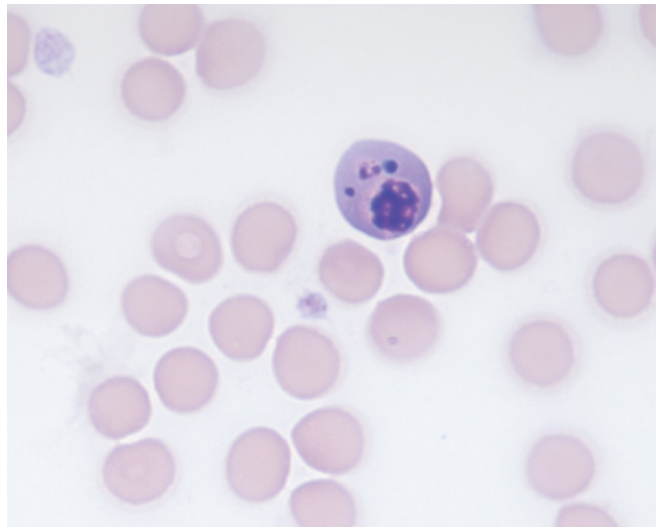

FIGURE 49.8 Blood smear of a dysplastic nucleated RBC. Wright stain. (Courtesy of IDEXX Reference Laboratories teaching files.)

APLASTIC PANCYTOPENIA (APLASTIC ANEMIA)

Similar to MDS, aplastic anemia results in peripheral cytopenias; however, the marrow is severely hypocellular or acellular and the hematopoietic space is replaced by adipose tissue (see Chapter 39). Etiologies of aplastic pancytopenia in the cat include: infectious agents (*Ehrlichia* sp., parvovirus, FeLV, FIV), drugs (chemotherapeutics, sulfadiazine, griseofulvin, albendazole) and idiopathic causes.[32]

New Techniques for Assessment of Avian Leukocytes

Acronyms and Abbreviations

ACTH, adrenocorticotropic hormone; CBC, complete blood count; EDTA, ethylenediamine tetraacetic acid; H:L, heterophil:lymphocyte ratio; WBC, white blood cell.

Mammalian hematology has advanced rapidly over the past three decades owing to the introduction of semi-automated or automated technology (that provides a total leukocyte count and complete or 2- or 3-part differential leukocyte count). Published literature exists detailing clinical hematologic responses to disease in mammalian species. In contrast, avian hematology is still in its infancy. Descriptive accounts of avian blood-cell morphology[9,39,42,44] and techniques of performing avian white blood cell (WBC) counts[10,21,57,77] have been published. However, the progress of avian hematology has been inhibited by lack of automated technology, lack of appropriate reference intervals for most major avian species, and lack of carefully controlled experimental studies to interpret avian WBC responses. Presented in this chapter is a brief overview of avian WBCs with respect to quantitation of WBC data, establishment of reference intervals, and interpretation of WBC responses in health and disease. Much of the research to date has been done in domestic poultry, which provides a model for avian WBC development and function.[43] Although generalizations can be drawn concerning avian leukocyte production, morphology, function, and response in health and disease, differences are sometimes apparent among and between species of birds.

LEUKOCYTE COUNT

In avian hematology, only the red blood cell (RBC) count can be determined routinely by automated methods (electronic particle counter).[21] Therefore, three manual approaches are used to determine or estimate the WBC count. These include (1) the direct WBC count with a hemacytometer and Natt and Herrick's solution, (2) the indirect WBC count using a hemacytometer and eosinophil Unopette® in conjunction with the stained blood smear, and (3) the estimated WBC count using the stained blood smear. Specific technical procedures for these counting methods can be found in the literature.[9,22,33,36,77]

The avian WBC count can be determined directly with a Neubauer-ruled hemacytometer, pipettes, and methyl violet 2B diluent.[57] The advantage of this technique is that all WBCs are visualized and enumerated. The disadvantages are that this WBC counting technique is labor intensive, care must be taken to differentiate thrombocytes from small lymphocytes, and WBCs may distort if analysis of the diluted specimen is delayed.[43] This method works well for an in-house laboratory but may prove difficult with samples that are mailed to a diagnostic laboratory. In the latter instance, prolonged exposure to ethylenediaminetetraacetic acid (EDTA) anticoagulant can cause erythrolysis and viscosity changes of hematologic specimens from crowned cranes, crows, jays, brush turkeys, hornbills, magpies, and some ratites.[21,64] In addition, WBC morphology can be altered upon prolonged exposure to EDTA. Specimens collected in heparin eventually clot, and heparin also interferes with Romanowsky staining of blood smears.

The WBC count can be quantitated indirectly with the eosinophil Unopette #5877 system. In this technique, heterophils and eosinophils are selectively stained by phloxine dye and counted in a hemacytometer.[10,65] Based on the WBC differential cell count of a stained blood smear, the combined heterophil and eosinophil hemacytometer count is mathematically corrected to account for basophils and mononuclear cells (i.e. lymphocytes and monocytes) that were not counted. Thus, the total WBC count per microliter of blood has been determined indirectly. Advantages of this system are that heterophils and eosinophils are directly identified and counted in a hemacytometer. There also is no confusion between lymphocytes and thrombocytes because they are not counted with the hemacytometer. However, hemacytometer counts are labor intensive, a greater potential for mathematical errors exists, and WBC distribution on stained blood smears may not be random.

One can estimate WBC counts from the stained blood smear by multiplying the average number of WBCs per field of view by a given factor (the factor is usually 1,500 for the 40× to 45× high-dry microscope objective or 2,000 for the 50× oil-immersion microscope objectives, respectively). Advantages of this technique include the stability of the blood film and the labor-efficient process of WBC count estimation. The major disadvantage is that the WBC count is estimated instead of quantitated. Thus, estimated WBC counts may not be reproducible, poor smear technique may influence the estimate because of cell lysis or maldistribution. Coefficient of variation for hemacytometer-derived WBC counts (eosinophil Unopette method) are 12.7% as opposed to 28% for estimated WBC counts from stained blood smears.[68] However, the latter technique may be useful to indicate hematologic trends for which the lability or volume of the blood specimen would otherwise preclude hematologic study. Ultimately, the future of avian hematology depends on the development of semi-automated or automated techniques to determine avian WBC counts in a rapid, accurate, economical, and labor-efficient manner.

STAINED BLOOD SMEAR

The stained blood smear is used to perform the WBC differential cell count and morphologic examination of WBCs. Although considerable discussion has revolved around the best method to produce acceptable avian blood smears, both the wedge technique (with two glass slides) and coverslip technique (with two square glass coverslips) can be used. The major factors in producing high-quality smears are manual dexterity and practice.

It is generally assumed that WBCs are randomly distributed in blood smears, which may not be the case. Hematologic studies have shown that WBCs are more randomly distributed in coverslip smears than in wedge smears where large cells, such as monocytes, tend to be carried to the lateral margins and feathered edge of the smear. Furthermore, this problem is magnified with poor smear technique. Depending on the type of smear and the method of examination, WBC differential counts may vary. The accuracy of the WBC differential count can be increased by counting more cells. To increase the accuracy of the differential count significantly, one must perform a 400-cell count as opposed to 100 cell WBC differential count.

In summary, the smear quality directly influences the accuracy of the differential cell count and estimated WBC counts. Also, smears that are made at the time of blood specimen collection reflect the morphologic changes in WBCs at that point. If smears are made from the blood specimen at a later time, potential artifacts include increased numbers of smudge cells, distortion of WBCs and thrombocytes, vacuolation of monocytes, swelling of lymphocytes, and changes in WBC tinctorial properties.[43]

LEUKOCYTE DIFFERENTIAL COUNT

White blood cell morphology may vary between species of birds (see Chapters 122–125). Examples include the appearance of granule morphology and cytoplasmic coloration of raptor eosinophils[4] and the shape of heterophil granules in certain species of birds.[7] With currently accepted criteria of WBC identification,

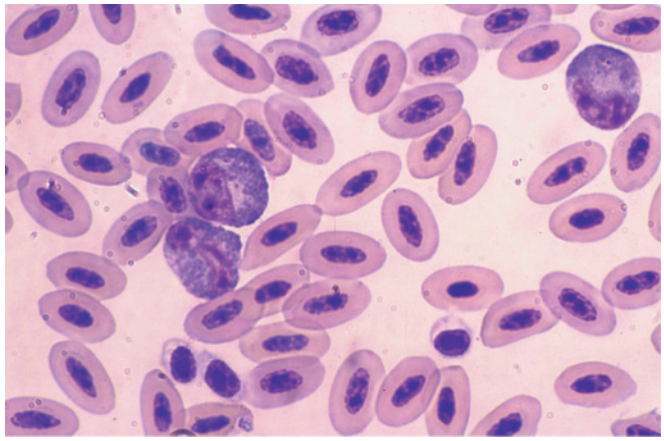

FIGURE 50.1 Blood smear from an African grey parrot. A left shift is indicated by the presence of immature heterophils (band, metamyelocyte, and myelocyte). All of these cells display mild toxic change (cytoplasmic basophilia).

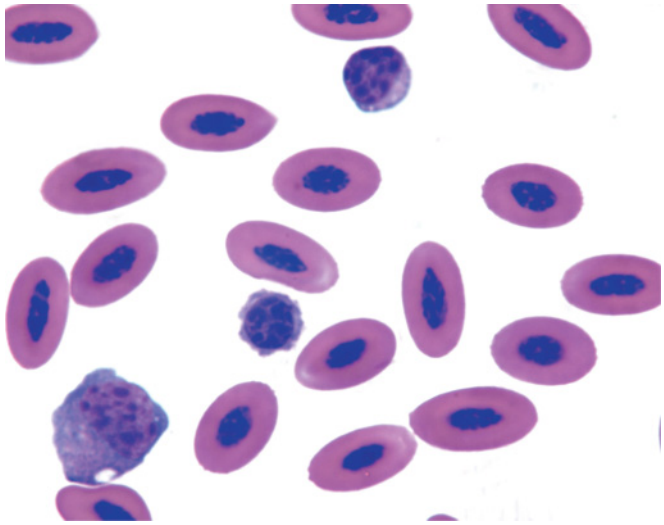

FIGURE 50.2 Blood smear from a great horned owl. A monocyte (lower left), thrombocyte (center), and lymphocyte (top) are present.

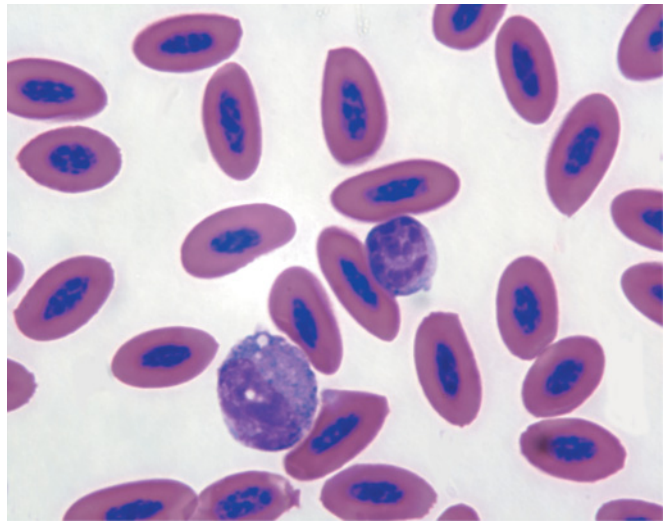

FIGURE 50.3 Blood smear from a great horned owl. A monocyte (lower left) and lymphocyte (upper right) are present.

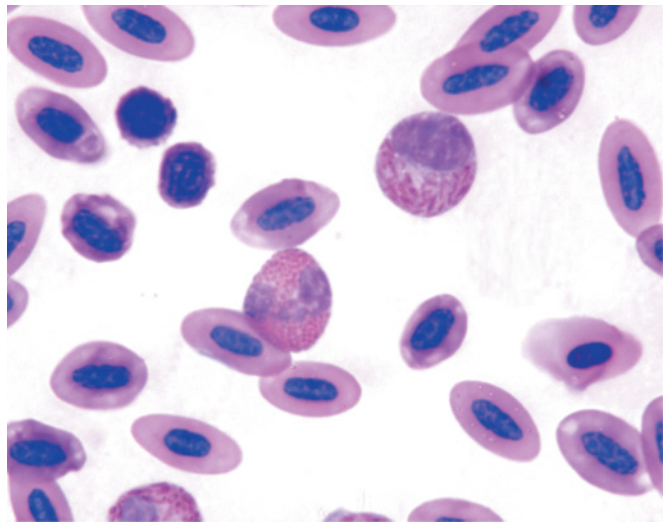

FIGURE 50.4 Blood smear from a red-tailed hawk. The myelocytic heterophil (top right) has needle-shaped, dull red granules, whereas the eosinophil (left) has round, bright, red-orange granules.

performance of the WBC differential count in healthy and sick birds may be challenging and requires practice. Problems may be encountered in identifying left shifts in the heterophil population[43] (Fig. 50.1) and in distinguishing some small lymphocytes from thrombocytes[73] (Fig. 50.2), monocytes from large lymphocytes (Fig. 50.3), reactive lymphocytes from rubricytes,[5] heterophils from eosinophils[21,42] (Fig. 50.4), and extremely toxic promyelocytes (mesomyelocytes) from basophils[68] (Fig. 50.5).

Detection of left shifts in avian blood is more difficult because avian heterophils have less nuclear segmentation than mammalian neutrophils.[43] Furthermore, heterophil granules tend to obscure nuclear morphology in Romanowsky-stained blood smears. With these preparations, only marked left shifts can be easily identified (Fig. 50.1). The presence of promyelocytes, that contain both basophilic and eosinophilic granules,[28] indicates an intense left shift[43] (Fig. 50.5). Subtle left shifts can be accurately quantitated by examination of hematoxylin-stained blood smears in which the nucleus is stained but the granules remain unstained.[43] This technique permits determination of a nuclear lobulation score, a sensitive indicator of a left shift.

CHANGES IN LEUKOCYTE MORPHOLOGY

Changes in leukocyte morphology are important observations that permit assessment of the severity of the disease process. Occasionally, morphologic changes in leukocytes may provide a definitive medical diagnosis.

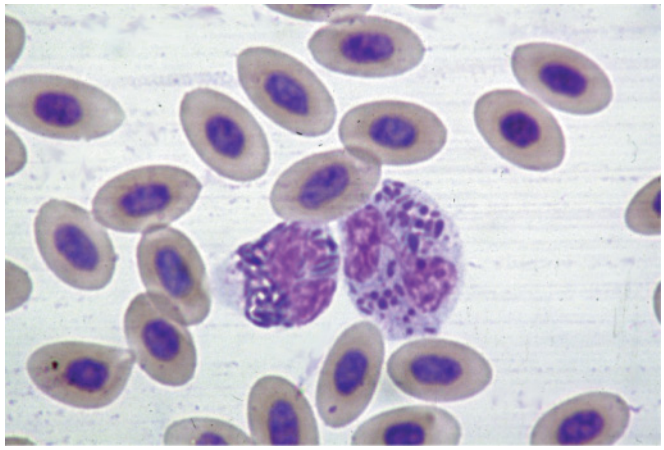

FIGURE 50.5 Blood smear from a chicken. Segmented heterophil and toxic heterophil promyelocyte. Note purple and red granules in the promyelocyte.

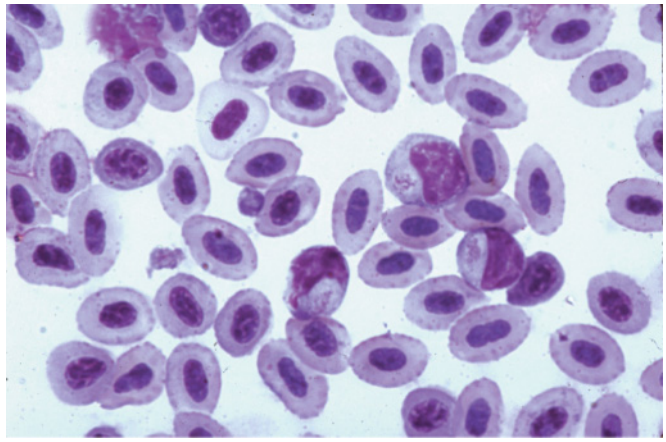

FIGURE 50.7 Blood smear form a Bali mynah that has disseminated toxoplasmosis. Note round to oval intracytoplasmic organisms in the mononuclear cells.

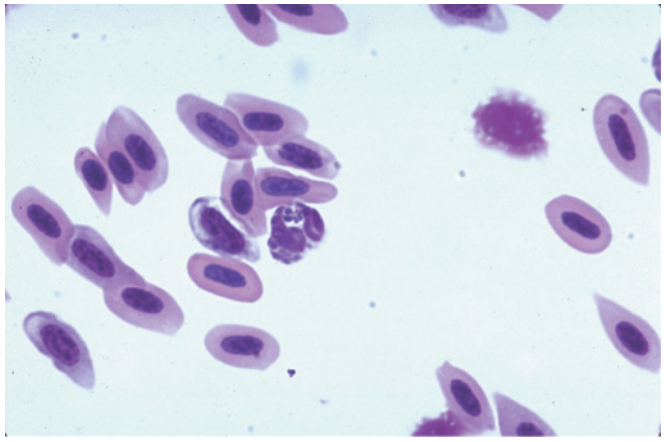

FIGURE 50.6 Blood smear from an Amazon parrot that has septicemia. Note the phagocytosed bacterial cocci within a heterophil.

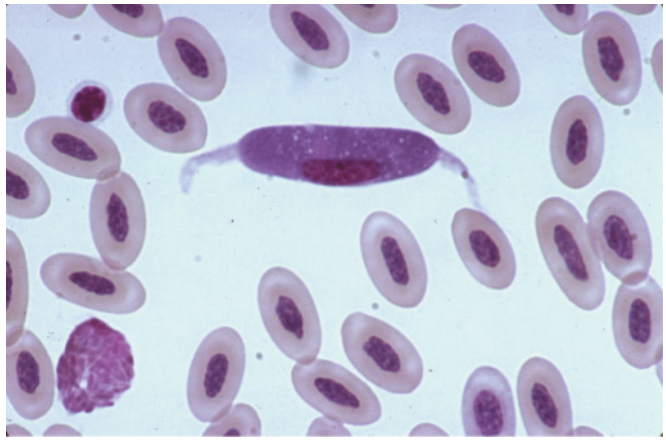

FIGURE 50.8 Blood smear from a great horned owl. *Leukocytozoon* sp. gametocyte is present in a leukocyte. The affected cell is enlarged, elongated, and has pointed cell margins.

Toxic Changes

Variable degrees of degranulation, cytoplasmic basophilia, cytoplasmic vacuolation, and cellular swelling constitute toxic changes in avian heterophils[40] (Figs. 50.1 and 50.5). Ultrastructurally, cellular swelling and cytoplasmic vacuolation are the result of intracellular edema. Degranulation is a sequel to dissolution of the granule matrix. Cytoplasmic basophilia is explained by the persistence of ribosomes. In Romanowsky-stained avian blood smears, cytoplasmic basophilia is the last manifestation of toxic change to disappear with convalescence.[40]

Infectious Disease

Inclusions in avian WBCs are seen infrequently but may provide a definitive diagnosis when observed. Examples include phagocytosed bacteria in heterophils of septicemic birds (Fig. 50.6), *Atoxoplasma* sp. organisms in the cytoplasm of monocytes (Fig. 50.7), *Leukocytozoon* sp. organisms in the cytoplasm of WBCs or erythrocytes (Fig. 50.8), and elementary bodies of *Chlamydophila psittaci* in the cytoplasm of various WBCs (Fig. 50.9).

After exposure to antigens and stimulation of the immune system, scattered lymphocytes may become larger (a prelude to blast transformation or plasmacytoid differentiation) and have dark blue granular cytoplasm. Such cells are classified as reactive lymphocytes morphologically. In lymphoid neoplasia, the majority of lymphocytes may appear immature or reactive.

The clinician also should be familiar with stain-induced changes in cellular morphology. Stain-induced artifacts, such as degranulation and intensified cytoplasmic coloration of heterophils in Diff-Quik®-stained preparations, should not be mistaken for toxic changes.[43] Also, partial heterophil degranulation may leave a round granule core, causing affected cells to resemble eosinophils.[43,65] This condition is frequently seen with aqueous-based stains when short fixation times are

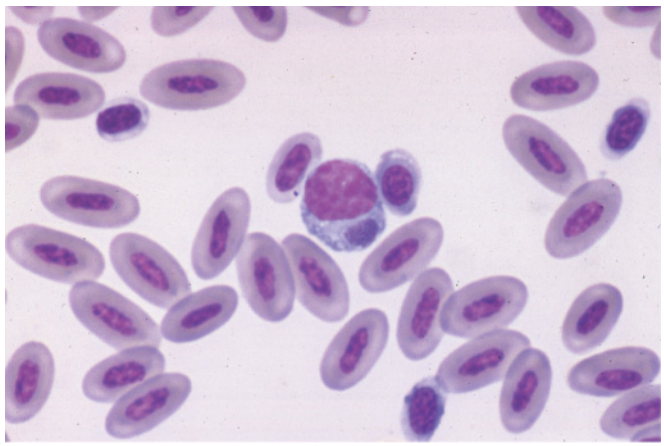

FIGURE 50.9 Blood smear from parrot that has chlamydiosis. Intracytoplasmic elementary bodies of *Chlamydophila psittaci* are present in a monocyte. (Courtesy of Dr. Michele Menard, Veterinary Cytopathology, Gresham, OR.)

used. Cytochemical staining has the potential to reliably distinguish heterophils from eosinophils for which cellular identification is uncertain.[3]

As avian hematology progresses, laboratories should undertake a coordinated effort to modernize avian leukocyte nomenclature, uniformly evaluate morphologic changes in blood cells, and consistently report semiquantitative hematologic data. Standardized guidelines will facilitate comparison of hematologic data between laboratories.

REFERENCE INTERVALS

Reference intervals are used to identify laboratory test results or values that discriminate between health and disease (see Chapter 131). Establishment of meaningful reference intervals requires data collection from an adequate number of individuals constituting a precisely defined population. The population must be defined precisely because test values can be influenced by species of bird, age, sex, health and reproductive status, diet, and climate or environment. In addition, the method of specimen collection and analytical technique can influence test results. With these intervals, laboratory test values suggestive of health or disease may be distinguished more reliably.

Reference intervals for various species of companion and exotic birds have been published in journals and textbooks. Several of these publications are especially noteworthy based on the large numbers of individuals sampled, a defined reference population, and attention to age-related changes in hematologic data.[19–23] Sometimes, avian clinicians are presented with ill patients that are rare exotic birds or juvenile birds of common species for which reliable reference intervals do not exist. In such cases, analysis of control blood samples from clinically healthy birds of the same species, age, sex, and environment permit identification of abnormal hematologic trends.[29–31,74]

HEMATOPOIESIS WITH EMPHASIS ON LEUKOCYTE PRODUCTION

Primitive cells in the yolk sac initiate blood-cell development during the first few days of embryonic incubation. Early erythroblasts are recognizable by day 5 in the developing lung, and their appearance precedes vasculogenesis.[45] By 10–15 days of incubation, hemopoietic activity peaks in the yolk sac and is widespread in other tissues, including bone marrow, liver, kidney, spleen, thymus, bursa of Fabricius, aorta, heart, pharynx, cranial nerves, spinal ganglia, subcutaneous tissues, and muscles.[47] Although the bone marrow is the major site of hematopoietic activity post-hatching, foci of hematopoiesis also may be observed in the liver, spleen, and kidney of companion birds.[69] In birds, extramedullary hematopoiesis is widespread and involves granulopoiesis, wherein the majority of the cells contain eosinophilic granules and nuclei in various stages of lobulation. Granulopoiesis is especially prominent in the liver, kidney, and spleen, but it may involve the heart and subdural spaces. Granulopoiesis, especially in the spleen, bursa, and thymus, involves production of heterophils.[47]

In bird bone marrow, granulopoiesis occurs in the extravascular spaces, whereas erythropoiesis and thrombopoiesis occur in the bone marrow vascular sinuses. Sites of hematopoiesis in birds involve nonpneumatized long bones and the axial skeleton. A practical example is acquisition of bone marrow aspirates from the tibia because the humerus and femur frequently are pneumatized. During early life, hematopoiesis is distributed throughout the skeleton, except for the skull.[63,70]

Lymphocyte production occurs in primary (thymus, bursa of Fabricius) and secondary (spleen; gut-associated lymphoid tissue, including cecal tonsils; bronchial-associated lymphoid tissues; paraocular tissues, including conjunctival-associated lymphoid tissue; paranasal sinuses, and miscellaneous lymphoid follicles along lymphatic vessels) extramedullary tissues. Lymphocytes are present in the thymus and bursa of the embryo by 10–14 days of incubation. As lymphopoiesis progresses, the secondary lymphoid tissues produce the majority of the lymphocytes, whereas the primary lymphoid tissues (thymus and bursa) involute with sexual maturity.

LEUKOCYTE FUNCTION AND RESPONSE IN HEALTH AND DISEASE

Interpretation of avian leukograms should be based on absolute leukocyte values per microliter of blood. This results in fewer erroneous interpretations compared to reliance on relative percentages alone.[39] Although diurnal rhythms of leukocyte counts have been demonstrated occasionally in birds (e.g. chickens),[35] these fluctuations have little effect on leukogram interpretations in a clinical setting.

Few scientifically-controlled studies have been performed to evaluate avian WBC responses.[43] Therefore, interpretation of avian leukograms has relied on extrapolations from the veterinary literature and individual clinical experience. Although hematologic studies of patients with spontaneous disease have increased our knowledge of avian hematology, precise interpretation of avian WBC responses is obscured by numerous variables and incomplete patient data concerning sample collection, method of analysis, restraint, drug administration, etc. The following discussion is intended to provide basic guidelines for leukogram interpretation.

HETEROPHIL OR LYMPHOCYTE PREDOMINANCE IN THE BLOOD IN STATES OF RELATIVE HEALTH

Birds are similar to rodents in that the primary circulating WBC in some species is the heterophil, whereas in other species the lymphocyte predominates. Examples of birds that have a predominance of heterophils include greater sulfur-crested cockatoos, herring gulls, hyacinth macaws, rainbow lorikeets, yellow-crowned Amazon parrots, African grey parrots, and pigeons. Examples of birds that have a predominance of lymphocytes include budgerigars, canaries, cockatiels, finches, rose-ringed parakeets, and many species of Amazon parrots. Hematologic studies of some species of adult birds, such as flamingos and white-naped cranes, are contradictory in that either heterophils or lymphocytes have been identified as the major circulating leukocyte in health. Possible explanations for these divergent observations include stress of capture, handling, caging, social interactions, and environmental conditions. These variables, singly or in combination, could induce heterophilia or lymphopenia, resulting in aberrant reference intervals.

Hematologic study of neonatal and juvenile birds indicates that heterophilic leukocytosis can be observed with some frequency.[15–17] The presumed mechanism for this observation is stress. Furthermore, some birds that have a predominance of lymphocytes in the adult leukogram frequently have a predominance of heterophils during the post-hatch and juvenile periods. Transition to the normal adult leukogram eventually occurs with age (generally 8–12 weeks of age), a similar process typically occurs in young ruminants by weaning age. Total WBC counts frequently are elevated post-hatch (a stressful period of neonatal life) and decrease with age.

From the discussion and examples given above, one can readily appreciate the need for reference intervals so that leukograms from birds of various species and ages are interpreted correctly. In the case of expensive or rare birds, an annual physical examination and CBC provide individual reference data to detect subtle changes in individual health status. This procedure is expensive, but has proven to be effective in human health care.

LEUKOCYTOSIS AND LEUKOPENIA

Leukocytosis

Leukocytosis, is frequently the result of physiologic processes, infection, or inflammation. Physiologic leukocytosis is precipitated by excitement, fear, forced flight, and excessive muscular activity. Increases in heterophils or lymphocytes may account for the leukocytosis. If the mechanism in birds mimics that of mammals, leukocytosis could be related to epinephrine release or muscular exertion, both of which cause increased cardiac output, increased blood pressure, and a washout of leukocytes from the microvasculature into the mainstream of circulation.

In inflammatory and infectious conditions of birds, heterophilia frequently is observed and the degree of heterophilia may be more pronounced than comparable neutrophilia in mammals.[13] Examples include acute chlamydiosis, mycobacteriosis, and disseminated mycosis where the total WBC count may exceed 100,000 cells/μL of blood. In the case of birds that have a predominance of lymphocytes such as chickens, a heterophil-lymphocyte reversal may be observed.[11,43] In some infectious conditions of birds, a lymphocytosis may be noted. An example is chronic chlamydiosis where the immune system has been stimulated as observed by plasmacytosis, which is most notable in the liver and spleen.

Leukopenia

Leukopenia in birds that have a predominance of heterophils usually is the result of heteropenia. In birds that have a predominance of lymphocytes, leukopenia often is synonymous with lymphopenia. Causes of leukopenia vary, depending on whether heterophils, lymphocytes, or both cell lines are affected. Specific causes of heteropenia and lymphopenia, including those mechanisms resulting in leukopenia, are discussed in detail below.

HETEROPHIL RESPONSES

Heterophils provide a first line of defense against infection (Table 50.1). Avian heterophils and mammalian neutrophils differ both morphologically and biochemically. Morphologically, avian heterophils are identified by the presence of large, dull red, frequently needle-shaped granules (Fig. 50.4). The presence of these eosin-staining granules has given rise to the term heterophil (*heteros* from the Greek meaning different), as opposed to the mammalian neutrophil whose granules are generally neutral in Romanowsky-stained blood smears. A left shift exists when excess band heterophils are present in the blood. Because avian heterophils are less segmented in health compared with mammalian neutrophils, identification of left shifts is more challenging in avian species.[43]

TABLE 50.1 Causes of Heterophilia and Heteropenia in Birds

Heterophilia	
Physiologic response	
Infection	Bacteria, viruses, fungi, parasites
Tissue destruction or necrosis	Thrombosis and infarction, inflammation
Drug administration	Corticosteroids, estrogen
Miscellaneous	Acute, severe stress, foreign bodies, hemorrhage or hemolytic disease
Heteropenia	
Infection	Overwhelming bacterial infection, viral-induced hemopoietic cell destruction
Drug administration	
Predictable	Cyclophosphamide, progesterone
Idiosyncratic	Piperacillin or doxycycline
Neoplasia	Leukemia, metastatic disease (disseminated lymphosarcoma), radiation exposure

Toxic changes of heterophils include cytoplasmic basophilia, cytoplasmic vacuolation, variable degranulation, and cellular swelling (Figs. 50.1 and 50.5). Toxic degranulation must be distinguished from stain-induced degranulation. Toxic degranulation is the result of severe inflammation or infection and is associated with cytoplasmic basophilia. Stain-induced degranulation results from partial or complete granule dissolution when heterophils on the blood smear are exposed to aqueous-based stains (such as Diff-Quik® stain) with a short fixation time.[43]

Biochemically, avian heterophils lack myeloperoxidase, an enzyme that is largely responsible for the efficient oxidative bactericidal activity of mammalian neutrophils.[3,62] A measurable oxidative burst has been observed for avian heterophils, but it is insignificant in bacterial killing. Avian heterophils accomplish effective nonoxidative bacterial killing by myeloperoxidase-independent methods with granule-derived proteins.[62] These substances include lysozyme, acid phosphatase, cathepsin, and β-glucuronidase (hydrolase) activities, and cationic proteins.[18,19] The cationic proteins include β-defensins (e.g. gallinacins, chicken heterophil antimicrobial peptides, and turkey heterophil antimicrobial peptides), which are natural antimicrobials.[71] In addition to bacteria, avian heterophils have been shown to kill yeast (e.g. *Candida albicans*).

Avian heterophil function (adherence, chemotaxis, phagocytosis, and bacterial killing) is fairly efficient in host defense against bacteria in conjunction with the humoral immune system.[4,5,6,38] Avian heterophil functions are less well understood than mammalian neutrophil function and constitute an area for future research.

Physiologic Heterophilia

One can observe physiologic heterophilia after excitement, fear, or short-term strenuous exercise (the fright or flight response). The heterophilia occurs rapidly but is transient. The presumed mechanism, based on studies in other species, is an epinephrine- or exercise-mediated increase in microvascular blood flow that shifts marginated heterophils into the mainstream of circulation. Concurrent lymphocytosis also may be observed and may overshadow the heterophilia, especially in those species that have higher lymphocyte counts in health. Because of the frequent occurrence of physiologic leukocytosis, it is wise to obtain hematologic specimens before the patient is unduly perturbed. Physiologic responses are frequently confused with stress leukograms where lymphopenia is expected.[20]

Corticosteroid-induced Heterophilia

Corticosteroid-induced heterophilia is observed sporadically in diseased or severely stressed birds and is the result of corticosterone release from the adrenal cortex. An example of developing heterophilia in response to forced confinement has been reported in captive herring gulls.[2,7] Corticosteroid-induced heterophilia is observed more frequently with exogenous corticosteroid administration or injection of adrenocorticotropic hormone (ACTH), which stimulates endogenous corticosterone release. The phenomenon is dosage and route dependent.[1] Developing or concurrent lymphopenia separates this response from physiologic leukocytosis.

Inflammation- or Infection-induced Heterophilia

Heterophilia is frequently observed in conjunction with tissue damage induced by inflammation or bacterial infection (including chlamydiosis).[2,7,43] Occasionally, the source of tissue damage provoking heterophilia may be obscure. Examples include hemorrhage, oxidant-induced RBC destruction, and lead poisoning.[34,41,46] Experimental studies have shown that significant heterophilia can occur within 6 hours of induced inflammation and that cell counts peak 4-fold greater than baseline values by 12 hours post-inflammation.[43] As bone marrow reserves of segmented heterophils are depleted, a left shift accompanied by toxic changes of heterophils may appear within 24 hours. The presence of promyelocytes (cells with round nuclei and a mixture of purple and red cytoplasmic granules) indicates an intense shift.[43] As the bone marrow responds to tissue demands for heterophils, the leukocytosis and heterophilia intensify. A return toward baseline values with disappearance of the left shift and toxic change indicates convalescence. In companion birds, total leukocyte counts may exceed 100,000 cells/μL in chronic chlamydiosis and mycobacteriosis, especially in gray cheek parakeets and macaws.

