The presence or absence of systemic clinical signs in dogs or cats with generalized lymphadenopathy is helpful in guiding the clinician to a specific diagnosis, because severe systemic signs are more frequently associated with certain diseases, such as systemic mycoses, salmon poisoning, RMSF, leishmaniasis, and acute leukemias. In contrast, systemic signs can be absent or are mild in dogs and cats with lymphoma or chronic leukemia.

The distribution of lymphadenopathy is also of diagnostic relevance. When evaluating a patient with solitary or regional lymphadenopathy, the clinician should focus attention on the area drained by the lymph node or nodes, because the primary lesion probably will be found there. In contrast, most dogs and cats with generalized lymphadenopathy have systemic fungal or rickettsial infections, idiopathic lymph node hyperplasia, or hematopoietic neoplasia. Cats and dogs differ in their distribution pattern of peripheral malignant lymphoma. Where dogs usually have a generalized lymphadenopathy, cats usually have solitary or regional lymph node enlargement.

The palpable characteristics of the nodes may give additional information. In most instances of lymphadenopathy, lymph nodes are firmer than usual, are irregular, painless, do not feel warm, and do not adhere to the surrounding tissues. The main exception to this rule occurs in patients with lymphadenitis in which the nodes feels softer, tender (i.e. painful lymphadenopathy), warmer than normal, and adhere to surrounding structures (i.e. fixed lymphadenopathy).

From the clinical standpoint, the size of the affected lymph nodes is important. In our experience, marked lymphadenopathy (i.e. lymph node size 5–10 times normal) occurs almost exclusively with lymphadenitis (e.g. lymph node abscessation and tuberculosis) and with lymphomas. Rarely, metastatic lymph nodes enlarge to this degree. Dogs that have salmon poisoning also may present with marked generalized lymphadenopathy preceded by (or in conjunction with) bloody diarrhea.[16] Cats that have idiopathic reactive lymphadenopathy usually have significant generalized lymph node enlargement.[21,23,24] Mild lymph node enlargement (i.e. 2–4 times normal size) occurs most frequently in association with various reactive lymphadenopathies and lymphadenitidies (e.g. ehrlichiosis, RMSF, systemic mycoses) and in leukemias.[5,18–20]

As noted, a thorough examination of the area or areas draining the enlarged lymph node or nodes should be performed, paying particular attention to the skin, subcutis, and musculoskeletal structures. In patients that have generalized lymphadenopathy, it is important to evaluate other hemolymphatic organs, including the spleen, liver, and bone marrow.

Laboratory Evaluation

Obtaining a complete blood count (CBC) and a serum chemistry profile are of importance, particularly during evaluation of patients that have generalized lymphadenopathy. Changes in the CBC may suggest a systemic inflammatory process (e.g. leukocytosis caused by neutrophilia, left shift, and monocytosis in a dog with histoplasmosis or blastomycosis) or a diagnosis of hematopoietic neoplasia (e.g. presence of circulating blasts or marked lymphocytosis suggestive of chronic lymphocytic leukemia). Infrequently the etiologic agent can be identified by examining a blood or buffy coat smear (e.g. histoplasmosis, trypanosomiasis, babesiosis, ehrlichiosis).

Anemia in patients with lymphadenopathy can be caused by several mechanisms. Anemia of inflammatory disease can be seen in inflammatory, infectious, or neoplastic disorders; hemolytic anemia is usually present in patients with hemoparasitic lymphadenopathies or histiocytic/lymphoid malignancies; severe nonregenerative anemia can be observed in dogs that have chronic ehrlichiosis or immune-mediated disorders, in cats that have retroviral infections, and in dogs and cats that have primary bone marrow neoplasms (i.e. leukemias). Intra-abdominal lymphadenopathy in a dog that has relative iron deficiency anemia indicates the presence of a gastrointestinal neoplasm.[3,10] The reticulocyte hemoglobin content may help in these cases as a marker of iron deficiency.

Thrombocytopenia is a frequent finding in patients that have ehrlichiosis, RMSF, sepsis, lymphoma, leukemias, multiple myeloma, systemic mastocytosis, malignant histiocytosis, retroviral infections, and some immune-mediated disorders.[10–13,22,27,34,37] Pancytopenia is frequent in dogs that have chronic ehrlichiosis, histiocytoses, and systemic immune-mediated disorders; in dogs and cats that have leukemia; and in cats that have retroviral disorders.[5,17–20,37]

Two major serum chemistry abnormalities are of diagnostic value in dogs and cats that have lymphadenopathy are hypercalcemia and hyperglobulinemia.

Hypercalcemia can result from a paraneoplastic syndrome that occurs in approximately 10–20% of dogs that have lymphoma[34] or multiple myeloma;[22] it also has been documented in dogs with blastomycosis.[13] Hypercalcemia is rare in cats; neoplasms associated with hypercalcemia in this species include lymphoma, squamous cell carcinoma, fibrosarcoma, myeloma, and parathyroid tumors.[8,32] Monoclonal hyperglobulinemia can occur in dogs and cats that have multiple myeloma,[8,22] in dogs that have chronic lymphocytic leukemia (CLL),[20] and infrequently in dogs that have lymphoma,[34] ehrlichiosis,[4] or leishmaniasis.[15] Polyclonal hyperglobulinemia, however, is more frequently associated with infectious diseases like leishmaniasis, ehrlichiosis and systemic mycoses, and in cats with feline infectious peritonitis (FIP).[1,4,8,18]

Serologic testing (e.g. FIV, *Leishmania*, *Toxoplasma*, *Ehrlichia*), direct antigen tests (e.g. FeLV), or PCR techniques (e.g. FIP, *Ehrlichia*) are indicated when infectious causes for the lymphadenopathy are suspected.

Imaging

Radiographic abnormalities in dogs that have lymphadenopathy vary with the primary disorder. Generally, plain radiographs are beneficial in patients that have deep regional lymphadenopathy involving the thoracic and the abdominal cavities. Ultrasonography is a noninvasive procedure that provides great benefit in evaluating intra-abdominal lymphadenopathy. Especially in combination with color Doppler characteristics, ultrasonography may be useful in distinguishing neoplastic from inflammatory lymphadenopathy.[26,31] In addition, lymph nodes can be accurately imaged and measured, so that therapeutic progress can be monitored. Moreover, ultrasound-guided aspirates or biopsies can be performed in patients with minimal complications.[2]

Bone Marrow Findings

Evaluation of bone marrow aspirates or core biopsies can be beneficial in patients that have generalized lymphadenopathy caused by hematopoietic neoplasia or systemic infectious diseases (e.g. histoplasmosis, ehrlichiosis, leishmaniasis, see Chapter 19).

Lymph Node Aspirate

Cytologic evaluation of lymph node aspirates provides the clinician with a wealth of information and is frequently the definitive diagnostic procedure in patients that have lymphadenopathy.[35] Superficial lymph nodes can be aspirated with minimal difficulty; the successful aspiration of intrathoracic or intra-abdominal lymph nodes requires some expertise. For a fine needle aspirate of a superficial node to be obtained, the area does not need to be surgically prepared. Aspiration of intrathoracic and intra-abdominal structures requires surgical preparation of the area and adequate restraint of the patient; in addition, ultrasonographic guidance can be beneficial in obtaining the desired specimen. The technique for fine needle aspiration of lymph nodes is reviewed elsewhere.[9]

Several reports of cytologic evaluation of lymphoid tissues have appeared in the veterinary literature.[11,36] Briefly, normal lymph nodes are composed primarily of small lymphocytes (80–90% of all cells); a low number of macrophages, medium or large lymphocytes, plasma cells, and mast cells can also be found. Reactive lymph nodes are characterized by variable numbers of lymphoid cells in different stages of development (i.e. small, medium, and large lymphocytes; immunoblasts; and plasma cells). As discussed above, the cytologic features of lymphadenitis vary with the etiologic agent and the type of reaction elicited (i.e. neutrophils in suppurative inflammation; macrophages in granulomatous reactions; an admixture of both in pyogranulomatous reactions). Causal agents can frequently be identified in cytologic specimens obtained from affected nodes. Metastatic neoplasms have different cytologic features depending on the degree of involvement and the cell type. Primary lymphoid neoplasms (lymphomas) are characterized by a more monomorphic population of lymphoid cells, which are usually immature (centroblasts).[36]

Lymph Node Biopsy

When cytologic examination of an enlarged lymph node fails to provide a definitive diagnosis, excision of the affected node for histopathologic examination is indicated. In this regard, it is preferable to excise the whole node. Core or needle biopsies are difficult to interpret because nodal architecture is not preserved. Care should be exerted in handling the node during surgical manipulation, because trauma may induce artifacts and preclude interpretation of the specimen. The popliteal lymph nodes are easily accessible, and are the ones usually excised in dogs and cats that have generalized lymphadenopathy.

Once a node is excised, it should be halved lengthwise; impression smears should be made for cytology; and the node should be fixed in neutral buffered 10% formalin, at a rate of one part of tissue to nine parts of fixative. The specimen is then ready to be referred to a laboratory for paraffin embebbing and sectioning. Unfixed tissue also can be submitted in a sterile container for bacterial or fungal culture.

SELECTED DISORDERS ASSOCIATED WITH BENIGN LYMPHADENOPATHY IN DOGS AND CATS

In-depth discussion of all causes of lymphadenopathy is beyond the scope of this chapter, but Table 58.1 outlines the most frequent causes. The reader is referred to specific references regarding each condition or infectious agent. A discussion of a few conditions causing lymphadenopathy follows.

Bacterial Lymphadenitis

Two syndromes presumptively associated with pyogenic bacterial infections and lymphadenitis, contagious streptococcal lymphadenitis of cats and puppy strangles, have been described in small animals.[8] Also, localized streptococcal and staphylococcal infections may result in solitary or regional lymphadenopathy in these species.

Contagious streptococcal lymphadenitis was described in several kittens in a cat colony.[8,33] The kittens developed diarrhea and fever at 4 weeks of age and cervical lymphadenopathy 2 weeks later. The lymph nodes in these cats were significantly enlarged and developed draining purulent lesions. An unrelated adult cat, housed with these kittens, also developed similar signs and lesions, and the disease could be transmitted orally by administration of lymph node material from the affected cats. All the cats tested negative for circulating feline leukemia virus (FeLV) p27 antigen. Lancefield group G beta-hemolytic streptococci were isolated from abscessed lymph nodes and from heart blood in one kitten that died of septicemia. Most cats responded to treatment with penicillin.

Puppy strangles (i.e. juvenile cellulitis) is a disorder associated with cutaneous cellulitis of the head and neck, and mandibular and cervical lymphadenopathy in 4- to 12-week-old dogs.[38] Pups usually present with fever and facial skin lesions including edema, pustules, and crusts periorally, perioculary, on the chin or muzzle, or in the ears, along with lymphadenopathy. Sometimes the lymphadenopathy is not associated with skin lesions. More than one pup in the litter is frequently affected. Fine needle aspiration of affected lymph nodes reveals purulent lymphadenitis, and staphylococcal or streptococcal organisms may be cultured. However, due to lack of response to antibiotic therapy in a high proportion of cases, the absence of bacteria in most cultures obtained from affected areas, and the subsequent response to immunosuppressive doses of corticosteroids, a hypersensitivity reaction to staphylococcal antigens is suspected.

Idiopathic Lymphadenopathies

A syndrome, called idiopathic lymphadenopathy has been described in the cat in several reports.[21,23,24] In one report, 14 cats, that ranged in age from 5 months to 2 years, had generalized lymphadenopathy.[24] The term distinctive peripheral lymph node hyperplasia was chosen by the authors for this condition. Eight cats were clinically normal on initial physical examination, except for the presence of lymphadenopathy; clinical signs in the other six cats included fever (five cats), lethargy (three cats), anorexia (three cats), pallor, hematuria, eczema, vomiting, and mastitis (one cat each). Of the 14 cats for which CBCs were available, nine had anemia; one cat had neutrophilia and lymphocytosis; and three cats had neutropenia. Six of nine cats evaluated for FeLV antigens in peripheral blood were positive.

Therapy in affected cats included antibiotics, corticosteroids, and fluids. In six cats, the lymphadenopathy resolved within 2 weeks to 4 months; one of these cats subsequently developed intrathoracic lymphoma and died; one additional cat had recurrence of the lymphadenopathy in 5 years and was euthanized; three cats had persistent lymphadenopathy and also were euthanized within a month of the initial diagnosis; four cats were lost to follow-up.[7] Histologic changes in affected nodes included distortion of the architecture; proliferation of histiocytes, lymphocytes, plasma cells, and immunoblasts in paracortical regions; and numerous prominent postcapillary venules. These changes were similar to the ones observed in seven cats with experimental FeLV infection.[7] Based on these changes and the fact that six of the nine cats evaluated were FeLV-positive, the authors postulated that this syndrome is secondary to retroviral infection.

In another report, six young cats were described with marked generalized lymphadenopathy resembling lymphoma.[8] The cats ranged from 1 to 4 years in age and three of them were Main Coon cats. Most peripheral nodes were 2–3 cm in diameter and firm. Four cats had leukocytosis and one had leukopenia. One of the cats was anemic, and atypical lymphocytes were visualized in a blood smear. Five cats, evaluated for FeLV viremia, were negative. Serum protein electrophoresis in five cats revealed the presence of polyclonal gammopathies; one cat was hypercalcemic. Histological features were suggestive of lymphoma and included loss of normal lymph node architecture, presence of a uniform population of lymphoid cells in the paracortical areas, capsular and perinodal infiltration, and presence of large follicular structures without germinal centers. However, other features were not compatible with malignancy, including abundant vascularity; lymphoid follicles with active germinal centers; presence of a mixed population of lymphoid cells, plasma cells, histiocytes, and granulocytes in the sinuses. One of the cats was euthanized on presentation; the remaining five cats were not treated. Resolution of the lymphadenopathy was seen in all cats within 5–120 days and all cats were alive 12–84 months after initial diagnosis.

The clinical and pathologic features in cats that have idiopathic reactive lymphadenopathy are similar to those observed in cats naturally or experimentally infected with feline immunodeficiency virus (FIV).[5,6] It is improbable that all cats that have idiopathic reactive lymphadenopathy are infected with FIV; more likely, FIV represents one of the agents that can induce these changes in lymph nodes of domestic cats. Indeed, in one report few differences were found between FIV-infected cats and seronegative cats with regard to lymph node pathology.[28]

A clinical syndrome characterized by solitary cervical or inguinal lymphadenopathy in cats ranging in ages from 3 to 14 years, and referred to as plexiform vascularization of lymph nodes has been described.[21] The lesions were unilateral in seven of nine cats studied. Most cats were asymptomatic and the FeLV status was

not reported. Surgical removal of the affected nodes resulted in uneventful recovery in most cats; however, postoperative edema occurred in two cats. Histologically, the nodes showed replacement of the interfollicular pulp by a plexiform proliferation of small capillary-sized vascular channels and lymphoid atrophy. The pathogenesis of this syndrome has not been elucidated.

Mineral-Associated Lymphadenopathy

A primary lymph node disease termed mineral-associated lymphadenopathy was described in the 1980s and has been reported since exclusively in dogs in the United Kingdom.[12] Affected dogs have nonspecific clinical signs (e.g. malaise, pyrexia, inappetence) in combination with generalized lymphadenopathy. Histologic examination of lymph nodes reveals a granulomatous lymphadenitis with accumulation of large quantities of crystalline-appearing, mineral material in the node. Electron microprobe analysis of this mineral reveals it consists of a complex mixture of elements including aluminum, silicon, titanium, and nickel, suggesting an environmental origin. In affected lymph nodes, inflammatory cytokines (IL-1, TNF-α) are produced causing the clinical symptoms. In several cases concurrent diseases, like malignant lymphoma and immune-mediated diseases, are present. Apart from treating the concurrent disease, mineral-associated lymphadenopathy frequently responds favourable to anti-inflammatory treatment.

The Cell Cycle and Cancer

Acronyms and Abbreviations

APC, anaphase promoting complex; CAK, CDK-activating kinase; CDK, cyclin-dependent kinase; CDKI, CDK inhibitor; DNA, deoxyribonucleic acid; G(0), gap (0) phase; HDAC, histone deacetylase; IL, interleukin; MPF, maturation promoting factor; ORC, origin of replication complex; TGF-ß, transforming growth factor-ß.

In the late 1980s there was a confluence of several fields of research. Scientists studying cell division in budding yeast (*Saccharomyces cerevisiae*), in fission yeast (*Schizosaccharomyces pombe*), and in frog eggs (*Xenopus laevis*) discovered a group of proteins that were responsible for cell cycle oscillation.[4,7,15] Because the proteins were expressed cyclically, they were named cyclins. In short order, a "cell cycle engine" that functions in all eukaryotic organisms was defined. This mechanism consists of cyclin-regulated cell cycle kinases that provide the crucial checkpoints and feedback controls that regulate cell division.

THE CELL CYCLE ENGINE

To simplify its study, the cell cycle has been subdivided into various steps (Fig. 59.1). These steps include Gap (G0), or the phase at which cells are in a resting or non-proliferative phase; G1, which defines entry into the cell cycle and is characterized by increased cellular metabolism and growth; Synthesis (S), in which the whole genetic complement of the cell is replicated; G2, where the cell finishes the growth processes necessary for division; and finally mitosis (M), where division of one cell into two daughter cells finally takes place.[8] In normal cells, transitions among these states are defined functionally and are exquisitely fine-tuned. The balanced action of proliferative and anti-proliferative signals ultimately determines whether cells enter the cell cycle, exit the cell cycle, or undergo programmed cell death (i.e. apoptosis).[6]

The cell cycle engine defines a regulatory network whose key components include proteins from two unrelated gene families, the cyclins and the cyclin-dependent kinases (CDKs). These proteins control phase transition, and are regulated transcriptionally and post-transcriptionally. In this chapter, we will use T cells to illustrate the transition steps that regulate cell cycle entry, progression, and exit.

Cyclins

Cyclins are highly conserved in all eukaryotic species studied. More than 12 mammalian cyclin homologue genes have been characterized, but here we will focus only on those genes that control cell cycle transitions. Cyclins function as regulatory subunits for the CDKs,

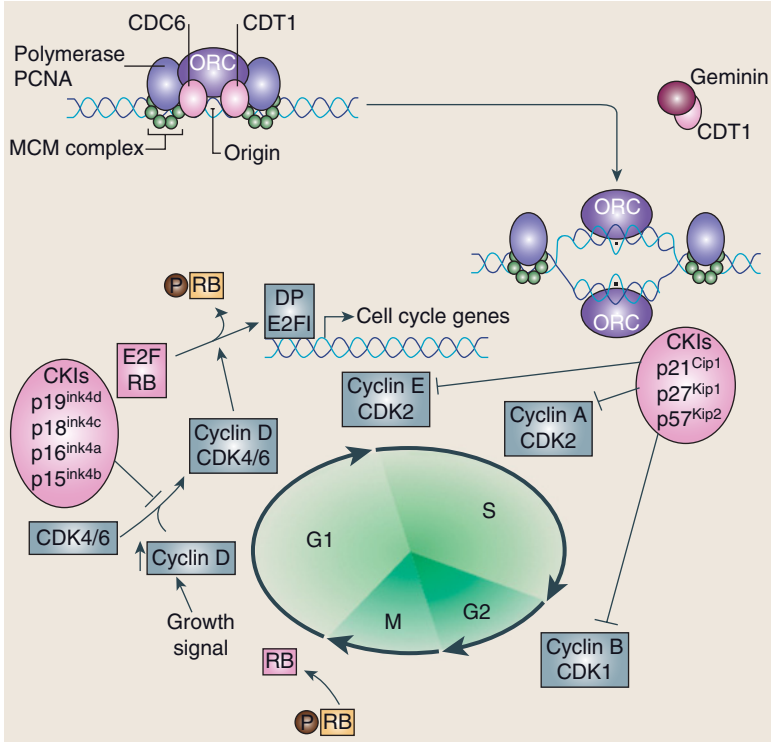

FIGURE 59.1 A schematic representation of the cell cycle. Cells enter the cell cycle in the G1 phase. G0 is a specialized form of G1 (highly differentiated cells, which are unlikely to divide unless provoked, remain in G0). During late G1 the cell commits to divide, typically marked by phosphorylation of Rb, and activation of E2F, which in association with DP1 binds to the promoters of various cell cycle genes. The process of replication of the entire genome is completed during the S phase, resulting in doubling of DNA content of the cell. The mechanical components that will organize chromosomes and physically divide the cell are assembled during the G2 phase, and a complex cytological event that accurately divides the duplicated sets of chromosomes and coordinates the events of fission to produce two cells from one is executed during the M phase. Many events take place during M phase, including dephosphorylation of RB. Upon completion of M phase, both daughter cells re-enter G1 and a new cell cycle is set to begin. Proteins that drive or inhibit the cell cycle are shown in gray or pink boxes, respectively. Cyclins are activator proteins that are up- or down-regulated depending on the phase of the cell cycle. CDKs are serine/threonine kinases that require the binding of a cyclin (or related protein) for full activity. Their range of substrates is not fully defined, but interfering with their activity arrests or slows the cycle. CDKIs are small peptides that block cyclin/CDK activity either by forming an inactive complex or by acting as a competitive CDK ligand. DNA polymerases, proliferating cell nuclear antigen (PCNA), and mini-chromosome maintenance (MCM) proteins initiate replication only once per cycle. The checkpoint proteins are members of a network of proteins that monitor DNA integrity and arrest the cell cycle until DNA damage can be repaired. (Reproduced from Herrup K, Yang Y, Cell cycle regulation in the postmitotic neuron: oxymoron or new biology? Nat Rev Neurosci 2007;8:368–378, with permission. ©Macmillan.)

because monomeric CDKs have essentially no catalytic function.[17] However, the association of a CDK and a cyclin into a complex is only one regulatory step in the activation of these protein kinases. The cyclins are divided into groups according to the phase of the cell cycle in which they are expressed. Examples include the mitotic cyclins (B-type cyclins), S phase cyclins (cyclins A and E), and G1 cyclins (cyclins D1-3, cyclin E). Cyclin H is part of an enzyme complex called CDK-activating kinase (CAK). The nucleotide and amino acid sequence homology among cyclin proteins is limited (<30% at the amino acid level), and is restricted to a highly conserved region called the cyclin box. This cyclin box is required for association with a CDK, along with an independent, protein-specific sequence that mediates binding to small molecules called cyclin-dependent kinase inhibitors (CDKIs) that facilitate assembly of the cyclin-CDK complex.[10]

Cyclin-dependent Kinases

In higher eukaryotes, the CDKs comprise a family of more than 12 proline-directed, serine and threonine protein kinases that share a PSTAIRE motif. Those members of the CDK family that control cell cycle transitions are subdivided into proteins closely related to CDK1 (the mammalian Cdc2 homolog) that include CDK2, CDK3, CDK 4, CDK5, and CDK6.

Cyclin-dependent Kinase Inhibitors

The CDKIs are products from various distinct gene families, the prototypes of which are p16 (CDKN2A), and the closely related p21 (CDKN1A) and p27 (CDKN1B).[16,18] Proteins in the p16 family (p15, p16, p18, p19) are specific inhibitors of CDK4 and CDK6, and their expression and function are dependent on a func-

tional *RB*-1 gene product (Rb). Indeed, the absence of Rb appears to make these CDKIs, as well as CDK4 and CDK6, inconsequential in their cell cycle regulatory function. In normal cells, the up-regulation of p16-related proteins is inducible by transforming growth factor-ß (TGF-ß). The expression of p21 is closely regulated by another unrelated tumor suppressor gene called p53. The p21 gene may be inducible as an effector of growth arrest before S phase entry if the cell must undergo DNA repair. The function of members of the p27 family (p27, p57) appears to be regulated by various signaling pathways that affect cell cycle progression, including those that are mediated by TGF-ß or by cyclic AMP.

Regulation of Cyclin-dependent Kinase Activity

Each CDK can associate with multiple cyclins: among the G1 CDKs (CDK2, CDK4, CDK6), CDK2 associates with A, E, and D-type cyclins, whereas CDK4 and CDK6 form complexes only with D-type cyclins. The cyclin partner is required for activation of the kinase, it confers substrate specificity, and it regulates the interactions of the complex with other proteins.

Inactivation of the kinases occurs in part due to the proteolytic degradation of the cyclin partner. CDK activity also is controlled by other kinases and phosphatases. Phosphorylation and dephosphorylation reactions occur at defined residues that are highly conserved throughout the CDK family; for example, phosphorylation of a distal threonine residue (T160/172 in CDK2 and CDK4, respectively) by CAK is an important activating event for all CDKs. Another critical event is dephosphorylation of N-terminal threonine (T14) and tyrosine (Y15/17) residues near the ATP binding site by a bifunctional protein phosphatase of the Cdc25 family. Conversely, phosphorylation of T14 and Y15/17 by the Wee1 bifunctional protein kinase, and dephosphorylation of T161/172 by a protein similar to protein phosphatase 1 are important to inactivate the CDKs. The kinases and phosphatases that carry out this phase of CDK regulation provide additional links between environmental signals and activation of the cell cycle machinery.

MAINTENANCE OF G0

Cell growth and proliferation are integral parts of the immune response. Mature peripheral T cells generally maintain homeostasis in a true resting (G0) state where the cell cycle kinases (CDK1, CDK2, CDK4, or CDK6) and their cyclin partners (cyclin D2, cyclin D3, cyclin E, cyclin A, or cyclin B) are not expressed.[14]

Negative Regulation of Cell Cycle Entry

The process of thymic education dictates that naïve T cells must interact with self-peptides presented by MHC (i.e. potential autoantigens) in order to survive. Naïve T cells express high levels of T cell receptors, so the avidity for self-MHC might trigger their activation and result in autoimmunity. To prevent such activation, several interrelated negative regulatory pathways in lymphocytes enforce quiescence. Regulatory molecules in these pathways include those that dampen signaling such as Ian5 and negative transcriptional regulators such as the transducer of ErbB2-1 (Tob1), nuclear factor of activated T cells-c2 (Nfatc2) and Smad3, which is primarily responsible for integrating anti-proliferative and pro-survival signals delivered through the TGF-ß receptor.[11,20] Mutations in these genes result in T cells that survive poorly (IAN5 knockout), fulminant autoimmunity (TGF-ß receptor dominant negative), or cells that show cell cycle dysregulation with eventual tumor formation (Tob-1 and NFATc2 knockouts). Intriguingly, the tumor phenotypes for Tob-1 and NFATc2 deficiency are B-cell lymphomas, and a recent study suggests that these proteins contribute to this subtype of lymphoma in dogs (A. Frantz and J. Modiano, unpublished data).

THE G0 TO G1 TRANSITION AND G1 PHASE PROGRESSION

Antigen binding to the T cell receptor complex triggers a series of events that give rise to a number of interactive, non-linear biochemical cascades that disengage negative regulation and activate the cell cycle machinery. Events during the G1 phase are essential to integrate environmental signals with cellular responses. In some instances, cell proliferation may be separated from other biological responses. For example, stimuli that incite production of interleukins can promote lymphocyte maturation and differentiation, immunoglobulin production, or enhanced cytotoxic or antigen presenting functions and may not lead to cell division. Conversely exogenously provided cytokines may promote proliferation of receptive lymphocytes in a paracrine or endocrine fashion.

Unlike embryonic cells where the length of the cell cycle is temporally fixed, transit time through the G1 phase is variable in adult somatic cells. Potentially transforming events can significantly shorten the G1 phase. In most cases, this prompts activation of checkpoints that prevent transition to the S phase or leads to apoptosis. Cancer cells must, therefore acquire mutations that allow them to overcome these safeguards.[18]

The G1 Restriction Point

Cell cycle entry, defined as the transition from G0 to G1, is reversible. This transition point can be defined by partial activation of the CDK4/cyclin D2 holoenzyme complex and phosphorylation of the retinoblastoma susceptibility protein Rb, the product of the RB-1 prototypical tumor suppressor gene. Transition into G1 also requires activation of CDK6 and CDK2. The CDKI p27 protein may be especially important in control of G1 progression. At least part of the observed increase

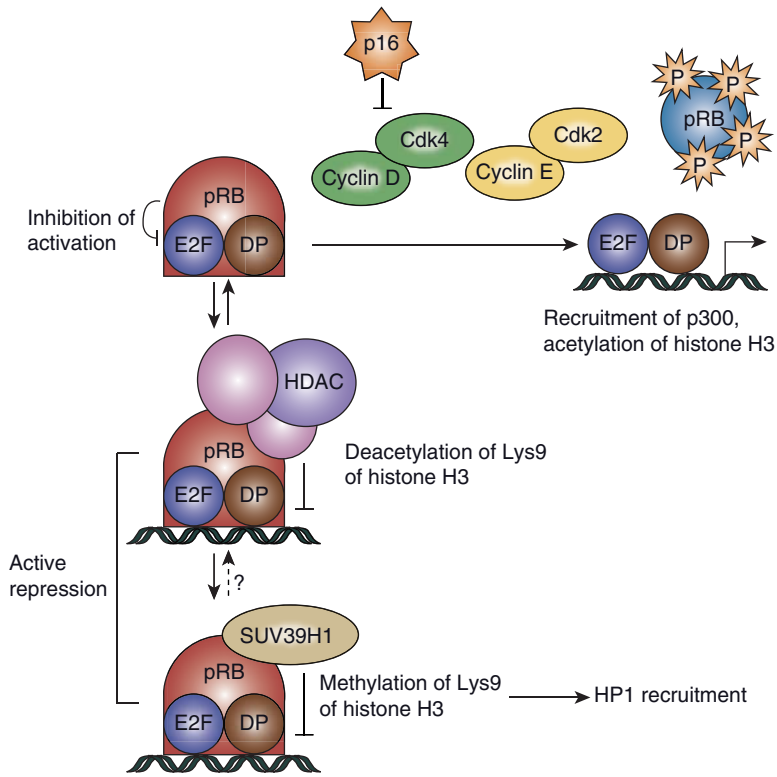

FIGURE 59.2 General mechanisms that control the repressive activity of E2F. The retinoblastoma protein binds to an E2F–DP complex in G0/G1 cells and this leads to repression of E2F-responsive genes through two possible mechanisms. First, phosphorylated RB (pRb) inhibits E2F from activating transcription by binding to its transactivation domain and preventing its interaction with the core transcriptional machinery. Second, the resulting complex binds to the promoters of E2F-responsive genes and enforces their "active repression" through recruitment of either histone deacetylases (HDACs), which remove the acetyl group from lysine 9 (Lys9) of the histone H3 tail and thereby facilitate nucleosome packing, or SUV39H1, which methylates the same lysine residue to create binding sites for HP1, leading to transcriptional silencing. Cell-cycle entry is dependent on the sequential activation of the cell-cycle-dependent kinases, CDK4/6–cyclin D and CDK2–cyclin E, which phosphorylate pRB and cause it to release E2F. The resultant activation of E2F-responsive genes seems to be at least partially dependent on the ability of E2F to recruit p300, leading to the acetylation of Lys9 of histone H3. Several key components of the pRB regulatory pathway are known to be tumor suppressors (pRB, p16) or oncogenes (cyclin D, Cdk4). DP, differentiation regulated transcription factor (DRTF) protein; pRB, retinoblastoma protein. (Reproduced from Trimarchi JM, Lees JA, Sibling rivalry in the E2F family. Nat Rev Mol Cell Biol 2002;3:11–20, with permission. ©Macmillan.)

in CDK2 activity in activated T cells may be due to IL-2-induced dissociation of p27 from CDK2 kinase complexes, and T cells from p27-knockout mice have exaggerated T cell responses.[5] Cells that reach this stage of activation acquire the capability to respond to proliferative signals, but are not committed to continue transit into the S phase until they cross the restriction point, R.[14] This occurs at least in part by activation of CDK4/cyclin D3 and CDK2/cyclin E complexes.

Regulation of the G1 to S Transition by Rb

The so called pocket proteins of the Rb family is a group of proteins that promote (or suppress) the expression of genes that control the G1/S transition, including members of the E2F family of transcription factors and histone deacetylases (HDACs). In the hypophosphorylated state, modulation of these proteins by Rb acts as a cell cycle brake. Phosphorylation of Rb by the CDKs leads to functional collapse of the pocket, releasing latent transcription factors and allowing their activation. It appears that phosphorylation by CDK4 releases HDACs, relieving transcriptional repression for some genes such as cyclin E, and opens the conformation of Rb, making it permissive for phosphorylation by CDK2. Subsequent Rb phosphorylation by CDK2/cyclin E releases E2F transcription factors. The activation of E2F factors requires their association with DP-1 or DP-2 to form heterodimers that orchestrate transcription of genes necessary for DNA synthesis (Fig. 59.2). In lymphocytes, activation of Aurora B in conjunction with Survivin and mTOR is an essential step to complete the transition from G1 to the S phase.

S PHASE PROGRESSION

In mammalian cells, an important control element in the process of DNA replication is assembly and activation of pre-replication complexes at 20,000–40,000 genetic sites when a complete single copy of DNA complement is made. Initiation sites (the replication origin) interact

with a group of proteins called the Origin of Replication Complex (ORC).[19] This allows helicases and other enzymes to unwind the double strand and recruit polymerases. Replication forks then move away from the origin in either direction (Fig. 59.1).

As is true with abnormal G1 transit, partial re-replication triggers checkpoints that arrest cell cycle progression or promote apoptosis. Re-replication is in some ways unavoidable and may be a driver of evolution. Indeed, it is now clear that subtle differences in DNA copy number exist among individuals within a species, and in dogs these might be conserved within members of the same breed, similarly to microsatellites and single nucleotide polymorphisms.[3,12]

Checkpoint Transit

The S-phase checkpoint relies on detection of stalled replication forks (usually due to insufficient trinucleotide building blocks) or DNA damage. Members of the ATM/ATR kinase families (ataxia-telangiectasia mutated-and Rad3 related) act as sensor kinases, which in turn activate the effector kinase Chk2. Chk2 activation delays or arrests S phase progression. Persistent stalled forks or DNA damage that cannot be repaired triggers apoptosis of normal cells.

Regulation of the Origin or Replication

Cells must avoid extensive re-replication during DNA synthesis. The ORC contains six stable subunits that bind to DNA in the transition from mitosis to G1 (or G0), followed by additional proteins, such as MCM helicases, that are synthesized or stabilized at or near the G1 to S transition to form the pre-replicative complexes. CDK2/cyclin E (and other S phase kinases) primes these pre-replicative complexes to form pre-initiation complexes that are necessary for activation of DNA polymerases. Progression through S phase requires transition from CDK2/cyclin E to CDK2/cyclin A complexes, which are followed by the appearance of CDK1 complexed to cyclin A and cyclin B. Substrate specificity is probably important to prevent re-replication and to maintain the fidelity of DNA polymerases.

G2 PHASE PROGRESSION

Transition from S to the G2 phase occurs upon completion of DNA replication. At this point, somatic cells are tetraploid (i.e. have four copies of DNA) and are destined to divide.

DNA Damage Checkpoint

The S phase checkpoint is fallible, so a partially redundant checkpoint exists during the G2 phase. ATM/ATR kinases also act as G2-DNA damage sensors. Lymphocytes that undergo physiologic DNA double strand breaks during antigen receptor gene rearrangement are particularly susceptible to chromosomal instability, which is why patients with ataxia telangiectasia have hypofunctional adaptive immune responses and a significantly higher risk of developing cancer.[2] The primary G2 DNA damage effector kinase is Chk1, which controls G2 phase progression and M phase entry, primarily by phosphorylating the CDK-regulatory CDC25 phosphatases.

Preparation for Mitosis

Proper chromatid alignment and association is necessary for normal separation during mitosis. Spindle assembly and the spindle checkpoint are regulated by CDK1 in conjunction with the Aurora A and Aurora B kinases, respectively. Aurora C kinase controls chromosomal segregation in mitosis.

M PHASE PROGRESSION

Chromatin condensation occurs throughout the cell cycle until the onset of mitosis, when the chromatin is packaged into species-specific units called chromosomes. M phase progression begins with the dissolution of the nuclear membrane, continues with the assembly of the mitotic spindle, and culminates with division into two daughter cells, each with a diploid complement of DNA.

Prophase

Breakdown of the nuclear envelope proceeds at the end stage of chromosome condensation by phosphorylation of lamins. This precedes spindle formation, which is mediated by complex interactions of microtubules and kinetochores. Centromeres allow chromosomes to attach to the spindle, a process that also may be controlled through Aurora B kinase and Survivin.[1]

Metaphase

As cells approach metaphase, chromosomes align along the spindle at equal distance from each pole to form the traditional metaphase plate in a process called congression.

Anaphase

Cyclin B is rapidly degraded by the anaphase promoting complex (APC), which functions as an E3 ubiquitin ligase; this is followed by separation of sister chromatids. Anaphase promoting complex activity is restrained by the spindle checkpoint until kinetochore alignment is complete. Sister chromatid separation is itself a complex process, and is controlled at least in part by DNA topoisomerase II. The importance of this enzyme in mitosis is underscored by the exacting sensitivity of cancer cells to camptothecin and other topoisomerase II inhibitors.

After the separation of sister chromatids, there is little resistance for chromosome segregation towards the poles. Vesicles on the chromosomes promote reformation of the nuclear envelope and cytokinesis ensues as CDK1/cyclin B activity subsides. Each daughter cell can then resume its normal function or re-enter the cell cycle.

THE CELL CYCLE AND CANCER

Cancer is a condition where cells divide uncontrollably, making it easy to see how it can be linked to abnormal cell cycle function. Common abnormalities include inactivation of CDKIs through mutation or deletion, inappropriate expression of D-type cyclins, inactivation of Rb, and malfunction of DNA damage checkpoints, among others.[9] Not surprisingly, these gross abnormalities are prognostic, but even subtle quantitative differences in cyclin expression, Rb phosphorylation, etc., can influence tumor progression and serve as useful indicators of prognosis for hematopoietic tumors.[13] Indeed, recent unpublished data from our laboratory suggest that gene expression signatures that are indicative of aberrant cell cycle regulation are hallmarks of canine high-grade B cell malignancies and canine osteosarcomas that respond poorly to conventional therapy (K. Gavin, A. Frantz, A. Sarver, T. Phang, and J. Modiano, unpublished observations).

Conclusions

Acronyms and Abbreviations

2,4-D, 2,4-dichlorophenoxyacetic acid; BLV, bovine leukemia virus; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; VDL, veterinary diagnostic laboratory.

The simplest definition of epidemiology is the study of factors which define a population's risk of susceptibility to a given disease. Both genetic and environmental influences are usually important, particularly when identifying risk factors for neoplasia. Epidemiology data have inherent uncertainty, as they seek to identify the probability that disease will develop within a given population or the risk of one population to develop a particular disease as compared to another population without that risk. The predominant statistical terms used in cancer epidemiology are relative risk and absolute risk. Relative risk is the comparison between two groups: one group has a given risk factor and the other group does not. Absolute risk is the probability that cancer will develop within a defined period of time. If the period of time is from birth to death it is referred to as lifetime risk (Fig. 60.1). In order to establish risk factors, data from a test population are compared to a reference population. Replication of the data is required for validation. The ultimate goal is to have the most representative group to which other populations can be objectively compared. There are vast amounts of information of this type available for neoplasia in human beings; however, it is significantly lacking for other species.

Epidemiology of hematopoietic neoplasia in domestic animals is an understudied area. By far, the most information available is for dogs. Yet even in dogs, the most current database regarding a reference population is 40 years old. The reference population itself has changed considerably and needs to be updated to reflect: (1) breed popularity changes; (2) changes in breeding practices to produce different desirable traits; (3) changes in production management and husbandry practices; (4) popular sire effects; (5) development of new breeds, and breeds from narrow gene pools; (6) geographical changes; and (7) changing infectious disease influences. More recent studies generally have involved significantly smaller numbers of animals and have not been based on reference populations. This means many specific risk factors will be difficult to identify.

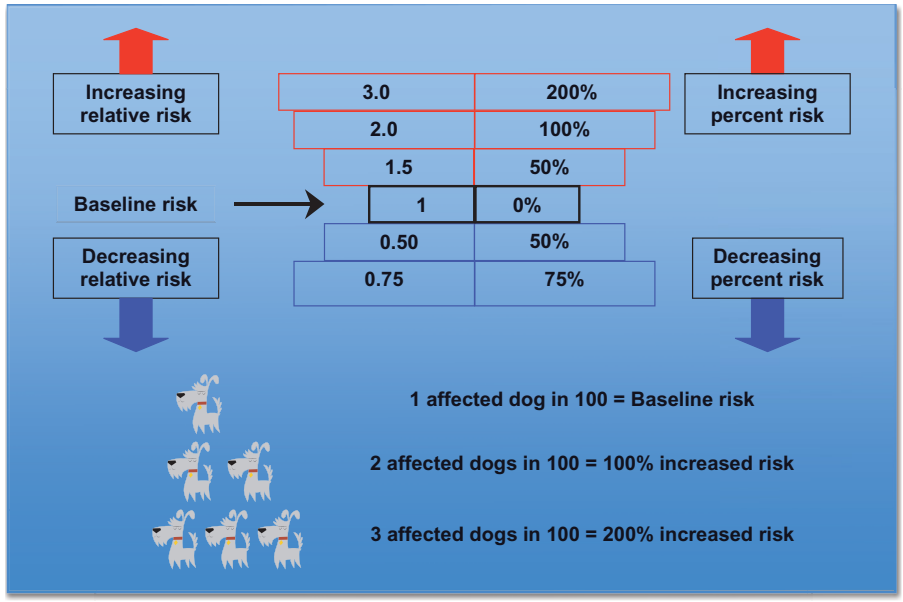

FIGURE 60.1 Two different ways of looking at cancer risk. In the upper portion of the figure, baseline relative risk is equivalent to 1 or 0% risk in the population. When risk increases to 50%, relative risk increases by 1.5× the baseline. When the overall risk decreases by 50%, relative risk decreases to 0.5× the baseline. In the bottom portion of the figure, this is represented by the example of a baseline risk of one affected dog in a given population of 100 dogs: when two dogs are affected, the risk increases by 100%; when three dogs are affected, the risk increases by 200%.

HEMATOPOIETIC NEOPLASIA EPIDEMIOLOGY BASED ON A REFERENCE POPULATION

A pioneering study on cancer epidemiology in dogs and cats was the first of its kind to investigate the implications of sex and age in a defined population in 1968.[4] Although the data encompassed a limited geographical region, this paper was among the first to describe a higher incidence of cancer in purebred dogs compared to mixed breeds. Above all, this paper underscored the need for a more geographically comprehensive reference regarding the susceptibilities and risks of domestic animals for developing neoplasia. A much broader study and the only animal cancer reference population still available today comes from a compilation of data from 15 veterinary schools in the USA and Canada through the years 1964–1977.[22] The geographical bias is somewhat minimized, however, by comparing animals from schools from a diverse group of geographic locations.

Reference Population Information for Dogs

In dogs with hematopoietic neoplasms, lymphoma represented the most cases (1,324), followed distantly by hemangiosarcoma of the spleen (referred to as angiosarcoma) with 165 cases, and leukemia (subclassifications not defined) at 151 cases. Breeds that represented the highest risk for lymphoma, leukemia, and hemangiosarcoma (spleen) included Boxers, Basset hounds, and St. Bernards, which were 3–4 times as likely as all breeds combined (reference population) to develop these cancers. Breeds twice as likely to develop lymphoma, hemangiosarcoma, and leukemia included Scottish terriers, Bulldogs, Airedales, Weimaraners, golden retrievers, Doberman pinschers, Labrador retrievers, English setters, and Great Danes. Dogs considered less likely to develop these tumors (relative risk < 1) were mixed breeds, miniature and toy poodles, Pomeranians, Chihuahuas, Boston terriers, Cocker spaniels, and dachshunds.