Heteropenia

The three most common mechanisms for production of neutropenia in mammals include deficient neutrophil production in the bone marrow, a shift in neutrophils

from the circulating to marginal cell pool, and emigration of neutrophils from the blood into the tissues at a rate that exceeds neutrophil replacement from the bone marrow.[39] Similar mechanisms undoubtedly exist in birds but have not received detailed study. However, anecdotal reports in the literature and personal observations tend to support these mechanisms.

Any instance of heteropenia suggests a guarded prognosis until favorable resolution of the condition can be ascertained by additional hematologic study.

Deficient Heterophil Production

Deficient heterophil production can be the result of hemopoietic stem cell destruction by infectious agents, drugs, or ionizing radiation and myelophthisis-associated loss of hemopoietic space.

Leukopenia and heteropenia have been reported in pet birds due to viral infections (herpesvirus, polyomavirus, and psittacine reovirus); however, such reports largely represent undocumented clinical or laboratory impressions.[24,25,66] Drug-induced myelosuppression may be predictable, as observed in cyclophosphamide-treated chickens and turkeys,[24] or may be an idiosyncratic adverse drug reaction, as observed in a budgerigar after antibiotic (piperacillin or doxycycline) treatment.[67] Toxic change of heterophils and vacuolation of hematopoietic precursor cells may be observed with drug toxicity.

Myelophthisis-associated loss of hematopoietic space is observed infrequently in clinical practice. In our experience, this cause of heteropenia has been associated with disseminated lymphoid neoplasia wherein proliferating neoplastic lymphocytes replace normal hemopoietic cells.

Heterophil Shifts from the Circulating to Marginal Pool

In mammals, early endotoxemia or Gram-negative sepsis results in a shift of neutrophils from the circulating to marginal cell pools where they are not quantitated by the WBC count. The neutropenia is transient (1–3 hours duration) and is followed by a rebound leukocytosis if the patient survives. This mechanism may occur in birds but is not well documented.

Severe Tissue Demands for Heterophils

Overwhelming tissue demand for heterophils at a rate that exceeds cell replacement by the bone marrow also produces heteropenia. Examples include acute severe peritonitis and necrotizing enteritis. Heteropenia may be accompanied by a degenerative left shift and toxic change of heterophils.

LYMPHOCYTE RESPONSES

As mentioned previously, lymphocytes may be the major circulating leukocyte in the blood of some avian species (Figs. 50.2 and 50.3). Characterization of the blood lymphocyte population in mammals indicates that the majority of these cells are small, mature, long-lived, memory T cells. This probably is the case in avian species. For example, chicken blood lymphocytes have shown to be approximately 14% B cells and 72% T cells by direct and indirect immunofluoresence, respectively.[60] The remaining blood lymphocytes (approximately 14%) are probably natural killer or null cells.

Lymphocytosis

Physiologic lymphocytosis represents a transient phenomenon in birds after excitement, fright, or struggling during venipuncture (Table 50.2). Lymphocytosis may overshadow any heterophilia. This response may be especially noticeable in healthy birds that have high circulating lymphocyte counts, and may be more prominent in young birds (Fig. 50.10).

TABLE 50.2 Causes of Lymphocytosis and Lymphopenia in Birds

Lymphocytosis	
Physiologic response	
Antigenic stimulation	Chronic viral infection, chronic bacterial infection, chronic fungal infection, parasitic diseases
Lymphoid neoplasia	Lymphosarcoma, lymphocytic leukemia
Lymphopenia	
Acute systemic infection	
Corticosteroid-induced	Exogenous corticosteroid administration
	Endogenous corticosterone release (acute, severe stress)
Immunosuppression	Immunosuppressive drugs, radiation

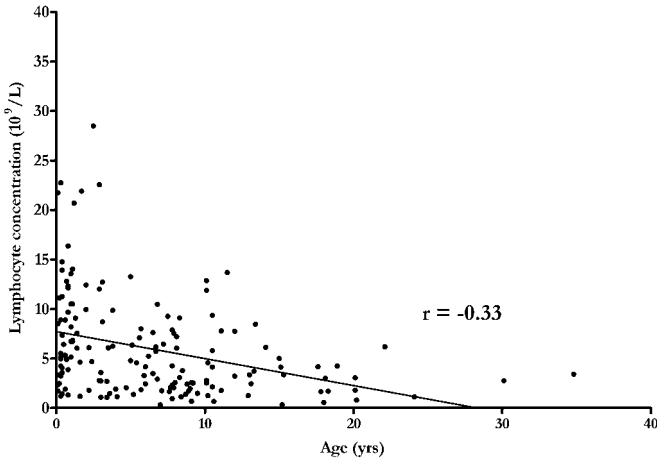

FIGURE 50.10 Relationship of the lymphocyte count with age in 169 blood samples from clinically healthy psittacine birds. Relatively high lymphocyte counts were common in birds less than 4 years of age.

Lymphocytosis secondary to antigenic stimulation is frequently observed in birds that have chronic infectious (bacterial, viral, fungal, or parasitic) or inflammatory diseases wherein the blood lymphocyte pool is expanded because of persistent antigen exposure, most notably in chronic bacterial or viral diseases.[43] Occasionally, the lymphocytosis is extreme as in a crane that had granulomatous disease and an absolute lymphocyte count of 45,900 cells/μL.

Lymphoid neoplasia such as lymphosarcoma with a leukemic blood picture[27,58] (Fig. 50.11), or lymphoid leukemia (Fig. 50.12), may be associated with lymphocytosis. In our experience, lymphoid leukemias produce extreme elevations in the absolute lymphocyte count (as much as 200,000 lymphocytes/μL).

Lymphopenia

Lymphopenia is frequently the result of severe stress-induced endogenous corticosterone release or exogenous corticosteroid administration (Table 50.2). Corticosteroid administration produces a rapid, predictable, transient redistribution of mammalian T cells to the bone marrow or other tissue compartments, resulting in lymphopenia.[1] Studies in chickens have documented a rapidly developing but transient lymphopenia after corticosteroid administration. Stress-associated lymphopenia is more variable and often difficult to document hematologically in apparently clinically stressed birds. Heterophilia and concurrent lymphopenia are the hallmarks of a stress leukogram and may be observed in diseased or severely stressed birds, such as those subjected to forced molting through severe feed restriction.[32]

Lymphopenia of acute infection may have a complex origin, involving one or more mechanisms. These mechanisms include endogenous corticosterone release with temporary lymphocyte redistribution, temporary trapping of recirculating lymphocytes within lymphoid tissues to promote antigen contact, and direct destruction of lymphoid tissue, especially during viral infection.[39]

Last, drug- or toxin-induced lymphopenia may be observed infrequently. Examples include cyclophosphamide administration in chickens and turkeys, and crude oil ingestion by gulls.

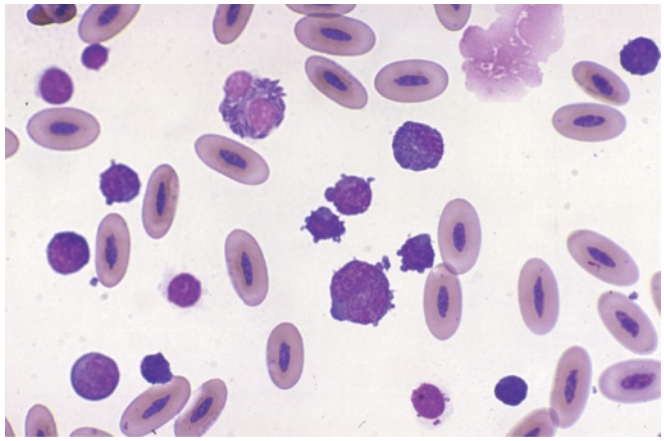

FIGURE 50.11 Blood smear from an emu that has disseminated lymphoma. Immature, neoplastic lymphocytes within the blood smear have dark blue cytoplasm with broad pseudopodia.

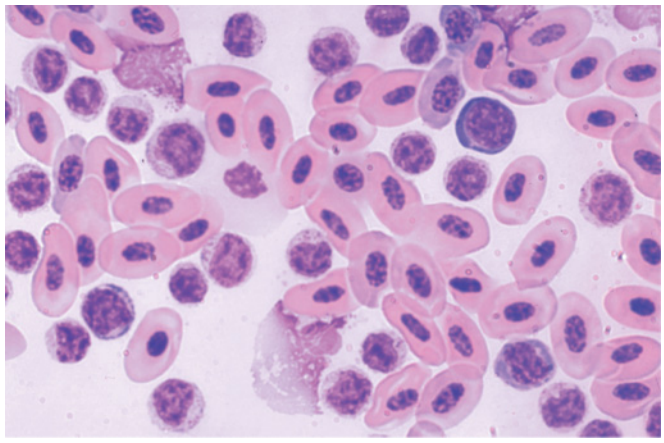

FIGURE 50.12 Blood smear from a cockatoo that has lymphocytic leukemia. The leukocytes are predominately mature, well-differentiated lymphocytes.

MONOCYTE RESPONSES

The monocyte-macrophage system is composed of stem cells, monoblasts, and promonocytes in the bone marrow; monocytes in the bone marrow and blood; and macrophages within various body tissues. Studies in turkeys indicate that phagocytic uptake of blood particulate material occurs predominantly by macrophages in the liver, spleen, and bone marrow.[55]

Monocytes are produced in the bone marrow and released into the blood at an early age compared with heterophils. A bone marrow storage pool of monocytes apparently does not exist. Once released into the blood, monocytes circulate for a short time and emigrate from the blood vessels into the tissues (Fig. 50.3 and Fig. 50.13). Those monocytes that mature into tissue macrophages may have an extended lifespan ranging from days to months.

Tissue demands for macrophages are met primarily by recruiting monocytes from the blood and increasing monocyte production in the bone marrow.[60] Macrophages can undergo limited mitosis in situ, but such activity generally accounts for less than 5% of the total macrophage population.

Monocytes are generally the largest circulating leukocyte in avian blood in health and typically account for 1–3% of the circulating WBC population. These cells have round to oval nuclei, slightly condensed chromatin, gray cytoplasm, and occasional pseudopodia. Cytoplasmic vacuolation also may be observed, but is more prominent if the blood stands for a while before smears are made. Difficulty can be encountered in distinguishing monocytes from large lymphocytes in some

birds. In such cases, cytochemistry can be used for definitive cell identification.[61]

Monocytosis

Monocytosis frequently is associated with chronic diseases such as granulomatous lesions, nonspecific tissue necrosis, bacterial infections (e.g. mycobacteriosis and chlamydiosis), deep mycosis (e.g. aspergillosis, parasitism), and zinc-deficient diets (Table 50.3).[26,76] A frequent misconception among avian clinicians, however, is that monocytosis is only seen in chronic diseases and, when present, is indicative of granulomatous inflammation. In fact, monocytosis can be observed in both acute and chronic diseases. Experimental studies in chickens have shown that significant monocytosis can be observed in the blood within 12 hours after induced inflammation or bacterial airsacculitis, with peak monocyte counts occurring within 24 to 48 hours.[14,43]

Monocytopenia

Monocytopenia is clinically unimportant and difficult to document because of the wide range in avian monocyte counts. In instances of pancytopenia, such as viral-induced hematopoietic cell damage, heteropenia deserves more clinical attention because of the possibility of secondary infections.

	Chlamydiosis (chronic)
Fungal infection	Aspergillosis
Parasitism	
Zinc-deficient diets	

BASOPHIL RESPONSES

Avian basophils are recognized by their round to oval nucleus and prominent, round, purple granules in Romanowsky-stained blood smears (Fig. 50.13). In healthy birds, basophils usually are more numerous in the blood than are eosinophils. This observation has been made in many avian species.

Functions of avian basophils appear to be similar to those of mammalian basophils (see Chapter 44) but investigations of cell function are sparse or anecdotal. The involvement of avian basophils in acute inflammation is well documented. In chickens, basophilic infiltration of tissues has been observed with early (1.5–3 hours) inflammation of skin, wattle, skeletal muscle, and mesentery.[12,54,72] Involvement of basophils has also been demonstrated in avian cutaneous hypersensitivity and systemic anaphylaxis.[52] Clinical and experimental evidence also suggests that avian basophils are involved in the host response to internal and external parasites, including schistosomes, soft-bodied ticks, and air sac mites. Evidence also exists for basophil-associated tumor cytotoxicity wherein intense basophilic infiltrates have been observed in experimentally induced Rous sarcomas in chicken wing webs. In contrast to mammalian basophils, avian basophils also are actively phagocytic.[37]

Basophilia

Generally, only sustained overt basophilia can be detected by routine hematologic methods wherein basophils constitute at least 3–6% of the leukocyte differential cell count. Although absolute basophil counts, determined using a hemacytometer and toluidine blue diluent, have been performed in birds,[52] reports of blood basophil responses in disease are sporadic (Table 50.4).

Basophilia is reported to occur with respiratory diseases and severe tissue damage in pet birds.[59] This finding is partially corroborated by a trend toward development of basophilia in chickens that have experimentally-induced salmonellosis wherein basophil counts tended to increase within the first week of infection. Although the mechanism of basophilia is unknown, it may be related to the proinflammatory response observed in humans.[65] Blood basophilia also has been

TABLE 50.4 Causes of Basophilia in Birds

Tissue damage or perturbation	Acute inflammation (skin, wattle, muscle, mesentery)
	Severe nonspecific tissue damage
	Bacterial infection
	Respiratory disease
	Systemic anaphylaxis
Stress	Feed restriction, starvation
	Forced molting
Parasitism	Schistosomes, ticks, air sac mites
Miscellaneous	Ingestion of mycotoxin-contaminated feed

observed with internal and external parasitism. Examples include experimental infection of chickens that have *Austrobilharzia variglandis*, and natural infestation of canaries and finches with air sac mites. Basophilia can occur alone or in conjunction with eosinophilia. Basophilia also has been observed in chickens[49,53] and ducks after significant feed restriction, and is presumed to be a harbinger of severe stress. Apparently birds differ from mammals in that basophilia occurs in stress and that blood basophil counts apparently are unaffected by corticosteroid administration.[49] Basophilia also has been reported in chickens, presumably in response to mycotoxin-contaminated feed.[50]

Basopenia

Basopenia cannot be detected reliably without performing absolute basophil counts. The presence of basopenia in other species is of limited clinical importance in routine health care, as may be the case in avian patients.

EOSINOPHIL RESPONSES

Avian eosinophils are recognized by their round, often red-orange granules, and light blue cytoplasm in Romanowsky-stained blood smears. However, raptor eosinophil granules may occasionally be rod shaped, and granule tinctorial properties may vary slightly between species. Eosinophils generally are the least frequently encountered leukocyte in avian blood smears, with the exception of raptors in which these cells may account for 15% of the leukocyte differential cell count. In some species of birds, such as Amazon parrots, a leukocyte with round, colorless to light blue granules may be observed in the stained blood smear. The common practice is to identify such cells as eosinophils because typical eosinophils with red-orange granules have not been observed. Ultimate identification of this unusual leukocyte will require both ultrastructural and cytochemical study.

Eosinophilia

Avian species are similar to horses in that eosinophilia is observed infrequently in species other than raptors, although parasitism is observed frequently (Table 50.5). Eosinophilia has been observed in chickens that have facial edema; chickens experimentally infected with schistosomes or naturally infected with *Trichostrongylus tenuis*; and in quails, chickens, and ducks injected intraperitoneally with horse serum or bovine serum albumin. The magnitude of the eosinophilia ranges from 6% to 56% of the leukocyte differential count in both experimental and natural disease. Furthermore, lymphocyte–eosinophil interaction has been demonstrated indirectly. Marked secondary eosinophilia has been observed in chickens and ducks after repeated antigen administration.[48] Irradiation has been shown to depress development of eosinophilia in chickens, whereas thymectomy had little effect.[51] The reason for this apparent paradoxical observation is that total-body irradiation affects all lymphocytes and it is difficult to remove all thymic tissue.

TABLE 50.5 Causes of Eosinophilia and Eosinopenia in Birds

Eosinophilia	
Facial edema	
Parasitism	
Exposure to foreign antigens	Horse serum, bovine serum albumin
Eosinopenia	
Severe stress	
Corticosteroid administration	

Eosinopenia

Eosinopenia is best defined by clinical experience. Because eosinophils are infrequently encountered in avian blood except for raptors, absolute eosinophil counts are necessary for a quantitative study of avian eosinopenia. A problem is readily apparent in that it may be difficult to distinguish eosinophils from heterophils in absolute counts unless cytochemistry is used.

In mammals, eosinopenia is observed after corticosteroid or ACTH administration. Single-dose administration results in sequestration of eosinophils and delayed eosinophil release from the bone marrow. Prolonged high-dose corticosteroid treatment causes decreased eosinophil production.

Eosinophil responses in sick birds are seldom mentioned, although indication of eosinopenia sometimes is apparent. Injection of long-acting ACTH into immature chickens has shown a suggestion of slight eosinopenia, but routine hematologic methods lacked the sensitivity needed for adequate quantitation of the cellular response. In summary, clarification of avian eosinophil responses in blood relies on evaluation of absolute cell counts. In addition, the importance of avian eosinophil responses within the tissues will only be clarified by immunohistochemical staining to reliably distinguish eosinophils from heterophils.

REMARKS ON PROGNOSIS AND HEMATOLOGIC TRENDS

Heterophil:Lymphocyte Ratios

Introduced as an indicator of stress in chickens, the heterophil:lymphocyte (H:L) ratio has been calculated on the basis of both absolute heterophil and lymphocyte counts or on relative percentages of these WBCs from the stained blood smear. When interpreting H:L ratios, one must remember that the ratio can increase with absolute heterophilia when the lymphocyte count is in the reference interval or with absolute lymphopenia when heterophil counts are in the reference interval. The true stress response, that is observed after

corticosteroid administration, is absolute heterophilia in conjunction with developing lymphopenia. In an experiment on feed restriction, ducks showed no change in H:L ratios; however, H:L ratios were increased in chickens and turkeys. In this study, it was felt that developing basophilia in chickens, turkeys, and ducks was a more uniform hematologic change denoting severe stress. In our opinion, H:L ratios currently represent another mathematical manipulation of limited clinical value in assessing stress in birds.

Unfavorable Prognostic Features

A guarded prognosis is suggested with heteropenia of any cause, especially if a left shift and toxic changes of heterophils are observed. If a left shift intensifies or becomes degenerative (where band heterophils and younger forms outnumber segmented heterophils), a guarded prognosis is suggested. Extreme leukocytosis also suggests a guarded prognosis until chlamydiosis, mycobacteriosis, deep mycosis, and leukemia are excluded.

Favorable Hematologic Trends

Hematologic trends in birds that are suggestive of recovery include resolution of extreme leukocytosis, leukopenia, heteropenia, left shift, toxic changes of heterophils, and lymphopenia.

NEW TECHNIQUES FOR ASSESSMENT OF AVIAN LEUKOCYTES

A flow cytometric technique for enumeration of quail, chicken and goose WBCs has been described.[76,77] The technique relies on the differential affinity of avian RBCs and WBC types for fluorescent lipophilic dyes such as 3,3-dihexyloxacarbocyanine [($DiOC_6(3)$], permitting cell separation based on fluorescence.[56,75] This technique holds promise for application in other avian species because antibodies specific for cell surface markers are not required; however, a flow cytometer capable of fluorescence detection is necessary. Classification of avian lymphocytes into subtypes of T cells and B cells,[1] and distinction of thrombocytes from lymphocytes with antibodies specific for chicken thrombocytes,[8] are established research techniques, but their incorporation into routine hematology is limited by the need for species-specific antibodies to WBC antigens and need of a flow cytometer.

Acronyms and Abbreviations

ADCC, antibody-dependent cell-mediated cytotoxicity; APC, antigen presenting cell; BCR, B cell receptor; CD, cluster of differentiation; CTLA-4, cytotoxic T lymphocyte antigen 4; DAMP, damage-associated molecular pattern; Foxp3, forkhead box P3; GITR, glucocorticoid-induced TNF-receptor regulated gene; HEV, high endothelial venule; IFN, interferon; Ig, immunoglobulin; IL, interleukin; LGL, large granular lymphocyte; MAMP, microbe-associated molecular pattern; MHC, major histocompatibility complex; NFκB, nuclear factor kappa B; NK, natural killer; NOD, nucleotide-binding oligomerisation domain; PAMP, pathogen-associated molecular pattern; PRR, pattern recognition receptor; RIG, retinoic-acid-inducible gene; SCID, severe combined immunodeficiency; SmIg, surface membrane immunoglobulin; STAT, signal transducer and activator of transcription; TCR, T cell receptor; Th, T helper cell; TGF, transforming growth factor; TNF, tumor necrosis factor; Tr or T-reg, T regulatory cell.

The lymphoid cells are key components of the immune system. An increasing number of lymphoid subsets are now defined (Table 51.1). Some have roles in the innate immune response (natural killer [NK] cells and T cells expressing the γδ T cell receptor [TCR]), but most are responsible for mediating adaptive immunity. These latter cells regulate the production of antibody (humoral immunity) or are responsible for cell-mediated immune effects such as cytotoxicity or delayed-type hypersensitivity. The fundamental importance of lymphoid cells is clearly demonstrated in animals with genetic inability to produce such cells (e.g. severe combined immunodeficiency; SCID) that are profoundly immunodeficient and readily succumb to infectious disease.[34,36]

Lymphocyte subsets may be defined:

- phenotypically, by the expression of surface molecules
- anatomically, by their developmental pathways and distribution within lymphoid tissue
- functionally, by their end-effects in an immune response which relates to expression of particular membrane molecules and release of specific cytokines.

Lymphocyte biology is best defined in humans and rodents, but most features are highly conserved and have parallels in veterinary species.

THE INNATE AND ADAPTIVE IMMUNE RESPONSE

The innate immune response encompasses an evolutionarily older, more simplistic form of immunity that is continually present to provide immediate first-line defense from potential pathogens.[25] As the encounter with pathogens is most likely to occur at mucocutaneous surfaces, these are the anatomical regions that are particularly enriched for components of the innate immune system. A key part of the innate response is the presence of an epithelial barrier that has specific regional adaptations to enhance its effectiveness (e.g. the mucociliary escalator of the upper respiratory tract, keratinization of the cutaneous squamous epidermis). Mucocutaneous surfaces also frequently are bathed in antimicrobial secretions that contain a cocktail of enzymes (e.g. lysozyme), small antibacterial molecules

TABLE 51.1 Lymphocyte Subsets

Cell Type	Phenotypic Subtype	Functional Subtype	Function
B cell			Plasma cell precursor
Plasma cell			Immunoglobulin secretion
T cell	αβ TCR+ CD4+	Th0	Precursor to functional CD4+ T cell subsets described below
		Th1	Cell-mediated immunity; limited help for antibody production. Mediates "type 1" immune response
		Th2	Help for antibody production, particularly IgE, IgG subclass and IgA. Mediates "type 2" immune response
		Th3	Regulatory T cell mediates oral tolerance
		Th17	Mediates proinflammatory immunopathology, response to infections and autoimmunity
		Treg	CD25+ CD4+ "natural suppressor" cell. Normally present to control autoimmune and allergic responses
		Tr1	IL-10 producing "induced suppressor" cell stimulated during immune response to exogenous antigen
	γδ TCR+ CD4+		Predominantly surface intraepithelial population important in first-line defence to bacterial pathogens. May be type 1 and 2 subsets
	αβ TCR+ CD8+		Cytotoxic T cells. May be type 1 and 2 subsets
NKT cell	Types I and II		Recognize lipid antigen expressed by CD1d
NK cell			Cytotoxic cell; performs antibody-dependent cell-mediated cytotoxicity (ADCC)

(e.g. defensins, alternative pathway complement molecules) and low-specificity polyreactive antibodies of the immunoglobulin (Ig) A and IgM classes. Within, and immediately beneath, the epithelial barrier are populations of innate immune cells including phagocytic cells (e.g. neutrophils, macrophages), NK cells and γδ TCR+ T cells.

Another important leukocyte involved in innate immunity is the dendritic cell. In recent years, this cell has become the focus of intense interest with the recognition that it provides the key link between the innate and adaptive immune systems.[16,20] The dendritic cell (so named because of its characteristic elongate cytoplasmic dendrites) is located within or beneath the epithelial barrier where it is well placed to encounter and sample foreign antigen as it is first exposed to the body. The means by which this reaction occurs, and the way in which dendritic cells subsequently direct the nature of the ensuing adaptive immune response, will be discussed in detail below.

Whereas the innate immune system is continually present and able to react immediately to foreign antigen, one major feature of the adaptive response is a delay in onset. This delay is accounted for by the requirement for a sequence of complex intercellular interactions leading to production of antigen-specific T and B effector lymphocytes that must migrate from organized lymphoid tissue (where they are generated) to the site of antigenic exposure via the lymphatic and blood vascular systems. The adaptive immune response also encompasses the generation of populations of antigen-specific regulatory (i.e. suppressor) lymphocytes that control the immune response by down-regulating (suppressing) effector cells when they are no longer required to be active. Immunological memory is the lasting sequel to this regulatory process.

T CELLS

Definition and Development

T cells are defined by the expression of a T cell receptor (TCR) that confers unique antigen specificity to the cell. The TCR complex comprises a central two chain transmembrane portion involved in antigen recognition that is associated with a series of minor components (collectively called CD3 and comprising γ, δ, ε and ζ chains) that act as signal transducers following recognition of specific antigen (Fig. 51.1). The majority of T cells utilise α and β chains in forming the central portion of the TCR complex, and a second group of T cells have γδ TCRs. The diverse specificity of TCRs is achieved by the variable genetic combination of an array of gene segments that encode portions of the TCR chains (see Chapter 10). The total repertoire of TCRs in the body is sufficient to permit an animal to potentially recognise any possible antigen that it may encounter. Most mature T cells also express one of two mutually exclusive surface molecules, CD4 or CD8 that define non-overlapping T cell subsets; however, double negative (CD4– CD8–) or double-positive (CD4+ CD8+) T cells are found at certain stages of development.

All lymphoid cells, including T cells, arise from the common bone marrow stem cell (see Chapter 10). Immature T cell precursors are then exported from the marrow to undergo development and maturation in the thymus.[4,37] Intrathymic development of T cells is

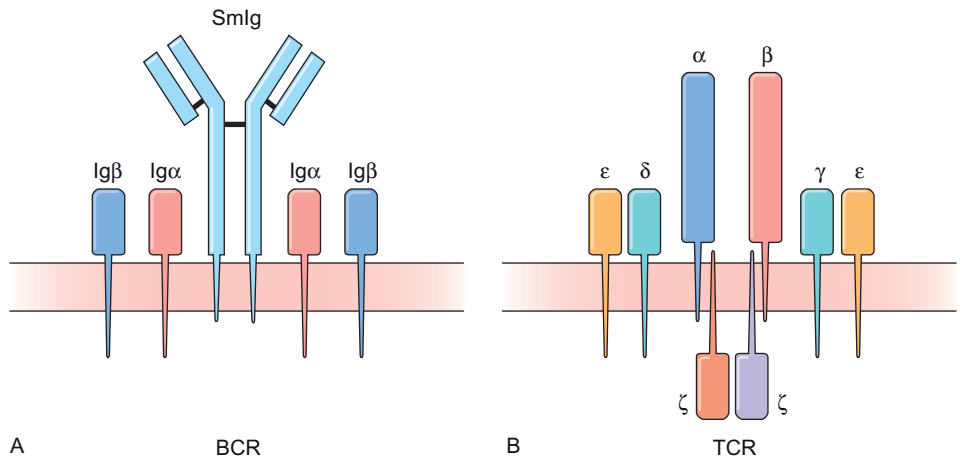

FIGURE 51.1 Diagrammatic representation of the B cell receptor (BCR) and T cell receptor (TCR). Antigen recognition is mediated by the surface membrane immunoglobulin of the BCR, or the αβ chains (alternative γδ chains not shown) of the TCR. The signal transduction molecules of the BCR are collectively known as CD79, and those of the TCR as CD3.

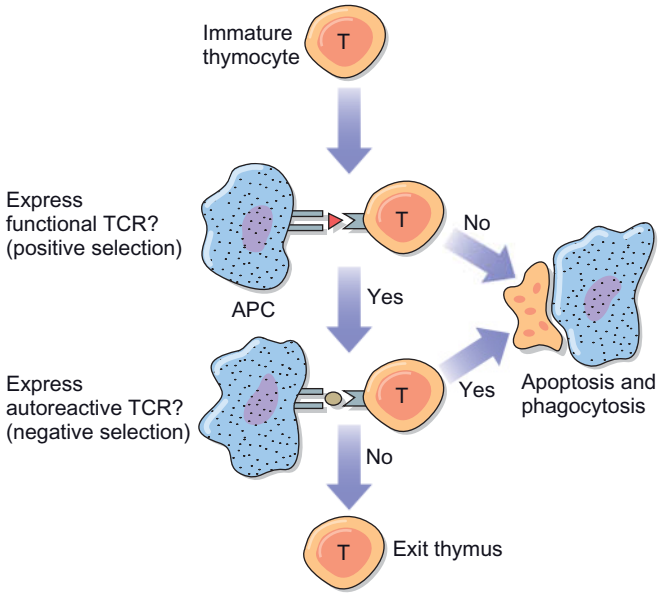

FIGURE 51.2 Intrathymic development of T cells. Developing thymocytes must express a T cell receptor able to productively interact with MHC and peptide, but must not recognize self-antigens that are capable of inducing an autoimmune response. Only T cells that satisfy these requirements are permitted to leave the thymus and enter the peripheral recirculation pathway.

complex, and involves a series of interactions between the developing thymocytes and populations of antigen-presenting cells (APCs) such as thymic epithelial cells or dendritic cells. These tests of developing thymocytes determine whether the cells express a functional TCR capable of antigen recognition (positive selection) or a TCR that recognizes self antigens and induces autoimmunity (negative selection); T cells that fail either test undergo apoptosis (programmed cell death or cell suicide) within the thymus and the remnants of the cell are phagocytosed by macrophages (Fig. 51.2).

Mature CD4+ or CD8+ T cells leave the thymus and seed the peripheral lymphoid tissue, particularly the lymph node paracortex, splenic periarteriolar lymphoid sheath, or perifollicular regions of mucosa-associated lymphoid tissue (Fig. 51.3).

However, lymphocytes do not remain static within these locations. There is continual and massive recirculation of lymphoid cells throughout the body, via the pathway depicted in Figure 51.4. Such recirculation is necessary in order to optimize the chance of contact with specific antigen, and to orchestrate and regulate an immune response in appropriate areas of the body. Lymphocyte recirculation and vascular egress of these cells is carefully regulated by a complex network of adhesion molecules expressed by the recirculating lymphocytes and modified vascular endothelium (high endothelial venules; HEV) found normally in some lymphoid tissues or induced at sites of inflammation.[1,35]

Lymphocytes are considered functionally naïve until they encounter the antigen that they are programmed to recognize via their specific TCR; following participation in an immune response, a population of memory lymphocytes persists for generation of the more effective anamnestic (memory) immune response.

T Cell Activation

T cells have specialized requirements for activation. Intact antigen is generally unable to stimulate T cells and must first be processed and presented by populations of APCs.[6] Naïve T cells are most effectively activated when antigen is presented to them by dendritic cells, but macrophages and B cells can present antigen, and in some circumstances a wide variety of other cells (e.g. endothelia, epithelia, fibroblasts) can be induced to present antigen (non-professional APC).

Major breakthroughs have been made in expanding understanding of the key role of dendritic cells in T cell activation. Although considered part of innate immu-

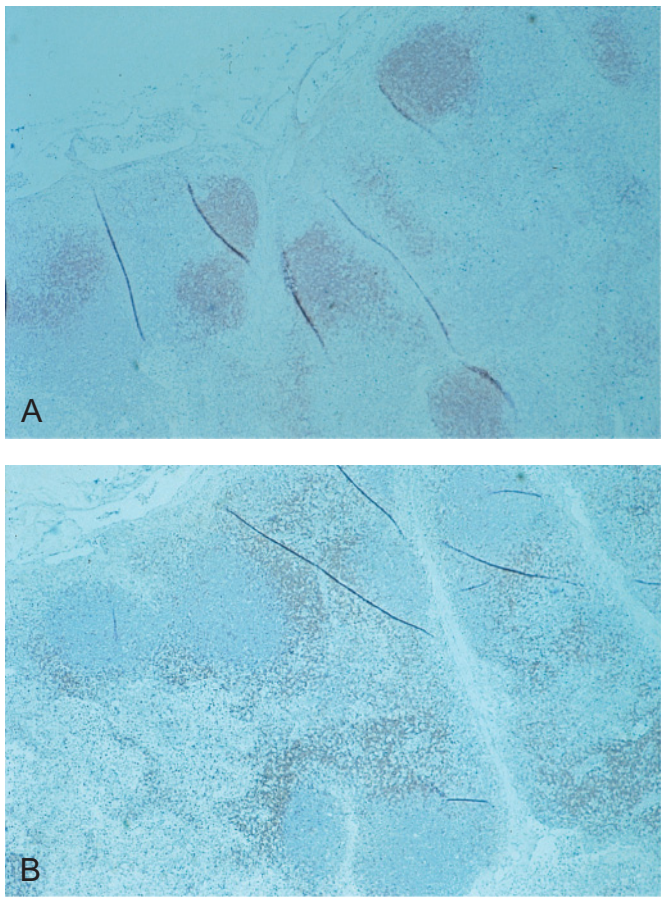

FIGURE 51.3 Sections of canine lymph node immunohistochemically labelled for expression of (**A**) CD79 and (**B**) CD3. The two antibodies clearly delineate cortical aggregates of B cells (**A**) and surrounding paracortical T cells (**B**).

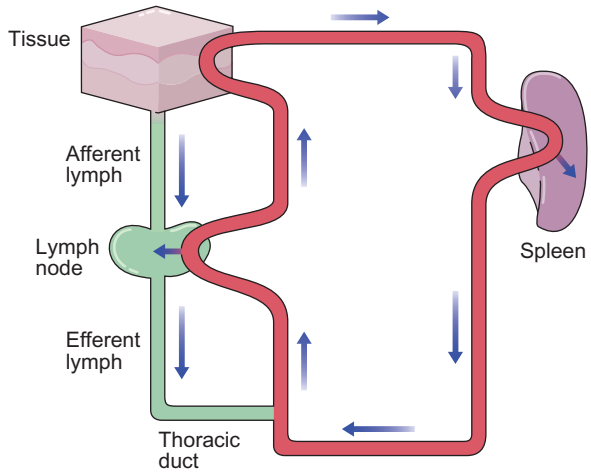

FIGURE 51.4 Pathways of lymphocyte recirculation. Lymphoid cells from the tissues drain to regional lymph nodes via the afferent lymph and exit the lymph node through efferent lymph, subsequently entering the blood via the thoracic duct. Lymphocytes circulate in the bloodstream and may leave the vasculature to enter lymphoid tissue or other body tissues when there is expression of appropriate adhesion molecules by the local vascular endothelium.

nity, it is now known that the dendritic cells direct the nature of the specific adaptive immune response and that this in turn is dependent on the nature of the stimulating antigen. The dendritic cell is endowed with a series of surface and cytoplasmic molecules collectively termed pattern recognition receptors (PRRs). The surface PRRs are also known as Toll-like receptors (TLRs) after the molecule Toll that was identified in the fruit fly *Drosophila* as a key immune-defense molecule in that insect.[33] TLRs are few in number and are highly conserved throughout evolution. Cytoplasmic PRRs include the NOD- and RIG-like receptor molecules.[39]

The ligands for PRRs are antigenic epitopes expressed by microbes or damaged tissue cells. The former are known as pathogen-associated molecular patterns (PAMPs) or microbe-associated molecular patterns (MAMPs) and the latter as damage-associated molecular patterns (DAMPs). These are structurally conserved molecules that may be protein, carbohydrate, or nucleic acid in origin. Particular PAMPs interact with combinations of specific PRRs; for example, the peptidoglycan of Gram-positive bacteria binds to TLR-2, whereas the lipopolysaccharide of Gram-negative bacteria interacts with TLR-4. The surface PRRs are associated with signal transduction molecules such as MyD88 and ligation of the PRR triggers an intracytoplasmic and intranuclear signaling pathway that leads to differential gene expression via nuclear factor kappa B (NF κB) and other transcription factors. This gene expression determines how the APC will signal the responding T cell (as discussed below) and therefore determines the nature of the ensuing T cell response.

In parallel with these signalling events, antigen is also internalized by the APC, processed and presented on the cell surface in association with molecules of the major histocompatibility complex (MHC). There are two broad pathways of antigen presentation. Most exogenous antigens (the majority of antigens such as infectious agents or allergens) are taken up by phagocytosis or macropinocytosis and placed in a phagosome where they are enzymatically degraded to small peptide fragments that associate with Class II molecules of the MHC. The combination of antigenic peptide-MHC is then expressed on the surface of the APC in a manner that can be recognised by the TCR. Endogenous antigens, that are derived from the cell cytoplasm, (e.g. viral, tumor or self molecules), undergo an alternative process involving degradation within a cytoplasmic proteasome and transport into the endoplasmic reticulum (mediated by transporter proteins), where they associate with Class I MHC molecules. After transfer to the Golgi apparatus, the combination of antigenic peptide-MHC is similarly expressed on the surface of the APC (Fig. 51.5).

Endogenous peptides also can be presented by MHC Class II molecules and exogenous peptides by MHC Class I molecules in a phenomenon known as cross-presentation. Certain lipid antigens (e.g. derived from *Mycobacterium*) are presented via a third pathway involving endosomal process and presentation in association with molecules of the CD1 family.[7] T cells that

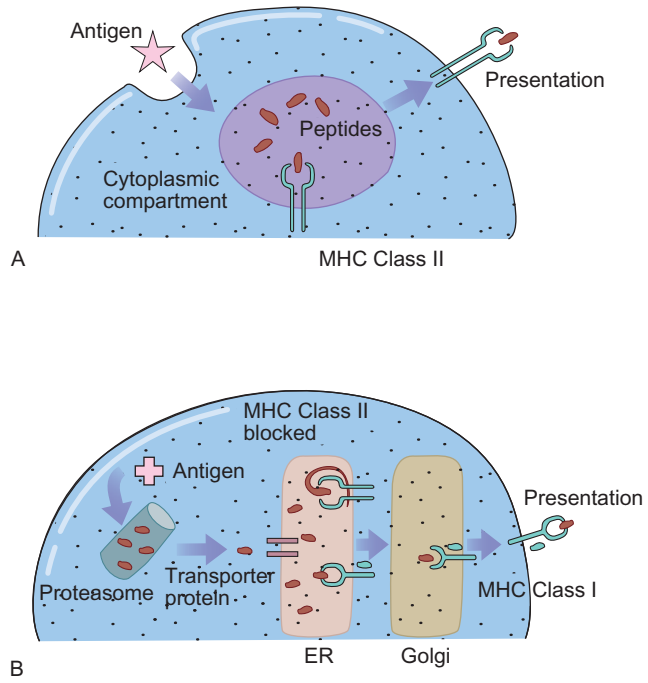

FIGURE 51.5 Processing and presentation of (**A**) exogenous antigen and (**B**) endogenous antigen. Exogenous antigen is degraded in a cytoplasmic compartment where there is association between peptide fragments of antigen and class II molecules of the major histocompatibility complex. Endogenously derived antigen is degraded within cytoplasmic proteasomes and transported to the endoplasmic reticulum where peptide fragments become associated with MHC class I molecules. In each case, the processed antigen is presented on the surface of the antigen-presenting cell by MHC for T cell recognition.

recognize lipid antigen expressed by CD1a, CD1b, or CD1c are likely similar in nature to peptide-specific T cells, whereas only NKT cells (see below) recognize antigen expressed by CD1d.[13]

T cell activation is, therefore, a complex event that is driven primarily by the APC. A series of molecular interactions occurs between these two cells that lead to activation of T cells of a specific type that is most relevant to the inciting antigen. These molecular events include: (1) Recognition of the combination of antigenic peptide and MHC residues by the TCR leading to signalling via CD3; (2) cognate interaction of the APC and T cell via an array of other surface molecules (e.g. B7 and CD28). In one such interaction, the CD4 molecule binds to MHC Class II and CD8 to MHC Class I. This renders the CD4+ T cells susceptible to stimulation only when antigen is presented by Class II, and CD8+ T cells to activation only following recognition of peptide in the context of Class I; (3) release of co-stimulatory cytokine/s by the APC that bind cytokine receptors on the T cell. The nature of cytokines released by the APC is determined by the PAMP-PRR interaction. APC-derived co-stimulatory cytokines bind specific cytokine receptors on the surface of the T cell, and when aggregated such receptors signal via activating cytoplasmic tyrosine kinases (Janus kinases) that phosphorylate the cytosolic signal transducers and activators of transcription (STATs), subsequently migrate to the nucleus, and initiate gene activation via the effects of specific transcription factors.

Following activation, the T cell undergoes blast transformation and cytokine secretion (e.g. interleukin 2; IL-2), and the process of clonal proliferation and differentiation, whereby large numbers of T cells with identical antigen-MHC specificity are generated to participate as effector cells in the immune response. Such T cell activation generally occurs within the secondary lymphoid tissue (e.g. lymph node paracortex) and activated T lymphocytes enter the recirculation pathway to arrive at the site of antigen exposure, or other lymphoid tissues.

T Cell Functions

The end effect of T cell activation is to orchestrate some component of an antigen-specific immune response. T cells may be regulatory, providing either positive (helper) or negative (suppressor) signals to other leukocytes, or be cytotoxic in function.

Function of CD4+ T Cells

T cells bearing the CD4 molecule regulate the function of a variety of leukocytes or cross-regulate the function of each other. The recognition of CD4+ T cell subsets has fundamentally reshaped study of the immune response in recent years.[32] First recognized were two subsets of αβ TCR+ CD4+ T cells, known as Th1 (T helper) and Th2. Although phenotypically indistinguishable, these subpopulations have distinct function conferred upon them by the secretion of two non-overlapping cytokine profiles (Fig. 51.6).

Th1 cells selectively secrete the cytokines IL-2 and interferon gamma (IFN-γ) and enhance the cytotoxic effects of CD8+ and natural killer (NK) cells, the killing of intracytoplasmic pathogens (e.g. *Leishmania*, *Mycobacterium*) by macrophages, and the selective production of antibody of a specific IgG subclass (IgG2a in mice). Th2 cells selectively secrete IL-4, -5, -6, -9, -10, and -13, provide help for B cell and plasma cell development, and promote secretion of IgE, IgA, and another subclass of IgG (IgG1 in mice). The two subsets are mutually exclusive in function as the cytokines produced by each are antagonistic of the other population. For example, IFN-γ will down-regulate the function of Th2 cells, whereas IL-4, -10, and -13 are suppressive of Th1 function either directly or indirectly through influencing the function of the APC. In practice, this exclusivity (known as immune-deviation) is not absolute, as elements of Th1 and Th2 immunology are involved in many immune responses, although some examples of distinctly polarized responses exist (e.g. Th1 requirement for resolution of intracellular infections; Th2 requirement for expression of type I hypersensitivity disease). Th1 and Th2 cells may follow selective recirculation pathways to different tissue sites as they may express unique adhesion molecules,[5] and be chemotac-

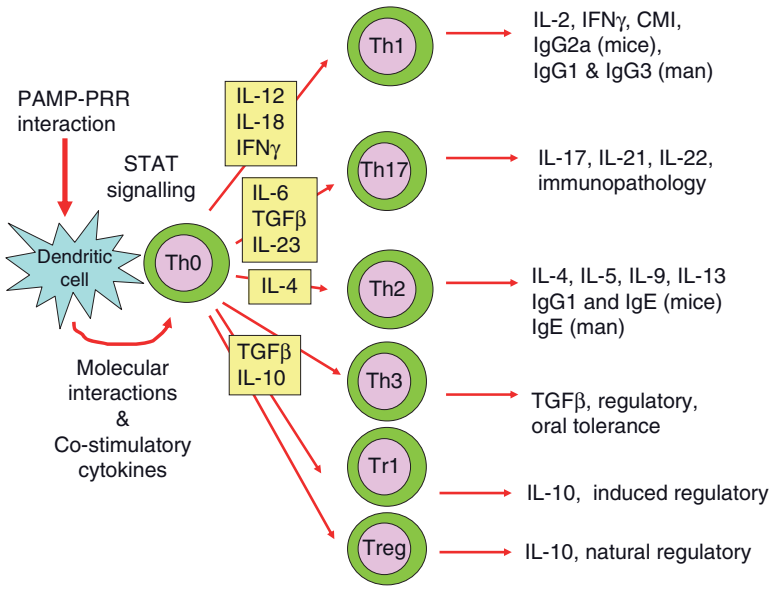

FIGURE 51.6 The functional subsets of CD4+ T cells produce distinct cytokine profiles and mediate different immune functions. The subsets have a common precursor (Th0) and a number of factors determine which of the subsets will predominate in any particular immune response, in particular the nature of the stimulating antigen and its interaction with dendritic cell pattern recognition receptors, which in turn determines the type of co-stimulatory cytokine and STAT signalling that stimulates the naïve precursor lymphocyte. Th1 cells regulate cell-mediated immunity whereas Th2 cells control humoral immune responses. Th17 cells have a proinflammatory effector role and are frequently activated in parallel to Th1 cells. The three key regulatory populations are T-reg "natural" suppressors, Tr1 "induced" suppressors, and Th3 regulatory cells.

tically attracted by specific molecules (chemokines) for which they bear receptors.[11] Th1 and Th2 cells are now characterized in several domestic animal species and their role in particular diseases has been defined.[22]

Th1 and Th2 subsets are proposed to be related through a common Th0 precursor that secretes elements of both cytokine profiles. In any particular immune response, the response can be driven towards either type 1 (Th1) or type 2 (Th2) function by a range of factors including:

- antigen type (e.g. the nature of an infectious agent), dose, and route of delivery
- the nature of the APC presenting the antigen (e.g. dendritic cells or non-professional APC)
- local cytokine and hormonal environment in the lymphoid tissue generating the response; for example, the presence of high concentrations of endogenous corticosteroid or IL-4 may preferentially activate a Th2 response, whereas IL-12 will drive forward a Th1 response
- APC signalling as determined by the PAMP-PRR interaction. For example, viral RNA acting as a PAMP will induce dendritic cell production of IL-12 and IL-18 as co-stimulatory cytokines, resulting in signalling through STAT-4 and regulation through the transcription factor T-bet with induction of a Th1 immune response most appropriate for the viral pathogen. By contrast, antigen derived from a helminth induces IL-4 and IL-6 signalling, activation via STAT-6 and the transcription factor GATA3 with generation of a Th2 response best equipped to counteract the effects of such parasites.

A further CD4+ effector T-cell subpopulation has recently been identified. The Th-17 cell is engendered when Th0 precursors are signalled via IL-6, IL-23, and transforming growth factor (TGF)-β. Th-17 cells produce IL-17, IL-21, and IL-22 and have proinflammatory effects that are important in the clearance of certain classes of pathogen and the pathogenesis of some cell-mediated autoimmune diseases.[2,9]

The final CD4+ T cell subsets are regulatory (suppressive) rather than effector in nature. The most important of these is the CD4+ CD25+ natural T regulatory cell (T-reg).[2,23,30] These cells are spontaneously present and have a key role in controlling potentially deleterious autoimmune and allergic immune responses. They produce IL-10 but require direct physical contact (cognate interaction) with the cell that they are suppressing. T-reg also express Foxp3 (forkhead box P3 gene), GITR (glucocorticoid-induced TNF-receptor-regulated gene), CTLA-4 (cytotoxic T lymphocyte antigen 4), and some PRRs. T-reg have now been characterized in cats, dogs, and cattle.[10,40] By contrast, the induced regulatory T cells (Tr1 cells) appear as part of an immune response to foreign antigen (as opposed to being present naturally) and function mainly through production of the immunoregulatory cytokine IL-10 rather than requiring direct cognate interaction with their targets.[19] These cells have recently been characterized in the horse.[41] Intriguing recent studies have shown that in the late stages of some infectious diseases (classically leishmaniosis) protective Th1 cells may switch their functional phenotype from an effector IFN-γ production to an IL-10 producing regulatory population. This has the effect of permitting persistence of infection but limiting immune-mediated damage to tissue that may be secondary to an over-exuberant protective immune response.[3,38] Finally, the Th3 cell preferentially produces TGF-β and has been suggested to mediate the phenomenon of oral tolerance (failure to respond to systemic administration of antigen after prior feeding of the antigen).[42]

Function of CD8+ T Cells

The major function of CD8+ T cells is mediating cytotoxicity, and these cells are positively influenced by the

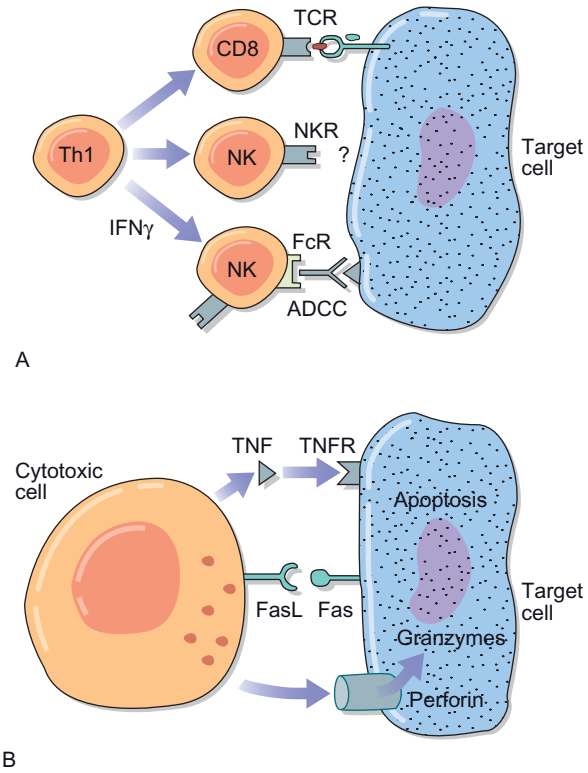

FIGURE 51.7 (**A**) Cytotoxic destruction of a target cell can be mediated by CD8+ T cells or natural killer cells. These populations are positively influenced by Th1 CD4+ T cells. (**B**) The cytotoxic process involves induction of target cell apoptosis by the interactions of Fas-Fas ligand and TNF-TNF receptor, membrane pore formation and osmotic imbalance, and cytoplasmic damage caused by granzymes released from the cytotoxic cell.

effects of the Th1 regulatory population. However, it has been recognized that CD8+ T cells are capable of producing type 2 cytokines (e.g. IL-4) and subsets of type 1 and type 2 CD8+ T cells are proposed.[14] The cytotoxic effect of lymphoid cells follows a similar sequence of events (Fig. 51.7) that are initiated following recognition of the target cell (e.g. virally infected, neoplastic, or incompatible graft cell) by cytotoxic cells.[12] In the case of CD8+ T cells, the recognition involves TCR interaction with endogenous peptide presented by MHC Class I. A range of other surface molecular interactions between the two cells is also required. After recognition, the cytotoxic effects are mediated by:

- induction of target cell apoptosis triggered by intracellular signals delivered following molecular interactions between Fas (on the target cell) and Fas-ligand (on the cytotoxic cell), or cytotoxic cell-derived TNF binding to TNF receptor on the target cell
- osmotic and enzymatic effects produced by the release of substances from the cytotoxic cell that form membrane channels in the target cell (perforins) permitting osmotic imbalance, or the delivery of toxic substances (granzymes) to the target cell cytoplasm.

Cytotoxic cells may then disengage from the killed target cell and subsequently attack other targets.

Function of γδ T Cells

In most species, T cells expressing the γδ TCR with a CD3 complex are primarily located in the skin and mucosal sites of the body; however, in ruminants a significant proportion of blood T cells may be of this phenotype[21] and the spleen of cattle and dogs are also enriched for these cells.[27] γδ T cells are poorly characterized but are known to develop in the thymus early in ontogeny. The γδ TCR has limited heterogeneity and may largely recognize conserved microbial (especially bacterial) molecules and thus have a role in the early immune response to such agents. The receptor may recognize antigen directly, or in association with particular forms of MHC class I molecules. Functional subsets of γδ T cells able to produce either IFN-γ or IL-4 have been proposed, and may be important in creating a cytokine milieu for subsequent development of the CD4+ αβ+ T-cell response.[15]

NKT Cells

NKT cells are a T cell subset distinct from CD4+ and CD8+ T cells that are not yet recognized in domestic animals. Two NKT subsets are reported. Type I NKT cells express a T cell receptor that comprises an invariant α chain combined with a limited number of β chains. Type II NKT cells have greater variability in α chain usage. Both cell types are also defined by recognition of antigen expressed by the CD1d molecule, and therefore predominantly respond to glycolipid molecules.[17]

NATURAL KILLER CELLS

The NK cell is observed microscopically as a large granular lymphocyte (LGL) and is defined by the presence of a series of NK stimulatory receptors that mediate the cytotoxic interaction with the target cell (Fig. 51.7). Such receptors are not encoded by genes that undergo recombination in the same way as those that encode T cell and B cell receptors (via the recombination-activating gene; RAG). This feature indicates that NK cells are considered part of the innate immune system. The cytotoxic function of an NK cell can be inhibited by the interaction of a second class of receptor (killer inhibitory receptors; KIRs) which recognize MHC Class I molecules on the target cell.[28] The balance between stimulatory and inhibitory receptors determines whether the NK cell will be activated to mediate cytotoxic destruction of the target.[31] The NK cell also may recognize the target cell via interaction of the membrane Fc immunoglobulin receptor and antibody bound to the target cell in the process of antibody-dependent cell-mediated cytotoxicity (ADCC; Fig. 51.7).

B CELLS AND PLASMA CELLS

B cells are defined by the expression of surface membrane immunoglobulin (SmIg) with a transmembrane

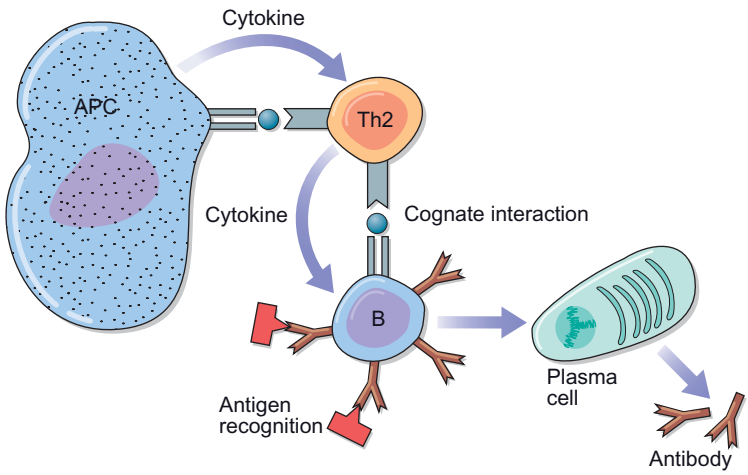

FIGURE 51.8 Activation of B cells requires recognition of antigen by surface membrane immunoglobulin and a range of interactions with helper Th2 cells. These latter include direct interaction of membrane molecules and binding of T cell-derived cytokines by specific receptors. B cell differentiation involves transformation to a plasma cell that secretes immunoglobulin.

domain that is associated with the signal transducing molecules Igα and Igβ (CD79). The complex is collectively referred to as the B-cell receptor (BCR). Each B cell expresses a unique BCR of single specificity and this diversity in the B cell repertoire is achieved by genetic combination of BCR gene segments in a similar fashion to formation of the TCR. A range of other surface molecules (e.g. Fc and complement receptors) are expressed by B cells.

B cells are derived from the bone marrow stem cell and are thought to undergo their development and maturation within the fetal liver and bone marrow of mammals. In some species, evidence suggests that the intestinal tract may be an alternative site of B cell development. The stages of B cell development are less well understood than for the T cell, but the principle of cellular interactions with marrow stroma, with deletion of nonfunctional or autoreactive B cells by apoptosis, is likely similar. B cell development is reliant upon direct contact with stromal cells that also provide appropriate growth factors (e.g. IL-7).[29] Developing B cells first express cytoplasmic immunoglobulin μ heavy chain, and following development to the naïve stage, express antigen-specific SmIg of both the IgM and IgD classes. B cells are exported from the marrow to particular anatomical locations (lymphoid follicles of the lymph node cortex, splenic white pulp, or mucosal lamina propria; Fig. 51.3) and recirculate throughout the body in the manner described for T cells.

B cell activation occurs in lymphoid tissue and requires a similar array of signals to those described for the T cells. The SmIg of the BCR recognizes antigenic epitopes directly, without the need for antigen processing or presentation by APC. The epitope may be larger and have conformational or planar shape, although peptides may also be recognized. B cells require costimulatory signals delivered by CD4+ helper T cells (Th2 or Th1). These take the form of cognate interactions between surface membrane molecules on the two cells (including TCR recognition of antigenic peptide presented on MHC Class II by the B cell) and cytokines derived from the T cell that bind receptors on the B cell (Fig. 51.8). Some antigens (thymus-independent antigens) are able to directly activate B cells in the absence of T cell help.

After activation, the B cell undergoes transformation to a lymphoblast (that may secrete IgM) and clonal proliferation and differentiation as described for T cells. As part of the differentiation process, the B cell undergoes the immunoglobulin class-switch, involving DNA rearrangement with substitution of the μ and δ genes by one of the other constant region genes to produce SmIg of the IgG, IgA or IgE class. This process appears to be cytokine-directed.

The initial contact of antigen-specific B and Th2 cells with APC (dendritic cells) and antigen occurs in the T cell zones of lymphoid tissue (e.g. lymph node paracortex) following egress of the T and B cells from the HEV. At this point, there is B cell proliferation and activated B and T cells migrate from this primary focus to the B cell area (primary follicle) to form a germinal centre within the follicle.[26] These activated B cells (centroblasts) accumulate within the dark zone of the germinal center of this secondary follicle, and then migrate to the edge of the germinal center (light zone) where as centrocytes they re-encounter antigen on follicular dendritic cells. The mantle zone of this secondary follicle is composed of inactive B cells that are not specific for the antigen driving the immune response. Most of the centrocytes have BCRs that recognise antigen with low affinity and this interaction causes them to undergo apoptosis; however, those centrocytes with appropriate receptors undergo further interactions with Th cells, and leave the germinal centers to differentiate into plasma cells (that secrete immunoglobulin but do not have SmIg), or the population of memory B cells that mediate the secondary immune response on re-encounter with antigen.[24] Plasma cells migrate as precursor plasmablasts and are largely located in lymph node medullary cords, splenic red pulp, bone marrow and the mucosal lamina propria. They have a limited lifespan (weeks) at these sites. Memory T and B cells are long-lived cells that may be periodically restimulated by depots of antigen that persist associated with

dendritic cells in lymphoid tissue, or are reintroduced to the body by vaccination or exposure to microorganisms bearing cross-reactive epitopes.[8,18]

Hemopoietic System Cells and Organs
Functional Anatomy of the Hemopoietic System
  Thymus
  Spleen
  Lymph Nodes
Lymphoid Systems of Body Surfaces

Acronyms and Abbreviations

BLV, bovine leukemia virus; FeLV, feline leukemia virus; MALT, mucosa-associated lymphoid tissue; MHC, major histocompatibility complex; TCR, T cell receptor genes; RBC, red blood cell.

HEMOPOIETIC SYSTEM CELLS AND ORGANS

The hematopoietic system consists of the cascade of cells produced by the bone marrow as well as their specialized conducting and supporting systems consisting of vascular endothelium and the connective tissue cells of the marrow, lymph nodes and spleen.[5,15,20,21,25] Other highly specialized supporting structures of the hematopoietic system include the epithelial cells of the thymus which sheath the blood vessels and form the saccular structures of the thymic cortex by which developing T cells gain their recognition of normal self antigens. The hematopoietic cells consist of the full range of differentiated products of pluripotential stem cells, including monocyte-macrophage and granulocytic cells of the neutrophil, eosinophil, and basophil type as well as the precursors of red blood cells (RBCs), platelets, and lymphocytes. The latter, including the thymic and bone marrow dependent arms of the lymphoid system are respectively responsible for cellular and humoral immunity.[15] The vascular endothelium of the hematopoietic system includes the apparently regionally undifferentiated cells lining the lymphatics as well as the regionally differentiated endothelial cells of the blood vascular system which include the high endothelial venules of the lymph node paracortex with specific cell surface markers permitting the adhesion of lymphocytes in transit and their transmural migration to enter the node paracortex.[14] The specialized circulating blood cells and their conducting and supporting structures are uniquely packaged in a series of organs of either separate design like the thymus, lymph nodes, and spleen or are incorporated into other organs like the bone marrow. These also include the free and fixed tissue macrophages and dendritic cells. These cells and organs of the blood vascular system constitute remarkably interrelated and integrated systems

FUNCTIONAL ANATOMY OF THE HEMOPOIETIC SYSTEM

Thymus

The thymus is cytologically simple but unique in containing both lymphocytes and epithelial cells, but is architecturally complex in having a lobular structure differentiated into cortical and medullary areas (Figs. 52.1 and 52.2). The epithelial cells of the thymus are derived from the third and fourth pharyngeal pouches that, in the embryo, migrate in two streams to form paired lobes of the thymus within the anterior mediastinum. This migration occurs very early in embryological development and is immediately followed by seeding of the thymus with progenitor cells from the blood islands of the yolk sac.[15]

The first stream of epithelial migration forms the isolated reticular epithelial cells of the cortex and medulla of the adult thymic lobule. The second epithelial migration forms the thymic duct epithelium and later the Hassall's corpuscles of the thymic medulla (Fig. 52.3).[21] Early reticular epithelial cells form loose cuffs around small vessels that persist in adult life and become obvious in conditions of lymphoid atrophy.

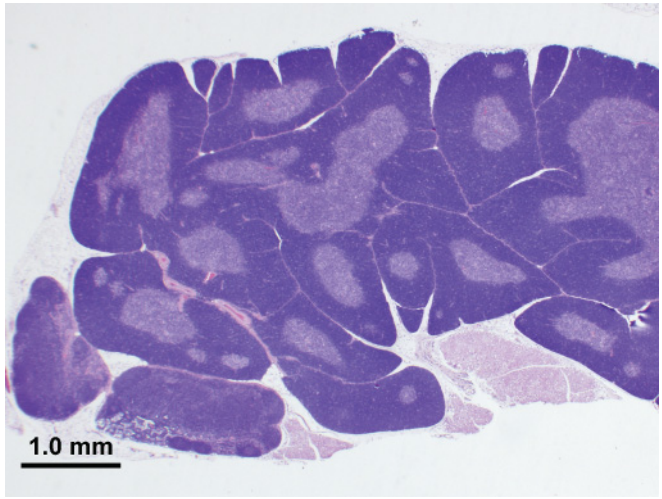

FIGURE 52.1 Thymus from a young adult male rat. The organ is composed of closely faceted lobules with a sharp distinction between the darker cortex and the lighter medullary areas of each lobule. Hematoxylin & eosin stain; bar = 1.0 mm.

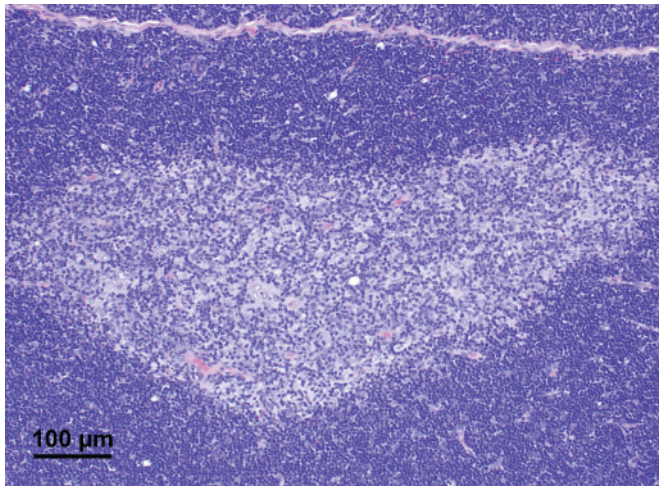

FIGURE 52.2 Mammalian thymus. In mammals, the medulla and cortex is sharply delineated in young healthy animals with the width of the cortices and medulla approximately equal to one-third the width of the lobe. Hematoxylin & eosin stain; bar = 100 µm.

Also, in early development, the ductular component of epithelium forms the branching system that communicates between the lobules of a single thymic lobe. These embryological relationships are important due to the mimicry of embryological events in thymic lesions of adult life. Thus, a thymic lesion with loss of corticomedullary distinction that might be medullary hyperplasia or thymoma can be differentiated by the presence of the reticular cuffs around the vessels seen in a thymoma. These epithelial cuffs of thymic vessels form a barrier to blood-borne antigens and naïve bone marrow lymphocytes receive their immunologic training solely from the reticular epithelial cells. Lymphoid germinal centers occurring in the thymus are not necessarily pathologic or an indication of autoimmune disease if

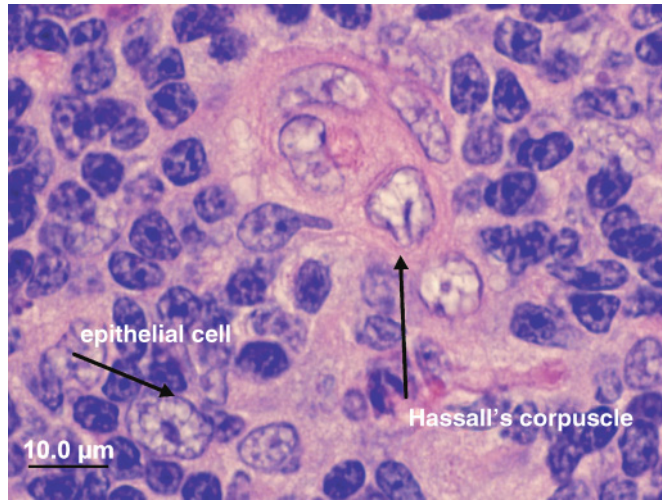

FIGURE 52.3 Hassall's corpuscle in the thymic medullary area consisting of concentric laminations of squamous epithelial cells. The surrounding lymphocytes are characteristically a mixture of small and medium cells and epithelial cells with large pale nuclei (arrow). These cells with moderately abundant cytoplasm separating the nuclei give the medulla a less dense appearance than the cortex on histological examination. Hematoxylin & eosin stain; bar = 10 µm.

they occur near a blood vessel and lie within the vascular epithelial sheath and are thus immunologically outside of the thymus. Detection of this relationship requires application of a cytokeratin stain. The medullary epithelium produces trophic hormones that assist lymphocytic colonization and are the source of cysts lined by ciliated epithelium that frequently develop in adult life but are rarely of clinical significance. An additional cellular component are myoid cells. They surround the Hassall's corpuscles and are important in the pathogenesis of myasthenia gravis.[21] In most species, the thymus reaches its maximal development about the time of puberty and then slowly decreases in size throughout adult life. An unusual antigenic stimulation during adolescent life may result in benign thymic hyperplasia, which, in the calf, may result in a chain of thymic lobules that extend from the rami of the mandibles to the base of the heart.