When hemangiosarcoma was evaluated separately from leukemia and lymphoma, breeds with the highest risk (2–3 times greater) included: Boxers, Great Danes, German shepherd dogs, English setters, golden retrievers, pointers and German shorthaired pointers. Breeds with decreased risk included miniature schnauzers, Brittany spaniels, Cocker spaniels, Beagles, Boston terriers, miniature and toy poodles, dachshunds, and Pekingese, with Chihuahuas showing the lowest risk.

There were 202 cases of mast cell tumors in the skin and 162 cases of cutaneous hemangiosarcoma in the database. The relative risk was similar to hematopoietic and lymphatic neoplasms; however, spayed females were 1.3 times more likely to develop these tumors. Also, it should be noted that the incidence of mast cell tumors was only reported in dogs.

Hematopoietic tumors not considered in this study included plasma cell tumors and histiocytic sarcomas (with the exception of histiocytomas which were considered along with benign neoplasia). Histiocytomas were by far more prevalent in dogs than cats.

An independent study that reviewed the database of the Veterinary Medical Data Program from 1964 to 1989 to determine the incidence of neoplasia in dogs of 6 months of age or younger showed that cancers of the hematopoietic system were most frequent in this population.[13]

Reference Population Information for Cats

Lymphoma was reported in 657 cats. Manx cats were 4.6 times more likely than non-Manx cats, and Burmese

were 3.1 times more likely than non-Burmese to develop lymphoma. Females, neutered and intact, had slightly lower relative risk than males. Four hundred and seventeen cases of leukemia were identified. Mixed breed cats were 1.3 times as likely to develop leukemia as purebred cats, and Persians were 1.2 times as likely as non-Persians to develop leukemia. Siamese cats had a lower relative risk than the average for the reference population. Feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) status were not evaluated.

Reference Population Information for Horses

Forty-eight cases of equine lymphoma were recorded, as were five cases of leukemia. Appaloosas, mixed breeds, and Standardbreds were 1.7, 1.5, and 1.2 times as likely to develop lymphoma respectively. Mares were 1.6 times as likely as geldings and stallions to develop lymphoma.

Reference Population Information for Cattle

There were 332 cases of bovine lymphoma and 56 cases of bovine leukemia recorded in the database. Gender was found to be the most significant risk factor. Steers were 3.8 times as likely as bulls, and cows were twice as likely as bulls to develop lymphoma. Bovine leukemia virus (BLV) status was not evaluated. Breeds at highest risk for lymphoma included Angus and Ayrshire (1.6×), Jerseys (1.5×), mixed breed dairy and shorthorns (1.3×), mixed breed beef and Holsteins (1.2×) while Guernseys, Herefords, and Charolais had lower relative risk.

HEMATOPOIETIC NEOPLASIA RISK ASSESSMENT IN DOGS

Lymphoma

Environmental Risk Factors

Because it is one of the most common malignant neoplasms affecting domestic dogs, lymphoma has been very extensively studied in dogs (see Chapters 62, 67, and 70). Many attempts have been made to associate lymphoma with environmental risk factors; however, none has been conclusively verified. One environmental risk factor evaluated was exposure to the lawn herbicide 2,4-dichlorophenoxyacetic acid (2,4-D). Although one study found a relationship, a subsequent re-evaluation was unable to confirm the association.[10,12] An association between exposure to electromagnetic fields and the subsequent development of lymphoma in dogs was published but follow-up studies have not been performed to validate that connection.[24]

A study retrospectively performed in the Tuscany region of Italy evaluated dogs with residential exposure to environmental pollutants from 1996 to 1998.[6] The results of this study suggested that there might be an increased risk of lymphoma in dogs living in or near industrial areas and dogs that may have had environmental exposure to household paints and solvents. However, the study's findings were subject to bias recall on the part of the dogs' owners (information obtained by questionnaires and telephone interviews), and specific information regarding types of chemical exposure and amount of exposure were not investigated. The authors of this study affirm that additional investigation is warranted to validate these potential associations.

Genetic/Heritable Risks

It has been postulated that perhaps no other species shows more variability and flexibility of its genome than the domestic dog.[20] *Canis familiaris* has, through selective breeding practices by humans, had its gene pool manipulated to produce more than 400 distinct breeds ranging in size from 2 kg to over 100 kg. Life expectancy, hair coat, skull and skeletal conformation, and behaviors all have been diversified in just 2,800 years.[20] There is abundant evidence that humans also have altered dogs' susceptibility to cancer. Epidemiologic evidence for genetic risk factors for lymphoma in domestic dogs is currently limited to breed associations. The occurrence of tumors is sporadic; however, their development is affected to an extent by heritability. The prevalence of lymphoid neoplasms in dogs differs among breeds as does the frequency of B cell and T cell neoplasms; however, heritable risk factors have not been identified.

More recent information regarding hematopoietic cancers in dogs can be obtained from health surveys privately commissioned by specific American Kennel Club National Breed Clubs. This information is collected via voluntary recruitment of members of the national breed clubs who complete a written survey. The data are then compiled by statisticians and are presented as a health report for the specific breed club. These surveys are not normalized to a reference population and may contain considerable bias. Diagnoses are unable to be directly confirmed by the investigators and sometimes by a veterinarian so there is considerable variation in the numbers of responses obtained. Nevertheless, taken within the context of their limitations, breed health surveys can provide further insight into the epidemiology of hematopoietic neoplasms in dogs.

Based on analysis of data for golden retrievers, Irish setters, Rottweilers, Portuguese water dogs, English Cocker spaniels, and Gordon setters, the risks for hematopoietic neoplasia were combined to include lymphoma, mast cell tumors, and hemangiosarcoma.[7,8,27–30] A meta-analysis of the available data, using the chi square test, indicates golden retrievers have the highest risk of the three hematopoietic tumors combined, followed distantly by Gordon setters, which, in turn were at higher risk than Portuguese water dogs, Rottweilers, and Irish setters.[27-30] The last three breeds were roughly equivalent in prevalence for these hematopoietic

neoplasms. When the prevalence of lymphoma was considered separately from mast cell tumors and hemangiosarcoma, the rank order of apparent breed risk did not change. When a non-hematopoietic neoplasia such as osteosarcoma was evaluated using the same breed survey information, the rank order of breed risk changed considerably. Irish setters had the highest absolute number of affected dogs followed by golden retrievers, Rottweilers, Gordon setters, and, more distantly by Portuguese water dogs. English Cocker spaniels had an insignificant risk for osteosarcoma.

Geographic Risk Factors

There may be geographic risk factors; however, data are regionalized and sporadic. For example, Jagielski et al. found in a study of dogs admitted to the Warsaw Veterinary College between 1998 and 2000 that the odds ratio for Rottweilers to be diagnosed with multicentric lymphoma was 6-fold greater than dogs from other breeds.[11] However, the study populations may not accurately reflect the general dog population in Poland or elsewhere. This information certainly is a valuable starting point for more thorough and controlled epidemiological studies; however, one must guard against over-interpretation of this type of data.

Similarly, a study comparing the lifetime occurrence of neoplasia in German Shepherd dogs and Belgian Malinois military working dogs (United States Department of Defense) during the year 1992 reported that more Belgian Malinois were diagnosed with lymphoma than were German Shepherd dogs and that more German Shepherd dogs were diagnosed with hemangiosarcoma.[21] The authors remind the readers that the study's limitations include that these dogs spend a proportion of their lives outside of the USA in various regions around the world, and that these dogs have a standard high nutritional plane and level of fitness as well as handlers that are extremely vigilant over their welfare. Thus, these groups are being evaluated as they relate to each other and the study's findings should not necessarily be generalized to the Belgian Malinois and German Shepherd dog breeds as a whole.

Investigators in Austria[9] classified subtypes of canine lymphoma and then compared their results with findings in other countries in Western Europe and found no difference in morphology and immunophenotype of lymphomas. They concluded from this information that Austrian dogs are unlikely to have significantly different risk factors than other canine populations in Western Europe.

Leukemia

Leukemia appears to be less common then lymphoma in the canine population and, although leukemia may be under diagnosed, there is no new information on the specific epidemiology of this neoplasm since the study by Priester and McKay (see Chapters 63 and 65).[22]

Histiocytic Sarcomas

Cutaneous histiocytomas are associated with young dogs (<6 years of age) and are typically benign in nature. Breeds historically associated with a higher incidence of cutaneous histiocytoma include Boxer dogs and Bulldogs. Scottish terriers, Doberman pinschers, and Cocker spaniels also have been suggested as breeds with higher risk to develop this neoplasm.[5]

The malignant counterparts of cutaneous histiocytic sarcoma are collectively known as the histiocytic sarcoma complex, which comprises a spectrum of malignancy rather than a static neoplastic process (see Chapter 71). The histiocytic sarcoma complex includes both localized and disseminated forms. Breeds at highest risk are reported to be Bernese mountain dogs, golden and flat coated retrievers, and Rottweilers.[5] It should be noted that histiocytic sarcomas are not related to malignant fibrous histiocytomas, which are classified with the tumor group of soft tissue sarcoma.

Plasma Cell Tumors

An increased frequency of lingual plasma cell tumors was found in Cocker spaniels.[3] This study evaluated 1196 cases of lingual lesions that were submitted to the Colorado State University Veterinary Diagnostic Laboratory during the years 1995–2004. Previously, Cocker spaniels were suspected of an increased risk to develop mucocutaneous plasmacytomas in a study of 75 cases published in 1989.[23]

Mast Cell Tumors

Mast cell tumors can occur in any breed of dog and mixed breed dogs; however, there have been associations made with specific dog breeds that seem to have increased susceptibility (see Chapter 66). A study from Sydney, Australia considering data from 1989 to 2001 at the University Veterinary Center found that Boxers, Australian cattle dogs, and Staffordshire bull terriers were at a significantly higher risk for mast cell tumors.[1] Pugs, Boston terriers, and other brachycephalic breeds also have been present in statistically significant numbers in other studies.

Hemangiosarcomas

Hemangiosarcoma has recently been suggested to originate from progenitor cells in the bone marrow rather than from endothelial lining cells of the organs in which the solid tumors have originated (see Chapter 72).[15] Recent evidence suggests that these tumors may merit reclassification from the soft tissue sarcoma group into the hematopoietic neoplasms. Interestingly, Priester and McKay also categorized lymphoma, leukemia, and hemangiosarcoma together in their publication in the late 1970s.[22]

Hemangiosarcoma is more common in dogs than any other species. Data from six consecutive years were used to evaluate the prevalence of canine hemangiosa-

rcoma. Two hundred and twenty two canine samples of nonvisceral hemangiosarcoma (mostly cutaneous) received by the Veterinary Diagnostic Laboratory (VDL) at Colorado State University in 1996, 1997, and 2002, revealed equal numbers of male and female dogs affected. The most common breeds, when corrected for popularity bias, included pit bull terriers (most common), and sight hounds (whippets, greyhounds, and Italian greyhounds, specifically). The largest number of submissions came from golden retrievers and German Shepherd dogs. Lingual hemangiosarcoma risk was shown to be increased in Border collies while Beagles were shown to have an increased risk for concurrent lingual and cutaneous hemangiosarcoma.[3] Three hundred and eight tissue samples of canine visceral hemangiosarcoma evaluated exclusively from year 6 of the VDL study showed an approximately equal sex distribution. However, the most common breeds affected were golden retriever (56 cases), Labrador retrievers (45 cases) and then German Shepherd dogs (30 cases).[25]

Srebernik and Appleby[31] reported a retrospective study of 4,535 cases of canine vascular tumors evaluated from 1968 to 1989 at the Royal Veterinary College (UK). This study showed a significantly higher risk among German Shepherd dogs for hemangiomas and hemangiosarcomas with roughly 66% of those cases being hemangiosarcomas. They also found that the spleen was the most frequent site in German Shepherd dogs with males being overrepresented. German Shepherd dogs had a lower frequency of cutaneous and subcutaneous hemangioma and hemangiosarcoma.

HEMATOPOIETIC NEOPLASIA RISK ASSESSMENT IN CATS

Lymphoma/Leukemia (Lymphoid Neoplasms)

Environmental

A recent questionnaire-based study suggested that cats with exposure of 5 years or longer to secondhand household tobacco smoke were 3.2 times more likely to develop lymphoma than cats from nonsmoking households.[2] Although some recall bias is inevitable in this type of study, it is more limited here as the study focused on only one parameter of which the owners would have a first hand knowledge. Nevertheless, this study needs to be further validated.

Infectious Diseases

Feline retroviruses as risk factors have had a significant impact on the development of lymphoid neoplasms in the cat. The so called "Feline leukemia virus infection era" comprises the late 1970s through 1983.[17] This period of time showed a high incidence of lymphoma in particular associated with FeLV infection. A retrospective study from 1968–1988 of 53 cats from the Pacific Northwest region with matched controls showed that cats infected with the FeLV virus had a 62.1 times greater risk of developing leukemia or lymphoma than cats that were uninfected.[26] Cats infected with both FeLV and FIV had an increased risk of 77.3 times greater than the control population for these neoplasms, and cats infected with FIV alone had a 5.6 times greater risk than uninfected cats.[26] After 1983, the impact of vaccination against FeLV and culling of infected animals determined by FeLV testing resulted in a significant reduction in FeLV infection. Cases of non-FeLV associated lymphoma (i.e. thymic and alimentary lymphomas) began to rise in the feline population.[26]

Genetic/Heritable

Siamese cats and other related Oriental breeds have demonstrated an increased risk for development of mediastinal lymphoma at younger than 4 years of age in multiple studies.[17,26] Some cats were infected with FeLV.[26] Nevertheless, this information indicates a potential shift in breed risk in feline lymphoma compared to the reference population evaluated 40 years ago.[22] In that population, Siamese cats had a lower than average risk of developing lymphoma.

Mast Cell Tumors

Siamese cats are predisposed to mast cell tumors compared with other breeds.[19] In an assessment of 41 cats with mast cell tumors published in 2006, young Siamese cats were shown to be more likely to present with a military histiocytic form of cutaneous mast cell tumors.[16] It appears that visceral mast cell tumors (majority in the spleen) are more common in cats. Currently, there is no known association of infectious disease with mast cell tumor development.

Hemangiosarcoma

Hemangiosarcoma continues to be a rare tumor in cats and no specific risk factors have yet been identified in this species. Evaluation of 72 histopathological samples of hemangiosarcomas in cats submitted to the VDL at Colorado State University over a 6 year period showed that the majority of these tumors were cutaneous (59 out of 72), there was no noted sex predilection, and the average cat age was 10 years.[25]

HEMATOPOIETIC NEOPLASIA RISK ASSESSMENT IN HORSES

The only current information on epidemiology of lymphoma suggests that T cell multicentric lymphomas are more common than B cell multicentric lymphomas in horses.[18] Hemangiosarcoma in horses is rare and no specific risk factors have yet been identified. A total of 11 samples of equine hemangiosarcoma were identified in the previously mentioned study by Schultheiss through the VDL at Colorado State University in a 6-year period.[25]

HEMATOPOIETIC NEOPLASIA RISK ASSESSMENT IN CATTLE

Lymphoma

The only hematopoietic neoplasia of clinical importance in cows, based on the literature to date, is lymphoma. One risk factor identified in cows for lymphoma is infection with bovine leukemia virus (BLV). It is estimated that 2–5% of BLV cows develop lymphoma, representing about 5,200 cows/year in the state of California alone.[14]

CONCLUSIONS

The paucity of specific data based on an updated reference population regarding hematopoietic neoplasia in domestic animals underscores the need to define specific risk factors for these diseases. By linking large databases with updated communication technology, and by addressing factors affecting populations of domestic animals that have relevance to development of hematopoietic cancer, more accurate perceptions of risk can be ascertained. Changes in breeding practices and husbandry based on better-defined risk factors can then be implemented to help reduce the incidence of hematopoietic neoplasia for those animals that are significantly threatened. In the big picture, by deepening our understanding of susceptibility to cancer we also come to understand its nature more profoundly which will lead us to earlier diagnosis and, ultimately, more effective therapy.

Acronyms and Abbreviations

DNA, deoxyribonucleic acid; HIF, hypoxia inducible factor; IL, interleukin; LOH, loss of heterozygosity; LTR, long terminal repeat; PDGF, platelet-derived growth factor; PDGFR, platelet-derived growth factor receptor; RCND, renal carcinoma and nodular dermatofibrosis; VEGF, vascular endothelial growth factor-A; VEGFR, vascular endothelial growth factor receptor; VHL, von Hippel-Lindau (tumor suppressor gene).

It is now clear that cancer is a disease driven by the accumulation of genetic abnormalities.[30] Hundreds of genetic abnormalities that are peculiarly associated with specific cancers have been identified. In fact, technological advances have allowed full sequencing of tumor genomes.[17] The information from these experiments has reinforced current concepts and provided insight into new areas of research. This chapter will focus on how interactions between genes and environment impact the origin, progression, and response to therapy of hematopoietic tumors.

GENES AND CANCER RISK

To understand cancer, one must first realize this is neither a single nor a simple disease. Rather, the term *cancer* describes a large number of diseases whose only common feature is uncontrolled cell growth and proliferation. An important concept that is universally accepted is that cancer is a genetic disease, although it is not always heritable. Tumors arise from the accumulation of mutations that eliminate normal constraints of proliferation and genetic integrity in a somatic cell. Among other causes, mutations can arise due to the inherent error rate of enzymes that control DNA replication, which introduces from 1 in 10 million to 1 in a million mutations for each base that is replicated during each round of cell division. Most mammalian genomes comprise 2–3 billion base pairs, so every time a cell divides, each daughter cell is likely to carry at least a few hundred mutations in its DNA. Most of these mutations are silent; that is, they do not hinder the cell's ability to function. However, others can disable tumor suppressor genes or activate proto-oncogenes that respectively inhibit or promote cell division and survival.

Heritable Cancer Syndromes

The existence of genetic predisposition to cancer is illustrated by well-defined heritable cancer syndromes.[6] Even though they account for fewer than 5% of all human cancers, studies of families with these syndromes provided many of the initial clues to understand the genetic basis of sporadic (non-heritable) cancers. Although inheritance is recessive, these familial cancer syndromes show dominant patterns of inheritance and have high penetrance. All but two of the

known familial cancer syndromes are due to mutations that inactivate tumor suppressor genes. As originally proposed by Knudson in his "two-hit" hypothesis from studies in children with retinoblastoma,[13] individuals at risk are obligate heterozygotes (they inherit a mutant allele and a wild type allele). As it happens, homozygous mutations in critical growth regulatory genes usually cause embryonic lethality; but in the case where a single allele is affected, the mutation is present in every cell in the body. Given the rate of spontaneous mutation described above, the probability that the second, wild type allele will be inactivated in at least one cell is extremely high, therefore facilitating tumorigenesis. This process is called loss of heterozygosity (LOH).

A mutation in a single gene can predispose individuals to distinct cancer syndromes, while independent, single mutations of different genes can result in virtually the same disease.[6] This is not surprising when we consider that commonly affected genes are multifunctional and are parts of complex interactive networks or circuits, so a mutation may only alter gene function along one biochemical pathway, leaving its interactions with other pathways intact. Moreover, mutations that contribute to most sporadic cancers are restricted to a small subset of genes, many of which also are associated with heritable cancer syndromes.

At least one heritable cancer syndrome (renal carcinoma and nodular dermatofibrosis; RCND) has been described in German Shepherd dogs.[19] The heritable factor (or *RCND* gene) for this syndrome maps to dog chromosome 5 (CFA 5), and specifically to the folliculin gene, which was recently described as corresponding to the human disease (Birt-Hogg-Dube syndrome).[26]

Genetic Influence in Sporadic Cancers

Both the environment and the individual's peculiar genetic background influence cancer risk and the natural history of tumors. This is especially clear in mice, where the relative rate of spontaneous cancers and the susceptibility to chemically induced cancers differ according to the genetic background of various inbred strains. Similar evidence exists for humans; for example, the risk of habitual smokers to develop lung cancer is tightly linked to a unique allele encoding the alpha-3 subunit of the high affinity nicotinic receptor.[1] There also is evidence to suggest that in some cases mutations are "directed" due to the presence of a "mutator phenotype," where the factors that control DNA replication and repair are prone to more errors than would be expected by simple random events. This leads to different rates of cancer predisposition, which would be higher than the mean in individuals bearing this mutator phenotype, and might explain why not all people or animals exposed to similar environmental carcinogens develop the same forms cancer at the same rate.[20]

In dogs and other domestic animals, the co-existence of genetic isolates in closed populations we call breeds, along with animals of mixed breeding, lends itself to study how a relatively homogeneous background influences cancer in outbred populations. Preliminary data from whole genome association studies suggest there are distinct heritable traits that segregate with common cancer phenotypes in dogs.[18,29] Some of these traits are shared between closely related breeds, whereas others seem to contribute to risk independently in different breeds. Perhaps more importantly, dogs are the first species where genetic background has been shown to mold tumor genomes and tumor gene expression profiles.[22,37,38] Together with the demonstration that causal, pathognomonic genetic abnormalities are conserved in homologous human and canine cancers, this opens up a new area to identify the precise contribution of heritable traits to sporadic cancers using comparative systems approaches.

THE HALLMARKS OF CANCER

Six essential, acquired characteristics are necessary for cellular transformation (Fig. 61.1).[9] These characteristics, are: (1) self-sufficiency in growth signal; (2) insensitivity to anti-growth signals; (3) the ability to evade apoptosis; (4) limitless replicative potential; (5) sustained angiogenesis; and (6) the capacity to invade tissues and metastasize. Some of the important concepts

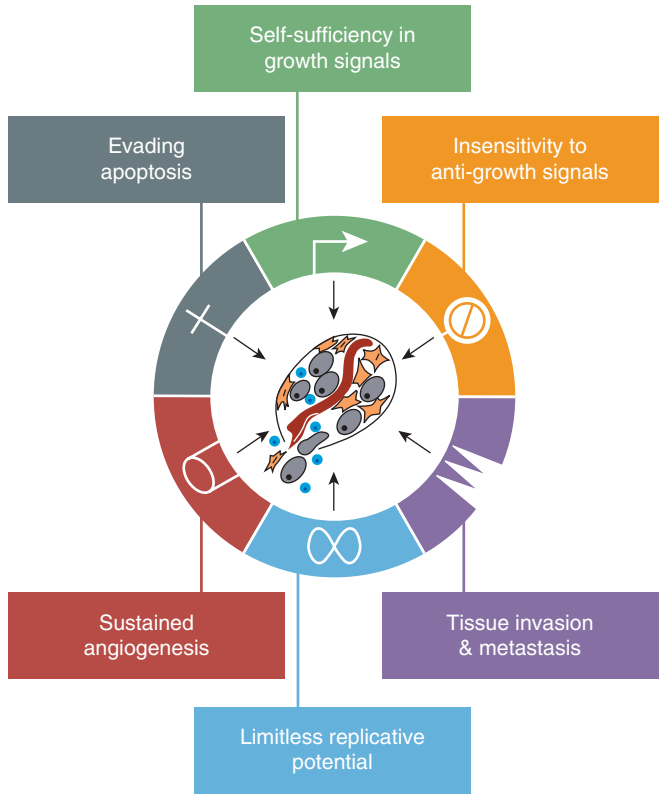

FIGURE 61.1 Acquired capabilities of cancer. Most if not all cancers acquire the same set of functional capabilities during their development, albeit through multiple mechanistic strategies. (Reproduced from Hanahan D, Weinberg RA. The hallmarks of cancer. Cell 2000;100:57–70, with permission. ©Elsevier.)

that are clarified by this list include: no single gene is universally responsible for transformation; five or six mutations are the minimum probable number required to endow the cancer phenotype; each step is regulated by multiple interactive biochemical pathways, thus, mutations of different genes along a pathway can result in equivalent phenotypes and conversely, mutations of the same gene can result in different cancers with distinct biology; tumors behave as tissues, and the interactions between the tumor and its microenvironment are major drivers of cancer behavior.

Self-Sufficiency of Growth Signals

Cells communicate with each other and integrate environmental signals by sensing cues and gradients. For example, migration, metabolism, and proliferation of mature hematopoietic cells are regulated in autocrine and paracrine fashions by locally secreted cytokines. The same cytokines may travel systemically and act in an endocrine fashion. Generally, the cytokines work by binding transmembrane receptors, which in turn initiate signaling cascades that culminate in transcriptional changes. The activity of these cytokines, their receptors, and the corresponding signaling molecules are finely tuned. The system can be shut down when the concentration of the cytokine falls below a threshold that can stably bind the receptor, when the receptor ceases to be expressed, or when signaling molecules are downregulated or otherwise inactivated. However, mutations in even one of the molecules involved in regulating these pathways can provide sustained growth signals in the absence of the initiating cytokine. Among many examples, there is a translocation between chromosome 2 and chromosome 5 (t(2;5)) that is present in almost half of human anaplastic lymphomas. The translocation creates a fusion protein between the nucleophosmin gene (NPM1) and the anaplastic lymphoma kinase gene (ALK), which aberrantly activates the Jak2/STAT5 signaling pathway[34] that is normally responsive to various interleukins (IL) including IL-2, IL-3, and IL-6. The genes that encode the normal growth promoting proteins (such as ALK, Jak2, and STAT5) are called proto-oncogenes; the mutated versions that allow cells to gain self-sufficiency from the environmental signals are called *oncogenes*. It is important to note that not all growth-promoting genes have the capacity to become oncogenes and that the outcome of oncogenic activation is most commonly apoptosis, unless there are additional events that promote stable transformation and survival.

Insensitivity to Anti-Growth Signals

To maintain homeostasis, cells also must integrate anti-growth signals from the environment. As noted in the previous section, quiescence in non-hematopoietic cells is enforced by signals delivered by contact inhibition. Hematopoietic cells, on the other hand, utilize cell-cell contacts to maintain interactions within the niche and to regulate the timing and intensity of hematopoiesis, inflammation, and immunity.[24] Stop signals are usually delivered and integrated by the products of tumor suppressor genes, which derive their name largely from the observation that their inactivation facilitates tumor formation. Tumor suppressor genes balance the activity of growth-promoting proto-oncogenes and tend to act in tandem with these in most biochemical pathways. Loss of function of one or more tumor suppressor genes occurs in virtually every cancer, with inactivation of p53, RB-1, PTEN, or CDKN2A each seen in >50% of all tumors. Each of these pathways may contribute to the pathogenesis of bone marrow-derived tumors in companion animals, and their dysfunction also may be predictive for outcomes.[5,15,16,23]

Evasion of Apoptosis

Apoptosis, or programmed cell death, is the imprinted outcome for every cell in multicellular organisms. Survival requires support from extrinsic (environmental) factors, as well as precise balance of cellular energetics and metabolism. Bone marrow derived cells normally undergo apoptosis when concentrations of survival factors (stem cell factor, IL-3, IL-7, etc.) or nutrients are limiting, or when there are severe disruptions to cellular bioenergetics. Evasion of apoptosis is an essential acquired feature of all cancers, and it can result from loss of pro-apoptotic tumor suppressor genes such as *p53* or *PTEN*, or by gain of function of anti-apoptotic genes such as *BCL2*.

Limitless Replicative Potential

Immortalization is another essential feature of cancer. The genetic program limits the number of times a cell is able to replicate, the so-called Hayflick limit, that when reached induces replicative senescence. Induction of replicative senescence does not induce death; cells maintain energetic homeostasis and remain functional, but they undergo significant genetic changes characterized by telomere erosion. Cells that are able to replicate must maintain the integrity of telomeres, "caps" made of repetitive DNA sequence that protect chromosomes from destruction. Solid tumors acquire immortalization predominantly by activation of the telomerase enzyme system and the consequent maintenance of telomere integrity. In hematopoietic cells, telomerase activity seems to be retained longer than in other somatic cells, so it is possible this facilitates immortalization in lymphoma and leukemia.[28]

Sustained Angiogenesis

The process of angiogenesis requires the coordinated action of a variety of growth factors and cell-adhesion molecules in endothelial and stromal cells. So far, vascular endothelial growth factor-A (VEGF) and its receptors comprise the best-characterized signaling pathway in tumor angiogenesis.[7] VEGF binds two

receptor tyrosine kinases, VEGFR-1 (Flt-1) and VEGFR-2 (KDR, Flk-1). VEGFR-2 is the major mediator of the angiogenic effects of VEGF. However, VEGFR-1 is expressed by some tumor cells and may mediate chemotactic signals, thus potentially having a role in cancer growth. The expression of VEGF is up-regulated by hypoxia and inflammation. The transcription factor hypoxia inducible factor-1 (HIF-1), which is part of a pathway that also includes regulation by the von Hippel-Lindau (VHL) tumor suppressor gene, is a major regulator of VEGF expression. Under conditions or normal oxygen tension, VHL protein targets HIF for degradation; under low oxygen conditions, HIF increases and VHL-mediated degradation is reduced, permitting upregulation of VEGF. Other signaling molecules that contribute to angiogenesis, include platelet-derived growth factor-ß (PDGF-ß) and its receptor (PDGFR), and the angiopoietins. PDGF-ß is required for recruitment of pericytes and maturation of new capillaries. Recent studies also document the importance of tumor-derived PDGF in recruitment of stroma that produces VEGF and other angiogenic factors (Fig. 61.2).

Angiogenesis appears to be important in hematopoietic tumors. Patients with chronic lymphocytic leukemia responded to treatment with anti-angiogenic compounds,[25] followed by similar success for some patients with multiple myeloma.[11] Furthermore, different histologic types of human non-Hodgkin lymphoma show different patterns of angiogenesis, and these can predict outcomes. One study has shown that microvessel density is similarly correlated with aggressive behavior of canine lymphoma,[32] and similar findings have been reported for other blood-derived and solid tumors of dogs such as mast cell cancer and mammary cancer.[31,33]

Invasion and Metastasis

The role of genetic events in invasion and metastasis is still incompletely understood. The classical model of metastasis proposed by Fidler[8] suggests a stepwise acquisition of assets that enables cells to leave the primary tumor site, travel through blood or lymph, invade stroma in favorable locations, and thus become re-established at distant sites. More recent work suggests that most tumors possess the ability to dislodge cells that travel to distant sites, and the ability of such cells to survive in capillary beds may be the most important step in the metastatic process.[12]

Bone marrow-derived cells have intrinsic properties that allow them to travel throughout the body, traffic through all major organs, and home to areas of inflammation. Thus, bone marrow-derived tumors are inherently metastatic. Nevertheless, hematopoietic tumors that are cytologically indistinguishable can have distinct and preferential tissue distribution. We do not fully understand what events make leukemic cells stay in the circulation, while cells from corresponding

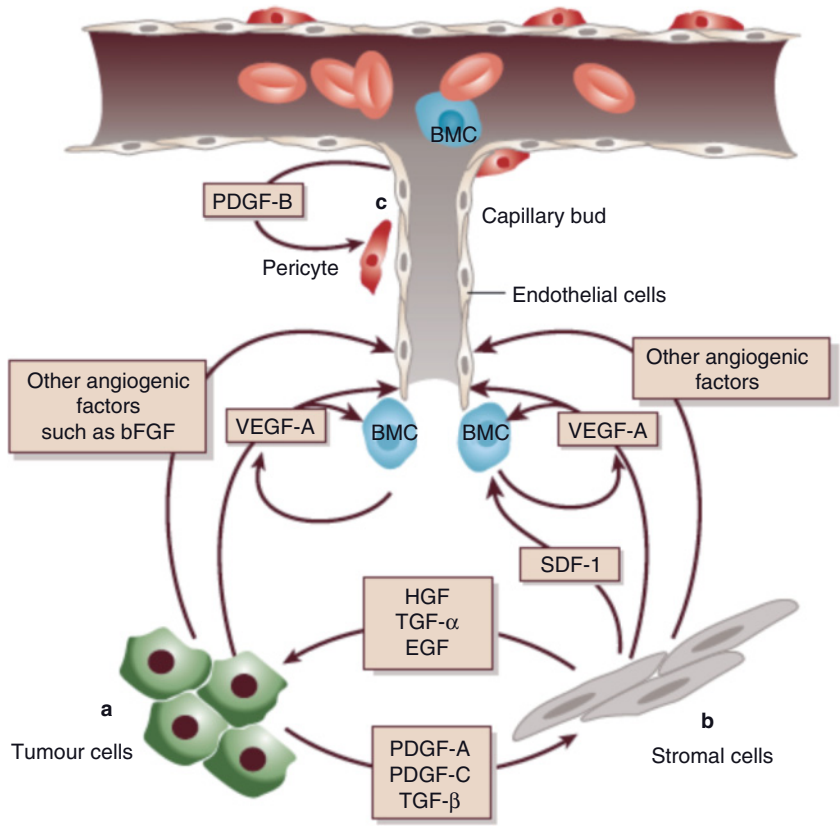

FIGURE 61.2 Molecular and cellular components of the tumor microvascular environment. (**a**) Tumor cells produce VEGF and other angiogenic factors such as basic fibroblast growth factor (bFGF), angiopoietins, and interleukin-8. These stimulate resident endothelial cells to proliferate and migrate. (**b**) An additional source of angiogenic factors is the stroma. This is a heterogeneous compartment, comprising fibroblastic, inflammatory and immune cells. Recent studies indicate that VEGF, as well as chemokines produced by tumor-associated fibroblasts, recruit bone-marrow-derived angiogenic cells (BMC). A well-established function of tumor-associated fibroblasts is the production of growth/survival factor for tumor cells such as epidermal growth factor (EGF), transforming growth factor-α (TGF-α), hepatocyte growth factor (HGF), and heregulin. (**c**) Endothelial cells produce PDGF-B, which promotes recruitment of pericytes in the microvasculature after activation of PDGFR. Tumor cell death will lead to dissolution of blood vessels and release of endothelial cells into the circulation. (Reproduced from Ferrara N, Kerbel RS. Angiogenesis as a therapeutic target. Nature 2005;438:967–974, with permission. ©Macmillan.)

lymphomas (or myeloid sarcomas) with virtually identical molecular signatures stay confined to lymphoid or visceral organs.

MOLECULAR EVENTS IN CARCINOGENESIS

Various models have been proposed to explain how cells acquire the features that lead to neoplastic transformation and eventually to clinical cancer. One model describes the process as stepwise accumulation of mutations that reduce constraints on growth and eventually promote transformation. Although this model is overly simplistic and technically flawed it is nevertheless useful to convey the events that lead to carcinogenesis.

Initiation, Promotion, Progression

Unlike diseases due to single gene defects, cancer is a complex, multigenic disease. The initiation, promotion, and progression model was among the first to propose a sequential progression of mutations that could account for cancer.[39] In this model, a genetic event would endow a somatic cell with limitless replicative potential or another growth or survival advantage from other cells in its environment (initiation). Alone, this would not be sufficient to give rise to a tumor, as the cell would remain constrained by environmental factors. A second event would further add to the cell's ability to out compete its neighbors in this environment, leading to its potential expansion into a recognizable tumor mass (promotion). Finally, a third event would reinforce the cell's malignant potential (invasion, tissue destruction and metastasis), leading to clinical disease (progression). It is important to note that an "event" is not equivalent to a single mutation, but rather is more likely to represent a series of mutations that act in concert to alter the cell's functional and morphological phenotype.

Genetic Instability

The stepwise model of clonal evolution is satisfying because it can be correlated with discrete pathological changes in tumor progression, especially for epithelial tumors where such progression can be seen in lesions that go through stages of hyperplasia, atypical hyperplasia (dysplasia), adenoma, carcinoma in situ, invasive carcinoma, and metastatic carcinoma. However, analysis of tumor genomes even in early stages usually shows aneuploidy (abnormal DNA copy number) as well as chaotic changes indicative of multiple numerical and structural DNA abnormalities. Similar abnormalities first noticed by Boveri more than 100 years ago in studies of sea urchin cells, which are described in a recently reprinted, annotated version of the original 1914 article translated into English,[3] led him to formulate the aneuploidy theory of cancer. We know now that aneuploidy is especially evident in solid tumors; based on this, Loeb proposed the existence of a "mutator phenotype" where cells are predisposed to undergo multiple mutations, some of which inevitably lead to cancer.[20] Some tenets of his hypothesis appear to be correct; however, direct measurements of mutation rates of sporadic tumors are much lower than those predicted if a "mutator phenotype" was operative in these tumors.

Still, genetic instability is a hallmark of most tumors, and while it can be partly explained by increased errors in DNA replication and chromosomal segregation in cells that are rapidly dividing, other mechanisms are clearly operative, involving telomeres and telomerase, as well as mechanisms of DNA replication and repair and chromosomal segregation. Although many of these changes are not recurrent and appear to be random products of instability, some may in fact contribute to proliferative crisis.[21] It is possible that the initiation events for many tumors occur early in life during highly proliferative stages of tissue growth and remodeling but they become evident late in life when a last series of mutations allows the transformed cell to reach this crisis stage. As we inferred above, hematopoietic tumors seem to avoid the chaotic chromosomal instability associated with solid tumors. We do not fully understand the reasons for this, although it may be partly due to intrinsic protective mechanisms associated with the proliferative rate of bone marrow precursor cells.

Epigenetic Events

Another observation is that events leading to cancer need not necessarily be caused by mutational events, but instead can be caused by epigenetic changes. Epigenetic events are those that can alter phenotype without changing the genotype. Two well-characterized epigenetic mechanisms regulate gene expression. Gene silencing can occur by methylation of CpG residues in promoter regions, as well as by histone deacetylation. Both of these events interfere with the transcriptional machinery and repress gene expression. Silencing specific genes by methylation is implicated in numerous cancers of humans and animals.[30] One important observation is that most (or all) genes that are subject to silencing by methylation in specific cancers (e.g. *CDKN2A* in T cell leukemia) are commonly inactivated by mutation or deletion in other cancers (e.g. *CDKN2A* in melanoma).

Genomic imprinting presents a unique example where heritable epigenetic changes influence cancer predisposition. Genomic imprinting refers to a pattern of gene expression that is determined by the parental origin of the gene; in other words, unlike most genes where both parental alleles are expressed, only one allele of an imprinted gene is expressed and the other one is permanently repressed. Epigenetic changes in Wilms' tumor and in heritable colon cancer (among others) alter the expression of the imprinted allele, leading to loss of imprinting that causes overexpression of the insulin growth factor-2 (*IGF2*) gene.[30]

CANCER STEM CELLS

Unlike diseases that arise from single gene defects, cancer is a complex, multigenic disease. In fact, a sequential progression of mutations is required to produce a tumor cell. We can think of many genes contributing to, rather than causing, the origin and progression of cancer. This model is consistent with many aspects of the natural behavior of tumors, and to some extent, it can predict risk and outcome.

A competing theory now exists whose main tenet is that self-renewal is limited to a small population of cancer stem cells.[2,4,10] The existence of cancer stem cells is documented; they are characterized both by peculiar phenotypes and by defined sets of mutations of a small number of genes.[10] Other mutations then endow their progeny with limited or extensive capacity to undergo programmed differentiation, hence resulting in distinct clinical phenotypes such as acute and chronic leukemias or high-grade and low-grade solid tumors. The strongest evidence for cancer stem cells comes from hematopoietic tumors, but cancer stem cells also have been identified in various solid tumors.[35] The origin of cancer stem cells is among the most important contemporary topics of cancer investigation. Cancer stem cells may arise from mutations that occur in bona fide stem cells, they may arise by de-differentiation of somatic cells that acquire mutations endowing them with stem cell-like properties, or they may develop by fusion of a transformed cell and a bone marrow-derived stem cell. In companion animals, putative cancer stem cells have been identified in hemangiosarcoma,[14] osteosarcoma,[40] brain tumors,[36] and possibly lymphoma.

ADAPTIVE EVOLUTION IN THE TUMOR MICROENVIRONMENT

The clonal evolution theory[27] addresses the significance of sequential genetic changes providing growth and survival advantages, but to this we must add the fact that, in addition to these self-sufficient events that influence growth and survival, tumor cells must also evade predators (e.g. inflammation and the immune system). Tumors have the capacity to modulate stromal cells to support their own growth by providing a suitable matrix and an abundance of nutrients, while maintaining antitumor responses at bay. Tumors that outgrow the capability of their immediate surroundings to support their growth will seek to become established in other favorable locations. Thus, adaptive evolution likely contributes to the anatomic distribution of hematopoietic tumors much as it does to the metastatic spread of solid tumors.

Acronyms and Abbreviations

ALSV, avian leukosis and sarcoma viruses; ALV, avian leukosis virus; ASV, avian sarcoma virus; ATL, adult T cell leukemia; BLV, bovine leukemia virus; CAEV, caprine arthritis encephalitis virus; CIS, common insertion or integration site; DNA, deoxyribonucleic acid; EIAV, equine infectious anemia virus; ENTV, enzootic nasal tumor virus; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; GALV, gibbon ape leukemia virus; HAM/TSP, HTLV-associated myelopathy/tropical spastic paraparesis; HIV, human immunodeficiency virus; HTLV, human T-lymphotropic virus; IL, interleukin; JSRV, Jaagsiekte sheep retrovirus; LRT, long terminal repeats; MMTV, mouse mammary tumor virus; MPMV, Mason-Pfizer monkey virus; MuLV, murine leukemia virus; RSV, Rous sarcoma virus; Sag, superantigen; SIV, simian immunodeficiency virus; STLV, simian T cell lymphotrophic virus; WDSV, Walleye dermal sarcoma virus.

Oncogenic retroviruses were first identified near the beginning of the 20th century when Rous and colleagues discovered that certain cancers could be transmitted between animals by the inoculation of cell-free extracts. Studies of these agents have resulted in many critical breakthroughs in the field of oncogenesis.

RETROVIRIDAE

Retroviruses are enveloped RNA viruses that replicate via a DNA intermediate that becomes integrated into the host genome. Seven genera of retroviruses are currently recognized.[5] Retroviruses exist both as exogenous (non-integrated) and endogenous forms (integrated

provirus). Endogenous retroviruses integrated into the host DNA comprise 5–8% of the human genome, and perhaps more than 10% of the genome in other mammals.

General Retroviral Structure

Retroviruses are single stranded, linear, positive sense RNA viruses with 7–13 kb genomes.[2,5] All retroviruses contain *gag*, *env*, *pol*, and *pro* genes while complex retroviruses also encode a variety of regulatory proteins. Viral RNA is characterized by the presence of R (repeated) and U (unique) regions at both ends of the genome that, once transcribed, result in identical copies being placed at each end of the newly produced DNA in a U3-R-U5 sequence to create long terminal repeats (LTRs). Long terminal repeats are used for integration into the host genome and serve as regulatory sequences for virus production.

Virions are approximately 100 nm in diameter. At the center is a highly condensed form of the genomic RNA in association with the nucleocapsid protein. The virion core also contains viral enzymes such as reverse transcriptase, integrase, and protease. The core is contained within a structural icosahedral capsid and then a matrix shell, both encoded by gag. The virion is enveloped by a lipid bilayer, encoded by env, that also produces distinctive glycoprotein cell surface spikes that are critical for virus binding and entry.

Retroviral Life Cycle

The retroviral life cycle is complex and includes variations between different retroviruses; however, the basic template is similar.[2] Virus binds via a specific cell-surface receptor. Retroviral receptors are diverse and include ion transporters, cell differentiation markers, chemokine receptors, the transferrin receptor, and Fas-like receptors. Internalization and uncoating occurs through fusion of the viral and plasma membrane or via endocytosis.

Reverse transcription of the RNA genome into double stranded DNA uniquely defines the retroviridae. Reverse transcription is a complex, multi-step process initiated by the creation of a negative sense DNA strand. Following degradation of the viral RNA by RNase H, the negative strand serves as a template to create a double stranded linear DNA. The double stranded linear DNA is then transported to the cell nucleus and integrated into the host DNA as a provirus.

Viral RNA and protein are expressed from the integrated provirus using the normal cellular processes of transcription and translation. Transcription by the RNA polymerase II system results in a complete unspliced viral genomic RNA that can serve as the genetic material to be packaged into progeny virions or as the template for production of viral proteins. The latter may require RNA splicing and processing of precursor proteins.

RNA packaging into developing virions is driven through Gag interactions. Gag also controls the assembly of the viral protein products whether it occurs at the plasma membrane or in the cytoplasm. Virions assembled in the cytoplasm are then transported to the membrane for envelopment and release. During the process of release, host membrane proteins are frequently incorporated into the virion envelope and several have been shown to be functionally significant.

CLASSIFICATION OF THE FAMILY RETROVIRIDAE

The current classification by the International Committee on Taxonomy of Viruses uses physical and morphologic properties of the virion, organization and replication of the genome, and biologic properties such as host range to classify viruses.[5] The family Retroviridae contains two subfamilies. The Orthoretroviruses contain six of the seven genera while Spumaretroviruses comprise only the spumaviruses.

Alpharetroviruses

Alpharetroviruses are simple retroviruses that encode only *gag*, *pro*, *pol*, and *env*. The *pro* and *gag* genes utilize the same reading frame. These C-type virions are assembled at the plasma membrane and do not appear to produce intermediate stage cytoplasmic particles. The virion has a centrally-located, condensed, spherical core and surface projections of intermediate prominence. Key examples of this genera include avian leukosis virus (ALV), Rous sarcoma virus (RSV), and avian sarcoma virus (ASV).

Betaretroviruses

Betaretroviruses are also simple retroviruses but have a B- or D-type virus morphology; they are assembled within the cytoplasm, transported to the plasma membrane, and become enveloped during budding. B-type virions are characterized by a condensed, eccentric core and have prominent surface envelope projections. The *gag*, *pro*, *pol*, and *env* genes are found in different reading frames. Viruses of significance include mouse mammary tumor virus (MMTV), Mason-Pfizer monkey virus (MPMV), Jaagsiekte sheep retrovirus (JSRV), and enzootic nasal tumor virus of sheep (ENTV).

Gammaretroviruses

Gammaretroviruses are also simple C-type retroviruses; however, the *pol*, *gag* and *pro*, sequences share a reading frame. Gammaretroviruses comprise the largest number of species and infect mammalian, avian, and reptilian hosts. This genus also contains a number of replication defective endogenous viruses. Key gammaretroviruses include feline leukemia virus (FeLV), the murine leukemia viruses (MuLV), and the avian reticuloendotheliosis virus group.

Deltaretroviruses

Deltaretroviruses are complex C-type retroviruses that contain *tax* and *rex* regulatory genes in addition to *gag*, *pro*, *pol*, and *env*. Protein expression requires frame shifts over several different reading frames. Bovine leukemia virus (BLV) and human T-lymphotropic virus (HTLV) are the best-known examples.

Epsilonretroviruses

Epsilonretroviruses are complex C-type retroviruses that contain one or more additional open reading frames. The prototype virus is Walleye dermal sarcoma virus (WDSV). Two other Walleye viruses are included in the genus and two additional fish viruses are proposed for inclusion.

Lentiviruses

Lentiviruses are complex retroviruses that are further categorized into five groups based on the host species they infect: primates, cats (domestic and non-domestic), horses, cattle, and sheep/goats. Virions have a distinctive conical morphology. Genomes contain a variable number of accessory genes that regulate viral replication. This genus includes several well-studied viruses including human immunodeficiency virus (HIV), simian immunodeficiency virus (SIV), feline immunodeficiency virus (FIV), equine infectious anemia virus (EIAV), caprine arthritis encephalitis virus (CAEV), and Maedi-Visna virus. Lentiviruses are characterized by the relatively long period between infection and disease development.

Spumaviruses (Foamy Viruses or Syncytial Viruses)

Spumaviruses are complex retroviruses with immature C-like virions that have a less condensed core and more prominent surface spikes. Virions are assembled in the cytoplasm and then bud through the endoplasmic reticulum as well as the plasma membrane. Newly formed virions uniquely contain large amounts of reverse transcribed DNA. While spumaviruses establish persistent infection in a number of species including humans, non-human primates, cattle, horses, and cats, they are not typically associated with clinical disease.

OVERVIEW OF RETROVIRUS-INDUCED DISEASE

Immunodeficiency

Modification of the immune system by viral proteins can enhance carcinogenesis through several mechanisms including disruption of tumor surveillance, atypical stimulation of the immune system, and alteration of the microenvironment (see Chapter 55). The association of lentivirus-induced immunodeficiency and cancer has been well established in several systems such as HIV infection and the development of Kaposi sarcomas and B cell lymphomas.

Leukomegenesis

One of the most common mechanisms of retroviral-induced leukemogenesis is through insertional activation, which is the activation of proto-oncogenes following proviral integration.

Direct Cytopathicity

Several viruses produce gene products that are directly cytopathic to the host. Examples include the neurologic damage induced by the Env SU subunit of some MuLVs, wasting syndrome induced by many of the avian viruses, and induction of cytopathicity by FeLVs with mutation in the Env SU subunit.

Host Determinants of Pathogenicity

Alterations in host genes can influence the progression of retroviral infection, particularly those that control the target cell availability through cell cycling, tumor suppression genes, and growth factors. Similarly, mutations within the genes responsible for the immune response can alter pathogenicity.

Stimulation of Host Cell Proliferation

While the primary means of inducing host cell proliferation is through insertional activation, some oncogenic retroviruses use other mechanisms. One of the best understood is the superantigen (Sag) protein of MMTV that binds and activates T cells through common (non-antigen specific) areas on MHCII molecules. Alternatively, the spleen focus-forming viruses and the Env helper protein of MuLV activate erythroid proliferations through binding of the erythropoietin receptor.

Oncogenic Transformation

Retroviruses can induce oncogenic transformation through a number of mechanisms covered in detail in the next section.

RETROVIRUS-INDUCED ONCOGENES

Oncogenes are genes whose products contribute to the formation of cancer. Oncogenes arise as mutated forms of normal cellular genes (i.e. proto-oncogenes) coding for key proteins involved in growth control, development, and differentiation.

Role in Cancer

Carcinogenesis is a multistage process. Oncogenes may have direct or indirect roles at several stages in this process. Direct transformation occurs when a viral gene product interacts with a cellular gene or gene product

resulting in loss of internal regulation of normal proliferation, cell cycle, or cell death and neoplastic transformation in that cell. Indirect transformation occurs when the virus alters cells other than the tumor cell resulting in loss of external regulation. The oncogene may transform only a specific cell type or it may have more global effects.

Non-Acute

Non-acute transforming retroviruses are replication competent viruses that induce neoplasia after a latent period. These viruses do not typically induce morphologic transformation in culture. Oncogenesis is often initiated as proto-oncogenes are activated after viral integration. There are two general mechanisms by which this occurs. In promoter insertion, viral transcription "reads through" to the proto-oncogene each time the virus is replicated resulting in over-expression of the host gene. The second mechanism is enhancer activation in which the proto-oncogene promoter is activated by a viral enhancer.

Acute

Acute transforming retroviruses derive from non-acute retroviruses but have acquired an altered host proto-oncogene. Because they carry oncogenes, these viruses induce rapid transformation and tumor growth. Most acute transforming retroviruses are replication-defective and require replication-competent viruses for propagation. These host-derived oncogenes include growth factors, tyrosine and serine/threonine kinases, transcription proteins, and G-protein signaling proteins.

Mechanisms of Action

The primary mechanisms of oncogenic transformation are through transduction, cis-activation, and trans-activation. Less commonly, viral proteins such as Env may directly stimulate cell proliferation, interfere with cell cycle checkpoints, or inhibit surveillance for tumor cells.

Transduction

During replication, retroviruses can acquire host sequences through recombination errors. These viruses are usually defective and require helper viruses for replication. The transforming power of recombinant viruses depends on the cellular gene they have acquired, but many viruses with rapid transformative ability utilize this mechanism.[11] In general, transduction is uncommon in natural infections but is a useful research tool for studying oncogenesis in the laboratory.

Cis-Activation

Cis-activation occurs when a provirus inserts near a proto-oncogene. Activation of the proto-oncogene occurs by promoters or enhancer elements in the viral LTR. Cis-activation is commonly used by simple retroviruses.

Trans-Activation

Trans-activation occurs as a virally encoded protein such as Tax interacts with host transcriptional factors, thereby altering expression of normal cellular genes.

PROTOTYPICAL AND WELL-CHARACTERIZED ONCORETROVIRUSES

Avian Leukosis and Sarcoma Viruses

The avian leukosis and sarcoma viruses (ALSVs) cause tumors in a variety of avian species. ALVs are simple retroviruses that are transmitted both horizontally and vertically. However, while a large percentage of the flock may be infected, neoplasia develops in only a small percentage. Vaccination strategies have not been successful, making eradication of ALV from the breeding stock a critical control step. In the early 1980s, eradication of the five primary envelope subgroups had been reasonably successful. However in the mid 1980s, a highly pathogenic myeloid tumor-inducing subgroup J virus emerged to become one of the major infectious diseases facing the poultry industry.

Exogenous ALVs are transmitted as infectious virions while endogenous ALVs are incorporated into the host genome and transmitted genetically. The number of endogenous viruses varies among avian species and the biological significance of endogenous viruses is not entirely clear. Some forms appear to protect the host from infection by newly acquired ALV infection through receptor interference. However, endogenous viruses may also have a negative effect on the host.

ALVs are well-described oncogenic viruses. Both non-acute and acute transforming forms are recognized. Non-acute transforming viruses induce tumors that appear late in the period of infection. Typically, oncogenesis is induced through the insertion of the ALV genome near a proto-oncogene resulting in cis-activation. Lymphoid leukosis is one of the best-described examples. In lymphoid leukosis, the B cell c-*myc* gene is activated resulting in a multistage lymphomagenesis that produces neoplastic lymphoblasts resistant to apoptosis. Because multiple follicles can be affected nearly simultaneously, the disease can appear to be polyclonal.

In contrast, acute transforming ALVs contain one or more viral oncogenes. These ALVs tend to be replication incompetent due to mutations (usually deletions) within the structural genes and require co-infection with a non-defective helper virus. Several ALV strains carry the *myc* oncogene that tends to induce myelomonocytic neoplasia. Avian sarcoma viruses also tend to be acutely transforming. The best characterized is Rous sarcoma virus which encodes a protein kinase through *src* viral oncogene.

In addition to their known neoplastic induction, certain ALVs serve as a model of viral associated obesity. For example, the Rous-associated virus type 7 ALV induces a syndrome of hypertriglyceridemia and hypercholesterolemia.

Bovine Leukemia Virus

Bovine leukemia virus (BLV) is a type C deltaretrovirus that infects cattle and sheep. Bovine leukemia virus replication is primarily dependent on cell proliferation and mitotic division. Virus infection stimulates a polyclonal expansion of B cells, called persistent lymphocytosis, in approximately one-third of infected animals. In cattle, only a small percentage of infected animals develop bovine enzootic leukosis, a polyclonal, but neoplastic, B cell expansion. A higher rate of neoplasia is seen in experimentally infected sheep. Transmission is primarily horizontal through the transfer of infected cells by direct contact and possibly through blood-sucking insects. Vertical transmission is less common but may occur in utero, at parturition, or through milk ingestion.

Bovine leukemia virus is related to the primate lymphotrophic viruses but has over 40% phylogenetic divergence. While the primate viruses infect T cells, BLV primarily infects B cells, particularly those expressing surface IgM, but also can infect monocytes and macrophages. Bovine leukemia virus encodes both Rex and Tax proteins, Tax being the primary oncogenic protein. Transmission by cell-free virus is inefficient and cell-to-cell transmission by cell fusion predominates. After infection of a new cell, BLV integrates randomly into the host genome. Virus replication is primarily through the production of daughter cells via mitotic division.

Feline Leukemia Virus

Feline leukemia virus (FeLV) is a simple retrovirus that infects domestic cats as well as non-domestic felids. FeLV has high sequence homology with MuLV, supporting the hypothesis that infection of cats resulted from MuLV cross-species transmission. Three genotypes of FeLV have been described: types A, B, and C. Type A FeLV is the dominant virus in nature. This exogenously transmitted retrovirus is ubiquitous, readily transmitted, and highly conserved. Types B and C result from mutation and recombination of type A FeLV with endogenous retroviral sequences. The variability in viral recombination corresponds with variability in the pathogenesis and disease outcomes including aplastic anemia, T cell lymphoma/leukemia, myeloid leukemia, and immunosuppression.

Feline leukemia virus is transmitted horizontally, primarily through saliva, biting, and other close contact. Vertical transmission occurs both in utero and by ingestion of infected milk. Susceptibility is inversely correlated with age; thus the highest potential for transmission and infection occurs during the first 4–6 months of age. Approximately 30% of infected cats develop persistent viremia and secondary diseases including immunodeficiency, hematopoietic and other neoplasia, and opportunistic infections. The majority (60–65%) of all infected cats rapidly or eventually clear the virus after infection due to a robust immune response, minimal virus exposure, or a combination of the two, and remain antigen negative by enzyme-linked immunosorbent assay (ELISA). A small percentage of cats develop a transient antigen-positive viremia but then become persistently aviremic and antigen negative. Finally, 5–10% of all infected cats may develop an "atypical" infection due to localized or sequestered infection and have mixed or inconsistent test results. These cats may maintain a lifelong latent infection, but may progress to outright viremia or viral clearance. Latent FeLV may be reactivated through secondary diseases or treatments that result in impairment of the immune system.

Gibbon Ape Leukemia Virus

Gibbon ape leukemia virus (GALV) is genetically related to simian sarcoma associated virus, murine leukemia virus, and feline leukemia virus. Gibbon ape leukemia virus is a highly oncogenic C-type retrovirus that induces myeloproliferative disorders, particularly in juvenile animals. To date, four strains of GALV have been identified from captive gibbons. Because the virus has not been identified in wild animals, it is uncertain if GALV is of simian origin or represents an endogenous retrovirus transferred betweens species. Because GALV infects a wide variety of cell types from different species, several GALV-based retroviral vectors have been developed for gene transfer.

Human T Cell Lymphotrophic Viruses

Type 1 and type 2 human T cell lymphotrophic virus (HTLV) are closely related viruses that share significant nucleotide similarly but also have important differences. Recently, additional members of the HTLV family, HTLV-3 and HTLV-4 have been identified.[6] The HTLVs are complex retroviruses with several regulatory and accessory genes. The HTLVs are genetically stable viruses whose replication is limited by the immune response. HTLV replication primarily occurs through clonal replication of infected cells. HTLV-1 is endemic in South-East Asia including Japan, the Caribbean, Melanesia, as well as parts of South America, central Africa, and the Middle East. HTLV-1 infection can result in adult T cell leukemia (ATL) and HTLV-associated myelopathy/tropical spastic paraparesis (HAM/TSP); however, only a small percentage of infected individuals develop clinical disease.

Jaagsiekte Sheep Retrovirus and Enzootic Nasal Tumor Virus

Jaagsiekte sheep retrovirus (JSRV) is the causative agent of pulmonary adenomatosis in sheep. Pulmonary adenomatosis serves as a transmissible model of human

bronchioalveolar carcinoma. It is a simple retrovirus but includes an additional gene, *orf-x*. The mechanism of JSRV induced oncogenesis is not well defined but both *orf-x* and *env* have been proposed to play a role. The virus spreads horizontally through infection of type II pneumocytes and Clara cells in the lower respiratory tract. The time to tumorogenesis ranges from months to years, but disease progresses rapidly once clinical signs develop.

Enzootic nasal tumor virus (ENTV) has >95% genetic similarity with JSRV. While JSRV induces tumors in the lower respiratory tract, ENTV causes tumors in the nasal cavity.

Mouse Mammary Tumor Virus

Mouse mammary tumor virus (MMTV) induces mammary adenocarcinomas and, less commonly, T cell lymphoma. MMTV is transmitted genetically through the germ line and via infected breast milk. MMTV has been classified as a simple betaretrovirus but encodes Rem, a self-regulatory mRNA export protein related to the Rev protein of HIV.[3,7] MMTV also encodes *sag*, a superantigen that uniquely stimulates viral replication. B cells in the gut are the initial target for viral infection. B cell expression of the superantigen activates bystander CD4+ T cells that, in turn, induce clonal expansion of Sag expressing B cells responsible for trafficking to the mammary gland and infecting mammary epithelial cells.

Mouse mammary tumor virus tumorigenesis occurs primarily through viral insertion near a proto-oncogene and subsequent activation. Endogenous viruses are frequently truncated or defective; however, those mice with a functional *sag* gene have some degree of protection against infection with exogenous MMTV because the T cells that would normally react against the superantigen have been deleted during thymic maturation.

Recently, several sequences have been detected within the human genome and human cancers that have very high sequence homology with MMTV. Although somewhat controversial, this has led to speculation that these elements may play a role in human breast cancer and lymphoma as well as other diseases such as primary biliary cirrhosis.[1,4,8,9,10,12] While additional work is necessary to establish a causative link between MMTV-like sequences and these diseases, current studies are shifting our understanding of the role of endogenous retroviruses and retroelements.

Murine Leukemia Viruses

There are several strains of well-characterized murine leukemia viruses (MuLVs) including Friend, Moloney, and Rauscher viruses. MuLVs induce a wide spectrum of malignancies including T cell lymphoma/leukemia, myeloid leukemia, and erythroleukemia. These viruses can also affect the nervous system. The tumorigenic effects are driven by the LTR U3 region while neuropathicity is mediated by the Env SU. These simple retroviruses are further classified by host range and replication capacity. Ecotropic viruses replicate only in their natural host. Amphotropic or polytropic viruses replicate in both rodent and non-rodent species. Xenotropic viruses infect only non-murine cells. Wild rodents frequently harbor non-ecotropic viruses. Because these non-ecotropic viruses efficiently infect human cells, they make efficient gene delivery vectors.

Reticuloendotheliosis Virus

Reticuloendotheliosis virus (REV) is a simple gammaretrovirus that infects a number of avian species. Serologic studies suggest that the virus is prevalent in both chickens and turkeys, and appears to be transmitted vertically and horizontally. The name reticuloendotheliosis virus arises from the acute reticulum cell neoplasia seen in chickens experimentally inoculated with a unique replication defective laboratory strain containing the *rel* oncogene. However, most clinical isolates lack oncogenes and are replication competent. Reticuloendotheliosis virus induces three distinct clinical syndromes including a non-neoplastic runting syndrome associated with bursal and thymic atrophy, a variety of acute neoplastic diseases involving multiple organs, and chronic B and T cell lymphomas.

Simian T cell Lymphotrophic Virus

The simian T cell lymphotrophic viruses (STLVs) are complex deltaretroviruses closely related to HTLV. The genetic relatedness between STLV-1 and HTLV-1 supports the hypothesis that HTLV-1 originated from cross-species STLV transmission. STLV-1 infects over 20 species of Old World primate species while STLV-2 has a much more limited species range. Clinical disease is uncommon in STLV infected primates and, when seen, tends to occur following chronic infection.

Walleye Dermal Sarcoma Virus

Walleye dermal sarcoma virus (WDSV) is the best-characterized piscine retrovirus and is endemic in walleye throughout North America. It is a complex retrovirus with at least three accessory genes. Walleye dermal sarcoma virus replication and the induced dermal sarcomas have a unique cyclical pattern. Walleye dermal sarcoma virus-induced dermal sarcomas are benign tumors that develop in the fall when virus production is low. In the spring, virus replication increases and these tumors concurrently regress. These findings suggest that virus replication is dependent on host endocrine or immunologic changes associated with spawning and/or changes in water temperature.

CHAPTER 63

Bone Marrow-Derived Sarcomas

LESLIE C. SHARKEY and JAIME F. MODIANO

Tumors arising from Mesenchymal Progenitor Cells
Hemangiosarcomas

Acronyms and Abbreviations

AS, angiosarcoma; HSA, hemangiosarcoma; HSC, hematopoietic stem cell; LSC, leukemia stem cell; MSC, mesenchymal stem cell; OSA, osteosarcoma; OSX, osterix; PPAR-γ, peroxisome proliferator-activated receptor-gamma; VEGF, vascular endothelial growth factor; VEGFR, VEGF receptor.

Traditionally, tumors have been divided into two distinct categories according to their ontogeny. One category considers all solid tumors, which are those that do not originate from hematopoietic progenitors, and the other includes "liquid" tumors, so called because they arise from hematopoietic progenitors and have a tendency to exist in the circulation. Despite the colloquial misnomer (hematopoietic tumors can form solid masses in lymphatic organs, viscera, skin, etc.), this separation is the basis not only for diagnostic algorithms, but even for clinical specialization among medical oncologists and pathologists. While this simplified scheme has clinical relevance in many situations, it may overlook some complexities in the biological relationships between hematopoietic and mesenchymal tissues that are relevant to our understanding of tumor biology.

The shared origin of mesenchymal tissues and blood cells from the embryonic mesoderm has been appreciated for over a century. However, it is only recently that multipotent mesenchymal stem cells (MSCs) have been isolated from bone marrow.[26] Most investigators believe that MSCs are distinct from hematopoietic stem cells (HSCs), although this distinction is blurred by the acceptance, at least by some, of specialized progenitor cells that retain the potential to give rise to both mesenchymal cells and hematopoietic elements. For example, two groups showed independently that stem cells, which give rise to chronic myelogenous leukemia and which harbor the prototypical BCR-Abl (Philadelphia chromosome) translocation, can give rise to apparently normal vascular endothelial cells in vivo and under specialized culture conditions.[10,13] These findings suggest that a common multipotent hemangioblast precedes the formation of lineage committed hematopoietic progenitors and endothelial progenitors. Other experimental evidence is consistent with pre-adipocyte trans-differentiation into a macrophage-like cell,[5,18] further demonstrating the potential for plasticity of hematopoietic and mesenchymal precursors.

The plasticity of MSCs in the laboratory, as well as unique properties of mesenchymal tumors arising from bone marrow, has forced us to consider additional complexity within the bone marrow progenitor pool. Experimental evidence in vivo also supports the existence of multipotent MSCs from bone marrow. They are capable of differentiating along multiple lineages, including chondrocytes, osteoblasts, adipocytes, fibroblasts, and endothelial cells, depending on chemical signals, physical interactions with the environment, and potentially in response to mechanical factors such as hydrostatic pressure and fluid-induced shear.[14] Several key transcription factors appear to regulate osteoblastogenesis and adipogenesis in a reciprocal manner. Osteoblastogenesis is enhanced by Runx2 and osterix (OSX) and adipogenesis is stimulated by peroxisome proliferator-activated receptor-γ (PPAR-γ). PPAR-γ may contribute to age-related bone loss[26] or to anemia associated with chronic disease.[27] Moreover, there is evidence to support the existence of bone marrow angioblasts or hematoendothelial progenitors that can differentiate into both endothelial cells and hematopoietic elements.

The structure of the bone marrow and the relationship between the stromal and hematopoietic elements are described in Chapter 2.[22–24,36] Here, we will focus on

the possible significance of shared progenitor cells on non-hematopoietic bone marrow sarcomas.

TUMORS ARISING FROM MESENCHYMAL PROGENITOR CELLS

Various sarcomas may arise primarily from the medullary cavity of bone, potentially due to transformation of a mesenchymal progenitor cell. Osteosarcoma (OSA) is the most common of these tumors in most domestic species, especially the dog. Heterogeneous histologic subtypes (e.g. poorly differentiated, chondroblastic, fibroblastic, telangiectatic, and giant cell type) can present a diagnostic challenge to pathologists and may reflect the diverse paths for differentiation open to a transformed mesenchymal stem cell. It is not clear if the predominant histologic pattern reflects the underlying genetic abnormalities of the transformed cell, or is secondary to environmental influences on the differentiation of neoplastic tissue. Medullary fibrosarcoma, chondrosarcoma, and hemangiosarcoma (see below) are each less common, but are reported with some frequency in dogs, and may in some cases be difficult to differentiate from the more common but phenotypically variable OSA. Although not technically a primary tumor of marrow in veterinary species, myelolipoma is a benign tumor comprising a mix of mature adipose and hematopoietic tissue with occasional bone formation that can be identified in the liver, spleen, and adrenal glands of veterinary species.[37] The origin of these tumors is obscure; however, myelolipomas reinforce the interdependence of connective tissue and hematopoiesis.[8,19]

Hemangiosarcomas

Among the mesenchymal tumors arising from bone marrow, hemangiosarcoma (HSA) may be a special case. Hemangiosarcoma is a unique soft tissue sarcoma that is relatively common in dogs, occurs occasionally in other species, and appears to be ontogenetically related to human angiosarcoma (AS) and Kaposi sarcoma (KS), as all three are presumed to arise from hemangioblastic or endothelial progenitors and share signaling abnormalities.[7,11,15,34] The highly metastatic behavior and modest response to chemotherapy distinguish these tumors from other soft tissue sarcomas that are locally invasive and generally unresponsive to chemotherapy.

The histologic diagnosis of HSA is usually uncomplicated. It is a tumor of spindyloid cells that form dilated, tortuous, and leaky capillary spaces or sinusoids that generally contain blood. The abnormal vessel morphology disrupts laminar flow, often leading to clots that can devitalize the growing tumor. This in turn leads to necrosis and eventual rupture and hemorrhage, which are hallmarks of this insidious, progressive disease. It is not unusual for the tumor to be practically lost within large fibrinous blood clots at the time of diagnosis or at post-mortem analysis.

When the diagnosis of HSA is in doubt, it can be readily established by evaluating expression of endothelial cell markers, including CD31, factor VIII-related antigen (FVIII-ra; also called von Willebrand's antigen), and vascular endothelial growth factor receptor-2 (VEGFR-2, also called fetal liver kinase-1 or Flk-1 and kinase domain insert receptor or KDR).[1,3,11,16,25,35] Recently, our group showed that HSA cells also express the c-Kit receptor (CD117).[11] c-Kit is a common marker of early progenitor cells, expressed broadly across various lineages. Surprisingly, we also found that HSA cells express CD34,[20] an adhesion molecule that is normally present in hematopoietic progenitors as well as in some endothelial progenitors. The unanticipated finding, which raised questions about the ontogeny of HSA, was the consistent expression of CD45 by HSA cells, since this protein is a reliable marker of hematopoietic commitment.[20] Even more perplexing was the presence of various markers associated with myeloid differentiation, such as CD14. This led us to propose that HSA originates from a bone marrow progenitor with hematopoietic potential.

Concurrent work by Yoder et al. documented the existence of an endothelial precursor cell that is an intimate participant in vasculogenesis and angiogenesis, but which originates from a myeloid progenitor.[38] These cells are "vasculomimetic", expressing all or most of the proteins normally associated with endothelial ontogeny (e.g. CD31, FVIII-ra, and VEGFR2). In addition, these cells express markers associated with myeloid or hematopoietic lineages, including CD45, CD14, and the colony-stimulating factor-1 (CSF-1) receptor (CSF-1R or CD115), and had strong phagocytic activity against bacteria. Functionally, these cells could migrate along gradients of vascular demand, invade artificial matrices, and create structures that resemble vascular channels, but they did not line blood vessels and could not support microcirculation in a transplanted matrix. Yoder et al. also identified a distinct endothelial precursor cell that did not express the hematopoietic markers CD14, CD45, or CSF-1R, and which was capable of lining endothelial capillaries and supporting microcirculation in Matrigel implants.[4,17,38] This led them to propose that angiogenesis requires at least three cell types. In their model, two of the cells are those described above, which have distinct origins from hematopoietic (myeloid) and hemangioblastic (endothelial) progenitors, and which respectively form and line the vascular channels. The third cell type, which probably originates from a white fat MSC, differentiates into pericytes and other supporting structures.

It is thus possible that multiple lineages contribute to blood vessel formation, including one originating from a restricted angioblastic progenitor that gives rise to the endothelial lining cells and one originating from a myeloid progenitor that is responsible for creating (but not lining) vascular channels. In this scenario, plasticity of adult hematopoietic and mesenchymal stem cells would be limited, differentiation of myeloid progenitors into endothelial-like cells would have to reflect functional rather than ontogenetic plasticity, and we

should consider the possibility that HSA represents a subtype of myeloid sarcoma. We have data to support this possibility. Specifically, HSA may be unrelated to other vascular tumors such as hemangioblastoma and hemangioendothelioma that are characterized by mutations of the von Hippel-Lindau (VHL) gene.[12] Instead, HSA cells down-regulate expression of PLZF, a gene involved in myeloid cell differentiation,[29,32] and they show enrichment of gene sets involved in differentiation of promyelocytic leukemia cells, dendritic cells, and mast cells.[6,30,32,33,39] This is significant in light of the poor response to treatments and it may signal the need to revise the therapeutic approach to this disease as a tumor of hematopoietic origin.

However, the data do not exclude the possibility that HSA might arise from a common hematoendothelial progenitor cell and not from a lineage committed myeloid cell. Genes that regulate cellular metabolism, cell cycle and cell signaling, cell-cell interactions, survival and apoptosis, angiogenesis, transcription, and the immune response are among those dysregulated in HSA cells when compared to non-malignant proliferating endothelial cells.[32] Up-regulation of proinflammatory genes in HSA could result from selective pressures to create a favorable microenvironment for growth and survival. For example, among genes overexpressed in HSA, fibronectin-1 is involved in wound healing, blood coagulation, and cancer metastasis, and it also increases matrix metalloproteinase activity, which is involved in tumor cell invasion through the extracellular matrix.[2,9] This is an interesting correlation, since survival of HSA is exceptionally poor due to its exceedingly high metastatic potential. The possibility that fibronectin-1 promotes the metastatic phenotype has been the subject of intense study in other tumors,[21] but remains to be examined in HSA.

On the other hand, angiogenic and inflammatory signatures might reflect the shared hematoendothelial ontogeny of HSA rather than selection in the tumor microenvironment. Inflammatory infiltrates are commonly seen in this disease, but rather than reflecting recruitment of tumor-associated macrophages and myeloid cells due to inflammation, the presence of leukocytes may actually be derived from the same population of cancer stem cells that give rise to HSA. Recent data suggest that classical cell markers for endothelial and myeloid origin cells are less tissue specific than historically thought,[28] supporting the existence of the putative angioblast. Our data support the existence of rare progenitor cells in HSA that behave like cancer stem cells (see Chapter 3). There also is evidence for cancer stem cells that are capable of differentiating along different developmental paths to give rise to endothelial cells in chronic myelogenous leukemia and Burkitt lymphoma,[10,13,31] although the possibility of vascular mimicry rather than true vascular differentiation cannot be excluded.

A similar dilemma applies to another poorly understood variant of intramedullary HSA, which frequently is associated with osteoid matrix. This tumor may be an ossifying HSA or a telangiectatic osseous sarcoma, but the possibility that it is composed of vasculomimetic OSA cells cannot be excluded. The shared ontogeny of HSA and OSA allows us to consider an alternative, which is that these tumors arise from a multipotent MSC that can differentiate along the vascular endothelial and the osteogenic lineages depending on microenvironmental cues.

The eventual resolution of these contemporary questions will help to resolve important controversies in cancer biology, may improve our diagnostic accuracy, and may inform the development of effective strategies to treat these intractable cancers in pets and people.

CHAPTER 64

Classification of Leukemia and Lymphoma

V.E. TED VALLI and WILLIAM VERNAU

Early Systems of Lymphoma Classification
The Kiel Classification, The Lukes and Collins Classification, The World Health Organization Classification
The International Working Formulation for Clinical Usage
The European-American Classification of Lymphoid Neoplasms
World Health Organization Classification of Hematologic Malignancies

Acronyms and Abbreviations

FISH, fluorescent in situ hybridization; REAL, revised European-American lymphoma classification system; WHO, World Health Organization.

Hematopathology has the dubious distinction of being one of the most chaotic areas of disease classification. In retrospect, the major reason for this is that cell characteristics, on which classical classification systems depend, differ only very slightly and these changes are only detectible by experienced investigators. Thus, early classification systems, based mainly on morphologic characteristics, continued to evolve because it became apparent that cells with similar morphology had different behaviors. The advantage of current classification systems, that are based on disease characteristics, is that the total entity (i.e. cell type and origin, topography of areas affected, and phenotype and genotype) are all included in the definition of the disease.[11,12,16,17,20,27,34] Many factors have driven development of disease classifications, including recognition that closely related diseases may have widely variable survival rates and that disease subtypes with differing biology could be tied to definable differences in histology and responses to treatment. The evolution in classification of lymphomas has occurred through heated discussion and survived national and geographic preferences. It is immediately apparent that research progress is greatly hampered by competing systems of classification because it cannot be firmly established that people conducting clinical trials are actually dealing with the same disease entity.

An encyclopedic treatment of the history of lymphoma classification is described by Ferry and Harris.[8] Virchow named leukemia in 1845 and lymphosarcoma as a distinct form of lymphoid tumor in 1863. Because of some of the similarities between benign hyperplasia and clonal lymphoid disease, Bilroth suggested the term malignant lymphoma in 1871. These terms have persisted to the present with interesting connotations. Renewed interest in lymphoid neoplasms began in the latter part of the 20th century when it was shown that some types of Hodgkin's lymphoma could be cured with irradiation. In veterinary medicine, many have chosen to continue to use the term lymphosarcoma as an all-encompassing term to describe lymphoid neoplasms. While not incorrect, this approach has the disadvantage of separating understanding of animal lymphoid tumors from the advances made in human hematopathology. The current understanding is that some lymphomas, of both B and T cell types, while clonal, are indolent and slowly progressive with the animals occasionally dying of other causes. In that context, these diseases are more conveniently recognized and identified as "indolent lymphomas," thereby appropriately differentiating them for diagnosticians and therapists, from the aggressive lymphomas that should be identified as lymphosarcoma.

EARLY SYSTEMS OF LYMPHOMA CLASSIFICATION

One of the first classifications of lymphoma was that of the American Registry of Pathology: "Classification of

Lymphatic and Reticular Tumors" in 1934.[4] This classification system included these divisions; lymphocytic (indicating small cell), lymphosarcoma (indicating medium-sized cell), and reticulum cell (including all large cells). The lymphocytic group was subdivided into acute and chronic leukemic forms as well as solid tumors of diffuse and nodular types that were aleukemic. The lymphosarcomas or medium-sized tumors were divided into those that were aleukemic solid tumors and leukemic forms. The reticulum cell sarcomas included leukemic reticulocytoma but also included the monocytic leukemias and aleukemic forms of the same cell types. Reticulum cell sarcoma was a term retained for only the large cell lymphomas.

The major classification systems following that of the American Registry of Pathology included that of Robb-Smith (1938)[31] in England, whose system was very complex and was based on the concept that there was a benign and malignant counterpart for each cell type recognized within the concept of the reticuloendothelial system. In 1942, Gall and Mallory at the Massachusetts General Hospital reviewed their 1,618 cases of lymphoid neoplasms and provided a new system of classification that included the following list of tumors: reticulum cell sarcoma, stem cell lymphoma, clasmatocytic lymphoma, lymphoblastic lymphoma, lymphocytic lymphoma, follicular lymphoma, Hodgkin's lymphoma, and Hodgkin's sarcoma.[10] Following Gall and Mallory, Jackson and Parker (1939 and 1944) published their classification that subdivided Hodgkin's disease into paragranuloma, granuloma, and sarcoma that rapidly became the standard in the United States and remained so until the mid 1960s.[13–15] The next major change was the introduction of the Rappaport classification system (1956[30] and 1966[29]) that brought a new parameter to classification based on pattern or architecture. Therefore, this system separated follicular neoplasms from those with diffuse architecture. Rappaport concluded that regardless of cell type all lymphoid neoplasms including Hodgkin's disease have a better prognosis if accompanied by a nodular or follicular architectural pattern. A disadvantage of the Rappaport system was that the specific entity of aggressive small cell lymphoblastic lymphoma was lost and combined with diffuse poorly differentiated lymphocytic lymphoma. Another disadvantage of the Rappaport system was that Hodgkin's lymphoma lost recognition of the subtype with lymphocyte depletion and predominance of Reed Sternberg cells known as Hodgkin's sarcoma. Although now considered a regressive step in terms of understanding of lymphomas, the Rappaport system became the standard in the United States because it required pattern recognition that separated the indolent follicular lymphomas from the clinically more aggressive diffuse lymphomas. A large study at Stanford University in 1974 confirmed that the Rappaport system actually had "clinical significance", causing the system to become the standard in North America.[7,18]

In the 1960s, it was shown that Hodgkin's disease could be cured with radiation therapy.[32] Lukes and Butler in 1966,[24] using material from the Armed Forces Institute of Pathology, described a new classification of Hodgkin's disease in which the older system of Jackson and Parker was modified by dividing the granuloma category into two subtypes of *nodular sclerosis* and *mixed cellularity*. A clinical conference on Hodgkin's lymphoma held in Rye, New York, reviewed previous systems and adopted a modified version of the Jackson and Parker system. This modified version of the Jackson and Parker system rapidly became a world standard, subsequently known as the Rye classification of Hodgkin's disease.[26]

THE KIEL CLASSIFICATION, THE LUKES AND COLLINS CLASSIFICATION, THE WORLD HEALTH ORGANIZATION CLASSIFICATION

Karl Lennert of Kiel, Germany, much like Robb-Smith of England, looked for malignant counterparts of benign cells. Lennert realized that many lymphomas consisted of cells that resemble those present in benign germinal centers and could be shown to produce immunoglobulin consistent with germinal center B cells.[22,23,33] The strategy employed in the Kiel classification was based on a proposed scheme of leukocyte differentiation. Most of the entities defined were of B cell type but several T cell lymphomas were also described. In this scheme the lymphomas were grouped according to cytologic features; low-grade lymphomas consisting of those with more dominance of small cells were named ending in "cytes" and high grade tumors with a predominance of large cells were named with terms ending in "blasts". This classification was updated further in 1992[22] and the system became widely used in Europe but was never accepted in the United States.

The Lukes and Collins classification, published in 1974,[25] was based on the same observations of cell type as the Kiel classification and included what immunologic data were known at the time. A major drawback with this system was it first required lymphomas to be divided into T and B cell lineages but phenotyping was not generally available at that time. Further, there were no data to indicate whether the distinction of phenotype was an important prognostic factor. The Lukes and Collins classification did not recognize histologic pattern as having any influence and contended that cell type alone could predict clinical outcome. Another major problem with this classification was that a single category based on tumors arising from malignant follicles contained a vast majority of all lymphomas. The Lukes and Collins system never achieved wide use.

After the description of the Kiel, and the Lukes and Collins classifications, three others were proposed including a working classification by Dorfman[6] and a proposal by Bennett and co-workers[1] that became the British National Lymphoma investigation classification. The third was the World Health Organization (WHO) classification that reflected immunology being applied to the Rappaport classification, with large cell lymphomas recognized to be of lymphoid rather than histiocytic origin. The Dorfman and WHO classifications

failed to achieve widespread use, but the Bennett classification was widely used in the United Kingdom.

THE INTERNATIONAL WORKING FORMULATION FOR CLINICAL USAGE

In the mid 1970s, several international meetings were held to resolve the situation without any consensus resulting. The American National Cancer Institute undertook a large-scale blinded review project based on patients who had been enrolled in clinical trials at cancer treatment centers around the world. Their strategy was to review a large number of cases, for which the outcome was known, using each of the six current lymphoma classifications. The goal was to determine which of these classifications most accurately predicted the outcome and thus clinical behavior of each lymphoma subtype. The major finding of the study was that none of the classification systems were superior in predicting survival and that the intra- and inter-observer reproducibility was poor for all of the proposed classification systems. This study resulted in a "working formulation for clinical usage" to "translate" and identify specific cell types between the different classifications.[5] Essential characteristics of the Working Formulation[27] were that it used the Rappaport categories but inserted terminology, primarily from the Lukes and Collins classification, that was accepted to be biologically more correct (i.e. small lymphocytic, rather than well-differentiated lymphocytic; small cleaved cell rather than poorly differentiated lymphocytic; large cell lymphoma rather than histiocytic). A number of inconsistencies remained, including the category of diffuse mixed small and large cell that included follicular center lymphomas that had progressed to the point of becoming diffuse. Large cell lymphomas were divided into immunoblastic types consisting of cells with a single central nucleolus, that were felt to be high grade tumors, and centroblastic types that consisted of cells with peripheralized nucleoli and that were felt to be of intermediate grade, without phenotype being known for either. Novel features of the Working Formulation classification were the division of lymphomas into low-, intermediate-, and high-grade types and with each subtype having a letter designation alphabetically, a-j, meant to simplify terminology. An important inconsistency arising from the proposal was that the clinical grades of the Working Formulation were based on survival, while the histologic grades of the Kiel classification were based on morphologic features of the tumors such as the cell size, nuclear chromatin features, and mitotic rate.

Oncologists tended to treat the entities within the low-, intermediate- and high-grade areas with the same protocols, assuming they were all of similar biology based on survival. One problem with the application of the Working Formulation was that pathologists could not reliably distinguish between immunoblastic cell types, considered to be high-grade, and other large-cleaved or non-cleaved cell types, with what is now called centroblastic nuclear morphology. Despite these drawbacks, the Working Formulation became widely used in North America. The result was that well over half of all lymphomas could be diagnosed and adequately treated according to the Working Formulation criteria. The lack of specificity grew out of mixing criteria in oncology trials.

By the 1980s and 1990s many new disease entities had been described that were not included in either the Kiel classification system or the Working Formulation. A continuing dislocation was the fact that the Kiel classification was primarily used in European countries while the Working Formulation was primarily used in North America. As a result, many hematopathologists began to design new classifications.[23]

THE EUROPEAN-AMERICAN CLASSIFICATION OF LYMPHOID NEOPLASMS

An informal group of 19 hematopathologists from Europe, the United States and Asia had been meeting since the beginning of the 1990s and reached consensus on a new approach to lymphoma classification. It was decided that all available information from each case would be used to define lymphomas. The data included cell morphology, immunophenotype, genetic and clinical features, tumor topography, and clinical behavior of the tumor.[5] Different criteria were given variable importance in defining each of the lymphoma subtypes. The cellular morphology was always important, and in some cases was the defining feature. Pattern or architecture was singularly important in defining follicular lymphomas. Vascular proliferation was noted to be a key feature in what was called angioimmunoblastic T cell lymphoma and the connective tissue component was of major importance in the nodular sclerosis type of Hodgkin's lymphoma. Some diseases were largely defined by immunophenotype and pattern, such as (B cell) mantle cell lymphoma and marginal zone lymphoma (see Chapter 69). In anaplastic large cell lymphoma, the abundant cytoplasm, remarkable anisokaryosis, and peculiar horse shoe-shaped nuclei were recognized to be of primary diagnostic importance. In some lymphomas, and particularly in primary leukemias, the genetic changes (e.g. chromosomal translocations) were recognized as important. Finally, in some instances, topography was of particular importance.