At the physiological level, the thymic cortex receives a continuous stream of uncommitted lymphocytes of bone marrow origin which undergo immunological selection for tolerance to self-antigens in contact with the reticular epithelial cells which form thin-walled pouches (caveolae) in cortical tissue (see Chapter 51). Paradoxically, the thymic cortical lymphocytes have small densely stained nuclei without apparent nucleoli, yet this is a region of intense cellular proliferation in which the great majority of the progeny die and are removed by tingible body macrophages (Fig. 52.4). These latter cells become more prominent in conditions resulting in cortical lympholysis such as certain viral infections, irradiation, or corticosteroid therapy. Marrow-derived lymphocytes have the cell surface molecules to selectively home to thymic cortical

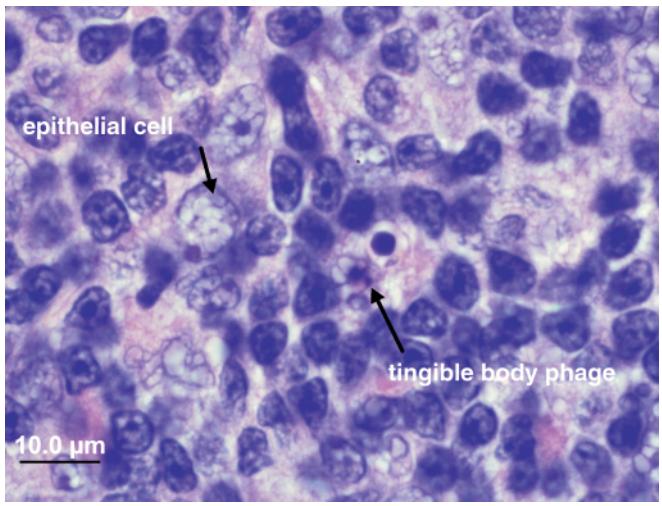

FIGURE 52.4 Thymic cortex composed of densely packed small lymphocytes. A macrophage in the center has cytoplasm that contains several pyknotic nuclear fragments (tingible bodies) of apoptotic cortical thymocytes. The larger vesicular nuclei above and to the left of the macrophage are probably epithelial cells involved in the self-recognition selection process of developing T cells. Hematoxylin & eosin stain; bar = 10µm.

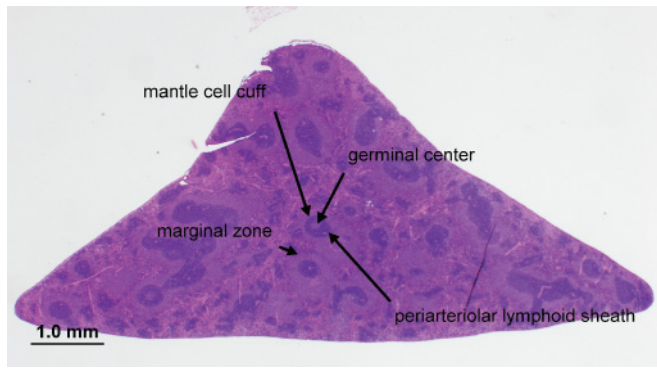

FIGURE 52.5 Cross-section of spleen from a young adult male rat. At the architectural level, the spleen is occupied by multiple, dispersed round dark areas representing lymphoid nodules with the intervening lighter areas consisting of sinuses. The lymphoid or white pulp areas may have a germinal center in the middle of the mantle cell cuff (arrows). These areas are surrounded by the lighter mantle and marginal zone areas. Hematoxylin & eosin stain; bar = 1.0mm.

vascular endothelium. The naïve T cells rearrange their T cell receptor genes (TCR) most to αβ and some to γδ type (see Chapter 51).[5]

Medullary lymphocytes are larger than the cortical cells, having larger and more vesicular nuclei, more cytoplasm, and reduced cell density. These cells give the medullary area less density on histological examination when routine stains are applied. Physiologic development continues when lymphocytes enter the medullary areas with exposure resulting in preferential homing of cells to the intestinal mucosa and Peyer's patches.

In young animals, particularly rabbits, heterophils are frequently found in the thymus, particularly in lobular connective tissue. Eosinophils may occasionally be found in the thymic connective tissues of other species and mast cells are present in the thymic capsules in most species and are particularly frequent in rats. Thymic hyperplasia occurs largely through an increase in number of lobules rather than increased lobule size, while thymic atrophy tends to result in a blurring of the corticomedullary distinction. Thymic function does not necessarily vary in proportion to thymic size and in the adult a small thymic remnant may be responsible for a persistent autoimmune disease. Recent work suggests that terminal maturation of T cells may occur in the intestinal tract as well as in the thymus.[13] It would not be surprising if similar activity was found in both the lung and skin which would provide a more comprehensive explanation for aberrant lymphoid reactions in both benign and malignant states.

Spleen

The spleen filters blood through a sinusoidal system. It has additional functions in lymphopoiesis and antibody production and hemopoiesis under conditions of increased demand for blood cells by colonization of sinusoids with pluripotential stem cells. Species with the genetic potential for sustained activity such as humans, dogs, cats, and horses have spleens with a contractile muscular capsule supported by equally contractile internal trabeculae. In contrast, species such as ruminants, which tend to group together for protection against their more agile predators tend to have spleens whose capsules are largely connective tissue with less capability for contraction. The major hazard to life after splenectomy appears to be septicemia. The spleen forms early in embryonic life and is a site of active erythropoiesis during the fetal period. The spleen is both architecturally and cytologically complex. It contains a wide variety of cells that vary in proportion in reactive and disease states. The spleen also has a diverse regional anatomy based on a complex vascular system able to alter internal anatomy with changes in overall size and volume.

The spleen is unique in having efferent but no afferent lymphatics. Thus, all antigen enters the spleen through the blood vascular system. Both the major arterial supply and venous outflow enter through the hilus of the spleen and arborize together throughout its length. This arborization is relatively random in mammals but in reptiles there is a system somewhat analogous to the bone marrow with a major central venous sinus. At the level of small and medium-sized arterioles, the vessels are sheathed in a cuff of small thymic-derived lymphocytes known as the periarteriolar lymphoid sheaths (Fig. 52.5). Very small branches from these "central" arteries give rise to germinal centers that are foci of B cell proliferation. Surrounding the dense cuff of lymphocytes of the periarteriolar lymphoid sheath is a more loosely aggregated area of lymphocytes of the mantle cell layer that is a mixture of T and B cells. This mantle cell layer surrounds the

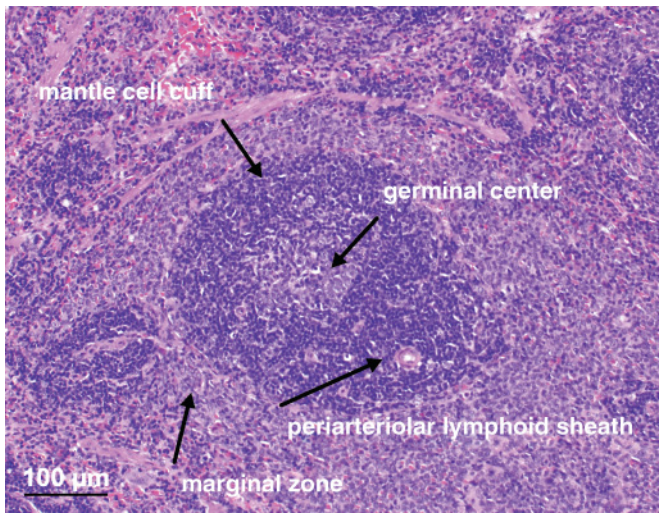

FIGURE 52.6 Details of Figure 52.5. Unlike larger mammals, rats tend not to have well-formed splenic germinal centers. In the middle of the image, a lighter zone constitutes the dendritic cell bed of an ill-defined germinal center eccentric to and abutting a small muscular arteriole at lower right (arrows). The germinal center is surrounded by a cuff of darker mantle lymphocytes that has an outer envelope of lighter-staining marginal zone cells that interface with the surrounding splenic red pulp. Hematoxylin & eosin stain; bar = 100 µm.

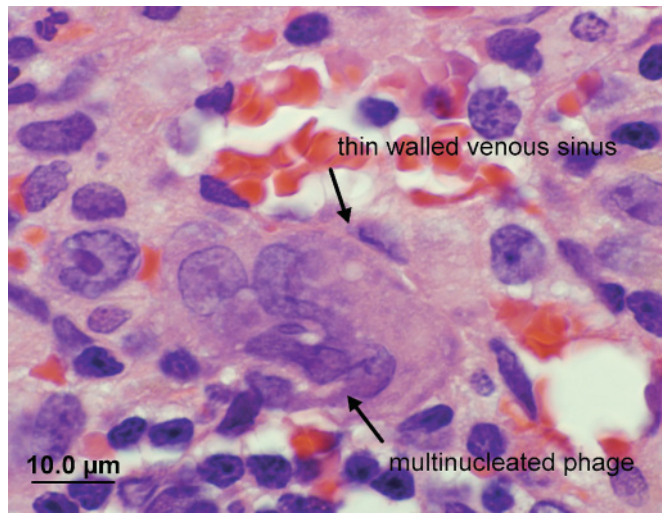

FIGURE 52.7 Splenic sinus area demonstrating the interposition of a large multinucleated macrophage and a thin walled sinus facilitating the filtering system of the spleen. Hematoxylin & eosin stain; bar = 10 µm.

germinal centers that arise adjacent to the central arterioles. A marginal zone of B cells lies outside the mantle cells (Fig. 52.6). Whereas the cells of the periarteriolar sheath and germinal center are composed of resident cells with movement largely through negative selection and replenishment, the lymphocytes of the mantle cell layer interchange with cells of the germinal center. The width of marginal zone cells varies widely with immune activity and is itself surrounded by a trough or sinus area that receives blood coming through the germinal center. This area may appear more red in histological section and contains cells currently in the general circulation; it may be viewed to assess the levels of cells in circulation. In humans and the cat this peripheral sinus or perifollicular zone lies between the mantle cell cuff and the marginal zone layer. The rat and mouse have a definite stromal appearing boundary around the mantle cells and germinal center that is not present in humans or domestic animals. The small branches of the central arteriole may terminate in germinal centers or pass through mantle and marginal zones to terminate in a penicillary array of small branches that feed directly into the sinusoids. The penicillary vessels are ensheathed by a few plump reticular cells forming a contractile ellipsoid which under neural and hormonal control adjusts the level of blood entering venous sinuses.

The venous sinuses of the spleen constitute the expansile regions of the organ and thus may vary greatly in their content of blood in species with a high level of smooth muscle in the splenic capsule. The walls of the splenic sinusoids are unique in consisting of elongated endothelial cells arranged like the staves of a barrel which are without junctions to their neighbors but are maintained in alignment by a discontinuous encirclement of fine reticular fibers (Fig. 52.7). The lumen of these sinuses communicates directly to the exiting vein of the spleen while the exterior of these veins is in contact with the filtering area of spleen that consists of macrophages suspended in a loose reticular supporting framework. Under normal circumstances 97% of the arteriolar blood entering the spleen exists directly via the penicillary vessels into a major sinus and quickly re-enters the central circulation. The remaining 3% passes into the filtering extrasinusoidal area to regain the central circulation by passing between the walls of the sinus endothelial cells. Reticulocytes and normal RBCs and leukocytes readily achieve this transit back into the circulation while senescent RBCs, those containing Howell-Jolly bodies, senescent leukocytes and foreign material, are phagocytosed by the macrophages of the red pulp areas. By this process, the entire blood volume passes through the filtering system of the spleen once each day. In a muscular spleen in the contracted state, all of the blood would pass directly from the arteriole to the venous system in a "closed" circulation, permitting maximal utilization of blood cells in the systemic circulation. In contrast, any influence that causes the splenic capsule to dilate (e.g. anesthesia, portal hypertension due to hepatic fibrosis or marked increase in extrasinusoidal macrophages) results in a greater proportion of blood passing through the filtering system. Due to the slow flow of blood through the red pulp, cells are exposed to lower glucose, cholesterol, and pH than in the central circulation. Collectively, these biochemical changes can contribute to premature aging of RBC and platelets resulting in accelerated destruction. Thus, an enlarged spleen of any cause is a distinct hazard to RBC and platelet lifespan.[1]

A variety of changes occur in the spleen in response to systemic states. Acute toxic diseases will result in

lysis of lymphocytes in the germinal centers and replacement by residual proteinaceous debris referred to as follicular hyalinosis. Diagnosticians are aided by the fact that nuclear debris after acute lympholysis is cleared within 24 hours but the hyalin debris may remain for many months. In systemic amyloidosis, the germinal centers may become sites of amyloid deposition, while atrophic changes due to starvation, aging, cancer, or chemotherapy may result in atrophy which impacts one or both of the thymic-dependent arteriolar sheaths or bone marrow-dependent germinal center systems. In chronic hemolytic anemias, a marked increase in hemosiderin-bearing macrophages in sinus areas and iron deposition can occur in the connective tissue of the spleen, particularly in old dogs. Splenic infarction occurs in focal areas of the spleen in dogs with hemangiosarcoma and is always of hemorrhagic type. Ischemic infarction can occur in dogs with myeloma due in part to the greater viscosity of blood. Splenic torsion occurs primarily in dogs and humans and rarely in adult pigs and is surprisingly compatible with life. These events in the dog are apparently painful and dogs with focal infarction due to hemangiosarcoma resist activity and become anorexic even without abdominal hemorrhage.

Lymph Nodes

Histogenetically, lymph nodes form at the confluence of an afferent lymphatic sprig with a dilated sheath of vascular serosa. The blood vessels covered by the serosal sheath then produce a fine arborization of vessels within this area of dilation, thus forming an architectural framework for lymphocytic colonization. The vascular distribution to lymph nodes is highly organized with the arteriolar and venous branches arborizing through the medullary cords to form microcirculatory units that become the functional basis for germinal center formation. Specialized high endothelial venules form in the paracortical areas between, and never within, the germinal centers and present specific adhesion molecules by which transmural lymphocyte traffic from blood to node paracortex is regulated.[3] The normal development of lymph nodes is dependent upon cells and antigens entering through the afferent lymphatics that drain into the peripheral capsule of the node. Virgin (non-activated) lymphocytes apparently circulate randomly in the blood; however, once these cells are involved in antigen recognition in the node cortex, their further migration becomes altered. Activated B cells migrate preferentially to mucosa-associated lymphoid tissues (MALT), while T cells migrate to peripheral lymph nodes.[5,7] This system of organ-specific lymphocyte homing receptors functions in neoplastic as well as inflammatory conditions, with the spread of malignant lymphocytes limited by their capacity to migrate into various tissues. Malignant lymphocytes tend to mimic their benign counterparts with B cell neoplasms like reactive B cells binding to endothelial venules in certain anatomic sites, including tonsil and lymph node. Thus, the spread of lymphoma to lymphoid structures is not a function of the tumor cells being able to enter the peripheral blood, but rather an indication that the cells have successfully bound to endothelial venules in order to migrate into additional lymphoid structures.[15] By this understanding, lymphoid neoplasms circulate in the blood, but their degree of dissemination is limited to their binding capability; this has led to the new assessment of leukemia versus lymphoma based simply on the tissue with the greatest volume of tumor.

The afferent lymphatics and the peripheral capsule and the subcapsular sinus are the delivery systems whereby lymph, blood cells, and antigens are delivered to the interior of the lymph node (Fig. 52.8). The peripheral capsule will be thin and taut in conditions in which there has been rapid enlargement of a lymph node of benign or malignant cause. In contrast, lymph node atrophy results in the histologic appearance of a capsule that is thickened and wavy, with the peripheral sinus widened. Chronic stimulation of a node from either hyperimmune or septic cause results in thickening and sclerosis of the capsule with thickening of the fibrous raphe which spans the cortex and terminate in a dense collagenous medullary fibrovascular network.[19] In cattle and likely in other species, the lymph node capsule is contractile and under neural control, thus assisting lymph flow.[12]

The lymph node cortex and germinal centers form the first order of filtering system through channels extending from the inner lining of the peripheral sinus to the microcirculatory units in the node cortex. A fully developed germinal center is a highly organized structure consisting of a progression of cell types in a proliferative gradient that provides the germinal center with an easily recognized polarity (Figs. 52.9 and 52.10).[16]

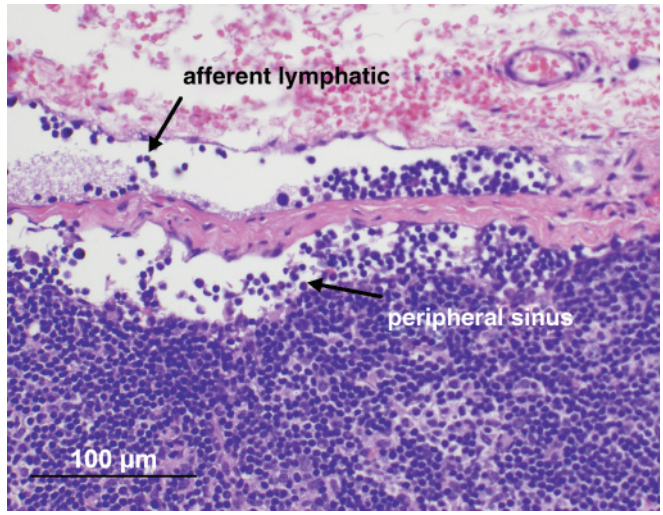

FIGURE 52.8 Lymph node outer cortex from a healthy dog. An afferent lymphatic (arrow) leads into the peripheral sinus beneath the node capsule. The sinus is open and contains a few cells in transit, whereas to the left and right, the sinus is compressed by developing germinal centers. Hematoxylin & eosin stain; bar = 100 µm.

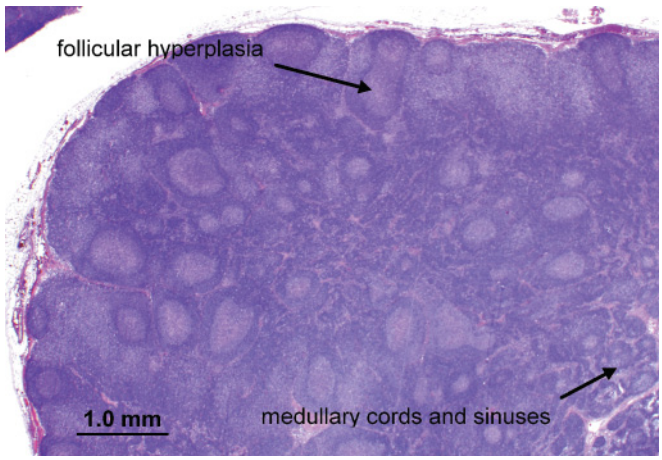

FIGURE 52.9 Architecture of the lymph node in Figure 52.8 showing follicular hyperplasia and densely cellular medullary cords and sinuses (arrows). Hematoxylin & eosin stain; bar = 1.0 mm.

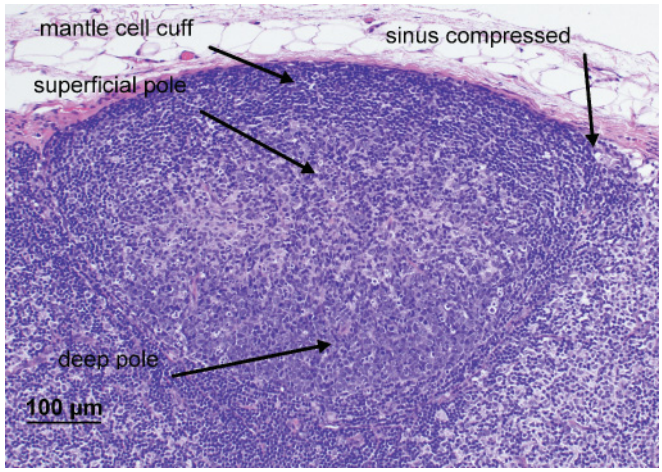

FIGURE 52.10 Lymph node cortex of Figure 52.9 with subcapsular germinal center having a polarity directed toward the antigens being delivered from the peripheral sinus into the superficial pole of small lymphocytes. In the middle of the germinal center, there are small and large lymphocytes with macrophages removing apoptotic lymphocyte nuclei. Near the bottom of the picture, the deep pole area consists of lymphocytes with large nuclei and a narrow rim of highly basophilic cytoplasm. Hematoxylin & eosin stain; bar = 100 µm.

The polarity gradient of the germinal center consists of a mantle cuff of small lymphocytes at the superficial pole, just beneath the inner lining of the peripheral sinus. Antigen sorting and processing occurs through a focusing process, with the antigen presenting dendritic reticular cells in the middle of the germinal center accompanied by tingible body macrophages. Morphologically, the lymphocytes of the superficial pole have small dense nuclei with abundant lightly stained cytoplasm, while those in the deep pole have large nuclei with multiple prominent usually peripheral nucleoli and only a narrow rim of very basophilic cytoplasm. The mantle cell cuff is eccentrically thickened at the superficial or capsular pole and thinned at the base of the deep pole. In follicular hyperplasias, the germinal centers beneath the node capsule are usually sectioned in a plane that allows their antigen orientation to be recognized, but those in medullary areas are oriented in a variety of planes such that all levels of the proliferative progression of cells will be viewed.[8] This point is worth emphasizing since it is essential to recognize polarity of germinal centers to distinguish benign and atypical follicular hyperplasias from follicular lymphomas. Follicular lymphomas whether of small cleaved cells of centrocytes, or large cells of centroblasts, or more often a mixture of these, completely lack a mantle cell cuff and are surrounded by a few residual small benign lymphocytes and the aggregations of postcapillary venules. A further distinction of follicular lymphomas is that whatever combination of cell types are present, each follicle will have only that same clonal assembly and lack the variety of benign follicles. Also, unlike benign follicles, those of follicular lymphoma have few or no tingible body macrophages as the tumor cells, unlike the benign cell selection process, are not undergoing apoptosis. A further distinction between true follicular lesions, whether benign or malignant, and pseudofollicular lesions is that the post-capillary venules are always between the follicular or nodular proliferations and never within them.

The dendritic reticulum cells are derived from a variety of sources and can derive from either myeloid or lymphoid precursors.[4,9,10,17] Dendritic cells at various anatomic sites have different phenotypic characteristics.[10] Ultrastructurally, the dendritic cells are characterized by cytoplasmic tendrils that are joined by tight junctions. In conditions of lymphoid depletion, the dendritic cells become exposed in germinal centers as the eosinophilic background of large pale cells.

One of the more difficult decisions in examining lymph nodes is the distinction between florid hyperplasia and lymphoma.[24] The syndrome of transformation of germinal centers to malignant disease is described in humans[6,14] and it would appear that in animals chronic lymphoid proliferation of any cause can be a serious risk factor for lymphoma. Examples of this type of interaction in animals include infection with FeLV or BLV and immunoproliferative small intestinal disease of idiopathic cause. A type of nodular or follicular lymphoma in which the malignant cells are derived from the corona of cells surrounding the germinal center occurs in both humans and animals and is known as mantle zone lymphoma. Morphologically, the disease is characterized by coalescing nodular proliferations of moderate-sized lymphocytes surrounding fading germinal centers.

In the paracortex of lymph nodes, there are nodular structures distinct from germinal centers,[24] that are particularly common in the mesenteric nodes of mature rats.[3] These deep cortical units form as a result of antigenic stimulation, with cellular input from a distinct afferent lymphatic radical (Fig. 52.11). They form semicircular or oval structures beneath the germinal centers of the outer cortex and are most easily seen in lymph nodes with some degree of paracortical atrophy, making the nodules more apparent. Central areas of these

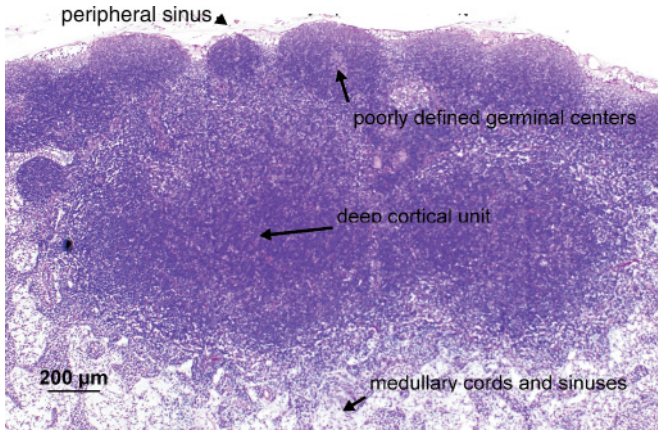

FIGURE 52.11 Cross-section of rat mesenteric lymph node. The upper area of the node is occupied by typically poorly defined germinal centers. The medullary cords and sinuses lie along the bottom of the image and abut a large uniformly dense oval deep cortical unit that lies across the cut surface of the node. The unit is lightly outlined by a rim of less dense cellularity. Hematoxylin & eosin stain; bar = 200 µm.

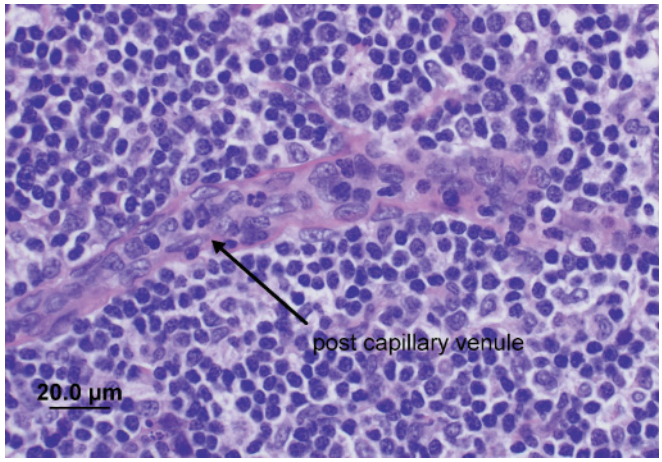

FIGURE 52.12 Paracortex of rat mesenteric lymph node with a high endothelial post-capillary venule crossing the center. Several lymphocytes within the wall of the venule can be seen to be in transmural transit exiting the blood to enter the node cortex (near arrow). Hematoxylin & eosin stain; bar = 20 µm.

nodules are somewhat mottled in appearance due to varying proportions of large and small lymphocytes with some macrophages and post-capillary venules (Fig. 52.12). Edges of these nodules gradually meld with the surrounding medullary cords and sinuses and are apparently the areas where cells exiting these nodules enter the efferent lymph channels.[3] The main significance of the deep cortical nodules is to recognize that they are normal structures and not to confuse them with a malignant lymphoid proliferation.[3]

The medullary cords and medullary sinuses are best considered together because they form an interwoven matrix that waxes and wanes in unison or at the expense of each other (Fig. 52.13). A medullary unit consists of a radical of vascular structures from the deep pole of

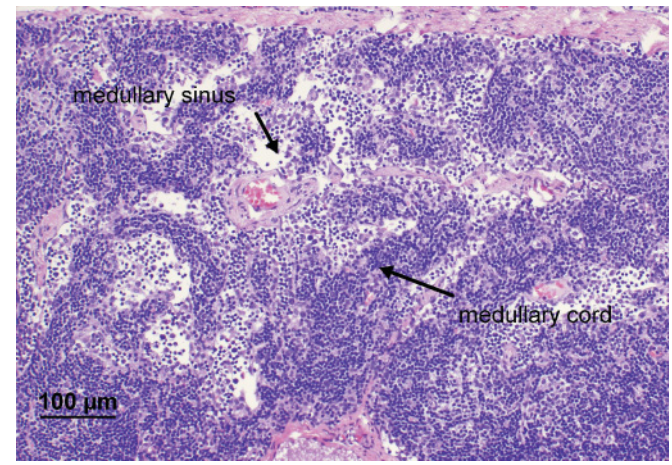

FIGURE 52.13 Medulla of a lymph node from a dog with normal cords and sinuses. The cords are densely cellular and surrounded by a thin endothelial membrane with the sinuses containing a few fixed macrophages and cells in transit in a background of lymph. Hematoxylin & eosin stain; bar = 100 µm.

the node hilus consisting of an artery, vein, and lymphatic surrounded by a variable amount of connective tissue and invested with a thin endothelial covering. These vascular structures form the center of many medullary sinuses as they are seen in a cross-sectional profile. The sinus area constitutes the space between the endothelial wall of the vascular structures and the similar endothelial wall of the medullary cords. The medullary sinuses may extend up to the inner surface of the subcapsular sinus in nodes in which there is severe paracortical and follicular atrophy. Such a circumstance occurs in the mesenteric nodes of cattle dying of acute bovine viral diarrhea virus infection with massive B cell lysis in which the sinuses tend to be filled with macrophages, thus forming sinus histiocytosis.

The cellularity of the medullary sinuses will vary widely. In diseases characterized by chronic immune stimulation, there usually are large numbers of sinus macrophages which are apparently suspended in a syncytial network. In nodes draining areas of chronic dermatitis, the macrophages of the superficial cortex and those of the medullary sinuses frequently contain abundant normal-appearing melanin granules.[18] Similarly, nodes draining areas of hemorrhage have numerous hemosiderin-bearing macrophages in medullary areas. The transit of RBCs to the lymph node and the process of RBC intracellular degradation is remarkably rapid; thus any amount of erythrophagocytosis by medullary macrophages must be looked on as a very recent event.

The medullary cords contain recirculating lymphocytes that have received antigenic orientation by passage through the outer cortex. The medullary cords may contain small or medium lymphocytes rather than plasma cells, even in reactions that have persisted for many weeks. The fine reticular network of the medullary cords forms a fertile microenvironment for extramedullary hematopoiesis. In myeloid leukemias, the malignant cells also colonize the medullary cords,

and under these circumstances, there may be both tumor and benign extramedullary hematopoiesis coexisting.

LYMPHOID SYSTEMS OF BODY SURFACES

In the context referred to herein, body surfaces include the skin as well as the lining of the upper and lower respiratory and enteric systems. Intraepithelial lymphocytes in all these locations are not primarily cells on the way to being lost to the exterior but rather cells in training, which, following their specific sensitization, return to deeper lymphoid structures to perform a specific function in differentiation and proliferation.

In the skin, keratinocytes constitute 85% of the epidermis with the remaining cells constituting melanocytes, Langerhans' cells, Merkel cells and dendritic cells of uncertain type. In humans and cattle, the Langerhans' cells contain a typical cytoplasmic organelle visible on ultrastructure that is rod-shaped with a unipolar bulb, the Birbeck granule. The Langerhans' cells are products of a variety of precursors and constitute the major antigen presenting cell of the epidermis.[1] The presence of Birbeck granules permitted identification of Langerhans' cells in the paracortex of lymph nodes draining skin. These cells ingest foreign molecules without degrading them and migrate to the local lymph nodes where these antigens are exposed to naïve lymphocytes in specific MHC context. Both T and B cells are present in the skin where their function is largely unknown.[2] A fairly consistent proportion of cutaneous lymphocytes are suppressor T cells which may be resident in situ to dampen cutaneous immune sensitization.

The mucosa-associated lymphoid tissue of the respiratory and enteric systems is in common in the tonsils and pharyngeal areas, which in humans, are collectively known as Waldeyer's ring. In the respiratory system, the epithelium of the nasal mucosa as well as the larynx, trachea, and bronchi are infiltrated to a variable extent with lymphocytes and to a lesser extent with neutrophils and macrophages. Mucosal infiltration is also more prominent above areas of submucosal lymphoid proliferation such as occurs in the tonsil and in bronchiolar-associated lymphoid tissues.[2] In general, the level of reactivity in these areas is related to the level of antigenic stimulation. Lymphoid proliferation in the tonsil is usually characterized by prominent germinal center formation, while in the lower lung, in conditions of health, the lymphoid tissue may be minimal and restricted to diffuse accumulations of cells between the bronchial epithelium and the supporting smooth muscle and cartilaginous plates (Fig. 52.14).[20] The impact of ambient air quality in terms of freedom from dust particles and airborne infectious agents is immediately apparent in the histology of laboratory animals. Animals maintained in facilities where the air is well filtered have minimal bronchiolar-associated lymph node tissue and few intra-epithelial lymphocytes. In contrast, animals maintained in less pristine circumstances characteristically have diffuse lymphoid proliferation in the proximal trachea and laryngeal areas with heavy and mixed cellular infiltration of the surface epithelium. In the lower lung, the lymphoid proliferation, which may contain germinal centers but is usually diffuse, may be of sufficient volume to partially occlude airways. As in other areas, the lymph nodes draining the lung at the base of the heart and in the caudal mediastinum bear the evidence of past environmental experiences including contact with smoke and other inhaled particulate matter.

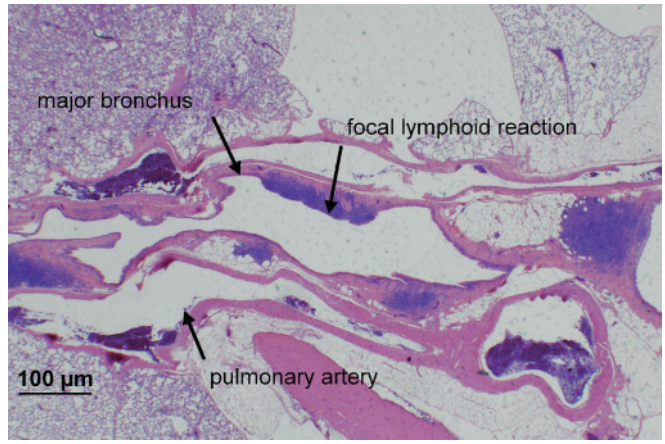

FIGURE 52.14 Lung from a normal rat with longitudinal section of a major bronchus. Note that the focal areas of lymphoid proliferation are both peribronchiolar and subepithelial. Hematoxylin & eosin stain; bar = 100 µm.