The emphasis on defining diseases based on utilization of all available information represented a new paradigm in recognizing lymphoma subtypes. A further aspect of this approach, of particular importance to animals, is that poorly described diseases can be given a conditional classification that becomes more specific as new knowledge is developed. Furthermore, as new entities become fully defined, they take a natural position within the classification as it currently exists, negating the need to develop a new classification system. Similarly, two closely similar entities can be shown to be specific diseases with criteria defined for distinguishing between them.

WORLD HEALTH ORGANIZATION CLASSIFICATION OF HEMATOLOGIC MALIGNANCIES

The WHO convened more than 50 pathologists with worldwide representation, as well as a large clinical advisory committee. This group largely adopted the revised European-American lymphoma classification system (REAL). They agreed that the new revised WHO Classification would replace all current systems of classification and thus brought about the first international consensus on classification of hematologic neoplasms.

Veterinarians were at first apprehensive about the application of the revised WHO system because it was suspected that a level of genetic and cytogenetic information not currently available in animal pathology would be required for application of the system. This has been a continuing factor in the diagnosis of hematologic malignancies in animals, where the large number of chromosomes in many animal species hampers cytogenetic analysis. The advent of molecular genetics has added greatly to the ability to diagnose chromosomal injuries in human medicine and has permitted animal biologists to identify chromosomal injuries in animal cells by methods such as fluorescent in situ hybridization (FISH).[2,28] An advantage of the latter system is that it can be carried out on interphase cells and makes possible analysis of cells in archived paraffin blocks. The current situation is that veterinary pathologists have found that the WHO system can be applied to the great majority of animal hematologic malignancies on the basis of cell type and phenotype alone. Clonality assessment is a major current adjunct (see Chapter 143) for those cases of lymphoproliferative disease where hyperplasia or neoplasia must to be differentiated.[3,37]

A number of publications have demonstrated the use of the WHO system in animals, and remarkable similarities are being found in lymphomas of humans and animals.[2,35,36] The more recently recognized subtypes of lymphoma in humans, including mantle cell and marginal zone lymphoma of B cell type and panniculitis-like T cell lymphoma, have now been described in domestic animals.[9,19,35,36] Animal lymphomas are now being studied to identify molecular changes in genes that will point to their identification in humans.[2,9] The genome of the pure bred dog is far more homogeneous than the outbred genome of humans. That reality makes the specific changes leading to tumors such as diffuse large B cell lymphoma more easily identified in dogs.

Acronyms and Abbreviations

ALL, acute lymphocytic (lymphoblastic) leukemia; AML, acute myelogenous (myeloid) leukemia; CBC, complete blood count; CGH, comparative genomic hybridization; CHOP, cyclophosphamide, vincristine, doxorubicin, and prednisone; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; COP, cyclophosphamide-vincristine-prednisone; CSF, colony-stimulating factor; CSFR, colony-stimulating factor receptor; FAB, French-American-British; FeLV, feline leukemia virus; FISH, fluorescent in situ hybridization; FIV, feline immunodeficiency virus; GI, gastrointestinal; GL, granular lymphocyte; HSA, hemangiosarcoma; HSC, hematopoietic stem cell; KS, Kaposi sarcoma; LSC, leukemia stem cell; MSC, mesenchymal stem cells; OSA, osteosarcoma; PCR, polymerase chain reaction; PCV, packed cell volume; REAL, revised European American classification of lymphoid neoplasms; RECIST, response evaluation criteria in solid tumors; WBC, white blood cell; WHO, World Health Organization.

LYMPHOMA

Much has been written about lymphoma in companion animals and the details of clinical presentation, diagnostics, and therapeutics are well described.[63,64] For most affected dogs and cats, the disease is treatable but not curable. Despite initial responsiveness of most high grade lymphomas, resistance to chemotherapy, associated with progressive disease, is inevitable and is generally the reason why most dogs and cats succumb to this illness. Survival times and clinical disease-free intervals have not changed appreciably over the past 20 years despite many studies investigating new approaches to treatment. Nonetheless, chemotherapy remains the mainstay of treatment and a limited assortment of chemotherapeutic agents is widely used in practice to arrest tumor cell proliferation. Regardless of drugs used, the endpoints are almost always the same.

More recently, advances have dealt with defining prognosis for animals with malignant lymphoma. The most significant contribution in this regard is introduction and validation of the World Health Organization (WHO) classification system to veterinary oncology (see Chapter 64). This system subdivides lymphoma based on a variety of distinct histological patterns and cellular morphologies that also appear to correlate with prognosis and response to chemotherapy. Recognition of canine lymphoma as a heterogeneous malignancy has greatly advance the clinical approach to lymphoma patients. General use of this classification system has been slow and reluctance of owners of animals with lymphoma to authorize lymph node biopsy when a diagnosis can be rendered by the less invasive and more economical fine needle aspirate has been an impediment to universal usage of this classification system. The WHO classification system may be predictive of

response to chemotherapy as well as contributing reliable information about the expected clinical course without treatment. Including the WHO classification as part of the database for evaluating new cases of lymphoma may be helpful in advising clients and selecting chemotherapeutic strategies.

Immunophenotyping lymphomas has likewise assisted with prognosis. Although it has taken nearly 20 years for this to become widely used in assessing lymphoma patients in small animal oncology,[19] immunophenotyping is now widely regarded as part of the minimum database in evaluating newly diagnosed lymphoma in dogs and cats. For example, multiple studies have confirmed that approximately two-thirds of cases of multicentric lymphoma are B cell-type, with the remainder being T cell-type. Furthermore, as a general rule, dogs with B cell multicentric lymphoma have longer survival times than dogs with T cell lymphoma.[36] The notable exception is a form of small T cell lymphoma (T zone lymphoma) that has a better prognosis, with affected dogs surviving well past one year. Immunophenotyping feline lymphoma is less predictive of clinical outcome although there is considerable variability between immunophenotypes among the various forms of feline lymphoma.

Considered singly or in combination, cellular features (high grade versus low grade), histological classification, and immunophenotype may not always predict outcome. For example, it is possible to initiate multi-agent chemotherapy such as CHOP (i.e. cyclophosphamide, vincristine, doxorubicin, prednisone) for two dogs with identical anatomical distribution of disease (stage), identical histological classification (e.g. high grade diffuse lymphoblastic lymphoma), immunophenotype (e.g. B cell), clinical performance status (i.e. substage "a", not sick), and normal hematological and biochemical parameters, and one animal will go rapidly into complete remission and lives for 16 months while another only partially responds for 4 weeks, develops chemoresistant lymphoma, progressive disease, and survives less than 6 months. Understanding the basis for these different outcomes is one of the major challenges to improving lymphoma therapeutics. Perhaps differences in expression of oncoproteins between dogs, such as c-myc seen in some canine high-grade B cell tumors (e.g. diffuse large B cell lymphoma and Burkitt-type lymphoma) may account for these divergent clinical behaviors.[16] In the case of some high-grade canine T cell lymphomas, loss of function of tumor suppressor proteins, such as the p16 cyclin-dependent kinase inhibitor that serves to regulate cellular progression through the cell cycle via the retinoblastoma (Rb) gene product, may account for different clinical outcomes between dogs that seemingly present with identical clinical, histopathological, and immunophenotypical features.[16]

Improving prognostic criteria for lymphoma would be of great benefit to clinicians and pet owners alike. This could assist owners in addressing difficult choices associated with treatment and end-of-life decisions. It could also move us closer to tailoring treatments to individual patients, which may result in improved clinical outcomes, reduced client cost, and reduced treatment-associated toxicity. Discovery is key to clarifying subcellular pathologies that could account for differences in clinical outcome.

Clinical Presentation

In both dogs and cats, several distinct anatomic forms of lymphoma predominate (see Chapters 69 and 72). In the dog, the multicentric form is most commonly seen while the gastrointestinal (GI) tract is most commonly affected in the cat. Multicentric lymphoma in cats is rare. Canine multicentric lymphoma typically involves all peripheral lymph nodes and internal lymphoid tissues including tracheobronchial, sublumbar, and mesenteric lymph nodes; tonsils, spleen, and liver are also frequently involved (Fig. 65.1). The widespread use of abdominal ultrasonography has helped to demonstrate abdominal nodal involvement in many affected dogs that might have otherwise gone undetected. Thus, there is often overlap in the various anatomic presentations.

Dogs appear to have a primary gastrointestinal (GI) lymphoma in which malignant lymphocytes preferentially home to the gastric and intestinal walls and frequently infiltrate other abdominal organs including the liver, spleen, and mesenteric lymph nodes. Curiously,

FIGURE 65.1 Pitting edema of the face of a dog with multicentric lymphoma. Lymphatic obstruction caused by massively enlarged submandibular lymph nodes and a cranial mediastinal mass resulted in edema fluid accumulation throughout the dog's head.

peripheral lymph nodes seem not to be affected. This is a particularly aggressive form of lymphoma associated with a recently reported median survival time of 77 days, despite treatment with intensive chemotherapy.[48] Presumably the poor survival time is associated with inherent resistance to chemotherapy of T cell lymphoma that predominated (63%) in this study.[48]

Feline alimentary lymphoma occurs as both a large cell and small cell subtype. There is considerable variability in the literature regarding immunophenotype and cell morphology. Immunophenotypical and histopathological classification of GI lymphoma in a series of 50 cats indicated that approximately half were high-grade B cell tumors and 38% were T cell lymphomas; most were small cell. Gastric lymphomas were exclusively B cell.[46] The heterogeneity of feline GI lymphoma as well as variable proliferation rates[10] may account for the variability in clinical response to chemotherapeutics. More aggressive forms present with large mesenteric masses, often due to confluence of malignant mesenteric lymph nodes. Bleeding within the GI tract contributes to anemia, and bone marrow RBC regeneration may be quite slow. In the authors experience, anemia (e.g. PCV < 25%) is a negative prognostic indicator for cats newly diagnosed with GI lymphoma. Anemia in dogs (i.e. PCV < 37%) with newly diagnosed multicentric lymphoma is also a negative prognostic sign.[1,38]

Cats have been recognized with a form of lymphoma that preferentially involves the nasal passage or nasopharyngeal tissues.[22,31] Clinical presentation is typical of nasal cancer, mainly sneezing, nasal discharge (serous, mucoid, or blood tinged), and occasionally, facial deformity. Imaging of the skull (e.g. computed tomography) can reveal bone destruction within the head and penetration of the cribriform plate by the tumor (Fig. 65.2). Clinical staging usually fails to reveal lymphoma in other sites. The majority of these cats are affected by a high-grade immunoblastic B cell lymphoma. This form of lymphoma lends itself to treatment with radiation therapy, although multi-agent chemotherapy (alone or in combination with radiation) is also effective (median survival time = 536 days).[22] Once again, anemia was determined to be a negative independent prognostic variable.

There are many other presentations of lymphoma in dogs and cats. Some are organ specific (e.g. kidney, skin, liver, central nervous system) while others involve multiple organs. With the exception of canine epitheliotropic lymphoma known to be a distinct CD3+, CD8+ T-cell disease,[40] little is known about these site-specific lymphomas.

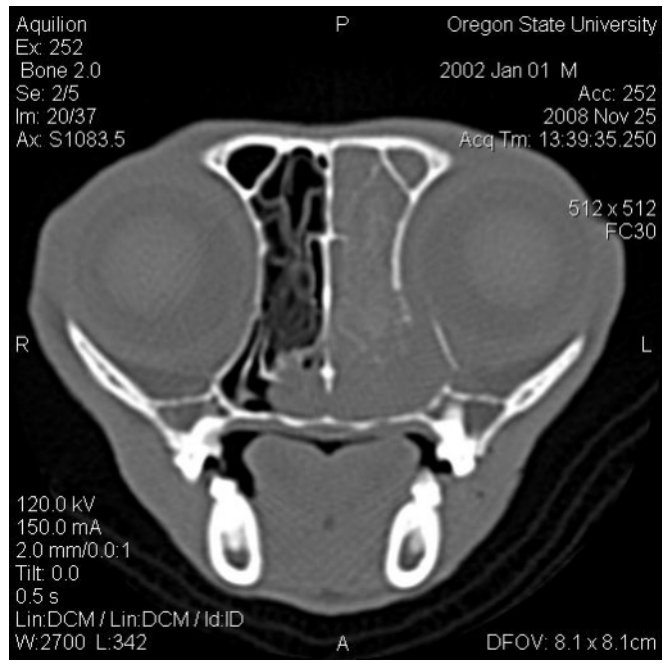

FIGURE 65.2 Computed tomography scan of a cat with intranasal lymphoma. Note the opacity filling the entire left nasal passage with extension to the right side ventrally. The medial bony orbit of the left eye has been penetrated by the tumor. This was a lymphoblastic B cell lymphoma.

Chemotherapy

With the exception of uniquely localized disease (e.g. nasal lymphoma), chemotherapy is the treatment of choice for most veterinary patients. As a general rule, malignant lymphoma is the most chemo-responsive cancer encountered in veterinary oncology with complete and partial remission rates of canine multicentric lymphoma reported to be in the range 75–85%. Regardless of the specific protocol used to treat newly diagnosed lymphoma in dogs and cats, some common themes are apparent. High-grade lymphomas require more intensive treatment than low-grade forms and multi-agent chemotherapy provides longer and more durable remissions than does treatment with single agents. Specific protocols vary by acronyms, but usually not by agents comprising them. Most treatment protocols (e.g. CHOP, VELCAP, L-COPA) employ combinations of vincristine, cyclophosphamide, doxorubicin, and prednisone as induction agents. L-asparaginase has also been used both in canine and feline protocols but it does not appear to confer a survival advantage in treatment of canine multicentric lymphoma.[35] The first author prefers to reserve this drug for dogs that relapse or animals facing imminent organ failure when initially presented. More recent information would suggest that cats should receive prednisolone instead of prednisone because it has greater bioavailability in this species compared to prednisone.[33] Despite their long-standing inclusion in the treatment of lymphoma, the use of glucocorticoids arguably are the least understood drugs for treating this disease. Long thought to induce apoptosis of lymphoid cells by interaction with the glucocorticoid receptor, additional mechanisms may be important.[52,56] Developing a better understanding of the mechanism of action and resistance may help to clarify optimum dosing schemes with prednisone/prednisolone in lymphoma chemotherapy protocols.

Despite the myriad of published protocols, the median survival time of high-grade canine lymphoma

has remained approximately 1 year. Approximately 20% of dogs will survive 2 years. Similar results were recently reported for cats treated with a cyclic multi-agent protocol,[55] although another report by Hadden et al. suggests that intensive chemotherapy (VELCAP) may not be that helpful.[20] The addition of doxorubicin has contributed to improved outcomes in multi-agent protocols. Taken together, these results suggest that the maximum benefit from chemotherapy has probably been attained and future improvements in the survival time of dogs and cats with high-grade lymphoma will need to come from other therapeutic modalities. Developing effective ways to overcome chemo-resistance may someday prove fruitful as well.[8]

Unlike high-grade lymphomas, dogs and cats with low-grade lymphomas do not appear to benefit by more aggressive doxorubicin-containing protocols. Presumably this is attributed to the lower mitotic index and slower growth of the malignant cells. In both species, therapy is conservative and consists of intermittent treatment with chlorambucil and predniso(lo)ne.[28] Clinicians routinely rely on cell morphology determined from samples obtained by fine needle aspiration. The cytological description of small cell morphology is typically inferred to indicate low-grade malignancy (which is not always the case). In the cat, small intestinal lymphoma often presents with small cell morphology and immunophenotyping confirms T cell lineage of the small cells.[10,46,65] Typically, these cats are treated with chlorambucil and prednisolone and some survive for more than 2 years. However, the cats are not rendered free of disease and may have intermittent bouts of diarrhea. Necropsy reveals persistence of tumor cells in the submucosa, and villi are often blunted and fused accounting for chronically thin animals that do not gain weight. Nonetheless, quality of life can be excellent and owners are usually satisfied with this level of control. A case report indicated excellent response of a cat with hepatosplenic erythrophagocytic small T cell lymphoma treated with chlorambucil and prednisolone.[9] Dogs with multicentric T zone lymphoma, considered a low grade neoplasm, treated with chlorambucil and prednisone, enjoy excellent quality of life, often for several years. Lymphadenopathy is persistent, although the first author has seen partial reduction in lymph node size with this conservative therapy after several months of treatment. Conversely, the authors have not seen clinical responses (i.e. reduction of node size) in dogs with this condition when treated with the more intensive CHOP protocol. Taken together, anecdotal evidence of a role for chlorambucil and predniso(lo)ne for treatment of chronic low-grade lymphoma in dogs and cats is supported by recent clinical reports.

Assessing Remission

Assessing therapeutic response to lymphoma therapy is not as straightforward as it would seem. Size of peripheral lymph nodes can be an easy gauge of response to treatment in dogs. However, there are no standards as to what is a big lymph node. Furthermore, considering the large size variation in the canine population, it is easy to appreciate that a "big" lymph node in a 10 kg dog may be "normal" sized in a 35 kg dog. Palpation of lymph nodes is an extremely subjective means by which to evaluate response to therapy. Nevertheless, marked changes are readily appreciated while subtle ones are less clear. Caliper measurements can provide rough approximations of size, but here too, there is variability between clinicians measuring the same dog's lymph nodes at the same time, let alone at different times. In addition, some nodes are surrounded by more fat than others further impacting the accuracy of measurements. The prescapular (i.e. caudal superficial cervical) lymph nodes are deep to the subcutis and several thin muscle layers overlay them routinely, sometimes giving them the feel of being enlarged. Caliper measurements in one dimension can be a challenge while obtaining measurements in two dimensions is harder yet. Standardizing methods for measuring lymph nodes, such as using some of the guidelines in the Response Evaluation Criteria in Solid Tumors (RECIST) criteria,[15] might help to establish a uniform approach to the seemingly straightforward task of measuring lymph nodes.

Recognizing caveats associated with determining lymph node size is important in how we evaluate response to treatment. Periodic fine needle aspiration of peripheral lymph nodes for cytological evaluation is a reasonable and complementary procedure to accompany measurements. Aspirates from suspicious nodes while animals are undergoing induction chemotherapy are helpful in assessing response on a cellular level and can provide information that may indicate a need to alter treatment or indicate cytological remission. However, it must be recognized that lymph node aspinates from lymphoma dogs undergoing chemotherapy rarely look entirely normal, even when in clinical remission.

Molecular assessment of remission is perhaps the most rigorous means of detecting minimal residual disease and is orders of magnitude more sensitive than node size and light microscopy. Using a real-time polymerase chain reaction strategy. One study detected 1 lymphoma cell per 10,000 cells with primers specific for canine antigen receptor gene rearrangement of T cells and rearrangement of immunoglobulin heavy chain in B cells (see Chapter 143).[73] They used this approach to detect and quantify circulating lymphoma cells in the blood of dogs undergoing chemotherapy for multicentric lymphoma. While decreasing lymph node size in response to chemotherapy paralleled decreases in the number of circulating lymphoma cells, circulating lymphoma cells were detectable in all seven dogs in the study at a time when the dogs were considered to be in clinical remission by conventional means.

Assessing remission in tissues that are not readily accessible for repeated sampling such as the intestinal tract, presents other unique challenges. Intestinal lymphoma is often a diffuse disease that involves large segments of the GI tract. Repetitive abdominal ultrasonographic examinations are helpful in evaluating

mural thickness and layering of the intestines, but repeated surgical or endoscopic intestinal biopsies are rarely done. Ultrasound guided fine needle aspiration of mesenteric lymph nodes is helpful, but rigorous ante mortem methods, other than biopsy, that unequivocally clarify remission status of GI lymphoma are not available. Instead, clinicians usually rely on surrogate readouts of response such as resolution of GI signs, appetite, weight gain, and improved hematocrit to aid in assessing remission. Serum cobalamin concentrations of cats with GI lymphoma are often low[28] at diagnosis, presumably due to malabsorption; repeated measurements could also be helpful to assess improvement in gut function in response to therapy.

Lymphoma Relapse

For most dogs and cats with lymphoma, relapse is inevitable. Animals enjoying complete clinical remission still harbor malignant cells. Why chemotherapy that is so effective in reducing tumor burden is ineffective in curing the majority of lymphoma patients awaits clarification. Innate resistance, predicted by the Goldie-Coldman hypothesis, acquired resistance associated with upregulation of cellular transporters such as p-glycoprotein,[3] and uniquely resistant cancer stem cells may in part help to explain the failure of chemotherapy to be curative for most animals in veterinary oncology. Most animals have excellent quality of life at the time of relapse so it is difficult for owners and clinicians to just give up when relapse is detected.

More is known about responses in relapsed dogs than cats. Regardless of drugs used to treat relapsed canine lymphoma patients, we know that responses are not as robust or durable compared to those obtained when treating newly diagnosed patients. While there are a number of choices available for second induction chemotherapy (also known as rescue or salvage chemotherapy), most approaches fail to control relapsed lymphoma for longer than 2–4 months. Typically, when an animal fails one rescue protocol, another is offered, often based on clinician's bias. In the end, it probably does not make a difference which drugs are used to treat relapsed lymphoma patients, which raises the question, Does rescue chemotherapy really rescue?

In the first author's experience, animals deemed to be in complete remission (i.e. >3 months following completion of CHOP induction) will likely respond to the protocol again, albeit for shorter duration. Keep in mind that doxorubicin use is limited in the rescue setting due to its cumulative cardiotoxic effects. Sometimes at the first author's institution, an abbreviated course of CHOP (e.g. eight treatments) is administered in the rescue setting. L-asparaginase is very effective for short-term gains, especially as a "quick fix" to cytoreduce relapsed lymphoma when owners may need time to consider their options or when a dog is being adversely affected by the relapse (e.g. airway obstruction by lymphomatous tonsils, etc.). Lomustine has become widely used in the relapse setting based on the report by Moore et al. over 10 years ago.[41] Given orally as a capsule, it is simple and appealing to owners. However, duration of response is less than 3 months and it can have a profoundly suppressive effect on bone marrow. The dosage used in the initial report was high (90 mg/m^2), a dosage that many have found to be toxic (typical starting dosage is 60 mg/m^2) and the benefit of lomustine is relatively short-lived in dogs. In an effort to enhance lomustine's efficacy, Saba et al. combined lomustine with L-asparaginase concurrently hoping to obtain additive (or synergistic) benefits from the combination.[51] The median time to disease progression was 63 days indicating the combination did not confer an advantage over lomustine alone. Based on this result it is probably reasonable to separate administration of these two drugs with L-asparaginase given first considering its typically rapid response, followed by lomustine 1–2 weeks later. A plethora of drugs or drug combinations have been used to treat relapsed lymphoma, including mechlorethamine, procarbazine, actinomycin-D, cisplatin, carbaplatin dacarbazine, etoposide, and bleomycin to name a few. None have distinguished themselves as the antidote for relapsed lymphoma. New approaches are needed for relapsed lymphoma.

Hematopoietic stem cell transfer (also known as bone marrow transplant) has been on the fringes of veterinary oncology for many years. Despite the use of research dogs for the development of this procedure in human oncology, the expense, support, and need for expertise in tissue typing have impeded implementation of this procedure in veterinary oncology. Nonetheless, the recent case report by Lupu et al. of a successful and seemingly curative allogeneic hematopoietic stem cell transplant in a golden retriever with relapsed T cell lymphoma has renewed enthusiasm amongst oncologists.[34] As of this writing, an autologous bone marrow transplant program for dogs with lymphoma has been established at North Carolina State University.

A promising approach for human B cell lymphoma employs a monoclonal antibody (rituximab) that binds to CD20 on the surface of human B cells. Once bound, the antibody can mediate antibody-dependent cellular cytotoxicity or it can be armed with an isotope or toxin for targeted delivery. Impressive results with these approaches have been published. While normal and malignant canine B cells express CD20,[27] disappointingly, rituximab failed to bind or deplete canine B cells.[25,27] Developing CD20 as a therapeutic target in canine B cell lymphoma will require identification or generation of unique antibodies that recognize the extracellular domain of this homolog in the dog.

Prognostic Factors

Lymphoma is a heterogeneous disease and treatment outcomes can differ widely between animals that present with similar clinical features. Thus, identifying factors that predict outcome is important in setting expectations for pet owners as well as clinicians. More

is known about prognostic features in canine lymphoma than for feline lymphoma. In dogs, the list of prognostic variables has slowly increased. Immunophenotype remains one of the strongest prognostic variables. Degree of cellular differentiation is also prognostic. Dogs with ≥50% bone marrow infiltration by lymphoma cells (stage V) are predicted to do poorly even with chemotherapy. Clinical illness at initial presentation (i.e. substage "b") is likewise a negative predictive feature, as is anemia.[38] High expression of the anti-apoptotic protein, survivin, predicts early relapse in dogs with stage IIIa or IVa B cell lymphoma.[49] In contrast to dogs, immunophenotype has not been predictive of outcome in cats, but anemia in cats with nasal lymphoma is a negative prognostic factor. Recognizing features and biomarkers that directly correlate with clinical outcome enhances our understanding of lymphoma and provides a framework to explain different outcomes between affected animals.

LEUKEMIA

Leukemias are a group of neoplastic diseases, described in dogs, cats, horses, cattle, humans, and a variety of other species, characterized by the clonal proliferation of malignant hematopoietic progenitor cells in the bone marrow. Leukemias are broadly categorized as being of either lymphoid or myeloid origin. Myeloid neoplasms are further classified by cellular lineage into four major categories including granulocytic (neutrophils, eosinophils, and basophils), monocytic, erythroid, and megakaryocytic. Occasionally, myeloid leukemias may be of mixed-cell lineage. Both lymphoid and myeloid leukemias are further divided into acute and chronic types based on clinical presentation and proliferative rate of the neoplastic clone.

Leukemogenesis

Leukemias are thought to represent an aberrant hematopoietic process initiated by rare leukemia stem cells (LSCs) that have maintained or reacquired the capacity for indefinite proliferation through accumulated mutations and/or epigenetic changes. In normal hematopoiesis (Section I), stepwise differentiation of hematopoietic stem cells (HSCs) generates a hierarchy of progenitor populations, each with a progressively restricted developmental potential, ultimately producing all lineages of mature blood cells. In contrast to HSCs, which can self-renew for life, multipotent myeloid and lymphoid progenitors do not have self-renewal capacity. Similarly, leukemic stem cells may have limitless self-renewal capacity and give rise to clonogenic leukemic progenitors. These cells may not have self-renewal capacity but are incapable of normal hematopoietic differentiation.[43] Experimentally, leukemias may be initiated by transforming events that take place in the HSC population, or from more committed progenitors owing to mutations, epigenetic changes, and/or selective gene expression which enhances their otherwise limited self-renewal capabilities. In fact, deregulation of self-renewal pathways appears to be a common mechanism used by acute myeloid leukemia (AML)-associated fusion genes to transform both HSC and progenitor cell populations.[43,44]

The understanding of the molecular basis of leukemia is the most advanced for chronic myelogenous leukemia (CML). Based on the molecular pathogenesis of CML in humans, it has been suggested that leukemias in general result from mutations in genes that encode key molecules that dysregulate the normal strict cytokine/receptor dependent control of the decision of hematopoietic cells to undergo proliferative expansion.[57] For a leukemia to develop, a selective growth advantage must occur in a single mutated cell (typically a rare HSC, or, if self-renewal capabilities are restored, a more committed progenitor), thereby allowing its progeny to undergo proliferative expansion, which ultimately leads to accumulation and dissemination of leukemia cells.[43,44] In the case of human CML, the BCR-ABL mutation provides that selective growth advantage by perturbing the cytokine/receptor/JAK/STAT/cyclin D pathway, proliferative expansion, and subsequent accumulation of multiple additional mutations and blast transformation.[57]

Classification of Leukemias

The pathological classification used to describe lymphoid and myeloid leukemias in animals is the current WHO[67] classification system that is modified from the human French-American-British (FAB)[2] and REAL systems[23] (see Chapter 64). The FAB system has been applied previously to animal hematopathology.[26] An important feature of the REAL/WHO classification system is that it attempts to define specific disease entities (i.e. not just different histopathological diagnoses based on morphology alone). Nonetheless, in some cases, proposed pathologically defined disease entities lack good clinical descriptions as uniquely defined clinical entities. However, this classification system also recognizes that essentially the same disease may present clinically in different forms. For example, in this system, it is recognized that the distinction between leukemia and lymphoma in some cases may be imperfect and merely represents a continuum of clinical presentation of the same disease.[4] In this case, the diagnostic distinction is based on determining the tissue with the greatest volume of tumor:[66] if most of the neoplasm is in the bone marrow it is termed leukemia, and if most is in peripheral tissues it is termed lymphoma.

Diagnosis of Leukemias

The initial clinical presentation of an animal with leukemia varies; however, as the names suggest, animals with acute leukemias usually present initially with acute systemic signs, whereas those with chronic leukemias often present with chronic, less severe clinical signs. Initial evaluation of an animal with leukemia

starts with a physical examination and complete blood count (CBC). Once a presumptive diagnosis of leukemia is established, based upon the physical examination and CBC findings, a minimum database including a serum biochemical profile, urinalysis, and bone marrow aspirate and/or core biopsy should be obtained. Diagnostic imaging of the patient provides additional information regarding involvement of other organs.

Morphology

Until relatively recently, a diagnosis of leukemia was based primarily on cytological examination of blood smears, and cytological and histological morphology of bone marrow aspirates and core biopsies, respectively, from affected animals. The subsequent development of enzyme cytochemistry, immunophenotyping techniques, clonality assays, gene expression profiling, and assessment of chromosomal aberrations, have illustrated that, although useful, and even necessary, as a first level of evaluation, morphology alone is insufficient for correctly classifying many leukemias.[68] Information gained through these additional techniques has been incorporated into the REAL/WHO classification system.

The initial diagnosis of leukemia is usually made based on morphological assessment of a peripheral blood smear and bone marrow aspirate and/or core biopsy (see Chapter 132). Neoplastic cells are frequently identified in the blood smear, although aleukemic leukemias occur rarely. Identification of malignant hematopoietic cells in the blood and bone marrow can usually be made based on morphology alone, however further classification of the leukemia is often misleading or impossible based on morphology alone.

Immunophenotyping

Flow cytometry (see Chapter 137), used in conjunction with a panel of cell surface markers, can be used to identify and characterize malignant cell populations in blood and bone marrow.[17,68,70] The immunophenotype of leukemic cells provides information regarding the presumptive cell lineage, a critical component to correct classification (see Chapters 4 and 144). The antibodies available for immunophenotyping hematopoietic cells in dogs, cats, and other domestic animals are more limited than in humans and mice. Table 65.1 is an example of a diagnostic panel of antibodies that can be used to immunophenotype canine leukemias. Unfortunately, there remains a paucity of validated myeloid lineage markers, so subclassification of myeloid leukemias is difficult.

TABLE 65.1 Monoclonal Antibodies used for Immunophenotyping Canine Leukemias and Lymphomas by Flow Cytometry and Immunocytochemistry

Antigen	Clone
IgG1 (controls)	W3/25
CD1a	CA9.AG5
CD1c	CA13.9H11
CD3	CA 17.2 A12
CD3ε	CD3-12
CD4	YKIX 302.9
CD4	CA13.1E4
CD5	YKIX 322.3
CD8	YCATE 55.9
CD8	CA9.JD3
CD8	CA15.4G2
CD11a	CA11.4D3
CD11a	CA16.1B11
CD11b	CA16.3E10
CD11c	CA11.6A1
CD11d	CA11.8H2
CD14	TUK 4
CD18	YFC 118.3
CD18	CA1.4E9
CD20	polyclonal
CD21	B-ly4
CD21	CA2.1D6
CD22	RFB4
CD34	1 H6
CD45	YKIX 716.13
CD45	CA12.10C12
CD45RA	CA4.1D3
CD49-like (VLA-4)	CA4.5B3
CD54 (ICAM-1)	CL18.1D8
CD56	B159
CD79a (MB-1)	HM57
CD90 (Thy-1)	CA1.4G8
CD117 (c-Kit)	YB5.88
MHC I	H58A
MHC II	YKIX 3342
MHC II	CA2.1C12
TCRαβ	CA15.8G7
TCRγδ	CA20.8H1
TCRγδ	CA20.6A3
MPO	CA25.10A6
Mac387 (L1-calprotectin)	Polyclonal

Clonality Assays

Leukemias generally are considered to be clonal or oligoclonal diseases; therefore, demonstration of a clonal population of cells in the blood or bone marrow is supportive of a diagnosis of leukemia. Clonality of lymphoid cell populations can be determined using PCR-based assays for immunoglobulin and T cell receptor gene rearrangements (see Chapter 143).[7] A similar diagnostic test is not available for demonstrating clonality for myeloid leukemias. A negative clonality test for immunoglobulin or T cell receptor gene rearrangement is consistent with, but not diagnostic for, myeloid leukemia.

Recurrent Cytogenetic Abnormalities

In humans, the WHO classification recognizes certain leukemias with recurrent cytogenetic abnormalities as

distinct disease entities. Recent studies using standard cytogenetic, fluorescent in situ hybridization (FISH), comparative genomic hyrbridization (CGH), and other molecular and genomic techniques have begun to identify recurrent cytogenetic abnormalities in canine lymphomas and leukemias (see Chapter 148).[21,47,61,62]

Leukemias in Dogs and Cats

Leukemias are rare in dogs and cats however their true incidence is unknown. Although most leukemias are considered to be spontaneous in origin, the association of specific leukemia/lymphoma subtypes with certain breeds of dogs and identification of recurrent chromosomal aberrations indicate that a heritable component contributes to the pathogenesis of leukemia in this species.[6] Leukemias have been induced in dogs with experimental radiation exposure[39] and certain gene therapy vectors.[53,74] Viral particles have been identified in leukemic cells in a few instances,[18,45,74]but a clear role for a virus in leukemia pathogenesis has not been demonstrated. In the cat, both lymphoid and myeloid leukemias have been associated with feline leukemia virus (FeLV; see Chapter 62)[50] and myeloid leukemias with feline immunodeficiency virus (FIV) infection (see Chapter 55).[24,54]

Acute Leukemias

Acute lymphocytic (lymphoblastic) leukemia (ALL) is a clonal proliferation of malignant lymphoid progenitors in the bone marrow. Cells show little differentiation. Blasts and prolymphocytes are the predominant cell population. Acute myelogenous leukemias (AMLs) are neoplastic myeloproliferative disorders originating from hematopoietic stem cells that differentiate to granulocytic, monocytic, erythrocytic, and megakaryocytic lineages. Acute myelogenous leukemias are characterized by greater than 20% blasts in the bone marrow, with an elevated white blood cell (WBC) count and high numbers of circulating atypical blasts.

In animals, acute leukemias can occur in most domestic and exotic species; however, it is probably most significant as a clinical entity in dogs and cats. Bovine leukemia complex (see Chapter 62) is an important retroviral-induced tumor.[42] The incidence of acute leukemias in dogs and cats is uncertain, although it is generally thought to be less common than lymphoma. Historically, AML in the dog has been reported to be more common than ALL. In two recent studies where immunophenotyping was performed, AML was more frequent;[69,70] AMLs comprised 21 of 38 (58%) and 31 of 46 (67%) of acute leukemias, respectively. However, the true frequency of AML versus ALL is unresolved given the case selection biases in these studies.

Lymphoid leukemia is reported to be the most common leukemia in cats, with ALL the most common lymphoid leukemia.[12] Acute lymphocytic leukemia in the cat had been highly correlated with FeLV infection, although this may be changing. Myelomonocytic (M4) is the most common acute myeloid leukemia reported in the cat.[5] With improved control of retroviral diseases in cats, there has been an apparent decrease in the incidence of FeLV-associated tumors in cats.[32] Immunophenotyping of a large series of acute leukemias in cats has not been reported.

The FAB cooperative group classification system has been applied to the classification of acute leukemias in the dog and cat[26] and has been incorporated into the REAL/WHO classification system. For the most part, detailed clinical description of many of the pathologically defined disease entities is limited. Until relatively recently, enzyme cytochemical analysis was the primary method used to identify the origin (i.e. cell lineage) of hematopoietic tumor cells. Immunophenotyping of leukemia, primarily using flow cytometry, has largely replaced enzyme cytochemical staining for diagnosing and classifying leukemias in cats and dogs (although cytochemical stains may provide confirmatory, or additional diagnostic information). In people, the presence of specific recurrent cytogenetic abnormalities is being incorporated into the WHO classification system and in some cases is being used to define specific leukemia diagnoses.[59,60]

The clinical signs and physical examination findings in dogs with acute leukemia may be vague and nonspecific.[13] In contrast to most dogs with lymphoma, dogs with acute leukemia usually are clinically ill at initial presentation. Dogs may present with anorexia, lethargy, fever, weight loss, shifting limb lameness, or neurologic signs. On physical examination splenomegaly, hepatomegaly, pale mucous membranes, petechia or ecchymosis, and mild generalized lymphadenopathy are common findings. Shifting limb lameness, fever, and ocular lesions have been reported to be more common in AML, and neurologic signs are reportedly more common in ALL.[13]

Neoplastic (leukemic) cells are present in the peripheral blood of most dogs with acute leukemia. The total WBC count tends to be higher in ALL. Acute leukemias with WBC counts greater than 150,000/μL, are generally ALL. Almost all dogs with acute leukemia have mono-, bi-, or pancytopenias present. Most affected dogs are anemic and thrombocytopenic.[13]

A diagnosis of acute leukemia can usually be made based on the history, physical examination findings, and CBC. Dogs with aleukemic leukemia require a bone marrow biopsy or aspirate to confirm the diagnosis. Greater than 20% blasts present in the bone marrow is consistent with a diagnosis of leukemia. Further diagnostic testing to assess the patient and determine the extent of disease includes abdominal ultrasound with lymph node, liver, and splenic aspirates. Flow cytometry of bone marrow aspirates and/or blood are required to determine immunophenotype. It is well documented that morphology alone is insufficient for distinguishing lymphoid from myeloid leukemia.[70]

Distinguishing acute leukemia from high-grade lymphoma in dogs with mild lymphadenopathy, significant bone marrow involvement (WHO clinical stage V), and a low number of circulating blasts, also can be dif-

ficult. In such cases, dogs that are systemically ill, have bicytopenia or pancytoenia, or a high percentage of blasts in bone marrow, are more likely to have ALL.[13] Immunophenotyping also provides valuable information to make the distinction of lymphoma versus leukemia. CD34 is usually expressed in acute leukemias, whereas lymphomas are CD34-negative greater than 70% of the time.[70,71]

Cats with acute leukemias usually show similar clinical signs (pale mucous membranes, splenomegaly, fever). Leukemic cats are likely to have malignant cells infiltrating in other organs besides bone marrow.[5] All cats with leukemia should be tested for FeLV and FIV. Treatment of ALL in cats is disappointing. A 27% complete response rate and median remission of 7 months was reported using a COP chemotherapy protocol.[11] Intensive supportive therapy, including blood transfusions, antibiotics, and nutritional support is frequently needed.

Determination of the specific type of leukemia has potential prognostic and therapeutic implications in dogs and cats; however, in general, both ALL and AML have a very poor prognosis. Remissions are usually difficult to achieve and survival times are short, even with treatment.[14] Treatment of acute leukemias has, for the most part, been extrapolated from chemotherapy protocols used to treat people with what appear to be similar diseases. Treatment of acute leukemias in dogs and cats has not been rigorously evaluated. Only retrospective data have been reported. These animals usually require intensive supportive treatment. More than half of dogs treated for acute leukemia die of sepsis or bleeding.[13,14] ALL is typically treated with the same combination and sequential chemotherapy protocols as is used to treat lymphoma, with doxorubicin-based protocols generally being preferred. Remission rates are considerably lower than those observed for solid lymphomas (20–40%). Survival times are also shorter, averaging 1–3 months.[13,14] The prognosis for animals with AML is particularly poor: most animals die or are euthanized shortly after diagnosis. Treatment usually consists of cytosine arabinoside, either as a single agent, or combined with other chemotherapeutics.[14] Remissions are rare, and when they occur short-lived.

Chronic Leukemias

Chronic lymphocytic leukemia (CLL) is a neoplastic clonal proliferation of small and morphologically mature-appearing lymphocytes that manifests as a persistent (>3 months), often marked, peripheral lymphocytosis.[72] Anecdotally, it is thought to be the most common leukemia in cats and dogs, but the true incidence is unknown. In the dog, CLL is seen most commonly in middle-aged to older dogs, with a reported median age of about 10 years, and a range of 1.5–15 years.[72] CLL has been reported in many different breeds and mixed breed dogs. In one study, golden retrievers and German shepherd dogs were reported to be overrepresented.[37] CLL occurs in cats; however, beyond case reports, little has been published. Anecdotally, CLL appears to occur primarily in older cats, with an approximate mean age of 12.2 years and a range of 6–19 years (W. Vernau, personal communication). The cause of CLL in animals is unknown, but for the most part has not been studied. Recently, Breen and Modiano showed hemizygous or homozygous deletion of the *RB1* locus (including the microRNA cluster encoding mir15 and mir16) in five of seven cases of canine CLL, with associated loss or reduction of RB protein in nine of ten cases.[6] This was reported to be homologous to the common deletion in the q arm of chromosome 13 (13q14) seen in people with CLL.

CLL is a heterogeneous disease, in the sense that it can involve proliferation of morphologically mature members of any of the different lymphocyte subsets. The clinical presentation of CLL in dogs and cats is variable; however, most commonly animals are asymptomatic at initial diagnosis. In fact, the initial suspicion of CLL frequently is based on an incidental finding of lymphocytosis found during a geriatric wellness examination or before planned surgical procedure. Clinical signs are often vague and nonspecific, including lethargy, reduced appetite, and slowly progressive weight loss.[72] Physical examination findings may be unremarkable, or include mild generalized lymphadenopathy, splenomegaly, hepatomegaly, pale mucous membranes, and pyrexia.[72]

The primary laboratory finding in CLL is leukocytosis caused by an absolute lymphocytosis. Lymphocytosis can range from mild to marked and can fluctuate, even without therapy. Reported lymphocyte counts in dogs with CLL have been reported as varying from just outside the laboratory normal range to over 1,000,000/μL.[37,72] In the cat, lymphocyte counts varying from 36,000 to 250,000/μL have been reported. Other hematological findings may include normocytic normochromic nonregenerative anemia in greater than 50% of affected dogs, and thrombocytopenia in 25–50% of dogs with CLL. Neutropenia is rarely observed. In cats, hematological findings included anemia (61%), thrombocytopenia (38%), neutropenia (16%), and neutrophilia (50%). Monoclonal gammopathies are reported in approximately two-thirds of dogs with CLL. That is a paradoxical finding, given that the majority of CLLs in dogs are T cell neoplasms. Other paraneoplastic syndromes that may occur include immune-mediated hemolytic anemia, pure red cell aplasia, and hypercalcemia.

B cell CLL in the dog, as is the case in people, is a primary bone marrow disease. Similar to people, dogs with B cell CLL typically have significant (>30%) proliferation of small mature lymphocytes in bone marrow.[72] In contrast, canine T cell CLL of the large granular lymphocyte type (GL CLL) does not seem to be a primary bone marrow disease, but rather a primary splenic disease.[37,72] A similar splenic origin for large GL leukemia is well-characterized in Fischer 344 rats.[58] Feline CLL appears to be primarily a helper T cell disease, although other T cell immunophenotypes occur (W. Vernau, personal communication).

Absolute lymphocytosis is the major diagnostic criterion for CLL in dogs. Other differential diagnoses for dogs with mild lymphocytosis (7,000–20,000/μL) include ehrlichiosis, babesiosis, leischmaniasis, Rocky Mountain spotted fever, Chagas' disease, hypoadrenocorticism, and physiologic leukocytosis. Lymphocytosis (>20,000/μL in the dog or >25,000/μL in the cat) is consistent with CLL. In those cases where the differentiation of CLL from other diseases is problematic, immunophenotyping and clonality assessment can be useful.

In people, B cell CLL (CD5+, CD79a+, CD21+), involving proliferation of the CD5+ B-1 subset of B cells, accounts for more than 95% of CLL cases. In contrast, in the dog, T cell CLL appears to be far more common than B cell CLL.[68,72] In the largest reported study of 73 dogs with immunophenotyped CLL, 73% of cases involved proliferation of T cells and 74% of those had GL morphology. Most GL CLLs had a cytotoxic T cell immunophenotype (CD3+, CD8+, CD11d+). B cell CLL comprised 26% of canine CLL cases in this study, based on expression of CD21 or CD79a and lack of expression of any T cell antigens.[68] In cats with CLL, the predominant immunophenotype appears to be that of the T helper cell (CD3+, CD4+, CD5+), accounting for 75% of cases. Cytotoxic T cell (CD3+, CD8+, CD5+), double-positive (CD4+, CD8+), and double negative (CD4–, CD8–) immunophenotypes also can occur. In situations where CLL is the primary differential diagnosis, but where doubt still exists, assessment of clonality by PCR can be particularly useful.

CLL in the dog is generally indolent; however, prospective studies with regular and close clinical follow-up are lacking. While the disease has been generally perceived to inexorably progress to blast transformation, a recent study showed that dogs with absolute lymphocyte counts of <30,000/μL had prolonged survival with conservative management.[71] In the authors experience, uncomplicated (lymphocytosis without other cytopenias, no or mild anemia, minimal organ involvement) CLL is indeed indolent. With treatment, dogs with uncomplicated CLL may live more than 3 years with their disease.[29,68,72] However, survival times can be quite short in complicated (lymphocytosis, moderate or severe anemia, significant organ involvement, presence of paraneoplastic syndromes, poor clinical response to chemotherapy) CLL, so it is appropriate to describe CLL as a heterogeneous disease with realistic survival expectations from ~1 to 3 years.[29] The prognostic significance of CLL immunophenotype has only begun to be investigated. In the largest published retrospective study, immunophenotype was not correlated with prognosis.[68]

Because CLL is often an indolent disease, approaches to treatment vary. Some oncologists prefer to manage asymptomatic dogs with mild to moderate lymphocytosis using "watchful waiting," to monitor for progression, an approach that is similar to the clinical management for people with CLL. In cases where there is progression (defined by a persistent trend of increasing absolute lymphocyte counts in peripheral blood or appearance of other systemic signs), management with chemotherapy is instituted. In the authors practices, most dogs and cats with CLL are managed with chemotherapy at the onset of diagnosis. Dogs are generally treated with pulse dose chlorambucil at a dosage of 20 mg/m^2 orally once every 14 days.[14] Corticosteroids, prednisone, at a dosage of 50 mg/m^2 orally once daily for 7 days, then 25 mg/m^2 orally every other day, may be included, particularly if paraneoplastic syndromes are present. Responses to treatment are typically slow, probably because the growth fraction of neoplastic lymphocytes in CLL appears to be low. Generally, it takes at least a month of treatment to observe a response to therapy and may take as long as 6 months.[14] A consensus on the best approach to manage uncomplicated CLL will require prospective assessment of observation versus therapy in a controlled setting.

Chronic myeloid leukemia (CML) is extremely rare and is poorly characterized in dogs and cats.[30] The chronic myeloid leukemias include chronic myelogenous or granulocytic, chronic monocytic, and chronic myelomonocytic leukemias. The clinical signs and physical examination findings in dogs and cats with CML appear to be similar to those in dogs and cats with CLL. Blast crisis, manifested by the appearance of immature blast cells in blood and bone marrow, occurs in dogs and humans with CML months to years after initial diagnosis. Blast crisis appear to be rare in dogs with CML. The hematological features of CML in dogs are poorly characterized. Leukocytosis with a left shift that includes myelocytes and occasional myeloblasts, anemia, and thrombocytopenia or thrombocytosis, can occur. Typically, mature forms are more numerous, but are left-shifted. Signs of dysplasia may be present, including hypersegmentation, ringed nuclei, and giant forms. The diagnosis of CML in the dog and cat is challenging, particularly because the disease is so poorly characterized. Other differential diagnoses include severe neutrophilic leukocytosis and leukemoid reactions caused by inflammation or immune-mediated disease.

In humans, CML is characterized by the presence of a recurrent chromosomal aberration, referred to as the Philadelphia chromosome, which represents a reciprocal translocation between the *c-abl* oncogene located in 9q34 (*ABL* locus) and the breakpoint cluster region (BCR) located at 22q11. Recently, a homologous translocation was demonstrated to occur in dogs with spontaneously occurring CML.[6] The prevalence of this translocation in canine CML has yet to be determined. Treatment of CML in dogs with hydroxyurea has been extrapolated from the human literature. Based on anecdotal and case reports, the prognosis does not appear to be as good as that for dogs with CLL, with reported survival times ranging from 4 to 15 months. Presumably, the tyrosine kinase inhibitors imatinib (Gleevec) and sunitinib (Sutent), and the new tyrosine kinase inhibitors developed for the veterinary market, toceranib phosphate (Palladia) and masitinib (Kinavet), may be

effective in animals with dysregulated Abl protein expression. However, there are no verified reports of their efficacy to treat canine or feline CML.

CHAPTER 66

Myelodysplastic Syndromes

DOUGLAS J. WEISS

Classification of Myelodysplastic Syndromes
Myelodysplastic Syndromes in Dogs
  Refractory Anemia
  Refractory Anemia with Ringed Sideroblasts
  Refractory Cytopenia with Multilineage Dysplasia
  Refractory Anemia with Excess Blasts
  Myelodysplastic Syndrome Unclassifiable
  Secondary Myelodysplastic Syndromes
Secondary Dysmyelopoiesis in Dogs
  Diseases/Drugs/Toxins
  Congenital Dysmyelopoiesis (see Chapter 29)
Myelodysplastic Syndromes in Cats
  Refractory Anemia
  Refractory Anemia with Ringed Sideroblasts
  Refractory Cytopenia with Multilineage Dysplasia
  Refractory Anemia with Excess Blasts
Secondary Dysmyelopoiesis in Cats
  Diseases/Drugs/Toxins
Myelodysplastic Syndrome in Horses

Acronyms and Abbreviations

DNA, deoxyribonucleic acid; FeLV, feline leukemia virus; MCV, mean corpuscular volume; MDS, myelodysplastic syndrome; RA, refractory anemia; RAEB, refractory anemia with excess myeloblasts; RAMD, refractory anemia with excess myeloblasts; RARS, refractory anemia with ringed sideroblasts; RBC, red blood cell; RCMD, refractory cytopenia with multilineage dysplasia; WHO, World Health Organization.

Myelodysplastic syndromes (MDSs) are a group of acquired clonal hematologic disorders, described in dogs, cats, horses, and humans, that originate from acquired genetic mutations in hematopoietic stem cells.[3,5,8,13,41] A clonal origin of MDS has been documented in human beings by homozygosity for glucose-6-phosphatase isoenzymes, cytogenetic analysis, and X-linked restriction length polymorphism.[2,16] A clonal origin has been documented in cats infected with feline leukemia virus (FeLV).[16] Myelodysplastic syndromes in dogs has been assumed to be clonal because of the lack of concurrent diseases or drug or toxin exposure, and because of the similarity of these disorders to those described in humans.[21,41] As in other neoplasms, clonal expansion is usually the result of multiple mutations in oncogenes and tumor suppresser genes (see Chapter 61).[2,16] These syndromes are heterogeneous but are characterized by cytopenias in the blood and dysplastic changes in one or more cell lineages in bone marrow. Cytopenias result from a combination of defects in growth and differentiation and increased apoptosis of hematopoietic cells. These defects result in ineffective hematopoiesis.[5,22,28] Myelodysplastic syndromes are highly heterogeneous and major subtypes must be differentiated in order to determine appropriate treatment and to establish a prognosis. Myelodysplastic syndromes must also be differentiated from dysmyelopoiesis occurring secondary to diseases, drug and toxin exposure, and as a result of congenital disorders.[1,15,32,35,38] The most reliable features that help to differentiate MDS from secondary dysmyelopoiesis include the presence of increased numbers of myeloblasts or rubriblasts in bone marrow, a high percentage of dysplastic cells in bone marrow, and the presence of prominent megaloblastic changes in erythroid precursor cells.[5,38] Congenital dysmyelopoiesis is generally seen in juvenile animals and may be breed-restricted (see Chapter 30).

CLASSIFICATION OF MYELODYSPLASTIC SYNDROMES

Myelodysplastic syndromes were initially classified by the French-American-British co-operative group (Table 66.1; see Chapter 64).[4] This system has been applied to

both dogs and cats.[5] The French-American-British system categorized MDS into five categories primarily based on the distribution and type of dysplastic features and the percentage of myeloblasts present. These five categories included refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transition (i.e. 20–30% myeloblasts in bone marrow), and chronic myelomonocytic leukemia. Acute leukemia was defined as greater than 30% myeloblasts in bone marrow.[4] More recently, the World Health Organization (WHO) modified the French-American-British classification system incorporating some new diagnostic information including cytogenetics, immunologic markers, and molecular genetics.[13] In the WHO classification system, RA is defined as nonregenerative anemia with dysplastic changes primarily in the erythroid lineage and less than 5% myeloblasts in bone marrow (Figs. 66.1 and 66.2). Refractory anemia with ringed sideroblasts is defined as dyserythropoiesis characterized by siderocytes, sideroblasts, and ringed sideroblasts, and with dysplastic features primarily in the erythroid lineage and less than 5% myeloblasts in bone marrow. Sideroblasts are nucleated erythroid cells that contain many large iron deposits within mitochondria. Because mitochondria are distributed around the nucleus, iron deposits frequently form a perinuclear collar and the cells are termed ringed sideroblasts (Fig. 66.3). Refractory cytopenia with multilineage dysplasia (RCMD) is characterized by dysplastic changes in all hematopoietic cell lineages but no increase in the number of myeloblasts in bone marrow. Refractory

TABLE 66.1 Classification Systems for Myelodysplastic Syndromes

French-American-British	World Health Organization	Dog/Cat System
Refractory anemia	Refractory anemia	MDS with refractory cytopenia
Refractory anemia with ringed sideroblasts	Refractory anemia with ringed sideroblasts Refractory cytopenias with miltilineage dysplasia	MDS with sideroblastic differentation
Refractory anemia with excess blasts	Refractory anemia with excess blasts-1 (5–10% blasts)	MDS with excess blasts (5–30% blasts)
Refractory anemia with excess blasts in transition	Refractory anemia with excess blasts-2 (10–20% blasts) MDS with isolated del(5q) chromosome abnormality MDS unclassifiable	MDS unclassifiable
Chronic myelomonocytic leukemia		
Acute myeloid leukemia (>30% blasts)	Acute myeloid leukemia (>20% blasts)	Acute myeloid leukemia (>30% blasts)

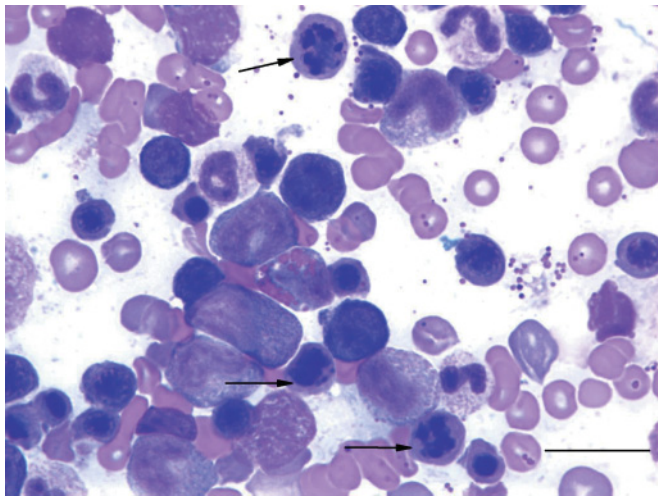

FIGURE 66.1 Dyserythropoiesis in a bone marrow aspiration smear from a dog with refractory anemia. Note the presence of fragmented nuclei in rubricytes (arrows). Wright-Giemsa stain; bar = 20 µm.

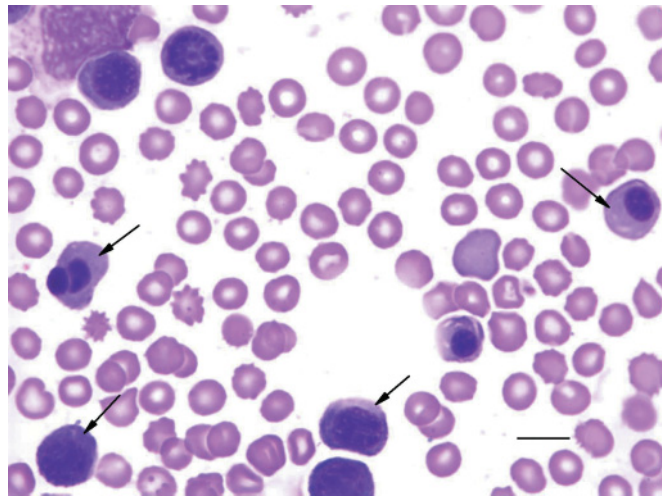

FIGURE 66.2 Mild megaloblastic dyserythropoiesis in a bone marrow aspirate from a dog with refractory anemia. Note the large size of nuclei in rubricytes relative to their maturity (arrows). Wright-Giemsa stain; bar = 10 µm.

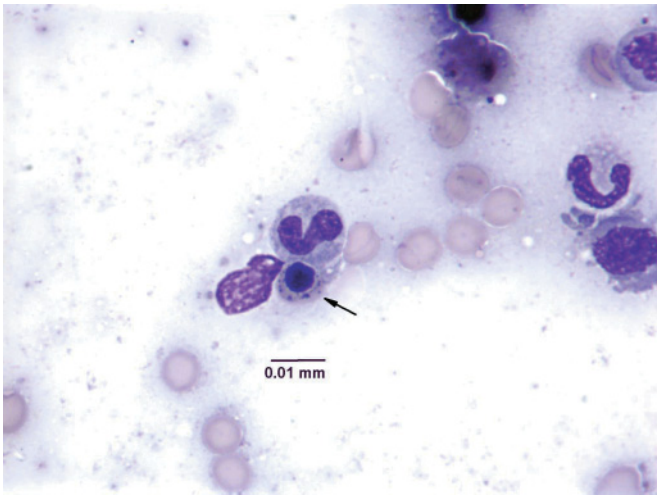

FIGURE 66.3 Ringed sideroblast (arrow) in a bone marrow aspirate from a dog with sideroblastic-type refractory cytopenias with multilineage dysplasia. Wright-Giemsa stain.

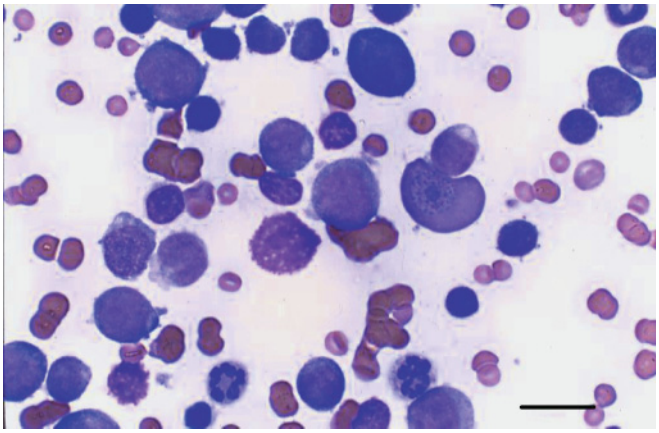

FIGURE 66.4 Increased numbers of myeloblasts and multilineage dysplasia in a bone marrow aspirate from a cat with refractory anemia with excess blasts. Note a large megaloblastic rubricyte and hypersegmented neutrophils. Wright-Giemsa stain; bar = 20 µm.

anemia with excess blasts-I is defined as 5–10% myeloblasts in bone marrow and RAEB-II is defined as 10–20% myeloblasts in bone marrow (Fig. 66.4).[13] In humans, MDS associated with isolated del(5q) chromosome abnormality has been shown to be sufficiently homogeneous to merit its own categorical classification. Unclassified forms of MDS include hypoplastic MDS and MDS with fibrosis. Acute myeloid leukemia is defined as greater than 20% myeloblasts in bone marrow. Chronic myelomonocytic leukemia is not included in the definition of MDS.

In addition to the WHO classification system, an International Prognostic Scoring System has been developed.[3] This system combines the percentage of myeloblasts, karyotype, and the number of cytopenias to generate a score that estimates both survival and risk of transformation to acute leukemia.[3] This scoring system can be combined with morphologic criteria to provide even more accurate prognostic information.[3]

A modified classification system has been described for dogs and cats.[20,23,32] In this system, major categories include MDS with refractory cytopenias, MDS with sideroblastic differentiation, and MDS with excess myeloblasts. Myelodysplastic syndrome with refractory cytopenia is characterized by nonregenerative anemia or multiple cytopenias in the blood, dysplastic features usually most prominent in the erythroid lineage, and less than 5% myeloblasts in bone marrow. Myelodysplastic syndrome with sideroblastic differentiation is characterized by microcytic or hypochromic anemia and sideroblasts and ringed sideroblasts in bone marrow.[39]

MYELODYSPLASTIC SYNDROMES IN DOGS

In a retrospective study of clinical bone marrow reports at a veterinary teaching hospital, MDS was reported in 4% of dogs, whereas acute leukemia of all types was observed in 6.4% of dogs.[36,41] If classified by the WHO system, 27% would be classified as RA, 62% as RAEB, and 11% as RCMD (Table 66.2).[41]

TABLE 66.2 Classification and Characteristics of Myelodysplastic Syndromes in Dogs

Condition	Signalment	Clinical Signs	Peripheral Blood Findings	Bone Marrow Findings
RA	Middle-aged to old	Lethargy, exercise intolerance	Normocytic normochromic nonregenerative anemia	Dyserythropoiesis, variable increase in rubriblasts, <5% myeloblasts
RARS	Middle-aged to old	Lethargy, exercise intolerance	Nonregenerative anemia ± thrombocytopenia or leukopenia	Dyserythropoiesis, variable increase in rubriblasts, sideroblasts, ringed sideroblasts
RCMD	Middle-aged to old	Uncertain	Normocytic normochromic nonregenerative anemia	Dysplasia in multiple cell lineages, <5% myeloblasts
RAEB	Middle-aged to old	Lethargy, anorexia, fever, petechial hemorrhage	Bicytopenia or pancytopenia	Dyserythropoiesis, dysgranulopoiesis, dysmegakaryopoiesis, 5–20% myeloblasts

Refractory Anemia

Dogs with RA (also called MDS with refractory cytopenias) are typically greater than 7 years old with no breed predilection (Table 66.2).[21,40,41] Affected dogs have an insidious onset of clinical signs consisting of lethargy and exercise intolerance. Pale mucous membranes, increased heart and respiratory rates, and anemia-related heart murmur are frequent findings on physical examination. Hematologic alterations consist of moderate to severe nonregenerative normocytic normochromic anemia. Total leukocyte and platelet counts are usually within reference ranges. Bone marrow is normocellular or hypercellular with a normal or decreased myeloid-to-erythroid ratio. Rubriblasts are frequently increased in number ranging between 5% and 30% of all nucleated bone marrow cells and myeloblasts are consistently less than 5% of all nucleated bone marrow cells.[41] Dysplastic features are usually limited to the erythroid series. Features of dyserythropoiesis include binucleation, megaloblastosis, nuclear fragmentation, and asynchronous maturation.[38,41]

Treatment of dogs with RA has included cyclophosphamide, cytosine arabinoside, and erythropoietin.[7,30,41] Most dogs for which follow-up was available survived for months to years with no reports of progression to acute leukemia.[7,41] Of three dogs treated with recombinant erythropoietin, all had significant improvement in hematocrit and were nonanemic at last contact.[7,41] In the limited number of cases reported, response to treatment or survival did not appear to be dependent on the percentage of rubriblasts in bone marrow.

Refractory Anemia with Ringed Sideroblasts

Several cases of MDS with sideroblastic differentiation have been described.[36,39,41] However, because these conditions consistently had prominent dysplastic features in all cell lineages, they are best categorized as RCMD.

Refractory Cytopenia with Multilineage Dysplasia

Refractory cytopenia with multilineage dysplasia is characterized by prominent dysplastic features in two or more hematopoietic cell lineages but no increase in myeloblasts in bone marrow.[11,33,36,39,41] Dogs with RCMD include dogs with sideroblastic- and nonsideroblastic-types of anemia (Table 66.2).[21,36,39] Several dogs with nonsideroblastic anemia had normocytic normochromic nonregenerative anemia, thrombocytopenia, and dysplastic features in all hematopoietic cell lineages.[11,21] One dog was treated with low-dose aclarubicin, a differentiation-induction therapy. Hematologic improvement resulted and the dog survived for more than 2 years. Another dog was treated with prednisolone, cyclosporine, and hydroxycarbamide but died of congestive heart failure. Another dog was maintained for over 2 years with treatment consisting of prednisolone and cytarabine ocfosfate.[18]

Dogs with sideroblastic-type RCMD tended to have an insidious onset of clinical signs consisting of lethargy and exercise intolerance. Pale mucous membranes and increased heart and respiratory rates are frequent findings on physical examination. Hematologic alterations consist of a microcytic or hypochromic nonregenerative anemia with many siderocytes in blood smears. The presence of siderocytes can be confirmed by staining the iron-containing granules with Prussian blue stain. Bone marrow is normocellular or hypercellular and usually contains increased amounts of hemosiderin. A characteristic feature is the presence of five or more large iron deposits in rubricytes and metarubricytes.[39] Many rubricytes and metarubricytes in normal adult dogs contain 1–3 small siderotic granules that are visible when stained with Prussian blue stain.[9] Variable numbers of ringed sideroblasts are also present. Although rubriblasts are frequently increased, myeloblasts are usually less than 5% of all nucleated cells. Too few cases of sideroblastic-type RCMD have been reported to establish treatment protocols or to evaluate outcome. However, among the few cases observed by the author, both response to treatment and survival time appear to be less than that for RA. Cases of RCMD must be differentiated from sideroblastic anemia. Sideroblastic anemia has been associated with inflammatory diseases, myelofibrosis, and chloramphenicol therapy.[15,33]

Refractory Anemia with Excess Blasts

Refractory anemia with excess blasts (also termed MDS with excess blasts) is the most frequently occurring primary type of myelodysplastic syndrome in dogs.[21,40,41] RAEB is a disease of middle-aged to old dogs (range 4–13 years) with no apparent breed or sex predilection (Table 66.2).[41] Dogs with RAEB usually appear more ill than those with RA. Signs of illness include lethargy, depression, anorexia, diarrhea, and fever.[41] These signs may appear acutely or progressively worsen over weeks to months. Hematologic alterations include moderate to severe normocytic normochromic nonregenerative anemia, neutropenia, and thrombocytopenia. Bone marrow is usually hypercellular with an increased myeloid-to-erythroid ratio. A hallmark feature of RAEB is the presence of increased numbers of myeloblasts that vary from 6% to 20% of all nucleated cells in bone marrow.[41] Dysplastic features are typically present in all bone marrow cell lineages. Features of dysgranulopoiesis include small myeloblasts and promyelocytes, giant metamyelocytes and band cells, asynchronous maturation, and hypersegmentation.[3,38] Features of dyserythropoiesis include megaloblastic changes, asynchronous maturation, binucleation or trinucleation, nuclear fragmentation, and micrometarubricytes.[3,38] Features of dysmegakaryopoiesis include asynchronous maturation, large hypolobulated forms, dwarf megakaryocytes, and dispersed nuclei.[3,38]

Treatment of RAEB in dogs has been mostly supportive.[11,21,41] Broad spectrum antibiotics are indicated when severe neutropenia, fever, or sepsis is present. Red blood cell (RBC) or whole blood transfusions are indicated to treat severe anemia. Erythropoietin and

other hematopoietic growth factors have been given. Although these treatments may improve the cytopenias, they do not appear to significantly prolong survival. Administration of chemotherapeutic agents, including hydroxyurea, low-dose cytosine arabinoside, and low-dose aclarubicin has been tried in individual cases. Hydroxyurea has been used most frequently. Some individual animals appear to respond to chemotherapy. At present, survival times of dogs with RAEB are short, ranging from days to months.[11,41] Death or euthanasia is frequently associated with sepsis, organ failure, bleeding, or disseminated intravascular coagulopathy. Progression to acute myeloid leukemia has been documented in approximately 25% of reported cases. In general, survival and progression to acute myeloid leukemia can be predicted by the percentage of myeloblasts present in bone marrow.

Myelodysplastic Syndrome Unclassifiable

Variant forms of MDS are occasionally seen. These probably result from different combinations of genetic mutations in hematopoietic stem cells. A primary dysmegakaryopoiesis is one variant form.[31] Affected dogs have a history of chronic moderate to severe thrombocytopenia that is unresponsive to immunosuppressive therapy. In bone marrow, dysplastic features, including large hypolobulated forms, dwarf megakaryocytes, asynchronous maturation, and discrete rather than lobulated nuclei, are limited to megakaryocytes. Causes of secondary dysmegakaryopoiesis, including immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, ehrlichiosis, and lymphosarcoma, should be ruled out before a diagnosis of MDS is made.[31] Affected dogs appear to have prolonged survival.

Secondary Myelodysplastic Syndromes

Secondary MDS is a clonal disorder of hematopoietic stem cells that is associated with drug or radiation treatment or toxin exposure.[26] In humans, secondary MDS has been associated with benzene exposure and treatment with alkylating agents and radiation. Secondary MDS frequently occurs months to years after exposure. Drug-associated MDS has not been reported in dogs but dysmegakaryopoiesis has been reported to occur as a preleukemic change in dogs after exposure to gamma radiation.[27] With ever increasing use of chemotherapeutic agents and radiation therapy in veterinary medicine, secondary MDS may be recognized more frequently.

SECONDARY DYSMYELOPOIESIS IN DOGS

Diseases/Drugs/Toxins

Secondary dysmyelopoiesis includes nonclonal dysplastic conditions that should not be classified as MDS. Secondary dysmyelopoiesis is associated with a variety of conditions including specific disease processes, administration of certain drugs (see Chapter 16), exposure to heavy metals (see Chapter 17) iron deficiency (see Chapter 26), and some congenital conditions (see Chapter 30).[14,31,33,38] In one study, the most frequent diseases associated with secondary dysmyelopoiesis in dogs included immune-mediated hemolytic anemia/immune-mediated thrombocytopenia (45%), lymphosarcoma (25%), and myelofibrosis (15%).[38]

A variety of drugs have been associated with dysmyelopoiesis. These include chemotherapeutic drugs, phenobarbital, estrogen, cephalosporins, chloramphenicol, and colchicine.[1,15,19] Drugs that interfere with DNA synthesis, including antimetabolites (e.g. azathioprine, cytosine arabinoside, hydroxyurea), folate antagonists (e.g. methotrexate), plant alkaloids (e.g. vincristine), and alkylating agents (e.g. cyclophosphamide) frequently induce dysplastic changes.[1,5] These dysplastic changes are usually most prominent in the erythroid lineage.[5,32] Binucleation, fragmented nuclei, giant forms, atypical mitotic figures, and megaloblasts are frequently observed. Phenobarbital therapy has been associated with a severe normocytic normochromic nonregenerative anemia and dyserythropoiesis.[19] In general, the dysplastic features are identified during treatment and resolve within days after cessation of treatment. This is unlike drug- or toxin-induced secondary MDS in which dysplastic features are identified months to years after exposure and persist. Sideroblastic anemia was documented in a dog treated with chloramphenicol.[15]

Secondary dysmyelopoiesis has also been associated with iron deficiency, lead, zinc, and arsenic poisoning, and with leishmaniasis.[5,10,12,14,15,29] Iron deficiency is characterized by a microcytic, hypochromic anemia. Dysplastic features are restricted to the erythroid lineage and are characterized by rubricytes and metarubricytes with a ragged rim of cytoplasm and patchy areas of basophilia within the cytoplasm.[14] A late stage maturation arrest in the erythroid series may be present in some dogs. Lead inhibits several enzymes in the heme synthesis pathway.[12] Resultant inhibition of heme synthesis leads to iron accumulation in erythroid precursors and sideroblastic anemia. Lead also inhibits a pyridine specific 5′ nucleotidase that is involved in degradation of ribosomal ribonucleic acids. Retention of ribosomes may result in basophilic stippling. Arsenic poisoning causes marked dyserythropoiesis characterized by karyorrhexis, megaloblastosis, and multinuclearity. Leishmania infection in dogs has been associated with dysmegakaryopoiesis and dyserythropoiesis.[10]

Variant forms of secondary dysmyelopoiesis include selective dysmegakaryopoiesis and sideroblastic anemia.[31,33] Dysmegakaryopoiesis is associated with the same spectrum of disease conditions as other forms of secondary dysmyelopoiesis. Secondary dysmegakaryopoiesis must be differentiated from megakaryoblastic leukemia. Little or no increase in megakaryoblasts is seen in secondary dysmegakaryopoiesis, whereas, megakaryoblastic leukemia is characterized by a moderate to marked increase in megakaryoblasts in blood or bone marrow.[31] Unlike other types of secondary dysmyelopoiesis, sideroblastic anemias are associated with inflammatory diseases and myelofibrosis.[33] Affected

TABLE 66.3 Classification and Characteristics of Myelodysplastic Syndromes in Cats

Condition	Signalment	Clinical Signs	Peripheral Blood Findings	Bone Marrow Findings
RA	Reported cases presently classified as RCMD			
RARS	Few cases reported			
RCMD	Variable	Anorexia, depression, weight loss, weakness	Macrocytic normochromic nonregenerative anemia, bicytopenia or pancytopenia, metarubricytosis	Dysplasia in multiple cell lineages, <5% myeloblasts
RAEB	Variable	Lethargy, anorexia, fever, petechial hemorrhage	Normocytic or macrocytic nonregenerative anemia, bicytopenia or pancytopenia	Dyserythropoiesis, dysgranulopoiesis, dysmegakaryopoiesis, 5–20% myeloblasts

dogs have a moderate to severe microcytic or hypochromic anemia that may be confused with iron deficiency anemia. Dysplastic features are similar to those associated with RARS except that the percentage of rubriblasts in bone marrow is not increased. Dysplastic features are restricted to or are most prominent in the erythroid lineage. The role of pyridoxine deficiency as a cause of the sideroblastic changes has not been investigated.

Differentiating MDS from secondary dysmyelopoiesis is challenging.[5,32] Bone marrow features that differentiate MDS from secondary dysmyelopoiesis have been proposed.[5] This author proposed that the diagnosis of MDS be restricted to dogs with dysplastic features in more than one cell lineage and that have greater than 5% myeloblasts in bone marrow. With these criteria, all cases of RA would be categorized as secondary dysmyelopoiesis despite being classified as MDS in the human classification system. Other authors prefer a less restrictive definition.[23,32] In general, in secondary dysmyelopoiesis, the percentage of dysplastic cells is lower and the percentages of rubriblasts and myeloblasts are not increased. Exceptions include sepsis and bone marrow recovering from toxic injury. In the case of sepsis, a combination of increased myelopoiesis and rapid mobilization of mature myeloid cells into the blood results in a shift toward immaturity in the myeloid series. In marrow recovering from suppression, a wave of immature cells may be seen, resulting in a high percentage of blasts cells.[24] The presence of toxic changes in the myeloid cells is helpful in identifying sepsis-associated dysmyelopoiesis. Dysplastic features are usually more numerous in MDS compared to secondary dysmyelopoiesis and megaloblastic features are usually more prominent, but in individual cases these differences may be insufficient to make a conclusive diagnosis. Therefore, diagnosis necessitates evaluation for diseases, drug treatments, and toxin exposures that are known to cause secondary dysmyelopoiesis.[38]

MYELODYSPLASTIC SYNDROMES IN CATS

In a retrospective study of clinical bone marrow reports at a veterinary teaching hospital, 11.6% had a diagnosis of MDS. Of these, 4.3% had a diagnosis of RA, 0.5% had a diagnosis of RCMD, and 6.8% had a diagnosis of RAEB (Table 66.3).[37] A clonal origin of MDS in FeLV-infected cats has been documented.[16] Cytopenia in cats with MDS has been associated with decreased numbers of granulocytes-monocyte colony-forming units and erythroid colony-forming units in four of seven cats tested and decreased size of granulocytes-monocyte colony-forming units in all seven cats tested.[22] The probability of progression of FeLV-positive MDS cats to acute myeloid leukemia is considered to be high.[6]

Refractory Anemia

Cats previously categorized as RA have multiple cytopenias in the blood and dysplastic features in two or more cell lineages in blood or bone marrow. Therefore, they should be categorized as RCMD.[35]

Refractory Anemia with Ringed Sideroblasts

Several cats with sideroblastic anemia have been described.[17,25,35] At least one of these cats fits into the category of RARS.[35] Unlike dogs, cats with RARS have a macrocytic normochromic anemia. They also have dyserythropoiesis, less than 5% myeloblasts in bone marrow, the presence of siderocytes in blood and bone marrow and variable numbers of ringed sideroblasts. Healthy cats do not have siderocytes in bone marrow.[5] Increased eosinophil and basophil precursors were observed in bone marrow in one cat.[35] Eosinophilia in bone marrow is a frequent finding in cats with MDS.[20,25]

Refractory Cytopenia with Multilineage Dysplasia

Cats with previous diagnoses of RA and MDS-RC and some cats with a diagnosis of RARS appear to fit in this category because of the presence of multiple cytopenias in the blood and multilineage dysplasia in bone marrow (Table 66.3).[17,25,35] A few cats with macrocytic normochromic anemia, siderocytes, ringed sideroblasts, and multilineage dysplasia have been reported.[17,25] The age and FeLV status of these cats varied between studies. In some studies, the median age was approximately 3

years old and 70–90% of the cats were FeLV positive.[5,17,25] In another study, only 38% of cats were FeLV positive and the median age was 8.7 years old.[35] In general, these cats were less severely ill than cats with RAEB. Frequently encountered clinical signs include anorexia, depression, weakness, and loss of body mass. Affected cats have a moderate to severe macrocytic normochromic nonregenerative anemia and frequently have metarubricytosis and autoagglutination. Most cats are thrombocytopenic and some are leukopenic. Bone marrow is normocellular or hypercellular, myeloblasts are <5% of all nucleated cells and rubriblasts are typically increased. Dysplastic features are present in the erythroid line of all cats and frequently present in granulocyte and megakaryocyte lineages. Features of dysgranulopoiesis include maturation arrest, hypersegmentation, hyposegmentation, giant band and segmented neutrophils, and asynchronous maturation of nucleus and cytoplasm. Features of dyserythropoiesis included asynchronous maturation of nucleus and cytoplasm, binucleation, fragmented or lobulated nuclei, and megaloblastosis. Features of dysmegakaryopoiesis included large megakaryocytes with mature-appearing granulated cytoplasm but poorly lobulated or multiple discrete nuclei, megakaryocytes with mature hyperlobulated nuclei but immature-appearing homogeneous blue cytoplasm, and many small megakaryocytes with single or multiple discrete round nuclei. Evaluation of bone marrow core biopsy specimens revealed myelonecrosis and myelofibrosis in one-third of cats with RCMD.[35]

Although prognosis is guarded, some cats with RCMD respond partially or completely to symptomatic therapy and have prolonged survival.[35] Refractory anemia and RCMD appear to have less tendency to progress to acute myeloid leukemia and have a longer survival times compared to RAEB. However, this difference is difficult to prove statistically when small groups are compared.[17] Therapy has consisted of prednisolone, prednisolone and cytarabine, cyclosporine A, or combination chemotherapy consisting of daunorubicin, cytarabine, vincristine, and prednisolone.[17]

Refractory Anemia with Excess Blasts

Cats with RAEB are characterized by multiple cytopenias, multilineage dysplasia, and increased myeloblasts in bone marrow (Table 66.3). In studies in which most affected cats were FeLV-positive, the median age was approximately 3 years, whereas, in studies in which the majority of affected cats were FeLV-negative, the median age was approximately 9 years.[17,25,35] Cats with RAEB tended to be severely ill with clinical signs including anorexia, weakness, depression, loss of body mass, fever, vomiting, diarrhea, and platelet-related bleeding. Affected cats have a moderate to severe nonregenerative anemia and some have metarubricytosis and autoagglutination. Most cats are thrombocytopenic and some are leukopenic. Bone marrow is usually normocellular or hypercellular but may be hypocellular. Erythroid hypoplasia is a relatively frequent finding in FeLV-positive cats. All cats had 6% to 20% myeloblasts in bone marrow with variable increases in rubriblasts. Dysplastic features are present in all cell lines. Features of dysgranulopoiesis, dyserythropoiesis, and dysmegakaryopoiesis are similar to those associated with RCMD. Myelonecrosis and myelofibrosis are present in bone marrow of some affected cats.[35] Presently, survival for cats with RAEB varies from days to a few months with frequent progression to acute myeloid leukemia.[17,35]

SECONDARY DYSMYELOPOIESIS IN CATS

Diseases/Drugs/Toxins

In a retrospective study of clinical bone marrow reports in cats, 6.3% were categorized as secondary dysmyelopoiesis.[35] Disease conditions associated with secondary dysmyelopoiesis include immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, pure red cell aplasia, lymphosarcoma, glomerulonephritis, and feline infectious peritonitis.[35] Bone marrow has normal or increased cellularity and dysplastic features are most prominent in the erythroid series but can be found in granulocytes and megakaryocytes. In general, these changes are similar to those seen in MDS except that blast cells are not increased, the percentage of dysplastic changes is usually not as high, and megaloblasts are infrequently seen.

Myelodysplastic syndromes are difficult to differentiate from secondary dysmyelopoiesis associated with immune-mediated hemolytic anemia. Both syndromes are characterized by severe nonregenerative anemia and metarubricytosis.[35] Additionally, both syndromes can have autoagglutination present. Several factors are useful in differentiating these conditions. Marked macrocytosis (i.e. MCV > 65 fL) is a useful indicator of RA and RCMD. Additionally, >10% dysplastic changes in bone marrow are more consistent with MDS. Additionally, megaloblastic changes are prominent in MDS but rare in secondary dysmyelopoiesis. Additionally, cats with MDS typically have increased rubriblasts or myeloblasts while cats with secondary dysmyelopoiesis do not. An increased number of small lymphocytes in bone marrow is a consistent finding in IMHA and PRCA.[34]

MYELODYSPLASTIC SYNDROME IN HORSES

Myelodysplastic syndrome has been described in a Quarter Horse.[8] The MDS was characterized by a macrocytic nonregenerative anemia, leukopenia, and thrombocytopenia in the blood and a bone marrow that contained 9% myeloblasts, marked dyserythropoiesis, and increased plasma cells and eosinophils. Dyserythropoiesis was characterized by megaloblastic changes. This case appears to be most consistent with a diagnosis of RAEB.

OVERVIEW OF ACUTE MYELOID LEUKEMIA

Definition and Origin of Disease

Acute myeloid leukemias (AMLs) are a diverse group of non-lymphoid hematologic malignancies that are derived from hematopoietic stem cells. Acute myeloid leukemias are typically classified as originating from one or more of the four myeloid cell lines: granulocytic, monocytic, erythroid and megakaryocytic. Acute myeloid leukemia must be distinguished from other clonal myeloproliferative diseases (MPDs) such as chronic myeloid leukemia (CML; see Chapter 65) and myelodysplastic syndromes (MDSs; see Chapter 66).[8] In part, diagnosis is achieved through the identification of ≥20% blast cells in the patient's bone marrow and/or blood.[2,22,39] Proliferation of these blast cells in patients with AML eventually results in myelophthisis and consequently hematologic manifestation of disease.

In both humans and animals, AML may develop secondary to environmental carcinogens, immunomodulatory drugs, and prior cancer therapies, particularly topoisomerase inhibitors, alkylating agents, and ionizing radiation.[2,3] Alternatively, AML may develop de novo with no historical exposure, or may evolve from pre-existing MDS.[2,3,9,24,39]

Clinical and Laboratory Findings

Animals diagnosed with AML generally show nonspecific clinical signs including lethargy, weakness, anorexia, pyrexia and hepatosplenomegaly. Lymphadenopathy of varying severity may or may not be present. Unique clinical features noted in the horse include, edema of the limbs and ventral abdomen, harsh lung sounds, epistaxis and ulceration of the skin and mucous membranes.[11,25,30,31,33] Less commonly, severe systemic infections, such as aspergillosis, may occur.[4,9]

Common hematologic changes include moderate to severe nonregenerative anemia and thrombocytopenia. Changes in the leukogram are somewhat more variable. In overt cases of leukemia, a marked leukocytosis is often present with numerous circulating blast cells identified. These cases may be complicated by the development of leukostasis, where large numbers of circulating cells sludge within the vasculature of vital organs, particularly the lungs and brain.[5] Occasionally, few or no identifiable blast cells are noted in circulation. In such cases the terms subleukemic leukemia or aleukemic leukemia are applied, and diagnosis hinges on the identification of ≥20% blast cells in bone marrow.

In some cases of AML, light microscopic differentiation from acute lymphoblastic leukemia (ALL) or stage V lymphoma with circulating blast cells may prove challenging if not impossible. When compared to lymphoblasts, blast cells of AML are classically larger in size, have a lower nuclear to cytoplasmic ratio, variable nuclear contours, a more delicate chromatin pattern, more abundant cytoplasm and may contain cytoplasmic vacuoles or few to many fine azurophilic granules.[1,13,23,37] However in some cases of AML, light microscopic differentiation from acute lymphoblastic leukemic (ALL) or stage V lymphoma with circulating blast cells may be impossible. In these instances, cytochemical staining and immunophenotyping are essential tools for definitive diagnosis of AML.