The gut-associated lymphoid tissue forms a relatively continuous chain from the oral cavity to the anus in characteristic areas of proliferation. There are generally few lymphocytes in the epithelium and mucosa of the esophagus. Lymphoid proliferation with germinal center formation is not normal but relatively common beneath the gastric epithelium where lymphomas are relatively frequent in both humans and animals. In recent years, with discovery of the association between *Helicobacter* and human gastric ulceration, it has become apparent that most of the lymphoid tissue present in these cases is antigen dependent and rapidly recedes with long-term antibiotic therapy. Even more remarkably, cases of human gastric lymphoma in at least early stages of development appear to be antigen-dependent and may regress with antibiotic treatment alone. The organized areas of lymphoid tissue in the lower small intestine including the Peyer's patches are estimated to equal the thymus gland in young animals (Fig. 52.15). The epithelium overlying the intestinal germinal centers is generally devoid of goblet cells and villi, and glandular crypts are absent (Fig. 52.16). In these areas, the epithelium contains specialized cells with complex folding of the surface epithelium known as M cells.[23] M cells enfold lymphocytes within their membranes and function as antigen trephocytic cells able to metabolize particulate antigen to a level of digestion or nucleotide message that instructs the associated lymphocytes to specific immune reaction. Much of the immunoglobulin

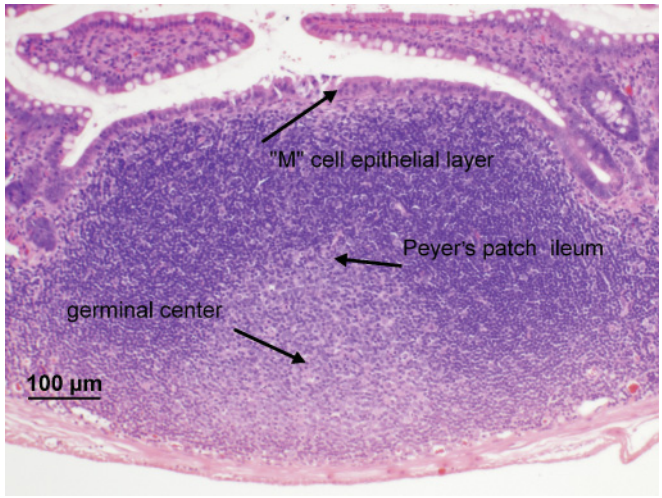

FIGURE 52.15 Lower small intestine of normal rat. A focal submucosal proliferation of lymphocytes in a dome area characterized by absent villi and modified epithelium to assist antigen recognition and sorting. Hematoxylin & eosin stain; bar = 100 µm.

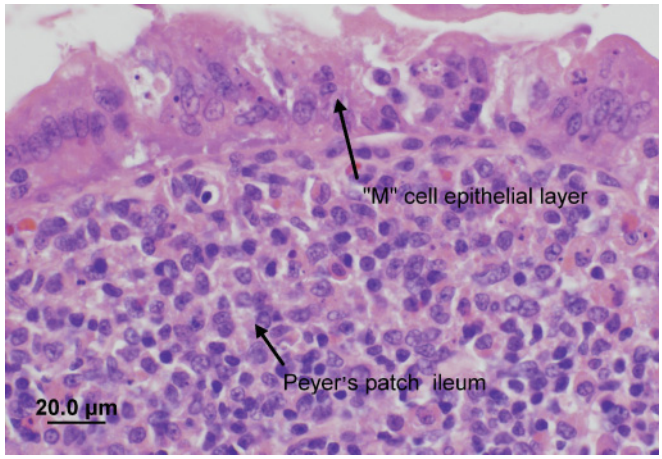

FIGURE 52.16 Details of Figure 52.15. The epithelium above the lymphoid follicle is modified to contain M cells that have deeply folded cellular membranes that enclose intraepithelial lymphocytes. The M cells are capable of uptake and of processing antigen from the intestinal lumen and providing immune instruction to maturing lymphocytes. In this area there are lymphocytes in the epithelium undergoing apoptosis presumably similar to the selection process in node germinal centers. Hematoxylin & eosin stain; bar = 20 µm.

produced in these areas is IgA-type with luminal and mucosal concentrations higher than that in blood.

Summary

Acronyms and Abbreviations

BSE, bovine spongiform encephalopathy; BVD-MD, bovine viral diarrhea-mucosal disease; GDV, gastric dilation and volvulus; IMHA, immune-mediated hemolytic anemia; RBC, red blood cell.

The spleen serves many important roles in mammals. These include the production of cells in fetal and adult life, phagocytosis and opsonization of particulate materials and pathogens, filtering of blood, storage and release of blood cells to meet physiologic demands, participation in the recycling and metabolism of iron, and immune reactivity. The spleen is critically important in defense against a variety of pathogens. A detailed review of anatomy and physiology of the spleen is found in Chapter 52.

SPECTRUM OF SPONTANEOUS SPLENIC DISEASE IN ANIMALS

There is a large amount of published information on disorders of the spleen in humans, but considerably less for spontaneous diseases of the spleen in domesticated animals. Good data on the prevalence of disease is available for dogs and cats. In two papers, Spangler and Culbertson [53,54] surveyed neoplastic and non-neoplastic splenic lesions in dogs and cats. Table 53.1 describes major neoplastic and non-neoplastic lesions in samples of dog spleens from three different sources. These data show that non-neoplastic disease accounts for approximately 60–80% of splenic lesions in dogs, depending on the source of the sample. A number of lesions of the canine spleen can be considered uncommon, occurring in 3% or less of samples submitted for diagnostic evaluation (Table 53.2).

Spangler and Culbertson also published data on the incidence of neoplastic and non-neoplastic lesions in the spleen of cats. Their data were formulated from evaluation of 455 specimens sent to the diagnostic laboratory of a teaching hospital (Table 53.3).[54] It is clear that in cats, neoplastic disease of the spleen is significant and that hyperplasia of various elements is noteworthy. The relative importance of a diagnosis of splenic congestion is problematic, given that many specimens collected from either species may have been done with benefit of anesthetic agents or from animals euthanized with barbiturates.

We have conducted a comprehensive review of the literature on splenic and hemolymphatic disease in horses.[44] Single and small cohort case reports on splenic rupture, abscessation, and infarction have appeared over the past 100 years, but given the paucity of this information, it appears that splenic disease is rarely a problem in horses. Horses, as dogs, show splenic enlargement when euthanized with barbiturate overdose, although to a lesser degree.

TABLE 53.1 Prevalence of Major Lesions Seen in the Spleens of Dogs Submitted for Evaluation

Diagnosis	Group 1[a] (*n* = 1,372)	Group 2[b] (*n* = 92)	Group 3[c] (*n* = 105)
Splenic hematoma	10%	19%	
Hyperplastic nodules	23%	6%	59%
Hematoma/nodules	10%	19%	
Hemangiosarcoma	10%	24%	9%
Neoplasm, not hemangiosarcoma	11%	21%	22%
Extramedullary hematopoiesis	6%		
Congestion	7%	2%	
Lymphoid hypoplasia	4%		

[a]Group 1. Specimens submitted to a diagnostic laboratory for evaluation by referring veterinary practitioners.
[b]Group 2. Specimens obtained by splenectomy at a teaching hospital.
[c]Group 3. Specimens obtained from a colony of Beagle dogs studied throughout their lifetime.[53]

TABLE 53.2 Uncommon (3% or less of diagnoses) Non-Neoplastic Lesions in the Canine Spleen from 1,372 Submissions to a Diagnostic Laboratory of a Teaching Hospital[53]

Diagnosis	% of Total Submissions
Accessory spleen	3%
Siderotic plaques	3%
Infarcts	1%
Arterial thrombosis	1%
Torsion	<1%
Splenitis	<1%
Abscess	<1%
Amyloidosis	<1%
Sinusoidal telangiectasis	<1%

Fibrosis	<1%
Capsulitis/peritonitis	<1%
Capsular mineralization	<1%
Traumatic rupture	<1%
Necrosis	<1%

Cattle and other ruminants have splenic involvement with a variety of infectious, inflammatory, and immune-mediated diseases (discussed more fully below). Splenic changes frequently accompany systemic granulomatous disease and parasitic diseases, these changes being reflective of a splenic response to pathogens. Several cases of splenic disease in cattle due to exposure to plant or environmental toxins are reviewed. Within the past 10 years, the importance of the spleen as a potential reservoir for prions has been studied both for the scrapie agent in sheep and for determining the role of the spleen in the pathogenesis of bovine spongiform encephalopathy.

Rodents, dogs, and non-human primates are sometimes used as translational models for human diseases.[17,18,32,45] Dogs, especially, are widely used as models for traumatic injury to the spleen, although the validity of the dog as a model might be questioned, given the low incidence of traumatic splenic rupture in dogs. Likewise, rodents and dogs have been used to study the effects of splenectomy; however, dogs appear to be rather resistant to post-splenectomy sepsis.[15] Unfortunately, there have been few studies of the pathobiology of this apparent resistance.[62] Non-human primates are primarily used in laboratory settings and there is a paucity of literature on spontaneous splenic lesions of wild non-human primates.

TABLE 53.3 Prevalence of Major Splenic Diseases in Cats obtained as Diagnoses from 455 Specimens Submitted to a Teaching Hospital Diagnostic Laboratory[54]

Diagnosis	% of Total Submissions
Neoplastic disease	54%
Congestion	9%
Lymphoid hyperplasia	7%
Lymphoid hypoplasia/atrophy	7%
Capsulitis/peritonitis	5%
Extramedullary hematopoiesis	4%
Accessory spleen	4%
Hyperplastic nodule	3%
Splenitis	2%
Infarct	1%
Necrosis	1%
Lymphoid necrosis	1%
Reticuloendothelial hyperplasia	1%
Fibrosis	<1%
Amyloidosis	<1%

DIAGNOSTICS

Studies over the past 10 years have resulted in several useful techniques for evaluation of normal and abnormal spleens. Several improvements have been made to standard and contrast enhanced splenography, ultrasonography, and to histopathologic methods of evaluation. Szatmari and co-workers[58] and Ohlerth and co-workers[37] described an ultrasonographic method, contrast harmonic imaging, to study the anatomy and kinetics of movement of a microbubble contrast agent in the spleen of normal dogs. The patterns of distribution and elimination of the agent were not adversely affected by age, gender, blood pressure, or blood composition variables. Rossi and co-workers[47] studied focal benign and malignant lesions, sonographically, in 26 dogs and 2 cats and correlated ultrasonographic interpretations with histopathology and cytology. They were able to distinguish disease-related ultrasonographic appearance for several types of malignancies. This confirmed earlier studies conducted with similar methods in 29 dogs and 3 cats.[4]

Cytologic interpretation of the spleen is becoming more commonplace. Christopher[13] presented a comprehensive overview of the use and interpretation of fine-needle aspirates in the diagnosis of splenic disorders. However, a study of ultrasound-guided splenic

biopsies by Ballegeer and co-workers[4] showed a relatively low rate (61%) of correlation between fine-needle aspiration biopsy diagnosis and histopathologic diagnosis. For non-neoplastic conditions, cytologic and histopathologic diagnosis agreed 11 out of 14 times. For neoplastic lesions, the cytologic diagnosis agreed with the histopathologic diagnosis in 8 out of 17 times.

DISORDERS OF THE SPLEEN

Developmental Defects

A rare congenital form of asplenia (familial isolated congenital asplenia) has been described in humans associated with mutations in connexin 43 and ZIC3 genes.[8,20] A mutation in the Hox11 gene produces isolated congenital asplenia in mice.[40] Common clinical problems seen in humans with asplenia or hyposplenism include a wide variety of vascular, autoimmune, and thrombotic diseases.[21,64] There have been few published reports of asplenia in domesticated animals.

Circulatory Disturbances – Infarction

In all mammals, the spleen is abundantly vascularized and has an anatomically unique and redundant circulation (see Chapter 52).[2] It is relatively resistant to circulatory compromise. Infarction of the spleen, from partial or complete occlusion of the splenic blood supply, can result in loss of splenic tissue and function. There are many causes. The presence of any occlusive bodies (e.g. thromboemboli, bacterial plaques, fat, air) that gain access to the circulation can cause splenic infarction. In ruminants, abscesses of the liver and mammary gland may erode the walls of major vessels in these organs, leading to septic embolic showers that infarct many organs, including the spleen. The enlargement of lesions in the mesentery, omentum, or in tissues and organs within the peritoneum (neoplasms and abscesses) are frequent causes of compression of the blood supply to the spleen, resulting in infarction. Partial blood flow and collateral circulation are important determinants in survival of splenic tissue after circulatory compromise. Wright and co-workers[65] introduced 20–500 µm microspheres into the circulation of dogs to investigate non-surgical methods for treatment of splenic masses. Dogs suffered few acute effects and within 6 weeks marked splenic fibrosis was noted.

Monsivais and co-workers[34] experimentally "infarcted" the spleens of 20 cats using total splenectomy. They then crushed and debrided a portion of the spleen, and reimplanted them with microvascular anastomosis after periods of one to several hours. Portions of the spleen that had adequate restoration of circulation returned to normal morphology and function, while those with residual circulatory deficits underwent atrophy by 8 weeks. This work demonstrated that restoration of circulation was requisite for function and this has direct implications in splenic infarction management in domesticated animals.

Gastric dilation and volvulus (GDV) in dogs frequently results in compromise of the blood supply to the spleen and can be a major cause of splenic infarction.[9,25] In a study of 295 cases of GDV, splenic torsion occurred at a rate of 20%.[9] Large breed and deep-chested phenotype are predisposing factors for torsion.[36] Splenectomy is recommended rather than de-torsion.[63] Release of myocardial depressant ions (potassium), microemboli, and bacterial toxins are all undesirable consequences of de-torsion. Complications associated with primary or secondary splenic torsion associated with GDV include cardiovascular compromise, hemorrhage, and coagulation disorders.[5]

Traumatic Lesions

Abdominal trauma can damage the spleen, leading to hemorrhage, hemoabdomen, and death. Common causes of trauma, including falling, impact with blunt objects (automobiles), and penetrating wounds (projectiles) all have been associated with splenic fracture or rupture. The spleen is generally protected from the direct effects of blunt trauma by intervening structures in the body wall, the cushioning effect of intraperitoneal fat, and the omentum. A complex but efficient system of ligaments and vessels hold its position.[6] The fibroelastic capsule that invests the spleen also protects it from trauma. As reported by Spangler and Culbertson,[53,54] rupture of the spleen occurs infrequently in dogs and cats. Splenic rupture in horses following episodes of falling, impalement, and dynamic force has been reported.[44]

While the normal spleen is highly resistant to rupture, the diseased spleen is not. Splenic hemangiosarcoma may breach or compromise the splenic capsule. Uncontrolled bleeding from ruptured neoplastic tumors frequently leads to hemoabdomen and collapse of affected animals. Likewise, non-neoplastic tumors may compromise the integrity of the spleen and also lead to rupture and bleeding. The friability of the spleen that accompanies viral, protozoal, and bacterial infections can lead to splenic rupture.[49] Mice infected with *Plasmodium berghei* show splenic enlargement that can predispose to splenic degeneration and rupture.[41]

Accessory spleens and small splenic remnants following omental implantation are routinely recognized as incidental findings at post-mortem examination of animals. There are several theories concerning their origin. Some accessory spleens and remnants are thought to represent ectopic development of tissue during embryogenesis. Implantation of small pieces of spleen in the omentum, following splenic trauma, have been recognized frequently during necropsy, and it is theorized that fragments dislodged during the traumatic event are encapsulated and vascularized by omental tissue shortly after injury. Experimental studies in dogs showed that small splenic implants readily vascularize in the omentum and sustain some functions of normal spleens.[50,61]

The differentiation of accessory splenic nodules and splenic remnants is important diagnostically when

encountering dogs with splenic hemangiosarcoma. Histological benign accessory spleens and remnants may be confused with implantation metastases. In these cases, samples of suspect "metastases" should be harvested and evaluated histopathologically.

Infectious, Inflammatory, and Immune Disorders

Infectious Agents That Affect the Spleen

Erythrotrophic Pathogens Pathogens that target red blood cells (RBCs) including *Mycoplasma* sp. (previously termed *Haemobartonella*), *Babesia* sp., *Plasmodium* sp., *Anaplasma* sp., *Theileria* sp., and *Eperythrozoon* sp. all produce splenic lesions consistent with the spleen's role in the management of degenerate RBCs.[14,29,44,57] All are important pathogens of domestic animals or humans, causing significant economic loss, morbidity, and mortality. Many are transmitted through intermediate vectors. A few merit further discussion.

Mycoplasma felis is an important acute and chronic disease in cats (see Chapter 31).[44] The spleen plays the major role in extravascular destruction of infected RBCs. During the course of disease, splenomegaly is a reflection of increased demand for splenic function. Various studies have considered the importance of the spleen in either participating in the pathogenesis of clinical signs or, conversely, in maintaining resistance to infection in cats. Although it was believed that most splenectomized cats would develop hemobartonellosis,[18] this has not been demonstrated in experimental studies.

Bartonella infection in cats is considered to be one of a number of related emerging zoonotic diseases.[7] At least five separate *Bartonella* species infect cats as intracellular parasites in RBCs and vascular endothelium, and separate species of the genus are widely distributed in other mammals. In the spleen, liver, and lymph nodes of infected cats, this pathogen can incite granulomatous inflammation. Subclinical disease has been reported and while not frequent, thrombocytopenia, neutropenia, and lymphocytosis have been detected in some infected cats. Definitive diagnosis of infection can be made with molecular probes (polymerase chain reaction). Other causes of splenic granulomatous disease in cats, including blastomycosis,[10] must be considered when evaluating cats with splenic nodules.

Lymphotrophic Pathogens Some pathogens exert their systemic effects by colonizing lymphoid tissues, including splenic white pulp. In these tissues, the response to infection can vary from tissue destruction to passive proliferation of the infectious agent. Numerous studies have documented the importance of silent infection and carrier states in the propagation of some infections. In the past decade, several lymphotrophic pathogens that affect splenic morphology and function have been more studied. Recent experimental studies of *Theileria parva*, the causative agent of East Coast fever of cattle in Africa, show that the tropism of the parasite for lymphoid tissue results in massive destruction of lymphocytes and splenic germinal centers.[31] Spleen collected from calves showed enlargement, caseous necrosis, and degeneration of both white and red pulp. Bovine viral diarrhea-mucosal disease (BVD-MD) appears to cause lympholysis in the spleen, lymph nodes, Peyer's patches and thymus. These changes were most prominent in younger animals and in those with more prominent clinical signs.[30] Experimental bovine herpesvirus-1 infection was associated with lympholysis in spleen and other lymphoid tissues and vascular endothelial degeneration and necrosis of tissues in aborted fetuses from heifers.[42]

Other Pathogens Affecting the Spleen Public attention has been focused on the transmission of prions in scrapie and bovine spongiform encephalopathy (BSE). Sheep inoculated experimentally with brain homogenate from BSE-positive cattle had accumulation and expression of scrapie-associated prion protein in spleen, gut-associated lymphoid tissues, and lymph nodes 6–9 months after exposure.[60] Subsequent to localization and expression of prion protein in lymphoid tissues, the spread of protein to neural tissue via gut-associated parasympathetic and sympathetic nerve roots was documented. This work underscores the complexity of infection and transmission of prions in disease, and a potentially facilitating role of the spleen in the pathogenesis of infection.

Infection of dogs with *Leishmania infantum* is widespread, especially in warmer climates, where vectors for the disease are commonplace (see Chapter 19). Various stages of the parasite are present in tissue including the spleen, liver, bone marrow, and skin.[48] The amount of parasitic DNA was consistently higher in the spleen than bone marrow, indicating a high level of tissue tropism in this infection.[43]

Inflammatory and Immune Disorders Affecting the Spleen

Amyloidosis is a relatively uncommon lesion of the spleen of dogs and cats (see Tables 53.2 and 53.3).[53,54] Amyloid deposition around arterioles is the most frequent presentation and such deposits, like amyloid in any tissue, can lead to progressive tissue hypoxia and dysfunction. Yamada and co-workers[66] studied the occurrence and distribution of AA amyloid in tissues of 25 cows diagnosed with systemic AA amyloidosis. Fibrils leading to tissue dysfunction were seen in the spleen as well as many other tissues. Ten cows had evidence of chronic inflammatory diseases including mastitis ($n = 6$) and pneumonia ($n = 4$), while a focus of inflammation could not be conclusively identified in other cattle.

In a recent study of the relationship of leukocytosis and tissue pathology in immune-mediated hemolytic anemia (IMHA) of dogs, ischemic necrosis of the spleen, liver, kidney, heart, and lungs were seen in varying degrees in 34 dogs and was attributed to thromboembolism and anemic hypoxia.[33] The presence and

severity of lesions in tissues was correlated to the severity of antemortem leukocytosis.

A single case report of eosinophilic syndrome involving the spleen of a dog has been reported.[3] The affected dog showed a mature, infiltrative eosinophilia of the spleen, musculature, and lymph nodes, as well as heart and lungs. A leukemoid eosinophilic response was present in the blood. The cause of this disease was not determined.

Toxic Injury

The spleen is not an organ that is typically the site of direct toxic injury, with the exception of lympholysis associated with exposure to corticosteroids, non-steroidal anti-inflammatory agents, and cancer chemotherapies. However, there have been recent reports of splenic lesions associated with exposure to citrus pulp, hairy vetch, and lead.

Iizuki and co-workers[26] performed detailed studies of seven cows that presented with urticaria, loss of lactation, and death after ingestion of a diet rich in citrus pulp. Severe granulomatous disease, with a lymphoplasmacytic and giant cell infiltrate, was seen in kidneys and spleen. Evaluation with immunohistochemical markers showed infiltrations with CD3+ T cells associated with a systemic hypersensitivity reaction to components of the diet.

Hairy vetch poisoning was associated with splenic lesions in eight herds in Brazil.[16] Granulomas, presumably associated with organ dysfunction, were observed in spleen and many other tissues. Granulomatous inflammation of the myocardium was considered the most significant clinical lesion.

Splenic hemosiderosis, as a consequence of exposure to high levels of environmental lead, was seen in a herd of Nelore cows in Brazil.[28] Thirty-five died within 2–7 days of exposure to fumes and forage contaminated with lead from a car battery recycling facility. Affected cattle developed secondary hemosiderosis of the spleen, liver, and kidney associated with lysis of RBCs.

Degenerative Conditions

Splenic atrophy has been reported in many aged horses.[44] Horses were euthanized for health problems ranging from chronic lameness and colic to failure to thrive. Age-associated thickening of the splenic capsule, focal capsular fibrosis, hypoplasia of red and white pulp, and parenchymal fibrosis were the most frequent histopathologic findings. Similar age-associated changes have been noted in the spleens of dogs, cats, and several species of ruminants.

Splenomegaly and Hypersplenism

There are many causes of splenomegaly. Pathologists most frequently encounter splenomegaly as a consequence of euthanasia in which barbiturate overdose is used. Another frequent cause is nodular proliferation. Many of these nodules are benign, while some are associated with tumors of the spleen, including hemangioma, hemangiosarcoma, and malignant lymphoma. The spleen is a frequent site for formation of granulomas associated with infectious organisms, such as *Mycobacterium* sp., fungi, and yeasts.

Hypersplenism is defined in human medicine by four criteria including peripheral cytopenia, improvement of cytopenia following splenectomy, reactive hyperplasia of the bone marrow, and splenomegaly.[56] Hypersplenism is not well defined as a disorder in veterinary medicine.

Splenic Histiocytosis

In two papers, Spangler and Kass[55,56] described several different types of lesions leading to splenomegaly in dogs. A distinctive form of splenic histiocytosis, associated with cytopenia, vomiting, depression, and fever was recognized by the analysis of specimens from 65 dogs.[56] The disease was most frequent in Golden Retriever, Labrador Retriever, and Shepherd-type dogs; a mean age of 8 years and a range of 2–15 years was reported. These breeds of dog also are some of the breeds at highest risk for the development of canine malignant lymphoma and hemangiosarcoma. Histologically, the spleens showed varying degrees of diffuse extramedullary hematopoiesis (termed myeloid metaplasia), reactive/proliferative histiocytosis, erythrophagocytosis, and vascular thrombosis leading to splenic infarction. In some cases, distinctive giant cells of histiocytic origin were observed. No consistent alterations in hematology or serum chemistry profiles were predictive of the course of disease in these patients. These authors hypothesized that these lesions may represent parts of a continuum of splenic histiocytosis that progresses to histiocytic neoplasia.

Fibrohistiocytic Nodules

In a separate paper Spangler and Kass[55] propose that fibrohistiocytic nodules form a continuum between splenic nodular lymphoid hyperplasia and malignant fibrous histiocytoma. Specimens of splenic lesions from 98 dogs were submitted for evaluation by a diagnostic pathology service. Microscopic evaluation of specimens had a high prevalence of fibrohistiocytic cells, demonstrated by immunohistochemical staining for vimentin and desmin. Variable numbers of lymphocytes, plasma cells, and hematopoietic cells formed the remainder of the nodules. About half of dogs with fibrohistiocytic nodules died within 12 months of the time of diagnosis; about half of the cases were felt to die as a direct result of the splenic lesions. No consistent alterations in hematology or serum chemistry profiles were predictive of the course of disease in these patients.

Splenic Neoplasms

In the dog, splenic neoplasms are considered to be a major cause of splenomegaly, although splenic hematoma and reactive hyperplasia are the most

frequent causes of splenomegaly.[53] Hemangiosarcoma is the most frequent tumor of the spleen, its frequency being as high as all other splenic tumors combined. Haematopoietic tumors (e.g. malignant lymphoma and malignant histiocytosis, hemangiomas) are other important tumors of the spleen of dogs. In the cat, primary and metastatic neoplasia account for one-third of all splenic lesions. In this species, however, the frequency of occurrence differs from the dog, with mast cell tumors being the most frequent and hemangiosarcomas a less frequent tumor type.[54]

Histiocytic sarcoma, formerly called malignant histiocytosis, is a tumour originating from myeloid dendritic antigen-presenting cells (see Chapter 73).[1,46,51] A few cases of malignant histiocytosis in the cat have been reported.[19] Discernible splenomegaly is seen in approximately 50% of dogs. A variant of the histiocytic sarcoma is the hemophagocytic histiocytic sarcoma; this was described in several dogs (see Chapter 73).[35] Diffuse splenomegaly was the main hallmark.

In both the alimentary and the multicentric form of malignant lymphoma in dogs, cats and cattle, the spleen can become involved in the disease process and become enlarged due to infiltration with neoplastic lymphoblasts and lymphocytes. Single involvement of the spleen in malignant lymphoma is uncommon.[59] The splenic form of lymphosarcoma in horses can produce dramatic splenomegaly and leukemia and is considered rare.[44]

Splenic hemangiomas and hemangiosarcomas occur more frequently in dogs (prevalence 0.3–2%[38,39]) than in any other species. Especially prone to develop these tumors are middle-aged and older large breed dogs, with German Shepherd dogs and Golden Retrievers having an unusually high incidence.[26] These tumors typically appear as large, solitary friable nodules that penetrate the capsule and easily bleed uncontrollably. Multiple nodules also may be seen. In dogs with hemangiosarcoma, regenerative anemia and thrombocytopenia are frequently observed, due to bleeding within and from the tumor. Some dogs die from hemorrhage after rupture of splenic hemangiosarcomas. Many tumors have metastasized to liver and lung by the time they are diagnosed. Although surgical resection of hemangiosarcoma has been the mainstay of treatment, survival times have been short. Median survival time after surgery alone is between 19 and 65 days.[11,24,26,39] Clinical staging may have some prognostic value. In one study, dogs with splenic hemangiosarcoma and hemoperitoneum had a median survival of 17 days. In contrast, the median survival of dogs with hemangiosarcoma, splenectomized before developing hemoperitoneum, was 121 days.[39] However, two other studies could not confirm this observation.[11,26] Chemotherapy with doxorubicin (30 mg/m^2 every other 3 weeks) and cyclophosphamide (50–75 mg/m^2 during three days, every other 3 weeks) as an adjuvant therapy to surgery in dogs with splenic hemangiosarcoma has been reported to prolong median survival to 180 days.[22,52] Preliminary results with continuous orally administered low-dose chemotherapy using a combination of cyclophosphamide, etoposide, and piroxicam as adjuvant therapy for dogs may be an effective alternative to conventional high-dose chemotherapy for treatment of dogs with hemangiosarcoma.[27]

Metastatic disease can also occur in the spleen, but is not common. In dogs and horses with myelogenous leukemia, the spleen can be markedly enlarged, due to filling of splenic sinusoids with neoplastic cells.[12]

Asplenia and Hyposplenism

Hyposplenism and asplenia are broad terms used to describe decreased or absent splenic function. Hyposplenism can be associated with decreased (or absent) splenic size (described above), but can also occur in the face of splenomegaly. These conditions have many causes. It is well recognized that asplenic human patients (after splenectomy) and those with hypofunctional spleens are highly susceptible to infection.[23,64] In dogs and cats, loss of splenic function can accompany therapeutic splenectomy (surgical intervention in trauma or neoplastic disease), suppression with drugs (e.g. corticosteroids, cancer chemotherapy), exposure to toxic chemicals, radiation, and with interruption of the splenic blood supply (primary infarction or secondary to torsion). In general, splenectomized dogs and cats appear to have a lower incidence of sepsis than do humans.

SUMMARY

Considerable study of splenic disorders has occurred in the past decade. Although this has improved our knowledge of many disease conditions, the arbitrary line dividing non-neoplastic and neoplastic diseases has become blurred, especially for histiocytic proliferative conditions. We expect continued enthusiasm for study of the role of the spleen in health and disease. Finally, veterinarians, when recognizing splenic disease, frequently remove the spleen. While this intervention is certainly indicated with localized neoplastic disease, it may warrant rethinking when dealing with trauma. In essence, the spleen is there for a reason and we should try to preserve it.[62]

Acronyms and Abbreviations

ANA, antinuclear antibody; ACR, American College of Rheumatology; APC, antigen-presenting cell; CBC, complete blood count; CD, cluster of differentiation; CIC, circulating immune complex; CTLA-4, cytotoxic T lymphocyte associated protein 4; DLA, dog leukocyte antigen; dsDNA, double-stranded DNA; ELISA, enzyme-linked immunosorbent assay; ENA, extractable nuclear antigen; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; H, histone; Ig, immunoglobulin; IMHA, immune-mediated hemolytic anemia; LE, lupus erythematosus; MHC, major histocompatibility complex; PCNA, proliferating cell nuclear antigen; PCR, polymerase chain reaction; RBC, red blood cell; RNP, ribonucleoprotein; SLE, systemic lupus erythematosus; SS-A, Sjögren syndrome antigen A; TCR, T cell receptor.

Systemic lupus erythematosus (SLE) is a chronic, recurrent inflammatory disorder characterized by autoantibodies directed against self-antigens, immune complex formation, and immune dysregulation. SLE causes damage of multiple organs and leads to a wide range of clinical manifestations. Previously believed to be a rare disease, there has been an increase in awareness and education about SLE since the 1960s. In the United States and Northern Europe, the prevalence in humans is approximately 1 case per 2000 people, but varies according to location and ethnicity. In animals, a number of inbred strains of mice (e.g. the New Zealand black/white strain) spontaneously develop lupus-like syndromes, and this has allowed intensive study of disease mechanisms. Systemic lupus erythematosus is recognized in monkeys,[1] dogs, cats, and horses. SLE-like disorders have also been reported in poikilothermic species, such as snakes and iguanas.[13]

This chapter will discuss SLE in dogs, cats and horses. Considered as an infrequent disease in the dog, many studies have been published on canine SLE since its initial description in 1965,[20] while feline and equine SLE

are rare. Thus, most information presented in this chapter derives from canine studies. Recently, an experimental canine model of SLE has been developed, and could be interesting for a better understanding of this complex disease and evaluation of new therapeutic approaches.[9]

RISK FACTORS

The cause of SLE remains unknown, although both genetic and environmental factors appear to play an important part in the induction and perpetuation of the disease.

Genetic Factors

Susceptibility loci with confirmed linkage to SLE have been identified in humans and mice. These loci contain genes encoding molecules involved in immune response and apoptosis. Most of these genes are associated with the major histocompatibility complex (MHC). The multitude of distinct genetic associations suggests a complex genetic predisposition for the disease, perhaps explaining the variable courses and organ system involvement.

The influence of genetic background in canine SLE is supported by studies of inbred lines and evidence of familial aggregation.[17,21,25,35] Systemic lupus erythematosus is associated with the dog leukocyte antigen (DLA): the MHC class I DLA-A7 allele confers risk for disease expression, whereas dogs possessing the DLA-A1 and DLA-B5 (a MHC class II allele) are at decreased risk.[35] Dogs with a specific complement C4 allotype, a class III gene, may be predisposed to a lupus-like syndrome characterized by non-erosive polyarthritis, pyrexia, and antinuclear antibodies (ANAs).[11]

Feline SLE may occur more frequently in purebred cats, particularly those with a Siamese or Persian background, which also suggests a genetic influence in this species.

Environmental Factors and Infectious Agents

Other factors capable of causing the disease include environmental factors and infectious agents. A higher risk of developing ANA or SLE in pet dogs owned by human patients with SLE has been occasionally reported and supports the idea that a common environmental factor or zoonotic agent may have a role in causing SLE.[8,19]

Light

Ultraviolet radiation is the most obvious environmental factor linked to SLE. Sunlight is known to be capable of triggering, or aggravating, SLE in humans, dogs, and cats. A photosensitive rash is a criterion of the American College of Rheumatology (ACR) for the diagnosis of the disease.[34]

Infectious Agents

While a microbial etiology for autoimmune diseases remains a popular theory, supportive evidence in SLE is limited. A role for viruses in the induction of canine SLE has been proposed. Antigens that cross-react with C-type retroviral particles have been identified on the cell membrane of blood lymphocytes from affected dogs, and cell-free extracts were able to transfer the serological abnormalities of SLE from affected to normal dogs.[29] However, these findings have not been widely corroborated and no direct isolation of virus from canine tissues has been described. In cats, the retroviruses feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) can induce disease with similarities to SLE (e.g. immune-mediated hemolytic anemia, IMHA), and ANA develops in some cats infected with FeLV. However, most cases of feline SLE are seronegative for both viruses.[27]

Geographic Influence

Canine SLE is rarely diagnosed in the United States, Northern Europe, and Australia, but seems more frequently recognized in Mediterranean countries. This may reflect an association with different factors including breed distribution, regional gene pools, sun exposure, and prevalence of infectious diseases (e.g. leishmaniasis).[7]

Drugs and Food

In humans, many drugs cause a variant of lupus called drug-induced lupus. The best known of these drugs are procainamide, hydralazine, and quinidine. Lupus-like syndromes have been induced by hydralazine in the dog,[3] and propylthiouracil in the cat.[2] Methimasole has been associated with the development of ANA in cats, but clinical signs of SLE have not been reported.[28]

Other possible factors implicated in humans include foods (celery, parsley) containing psoralens that could potentially increase photosensitivity, l-canavanine (found in alfalfa seeds, sprouts, and legumes) that is structurally related to hydralazine, hair dyes, exposure to vinyl chloride, and implantation of silicone polymers.

Sex Hormones

Since 90% of human patients with lupus are female, an important role for female hormones seems probable, but a protective role for male hormones or an effect of genes of the X chromosome is also possible. Such gender distribution is not clearly defined in the dog.