Grossly and histologically, organ involvement in AML may exhibit patterns distinct from those observed in some lymphomas. Splenic enlargement is typically symmetrical and diffuse. Histologically, there may be diffuse filling of the sinuses with neoplastic cells, loss of germinal center architecture and atrophy of periarteriolar lymphoid sheaths. Hepatic involvement is variable and may consist of sinus infiltration with neoplastic cells, centrolobular ischemic degeneration and focal hemorrhagic infarction. Lymph nodes typically exhibit variable degrees of lymphoid atrophy and infiltration of the medullary cords. As phthisis of the marrow progresses, lymph nodes and other organs may be colonized by benign bone marrow precursors in an effort to establish extramedullary hematopoiesis. Care must be taken not to rely solely on patterns of organ involvement, as both AML and ALL can appear similar.[38] Ultimately a multifaceted approach utilizing cytochemical stains, immunophenotyping, histology, and cytogenetic analysis (if available) will provide the most complete and accurate diagnosis.[14,26,27,32,34,41]

COMPARATIVE REVIEW OF THE CLASSIFICATION SCHEME OF MYELOID NEOPLASMS

French-American-British Classification

The French-American-British (FAB) cooperative group first proposed a classification scheme for the diagnosis of leukemia in 1976 (see Chapter 64). The goal of this meeting was to develop a system of classification that would allow for inter-case and inter-hospital comparisons and case prognostication. The proposals generated six sub-classifications of AML (M1–M6) based on a 30% blast count in bone marrow or blood and morphologic and cytochemical findings.[3] Revisions to the criteria for classification of AML were subsequently published in 1985 in order to address imprecision in the original scheme with regard to differentiation of these sub-classifications.[2,13,24,40]

The FAB classification scheme provided a consistent morphological and cytochemical framework for the diagnosis and classification of AML. This framework allowed for identification of specific genetic defects associated with leukemic states. In some instances the morphology of AML classification was able to reliably predict the genetic abnormality. But unfortunately, in many cases, correlations were not identified or were incorrect. These findings led to the realization that there was more genetic diversity among leukemic states than could be predicted by morphology and cytochemistry alone and prompted subsequent revisions by the World Health Organization (WHO).[2,40]

World Health Organization Revisions

In 2001, the WHO proposed revisions to the FAB classification based on concepts derived from clinical and scientific studies (Table 67.1). This reclassification is based on utilization of not only morphologic characteristics, but also incorporation of genetic aberrations, immunophenotypes, and biologic and clinical findings. Combined, these are a better predictor of prognosis than morphology alone.[2,40]

Classification is modified to reflect two main subgroups with differing pathogeneses: AML that develops de novo versus AML that occurs secondary to MDS or cancer therapy. In general, de novo AML is more responsive to chemotherapy, has no association with dysplastic morphologies, is associated with a single, low-risk cytogenetic defect, and has no age predisposition. In contrast, AML that develops secondary to MDS or chemotherapy is generally associated with a poorer prognosis, has multiple, high-risk cytogenetic defects, and is typically diagnosed in older patients.[2,10,14,22,34,40] Current categories of AML in lieu of AML-M numerical classification scheme are as follows: AML with recurrent genetic abnormalities, AML with multi-lineage dysplasia (with or without prior MDS), therapy-related AML and AML not otherwise categorized (AML-NOC). AML with recurrent genetic abnormalities includes four well-defined genetic abnormalities that are

TABLE 67.1 WHO Classification of Acute Myeloid Leukemia

Acute myeloid leukemia with recurrent genetic abnormalities
AML with t(8;21)(q22;q22)
AML with abnormal bone marrow eosinohpils and inv(16)(p13;q22) or t(16;16)(p13q22)
Acute promyelocytic leukemia with t(15;17)(q22;q12)
AML with 11q23 abnormalities
Acute myeloid leukemia with multilineage dysplasia
With prior MDS or MPD
Without prior MDS or MPD but with dysplasia in ≥50% of cells in 2 or more myeloid lineages
AML and MDS; therapy related
Prior alkylating agent or radiation
Prior topoisomerase inhibitor
AML-NOC (not otherwise categorized)
Acute myeloid leukemia, minimally differentiated (AML-M0)
Acute myeloid leukemia without maturation (AML-M1)
Acute myeloid leukemia with differentiation (AML-M2)
Acute myelomonocytic leukemia (AML-M4)
Acute monocytic/blastic leukemia (AML-M5a/b)
Acute erythroid/erythroid predominant leukemia (AML-M6a/b)
Acute megakaryoblastic leukemia (AML-M7)
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis
Myeloid sarcoma

typically associated with de novo AML. Most genetic abnormalities in this group are balanced translocations and inversions. Specifically they are t(8;21)(q22;q22), inv(16)(p13q22), t(15;17)(q22;q12), and abnormalities of 11q23. As additional genetic defects and their behaviors are identified, this sub-category of AML will likely expand, and consequently the category of AML-NOC will likely become smaller.[2,10,14,22,34,40]

Another notable change implemented in the WHO classification guidelines is lowering of the blast threshold from 30% to 20%. This recommendation is based on observations of the biologic behavior of MDS with blast cells in the range 20–29%. In the majority of cases, the disease process followed a similar, aggressive course to that of AML with multi-lineage dysplasia. This has led to the suggestion that the MDS with excess blasts in transformation is actually the same disease process as AML.[2,10 22,40]

Animal Leukemia Study Group Adaptations

In 1991 the Animal Leukemia Study Group (ALSG) sought to determine the applicability of the FAB classification scheme to veterinary patients. Veterinary hematopathologists utilized bone marrow and blood smears from 49 dogs believed to have MPD to adapt the human classification scheme. Subsequently, the 30% marrow or blood blast threshold and phenotypic AML-M classification scheme was adopted along with modifications of certain criteria and the addition of other parameters.[17,23]

Blast cells were redefined to include only type I and II myeloblasts, monoblasts and megakaryoblasts in AML-M1 through M5 and M7. Type III and IV myeloblasts, abnormal promyelocytes and promonocytes were either not recognized or specifically excluded. Because of the high prevalence of disease in feline leukemia virus (FeLV)-positive cats, AML with an erythroid phenotype (AML-M6) was expanded to include features not originally specified in the FAB scheme. Specifically, blast cells for AML-M6 were to be enumerated out of all non-erythroid cells (NECs), rather than all nucleated cells (ANCs).[17,23] Furthermore, AML-M6 was redefined to include a second phenotype, AML-M6Er, in which there is minimal myeloid or monocytoid contribution to the blast cell proliferation. This subtype, also referred to as pure erythroleukemia or erythroleukemia with erythroid predominance, was defined to have ≥30% of ANC as blasts *and* to include rubriblasts, in addition to myeloblasts, in this count. Similar modifications were eventually also introduced into the human classification scheme.[2,17,23,40]

Final additions and revisions included the recognition of acute undifferentiated leukemia (AUL) as a specific entity and recommendations not to separate AML of monocytoid origin into AML-5a (monoblastic) and AML-5b (monocytic) due to poor agreement.[3,17,21,39,23] Acute promyelocytic leukemia (AML-M3) was not recognized in the ALSG case set and criteria for its diagnosis were not included in their recommendations.[3,17,23] To date, spontaneous occurrence AML-M3 has only been recognized in a single pig.[7] Though acute megakaryoblastic leukemia (AML-M7) was not identified in the ALSG case set, criteria for its diagnosis were still included and described in their recommendations.[17,36]

At this time, the veterinary pathology community continues to utilize the AML-M classification system; however, reclassification, as supported by the recent identification of recurrent chromosomal abnormalities in canine leukemia and lymphoma that are similar or identical to those found in the homologous human diseases,[9] will likely be apparent as cytogenetic studies become practical in veterinary patients. Currently, there is no consensus regarding the use of 20% versus 30% blast cells in the bone marrow and/or blood as a cutoff for diagnosis of AML. The impetus for this change in human medicine was that the 20% cutoff better predicted biological or clinical features. Identification of a similar phenomenon in veterinary patients will likely be necessary before an agreement is reached. Tables in this chapter reflect a 20% blast cutoff for diagnosis of AML.

Recommendations for Diagnostic Work-up

Currently, the WHO recommendations for diagnostic evaluation of humans with suspected AML include a 200-cell differential white blood cell (WBC) count and a 500-cell differential count on a bone marrow aspirate stained using either Wright-Giemsa or May-Grünwald-Giemsa procedures. A bone marrow core biopsy also should be evaluated for architectural changes such as myelofibrosis, and for evaluation of focal hematopoietic disease. Panels of histochemical and cytochemical stains should be employed for confirmation of the origin of

blast cells. Finally, cytogenetic analysis is also an essential component of the diagnostic evaluation for AML.[2,22,40] With the exception of genetic analysis, the preceding recommendations are readily available for characterization of AML in veterinary species.

DIAGNOSIS OF ACUTE MYELOID LEUKEMIA

Nomenclature and Terminology

The cell types that give rise to AML, as well as the cytochemical stains and the immunologic markers used to define the maturation stages in the myeloid lineages are described in Chapters 132 and 144. The terminology used to describe AMLs in the literature is inconsistent and can be confusing. The following definitions are provided to clarify communication and case comparison in both the clinical and research settings.

The proper umbrella term for acute non-lymphoid leukemias (granulocytic, monocytic, megakaryocytic and erythroid) is acute myeloid leukemia (AML), rather than acute myeloblastic leukemia. The term *myeloblastic* should be reserved for specific subtypes of leukemia (M0, M1 and M2), where immature blast forms predominate.[2,23,40] The term *maturation* refers to morphologic changes that imply development of cellular functions. In leukemias with *maturation*, variable percentages of nucleated cells exhibit development beyond the blast stage (i.e. promyelocyte, myelocyte and metamyelocyte). These include AML-M2 through AML-M7.[2,23,40] The term *differentiation* implies commitment to a specific lineage (i.e. granulocytic, monocytic, megakaryocytic, erythroid or lymphoid). In *undifferentiated* leukemia, cells lack ultrastructural, morphologic, and cytochemical features that allow lineage designation. Therefore, in acute undifferentiated leukemia (AUL) lymphoid versus myeloid origin cannot be determined. In leukemias with *minimal differentiation*, early lineage commitment is evident only with the use of immunophenotyping and/or electron microscopy.[2,17,23,40] Traditionally, the term *blast* has been used to refer to the most immature or primitive cell within a certain lineage. However, the definition of a *blast* is expanded for the diagnosis of AML in human medicine. Precisely what constitutes a *blast* depends to some extent on the ultimate diagnosis. Blast counts are typically determined as a percentage of ANCs in the bone marrow with the exception of lymphocytes, plasma cells, mast cells, macrophages and cells involved in another hematopoietic neoplasm. Myeloblasts are always counted as part of the blast cell percentage in AML, with some other cells counted as blast equivalents. These equivalents include monoblasts in acute monocytic leukemia (AML-M5), monoblasts and promonocytes in acute myelomonocytic leukemia (AML-M4), abnormal promyelocytes in acute promyleocytic leukemia (AML-M3) and megakaryoblasts in acute megakaryoblastic leukemia (AML-M7). There is a slight paradigm shift for the erythroleukemias in veterinary medicine. In acute erythroleukemia (AML-M6a), blasts are counted as a percentage of non-erythroid cells (NEC) rather than as a percentage of ANCs, and in acute erythroleukemia with erythroid predominance (AML-M6b) erythroblasts are included as part of the blast count, in addition to myeloblasts (Table 67.2).[2,17,23,40]

Subtypes of Acute Myeloid Leukemia in Veterinary Medicine

Acute Undifferentiated Leukemia (AUL)

Acute undifferentiated leukemia represents a leukemic process in which the predominant cell is so immature it cannot be identified as being of either myeloid or lymphoid origin. Cells lack all identifiable morphologic, ultrastructural, immunologic, and cytochemical markers, thus precluding lineage assignment. Blast cells have a nondescript appearance and may have eccentric nuclei, prominent nucleoli, moderately basophilic cytoplasm, pseudopodia, and occasionally a few fine granules. Importantly, AUL blast cells are negative for traditional immunophenotypic markers with the exception of CD34, identifying them only as being of hematopoietic origin. In humans, AUL is associated with a poor prognosis.[13,17,21,37,38,39]

Acute Myeloblastic Leukemia (AML-M0, M1, M2)

Acute myeloblastic leukemia may be divided into three subtypes: acute myeloblastic leukemia, minimally differentiated (AML-M0), acute myeloblastic leukemia without maturation (AML-M1), and acute myeloblastic leukemia with maturation (AML-M2). In all acute myeloblastic leukemias, myeloblasts comprise ≥20% of ANCs, though blast percentages are typically much higher and may approach 100%.[13,17,37,38]

While nonregenerative anemia and thrombocytopenia are common, WBC counts are variable and may be elevated, normal, or decreased. However, because of impaired maturation, neutrophil counts are frequently low.[37,38]

AML-M0 is characterized by the presence of immature type I myeloblasts in the bone marrow and blood. These type I myeloblasts lack microscopically identifiable primary granules; thus this neoplasm cannot be distinguished from acute lymphocytic leukemia (ALL) by light microscopy. Furthermore, fewer than 3% of blast cells stain positively for myeloperoxidase (MPO), Sudan Black B (SBB) and/or chloroacetate esterase (CAE). Ultrastructural demonstration of MPO-positive granules is necessary for confirmation of myeloid lineage. Additionally, >20% of blasts should express surface markers consistent with myeloid lineage (CD13, CD33). A normal or mildly elevated leukocyte count is typically present in these patients.[13,17,37,38]

AML-M1 is distinguished from AML-M0 by the presence of >3% myeloblasts staining positive for MPO, SBB and/or CAE. Fewer than 10% of bone marrow cells exhibit maturation to the promyelocyte stage and beyond. Additionally, fewer than 10% of myeloblasts

TABLE 67.2 Diagnostic Criteria for Acute Myeloid Leukemia Veterinary Medicine

Acute undifferentiated leukemia (AUL)
- >20% (typically close to 100%) of ANCs are immature blasts
- Blast cells lack all morphologic, ultrastructural, cytochemical, and immunologic markers
- May be CD34 positive, indicating lympho-hematopoietic origin

Acute myeloblastic leukemia, minimally differentiated (AML-M0)
- >20% (often higher or close to 100%) of all ANCs are myeloblasts
- <3% of blasts stain positively for MPO, SBB or CAE
- >20% of blasts express one or more myeloid antigens (CD13, CD33)
- Myeloid lineage confirmed by ultrasturctural demonstration of MPO positive granules
- Negative for lymphoid antigens

Acute myeloblastic leukemia without maturation (AML-M1)
- >20% (often higher or close to 100%) of ANCs are myeloblasts
- >3% of blasts stain positively for MPO, SBB or CAE
- <10% of ANCs exhibit granulocytic differentiation to promyelocyte and beyond

Acute myeloblastic leukemia with maturation (AML-M2)
- >20% of ANCs are myeloblasts
- >3% of blasts stain positively for MPO, SBB or CAE
- >10% of ANCs exhibit granulocytic differentiation to promyelocyte and beyond
- <20% of ANCs exhibit monocytic differentiation
- +/– dysplasia in granulocytic lineage

Acute promyelocytic leukemia (AML-M3)
- Now classified under AML with recurrent cytogenetic abnormalities t(15;17)(q21;q22)
- >20% of ANCs are myeloblasts and abnormal promyelocytes
- Strongly positive with MPO/SBB; positive with CAE
- Hyper and hypo/microgranular variants are recognized
- Hypergranular variant is associated with Auer rods
- Extremely rare in veterinary species; typically hypogranular

Acute myelomonocytic leukemia (AML-M4)
- >20% of ANCs are myeloblasts, monoblasts and promonocytes
- >20% of ANCs are maturing granulocyte lineage (MPO/SBB positive)
- >20% of ANCs are maturing monocyte lineage (CD14 positive and NSE positive/negative with fluoride inhibition)
- M4-Eo variant in humans with evidence of eosinophilic differentiation

Acute monoblastic leukemia (AML-M5a)
- >80% of ANCs are monocytic origin with at least 20% myeloblasts, monoblasts and promonocytes
- >50% of monocytic cells are monoblasts
- Strongly NSE positive/negative with fluoride inhibition, CD14 positive
- MPO/SBB negative

Acute monocytic leukemia (AML-M5b)
- >80% of ANCs are monocytic origin with at least 20% myeloblasts, monoblasts and promonocytes
- >50% of monocytic cells are promonocytes
- Strongly NSE positive/negative with fluoride inhibition; CD14 positive
- MPO/SBB negative

Acute erythroleukemia (AML-M6a)
- >50% of ANCs are erythroid origin
- May have left shifting and dysplasia of the erythroid lineage
- >20% of NECs are myeloblasts
- Most common type of erythroleukemia in humans

Acute erythroleukemia with erythroid predominance (AML-M6b / Pure erythroleukemia)
- >50% of ANCs are erythroid origin
- May have left shifting and dysplasia of the erythroid lineage
- >20% of ANCs are myeloblasts or rubriblasts
- Most common type of erythroleukemia in veterinary species

Acute megakaryoblastic leukemia (AML-M7)
- >20% of ANCs are blasts
- >50% of blast cells are megakaryoblasts
- Megakaryoblasts are CD41/61 positive and stain with acetylcholinesterase, ANAE and PAS
- Marrows are often severely sclerotic and dry tap may result

exhibit primary cytoplasmic granulation (type I and some type II myeloblasts). Though this granulation allows for distinction from ALL, cytochemical and immunologic markers may still be necessary for accurate identification. A normal or mildly elevated leukocyte count is typically present in these patients.[13,17,37,38]

AML-M2 is distinguished from AML-M1 by the presence of ≥10% of bone marrow cells maturing to the promyelocyte stage and beyond. Primary cytoplasmic granulation is common and prominent due to the presence of many type II and III myeloblasts (though the latter were not identified or characterized by the ALSG). To distinguish AML-M2 from AMLs with a monocytic component, <20% of ANCs in bone marrow should exhibit monocytic differentiation. Additionally, >3% of blasts stain positively for MPO and/or SBB. Thrombocytopenia and nonregenerative anemia are typically present. A leukocytosis of up to 50,000 WBC/μL, including type I, II, and III myeloblasts, promyelocytes, and rare myelocytes is also commonly noted.[13,17,37,38]

Acute Promyelocytic Leukemia (AML-M3)

Acute promeylocytic leukemia (AML-M3) is characterized by the presence of atypical promyelocytes in bone marrow or blood. As in other types of AML, the blast percentage must comprise ≥20% of ANCs; however, in AML-M3, both myeloblasts and atypical promyelocytes are included in the blast percentage. In humans, these atypical promyelocytes often outnumber the myeloblasts and have two distinct microscopic appearances: the more common hypergranular variant, and the less common micro- or hypogranular variant. The hypergranular variant typically presents with anemia, thrombocytopenia, and leukopenia due to myelophthisis. The hypogranular variant is reported to present with a marked leukocytosis of approximately 50,000/μL, consisting predominantly of abnormal promyelocytes. Coagulopathies may be noted at the time of presentation or may develop after initiation of therapy. Diagnosis may be confirmed with positive staining for SBB, MPO and CAE.[13,17,37,38]

In humans, AML-M3 has been reclassified as AML with a recurrent genetic abnormality as it is associated with the chromosomal translocation t(15;17)(q22;q11-12). This results in the fusion of the retinoic receptor-alpha (RARA) gene with the zinc finger binding transcription factor, also known as the promyelocytic leukemia (PML) gene. This fusion product is known as PML-RARA. It results in impaired maturation and uncontrolled proliferation including down-regulation of repressor genes through limited hypermethylation, heterochromatin formation, and gene silencing. This unique pathogenesis allows for highly effective targeted therapy using alltrans-retinoic acid (ATRA) resulting in durable remission by stimulating differentiation of the neoplastic clones.[2,40,18,19]

AML-M3 is a rare condition in animals that to date has only been reported in the literature in a single boar and as a transgenic mouse model.[7,19] Peer reviewed case reports do not yet exist in dogs, cats, horses, cattle or sheep. Anecdotal reports suggest the hypogranular variant is more common in domestic animals, possibly presenting with signs referable to a coagulopathy. The severity of clinical disease due to pancytopenia and coagulopathy may hinder a full diagnostic evaluation and contribute to the apparent rarity of this condition.[37,38]

Acute Myelomonocytic Leukemia (AML-M4)

In acute myelomonocytic leukemia (AML-M4), leukemic cells appear to be of mixed lineage (Fig. 67.1). Three criteria must be met in the bone marrow to achieve a diagnosis of AML-4: ≥20% of ANCs must be blast cells, including myeloblasts, monoblasts and promonocytes; ≥20% of ANCs must be of monocytic lineage (CD14+, nonspecific esterase [NSE]-positive that is sensitive to fluoride inhibition); and ≥20% of ANCs must be of granulocytic lineage (SBB/MPO positive).[13,15,17,37,38]

Acute Monocytic Leukemia (AML-M5)

Acute leukemias of the monocytic lineage may be divided to the more immature acute monoblastic leukemia (AML-M5a) and the more mature acute monocytic leukemia (AML-M5b). Both subtypes are characterized by ≥80% of ANCs being of monocytic origin, and ≥20% of ANCs being myeloblasts, monoblasts, or promonocytes (Fig. 67.2). However, in AML-M5a ≥50% of all monocytic cells are monoblasts, whereas in AML-M5b ≥50% of all monocytic cells are promonocytes.[2,17,37,38,40] The ALSG did not recommend separating these AML-M5 subtypes because there was poor diagnostic agreement among the group pathologists due to the complexity of cellular identification.[17] Confirmation of monocytic lineage is achieved by demonstrating expression of CD14, and/or fluoride-sensitive NSE. Reportedly,

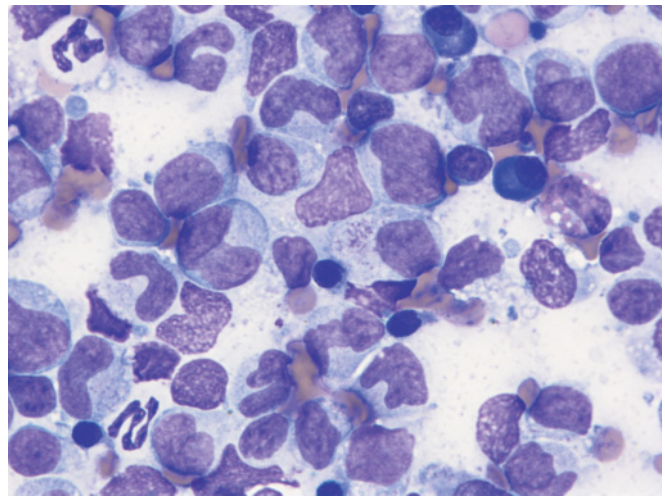

FIGURE 67.1 Acute myelomonocytic leukemia (AML-M4) in bone marrow from a dog. Notice infiltration of >20% blast cells with apparent granulocytic and monocytic differentiation but with maturation arrest evident by the paucity of mature forms. Note primary granules in myeloblast near the center of the image. Wright-Giemsa stain; original magnification ×1,000.

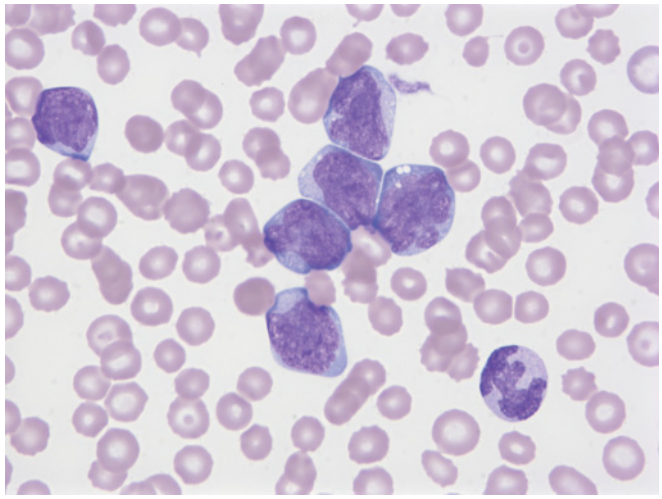

FIGURE 67.2 Acute monoblastic leukemia (AML-M5) in blood smear from a dog. Notice a population of monomorphic blast cells with large convoluted nuclei, lacy to finely stippled chromatin, and moderate to abundant vacuolated, basophilic cytoplasm. The cells resemble monocytic progenitors with no visible cytoplasmic granules. Wright-Giemsa stain; original magnification ×1,000.

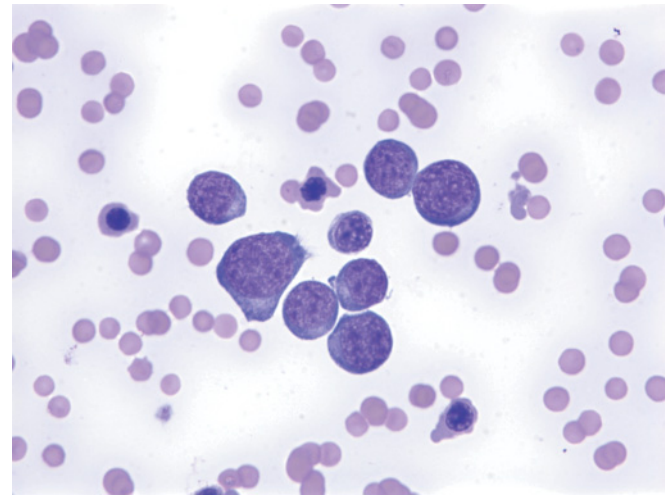

FIGURE 67.3 Erythroleukemia (AML-M6b) in blood smear from a cat. Notice a slightly pleomorphic population of cells that resemble erythroid progenitors, including erythroblasts, prorubricytes, rubricytes, and metarubricytes. There is apparent asynchronous maturation of these cells, and there are fewer than expected mature RBCs, WBC, and platelets. Wright-Giemsa stain; original magnification ×1,000.

AML-M5a is more common in young animals, whereas AML-M5b is more common in mature and older animals. Leukocyte counts vary from <25,000/µL in the early stages of disease, to >50,000/µL terminally.[13,17,37,38]

Acute Erythroleukemia (AML-M6)

The acute erythroleukemias are characterized by the presence of greater than 50% erythroid precursors in the bone marrow and can be further divided into two groups based on the blast composition (Fig. 67.3). In acute erythroleukemia (AML-M6a) there is myeloblastic predominance and ≥20% of all NECs in the bone marrow are myeloblasts. AML-M6a is the type of erythroleukemia most commonly observed in human patients. In contrast, acute erythroleukemia with erythroid predominance (AML-M6b) is characterized by a prominent rubriblastic component. In AML-M6b, ≥20% of ANCs in the marrow are myeloblasts and rubriblasts. AML-M6b is the type of erythroleukemia most commonly observed in veterinary patients, with many cases occurring in FeLV-positive cats during the FeLV epidemic (see Chapter 62). In both subtypes of AML-M6, left shifting and dysplasia of the erythroid lineage may be evident. The total nucleated cell count in the blood is commonly elevated, sometimes markedly, and may contain blast cells of the erythroid and myeloid lineage as well as other dysplastic erythroid precursor cells.[2,12,13,16,17,28,37,38,40]

Acute Megakaryoblastic Leukemia (AML-M7)

Like other types of AML, acute megakaryoblastic leukemia (AML-M7) is diagnosed on the basis of ≥20% blast cells in bone marrow. At least 50% of the blast cells must be megakaryoblasts. While features such as cytoplasmic blebbing, increased amounts of cytoplasm, and binucleation or multinucleation may be observed in megakaryoblasts, immunologic markers and cytochemical stains are essential for lineage determination. Though nonspecific, megakaryoblasts will often stain positive for acetylcholinesterase (AChE), periodic acid Schiff (PAS), and alpha-naphthylacetate esterase (ANAE) on cytochemistry.[2,13,20,37,38,40] Expression of CD41, which represent the glycoprotein (Gp) IIb and GpIIIa subunits (i.e. platelet integrin receptor for fibrinogen and factor VIII-related antigen) are considered the most specific lineage identifiers.[36] Additional features that may be observed in AML-M7 include thrombocytopenia and sclerotic bone marrow, which may make obtaining a bone marrow aspirate difficult.[37,38]

Species specific Information

All AML subtypes have been reported in veterinary species. As mentioned previously, published reports of AML-M3 only exist in a boar and a transgenic mouse model, but its occurrence cannot be excluded in other veterinary species.[7,19] The most commonly reported myeloid leukemias in the dog and cat appear to be the acute myeloid, myelomonocytic, and monocytic leukemias.[13,17,37,38] Erythroleukemia has been reported in both the dog and cat; however, reports and incidence in cats were more frequent before the FeLV epidemic was controlled. Acute myelomonocytic leukemia is believed to be the most common myeloid leukemia in horses.[5,9,25,31] Sporadic reports of AML in other mammalian species exist, including a recent report of AML with multilineage dysplasia in an alpaca.[35] Finally, retroviral induced

AML has been reported in poultry, primarily in conjunction with the avian leukosis/sarcoma virus (see Chapter 62). Myeloid leukosis in poultry has recently been attributed to the newly identified J envelope subgroup of the slowly transforming ALSVs.[29]

FUTURE DIRECTIONS IN VETERINARY MEDICINE

Complete immunophenotypic, cytochemical, and (rarely) ultrastructural characterization of all leukemic processes are necessary to determine the true incidence of AML in veterinary species. Other modalities that may allow for more precise and detailed characterization include cytogenetics, gene expression and microRNA profiling, proteomics, and stem cell biology (see Chapters 3 and 148). Additionally, recent studies have identified evolutionarily conserved chromosomal aberrations that link several canine hematologic malignancies in dogs to their human counterparts. These findings imply that the neoplasms are pathologically comparable and suggest that cellular and molecular analysis of canine leukemias may allow for improved characterization, classification, prognostication, and treatment.[6,23]

Equine Mast Cell Tumors

Acronyms and Abbreviations

AgNORs, agryophilic nucleolar staining organizing regions; CBC, complete blood count; GI, gastrointestinal; ITD, internal tandem duplication; MCT, mast cell tumor; MI, mitotic index; PCNA, proliferating cell nuclear antigen.

MAST CELL TUMOR IN THE DOG

Incidence, Signalment, Etiology

The mast cell tumor (MCT) is the most frequent skin tumor of the dog, and the second most frequent malignant tumor noted in the canine population. While MCTs are usually found in older dogs (mean age 8–9 years), they have also been reported in younger dogs and there is no apparent sex predilection. Several breeds appear to be at risk for the development of MCT including dogs of bulldog decent (boxer, Boston terrier, English bulldog, pug), Labrador and golden retrievers, cocker spaniels, Schnauzers, Staffordshire terriers, Beagles, Rhodesian ridgebacks, Weimeraners, and Sharpeis.[34] The etiopathogenesis of MCTs in the dog is unknown. The increased incidence of MCTs in certain breeds suggests the possibility of an underlying genetic cause and studies are ongoing to identify putative genetic risk factors. Interestingly, while dogs of bulldog ancestry are at higher risk for MCT development, it is generally accepted that MCTs in these dogs are more likely to be benign. Pugs develop multiple mast cell tumors that behave in a benign fashion.[29] In contrast, anecdotal evidence suggests that Sharpeis develop MCTs that are biologically aggressive.

Several authors have recently identified the presence of Kit mutations in dog MCTs and these result in uncontrolled signaling.[10,22,25,50] In the majority of affected dogs, the Kit mutations consist of internal tandem duplications (ITDs) in the juxtamembrane domain of Kit (encoded by exons 11–12). This region of Kit is

responsible for negatively regulating receptor activation and evidence suggests that the ITDs disrupt the structure of this domain, resulting in a loss of this function. Up to 30% of all dog MCTs may carry Kit mutations and these have been shown to be significantly associated with tumor grade: mutations are rarely identified in well-differentiated tumors while approximately 35% of poorly differentiated tumors carry an ITD.[10,51] The Kit mutations are not germ-line in nature (i.e. are not inherited) and, therefore are not responsible for the observed breed predispositions to the development of MCTs. However, they do represent a target for therapy.

History and Clinical Signs

Most MCTs in the dog occur in the dermis and subcutaneous tissue.[2] However, primary MCTs may present in other sites such as the oral cavity, nasopharynx, larynx, and gastrointestinal (GI) tract.[35] Visceral MCT, involving the spleen, liver, and/or bone marrow (often referred to as disseminated mastocytosis), is usually the result of systemic spread of an aggressive primary cutaneous MCT, although it can occur as an independent syndrome.[37] Cutaneous MCTs usually occur as solitary nodules, although roughly 10% to 15% of dogs will present with multiple tumors.[16] Approximately 50% of cutaneous MCTs occur on the trunk and perineal region, 40% on limbs, and 10% on head and neck.[16] Perhaps most importantly, the clinical appearance of MCTs can vary widely and can resemble many other neoplastic and non-neoplastic lesions. Mast cell tumors that arise in subcutaneous tissue are frequently poorly circumscribed and may resemble lipomas, sometimes delaying diagnosis. In general, MCTs that are slow growing and present for at least 6 months are more likely to behave in a benign manner, while those that are rapidly growing large tumors are more likely to behave in a malignant manner.[2]

Clinical signs of MCTs are largely due to release of histamine, heparin and other vasoactive amines. Mechanical manipulation of the tumor during physical examination can induce degranulation leading to erythema and wheal formation (termed Darrier's sign) and occasionally, an owner will report that the tumor appears to change in size over short periods of time. Gastrointestinal ulceration is also a potential complication of MCTs; between 35% and 83% of dogs with MCTs that underwent necropsy had evidence of gastric ulcers, and plasma histamine concentrations were found to be elevated in dogs with MCT.[17] Elevated histamine levels presumably lead to stimulation of H2 receptors on parietal cells, excessive gastric acid production, and development of ulcers.

Diagnosis

Cytologic evaluation of fine needle aspirates is probably the easiest method to diagnose MCT. Poorly differentiated malignant mast cells may contain few, if any, granules in which case special stains (toluidine blue, Giemsa) may be necessary to observe granules. However, excisional biopsy is required for actual histologic grading of the tumor. If cytologic diagnosis proves difficult, a needle or punch biopsy of the tumor can be obtained before surgery. This is preferable to a larger incisional biopsy, because local release of mast cell mediators may inhibit healing, resulting in excessive bleeding.

Staging

CBC, Biochemistry Profile, Urinalysis

Dogs with MCTs may be anemic due to gastrointestinal bleeding.

Buffy Coat Smear

It was originally believed that while the buffy coat smear was not a sensitive test, it was specific for mast cell neoplasia. However, it is now clear that this is not the case, because dogs with many different kinds of disease, including pneumonia, parvovirus, pancreatitis, skin disease and GI diseases may have mast cells circulating in the blood. Therefore, this test is no longer routinely performed in the staging of MCT patients.

Bone Marrow Aspiration

In the normal bone marrow, mast cells are found infrequently. In a recent report evaluating 157 dogs with MCTs, the incidence of bone marrow infiltration at initial staging was only 2.8%.[11] While the presence of bone marrow involvement is indicative of systemic mast cell disease, it is usually easier to find evidence of systemic involvement in other organs (liver, spleen). Therefore, routine bone marrow aspiration is not recommended for most MCT patients.

Lymph Node Aspiration

All regional lymph nodes should be examined for signs of enlargement and suspicious nodes should be aspirated for cytologic examination. Because metastatic nodes may palpate within normal size, it is recommended that all accessible regional lymph nodes be aspirated. If necessary, ultrasound can be used to localize lymph nodes for aspiration. Malignant mast cells in metastatic lymph nodes are frequently found in clusters/aggregates rather than singly, aiding in a diagnosis of metastasis. If possible, lymph node aspiration should be performed before surgery, because post-operative inflammation can result in mast cell migration to local nodes and thus confuse the interpretation.

Evaluation of the Abdominal and Thoracic Cavities

Thoracic radiographs may be included as part of staging, although pulmonary involvement is uncommon. Abnormalities reported include lymphadenopathy (sternal, hilar), pleural effusion, and anterior mediastinal masses, although these are rare. Evaluation of the

TABLE 68.1 Proposed Clinical Staging for Canine Dermal Mast Cell Tumors

Stage	Tumor(s)	Regional LN	Metastasis
IA	1 tumor, confined to skin, <3 cm, well circumscribed	Negative	Negative
IB	>1 tumor, confined to skin, <3 cm, well circumscribed, interlesional distance >10 cm	Negative	Negative

III	Any	Positive	Negative
IV	Any	Any	Positive

A, without clinical signs; B, with clinical signs.

abdominal cavity is important in dogs with MCTs, as spread to the liver and spleen and abdominal lymph nodes may be noted. It is recommended that fine needle aspiration of the liver and spleen be performed if abnormalities are detected during ultrasound examination, or if the dog possesses negative prognostic indicators (i.e. rapidly growing tumor or evidence of lymph node metastasis.[15] For typical uncomplicated solitary MCTs, cytologic evaluation of an ultrasonographically normal liver or spleen was not found to be a clinically useful staging tool.

Clinical Staging System for Canine MCTs

Based on recent clinical studies, a revised staging system for dermal MCTs has been proposed (Table 68.1).

Prognostic Factors

Histologic Grade

The histologic grade of a MCT is determined after excisional biopsy of the tumor. It is the most consistent and reliable prognostic factor and correlates significantly with survival, but it will not predict the behavior of every MCT. Furthermore, there is disagreement about tumor grading among pathologists; in one study there was significant variation among pathologists in grading the MCTs ($P < 0.001$), although this was found to be less so if all pathologists strictly employed the system described by Patnaik.[34,35]

Grade 1: These MCTs are considered to behave in benign manner and complete surgical excision is usually curative.[2,34]

Grade 2: These represent at least 45% of all MCTs reported and their biologic behavior is more difficult to predict.[2,16,34] Many dogs are cured with complete excision of a Grade 2 MCT, and radiation therapy following incomplete excision of solitary Grade 2 MCTs can cure more than 80% of affected patients.[36] However, it is important to note that Grade 2 MCTs have the ability to spread to local lymph nodes, as well as distant sites, and a proportion of dogs that undergo definitive therapy (surgery and radiation) may go on to develop metastatic disease. Furthermore, some dogs that present with Grade 2 MCTs will already have evidence of metastatic disease making appropriate staging important. Given the wide variation in biologic behavior among Grade 2 tumors, there is now an effort to identify subcategories of Grade 2 tumors using additional prognostic indicators described below.

Grade 3: These represent between 20% and 40% of all MCT reported.[2,16,34] They often behave in a biologically aggressive manner, exhibiting metastasis early on in the course of disease. The mean survival time of dogs with Grade 3 MCT has been reported as 18 weeks when treated with surgery alone.[2] In one study, the percentage of dogs with Grade 3 MCTs surviving at 1500 days was reported as 6%, and in another study, the percentage of dogs surviving at 24 months was 7%, indicating that these tumors are particularly malignant.[34] With the recent addition of post-operative chemotherapy, survival times of Grade 3 MCT patients may be improved. Lastly, evidence suggests that radiation therapy of incompletely excised Grade 3 MCTs can result in prolonged tumor control (median disease free interval of 27.7 months).[14]

Clinical Stage

Recent evidence suggests that the historical staging system for MCTs is not reflective of tumor biology, and a new system has been proposed (Table 68.1). In two studies, the presence of mast cells in the regional lymph node was a negative prognostic factor for survival and disease-free interval.[20] However, an additional study revealed that dogs with Grade 2 tumors and lymph node metastasis treated with radiation post-surgery achieved long-term survival.[8] Other studies have shown that dogs with Grade 2 MCTs with lymph node metastasis may have a good prognosis if the affected lymph node is removed and adjuvant chemotherapy is administered.[6,46] Lastly, while it would seem intuitive that dogs with multiple cutaneous MCTs would experience a worse outcome compared to dogs presenting with a solitary MCT, two separate studies have demonstrated that the presence of multiple tumors does not affect prognosis.[32]

Anatomic Location

MCTs that develop in the oral cavity, nail bed, inguinal, preputial, and perineal regions were originally reported to behave in a more malignant fashion regardless of histologic grade.[13] Two reports now demonstrate that at least for MCTs in the inguinal, preputial, and perineal regions this is probably not true.[5] However, MCTs located in the muzzle are biologically aggressive tumors with higher regional metastatic rates than previously reported for MCT in other sites.[13] MCTs that originate in the viscera (GI tract, liver, spleen) or bone marrow have a grave prognosis.[45]

Growth Rate

Tumors present for long periods of time are more likely to be benign. In one study, 83% of dogs with tumors present for longer than 28 weeks before surgery survived for at least 30 weeks, compared to only 25% of dogs with tumors present for less than 28 weeks.[2]

Breed

Boxer and pug dogs have a high incidence of MCTs, but these tend to be more well differentiated and carry a better prognosis.[2,29] However, every MCT should be treated as potentially malignant, regardless of breed.

Markers of Proliferation

Several proliferative indices have been evaluated in an attempt to predict the outcome of canine MCTs. Perhaps the most useful is Ki-67, a protein found in the nucleus, the levels of which appear to correlate with cell proliferation. In one study, the mean number of Ki-67 positive nuclei was significantly higher for dogs that died of MCTs than for those that survived. For dogs with Grade 2 tumors, the number of Ki-67 positive nuclei was significantly associated with outcome. This was recently confirmed by an additional study that demonstrated the Ki-67 score can be used to divide Grade 2 MCTs into two groups with markedly different expected survival times.[42] A recent study showed that mitotic index (MI, number of mitoses per 10 high-power fields) may be useful for predicting the biologic behavior of canine MCTs.[41] When dogs presenting with metastatic disease were excluded from analysis, those with tumors possessing a MI ≤ 5 had a median survival time of 80 months, compared to 3 months for those possessing a MI > 5, suggesting that MI is a strong predictor of overall survival for dogs with MCTs. Other proliferation markers such as assessment of agryophilic nucleolar staining organizing regions (AgNORs) and PCNA have been used to try to determine biologic behavior of MCTs, although these may not be as reliable.[3] One study sought to establish a new grading scheme for MCTs using Kit immunohistochemical staining patterns as an indicator of tumor aggressiveness but it did not correlate well with survival time.[49] Lastly, investigators attempted to correlate histologic grading of mast cell tumors with a combined Ki67/PCNA/AgNOR/Kit immunohistochemical scoring.[1] No significant correlation was found for Kit staining and MCT grade, but high Ki67/PCNA/AgNOR scores all positively correlated with tumor grade (i.e. higher scores for higher grade). This study suggests that proliferation indices increase with increasing grade and are ultimately reflected in the eventual biologic behavior of the tumor.

Kit Mutations

As previously mentioned, mutations in Kit have been found in canine MCTs and research suggests they are associated with an increased risk of local recurrence, metastasis, and death of affected dogs.[10,51]

TABLE 68.2 Schematic for Treatment of Canine Mast Cell Tumors

Grade I	
Complete	No further therapy
Incomplete	Wider excision or radiation therapy if surgery not possible; may consider no further therapy
Grade II	
Complete	Chemotherapy only if negative prognostic factors present
Incomplete	Wider excision or radiation therapy if surgery not possible; may consider no further therapy if there are no negative prognostic indicators; chemotherapy if negative prognostic factors present
Grade III	
Complete	Chemotherapy
Incomplete	Chemotherapy +/– radiation therapy

Treatment

See Table 68.2.

Surgery

Historically, it has been recommended that the margins need to be at least 3 cm in each direction; deep margins are as important as the lateral margins. Recent studies demonstrated that all Grade 1 MCTs were completely excised with 1 cm of normal tissue around the MCT (lateral margins) and one fascial plane included in the excision (deep margin).[5,26,44] With respect to Grade 2 MCTs in both studies, 75% and 68% were completely excised with a 1 cm lateral margin and one fascial plane deep, while 100% and 89% of Grade 2 MCT were completely excised with a 2 cm lateral margin and one fascial plane deep. Neither of the studies evaluated Grade 3 MCTs. Because tumor grade is usually not known prior to surgery, it appears prudent to still recommend a 3 cm lateral margin and one fascial plane for the deep margin when feasible. All of the excised tissue should be submitted and margins should be labeled so the pathologist is able to specifically identify any areas of incomplete excision. However, even histologically clean margins do not guarantee that a tumor will not recur. In one study, 83% of dogs with Grade 1 MCT, 44% of dogs with Grade 2 MCT, and 6% of dogs with Grade 3 MCT were alive 1500 days after surgical excision.[34] A proportion of Grade 2 tumors that are incompletely excised will not recur post surgery. In a recent report, the estimated proportions of Grade 2 tumors that recurred locally at 1, 2, and 5 years were 17.3%, 22.1%, and 33.3% respectively.[43] Eleven (39.3%) dogs developed MCT at other cutaneous locations and median overall survival was 1426 days.