PATHOGENESIS

There is compelling evidence that the immune system plays a pathogenic role in SLE.[30] Systemic lupus erythematosus is the prototype multisystem autoimmune disease in which immune dysregulation leads to failure

of the mechanisms that normally prevent the development of self-response.

Induction of Autoimmunity

Breakdown in tolerance, either central or peripheral, is a fundamental process in autoimmune disease. Central tolerance involves bone marrow and thymic deletion of autoreactive lymphocytes (negative selection) and positive selection of T cells with low affinity for self-MHC. However, T and B cell clonal deletion is not absolute and self-reactive lymphocytes escape to the periphery where self-reactivity is regulated by other mechanisms (Fig. 54.1). Autoimmune disease occurs when these regulatory factors fail and allow activation of self-reactive T and B cells. Environmental stimulus (e.g. microbial infections or drugs) has the potential to initiate and perpetuate autoreactivity through cross reactivity and molecular mimicry, development of anti-idiotypic antibodies that cross-react with self antigens, development of altered self-antigens, the release of previously hidden antigens, and polyclonal stimulation of naturally-occurring autoantibody producing cells.

Autoantibodies

SLE patients develop a wide variety of autoantibodies (Table 54.1).[5,24,26,32] Increased production of autoanti-

TABLE 54.1 Autoantibodies in Canine SLE[a]

[a]ENA, extractable nuclear antigens; H, histone; ND, not done; RNP, ribonucleoprotein; SS-A/Ro, Sjögren syndrome A antigen (or its equivalent Ro).

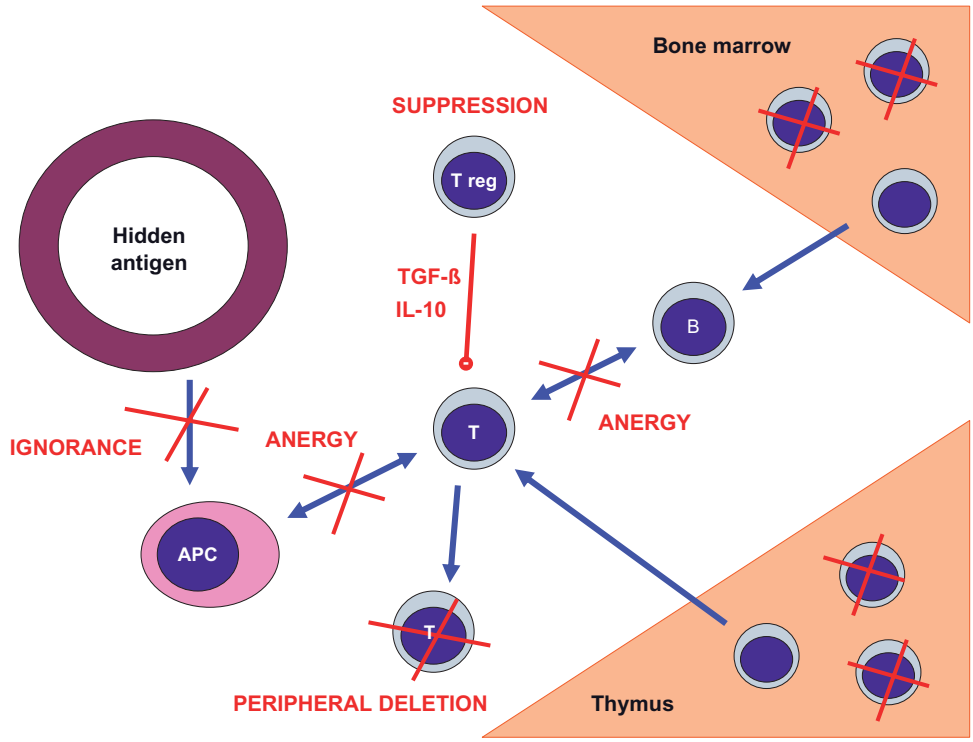

FIGURE 54.1 Potential mechanisms of immune tolerance: Autoreactive T and B cell clones that escape negative selection during maturation in the thymus or bone marrow, respectively, may be regulated in the periphery. Mechanisms involved to explain peripheral tolerance include: (1) ignorance of the antigen by the immune system (hidden antigen within cells or tissues and/or failure of antigen-presenting cells (APC) to present autoantigens to autoreactive T cells); (2) anergy (loss of co-stimulatory signals, down-regulation of receptors critical for T-cell activation); (3) peripheral deletion (apoptosis of autoreactive T cells due to recognition of autoantigen after release from the thymus); (4) suppression of autoreactive T and B cells by regulatory lymphoid populations (T reg, T-regulator cells).

bodies leads to immune complex formation and tissue damage from direct binding in tissues, immune complex deposition in tissues, or both.

Antinuclear Antibodies

Antibodies against the nuclear antigens are the most significant autoantibodies found in SLE. One proposed mechanism for development of ANAs involves a defect in apoptosis that causes increased cell death. During apoptosis, blebs of cellular material form on the surface of dying cells. Antigens that are normally buried within the cell are exposed on the surface of these blebs, and they may trigger an immune response (Fig. 54.2). These exposed antigens include nucleosomes (DNA and histone proteins), extractable nuclear antigens (ribonucleoproteins, RNP), and anionic phospholipids. The clearance of apoptotic debris is abnormal in patients with lupus. Normally, apoptotic cells are removed by phagocytes without causing inflammation. Macrophages from SLE patients, however, show defective phagocytosis of apoptotic cells, which as a result accumulate in tissues.

Unlike humans, dogs do not develop ANAs against native DNA (double-stranded DNA, dsDNA), and there is a restricted pattern of reactivity against the various individual histone antigens (H1, H2A, H3 and H4 polypeptides), while ANAs specific to nucleosome or histone-DNA complexes are rare.[5,24,26] Canine ANAs also appear to have additional reactivities not found with human SLE sera (e.g. for the glycoprotein hnRNP G).[31] In contrast, the pattern of reactivity of other extractable nuclear antigens found in dogs is similar to that found in humans; for example, anti-Sm antibodies and anti-SS-A/Ro antibodies. Antibodies to the proliferating cell nuclear antigen (PCNA) have also been described in dogs.

ANAs mediate tissue inflammation and injury in SLE either by direct pathogenic effect (e.g. anti-SS-A/Ro activity against skin) or due to their association with antigens to form immune complexes either in situ or in circulation. Moreover, a wide range of abnormalities contributes to an impaired clearance of circulating immune complexes (CIC) in SLE (e.g. abnormal complement receptors, deficiency of complement components), and CIC are not effectively removed from the circulation. Thus, the net result is prolonged high levels of CIC, which become available for deposition in non-lymphoid sites such as kidneys, synovium, or skin. Inappropriate tissue deposition or formation in situ may result in complement activation, granulocyte chemotaxis, and release of mediators of inflammation leading to vascular injury (type III hypersensitivity) and tissue damage.

B Cell Response

Although ANAs are characteristics of SLE, many other autoantibodies are produced suggesting that affected patients have abnormalities in B cell function resulting in B cell hyperactivity.

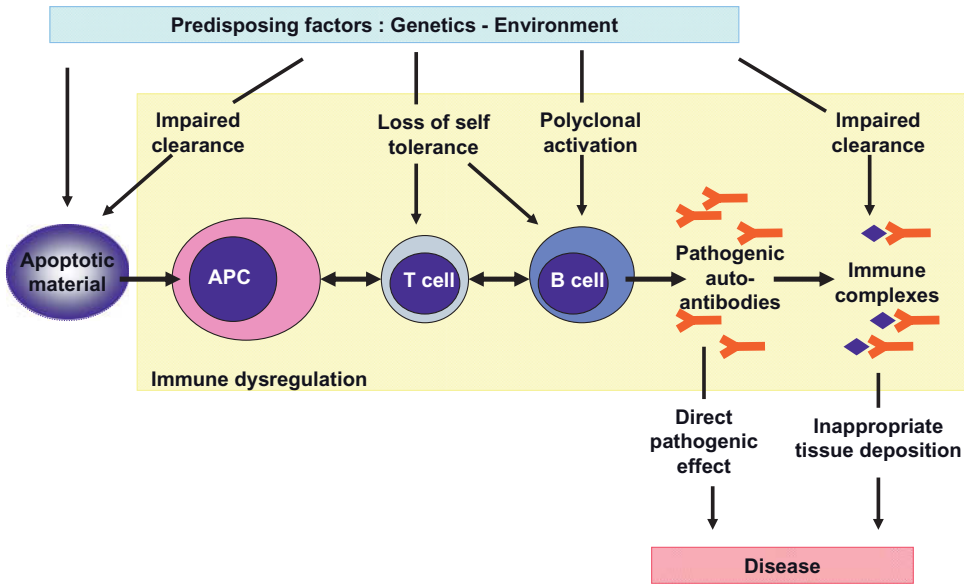

FIGURE 54.2 A simplified diagram of the immunologic events thought to occur in SLE leading to antinuclear antibody formation and immune complex deposition. Initiation of disease involves a combination of predisposing factors that give rise to accumulation of apoptotic debris and immune dysregulation. Antigens that are normally buried within the cells are exposed on the surface of the dying cell and trigger an immune response. Loss of tolerance toward self-antigens combined with polyclonal stimulation perpetuates autoantibody secretion. Autoantibodies may cause a direct pathogenic effect or lead to immune complex formation and tissue damage. Impaired clearance by the mononuclear phagocyte system promotes immune complex deposition. (Adapted from Rahman A, Isenberg DA. Systemic lupus erythematosus. New Engl J Med 2008;358:929–939, with permission.)

T Cell Defects

Abnormalities in T cell functions play a part in the induction and maintenance of B cell hyperactivity. T cell cytokines affect B cells by stimulating cell division, switching antibody production from IgM to IgG, and promoting a change in the molecular sequence of the secreted antibody so that it binds more strongly to the driving antigen. Thus, T cells help make possible the production of high-affinity IgG autoantibodies. Defective suppressor T cell function also can fail to regulate B cells.

Data from canine studies has shown immunologic alterations involving T cells and supports a defective suppressor T cell function: (1) a rapid decline in the level of a soluble thymic factor in canine SLE sera; (2) resistance to induced tolerance in some cases of canine SLE; (3) deficient concanavalin A-induced suppressor cell function; and (4) a decrease in the number of circulating CD8+ T cells as shown by studies on T-cell subsets.[5,6] The extent of this last abnormality is directly related to the severity of the disease.

Canine Experimental Model

Recently, an experimental model of canine SLE has been developed.[9] Systemic lupus erythematosus was induced in mongrel and mixed-breed dogs by immunization with heparan sulfate, the major glycosaminoglycan of the glomerular basement membrane. The dogs developed a lupus-like syndrome with proteinuria, skin lesions, and ANA. This model has been applied to gene therapy using a non-viral peptide vector encoding canine CTLA-4-Ig gene.[10] Cytotoxic T cell-associated protein 4 (CTLA-4 or CD152) found on activated T cells is the ligand for CD80 (B7-1) and CD86 (B7-2) expressed on APC (Fig. 54.3). The CTLA-4-Ig fusion protein blocks the CD28-B7 interaction and thus directly targets the interaction between T cells and APC by inhibiting co-stimulation.

CLINICAL PRESENTATION

SLE is a chronic, multifaceted inflammatory disease that can affect every organ system of the body. SLE is protean in its manifestations and follows a relapsing and remitting course.

Hematological Disorders

A history of multiple cytopenias such as leukopenia, lymphopenia, anemia, or thrombocytopenia may suggest SLE, among other etiologies. Hemolytic anemia and thrombocytopenia were the main clinical signs together with nephritis cited in the initial description of canine SLE.[21] In more recent canine studies, and in feline cases, hemolytic anemia is a moderately frequent finding as it is in human SLE, whereas thrombocytopenia is rare in dogs, cats, and humans. Coombs' test to denote antibodies on red blood cells (RBCs) and tests for anti-platelet antibody are used to demonstrate an immune-mediated mechanism (see Chapter 140). The Coombs' test is positive in 17% of canine SLE cases, even occasionally in the absence of clinical signs of hemolysis. A mild nonregenerative, Coombs' negative, anemia associated with chronic inflammation also can be present.

Leukopenia, due to lymphopenia, is not uncommon in SLE. During active disease, there is a marked lymphopenia, presumably secondary to the presence of anti-T cell antibodies. An analysis of canine lymphocyte subsets in the peripheral blood reveals a striking decrease in the CD8+ population, which is directly related to the severity of the disease. In contrast, although the percentage of CD4+ cells increases in SLE, the absolute number decreases. Consequently, the CD4:CD8 ratio may climb as high as 6 compared with a normal value of 2.3 in control dogs. Another important finding is the intense staining of T cells by activation markers.[6]

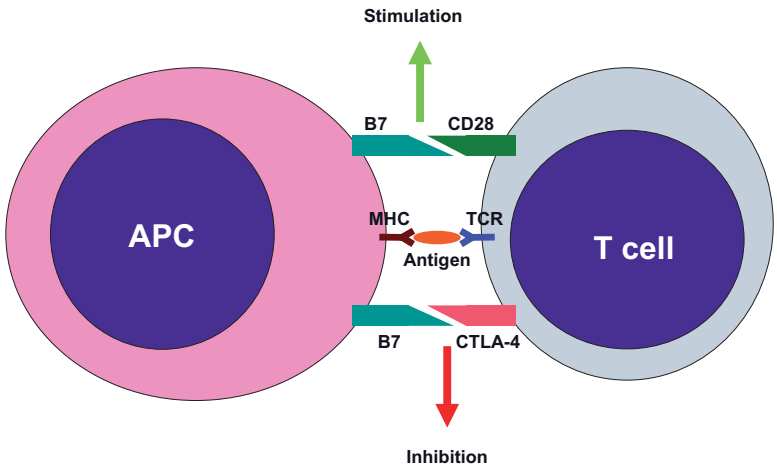

FIGURE 54.3 Interaction between a T cell and an antigen-presenting cell (APC). The APC binds antigen in a complex with a molecule from the MHC on its surface. This complex interacts with the T cell receptor (TCR). The effect on the T cells depends on the interaction between other molecules on the surfaces of the two cells. Two alternative interactions are shown: B7 with CD28, which is stimulatory, and B7 with cytotoxic T cell-associated protein 4 (CTLA-4), which is inhibitory. If the positive signal caused by the CD28-B7 interaction dominates, the T cell is activated, leading to cytokine release, B cell help, and inflammation. If the negative signal caused by the CTLA-4-B7 interaction dominates, activation is suppressed.

TABLE 54.2 Clinical Signs in Canine SLE

Signs	Percent positive
Fever	70–100
Non-erosive polyarthritis	80–90
Renal disorders	55–65
Muco-cutaneous lesions	45–60
Lymphadenopathy and/or splenomegaly	40–50
Hemolytic anemia	15
Thrombocytopenia	5–15
Leukopenia	15–20
Myositis	5–10
Pleuropericarditis	<10
Central nervous system disorders	<5
Polyneuritis	<2

Abnormalities in coagulation pathways can be identified in some patients, resulting in prolongation of the partial thromboplastin time, which fails to be corrected with the addition of normal plasma.[22,33] These abnormalities are due to the presence of "lupus anticoagulant", an antibody directed against phospholipids. In human patients, it defines the phospholipid antibody syndrome, which is associated with a thrombotic disorder.

Overview of the Disease

Canine SLE

Systemic lupus erythematosus is mainly recognized in middle-aged dogs. The clinical expression of canine SLE encompasses a wide range of clinical features (Table 54.2).[5,12,15,32] Symptoms come and go unpredictably, and are observed successively rather than simultaneously as the disease evolves, except in advanced cases.

Constitutional manifestations such as loss of body mass, inappetence, fatigue and fever are frequent when the disease is active. Musculoskeletal symptoms are the most frequent primary signs recognized in the dog, usually manifesting as polyarthritis, whereas polymyositis is occasionally identified. Joints most frequently involved are the distal joints (e.g. carpi, tarsi, elbows, and stifles). The vertebral articular facets could also be affected and, later in the course of the disease, the temporo-mandibular joints. The arthritis is usually symmetrical, non-erosive, and non-deforming. The arthritis/arthralgia may be evanescent, and recurrent. Synovial fluid analysis shows an increased nucleated cell count and predominance of neutrophils. Renal involvement is frequent, but can be asymptomatic initially. Proteinuria, or microhematuria, is the earliest manifestation and may be the only presenting renal symptom. Immune-complex glomerulonephritis can range in severity from minor mesangial changes to diffuse proliferative lesions. Skin manifestations are highly variable and involve both cutaneous and mucous membranes. The lesions usually are characterized by photosensitization, with selective localization in areas exposed to sunlight (the dorsal region of the anterior limbs, the face with lips, nose-pad, external ears in dogs with erect ears), and also in areas of thin skin poorly protected by the hair coat (axilla, inguinal region, ventral abdomen). Oral ulcers are infrequent but palatal ulcers are highly suggestive of SLE. Subacute cutaneous lupus erythematosus in humans defines a subgroup of SLE patients characterized by photosensitivity, non-scarring dermatitis, mild systemic features, and a low prevalence of nephritis. These patients are frequently ANA negative, but have antibodies to SS-A/Ro. Recent studies provide evidence supporting the hypothesis that vesicular cutaneous lupus erythematosus in the Rough Collie and Shetland dog is a homologue of subacute cutaneous lupus erythematosus.[18] Lymphadenopathy or splenomegaly are common presenting signs (50%). In some cases, there is acute extensive facial or hemifacial edema. Cytological examination of enlarged lymph nodes shows plasma cell hyperplasia with an increase in small nucleolated cells or eosinophilic lymphadenitis. Cardiopulmonary involvement is not commonly documented in canine SLE. Features include serositis (pleuritis, pericarditis), and myocarditis.[23] Also neurological manifestations are rare in canine SLE; however, subtle behavioral disturbances may go unrecognized in the dog.

Feline SLE

Systemic lupus erythematosus is a rare disease in the cat. Feline SLE involves the musculoskeletal, urinary, cutaneous, and hematopoietic systems with approximately equal frequency.[28,33,36] Fever is frequently reported in cats. Although the true prevalence of polyarthritis in feline SLE may be underestimated because it tends to be subclinical, articular symptoms seem to be common. Proteinuria or glomerulonephritis also are frequently reported. Cutaneous manifestations include generalized alopecia, erythema, scaling and crusting involving the face, ears, neck, ventrum, and limbs, and crusting of all digital pads. Neurological and behavioral disturbances may be not uncommon in feline SLE and include racing around the house; twitching of the ears, tail, or hind limbs; repeated licking; hyperesthesia along the dorsum; restless crying; disorientation; ataxia; and generalized seizures.[28,33]

Equine SLE

Equine lupus presents as generalized skin disease (alopecia, dermal ulceration, and crusting), accompanied by an antiglobulin-positive anemia. The disease is remarkable insofar as affected horses may be almost totally hairless. Affected horses may also have glomerulonephritis, synovitis, and lymphadenopathy.[14]

DIAGNOSIS

Systemic lupus erythematosus is a diagnosis that must be based on the proper constellation of clinical features and laboratory evidence.

Laboratory Findings

Antinuclear Antibodies

Antinuclear antibodies (see Chapter 140) are found in over 95% of dogs with SLE. The highest titers appear in the most severe clinical cases, and diminish progressively with treatment. The diminution always follows clinical remission, but with a certain time lag. Antinuclear antibodies can be encountered in other diseases, and even in healthy animals (up to 15% of healthy dogs, and around 20% in dogs with various infectious diseases). In the majority of cases their titers are low, but titers higher than 1:1,000 are occasionally found in healthy dogs, notably in German Shepherds.[26] The most frequently observed pattern is homogeneous, followed by speckled. The significance of these staining patterns is currently unclear in animals. Although the ANA test is very sensitive, it has a low specificity but is useful as a screening test.

In patients with high clinical suspicion or high ANA titer, additional testing is indicated for evaluation of ANA subtypes (such as histones, Sm, SS-A/Ro, hnRNP G). A number of methods are used to identify antibodies specific for the nuclear components (immunoprecipitation, ELISA, radioimmunoassay, western blotting). Unfortunately, these assays are rarely available outside the research setting. There are two categories of anti-extractable nuclear antigen (ENA) antibodies that, although their sensitivity is low, seem to be particularly interesting because of their high specificity for canine SLE. These categories are anti-Sm antibodies (found in 16% of patients), and anti-hnRNP G (found in 20% of patients).[5,26]

Other Immunodiagnostic Investigations

Formerly, the lupus erythematosus (LE) cell test was used for diagnosis of SLE. LE cells are neutrophils that have phagocytosed nuclei from dead and dying cells. Their presence may be detected in bone marrow and occasionally in buffy coat preparations. It is usually necessary to produce them in vitro using heparinized or clotted blood from patients. There is a high incidence of both false-positive and false-negative results. Because of this, the LE cell test is mostly of historical significance.

A wide variety of autoantibodies can be detected in sera or tissue: rheumatoid factors (seen at low titers in 20% of patients);[4] antiphospholipid antibodies; Coombs' test to demonstrate anti-RBC antibodies; tests for anti-platelet antibodies (see Chapter 140).

A skin biopsy can help to diagnose SLE with histopathologic evidence of an interface dermatitis or vasculitis. The demonstration of immune deposits at the basement membrane zone (the "lupus band test") by immunofluorescence or immunohistochemistry in both affected and unaffected sites that have been exposed to sun, although not specific, is supportive of the diagnosis of SLE. A renal biopsy is useful in identifying the specific type of glomerulonephritis present.

Circulating immune complex (CIC) level, serum complement function, and concentration of specific complement components also can be measured. Circulating immune complex will decrease and complement levels will rise to normal during clinical remission or following therapy. Reduced levels of complement in canine SLE are less likely to reflect inherited complement deficiency than utilization in immune complex clearance.

Other Laboratory Tests

Laboratory tests to diagnose possible SLE should include: a complete blood count to screen for leukopenia, lymphopenia, anemia, and thrombocytopenia; urinalysis to evaluate for proteinuria, hematuria, casts, or pyuria; kidney and liver serum chemistry tests to monitor kidney disease activity and response to immunosuppressive and anti-inflammatory drugs; and inflammatory markers (e.g. C-reactive protein). The latter may be elevated in any inflammatory condition, including SLE, but level changes could be interesting for monitoring disease activity.

Diagnostic Criteria

Many diagnostic criteria have been proposed for SLE in veterinary medicine, and have been modified from those given for humans. The American College of Rheumatology (ACR) established eleven criteria in 1982 that were updated in 1997 (Table 54.3).[16,34] These criteria summarize features necessary to diagnose SLE. However, more than diagnostic criteria, they were established for classification and use in scientific research (i.e. inclusion in randomized controlled trials); therefore, patients may have lupus but not meet all of the criteria.

In dogs and cats, the most frequently accepted and simplest diagnostic criteria include the presence of two separate manifestations of autoimmunity, together with significantly elevated titers of serum ANAs.[32] For a more stringent diagnosis, it would be recommended to use the 1982 revised ACR criteria that have been proposed and adapted for dogs (Table 54.4).[7,32] A rigorous approach (Fig. 54.4) is necessary for recognizing this complex disease and assessing particular cases of SLE.

Differential Diagnosis

Systemic lupus erythematosus is a challenging disease whose wide variety of manifestations makes it part of the differential diagnosis for patients with many different presenting complaints (e.g. fever of unknown origin, polyarthritis, IMHA, and nephritis). Infectious and neoplastic diseases must be excluded through imaging and appropriate biological testing, such as serology or polymerase chain reaction (PCR) for vector-borne diseases (e.g. ehrlichiosis, leishmaniasis).

TABLE 54.3 American College of Rheumatology (ACR) Classification Criteria for the Diagnosis of Systemic Lupus Erythematosus (Established in 1982, Updated in 1997)[a,b]

1. **Serositis**: pleuritis, by convincing history of pleuritic pain, rub heard by physician, or evidence of pleural effusion; or pericarditis documented by electrocardiography, rub heard by physician, or evidence of pericardial effusion
2. **Oral ulcers**: oral and nasopharyngeal ulceration, usually painless, observed by physician
3. **Arthritis**: non-erosive arthritis involving two or more peripheral joints, characterized by swelling, tenderness, or effusion
4. **Photosensitivity**: skin rash as a result of unusual reaction to sunlight, as determined by patient history or physician observation
5. **Hematologic disorder**: hemolytic anemia with reticulocytosis; or leukopenia, $<4.0 \times 10^9$/L on two or more occasions; or lymphopenia $<1.5 \times 10^9$/L on two or more occasions; or thrombocytopenia $<100 \times 10^9$/L in the absence of offending drug
6. **Renal disorder**: persistent proteinuria >0.5 g per day, or >3+ if quantification is not performed; or cellular casts (may be red blood cell, hemoglobin, granular, tubular, or mixed cellular casts)
7. **Antinuclear antibodies**: an abnormal ANA titer by immunofluorescence or equivalent assay at any time and in the absence of drugs known to be associated with drug-induced lupus
8. **Immunologic disorder**: antibody to dsDNA antigen (anti-dsDNA) in abnormal titer; or presence of antibody to Sm nuclear antigen (anti-Sm); or positive finding of anti-phospholipid antibody based on an abnormal serum level of IgG or IgM anticardiolipin antibodies, a positive test result for lupus anticoagulant using a standard method, or a false-positive serologic test for syphilis that is known to be positive for at least 6 months and is confirmed by negative *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
9. **Neurologic disorder**: seizures or psychosis occurring in the absence of offending drugs or known metabolic derangement (e.g. uremia, ketoacidosis, electrolyte imbalance)
10. **Malar rash**: fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabila folds
11. **Discoid rash**: erythematous raised patches with adherent keratotic scaling and follicular plugging; possibly atrophic scarring in older lesions

[a]ANA, antinuclear antibody; dsDNA, double-stranded DNA.
[b]Any combination of 4 or more of 11 criteria, well-documented at any time during a patient's history, makes it likely that the patient has SLE (specificity and sensitivity 95% and 75%, respectively).

TABLE 54.4 Proposed Criteria for the Diagnosis of Canine Systemic Lupus Erythematosus[a,b]

1. **Arthritis**: non-erosive arthritis involving two or more peripheral joints, characterized mainly by pain during movement (progressive forced flexion-extension), where swelling, or effusion are often not very marked
2. **Renal disorder**: persistent proteinuria in absence of urinary tract infection; or cellular casts (red blood cell, hemoglobin, granular, tubular, or mixed cellular casts)
3. **Cutaneous lesions**: depigmentation, erythema, erosions, ulcerations, crusts and keratotic scaling which selectively affect the areas of thin skin, or skin poorly protected by the hair-coat (in particular, the face: nose pad, forehead, lips and the periocular region)
4. **Oral ulcers**: oral or nasopharyngeal ulceration, usually painless
5. **Hematologic disorder**: hemolytic anemia; or leukopenia, $<3.0 \times 10^9$/L on two or more occasions; or lymphopenia, $<1.0 \times 10^9$/L on two or more occasions; or thrombocytopenia, $<100 \times 10^9$/L in the absence of offending drugs
6. **Serositis**: presence of a non-septic inflammatory cavity effusion (pleuritis or pericarditis)
7. **Neurologic disorders**: seizures or psychosis in the absence of offending drugs or known metabolic disorders (e.g. uremia, ketoacidosis, or electrolyte imbalances)
8. **Idiopathic inflammatory disease of the skeletal or cardiac muscles**: polymyositis or myocarditis
9. **Antinuclear antibody**: an abnormal ANA titer by immunofluorescence or an equivalent assay at any time and in the absence of drugs known to be associated with their formation
10. **Immunologic disorder**: antibody to histone; or antibody to the Sm nuclear antigen; or antibody to the hnRNP G nuclear antigen; or decrease in the CD8 population, $<0.2 \times 10^9$/L; or CD4/CD8 ratio higher than 4.0; or positive finding of anti-phospholipid antibody

[a]ANA, antinuclear antibody; RNP, ribonucleoprotein
[b]Any combination of 4 or more of 10 criteria, well-documented at any time during a patient's history, makes it likely that the dog has SLE.

PROGNOSIS AND TREATMENT

Prognosis

The disease is progressive so that the severity of lesions and the number of organ systems involved increases gradually in untreated cases. Many patients die from renal failure. The earlier a diagnosis is made, the better the chance in-depth treatment will lead to a cure. Secondary infections are an ever-present risk in animals on immunosuppressive therapy.

Clinical practice must take account of both activity and severity in establishing a prognosis. A dog suffering from slight polyarthritis cannot be compared to one

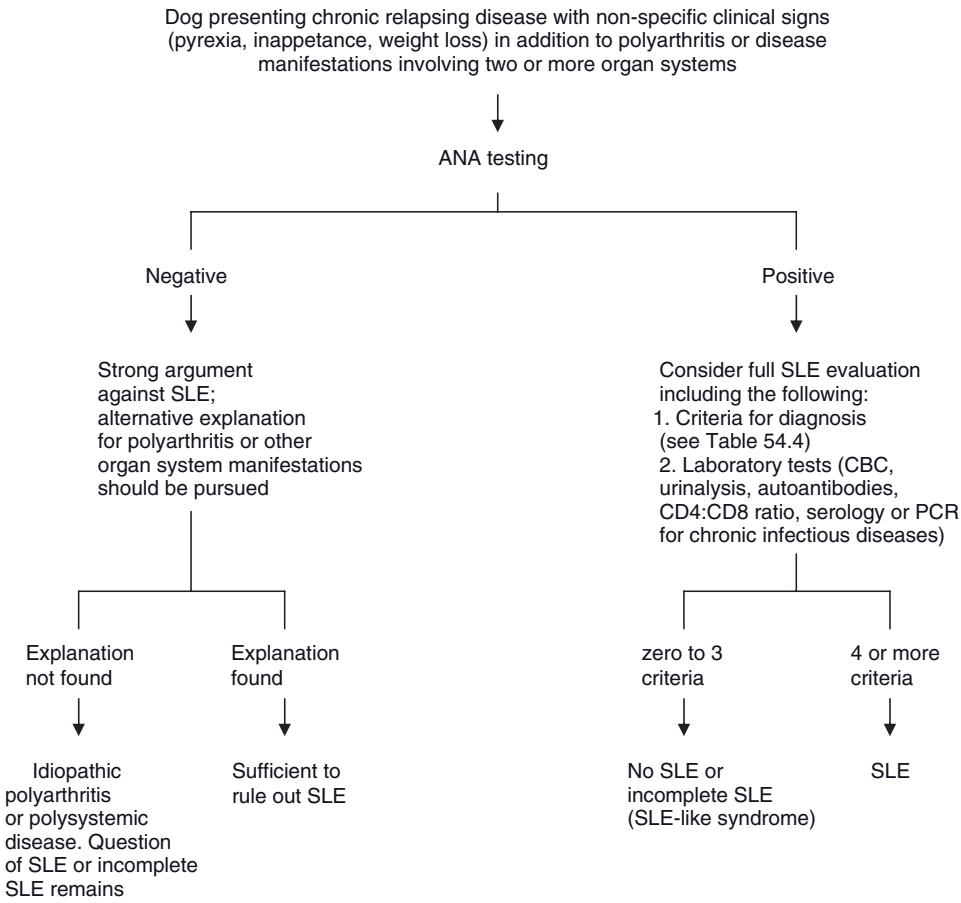

FIGURE 54.4 An algorithm for the diagnosis of systemic lupus erythematosus in the dog.

ANA, antinuclear antibody; CBC, complete blood count; PCR, polymerase chain reaction; SLE, systemic lupus erythematosus

that is in critical condition, with a combination of severe anemia and renal failure. Various parameters have been suggested to evaluate disease severity and to monitor patients throughout therapy and during periods of remission: clinical criteria, as in the indices of activity defined for humans by the ACR; the antinuclear antibody titer, which is in general proportional to the seriousness of the condition, but goes down slowly by comparison with clinical improvements; the serum levels of complement components, and evaluation of cellular immunity (e.g. enumeration of the circulating CD8+ lymphocytes, CD4:CD8 ratio, degree of lymphocyte activation).[6]

Treatment

Owing to the wide spectrum of clinical manifestations, treatment of SLE should be tailored to the severity and extent of disease in the individual patient. Treatment is mainly restricted to dealing with the symptoms. Medications are used to control the disease and prevent recurrence of symptoms, and reduce their severity and duration. Sunlight should be avoided if photosensitization occurs.

Immunosuppressive Agents

The standard primary approach to therapy in veterinary medicine involves the use of tapered high-dose corticosteroid therapy. Prednisone or prednisolone at doses of 2.2 mg/kg/day is recommended in most instances. Full doses are administered until remission is attained, and then tapered slowly. Remission is usually brief and permanent corticoid therapy at the lowest effective dose is generally required.

An additional immunosuppressive drug, such as cyclophosphamide or azathioprine in dogs or cyclophosphamide or chlorambucil in cats, is used in refractory cases or to reduce the corticosteroid dosage because of unacceptable side effects. Dogs with SLE have been treated by plasmapheresis in combination with low-dose corticosteroids, and cyclosporine has been employed in the treatment of refractory cases. Dexamethasone has been used in treatment of equine

SLE, but treatment of reported equine cases has been unsuccessful so far.

Levamisole

Levamisole is an anthelminthic drug, also used as an immunoadjuvant that stimulates T cell responses. It probably enhances suppressor cell function. Levamisole has been used with success in canine SLE.[6,12] Levamisole is administered orally at 5 mg/kg every 48 hours (a maximum of 150 mg/dog is used) together with prednisone (0.5–1 mg/kg twice a day). The prednisone is progressively tapered and discontinued after 2 months, while levamisole is given continuously for 4 months and then stopped. If relapse occurs, levamisole alone is reinstituted for a further 4-month period. This regimen is reported to produce long-term remission in over 50% of dogs with SLE. Side effects of long-term levamisole treatment are rare in dogs (neutropenia, aggressiveness, excited behavior).