Radiation Therapy

Substantial data suggest that radiation therapy is effective in eliminating remaining microscopic disease after incomplete excision of Grades 1 and 2 MCT (greater than 90% 3 year control rate).[20,36] Radiation therapy also was found to be useful for dogs with MCTs metastatic to local lymph node. In this report, administration of radiation to the incompletely excised tumor and to affected lymph node resulted in a median disease-free survival of 1240 days.[8] With respect to incompletely excised Grade 3 tumors, evidence suggests that radiation therapy can result in prolonged tumor control (median disease free interval of 27.7 months) although dogs with tumors greater than 3 cm before surgery did not fare as well.[14] It is likely that multi-modality therapy (i.e. combining surgery, radiation, and chemotherapy) would enhance this observed survival time. Radiation therapy has also been used to treat solid MCTs when surgery is not an option. Varying degrees of success have been found; in one study, a 60% 1-year control rate was obtained in dogs with non-resectable Grades 1–3 MCTs on the head or limb treated with prednisone and radiation. Coarse fractionated radiation has been used to treat dogs with non-resectable bulky, high grade MCTs, although it is important to note that systemic effects of degranulation following radiation may lead to vomiting, hypotension, and death.

Chemotherapy

The use of adjuvant chemotherapy is indicated after excision of Grade 3 MCTs, metastatic MCTs, non-resectable high-grade tumors, or for any other MCT with negative prognostic indices. While radiation therapy is the treatment of choice for incompletely excised Grades 1 and 2 MCTs, data indicate that post-operative chemotherapy may prevent local recurrence and, therefore should be considered for patients who are not candidates for radiation, if such therapy is not available or if the owners cannot afford the cost of therapy.

Corticosteroids The reported response rate of canine MCT to prednisone is 20–70%, although the study demonstrating the highest response rate was of short duration (median 10 days) precluding assessment of response durability.[27] Partial remissions are more common than complete remissions, and at least some of the observed response may be due to a decrease in tumor-associated edema secondary to stabilization of mast cell granules and a reduction in mast cell mediator production.

CCNU (Lomustine) In one study, 8 out of 19 dogs (42%) with measurable MCTs had an objective response to single agent CCNU for a median duration of 77 days.[38] Preliminary unpublished data suggest that CCNU given post-surgery, either alone or with prednisone and vinblastine, can significantly prolong survival times of dogs with high grade tumors or tumors with negative prognostic indicators. CCNU can induce hematopoietic and hepatic toxicity including neutropenia, thrombocytopenia, and liver failure. Patients receiving this drug should be monitored closely. In general, CCNU is dosed at 50–70 mg/m^2 orally every 3–4 weeks. A complete blood count (CBC) and liver panel should be performed before each dose.

Vinca Alkaloids Single agent response rates of vincristine, vinblastine and vinorelbine are 7%, 12% and 13%, respectively, suggesting that vinca alkaloids are not effective as sole agents for the treatment of MCTs.[27] Vinblastine has been combined with prednisone in other studies, inducing objective responses ranging from 27% to 47%.[46] A combination of vinblastine, cyclophosphamide and prednisone resulted in a 64% (7 out of 11) response rate in one study.[6] The dose of vinblastine is 2–3 mg/m^2 given intravenously every 1–3 weeks. The major toxicity of this drug is neutropenia (in approximately 5–6% of patients) and occasional gastrointestinal upsets. It is frequently used in an alternating manner with CCNU.

Kit Inhibitors Orally bioavailable small molecule inhibitors of Kit (SU11654 [Palladia] and AB1010 [Kinavet]) have recently been demonstrated to have activity against canine MCT.[22,23,24] In a placebo-controlled randomized study, response rate in Palladia-treated dogs was 37.2% versus 7.9% in placebo-treated dogs.[24] Of 58 dogs that received Palladia after placebo escape, 41.4% experienced an objective response. The overall response rate for dogs in this study receiving Palladia was 42.8%. Additionally, the commercially available Kit inhibitor imatinib mesylate (Gleevec) has been used to treat canine MCTs. A recent study demonstrated some response to therapy in 10 of 21 dogs treated with imatinib; the objective response rate was 100% in dogs whose MCTs possessed a Kit ITD.[17] Another study reported partial responses to therapy in three dogs with systemic mast cell disease treated with imatinib.[26] However, it is important to note that imatinib can cause severe idiosyncratic hepatotoxicity and is extremely expensive, thereby limiting its use.

Supportive Care

H2 Antagonists

Mast cell tumors may cause GI ulceration because histamine stimulates gastric acid production by parietal cells. This is especially relevant for dogs with evidence of systemic involvement. To prevent this, any of the standard H2 antagonists (cimetidine, ranitidine, or famotidine) should be administered to affected dogs. Alternatively, proton pump inhibitors such as omeprazole may be utilized; these inhibitors are probably more useful in the setting of gross mast cell disease where standard H2 antagonists may be less effective.

H1 Antagonists

Massive mast cell degranulation can lead to hypotensive shock and death. Therefore, all patients with gross

mast cell disease, or evidence of systemic involvement should be placed on the H1 antagonist diphenhydramine.

FELINE MAST CELL TUMORS

Mast cell neoplasia in the cat occurs in three basic forms: cutaneous MCT, splenic mast cell disease (sometimes referred to as lymphoreticular) and intestinal MCT. The biologic behavior of these diseases is strikingly different, so they will each be considered separately.

Cutaneous Feline MCT

Cutaneous MCTs represent the second most commonly encountered cutaneous tumor in the cat.[30] Two forms have been reported: mastocytic MCTs that appear histologically similar to those found in dogs, and histiocytic MCTs, a rare variant known to spontaneously regress, that possess features of histiocytic cells.[9] In general, feline cutaneous MCTs are solitary, raised, firm, hairless, well-circumscribed dermal nodules between 0.5 and 3 cm in diameter.[7,30] Occasionally, the surface of the tumor may be ulcerated; some tumors will present as plaque-like lesions, and tumors can be multiple.[7] These tumors are most likely to occur on the head and neck (frequently involving the pinna near the base of the ear), trunk, and limbs.[7,30] Affected cats usually do not exhibit clinical signs of disease other than pruritus.

As with canine tumors, feline MCTs are usually easily diagnosed by cytologic examination of fine needle aspirates. Cats with cutaneous MCT should be evaluated for evidence of additional tumors, as well as potential splenic involvement as a recent study found that some cats with multiple cutaneous MCTs also have splenic disease.[21] In addition, a minimum database is recommended, along with careful examination of local lymph nodes for evidence of lymphadenopathy.

With respect to the typical mastocytic variant of feline MCT, they are usually categorized as either compact (representing 50–90% of all cases) or diffuse (histologically anaplastic).[7] Several studies have demonstrated that well-differentiated compact tumors tend to behave in a benign manner and metastasis is uncommon.[21,31] In contrast, anaplastic tumors may have a high MI, and marked cellular and nuclear pleomorphism, with infiltration into subcutaneous tissues. These behave in a more malignant manner, metastasizing to local lymph nodes, spleen, blood, and bone marrow. However, a more recent study evaluated pleomorphic cutaneous MCTs from 15 cats and found that the majority were behaviorally benign; only one cat was euthanized due to disease progression.[19] Interestingly, in both studies, tumors with a high MI were most likely to recur or exhibit metastasis, suggesting that this feature is useful for predicting biologic behavior.

The definitive treatment for cutaneous feline MCT is surgical excision. In a series of 32 cats with cutaneous MCT, five recurred after surgical excision, but no cats died of the disease. In this study, completeness of excision and histopathologic factors, such as nuclear pleomorphism and MI, were not associated with tumor recurrence.[31] Other reports have demonstrated local recurrence rates after excision of between 0% and 24%.[7,19,21] Systemic spread of cutaneous tumors has been reported in 0% to 22% of cases, although those that metastasized may have been anaplastic tumors.[19,31] As previously discussed, those tumors with a high MI are more likely to recur post-surgery or metastasize.[19]

Radiation therapy may be considered for tumors that are incompletely excised. A recent study demonstrated that feline cutaneous MCTs treated with strontium 90 irradiation exhibited a 98% control rate, with median survival times greater than 3 years.[48] Limited information exists concerning the utility of chemotherapy in cats with MCT. It is generally believed that feline MCTs are less responsive to prednisone than their canine counterparts. Responses to CCNU have been reported in cats: of 20 cats with cutaneous MCTs, 10 exhibited complete (n = 2) or partial (n = 8) response to CCNU.[39] Some investigators have utilized a combination of prednisone and chlorambucil to treat metastatic or multiple tumors. This is generally well-tolerated, although its effectiveness is unclear.

Splenic (Visceral) MCT

This form of neoplastic mast cell disease is also referred to as visceral or lymphoreticular MCT. It is the most frequent disease of the spleen of cats, affecting older animals (mean age 10 years) with no sex or breed predilection.[7,21] While the spleen is the primary site affected by this disease, other organs may also be involved including the liver, mesenteric lymph nodes, bone marrow, lung, and intestine.[7,12] Circulating mast cells may be found in many cases and pleural and/or peritoneal effusions may be noted.[7,12] The majority of cats with splenic MCTs do not have a history of cutaneous MCT, although recent evidence suggests that cats with multiple cutaneous MCTs may also have splenic involvement.[21] Cats with splenic MCT frequently present with signs of systemic illness including vomiting, anorexia, and weight loss.[7,12] Dyspnea may be evident if pleural effusion is present. Abdominal palpation usually reveals a markedly enlarged spleen and/or liver. Clinical signs associated with release of mast cell mediators include GI ulceration, hemorrhage, hypotensive shock, and labored breathing.

Cats with suspected splenic MCT should undergo a standard clinical evaluation including a CBC, chemistry profile, urinalysis, abdominal ultrasound, and thoracic radiographs. Unlike the cutaneous form of MCT in cats and dogs, splenic MCT in the cat is frequently associated with circulating mast cells and up to 50% of cats will have evidence of bone marrow infiltration by mast cells.[7,12] It is important to note that the finding of multiorgan involvement does not necessarily indicate a poorer prognosis. Anemia is also a frequent hematologic finding, with eosinophilia less likely to be observed.[7,12] Lastly, in one report of 43 cats with splenic

mast cell disease, 90% had an abnormal coagulation profile, although there was no evidence of clinical bleeding.[12]

Splenectomy is the treatment of choice for cats with splenic MCT, even if other organ involvement is noted. Pre-treatment with H1 and H2 blockers before therapy is indicated; intraoperative death may occur due to the release of mast cell mediators. Median survival times of 12–19 months after splenectomy alone have been reported in cats with splenic MCT with bone marrow/blood involvement.[12] While mastocytosis in the circulation usually does not completely resolve, it does decline significantly and cats experience good quality of life for long periods of time. Cats should be followed postoperatively with buffy coat smears, as a rise in the number of mast cells in the blood may indicate disease progression. Anorexia, significant loss of body mass and the male sex were found to be negative prognostic indicators in one study.[12] Adjunctive chemotherapy with prednisone, lomustine, and/or chlorambucil has been attempted in a limited number of cases, but clinical value is uncertain. Recently, a cat with splenic mast cell disease and systemic mastocytosis was treated with the Kit inhibitor imatinib and exhibited a significant response to therapy including complete resolution of tumor masses and marked reduction in circulating mast cells.[18]

Feline Intestinal MCT

Mast cell tumors represent the third most common intestinal tumor in the cat, with lymphoma and adenocarcinoma first and second, respectively.[7] Most cats have a history of vomiting, diarrhea and anorexia, and a solitary palpable abdominal mass is usually evident on physical examination.[7] As metastasis is common with this disease, enlarged mesenteric lymph nodes and/or hepatomegaly may also be noted. A peritoneal effusion may be present, and this frequently contains mast cells and eosinophils. Diagnosis may be made by fine needle aspiration of the mass or involved organs. As with splenic MCT, these cats should be staged by performing a CBC, chemistry profile, urinalysis, thoracic radiographs, and abdominal ultrasound. Buffy coat smear and bone marrow aspiration may also be performed, although unlike splenic MCT, intestinal MCT rarely involves these organs. However, it may be useful to distinguish splenic MCT with intestinal involvement from the distinct syndrome of intestinal MCT.

Surgery is the treatment of choice for intestinal MCT. Wide surgical margins are necessary (5–10 cm) as the tumor frequently extends well beyond the observable gross disease.[7] The historical survival times of cats with intestinal MCT are poor, as metastasis is common at the time of diagnosis. Limited information regarding the use of chemotherapy in these cases is available, although anecdotal responses to lomustine and chlorambucil have been reported. Recently, two cats had objective responses (one complete, one partial) after treatment with lomustine.[39]

EQUINE MAST CELL TUMORS

Mast cell tumors are known to occur in the horse and the majority are cutaneous in nature.[28,40] The largest series of tumors reported evaluated 32 cutaneous MCTs and found that 22 of 25 did not recur for up to 6 years after removal, two recurred at the surgical site, and one spontaneously regressed within 3 months after biopsy.[28] The majority of published data indicate that equine cutaneous MCTs are benign in behavior, seldom recurring after surgical excision.

Acronyms and Abbreviations

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CB, centroblastic; CHOP, cyclophosphamide, vincristine, doxorubicin, prednisone; CLL, chronic lymphocytic leukemia; DLBCL, diffuse large B cell lymphoma; EBV, Epstein-Barr virus; FAB, French-American-British; FL, follicular lymphoma; IB, immunoblastic; ICAM, intercellular adhesion molecule; LPL, lymphoplasmacytic lymphoma; MCL, marginal cell lymphoma; MZL, marginal zone lymphoma; PCR, polymerase chain reaction; PLL, prolymphocytic leukemia; RBC, red blood cell; SLL, small lymphoblastic leukemias; SNP, single nucleotide polymorphism; WBC, white blood cell; WHO, World Health Organization.

Lymphoid tumors have been enigmatic neoplasms for much of the time that they have been diagnosed by pathologists. A problem for clinicians and diagnosticians has always been the basis for distinguishing leukemia from lymphoma. Both diseases were found to have cells of identical immunophenotypes. This difficulty was overcome in the revised WHO classification system that pragmatically linked the diagnosis to the topographical area with the greatest volume of tumor. By this system, if most of the tumor was in bone marrow the disease was termed leukemia and if most was in peripheral tissues it was termed lymphoma.

A further advance in our understanding of lymphomas is that there are always neoplastic cells in circulation with the risk of dissemination related to surface adhesion molecules (ICAMs) that function like the address on an envelope and determine where the cells bearing those markers can adhere to the vessel wall and exit the blood vascular system. In this context, the cells of acute leukemias lack most adhesion sites and tend to remain in circulation. The other extreme is MALT-type lymphomas that may remain so tightly adhered to a single location that they can be successfully managed by surgical removal.

A generality of lymphoid proliferation is that malignancy of poorly differentiated lymphocytes is likely to occur in bone marrow of young individuals and present as leukemia, while malignancy of mature lymphocytes

will likely occur in peripheral tissues of mature humans or animals and present as lymphoma (R. Brunning, personal communication). An interesting exception to that thumb rule is seen in the gamma delta T cell lymphomas of humans, dogs, and cats that arise in intestine and involve the spleen.

When bone marrow is invaded by a hematopoietic neoplasm, some degree of marrow failure will be apparent when 50% or greater volume of marrow is involved with neoplastic cells. Significant clinical cytopenias may be apparent with much less than 50% of marrow involved in some peripheral T cell lymphomas where the neoplastic cells induce suppression of normal marrow cell production. Cats may present with weight loss, vomiting, diarrhea, and inflammatory bowel-type disease with tumor cells usually spreading to spleen and marrow at the time of diagnosis. Similar conditions seem to occur in dogs; however, neutropenia is not a feature of large granular lymphomas in either dogs or cats.

B and T cell leukemias are classified according to the French-American-British (FAB) system (Table 69.1). With this system the cells of acute lymphocytic leukemia are designated as L1, L2, or L3 types based on cell morphology. This system is less commonly applied today in human medicine because of their reliance on genetics and immunocytochemistry. The FAB system still has relevance in veterinary pathology where early diagnostic interpretation is based on the appearance of leukemic cells in Wright-Giemsa-stained preparations. Differentiating acute myeloid from acute lymphoid leukemias in animals remains a major difficulty. The

availability of a myeloperoxidase stain that works in both immunocytochemistry and immunohistochemistry on canine and feline cells has greatly assisted our ability to recognize acute myeloid leukemia (AML).

PRECURSOR B CELL NEOPLASMS

B Cell Acute Lymphoblastic Leukemias (ALL) L1

B cell lymphoblastic leukemias are clonal diseases primarily involving bone marrow that present with mild to moderate levels of leukemic lymphocytosis but can be characterized by leukopenia.[7,37] The disease is associated with splenomegaly but not with a mediastinal mass seen in T cell-type ALL.

Clinical Features

L1 B cell ALL are relatively infrequent lymphomas usually of young animals.[31] It is most often recognized in dogs and cats but probably occurs in all mammals. L1-type B cell ALL is a disease of acute onset. Affected animals are in good condition with acute loss of appetite. Organomegaly is usually mild but spleen is symmetrically enlarged and nodal changes are irregular or absent.

Leukemia blast cells are always present in the blood varying between 10,000 and 50,000/μL and the total white blood cell (WBC) count may be normal or decreased. The key to the diagnosis is the recognition of a homogeneous population of cells with round densely stained nuclei only slightly larger than RBCs. The nucleoli are obscured by the dispersed chromatin and are only recognized if carefully looked for. The cytoplasm is scant and visible over about one-third of the nuclear circumference. Mitoses are usually present in the blood.

Marrow is always involved and there may be some degree of phthisis with reduced erythropoietic cells and megakaryocytes (Fig. 69.1). Hemorrhage is present in marrow and is usually identified on gross examination of marrow. In early stages, lymph nodes may have few changes but, if involved, there will be atrophy of germinal centers with colonization of the inner paracortical areas and medullary cords with cells as described for marrow (Fig. 69.2). With progression and marrow failure, there will be extramedullary hematopoiesis in both medullary cords and sinuses. The spleen will have uniform involvement with resultant rounded borders and may have focal areas of hemorrhagic infarction. There is atrophy of the lymphoid follicles and of periarteriolar lymphoid sheaths with variable sinus colonization (Fig. 69.3). There may be colonization of subendothelial areas of large muscular veins. The liver also may be involved. The involvement is tightly periportal and tends to spread in solid proliferation. Other tissues that may be involved include skeletal muscle, intestine, brain, and testis.

In terms of phenotype, L1 may be of B cell- or T cell-type; not all cells of L1 type will stain with CD3 (T cell marker) or CD79a (B cell marker), but almost none of them stain with both. Therefore, even slight staining is taken as a specific indication of lineage. These cells stain equally well in cytologic and histologic preparations with CD20 (B cell marker) that is more reliable in cats than CD79a. CD20 will occasionally stain T cells and if the population is questionably marked by both CD20 and CD3 the cells should be considered to be T cells.

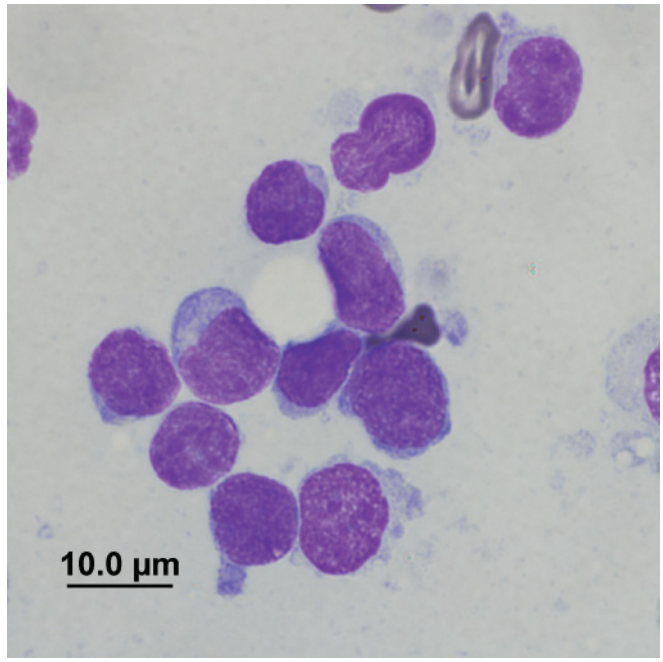

FIGURE 69.1 Bone marrow aspirate from a dog with L1 acute lymphoblastic leukemia. There is phthisis of normal cells and replacement by small neoplastic lymphocytes. Note the size of the nuclei of the smaller cells in comparison to RBCs. The chromatin is densely stained and uniformly distributed with nucleoli not apparent. Cytoplasm is limited to a very narrow ellipse not visible on all cells. The larger cells with more red stained nuclei are the dividing cells. Wright-Giemsa stain.

In flow cytometric analysis, L1 B cell ALL is identified by CD45-positive blasts of very small cell size. In addition, in human medicine, the B cell blasts are positive for CD10, CD19, and HLA-DR and negative for the T cell marker CD7. In contrast, the L1-type T cells are identified in flow cytometry as small blast cells that are positive for CD7 and are doubly positive with CD4 and CD8.

Few molecular changes are defined in animals with L1-type ALL. Hyperdiploidy is present in nearly half of human cases occurring in children. The most common chromosomal alteration in children occurs in about 10% of cases and involves translocations and deletions in chromosome 12.

Presumably the benign counterpart cell of origin is a primitive precursor in marrow in the early B cell lineage. Human subsets are identified as pre-B cell ALL and B acute ALL based on the level of immunoglobulin gene expression.

The L1-type ALL is defined as tumors in which the neoplastic nuclei are larger than RBCs but less than

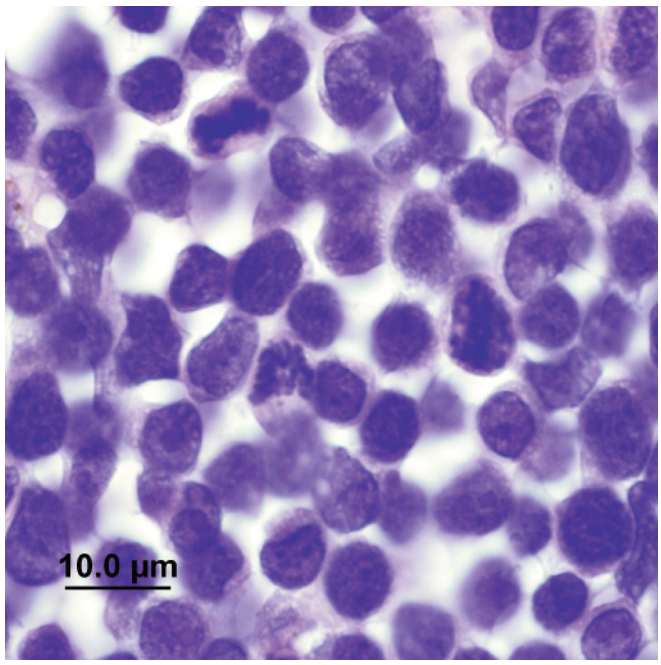

FIGURE 69.2 Lymph node from a dog with L1 acute lymphoblastic leukemia. The nuclei are round and small to intermediate in size with dispersed chromatin. Nucleoli are obscured and only irregularly apparent. There are three mitotic figures in the upper left and two in left and right center. Note that the metaphase chromatin of lymphoblastic lymphoma in histological preparations do not have the sharp outline of chromosomes as is seen in other subtypes of lymphoma. Hematoxylin & Eosin stain.

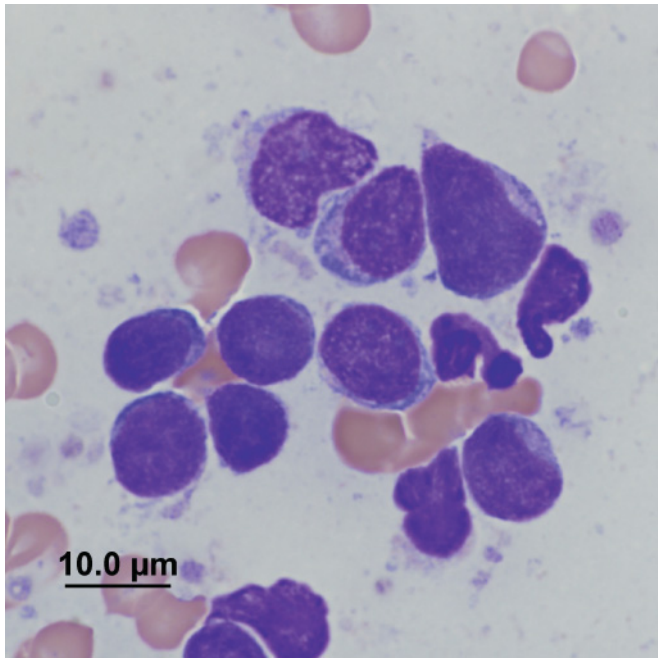

FIGURE 69.3 Splenic aspirate from a dog with L1 acute lymphoblastic leukemia. Note the size of the smaller cells as compared to RBCs with cell type identical to that noted in bone marrow. Wright-Giemsa stain.

1.5 RBC diameters. The chromatin pattern is coarsely stained and may have a coarse cribriform chromatin structure with the nucleoli obscured. This is important because in lymphoblastic lymphoma the chromatin is dispersed and the nucleoli are present but obscured. Additionally, L1-type ALL cells have very little cytoplasm.

In the FAB system the L1 form is essentially the leukemic form of lymphoblastic lymphoma. In histopathologic preparations, both L1 and L2 are virtually indistinguishable from lymphoblastic lymphoma. B cell ALL must be distinguished from T cell ALL that is morphologically identical. B cell ALL is not associated with hypercalcemia or a mediastinal mass both of which occur in a proportion of L1-type T cell ALL. CD3 is the best marker for T cell ALL. The most important topographic finding in T cell ALL is an anterior mediastinal mass.

Staging of B cell ALL in animals is primarly based on the degree of bone marrow involvement and on the presence of cytopenias in the blood. All cases of B cell ALL can be expected to advance rapidly. Treatment usually consists of multi-agent protocols with both B cell and T cell ALL considered to have a very poor prognosis in dogs and cats; aggressive therapy is generally not given to other species. Evaluation of treated cases is essentially monitoring the levels of tumor cells in the blood and monitoring developing cytopenias. Most cases progress to marrow failure.

Acute Lymphoblastic Leukemia L2

B cell lymphoblastic leukemia of L2 type is a clonal disease involving bone marrow that presents with mild to moderate levels of leukemic lymphocytosis but can be characterized by leukopenia. The disease is associated with organomegaly that includes at least moderate involvement of spleen, liver, and lymph nodes, and may involve the kidneys, intestinal tract, and reproductive tract. Most acute lymphoid leukemias of animals are of the L2 ALL type. The L2 type of B cell ALL is seen in the dog, cat, calves, cattle, horses, and laboratory species. In human cases, the L1 and L2 ALL do not appear to be biologically different diseases. Consequently, L2 B cell ALL can be considered to be like L1 B cell ALL.

The L2-type lymphomas are characterized by nuclei that are fully 2 RBCs in diameter and have sharp shallow nuclear indentation. The chromatin pattern is coarsely cribriform with dense staining and occasional chromatin aggregations. These aggregates frequently surround the nucleolus giving it added prominence (Fig. 69.4). Mitoses are usually seen in cytologic preparations. There is a high N:C ratio with cytoplasm seen around no more than half of the nucleus.

In L2 ALL cases without nuclear indentations, the cells resemble AML of the FAB M0 or M1 blast type. Some cases of L2 ALL may be of the large granular lymphocyte type and these tend to have a worse prognosis in humans and it appears that this also applies in cats and dogs. In general the same immunologic char-

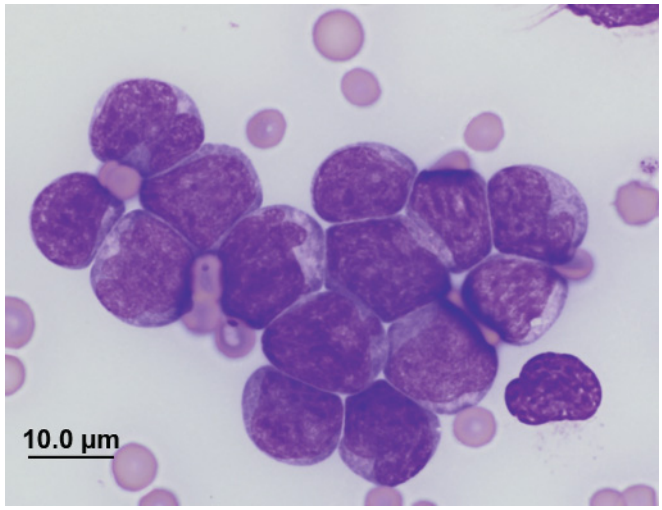

FIGURE 69.4 Blood smear from a dog with L2 acute lymphoblastic leukemia. The nuclei are generally 2–2.5 RBCs in diameter with frequent deep nuclear indentations and irregular rounded projections. The chromatin is deeply stained with irregular formation of dark chromocenters that outline some nucleoli. The cytoplasm is generally minimal in volume without an apparent complete covering of nuclei. There is moderate cytoplasmic basophilia without vacuolation or granulation. Wright-Giemsa stain.

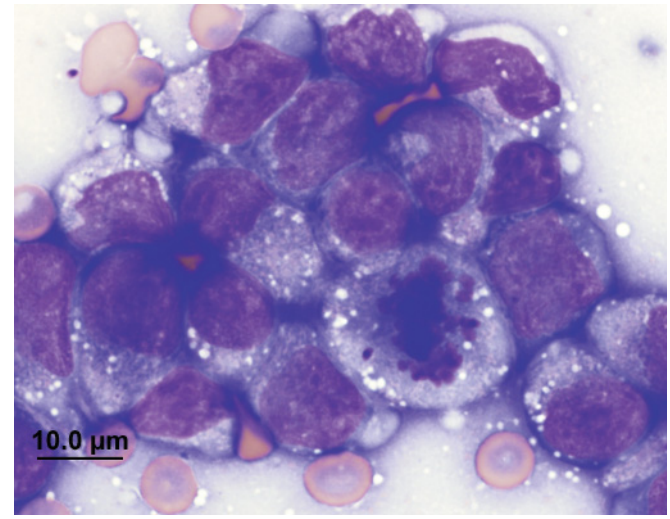

FIGURE 69.5 Lymph node aspirate from a dog with L3 acute lymphoblastic leukemia. The nuclei have mild anisokaryosis with deeply stained chromatin with apparent large densely stained chromocenters. Nucleoli are small and multiple and most apparent in the nucleus in lower right. The cytoplasmic vacuolation usually appears beneath the cytoplasmic membrane. Wright-Giemsa stain.

acteristics can be applied to L2 ALL as for L1 ALL with the exception of differences due to cell size and cytoplasmic volume.

Acute Lymphoblastic Leukemia L3

Acute lymphoblastic leukemias of the L3 type are acute clonal neoplasms involving marrow and generally are associated with organomegaly. L3-type ALL occurs in most mammals, being relatively frequent in dog, cat, and cattle, and less common in horses. L3-type ALL cells have fine peripheral cytoplasmic vacuolization that may stain positively for fat (Fig 69.5). The cytoplasm is similar in volume to the L2-type ALL and usually deeply basophilic. Nuclei vary from 2 to 3 RBCs in diameter. The chromatin is deeply stained and may be dense and dispersed or cribriform with some dense chromocenters that may encircle nucleoli that are multiple and moderately well defined. In some individual cases, nuclei mold into oval shapes and there may be deep nuclear indentations particularly in cattle. Mitoses are generally present.

In both cytologic and histologic preparations L3 ALL is not reliably distinguishable from Burkitt-type lymphoma or Burkitt-like lymphoma. The anisokaryosis that is seen in the cytologic preparations of L3-type ALL is also evident in the Burkitt-like lymphomas.

The L3 ALL cells also may be confused with large T cell lymphoma, megakaryocytic leukemia, and monocytic leukemias, all of which may have cytoplasmic vacuolizations. Like L3 ALL, these tumors are negative with myeloperoxidase staining. L3 B cells stain positively for CD79a and CD20 and negatively for CD3. In humans, almost all L1 and L2 ALL have the terminal deoxynucleotidyl transferase (TdT) marker typical of cells of primitive differentiation and as an indication of maturation. This marker is absent in L3 ALL.

In human cases the L3 type ALLs are felt to respond poorly to therapy when compared to L1 and L2 ALL. Acute lymphoblastic leukemia type distinction has not had sufficient attention in animals for comment to be made on biological differences in response to treatment.

MATURE (PERIPHERAL) B CELL NEOPLASMS

B Cell Chronic Lymphocytic Leukemias/Small Lymphocytic Lymphomas

Chronic lymphocytic leukemia (CLL) of B cell type is a clonal disease with primary involvement of the bone marrow. The disease is primarily one of accumulation of long-lived cells of low proliferative rate and not of excess proliferation.[12,17,41,46] The neoplastic cells are small and uniform in appearance and are immunologically competent. Small B cell lymphocytic lymphoma (SLL) is a solid clonal neoplasm of low grade primarily involving lymph nodes, spleen, and all parenchymal organs that is morphologically indistinguishable from B cell CLL.

Pathologic Features

In CLL, lymphocytosis is present in blood (frequently >100,000/µL) and bone marrow. In cats, where the

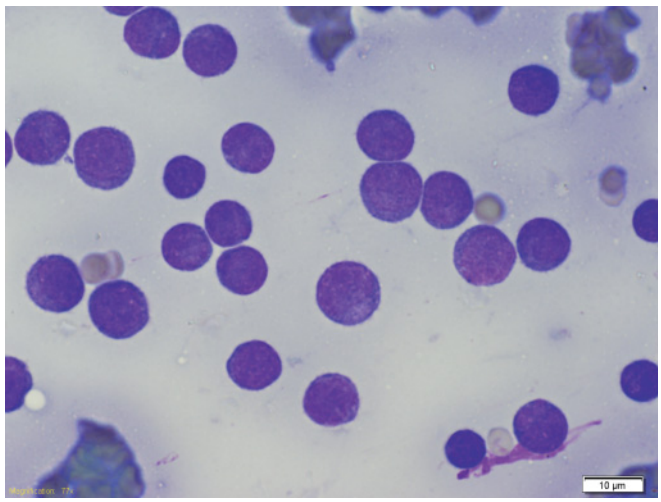

FIGURE 69.6 Blood smear from a cat with chronic lymphocytic leukemia. The leukocyte count was >600,000/μL with the cat likely entering an accelerated phase of the disease. The smaller nuclei are more typical of the chronic disease with the larger nuclei part of a dividing population. The chromatin is quite densely stained with a narrow rim of quite basophilic cytoplasm. Nucleoli are not apparent in most nuclei. Wright-Giemsa stain.

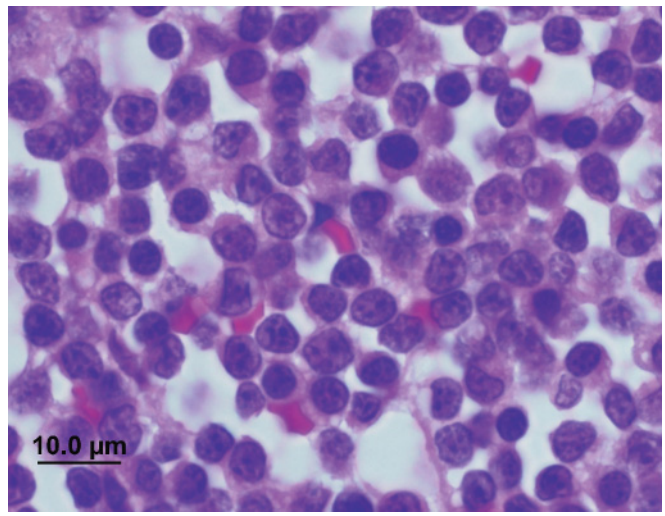

FIGURE 69.7 Lymph node from a cat with chronic lymphocytic leukemia. Note the small size of the neoplastic cells in comparison to surrounding RBCs. The small more dense cells would be more typical during chronic stages of the disease with the larger nuclei being the dividing population. The cytoplasm is minimal with moderate staining density. Mitoses are infrequently encountered. Hematoxylin & Eosin stain.

disease appears most often, the cell type is of small cells with round nuclei typically 1 to 1.5 RBCs in diameter with a very narrow rim of cytoplasm. In dogs, the disease may be of similar cell type but, like humans, there is a second type with larger nuclei and much more abundant cytoplasm that is relatively lightly stained. Nucleoli are usually absent or very small and indistinct, and the chromatin is dense with little internal nuclear detail. Larger cells increase with progression of the disease (Fig. 69.6). These cells may have eosinophilic granules present indicating that they are large granular lymphocytes. Bone marrow is always heavily involved in CLL and there may be relatively solid involvement with almost complete phthisis of normal marrow cells. In early stages of CLL the bone marrow will be involved in a random fashion, unlike acute or chronic myeloid leukemias that tend to involve subendosteal areas first. Marrow is usually diagnostic with CLL and there is usually moderate involvement with SLL. In human CLL, with solid marrow involvement there are lighter stained areas that consist of slightly larger cells that have been recognized and described as proliferation centers. These consist of clusters of dividing cells and constitute part of the diagnostic criteria for CLL.

In cats with CLL, lymph nodes are rarely significantly enlarged and may be small or atrophic. In SLL, the nodes are enlarged with the capsule thinned and taut and the node has a diffuse architecture (Fig. 69.7). A remarkable finding in these nodes is numerous dilated lymphatics in what is likely a residual hilar area of the node that is distended with small lymphocytes of uniform type.

In CLL, the spleen is uniformly enlarged, primarily due to filling of the sinus areas with fading germinal centers arising from the arteriolar system, with an architectural presentation of a fine coalescing multifocal nodular proliferation.[47] There is frequently subendothelial involvement of the large muscular veins. In contrast small lymphocytic lymphoma tends to be multifocal and regional without uniform enlargement.

Chronic lymphocytic leukemia tends to involve most other tissues but most prominently the liver that presents with a periportal involvement. Other tissues involved include the choroid plexus of the brain, adrenal gland, and pancreas.

B cell CLL and SLL are uniformly positive with CD79a and CD1c and weakly positive for CD1a. They are negative for T cell markers.

The molecular specificities of CLL and SLL are largely undefined in animals, but probing of the immunoglobulin genes demonstrates clonality.[49] In humans, there is usually rearrangement of both the light and heavy immunoglobulin genes with some human cases of SLL also having rearrangement of the beta chain of the T cell receptor gene. About 10% of dogs with indolent B cell lymphomas have rearrangement of the T cell receptor gene.

The cell of origin for B cell CLL and SLL in animals is unknown. In humans, there is a lack of hypermutation of the variable portion of the immunoglobulin gene in both SLL and CLL that suggests that the origin of the tumor is a population of naive pre-germinal center B cells.[39]

Chronic lymphocytic leukemia and SLL need to be differentiated from benign reactive hyperplasia because the cells lack atypia and individually cannot be recognized as neoplastic. The degree of increase in cell numbers in tissue or blood and the homogeneity of proliferation with cells of small cell type are the most important criteria in defining a neoplastic condition.

The diagnosis of B cell CLL is made on finding a leukemic blood picture with a very high number of circulating lymphocytes that consist of small mature-appearing cells with a very low mitotic rate. If the diagnosis is in doubt, the safest route is to retest to prove that there is a sustained marked lymphocytosis that can then be reliably assumed to be clonal. If the blood lymphocyte count is sustained above a level of about 10,000/μL, a bone marrow biopsy is indicated. Heavy infiltration of bone marrow with small cells of similar type confirms the diagnosis. In terms of specific diagnosis it is important to determine phenotype because T cell-type small cell lymphomas are more common than B cell-type at least in the cat.

The diagnosis of SLL is based on irregular enlargement of lymph nodes with focal lesions in both the liver and spleen and all affected areas being involved with an infiltration of very small mature-appearing lymphocytes. The blood picture may appear relatively normal in SLL in early stages.

Clinical Features

Chronic lymphocytic leukemia and SLL are slowly progressive clonal neoplasms of mature small lymphocytes: CLL begins in bone marrow and SLL begins in peripheral tissues. SLL is usually T cell type and is recognized most frequently in cats, less often in dogs, and infrequently in cattle and horses. It is seen in mature animals 5–10 years of age and in dogs 10–15 years. The disease may occur in younger animals but seldom in animals under 5 years old.

The accumulation of small cells of CLL may cause few clinical signs and is most often diagnosed incidentally in animals undergoing routine blood examination. Chronic lymphocytic leukemias and SLL affect all breeds of dogs and cats. In a review of 600 lymphoid neoplasms in cats, 23 cases (3.8%) were felt to be CLL- or SLL-type with these related entities present in about even proportions. In dairy cattle, clinical signs may include reduced feed intake and milk production, lethargy, loss of appetite, and melena if there is an ulcerated gastric tumor. Affected animals are usually thin and have hepatosplenomegaly.

Staging has not been applied in animals with CLL, but the Binet system of human medicine is straightforward. This system defines the stage of disease progression once the diagnosis is made. The human stages of progression can be roughly transposed in this manner:

1. absence of anemia or thrombocytopenia, tumor present in fewer than three lymphoid areas
2. absence of anemia or thrombocytopenia and involvement of more than three lymphoid areas
3. presence of anemia with less than 10 g/dL of hemoglobin and the presence of thrombocytopenia as defined by levels of less than 100,000/μL.

In animals this process involves comparing the current blood picture and topographic distribution of tumor with previous examinations based on the duration between examinations and rate of progression. It should be remembered that if chemotherapeutic treatment is given, this will cause changes in cell type usually due to smaller cells that may mask the presence of conversion to an accelerated phase where there will be at least focal areas consisting of larger cells.

The survival of animals with SLL is largely undefined because the animals may have had the neoplasm for several years before diagnosis. When animals are presented in an accelerated phase, the tumor tends to be more responsive to treatment than when in a more indolent stage of disease. In general it is considered best to treat animals conservatively if they are not showing clinical signs. Treatment of non-clinical human cases of CLL may induce immune hemolytic anemia.

B Cell Prolymphocytic Leukemias

Prolymphocytic leukemia (PLL) is a clonal neoplasm involving the bone marrow and is characterized by a very high level of leukemic cells at presentation with marked splenomegaly, characteristic cellular morphology, and chronic course.[23,32] The disease in animals is largely based on cell type without definition of the clinical entity. PLL can be of B cell- or T cell-type and in humans the ratio is about 80% B cell and 20% T cell.

Clinical Features

Prolymphocytic leukemia occurs in cattle and rarely in sheep and goats, and is seen most frequently in dogs and cats where it is usually considered to be chronic lymphocytic leukemia that has progressed to an accelerated phase.[47,48] In humans, the disease has a well-defined presentation in elderly males that present with high levels of leukemic cells and marked splenomegaly.

Most cases described occur in older animals that are presented in poor condition with weight loss and marked splenomegaly. Lymph node involvement is seen. Typically the liver is not grossly enlarged but has histological involvement on a lobular basis.

Pathologic Features

Like CLL there is marked leukocytosis in excess of 50,000/μL typically present in the blood. The cells have a "hand mirror" shape and represent a stage of differentiation that is seen in both B and T cell types of PLL. The nuclei are round and the size of 2.0 RBCs with a moderate envelope of lightly stained cytoplasm. The chromatin has multiple (15–20) large densely stained chromocenters that are about 2 μm in diameter and are outlined by clear areas of parachromatin joined by short, thin chromatin bands. Most cells lack nucleoli. There are occasional cells present that have slightly larger nuclei with less well-defined chromocenters that have nucleoli, and are considered to be the dividing population (Fig. 69.8).

The pattern of involvement in lymph nodes is typical of the B cell infiltration in CLL. In human nodes, the

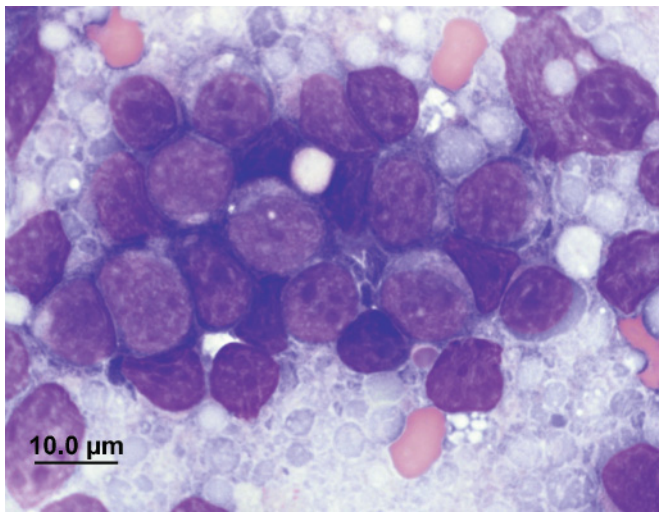

FIGURE 69.8 Lymph node aspirate from a dog with prolymphocytic leukemia. The nuclei are of intermediate size (1.5 RBCs in diameter). The chromatin pattern is characteristic with large chromocenters that are joined by broad chromatin bands with irregular parachromatin clearing that tends to give the nuclei a "spotted" nuclear pattern. Nucleoli are only visible in the larger nuclei and the cytoplasm is moderate in volume and staining density. Wright-Giemsa stain.

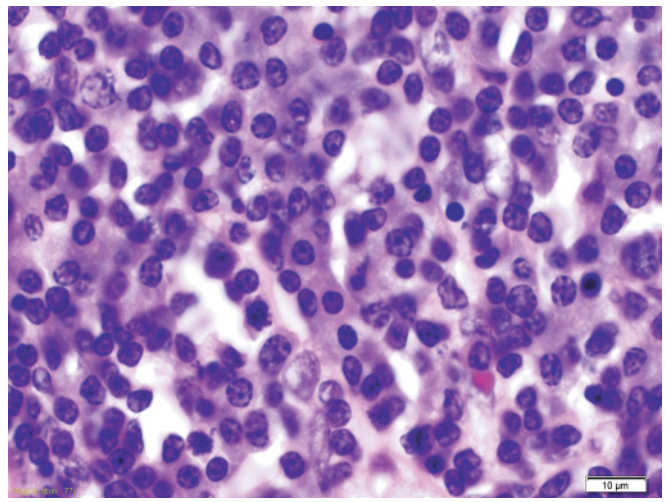

FIGURE 69.9 Kidney from cat with lymphoplasmacytic lymphoma. Histologically the lesion resembles chronic lymphocytic leukemia but with greater cytoplasmic volume that is more deeply amphophilic. Note the size of the nuclei in comparison to the RBC in the lower right. The cytoplasmic volume accounts for the wider spacing of the nuclei. Mitoses are infrequently encountered and cell boundaries are irregularly distinct. Wright-Giemsa stain.

early disease begins around fading germinal centers like mantle cell lymphoma with gradual involvement of the paracortex. Involvement of the spleen is present with a fine multinodular pattern related to the arteriolar sheath vessels.

B cell type PLL is positive for CD79a and probably for CD20 and negative for CD3. There is clonal rearrangement of the immunogloblulin gene.

The tumor is derived from a relatively mature progenitor of either B cell or T cell lineage. Because this appears to be a stage of morphologic differentiation, the normal benign counterpart probably passes through this stage without ever forming a recognizable tissue mass.

Prolymphocytic leukemia must be differentiated from CLL that may have some larger sized cells in blood or tissue, but the bulk of the tumor population will have small compact nuclei with uniformly dense chromatin. Leukemic phases of mantle cell lymphoma may appear similar but nucleoli differ in most cells.

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphoma (LPL) is a clonal neoplasm of intermediate size cells that have nuclei similar to those of CLL and SLL.[19] The cell type varies in having a greater cytoplasmic volume that is deeply amphophilic and gives the tissues a deep reddish tincture on architectural examination. The disease is otherwise similar to SLL with most nuclei lacking nucleoli and having a low mitotic rate (Fig. 69.9).

Lymphoplasmacytic lymphoma occurs in all domestic animals but is seen most frequently in older cats and horses.[38,40,48,49] It occurs in the intestines of horses. About half of the cases in the cat are also intestinal and some are mediastinal. The disease tends to be indolent.[28]

Pathologic Features

Lymphoplasmacytic lymphoma does not usually have a leukemic phase; however, hyperglobulinemia may be present. Most cases of LPL have both surface and cytoplasmic IgM, are positive with CD79a and CD20, and are negative for T cell markers. However, it is possible for cells to have plasmacytoid morphology and stain for T cell markers.

The diagnosis of lymphoplasmacytic lymphoma is made on the recognition of the specific cell types in lymph node, spleen, or bone marrow. The cytoplasmic volume and deep staining density are the unique features of cells from animals with this disease.

Marginal Zone Lymphoma

Marginal zone lymphoma (MZL) is a B cell lymphoma of distinctive architecture and cytologic features that develops in a concentric layer of proliferation outside the mantle cell cuff of germinal centers (see Chapter 52). In human pathology, cells of marginal zone-type are referred to as "monocytoid B cells."[3,6]

Marginal zone lymphomas probably occur in all animals but are recognized most frequently in mature dogs and less frequently in cats.[10,13,43] Marginal zone lymphoma appears to constitute approximately 15% of lymphomas in dogs and about 11% of non-Hodgkin's lymphomas in humans. In human pathology, where MZL is divided into three disease presentations, the extranodal MALT-type lymphoma constitutes about

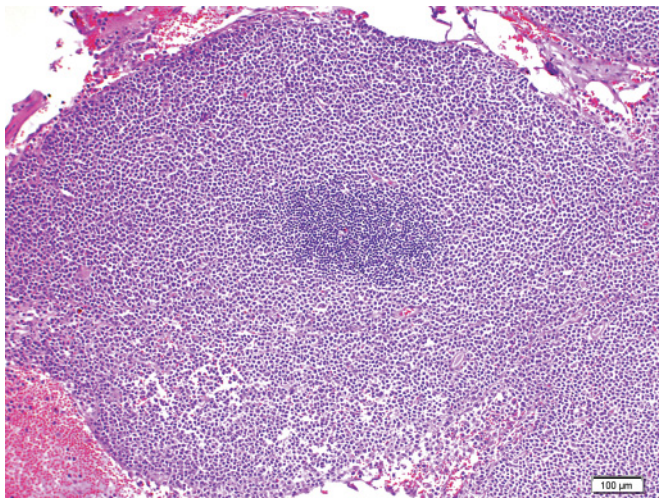

FIGURE 69.10 Lymph node from a dog with marginal zone lymphoma. The node has well advanced marginal zone lymphoma in which there is atrophy of surrounding paracortex with sinus ectasia. The small densely stained cells in the center are benign mantle cells that have collapsed into the dendritic bed of a fading germinal center. The surrounding cells are a malignant population of marginal zone cells. Note the lack of tingible body macrophages. Wright-Giemsa stain.

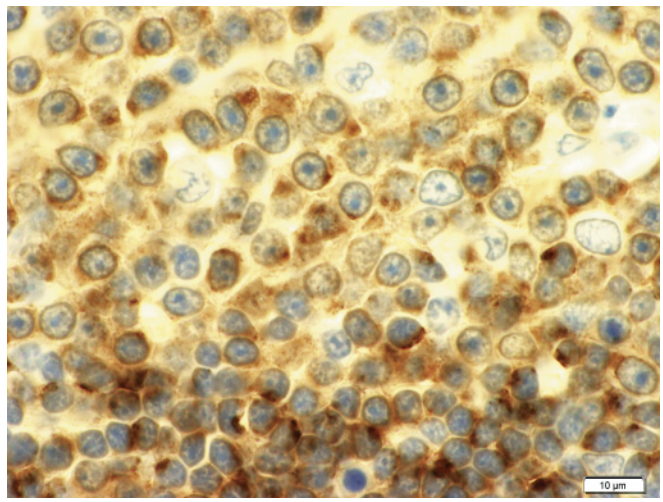

FIGURE 69.11 Lymph node from a dog with marginal zone lymphoma; CD79a stain. Cells at bottom of the lesion are mantle cuff cells at the edge of a fading germinal center. The marginal zone nuclei are 1.5 RBCs in diameter with a prominent single central nucleolus and with irregularly peripheralized chromatin with marked parachromatin clearing. The cytoplasm is relatively abundant which results in wider spacing of nuclei. Wright-Giemsa stain.

8% of all cases of non-Hodgkin's lymphoma, while the nodal-type is about 1.8%, and the splenic-type about 1% of total cases. A major species difference is that the disease always has diffuse involvement in humans and virtually always has focal and multinodular involvement in dogs.

Clinical Presentation

Marginal zone lymphoma occurs in mature large breed dogs, most frequently in submandibular lymph node, with only one site involved. The animals almost invariably feel well with normal appetite and activity. Nodes are always fully mobile. The second most frequent site in the dogs is the spleen with spread to hilar lymph nodes. Dogs eventually develop generalized lymphadenopathy but continue to feel well.

Pathologic Features

Leukemic manifestations of MZL have not been identified in animals. Bone marrow is seldom involved in MZL. The capsule of affected lymph nodes is thin and taut with the peripheral sinus preserved. Architecturally there is follicular hyperplasia with germinal centers extending into medullary areas. Usually there is some degree of medullary sclerosis indicating a long period of hyperplasia. In early stages, some germinal centers may still retain antigen-related polarity but with progression there is collapse of germinal centers with only a central area of mantle cells remaining. Marginal zones then appear as a lighter staining area of cells surrounding these dense clusters of smaller mantle cells (Fig. 69.10).

The splenic involvement invariably is multifocal and locally extensive. The distribution of tumor foci of MZL is related to splenic end arterioles that dictate a regular periodicity of nodular distribution. These nodules then irregularly coalesce with disease progression (Fig. 69. 11). Splenic MZL is usually accompanied by internodular areas of plasmacytosis often with atypical features and accompanied by focal areas of sclerosis that are usually identified as "fibrohistiocytic nodules." Because progression of MZL is slow, it is likely that many cases have been identified as areas of nodular hyperplasia. In general, when nodules are small and discrete, clonality studies tend to indicate that the condition is benign. Alternatively, when nodules are large and multifocal clonality studies usually indicate malignancy.

Marginal zone lymphomas in animals are strongly positive for B cell markers including CD79a and CD20, and are negative for T cell markers (Fig. 69. 12). Consistent cytogenetic and molecular changes in MZL have not been identified in animals. In humans, the most consistent features of this type are seen in the splenic form in which trisomy 3 and trisomy X and the deletion of (q22q24) have been reported in a small group of patients.

The cell of origin in MZL is not known in dogs. In humans, the close association between chronic immune stimulation caused by *Helicobacter* sp. gastritis and MALT lymphoma strongly suggests an origin from a post-germinal center B cell.

In all tissue areas the key to diagnosis of MZL is based on the recognition of cellular proliferation arising outside the mantle cell layer. In advanced cases, most areas will consist entirely of marginal zone cells but a few areas may be identified with fading marginal zone

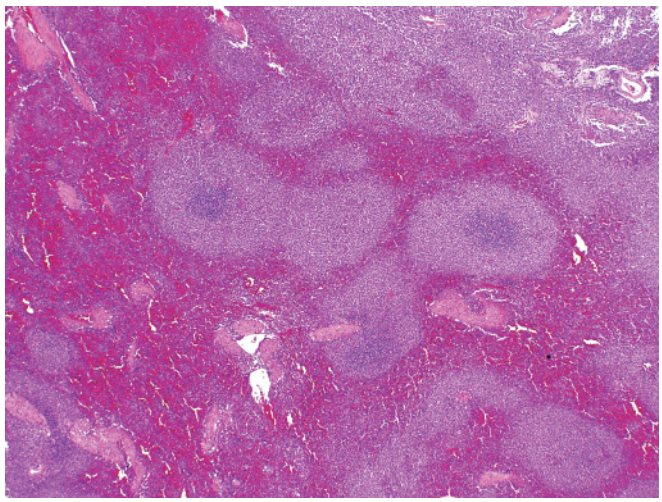

FIGURE 69.12 Spleen from a dog with marginal zone lymphoma. There are irregularly coalescing areas in the center and a large area of diffuse proliferation in the upper right. Note the atrophy of periarteriolar lymphoid sheaths. Wright-Giemsa stain.

cells. Marginal zone cells have nuclei 1.5–2 RBCs in diameter with moderately hyperchromatic chromatin that tends to be partially peripheralized onto the nuclear membrane with mild irregular parachromatin clearing. The other consistent finding is a prominent single central nucleolus. In addition, MZL tends to have relatively abundant and lightly stained cytoplasm. This combination of vesicular nuclei and abundant cytoplasm gives marginal zone areas a lighter staining aspect on architectural examination. A consistent cytologic characteristic of early MZL is that mitoses will be absent in most 400× fields. With progression in the dog (i.e. after 18 months to 2 years), there will be 3–4 mitoses per 400× field with an equivalent number of tingible body macrophages.

In lymph nodes, MZL needs to be differentiated from T cell lymphoma that may look similar at the architectural level because of the appearance of fading germinal centers. These centers are peripheralized in T cell lymphoma and in MZL the proliferating cells are surrounding the fading centers. Both types of lymphoma share a low mitotic rate. Differentiation is made on the basis of the T cell lymphomas tending to have smaller nuclei with more compact chromatin and less cytoplasm. Immunophenotyping is useful in differentiating these two types of lymphoma.

Clinical Features

Marginal zone lymphoma is generally not associated with clinical signs, but with current usage of ultrasound, splenic masses are readily identified. Because the most common form of focal splenic mass in the dog is hemangiosarcoma, splenectony is the most frequent approach to treatment. Almost invariably MZL has not spread to other sites at the time of splenectomy.

In contrast, MZL in lymph nodes in the dog tends to be diagnosed in more advanced cases, generally at stage 2a or 3a. In nodes that are completely effaced by MZL, the nodular nature of the disease may not be apparent until immunophenotyping is done. Most cases of nodal MZL in dogs involve peripheral nodes but occasionally internal nodes may be involved.

Marginal zone lymphoma can progress from focal to multifocal to generalized over time. At the architectural level, the lesion progresses from multinodular to diffuse and the cytologic changes include appearance of low numbers of mitotic figures and an accompanying presence of tingible body macrophages. MZL tends to respond well to chemotherapy at all stages of disease but may respond better as the number of mitotic figures increases.

Animals with a prior diagnosis of MZL tend to remain in phase 3a or 4a and tend not to become leukemic. Animals in advanced stages tend to retain normal appetite and activity and all nodes appear to be equally diagnostic for sampling purposes.

A major diagnostic concern with MZL is that the large nucleoli in intermediate-sized cells are cytologically interpreted as high-grade lymphoma. MZL can be accurately diagnosed if a 2 mm diameter Tru-cut biopsy needle is used in most tissues except liver and kidney.

Some cases of canine MZL will continue to respond to the same treatment protocol with prolonged remissions over a period of 1–2 years. An indication of the very slow spread of MZL is indicated by three cases treated only by splenectomy that did not have subsequent recurrence in other tissues. In humans, 5-year survival with the splenic form of MZL is 65%.

Mantle Cell Lymphoma

Mantle cell lymphoma (MCL) is a distinct subtype of lymphoma in humans and animals that is characterized by architectural origin around fading germinal centers with nuclei characteristically uniformly round and 1.5 RBCs in diameter with dense chromatin with little internal detail.[24,30,51] Most nuclei lack visible nucleoli and the tumor has a low mitotic rate. Mantle cell lymphoma has been recently recognized in human pathology and is identified as a distinct entity arising from a translocation T(11;14) and by over expression of cyclin D1 protein.

Mantle cell lymphoma is recognized in cats and dogs and probably occurs in all mammals. Mantle cell lymphoma constitutes 5% of human lymphoma in North America and twice that level in Europe with a 3:1 male predominance. In humans, the disease occurs in elderly patients. Eleven cases of canine MCL were identified in a collection of 461 cases with an incidence in the dog of about 2%. The age ranged from 1.5 to 15 years with a mean of just under 8 years. In a comparable period, since the diagnosis began to be recognized in 1992, one case has been recognized in 150 cases of lymphoma in cats.

Like MZL, MCL is much more likely to occur in the spleen in the dog. Mantle cell lymphoma tends to present as a multinodular and multifollicular prolifera-

tion that then undergoes coalescence. Associated changes in spleen include atypical plasmacytosis with fibrohistiocytic nodules and occasionally focal hemorrhagic infarction.

In both humans and dogs, a "blastoid variant" of MCL occurs that is identified by slightly larger nuclei with consistent small nucleoli. This form tends to become leukemic and develop bone marrow involvement. In the dog, this type of presentation has a characteristic diffuse multinodular architecture. The nodules enlarge in size and in so doing appear to compress their own blood supply undergoing ischemic degeneration followed by hemorrhage.

Pathologic Features

In dogs, the blastoid-type of MCL will present with febrile disease accompanied by anemia and gammopathy that is reversed on splenectomy.[5] In humans, a variable pattern is seen that tends to be paratrabecular with progression to a diffuse pattern. Lymph node MCL in the dog is generally identified in animals with generalized lymphadenopathy. Typically the nodes are markedly enlarged without involvement of perinodal tissues. Architecturally the nodes have a diffuse architecture with loss of germinal centers and proliferation compressing medullary structures generally without medullary sclerosis (Fig. 69.13). The follicular nature of MCL may only be evident on phenotypic staining.

Mantle cell lymphoma is more difficult to recognize histologically. The architectural identity becomes dependent on identifying a few slightly smaller more densely stained benign mantle cells at the center of rounded areas of cellular proliferation of slightly larger cells. Cytologically, MCL has round nuclei that are densely stained and generally lack nucleoli. The cells are of the same size or slightly larger than those of T-zone lymphoma and lack nuclear indentations. Nucleoli are small or inapparent and cells have a relatively wide rim of cytoplasm giving the nuclei a neatly separated appearance similar to T-zone lymphoma. Like other indolent lymphomas, the mitotic rate is low and none may be found in a 400× field with the small type of mantle cell lymphoma, whereas 3–4 per 400× field can be found with the blastoid-type of MCL. Typically tingible body macrophages are not present.

In dog and cat spleen, MCL is characterized by multifocal proliferation and is locally extensive (Fig. 69.14). With the small cell-type of MCL there will be progressive coalescence of splenic nodules and internodular areas of atypical plasmacytosis and fibrosis as occurs with marginal zone lymphoma. As noted earlier, the blastoid variant of MZL tends to involve the spleen uniformly in the dog and has not been identified in the cat. Cytologically the blastoid-type of MCL has nuclei that are 1.5 RBCs in diameter with much more variation in shape than with MZL. The chromatin pattern is hyperchromatic and coarse granular with irregular parachromatin clearing and each nucleus having 1–2 small nucleolus that are much smaller than the large single nucleolus of MZL. In splenic blastoid-type MCL in the dog there is typically subendothelial colonization of larger venous sinuses. Other tissues that are typically involved include lymph node, bone marrow, and liver. The liver involvement is by portal cuffing and occasionally implantation eccentric to central veins.

MCL is uniformly positive with the B cell markers CD79a and CD20, and negative with CD3 and other

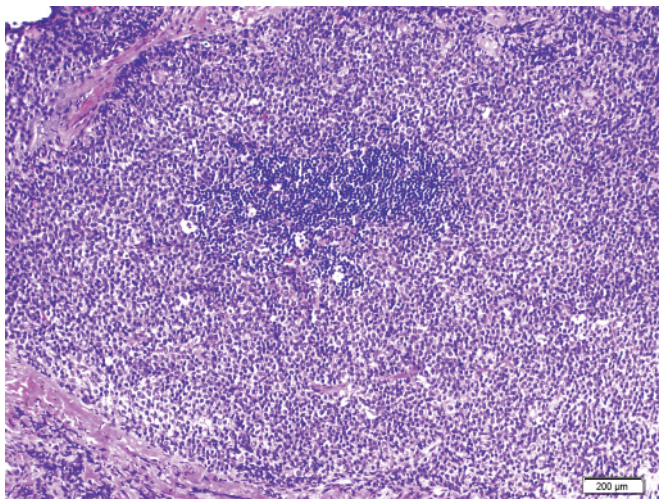

FIGURE 69.13 Lymph node from a dog with mantle cell lymphoma. Architecturally the pattern resembles marginal zone lymphoma with the proliferating cells surrounding a fading germinal center. The proliferation of cells around the mantle cell layer rather than eccentric to it identifies the neoplastic cells as B cells. Identification of the cells as small to intermediate nuclear type with small nucleoli is essential to recognize mantle cell lymphoma. Wright-Giemsa stain.

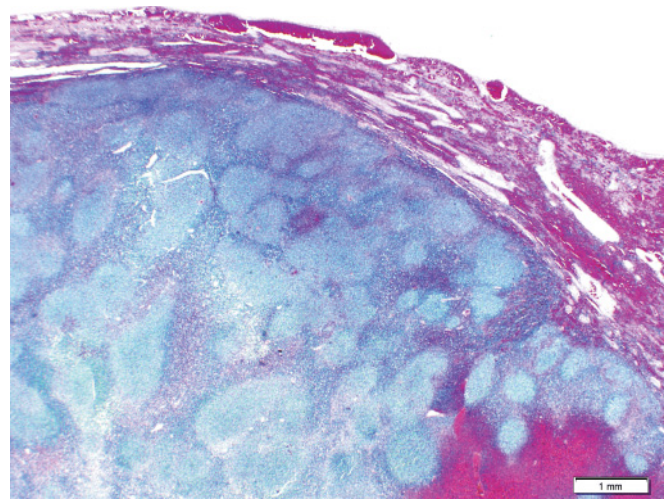

FIGURE 69.14 Spleen from a dog with mantle cell lymphoma. A cohesive nodule of coalescing foci is a typical presentation that is frequently accompanied by focal areas of hemorrhagic infarction as is apparent in lower right. The proliferating areas are lightly and irregularly outlined by more deeply stained cells consisting mostly of small benign plasma cells. Note the atrophy of periarteriolar lymphoid sheaths in surrounding more normal spleen (above and to the right).

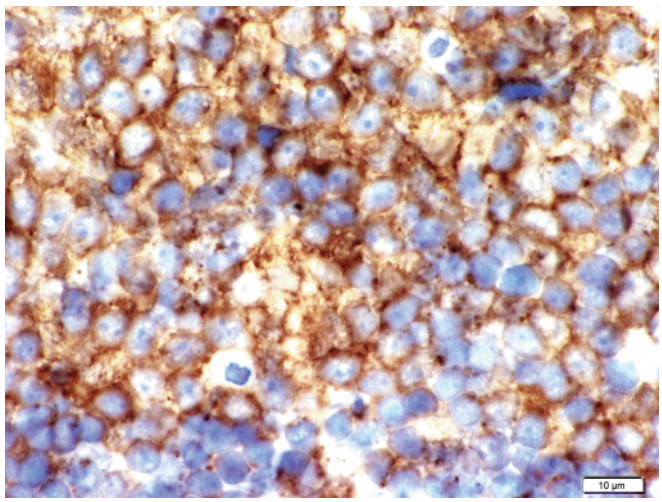

FIGURE 69.15 Lymph node from a dog with mantle cell lymphoma; CD79a stain. The closely aggregated nuclei at the bottom are the edge of the fading mantle cell cuff evident at lower power in Figure 69.13. Note that the major difference between the benign and malignant mantle cells is only a slight enlargement of nuclei with the presence of prominent small nucleoli, but with more abundant cytoplasm that is deeply stained with CD79a. While the nucleoli are apparent and occasionally even two are present, they are much smaller than those typical of marginal zone lymphoma and the nuclei themselves are smaller.

T-cell markers (Fig. 69.15). In dogs, MCL tends to stain lightly and uniformly for lambda light chain.

Nothing is known about genetic changes characteristic of MCL in animals. In human MCL, translocation (t11;t14)(q13;q32) is usually present and is considered presumptive for diagnosis of MCL. In human cases, the oncogene dysregulated by the translocation has been termed CCND1 and encodes for the cyclin D1 protein that is over expressed in tissues.

The cell of origin in animals is not known. In humans, it is hypothesized that MCL is derived from naive marrow B cells that are pre-germinal center and migrate from the marrow to the mantle cell area.

Mantle cell lymphoma is a type of lymphoid neoplasm with a nodular gross pattern in all tissues that is initially focal and becomes coalescent as the disease progresses. In early cases, apparent origin from germinal centers is evident by fading follicles within some foci of proliferation. An additional useful finding is the presence of areas of protein insudation that are present as follicular hyalinosis in a germinal center that has receded with the protein remaining.

Mantle cell lymphoma must be differentiated from other indolent lymphomas that have a nodular architecture including follicular lymphoma and MZL. MCL might be confused with follicular lymphoma grade I where the concentric sites tend to have nuclei that are more irregular in shape than those of MCLs. MCL is differentiated from MZL because of smaller nuclei without the prominent single central nucleolus characteristic of MZL. In advanced cases MCL needs to be differentiated from chronic lymphocytic leukemia.

Clinical Features

Mantle cell lymphoma in animals presents at advanced stages of 3–4 and staging is based on recognizing the number of areas of nodal involvement of both internal and peripheral nodes as well as hepatosplenomegaly. On fine needle aspirate, the cells are slightly larger than those of T-zone lymphoma and lack the shallow nuclear indentations. In advanced cases, tumor is present in the liver.

Little is known about the progression of MCL in animals. In humans, the most significant prognostic factor is shortened remission time after treatment preceding recurrence. Poor prognostic signs in humans are old age, poor performance at the time of diagnosis, advanced stage of the disease, increased lactate dehydrogenase levels, splenomegaly, and anemia. Other symptoms, consisting of fever, night sweats, and loss of body mass, are important negative factors in humans as well as for the appearance of leukemia.

Nothing is known about treatment or survival in animals with MCL. In human cases of MCL, survival is 3 years with an absence of long-term survivors and survival with the blastoid variant of MCL is generally less than 2 years. This seems to be at variance with very limited experience in dogs where splenectomy of dogs with blastoid-type MCL has been followed by long-term survival.

Follicular Lymphoma

Follicular lymphoma (FL) is a type of B cell neoplasm composed of centrocytes and centroblasts with at least partial follicular architecture.[14,20,42] A major distinguishing feature of follicular lymphoma is that the cell composition of each follicle must be exactly similar to that in other follicles. This serves to distinguish true FL from various stages of follicular hyperplasia.

True FL in animals is an uncommon diagnosis. In a collection of 502 cases of canine lymphoma, there were 20 cases of follicular lymphoma and 15 cases of benign and atypical follicular hyperplasia. The true incidence of the disease in dogs is likely somewhere between 2% and 4% of total lymphoma cases. In one review of 176 cases from the New York City area, there were eight cases of FL-type 3, two cases of FL-type 2, and none of FL-type 1 for a total incidence of 5.7%. Increased incidence in that population may have been because these cases had routine immunophenotyping carried out assisting recognition of advanced cases. In a major review of the WHO classification system of human lymphomas, it was found that architecture alone was adequate for diagnosis of FL. In a review of 602 cases of feline lymphoma by histopathology alone, there were six cases (1%) of FL. A review of 1198 cases of bovine lymphoma, identified by inspection at Canadian slaughter plants, identified four cases (0.3%) of FL.[50] Follicular lymphoma appears to be rare in the horse, where the incidence appears to be less than 1%.[27] In humans in North America and Western Europe, 25–40% of lymphoma cases are FL. Follicular lymphoma is infrequent

in developing countries: it is likely that there are local influences involved. In support of that concept, a review of 238 cases of canine lymphoma from Ohio, in which immunophenotyping was carried out, found one case of FL.

Clinical Presentation

Affected dogs vary between 2 years and greater than 10 years of age.[45] Animals with FL tend to have both peripheral and internal lymph node involvement. These nodes tend not to be enlarged, suggesting early spread and slow progression. In the dog, the nodes most likely involved are those around the head and neck, including prescapular and popliteal areas as well as mediastinal and sublumbar nodes. The nodes are always non-painful and they are not fixed to the skin or deeper structures. Follicular lymphoma, like chronic lymphocytic leukemia, is usually found on incidental examination for dental care or other routine examination. With extensive lymph node involvement there is usually at least focal involvement of liver and multifocal involvement of spleen. Bone marrow may be involved but it is not apparent on examination of blood.

Pathologic Features

Virtually nothing is known about the presence of cells in blood of animals with follicular lymphoma. In humans, neoplastic cells are seen in blood in about 30% of cases. These neoplastic cells resemble those seen in nodes of dogs with T-zone lymphoma and have very sharp shallow nuclear indentations.

In the few cases of FL examined in which bone marrow was involved, nonspecific changes of cancer were present including an increased coarse hemosiderin and plasmacytosis. The follicular pattern is maintained when FL involves the bone marrow and the tumor tends to have a paratrabecular distribution.

In FL, the disease usually occupies an entire lymph node, but rarely nodes have partial involvement.[48] The pattern consists of follicles that are tightly faceted (Fig. 69.16). A characteristic of FL is that there is complete absence of mantle cell cuffs and internodal areas tend to consist of the post-capillary venules and small arterioles with increased numbers of RBCs and a variable complement of small, medium, and large lymphocytes (Fig. 69.17). The peripheral capsule is characteristically thin and taut, with the peripheral sinus compressed and compromised in areas where there is colonization of extranodal tissues.

Cytologically most cases in the dog are recognized at a grade II level when there is a mixture of centrocytes being the smaller cells with small or inapparent nucleoli and centroblasts that are the large more rapidly dividing population with multiple usually peripheralized nucleoli. The same proportion of centrocytes to centroblasts will be present in each nodule: that is the primary distinction between FL and follicular hyperplasia (Fig. 69.16 and Fig. 69.17). In addition, whereas tingible body macrophages are a characteristic of benign follicular hyperplasia, they tend to be rare or absent in FL. Occasionally in areas where tingible body macrophages are still present these may be identified as areas of fading follicles.

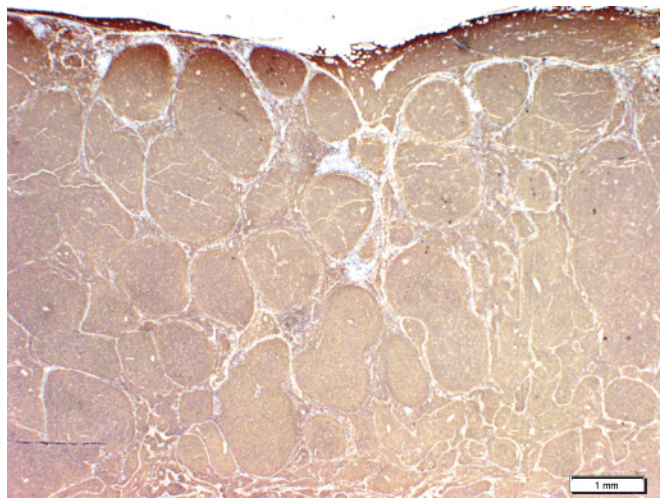

FIGURE 69.16 Lymph node from a dog with grade III follicular lymphoma; CD79a stain. With hematoxylin and eosin staining the definition of the follicles is lost and the node largely appears to have a diffuse proliferation except for follicles delineated near the node capsule. Note that in the upper right there is diffuse lymphoma proliferating outside of the node capsule with focal areas of diffuse progression acceptable in grade 3 lesions. A characteristic of follicular lymphoma, that distinguishes it from hyperplasia at the architectural level, is the complete absence of mantle cell cuffs. Note that follicular lymphoma cells of similar type extend right to the edge of each follicle. Detailed examination of the node reveals that small arterioles and post-capillary venules are all located between the nodules and never within them.

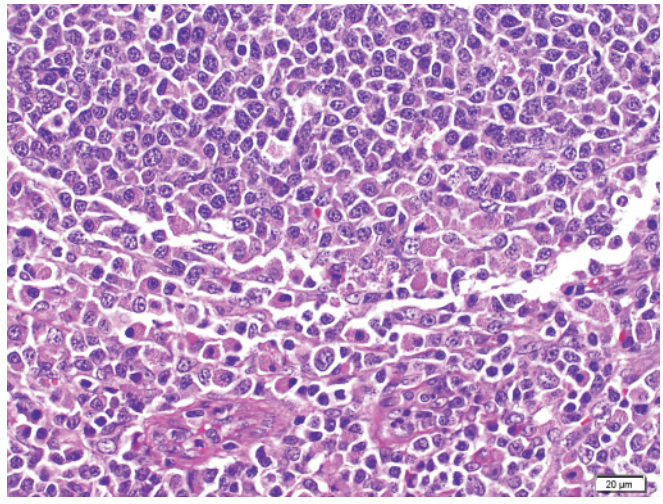

FIGURE 69.17 Lymph node from a dog with grade II follicular lymphoma. The cells in the upper half of the image are primarily centroblastic B cells of neoplastic follicles. A light stroma separates the follicle from the intrafollicular area below. There are two post-capillary venules in the internodal tissue that have heavy transmural cellular traffic. Note the variation in cell type in the interfollicular areas that includes plasma cells as well as small, medium, and large lymphocytes. Wright-Giemsa stain.

The WHO system of classifying FLs is a system of grading the proportion of centroblasts in each field. Basically, a level of 0–5 centroblasts per high power field (400×) is considered grade I, with 6–15 per high power field grade II, and more than 15 centroblasts per high power field is grade III. There is quite wide variation in grading between individuals. Because these diseases are so rare in animals, little effort has been made to count specific cell types other than to note that there is a general mixture present without centroblasts predominating.

Follicular lymphoma in the spleen is largely undescribed in animals. In humans, FL tends to symmetrically involve the entire spleen. On the basis of the few cases described in animals, involvement of the spleen in FL is characteristically diffuse with involvement on the entire body of the spleen. In cat and mouse, the sinus areas are spared with the focal proliferations quite sharply defined. Follicular lymphoma in the spleen is characterized by complete loss of mantle cell cuffs and, as in lymph nodes, there is the same distribution of cell types in all regions of each follicle.

The other organ most consistently involved is the liver. Follicular lymphoma in the liver tends to exclude areas of hematopoiesis from portal areas and similar changes are present in marrow with the follicles tending to be identified on low power examination by complete phthysis of fat cells and megakaryocytes.

Follicular lymphomas are strongly positive with CD79a and CD20 and are negative with CD3. In most cases of animal FL, cytoplasmic immunoglobulin can be identified by immune staining and most can be shown to stain positively with lambda light chain and negative with kappa light chain, which is also a useful means of identifying clonality.

It is well established in human pathology that FL is a result of neoplastic transformation of a post-germinal center cell. No specific characteristics have been identified for FLs in animals. In humans with FL, the heavy and light immunoglobulin chains are rearranged with the variable regions and there are extensive somatic mutations. In addition, there is extensive intraclonal diversity, indicating that mutations are ongoing similar to those that occur in benign germinal centers. In human FL, characteristic genetic alterations are chromosonal translocations of the long arms of chromosomes 14 and 18 with t(14;18)(q32;q21). A co-migrated segment that is transcribed is called BCL2 and this gene is over expressed in FL so providing a survival advantage by preventing the normal process of turning off the anti-apoptosis gene.

The major differential diagnosis for FL is benign or atypical follicular hyperplasia. In benign follicular hyperplasia there is usually some level of mantle cell cuff remaining, even in chronic follicular hyperplasia. A further distinction in follicular hyperplasia is that many of the follicles within the tissue have antigen-related polarity that signals that these structures are responding normally to antigen stimulation. In follicular hyperplasia, the involvement of perinodal tissue is frequently present but is almost never nodular or follicular as usually occurs in FL.

Clinical Features

Animals with FL, as is typical of all indolent lymphomas, retain normal appetite and activity and frequently present with advanced disease as a result of the owners noticing enlarged peripheral lymph nodes. Little is known about management of FL in animals, but the general management in humans appears logical. Animals having grades I–II lymphomas could be treated conservatively while those with grade III FL should be considered to have aggressive large B cell lymphoma and given multi-agent therapy.

Nothing is known of risk factors for survival of animals diagnosed with FL. Changes considered important in predicting survival in human patients with FL are age, time since diagnosis, presence of nodes larger than 3 cm in diameter, and the number of extranodal sites involved. Negative factors accompanying these are the presence of B cell symptoms including night sweats and elevations of serum lactic dehydrogenase.

Little is known about specific treatment for FL in animals. In humans, the major management therapy for patients in stage I or II of the disease is radiation which may provide relapse-free survival for 10 years or more. Alternatively, alkylating agents, including chlorambucil and cyclophosphamide, provide remission rates of 30–60% in previously untreated human patients. Newer strategies of therapy include anti-B cell antibodies. The current median survival of human patients with FL is about 9 years and after relapse about 4.5 years. In dogs with FL it is likely they have had the disease for up to 2 years before diagnosis and have a good chance of living 2–3 years after recognition and treatment.

Diffuse Large B Cell Lymphomas

Diffuse large B cell lymphomas (DLBCL) are tumors of large transformed lymphocytes with nuclei at least twice the size of two small lymphocytes.[2,18,29] The nuclei can vary markedly in shape and the cells generally have vesicular chromatin [21,22] The cytoplasmic volume and staining density vary with the subtypes. DLBCL are heterogeneous and have variable numbers of proliferating cells with wide variation in antigenicity, molecular and genetic features, and clinical behavior.[4,9]

Diffuse large B cell lymphomas occur in all domestic animals, including birds, and are the largest and most frequent lymphoid neoplasms in most species including humans.[33,44] In cats and cattle, DLBCL is associated with retroviral infection but lymphomas also occur in the absence of viral involvement. It is likely that in all species chronic benign lymphoid hyperplasia that occurs in association with a variety of chronic diseases may be a risk factor for malignant transformation of benign B cells.

A histological study of 1,198 lymphomas in cattle, without using immunohistochemistry, found that 366 were large cell-type and 424 were of large cleaved cell-type, together comprising 66% of the total cases. Characteristics of the population were not known, but because these were adult cattle sent for slaughter, most were assumed to be female and of dairy breed. In 136 cases of lymphomas in domestic pigs, 81 (60%) were of large cell-type and in 502 cases of canine lymphoma and leukemia there were 69 cases (14%) of large cell lymphoma including 19 cases of large cleaved cell-type. The median age of 47 of these dogs was 6.1 years and approximately equal numbers were male and female. Of 751 hematopoietic neoplasms of domestic cats, there were 314 (42%) cases of large cell lymphoma with 76 of these of large cleaved cell type, 184 cases of immunoblastic large cell lymphoma, and 115 cases of immunoblastic polymorphous type. In the total cat population, 58% of cats were male or neutered males with the remainder female or neutered females. The ages of cats with lymphoma ranged from 1 to 22 years. In 90 horses with lymphoid neoplasms there were 19 cases of diffuse large cell type and two cases of large cleaved cell type. In equines there was a slight majority of female cases, most of which were older than 10 years.

Pathologic Features

It is currently felt that neoplastic cells are always present in the blood with the conditions of spread determined by the intercellular adhesion molecules on the surface of malignant cells. In general, about 15% of cats with lymphoma are frankly leukemic with associated lymphocytosis. There is little prognostic value in identifying leukocytes in blood of an animal that has an established diagnosis of lymphoma and is not suffering any type of cytopenia. Examination of blood and marrow is an important and essential step in staging animals and predicting response to therapy.

It is easiest to recognize neoplastic cells in blood when such cells are large, and have nuclei with prominent nucleoli and uniformly finely distributed chromatin. That said, it is important to note that the neoplastic cells in blood frequently differ morphologically from the neoplastic population in marrow or in other tissues. Bone marrow is always involved in DLBCL if the disease has progressed for some time. The manner in which neoplastic cells involve the marrow may vary, including diffuse, paratrabecular, and multifocal interstitial. With focal heavy involvement of marrow there is usually exclusion of fat cells and phthisis of normal marrow lineages that is indicative of tumor formation. The advent of immunocytochemistry now permits the identification of minor populations of neoplastic cells in bone marrow that are not identified on routine examination.

A number of types of large B cell lymphomas are recognized in the recent WHO classification. Three of these are distinguished on the basis of their anatomic location including intravenous or intravascular, mediastinal, and primary effusion types of lymphoma. A new entity based cytology alone, is the plasmablastic-type that has general characteristics of plasma cells but with larger nuclei and nucleoli and a higher dividing fraction. Two subtypes of large B cell lymphoma are of mixed-type including the T cell-rich large B cell lymphoma and a closely related type known as lymphomatoid granulomatosis that tends to occur in the lung.

In general, lymph nodes enlarged in large B cell lymphomas have diffuse architecture, frequent bridging of the node capsule, and colonization of perinodal tissues. Large cell lymphomas tend to compress and destroy medullary structures and are not associated with medullary sclerosis as is usually found in the indolent lymphomas that appear to develop after a long period of benign hyperplasia. A common division of subtypes of large cell lymphomas is on the basis of nucleolar number and position. With this classification the immunoblastic lymphomas (IB) have a large single central nucleolus while the centroblastic (CB) types have multiple peripheral nucleoli (Figs. 69.18 and 69.19). These were recognized as distinct types in the working formulation with the assumption that the immunoblastic-type was of higher grade; however, little difference was found between these two in subsequent trials. Currently it seems reasonable to divide lymphomas cytologically on the basis of nucleolar type until it is possible to determine if this distinction infers a survival advantage in treated animals. In a study of 1,017 canine lymphomas, there were 150 cases of large cell lymphoma of CB-type

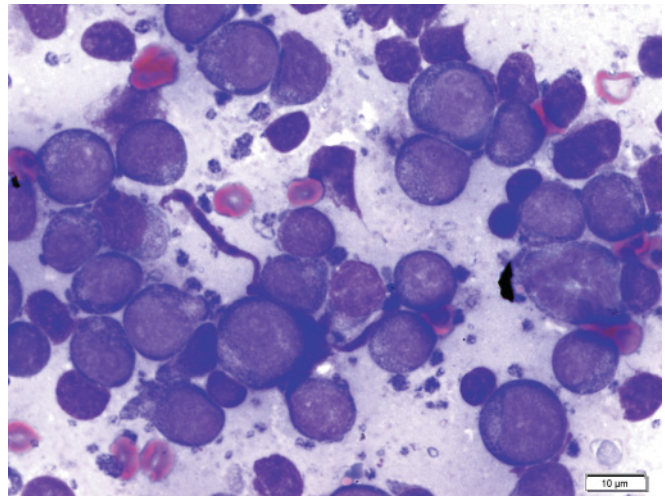

FIGURE 69.18 Lymph node aspirate from a dog with diffuse large B cell lymphoma; Wright-