Other Alternatives

In human SLE, polyarthritis is treated initially with non-steroidal anti-inflammatory drugs. Antimalarial agents (hydroxychloroquine) are used to control skin and joint symptoms and protect against the development of systemic disease. Selective immunotherapy methods are under investigation. The use of CTLA-4-Ig is one of the targeted therapeutic approaches in SLE. Results obtained in the canine SLE experimental model are promising.[10]

3TC, 2′,3′-dideoxy-3′-thiacytidine; AZT, 3′-azido-2′,3′-dideoxythymidine; CNS, central nervous system; CTL, cytotoxic T lymphocyte; ELISA, enzyme-linked immunosorbent assay; env, viral envelope; EPO, erythropoietin; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; gag, group-specific antigen; GM-CSF, granulocyte-macrophage colony-stimulating factor; HIV, human immunodeficiency virus; IFN, interferon; IGF, insulin-like growth factor; MDA, maternal-derived antibody; PCR, polymerase chain reaction; PMEA, 9-(2-phosphonomethoxyethyl) adenine; pol, polymerase; RBC, red blood cell; RT-PCR, reverse transcriptase PCR; TM, transmembrane; WBC, white blood cell.

Feline immunodeficiency virus (FIV) which was discovered in 1987 in California[38] is a retrovirus of the genus *Lentivirus* that is closely related to the human immunodeficiency virus (HIV), sharing a similar structure, life cycle, and pathogenesis.[51] Feline immunodeficiency viruses belong to a large and ancient group; species-specific strains have been isolated from a variety of non-domestic Felidae, including the puma, lion, leopard, and pallas cat.[4,6,9,35] As with all lentiviruses, FIV is a complex retrovirus, containing accessory genes in addition to *gag*, *pol* and *env.* The FIV *gag* gene encodes, among others, the capsid protein p24; the *pol* gene encodes the protease, integrase and reverse transcriptase and additional enzymes important to the virulence of FIV. Both *gag* and *pol* are relatively conserved between strains. The *env* gene encodes the viral surface glycoprotein (gp120) and the transmembrane protein (gp41), with the gp120 carrying the major determinants of viral diversity amongst isolates.[35] Five genetically distinct subtypes or clades (designated A to E) have been defined, that exhibit considerable sequence diversity (up to 26%) within the *env* genes.[52] The majority of viruses identified so far belong to either subtype A or B. Although multiple subtypes have been documented in cats from the same continent, geographic clustering of subtypes is evident (Fig. 55.1).

INCIDENCE AND EPIDEMIOLOGY

Feline immunodeficiency virus is endemic in domestic cat populations worldwide; the seroprevalence is highly variable between regions, with estimates of 1–14% in cats with no clinical signs and >20% in sick cats (Table 55.1). Sick adult cats, male cats, and free-roaming cats are most likely to be infected. The major route of natural transmission is believed to be via inoculation of saliva during fighting. Vertical transmission and transmission between socially well adapted cats appear to be relatively infrequent but have been described.[1] The majority of natural FIV infections are acquired by biting, presumably through the inoculation of virus, or virus-

TABLE 55.1 Prevalence of FIV Infection Segregated by Geographic Area and Cat Population

Geographic Area	Prevalence	Cat Population
Australia	6.5% (*n* = 200)	Healthy cats
	20.8% (*n* = 711)	Sick cats
Canada	7.6% (*n* = 607)	
Czech Republic	5.8% (*n* = 727)	
France	22.1% (*n* = 208)	Sick cats
Germany	5.4% (*n* = 1,911)	Random cats
Great Britain	12.8% (*n* = 431)	Sick cats
	27% (*n* = 90)	Feral cats
Netherlands	3% (*n* = 98)	Sick cats
Norway	10.1%	Sick cats
	5.9% (*n* = 224)	Healthy cats
Switzerland	3.7% (*n* = 775)	Sick cats
	2.8% (*n* = 178)	Healthy cats
USA, California	14.4% (*n* = 1,612)	
USA, Raleigh	2.3% (*n* = 733)	Unowned cats
USA, Florida	4.3% (*n* = 1,043)	Unowned cats
USA	2.5%	18,000 cats

infected cells, from the saliva of persistently infected cats. Transmission from mother to kittens may occur but only a proportion of the offspring become persistently infected. The proportion of kittens infected by their queens depends on the viral load of the queen during pregnancy and birth. For example, if the queen became infected at the time of mating (being bitten by an FIV infected tom cat), the viral load may be high at birth and up to 70% of the kittens may become infected at birth or via milk.[36] In contrast, if the queen had been infected before conception and was clinically healthy during gestation, the viral load of the queen would be low and the kittens would generally not become infected.[2] Oronasal or venereal transmission have not been documented under field conditions. However, under experimental conditions, cats can be infected by inoculation of virus into the nose, mouth, vagina, and rectum, and virus can be recovered from semen following natural or experimental infection.

PATHOGENESIS

The major targets for FIV infection are activated CD4+ T cells.[22] These cells typically function as T-helper cells which have a central role in immune function, facilitating the development of humoral and cell-mediated immunity. The primary receptor to which gp 120 binds, is the CD134 molecule.[50] After binding to CD134, a conformational change occurs in gp120 that gives rise to binding between another domain on the gp120 molecule and the viral co-receptor, CXCR4.[58] These steps mediate fusion of viral and cell membranes and subsequent viral entry. The reverse transcriptase synthesises a DNA strand complementary to the viral RNA that is transported to the nucleus where its insertion into the host DNA in the form of the so-called provirus is mediated by the integrase enzyme. As reverse transcriptase lacks a proofreading function, its fidelity is low and, as a consequence, FIV has a tendency to mutate. This, together with the development of the immune response, is the basis for genetic diversity, resulting in the generation of variants and immune evasion. Latent infection

is characterized by the presence of inactive provirus and a lack of synthesis of new progeny virions. As no viral antigens are exposed on the surface of latently infected cells, latent infection is not recognized by the immune system. Consequently, latently infected cells act as a reservoir of infection that may not be cleared by either a functioning immune system or vaccination.

In the first days after infection, FIV replicates in dendritic cells, macrophages, and CD4+ T lymphocytes. Within 1–2 weeks, a low level viremia develops.[34] The viral RNA content in plasma and provirus present in blood mononuclear cells increases with time, with highest loads found between 8 and 12 weeks post-infection.[7] This so-called "acute phase" of infection is overcome by a functioning immune system, giving rise to a long asymptomatic phase during which viral loads are stable at low levels. As infection progresses, the number of CD4+ T cells gradually decreases, eventually resulting in a decreased CD4:CD8 T cell ratio and an immune deficiency that is found in most infected cats (Fig. 55.2).[54] The loss of CD4+ cells is associated with apoptosis.[5] Immunodeficiency together with very high viral loads is accompanied by the clinical signs of AIDS and death.[30]

CLINICAL DISEASE

During the acute phase of the infection, mild to moderate clinical signs include lymphadenopathy, pyrexia, anorexia, and lethargy. While pyrexia, anorexia, and lethargy usually resolve rapidly, lymphadenopathy may persist over many weeks or months. Lymphadenopathy is caused by increased number and size of active germinal centers in lymph nodes. A decrease in plasma viral load marks the beginning of the so-called "asymptomatic" phase that can last for many years, or may be life-long. It is assumed that during the asymptomatic phase, viral replication is controlled by the immune system. As with the progression of HIV infection to AIDS, the course of FIV infection has been categorized into different phases. Progression to immunosuppression depends on the virulence of the infecting strain and age of the cat when infected.[39] Immunosuppression progresses faster in young cats than in older cats. If infection was acquired at an older age, progression to immunosuppression may not be seen until very old age or never.[30] Immunosuppression frequently manifests as chronic diseases such as persistent stomatitis/gingivitis, chronic rhinitis, skin disease, lymphadenopathy, and weight loss. Infected cats are prone to secondary or opportunitistic infections and neoplasia. B cell lymphomas, myeloproliferative disease, and squamous cell carcinoma have been reported in cats with FIV infection. Many concurrent viral, bacterial, fungal, and protozoal infections have been reported in FIV-positive cats, although some studies have found no significant association between FIV infection and pathogens such as *Cryptococcus*, *Cryptosporidium*, *Mycoplasma haemofelis/M. haemominutum*.

Chronic diarrhea is a frequent clinical sign associated with FIV infection and can result in severe weight loss. In most cases this cannot be attributed to secondary infection with opportunist organisms and it has been argued that FIV may have a direct effect on the gut.[37] Feline immunodeficiency virus was found to also infect the central nervous system (CNS).[13] Occasionally, FIV infection leads to abnormal behaviour, probably caused by activation of innate immunoreactivity.[28,44] Disrupted reproduction has been reported in FIV-infected cats when placental and fetal tissues are affected.[56] Also, an association between FIV infection and glomerular and tubulo-interstitial lesions combined with proteinuria has been documented.[43]

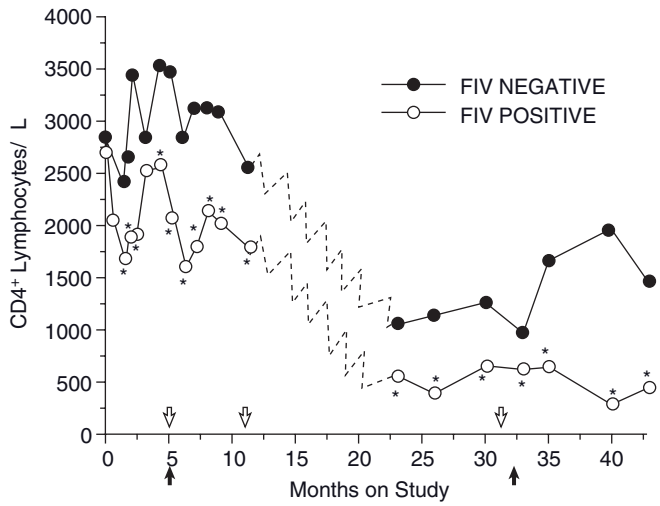

FIGURE 55.2 Decline in CD4+ lymphocyte counts in FIV-infected and control cats. Break marks in the data lines signify a separation into two different groups of cats, those with short-term infections on the left and those with long-term infections on the right. Statistically significant differences ($p < 0.05$) between FIV infected and control cats are indicated by asterisks. (Reproduced from Torten M, Franchini M, Barlough JE, et al. Progressive immune dysfunction in cats experimentally infected with feline immunodeficiency virus. J Virol 1991;65:2225–2230, with permission.)

HEMATOLOGIC DISORDERS

During the acute phase of FIV infection, lymphopenia and severe neutropenia have been described in experimental infections.[14] However, lymphopenia and neutropenia are not consistently found, probably reflecting differences among the FIV strains and differences in infectious doses used. The most frequent hematologic abnormalities in naturally-infected clinically sick cats include anemia, neutropenia, lymphopenia and monocytosis.[26,30,49] However, during the asymptomatic phase, the number of granulocyte/macrophage progenitors (CFU-GM) and erythroid progenitors (CFU-E and BFU-E, respectively) was found to be essentially unchanged compared to those of uninfected control

cats. The same authors found that sera from FIV-infected cats supported progenitor cell growth in vitro as well as normal cat sera. These results suggest that progenitor cells of RBCs and granulocytes/macrophages are not major targets of FIV infection.

IMMUNE REACTION

Soon after the discovery of FIV it was shown that antibodies to a laboratory-adapted FIV strain can confer passive protection against FIV infection.[25,45,61] After infection, cats readily develop high titers of antibodies to the different FIV components. These can be detected by immunofluorescence assays, enzyme-linked immunosorbent assay (ELISA), or immunochromatography tests.[33,38] Antibody specificity is usually determined by Western blots or radioimmunoprecipitation.[17,32] Anti-FIV antibodies are detectable from 2 to 4 weeks post-infection, or later if cats are exposed to low doses of virus.[27] Antibodies to gp41 appear within a few weeks after infection; those recognizing Gag and gp120 appear somewhat later.[8] Virus-neutralizing antibodies develop a few weeks after infection. However, cats cannot clear FIV infection, even if high titers of virus neutralizing antibodies are present.[19] As well as antibodies against FIV, cytotoxic T cells (CTLs) specific for FIV are important for immunity against FIV. However, it has not been fully elucidated to what degree antibodies and CTLs contribute to the control of infection. Cytotoxic T cells seem to have an important role: protection from experimental infection in cats vaccinated with formaldehyde-fixed FIV was found to be associated with the induction of CTLs specific for Gag and Env proteins.[34] FIV-specific CD8+ T cells were shown to appear as early as 2 weeks after infection. A population of CD8+ T cells termed $CD8^{low}$ has been observed in early FIV infection with some isolates;[57] these cells act as a marker of immune activation by more virulent strains of FIV and may contribute functionally to the non-cytolytic activity against FIV mediated by CD8+ T cells.[21]

The gradual loss of CD4+ T cells during FIV infection is usually not used to stage the level of immune dysfunction as the assays are complicated and usually pre-infection cell counts are not available.

DIAGNOSIS

FIV infection can be diagnosed directly by detecting the virus and indirectly by demonstrating the presence of antibodies.

Direct Detection of FIV

Virus Isolation

Isolation of FIV in cell culture was the first method used to demonstrate FIV infection in infected cats.[38] Blood lymphocytes are prepared from fresh samples of heparinized blood and are co-cultivated with primary feline T cells for up to 4 weeks. The presence of virus in culture supernatants is confirmed by measuring the levels of viral core proteins in the culture fluids[53] or by quantitation of provirus or FIV RNA using real-time polymerase chain reaction (PCR) or RT-PCR.[29] Virus isolation in culture is laborious and not used routinely.

Polymerase Chain Reaction

Polymerase chain reaction-based assays that detect presence of viral RNA or proviral DNA were introduced in 1992.[47] The advent of real-time PCR allowed also the quantitation of FIV-DNA and RNA.[29] PCR-based FIV detection is very sensitive; however, some isolates are not always detected as variations may occur in the DNA or RNA sequences where primers bind. Variation of FIV sequences may also explain discrepant results when identical samples are sent to different laboratories.[10] Discrepant results (seropositive, PCR negative) also can be explained by the presence of an FIV subtype not recognized by the PCR, rather than by the absence of FIV infection. Seropositive results in PCR-negative cats also can be explained by vaccination. In addition, discrepant results (seronegative, PCR positive) have been described in cats living in close contact with FIV-infected seropositive cats.[11] These cats have become infected at low levels and will eventually seroconvert once viral loads have increased sufficiently to induce antibody production.

Detection of Antibodies to FIV

During FIV infection, cats develop antibodies to all components of FIV.[17,27,32] Antibodies to the transmembrane (TM) protein gp 41 appear first, thereafter antibodies to the Gag and envelope glycoprotein gp 120.[8] For routine detection of antibodies to FIV, purified whole FIV, FIV-infected cells and purified proteins produced by recombinant DNA technology have been described.[33,53] Serological tests used in diagnostic laboratories are mostly based on a combination of p24 and TM components while immunochromatography tests usually contain synthetically produced parts of TM. Western blots are considered the "gold standard" for FIV serology and are used to confirm inconclusive results.[32] ELISA and immunochromatography tests are widely used under practice conditions but the diagnostic specificity of these tests is usually below 100% which means that some results are false positive. This is especially important in populations with low prevalence, such as in many countries in central Europe. If the FIV prevalence is 1% and the diagnostic specificity is 99%, two cats will test positive per hundred cats (i.e. the predictive value for a positive is only 50%). Therefore, any positive result in a cat without the typical history and clinical signs (e.g. young, healthy, indoor, pure bred cats) must be confirmed (e.g. by Western blot). A positive result in a cat from a high-risk group (e.g. a free roaming, older male with scratch wounds) is likely to be a true positive as the frequency of true positives will exceed the frequency of false positives in this

population. In contrast, negative results in low prevalence populations are generally very accurate, with the following exceptions. False negative results may be obtained early in infection, when cats are provirus positive but remain seronegative for several weeks to months. In addition, false negative results may be obtained in the terminal stages of disease due to immunosuppression and when high viral titres may lead to sequestration of anti-FIV antibodies in virus-antibody complexes.

Kittens born to FIV-infected queens may test seropositive as a result of passively acquired maternal antibodies (MDA). In such cases, kittens should be retested at approximately 16 weeks of age, by which time levels of MDA will have declined to undetectable levels. However, in rare cases antibodies may persist for up to 6 months. Therefore, a kitten testing seropositive at 16 weeks old should be retested 2 months later. If it is still positive at 6 months it is infected. If an earlier result is required, PCR may be used; however, it is important that the queen is tested in parallel to ensure that the PCR can detect the strain of virus causing the seropositive reaction.

Vaccination of cats against FIV infection with an inactivated, whole virus vaccine results in rapid and persistent production of antibodies that are indistinguishable from those used for diagnosis of FIV infection. This vaccine is available in the USA, Australia, New Zealand, and Japan but is not licensed in Europe. Vaccinated cats may be imported from a country where the vaccine is used and will test positive for antibodies to FIV. In such cases a positive test cannot distinguish between infection and vaccination.[46] An ELISA procedure has been described that may permit distinction between vaccination- and infection-induced antibodies.[31]

TREATMENT

Supportive Treatment

Symptomatic treatment of infected cats should be directed at the clinical signs that arise from secondary infections. During the early phase of FIV infection, cats usually respond as well as FIV-negative cats to appropriate medications, although a longer or more aggressive course of therapy (e.g. antibiotics) may be required. There are reports of clinical benefits using corticosteroids and other immune suppressive drugs in FIV-infected cats with chronic stomatitis, but their use is controversial because of potential side effects. Griseofulvin has been shown to cause bone marrow suppression in FIV-infected cats and therefore should not be used.[48]

Antiretroviral Drugs

There is no treatment of FIV infection that leads to complete clearance of the virus. However, as in HIV infection, there are several drugs with proven antiretroviral activity. As HIV and FIV share many characteristics, the mode of action and the efficacies of many antiretrovirals are similar for HIV and FIV.

Azidothymidine (AZT, 3′-azido-2′,3′-dideoxythymidine) is a nucleoside analog reverse transcriptase inhibitor that inhibits the reverse transcriptase of HIV and FIV and was shown to lead to significant improvement of clinical signs in FIV infected cats.[23] AZT can be given by injection or orally. Side effects of AZT (nonregenerative anemia) are seen in some cats, especially when the drug is used at higher doses. Other nucleoside analogs with a similar mode of action to AZT are used in HIV infection and are also efficacious in FIV infection. Stampidine (2′,3′-didehydro-3′-deoxy-5′-thymidylyl-l-alanine methyl ester) was shown to inhibit FIV replication in vitro and to be well tolerated by cats.[55]

Lamivudine (2′,3′-dideoxy-3′-thiacytidine, 3TC) was evaluated in vitro and in vivo in experimental infection and was found to inhibit FIV. The combination of 3TC and AZT was highly effective for prophylaxis but only marginally effective in chronically FIV-infected cats.[3] The acyclic purine nucleoside analogue (PMEA) was shown to efficiently inhibit FIV replication and to improve, in a dose dependent manner, clinical signs of FIV infection.[16] However, PMEA exhibited strong side effects, especially at higher doses, that precluded its use in privately owned cats with FIV infection. Enfuvirtide or T20 is a synthetic polypeptide with a strong similarity to the HIV TM protein. Enfuvirtide binds strongly to gp41 and thereby prevents the fusion of the virus with the cell; hence it is a fusion inhibitor. Similarly, an analogue to the FIV transmembrane protein was shown to inhibit FIV infection in vitro and to lead to a reduced viral load in vivo.[15] In spite of the fact that this fusion inhibitor is well tolerated by the cats, its use is hampered as it has a short half-life and has to be injected subcutaneously. Bicyclams, molecules developed in the late 1980s as anti-HIV drugs, were also found to inhibit FIV.[18] They interfere with the CXCR4 molecule, the primary receptor for FIV.[57,58] So far, no studies have been published on the use of bicyclams in naturally FIV infected cats.

Immune Modulators

Use of recombinant human granulocyte-macrophage colony-stimulating factor, (rHuGM-CSF) resulted in an increase in total white blood cell (WBC) counts, attributed to an increase in either neutrophils, lymphocytes, eosinophils, monocytes, or combinations thereof. In addition, blood mononuclear cell-associated FIV load in some of the treated cats increased by 1–2 logs.[3] Therefore, use of rHuGM-CSF in FIV infection is currently not recommended. When human recombinant granulocyte colony-stimulating factor (rHuG-CSF) was evaluated, significant increases in both neutrophils and the myeloid to erythroid ratio in bone marrow were observed without increased FIV expression.[42] However, 14–21 days after initiation of treatment, rHuG-CSF gave rise to the synthesis of anti-rHuG-CSF antibodies in some

of the cats.[42] Recombinant human erythropoietin (rHuEPO) led to a gradual increase in RBC and WBC counts in FIV-infected cats and because no increase of virus load was observed, the authors concluded that rhEPO can be used safely in FIV-infected cats.[3] Insulin-like growth factor-1 (IGF-1) is available as recombinant human product (rHuIGF-1).[59] Besides other actions, it has the capacity to induce thymic growth and to stimulate T cell function. In cats experimentally infected with FIV, the use of rHuIGF-1 resulted in increased thymus size and thymic cortical regeneration, leading to an increase in T cell numbers in the blood. Therefore, rHuIGF-1 could be considered as a supportive treatment in younger cats with FIV infection. Several cytokines have been evaluated for their capacity to inhibit FIV infection. Recombinant human interferon alpha (rHuIFNα) which mainly exerts an antiviral effect was administered orally in low doses (10 IU/kg per day) to cats naturally infected by FIV. Interestingly, the low-dose human IFNα treatment significantly prolonged the survival of the FIV-infected cats and improved their clinical signs compared to cats in the placebo group.[41] In 1986, Yamamoto and colleagues described a cell line producing a feline interferon that resembled feline IFNα;[60] later this was designated IFNω. Recombinant IFNω was shown to exert a strong anti-FIV effect in vitro and in vivo.[60] In a double blind study, treatment resulted in lower mortality and improvement of abnormal hematologic parameters.[12] However, there was no difference in the survival rates of treated and untreated cats.

PROGNOSIS

Disease progression in FIV infection is similar to that of HIV infection and under natural conditions, development of clinical signs may take many months to years. The mean survival time in untreated FIV-infected cats after diagnosis was reported to be slightly more than 2 years.[20] After the acute phase of infection, that develops a few weeks after infection, an asymptomatic phase follows which is paralleled by low but clearly detectable viral loads. Many months to years later, viral loads increase again and the CD4+ cell numbers and the CD4+:CD8+ ratio decrease.[54] Clinical signs of immune suppression and secondary infections usually manifest themselves when the number of CD4+ cells in blood falls below approximately 200 cells/μL.[24] The kinetics of disease progression is directly dependent on the initial FIV load in plasma and therefore mainly dependent on the virulence of the strain. In addition, the clinical course of FIV infection depends on the sex, age, roaming habits, and the immune status of the affected cat. Co-infections, especially with feline leukemia virus, lead to an accelerated disease progression.[40]

Acronyms and Abbreviations

Btk gene, Bruton tyrosine kinase gene; CVID, common variable immunodeficiency; HLA, human leukocyte antigen; IgA, immunoglobulin A; IgAD, IgA deficiency; IgG, immunoglobulin G; IgM, immunoglobulin M; SC, secretory component; sIgA, secretory IgA; XLA, X-linked agammaglobulinemia; *whm*(*winged-helix-nude*) gene.

IMMUNODEFICIENCY DISEASE

Immunodeficiency diseases, characterized clinically by an increased susceptibility to infection, are a diverse group of diseases that result from abnormalities in one or more components of the immune system. Immunodeficiency diseases can be broadly divided into two main categories: primary, or genetic, immunodeficiencies and secondary, or acquired, immunodeficiencies. Primary immunodeficiencies are diseases in which the animal is born with a genetic defect involving the immune system and clinical disease is a direct consequence of the hereditary defect. Because the primary immunodeficiency diseases are genetic, the majority of affected patients are neonates or young animals. Acquired immunodeficiencies are diseases in which the animal is born with an intact immune system, but as a result of some underlying disease process, their immune system becomes transiently or permanently impaired.

Animals that have immunodeficiencies generally suffer from recurrent or chronic infections. Some of the more frequent conditions associated with immunodeficiency diseases are respiratory infections, otitis, dermatitis, and pyoderma, diarrhea, growth retardation, adverse reactions to modified-live vaccines, and infection with usually nonpathogenic organisms (opportunistic infections). Although the possibility of an immunodeficiency should be considered in any animal that has too many infections, primary immunodeficiency diseases are relatively infrequent, so it is important to consider other causes that may lead to infection. Most of these conditions can be identified after a careful history and physical examination and can be confirmed by appropriate laboratory tests. When there is no apparent explanation for the recurrent infections, a primary immunodeficiency should be considered.

Several important primary immunodeficiency diseases are not discussed in this chapter, but can be found in Chapters 42 and 57. These diseases include canine

X-linked severe combined immunodeficiency, severe combined immunodeficiency in Arabian foals, severe combined immunodeficiency in Jack Russell terriers, and leukocyte adhesion deficiency in dogs and cattle.

DIAGNOSIS OF AN IMMUNODEFICIENCY

The severity of the defect and which part of the immune system is affected influences the type of infection involved and the clinical signs. Defects in the B cell (humoral immune) system usually result in increased susceptibility to bacterial infections. Animals with T cell (cell-mediated immune) deficiencies usually have an increased susceptibility to intracellular microorganisms such as fungal, protozoal, and viral infections. Note that since a humoral immune response is highly dependent on the T cell system, certain T cell deficiencies may also present as humoral immune deficiencies. Disorders of the phagocytic system are usually associated with skin infections or systemic infections with pyogenic microorganisms. Complement deficiencies are usually associated with recurrent infections with pyogenic microorganisms.

Although the clinical history and findings may be highly suggestive of an immunodeficiency, the diagnosis must be established by appropriate clinical immunologic testing. Many tests of immune function are available; however, the clinical immunologic tests listed below are commonly used to initially determine the competence of the various components of the immune system. These basic tests are becoming more available to the veterinary practitioner. Many of these tests are explained in detail in other chapters of this book (see Section X). Once an immunodeficiency has been established, other more sophisticated tests can be performed to localize the defect more precisely.

1. B cell system
   - Quantitation of serum immunoglobulin A (IgA), immunoglobulin G (IgG), and immunoglobulin M (IgM)
   - Phenotypic evaluation of B cells by flow cytometry.
2. T cell system
   - Lymphocyte transformation test
   - Phenotypic evaluation of T cells by flow cytometry.
3. Phagocytic system (see Chapter 141)
   - Bactericidal assay.
4. Complement system
   - Quantitation of serum C3.

The most practical test for evaluating the humoral immune system is to quantitate the serum concentrations of IgG, IgM, and IgA. Since the only published normal values are from normal adult animals, it is important not to overemphasize the significance of low immunoglobulin concentrations in young animals. Serum immunoglobulin concentrations are greatly influenced by age. For example, in dogs, IgM concentrations reach normal adult values within several months but IgG concentrations do not reach normal adult values until approximately 10–12 months of age and IgA concentrations until approximately 15–18 months of age. It is imperative to compare the immunoglobulin concentrations of young animals with age-matched healthy animals. If the immunoglobulin concentrations are less than 95% confidence limits for age-matched healthy animals, a diagnosis of a deficiency in one or more of the immunoglobulin classes (antibody deficiency) may be made. The lymphocyte transformation (blastogenesis) test is the simplest and most widely accepted in vitro test to evaluate the competence of the T cell system. This test evaluates the capacity of T cells to proliferate after stimulation. Animals with T cell deficiencies have an absent or a significantly reduced response to stimulation. If an abnormal lymphocyte transformation response is found in an animal, it is important to test the animal on at least two occasions to eliminate the possibility of transient T cell suppression from concurrent viral infection.

Because the main function of the phagocytic (neutrophil) system is to phagocytize and eliminate microorganisms from the body, neutrophil function is most frequently evaluated by bactericidal assays. This in vitro test measures the capacity of neutrophils to kill bacteria. It is important to test a healthy animal at the same time as the patient to control for test variables.

Several tests of the complement system exist. However, since the only documented complement deficiency is a C3 deficiency, quantitation of serum C3 concentrations is sufficient.

DISEASES INVOLVING THE B CELL (HUMORAL) IMMUNE SYSTEM

Equine Agammaglobulinemia

Agammaglobulinemia is a rare immunodeficiency that has been reported in Thoroughbreds and Standardbreds.[3,11] It has only been reported in males, suggesting an X-linked mode of inheritance with many similarities to X-linked agammaglobulinemia (XLA) in humans. XLA in humans is caused by a mutation in the Bruton tyrosine kinase (Btk) gene that is critical for normal B cell development.

Affected horses suffer from recurrent bacterial infections, such as pneumonia, enteritis, laminitis and arthritis. Clinical signs begin between 2 and 6 months of age with most affected horses dying before 2 years of age from generalized infections. The two major laboratory findings are the lack of peripheral B cells and low or absent IgA, IgG, and IgM. Specific antibody responses also are severely depressed. T cell function in these horses is normal.

Treatment is symptomatic including antibiotic therapy. Although administration of plasma may temporarily control infections, the long-term prognosis is poor.

Selective IgA Deficiency

A deficiency of IgA results in failure to mount a local immune response to bacteria and viruses, predisposing the individual to infections. IgA-deficient individuals also have an increased absorption of antigens, predisposing them to potential development of allergies and autoimmune disease. IgA deficiency has only been documented in humans and dogs.

IgA Deficiency in Humans

IgA deficiency (IgAD) is the most frequent primary immunodeficiency in humans.[5,8,19] The prevalence, based upon screening large populations of healthy adult blood donors, is approximately 1/600 in Western populations. IgAD is actually a heterogeneous group of diseases consisting of two main types: severe IgAD defined as undetectable IgA, and partial IgAD defined as low IgA. A further complication of IgAD, particularly in pediatric patients, is that it may be transient, with IgA levels normalizing by adulthood. This phenomenon is observed in approximately 8% of severe IgAD and 50% of partial IgAD pediatric patients.[18]

Although individuals with IgAD are frequently asymptomatic, reduced levels of IgA predispose to a variety of diseases, including upper respiratory infections, skin infections, neurologic problems, allergies, and autoimmune disease. In fact, symptomatic IgAD accounts for 10–15% of all cases of clinically important primary immunodeficiencies. Approximately 50% of IgAD patients present with recurrent infections, particularly of the upper respiratory tract. Other clinical conditions include chronic skin infections, atopic disease, nonspecific dermatitis, eczema, rheumatoid arthritis, and systemic lupus erythematosus.

Although the familial aggregation of IgAD is highly suggestive of a genetic basis for this condition, the mode of inheritance is unknown. There are associations with certain human leukocyte antigen (HLA) types.

IgA Deficiency in Dogs

The initial descriptions of IgAD in the dog were in the Beagle and Shar-pei.[12,20] The most frequent clinical problems in dogs with IgAD include recurrent upper respiratory infections due to *Bordetella bronchiseptica* and canine parainfluenza virus, otitis, staphylococcal dermatitis, and atopic dermatitis. The infections associated with IgAD in the dog begin in the first few months of life but are usually not life threatening. Several dogs have experienced convulsive episodes. During a 5 year study of dogs with chronic skin disease, 40 were identified with IgAD.[6] Breeds represented in this study included Shar-peis, German Shepherds, Cocker spaniels, Doberman pinschers, miniature Schnauzers, miniature pinchers, Akitas, and isolated cases in Yorkshire terriers, Welsh corgi, Newfoundland, West Highland White terrier, Keeshound, Irish setter, Wheaten terrier, and Old English sheepdog. The two major clinical presentations were atopy with secondary staphylococcal pyoderma (14 dogs) and chronic or recurrent staphylococcal pyoderma (12 dogs).

In a one year prospective study of Beagle puppies diagnosed with IgAD, the incidence of upper respiratory disease was 2.4 times greater in the IgAD dogs than in age-matched dogs with normal IgA concentrations. In addition, the IgAD dogs were three times more likely to be infected with *Giardia* than were dogs with normal IgA concentrations.[13]

Screening of large populations of adult dogs has demonstrated that IgAD is present in clinically normal adult dogs and can take the form of either severe or partial IgAD. Determination of IgA concentrations in 829 clinically normal adult Beagles revealed the presence of IgAD in approximately 9% of the dogs, 1% with severe IgAD and 8% with partial IgAD.[13] IgAD diagnosed in these healthy adult dogs appears to be persistent, similar to the observation in humans. A 2 year study of five severe IgAD and 15 partial IgAD healthy adult Beagles showed that all five of the dogs with severe IgAD remained severely IgA-deficient and 12 of 15 dogs with partial IgAD remained partially IgA-deficient. Six of these dogs developed nonspecific dermatitis during the study period, with 50% of these dogs having positive skin tests for several environmental allergens. Thirty-two percent of these dogs developed rheumatoid factor in the absence of overt clinical rheumatoid arthritis. Anti-IgA antibodies were found in 30% of the IgAD dogs. Partial IgAD has been reported to occur in up to 75% of clinically normal adult Shar-pei dogs,[20] and has been reported in German Shepherd dogs.[28,10]

Although the mode of inheritance of IgAD in dogs remains unknown, epidemiologic studies have shown that puppies born to clinically healthy IgAD mothers are at much higher risk of developing upper respiratory infections than puppies born to mothers with normal IgA concentrations.[26] An experimental breeding of an IgAD dam and IgAD sire resulted in a litter of five puppies. At 3 months of age, four of five puppies had undetectable IgA; at 1 year of age, one dog still had severe IgAD and two dogs had partial IgAD. All three IgAD dogs experienced recurrent upper respiratory infections during the one-year study.[13] The severe IgAD dog also experienced chronic dermatitis and several episodes of seizures.

The diagnosis of IgAD, both in humans and dogs, is based upon the quantitation of serum IgA. An important consideration in the diagnosis of IgAD is the age of the dog.[16] Levels of serum IgA are low in all puppies. By 3–4 months of age, serum IgA levels have increased to levels at which normal and IgAD dogs can be differentiated. Unlike IgM and IgG, serum IgA concentrations do not reach normal adult levels until 12–18 months of age. Therefore, it is imperative to compare a young, potentially IgAD dog with values for age-matched normal dogs. Another important consideration is the transient IgAD observed in some pediatric patients. Approximately 20% of dogs diagnosed with IgAD before 1 year of age will revert to normal IgA levels between 12 and 18 months of age; however,

approximately 90% of dogs diagnosed with IgAD after 1 year of age will remain IgAD.

Treatment of IgAD patients is limited to symptomatic treatment of the various infections, allergies, and/or autoimmune diseases. No specific immunotherapy exists for the treatment of IgAD. Immune globulin is contraindicated because many IgAD patients may possess or produce anti-IgA antibodies that could result in anaphylactic reactions. In addition, it would not replace sIgA that is the cause of IgAD.

Equine Selective IgM Deficiency

Traits that characterize selective IgM deficiency are reduced or absent serum IgM with normal or elevated serum concentrations of other immunoglobulin classes.[21,27] Although it occurs in different breeds of horses, it is most frequent in Arabians and Quarter Horses. The mode of inheritance is unknown. Two forms of the disease have been described. The most frequent form occurs in foals that develop severe pneumonia, arthritis, enteritis, and possibly septicemia. The bacterial infections are frequently caused by *Klebsiella* sp. Most of these foals die before 10 months of age. The second form also occurs in foals, but these foals may respond temporarily to antibiotic therapy resulting in recurrent infections and poor development. These foals usually die between 1 and 2 years of age.

The only significant laboratory abnormality is an absent or low serum IgM and is the basis for the diagnosis of this disease. T cells in horses with selective IgM deficiency have normal T cell function. In contrast to equine agammaglobulinemia, the proportion and absolute numbers of both B cells and T cells are normal. Other than supportive care and antibiotic therapy, there is no effective treatment for selective IgM deficiency.

Transient Hypogammaglobulinemia of Infancy in Dogs

Transient hypogammaglobulinemia of infancy is a self-limited immunoglobulin deficiency resulting from a delayed onset of IgG and IgA production by the neonate or young puppy.[14] Affected puppies are clinically normal during the time they possess maternal antibody. However, when the maternal antibody disappears, they have increased susceptibility to infection, primarily chronic or recurrent bacterial infections of the respiratory tract. Spontaneous recovery occurs between 5 and 7 months of age when the dog's own humoral immune system begins to produce sufficient immunoglobulin. Symptomatic treatment may be needed during this period.

The only significant laboratory finding is markedly reduced concentrations of serum immunoglobulin after the disappearance of maternal antibody, at around 2 months of age, that persists until 5–7 months of age. It is essential to monitor the immunoglobulin concentrations of puppies diagnosed as immunoglobulin deficient to determine if the defect is permanent or transient.

Immunodeficiency Syndrome in Shar-pei Dogs

A late-onset immunodeficiency that appears to be similar to common variable immunodeficiency in humans has been described in Shar-pei dogs.[22] Human common variable immunodeficiency (CVID) is a late-onset hypogammaglobulinemia with onset of symptoms between 20 and 30 years of age on average.[2,9] Common variable immunodeficiency patients suffer from recurrent upper respiratory and gastrointestinal infections and have an increased incidence of autoimmune disorders and malignancies, primarily malignant lymphoma and gastrointestinal adenocarcinomas. The major immunologic finding is low concentrations of two or all three of the immunoglobulin isotypes.

Affected dogs have normal proportions of peripheral B and T cells; however, they do demonstrate abnormalities in B and T cell function. The major laboratory findings are low serum concentrations of one or more of the serum immunoglobulins. Most affected dogs had low serum concentrations of IgM and IgA, and some dogs also had low levels of serum IgG. Approximately half of affected dogs had depressed T cell proliferative responses following mitogenic stimulation that correlated, like human CVID patients, with decreased serum concentrations of IgG.

The disease in Shar-peis is characterized by intermittent fever and recurrent infection of skin, respiratory system, and gastrointestinal system, including ulcerative colitis. The mean age at clinical onset is 3 years. In several reported cases, death occurred as the result of intestinal adenocarcinoma and malignant lymphoma. The mean age of dogs with malignant tumors was 6 years.

DISEASES INVOLVING THE T CELL (CELL-MEDIATED) IMMUNE SYSTEM

Hypotrichosis with Thymic Aplasia (Nude Kittens)

An autosomal recessive disease has been described in Birman cats[7] that appears to be the homologue of the T cell immunodeficient nude mouse and, more recently, T cell immunodeficient human nude patients. The disease is characterized by lack of hair growth and thymic development, and severe immunodeficiency. Kittens are born with no hair and fail to thrive, which results in death within a few days. Necropsy findings include lack of a thymus and severely aplastic lymph nodes with severe depletion of paracortical (T cell dependent) regions. The genetic defect in T cell deficient nude mice and human patients is a mutation in the *whm* (*winged-helix-nude*) gene that encodes a member of the forkhead/winged-helix transcription factor family with restricted expression in the thymus and skin.[15]

T Cell Deficiency in Growth Hormone Deficient Dogs

A growth hormone deficiency has been reported in an inbred family of Weimaraner dogs that also had an

associated T cell deficiency.[24] This is not surprising because there is increasing evidence that the thymus is a target organ for growth hormone.[25] Growth hormone is produced intrathymically by both thymic epithelial cells and thymocytes. Exogenous growth hormone enhances proliferation of and secretion of cytokines by thymic epithelial cells, and proliferation and differentiation of thymocytes. This is most likely mediated by IL-7 secreted by thymic epithelial cells.

Affected puppies appear normal at birth, but at 6–7 weeks of age they develop a wasting syndrome that is characterized by anemia, emaciation, lethargy, growth failure, and persistent infections, resulting in death. The peripheral T cells from affected dogs fail to respond to mitogenic stimulation. Serum immunoglobulin concentrations in affected dogs are within the reference interval, and the dogs are capable of producing specific antibody following immunization. The thymus is small and lacks cellularity. This syndrome is similar to that seen in several strains of immunodeficient mice. Replacement therapy with growth hormone results in marked increase in size and cellularity of the thymus and marked clinical improvement.[23]

Lethal Acrodermatitis in Bull Terriers

An acquired T cell deficiency has been described in Bull terriers secondary to an abnormality in absorption and metabolism of zinc.[17] The clinical signs include skin lesions (acrodermatitis, chronic pyoderma, and paronychia), diarrhea, and recurrent respiratory infections. Affected dogs also have a lighter pigmentation at birth that becomes progressively more noticeable with age. Growth retardation also is noticeable by 5–6 weeks of age when compared with their unaffected littermates. As affected puppies age they exhibit abnormal behavior characterized by diminished response to external stimuli and general activity. The median survival time for affected dogs is 7 months, with bronchopneumonia as the major cause of death. Immunological evaluation of affected dogs reveals normal immunoglobulin levels and severely depressed T cell response after mitogenic stimulation. Pathologic findings, in addition to skin pathology, include a small, frequently unidentifiable thymus, severe depletion of lymphocytes in the T cell areas of the lymph nodes and spleen, and dilatation of the cerebral ventricles. The mode of inheritance is autosomal recessive. Unlike other zinc deficiencies, affected dogs show little clinical improvement after zinc supplementation.

Viral Infections

Many viral infections are capable of producing an acquired immunodeficiency in dogs and cats, especially those that affect the lymphoid tissue. The viruses include canine distemper virus, canine parvovirus, feline leukemia virus, feline immunodeficiency virus, and feline panleukopenia virus. These viral infections cause primarily a T cell deficiency as the result of a direct lytic effect on lymphocytes or disruption in the normal immunoregulatory cytokine network.

DEFICIENCIES OF THE COMPLEMENT SYSTEM

C3 Deficiency

C3 is a component of the complement system important in the opsonization of bacteria. A C3 deficiency, with an autosomal recessive mode of inheritance, has been reported in Brittany spaniels.[4] Dogs that are homozygous for the trait have no detectable C3, whereas dogs that are heterozygous have C3 concentrations that are approximately 50% of normal and are clinically normal. The genetic defect is a deletion of cytosine at position 2,136 causing a frame-shift and generation of a premature stop codon resulting in a truncated protein <40% of the wild-type protein.[1]

Clinical signs are observed only in dogs that are homozygous for the C3 deficiency and are related to an increased susceptibility to bacterial infections, including septicemia, and renal disease. Older C3 deficient dogs may develop type 1 membranoglomerulonephritis and amyloidosis. The major immunologic abnormality is the absence of serum C3.

Acronyms and Abbreviations

ADA, adenosine deaminase; DNA-PK$_{CS}$ DNA-dependent protein kinase; EGFP, enhanced green fluorescent protein; FPS, Fell pony syndrome; IL2RG, interleukin-2 receptor common gamma chain; NK, natural killer; PCR, polymerase chain reaction; SCID, severe combined immunodeficiency; X-SCID, X-linked severe combined immunodeficiency.

Severe combined immunodeficiency (SCID) disorders are a rare (~1/100,000 live births) heterogeneous group of at least 11 congenital genetic conditions in humans characterized by profound defects in both humoral and cell-mediated immune responses, most often leading to infantile death.[7] SCID classification is based on four main disease mechanisms: (1) premature cell death due to accumulation of purine metabolites, seen in adenosine deaminase (ADA) deficiency; (2) defective cytokine-dependent survival signaling in T cell precursors, seen in common gamma (γc) chain or JAK3 mutations; (3) defective V(D)J rearrangements of T cell (TCR) and B cell (BCR) receptors, seen in RAG1 or RAG2 mutations; (4) defective pre-TCR and TCR signaling, seen in CD3δ or CD45 mutations.

Regardless of the mechanism, affected individuals are characterized by: (1) severely reduced numbers and functional capacities of T cells and, in some cases, B cells and natural killer (NK) cells; (2) failure to thrive; and (3) present with diarrhea and chronic infections after 2 months of age as protective maternal antibody titers decline. Most forms of SCID exhibit autosomal recessive inheritance with the X-linked recessive form of SCID (XSCID) being the most common (~50%). Both SCID and XSCID have been reported in the veterinary literature.

SEVERE COMBINED IMMUNODEFICIENCY IN ARABIAN FOALS

Severe combined immunodeficiency in Arabian foals, a uniformly fatal disease first reported in 1973,[16] is an autosomal recessive disorder limited to foals in which both dam and sire are descendants of Arabian horses.[20] SCID foals appear deceptively normal at birth, but they cannot generate antigen-specific immune responses[17] because they lack mature B and T cells. They have a profound lymphopenia and hypoplasia of their lymphoid organs.[14,15,29]

Molecular Basis of Disease

SCID in Arabian foals is caused by a mutation in a gene located on chromosome 9[1] encoding the catalytic subunit of DNA-dependent protein kinase (DNA-PK_{CS}), leading to a complete lack of expression of an active version of this enzyme.[24] DNA-PK_{CS} is an integral enzyme involved in the V(D)J recombination events of B and T cells antigen receptor rearrangements. A lack of V(D)J recombination results in B cells lacking expression of cell surface immunoglobulin M (IgM) and T cells lacking cell surface expression of antigen-specific receptors. These defective progenitors, which are unable to complete the maturation process, are eliminated resulting in profound lymphopenia. Therefore, this disease is similar mechanistically to human RAG1 or RAG2 deficient SCID where both B and T cells are affected with sparing of NK cells.

Sequence analysis revealed the same five base pair deletion in all cases.[24] The deletion causes a frameshift mutation at codon 3,155 and formation of a premature stop codon at amino acid position 3,160 (of 4,127 amino acids). The resulting 967 amino acid loss eliminates the protein kinase active sites which renders the enzyme functionally inactive.

Clinical Features

Most affected foals remain free of infections and grow well for 3–8 weeks if adequate colostrum is ingested. As maternal antibodies begin to wane, respiratory infections, which typically manifest as mucopurulent nasal and ocular discharge and respiratory abnormalities, become increasingly evident. Although initially responsive to antimicrobial therapy, the respiratory infections tend to increase in severity and frequency with a declining response to therapy. Affected foals lose body condition and inevitably die between 2 and 5 months of age.

A number of opportunistic infectious agents have been isolated from SCID foals, with equine adenovirus being the most frequent and important. Infection usually starts in the upper respiratory tract or intestinal epithelial cells, with spread to other sites including bronchiolar, renal, and pancreatic duct epithelial cells. The pancreas from a SCID foal infected with adenovirus has marked reduction in exocrine tissue and an increase in fibrous connective tissue, most likely contributing to the growth reduction and loss of condition in these patients. Notable opportunistic respiratory bacteria cultured from SCID foals include *Pneumoctstis carinii* and *Rhodococcus equi*. *Cryptosporidium parvum* infection can cause severe, life-threatening diarrhea and, when concomitant with respiratory disease, can dramatically shorten the time of onset of initial infection to death. Because SCID foals have normal NK cell numbers and activity, equine herpes viruses rarely cause serious infections.

Diagnosis

Foals with selective IgM deficiency (see Chapter 56) or failure to absorb adequate maternal immunoglobulin from colostrum can have clinical signs similar to SCID foals, although profound lymphopenia (>1,000 lymphocytes/μL of blood) and lymphoid tissue hypoplasia is not seen. Therefore, before 1997, a definitive diagnosis of SCID required demonstration of (1) profound lymphopenia, (2) absence of IgM in serum, and (3) hypoplasia of thymus and spleen. A tentative diagnosis could be reached by analyzing blood samples, but definitive diagnosis could only be confirmed by postmortem histologic examination of the spleen and lymphoid tissue.

The definitive molecular criteria of SCID diagnosis in Arabian foals were published in 1997.[24] DNA isolated from blood or buccal swabs from horses of any age is subjected to polymerase chain reaction (PCR) using primers that produce a product that spans the area of the five base pair deletion.[24,25] DNA from a normal horse produces a 130 bp amplicon, while DNA from a SCID horse produces a 125 bp amplicon. Horses heterozygous for the disease will produce amplicons of both sizes (Fig. 57.1). Using this test the diagnosis of SCID can be reached well before the expected time of onset of infectious diseases in immunodeficient foals. Importantly, this test can be used to unequivocally determine the definitive genotype of any horse and rule in or out SCID in foals with clinical signs such as recurrent infections or failure to thrive. The diagnostic test for SCID is available from VetGen Inc. (http://www.vetgen.com). SCID test kits can be ordered from the Arabian Foal Association (http://www.foal.org/TestKitsandForms.html).

Treatment

Unfortunately, SCID is uniformly fatal, with all foals incapable of generating antigen-specific immune responses to prevent or recover from opportunistic bacterial or viral infections. Although the clinical course of the disease can be prolonged with plasma transfusions as a source of antibodies in conjunction with antimicrobial therapy, SCID foals do not survive past 5 months of age when maintained under standard equine husbandry conditions.

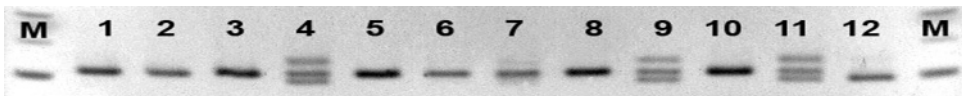

FIGURE 57.1 Genomic DNA PCR analysis for normal and SCID DNA-PK_{CS} sequences.* Lanes 1–9, clinical blood samples; lane 10, known unaffected foal; lane 11, known heterozygous foal; lane 12: known SCID affected foal; M, DNA marker. The foals in lanes 4 and 9 are heterozygous SCID carriers.

Bone marrow transplantation of a 32-day-old SCID foal using histocompatible, mixed-leukocyte-culture-nonreactive, sex-matched, full sibling marrow cells resulted in successful engraftment and reversal of the SCID phenotype.[19] Peripheral blood lymphocyte counts increased within 2 weeks of transplantation and, although a full year was required for normalization of immune functions, the foal developed the ability to respond to vaccine antigens and to resist infections, indirectly implying normal B and T cell function. The horse survived for 5 years before succumbing to an intestinal disorder unrelated to SCID or bone marrow transplantation. This experiment demonstrated that hematopoietic precursors in the donor marrow with a normal copy of DNA-PK_{CS} gene have a selective advantage in a SCID recipient with a rapid expansion of functional, mature B and T cells in bone marrow, thymus, and peripheral lymphoid organs. Equine bone marrow transplantation is, unfortunately, not currently a realistic solution for the treatment of SCID mainly due to expense, technical issues relating to marrow harvesting, and the need for a histocompatible donor.

Controlling SCID in the Arabian Horse Population

SCID in Arabian horses could be completely eliminated through careful genetic screening and selective breeding based on these results. Because only SCID foals can be produced when both the sire and dam are heterozygous for the mutant DNA-PK_{CS} gene, breeding programs can be structured to ensure that heterozygous stallions are never mated to heterozygous mares. Therefore, Arabian mares and stallions should be tested and classified as homozygous, heterozygous or normal for the DNA-PK_{CS} gene. Theoretically, barring any new spontaneous mutations, Arabian SCID could be completely eliminated from the population within a few generations. Canine XSCID was eliminated from the canine breeding population using this strategy.

Although not recommended, an alternative to breeding only homozygous normal horses would be the continued use of known heterozygous horses under carefully controlled conditions based on genetic screening. For example, a heterozygous SCID stallion could breed with a homozygous normal mare with subsequent testing of all the foals to determine the genotype. The homozygous normal foals could be selected for future breeding programs while the heterozygous colts could be gelded and all heterozygous offspring be used for nonreproductive activities. For a program such as this to be successful in controlling Arabian SCID, strict adherence to these guidelines is paramount.

FELL PONY SYNDROME

Fell pony syndrome (FPS), first described in an ancient breed of ponies bred mainly in upland areas of the UK,[23] is a uniformly fatal disease also seen in Europe[3] and the USA.[8] Similar to other primary immunodeficiencies, affected foals are usually normal at birth, but fail to thrive as maternal antibodies begin to wane. Unpublished genealogical studies suggest a possible autosomal recessive mode of inheritance, but the etiology, incidence, and pattern of inheritance of FPS have not been fully elucidated.

Clinical Presentation

At 4–8 weeks of age, affected foals begin to lose body condition and develop multiple, chronic infections that do not respond appropriately to antimicrobial therapy. Loss of body mass, diarrhea, bilateral nasal or oculonasal mucopurulent discharge, hypersalivation, coughing, and bronchopneumonia are the most frequent clinical signs. Other notable abnormalities include pyrexia, frequent chewing movements, halitosis, and a pale, friable, pseudomembranous and hyperkeratotic lingual coating. Severe normocytic normochromic anemia and lymphopenia are the most frequent blood dyscrasias. The bone marrow typically has a reduction in erythroid precursor cells. The foals deteriorate progressively and die or are euthanized, usually between 1 and 3 months of age.

Postmortem examination invariably reveals multisystemic necrotizing and inflammatory lesions associated with opportunistic infections with a wide variety of bacteria.[22] Rhinitis, sinitis, bronchitis, pneumonia, and glossal hyperkeratosis are the most frequent respiratory abnormalities. The most frequent gastrointestinal abnormalities include hepatitis, typhlocolitis, adenovirus-induced pancreatitis, and enteritis. Most ponies also have inconspicuous lymphoid tissue including small thymuses, a lack of lymph node follicles and germinal centers, and a paucity of splenic corpuscular tissue. Peripheral gangliopathy, characterized by neuronal chromatolysis and nuclear pyknosis of dorsal root ganglia, also has been documented.[23]

Immunologic Abnormalities

Fell pony syndrome foals have low IgM and IgA immunoglobulin levels,[8] while IgG levels can be variable, most likely reflecting the presence of maternally derived IgG antibodies from colostrum. Importantly, FPS foals have significantly reduced peripheral B cell numbers (<10%) when compared to age-matched normal Fell ponies. This correlates with immunohistochemical data showing a severe reduction of CD79a+ B cells in the lymph nodes, spleen, and bone marrow from FPS foals.[23] Lymphocyte function tests and the distribution of CD4+ or CD8+ T cells are typically normal, although depressed mitogenic responses have been described.[8] Lymphocyte cell surface expression of MHC class II is variable.

Diagnosis

At present, a definitive diagnosis of FPS relies on postmortem examination of lymph nodes, thymus, bone

marrow, and spleen. Clinical signs in a Fell pony, such as failure to thrive and recurrent infections beginning at 4–6 weeks of age can raise the level of suspicion of FPS. This, in conjunction with flow cytometric examination to determine if B cell numbers in peripheral blood are less than 10% of that in normal foals, may be used ante mortem to support the diagnosis of FPS.

Treatment

As with most primary immunodeficiencies in animals, there is no treatment for FPS. This disease probably is the result of a severe defect in B cell development at the level of the bone marrow, which contributes to failure of B cell expansion in the periphery. Implementation of appropriate breeding programs to reduce the incidence of FPS awaits elucidation of the underlying genetic lesion(s), proof of genetic inheritance, and the development of a carrier test, similar to SCID in Arabian foals.

X-LINKED SEVERE COMBINED IMMUNODEFICIENCY (XSCID)

X-linked recessive SCID (XSCID), the most frequent SCID in humans,[4] also has been reported in dogs.[6,9,13,21,27] Both species share common immunologic abnormalities including: peripheral T cell lymphopenia with variable numbers of phenotypically normal B cells that do not undergo isotype class-switching to IgG in vivo; peripheral T cells that do not proliferate in response to mitogens; and reduced production of NK cells.[18] This is in contrast to SCID in Arabian foals where patients have severely reduced peripheral B and T cell counts and normal NK activity. Similar to SCID Arabian foals, human and canine XSCID patients have reduced capacity to prevent or combat opportunistic infections resulting in infantile death.

Canine XSCID

Incidence of Canine XSCID

Canine XSCID was first reported in a litter of Basset Hounds in 1989.[13] Breeding studies confirmed the disease was X-linked. Additional cases of XSCID in the general Basset Hound population have not been reported. Canine XSCID was again recognized in 1997 in closely related Cardigan Welsh Corgi dogs.[21] Pedigree analysis of this family was consistent with X-linked inheritance, and the definitive diagnosis of XSCID was confirmed with DNA analysis. Subsequent pedigree DNA analysis identified the gene mutation in an affected male dog, related obligate carrier females, and grandmother of the affected dog. Subsequent genetic testing identified carrier females so they could be removed from the breeding population, which eliminated spread of the disease.

The genetic mutations responsible for XSCID in Basset hounds and Cardigan Welsh Corgis are probably due to random chance. Since genetic testing followed by controlled breeding has eliminated the disease from the Corgi and Basset populations, XSCID is no more likely to occur in these two breeds than in any other breed.

Molecular Basis of Canine XSCID

Similar to XSCID affected boys, canine XSCID is caused by mutations in the gene encoding the third or gamma chain of the interleukin-2 (IL-2) receptor.[12,26] The IL-2 receptor gamma chain also is a component of the cytokine receptors for IL-4, IL-7, IL-9, and IL-15.[15] The normal γc protein, which is 373 amino acids in length and 84% and 71% identical to the human and mouse protein sequences, respectively,[12] is composed of several evolutionarily conserved potential functional domains. Unlike human XSCID where hundreds of different γc mutations have been identified only two mutations have been identified in dogs. Basset Hounds have a four base pair deletion in the signal peptide region of the γc gene that causes a shift in the translation reading frame and premature truncation of the γc protein during its synthesis. The mutant, nonfunctional protein is only 21 amino acids in length.[12] Cardigan Welsh Corgi dogs have a single nucleotide insertion following nucleotide 582 that also causes a shift in the translation reading frame and premature truncation of the γc protein at amino acid 196. This effectively eliminates the transmembrane and the Src homology domains, resulting in a nonfunctional protein.

Clinical Presentation

Similar to XSCID boys, canine XSCID is characterized by a failure to thrive and an increased susceptibility to bacterial and viral infections at a young age.[13] Puppies appear normal at birth and are presumably protected from overwhelming infection by maternal antibodies for several weeks thereafter. As maternal antibodies wane, XSCID pups begin to lag behind their normal littermates in size and body mass and infections begin to develop. These infections include a wide range of opportunistic organisms that are rarely responsible for disease in normal animals. Bacterial pyoderma, otitis, and cystitis are common, as well as diarrhea secondary to gastrointestinal infections with various parasites (*Giardia*, *Coccidia*, *Campylobacter*, *Cryptosporidium*). Affected pups lack palpable peripheral lymph nodes and no thymic shadow is visible on thoracic radiographs. Antimicrobial therapy is generally ineffective in combating recurrent infections and puppies die or are euthanized by 5–6 months of age.

The thymuses of XSCID pups are frequently less than 10% of the mass of age-matched unaffected littermates and are usually obscured by adipose tissue. Histologically, thymuses from XSCID pups can range from simple dysplasia with no Hassall's corpuscles to relatively normal looking with many Hassall's corpuscles, although total thymocyte numbers are always reduced.

Immunologic Abnormalities

The most significant immunologic problem in XSCID is the defect in T cell function and development. XSCID puppies are variably lymphopenic, with normal or increased percentages of B cells, and usually decreased percentages of peripheral T cells. XSCID dogs can develop variable numbers of phenotypically mature peripheral T cells; their ability to proliferate in response to mitogenic stimulation or IL-2 binding is negligible due to a dysfunctional IL-2 receptor.

Treatment of XSCID

In humans, bone marrow transplantation is the only treatment for XSCID, with success ranging from 50% to nearly 100%. Gene therapy using retroviral vectors harboring a normal copy of the γc cDNA has cured a number of affected boys although two patients later developed leukemia, probably the result of insertional mutagenesis.[10]

XSCID puppies have received bone marrow transplants using unfractionated whole marrow collected from both normal and carrier littermates.[5] The transplanted dogs, none of which received pre-transplant cytoablative therapy, developed completely engrafted donor T cells, partially engrafted donor B cells, and were maintained in a conventional environment. XSCID puppies have also been transplanted with highly purified populations of CD34+ hematopoietic progenitor cells harvested from DLA-matched (dog leukocyte antigen) littermates.[11] All six dogs in this study went on to develop completely engrafted donor T cells from 1 to 3 months after transplantation, variable engrafted donor B cells, and were maintained in a conventional environment for over 6 months.

Retroviral gene therapy has been used to treat canine XSCID. In an initial study, a murine retroviral expression vector harboring enhanced green fluorescent protein (EGFP) and γc cDNAs was used for the ex vivo transduction of normal DLA-matched CD34+ cells followed by transplantation into XSCID affected littermates.[28] Three of the five transplanted dogs went on to develop prolonged immune reconstitution with up to 28% of peripheral blood T cells expressing EGFP. A more recent study used in vivo retroviral gene therapy whereby XSCID dogs were directly injected with a retroviral vector encoding a normal copy of the γc cDNA. Three of the four injected dogs attained normal numbers of gene-corrected peripheral T cells by 8 weeks after treatment.

SEVERE COMBINED IMMUNODEFICIENCY IN JACK RUSSELL TERRIERS

Severe combined immunodeficiency also has been reported in a single family of Jack Russell terriers. Twelve of 32 siblings from this single pair breeding succumbed to opportunistic infections within 8–14 weeks of age. Additional breedings permitted the elucidation of the underlying genetic defect responsible for the immunodeficiency.

Molecular Basis of Disease

Jack Russell terriers SCID that is inherited as an autosomal recessive trait, is a non-B/non-T SCID probably caused by a genetic DNA-PK_{CS} deficiency, similar to Arabian foal SCID.[2,17] A single nucleotide polymorphic transition (A/G) at position 95 of intron 5 results in a stop codon at nucleotide 10,828 and a premature termination at amino acid 517. This functionally null allele is responsible for lack of DNA-PK_{CS} activity and subsequent defective V(D)J recombination. The carrier frequency of the Jack Russell terriers SCID allele is less than 1.1%.

Clinical Features

The clinical features of SCID in Jack Russell terriers mirror those seen in most other SCID affected animals. Pups typically appear normal until maternal antibodies begin to wane, with most succumbing to a wide variety of opportunistic infections at 8–14 weeks of age. Extreme lymphopenia and agammaglobulinemia are seen, while thymic dysplasia, and peripheral lymphoid aplasia are the most frequent findings at necropsy.

Diagnosis

To this author's knowledge, standard testing of Jack Russell terrier SCID is not currently available.

Treatment

There are no published reports of Jack Russell terrier SCID treatment, although bone marrow transplantation using DLA-matched siblings is, at least theoretically, a possibility.

CBC, complete blood count; CLL, chronic lymphocytic leukaemia; FeLV, feline leukaemia virus; FIP, feline infectious peritonitis; FIV, feline immunodeficiency virus; IL-1, interleukin-1; RMSF, Rocky Mountain spotted fever; TNF, tumor necrosis factor.

Lymph nodes constitute a major component of the mononuclear phagocytic and immunologic systems. Because of their dynamic state, they constantly reshape and change in size in response to various stimuli. Most tissue changes within these structures result in lymph node enlargement. This enlargement frequently represents the only abnormality on physical examination in an otherwise healthy patient, and alerts the clinician to an ongoing disease process.

LYMPH NODE ANATOMY

The microscopic architecture of the lymph node is reviewed in Chapter 52 and elsewhere.[9,29] From a clinical standpoint, it is important to become familiar with the characteristics of palpable lymph nodes in normal dogs and cats, so that subtle changes can be detected. Palpable lymph nodes in dogs and cats include the mandibular, prescapular (or superficial cervical), axillary, superficial inguinal, and popliteal. Other lymph nodes become palpable only when enlarged; these include the facial, retropharyngeal, and iliac (or sublumbar) nodes.[9]

LYMPHADENOPATHY

Definitions

In the context of this chapter, the term lymphadenopathy refers to lymph node enlargement, although lymph node atrophy, for example, should also be considered a lymphadenopathy. Lymph node involution has been described in cases of chronic stress, anticancer chemotherapy, radiation, but also in the course of some viral infections, like parvoviral infections in young puppies or in the end stage of feline immunodeficiency virus (FIV) infection in cats.[14]

Solitary or isolated lymphadenopathy refers to enlargement of a single lymph node. Regional lymphadenopathy describes the enlargement of more than one lymph node draining a specific anatomic area; these nodes are usually interconnected. Generalized lymphadenopathy refers to multicentric lymph node enlargement affecting more than one anatomic area. Lymphadenopathies can also be classified as superficial or deep, according to their anatomical location.

Pathogenesis

Lymph nodes are in a dynamic state that results in constant reshaping. Lymph node enlargement usually occurs as a consequence of either enhanced proliferation of normal cells within the node or infiltration with normal or abnormal cells. When normal cells proliferate within a node, the term reactive lymphadenopathy is used. Proliferation of normal lymphoid or mononuclear phagocytic cells occurs in response to various stimuli, mainly infectious and immunologic, although occasionally the clinician will encounter a dog or cat with reactive lymphadenopathy in which an etiologic agent cannot be identified (i.e. idiopathic reactive lymphadenopathy). Basically the lymph node can react in three ways: (1) by hyperplasia of the follicles (B cell response); (2) by hyperplasia of the paracortical area (T cell response); and (3) by hyperplasia of the mononuclear histiocytic cells in the medullary sinuses. In the majority of cases the reaction is nonspecific leading to nonspecific reactive hyperplasia.

When polymorphonuclear leukocytes or inflammatory macrophages predominate in the lymph node infiltrate, the term lymphadenitis is used; this process frequently occurs secondary to infectious agents. If neutrophils predominate, the lymphadenitis is considered to be suppurative; if macrophages are the predominant cell, the inflammation is granulomatous; if macrophages and neutrophils occur, the term pyogranulomatous lymphadenitis is preferred.[9] Infectious diseases associated with lymphadenopathy in dogs and cats and their typical cellular infiltrate on lymph node cytology are listed in Table 58.1.

Infiltrative lymphadenopathies result from displacement of normal lymph node tissue by neoplastic or inflammatory cells. Inflammatory lymphadenopathies are classified by the predominant cell type present. Neoplasms involving the lymph nodes can be either primary hematopoietic malignancies or secondary (metastatic) neoplasms. Neoplastic causes of lymphadenopathy are discussed in Section V. Table 58.1 provides a classification scheme for lymphadenopathy in dogs and cats.

TABLE 58.1 Classification of Lymphadenopathy in Dogs and Cats

Type	Species[a]
Proliferative Lymphadenopathies

Algal (granulomatous/pyogranulomatous)[b]	
Protothecosis	C, D
Parasitic (cellular infiltrate varies with agent)[b]	
Demodicosis	C, D
Trypanosomiasis	D
Leishmaniasis	D
Hepatozoonosis	D
Babesiosis	D
Toxoplasmosis	C, D
Viral (cellular infiltrate varies with agent)[b]	
Infectious canine hepatitis	D
Canine herpesvirus	D
Canine viral enteritides	D
Feline retroviruses	C
Feline infectious peritonitis	C
Noninfectious	
Postvaccinal	C, D
Immune-mediated disorders	
Systemic lupus erytematosus	D
Rheumatoid arthritis	D
Immune-mediated polyarthritides	C, D
Localized inflammation	C, D
Aluminosilicate	D
Idiopathic	C, D
Infiltrative Lymphadenopathies	
Neoplastic	
Primary Hematopoietic Neoplasms	
Lymphomas	C, D
Histiocytic sarcomas	D
Leukemias	C, D
Multiple myeloma	C, D
Systemic mast cell disease	C, D
Metastatic Neoplasms	
Carcinomas	C, D
Sarcomas	C, D
Mast cell tumors	C, D
Malignant melanomas	D
Non-Neoplastic	
Mast cell infiltration (non-neoplastic)	C, D
Eosinophilic granuloma complex	C, D?
Lysosomal storage diseases	D, C?

[a]C, cats; D, dogs.
[b]Typical cellular infiltrate on cytology.

EVALUATION OF THE PATIENT WITH LYMPHADENOPATHY

Thorough evaluation of the patient with lymphadenopathy is essential for establishing an accurate diagnosis. Several reviews of this subject are available,[9,30] but brief summary of proper patient evaluation is included below.

Historical and Physical Examination Findings

Several clues of diagnostic value can be obtained from the history. A detailed travel history should be obtained in dogs presented for evaluation of generalized lymphadenopathy, because certain diseases have a definite geographical distribution (e.g. ehrlichiosis in the southwestern or southeastern United States). Other diseases associated with lymphadenopathy have a seasonal distribution (e.g. Rocky Mountain spotted fever [RMSF] in spring and summer). A vaccination history should also be obtained, because generalized reactive lymphadenopathy shortly after vaccination is relatively frequent. In addition, lymphadenopathy after administration of certain drugs also has been reported.[25]
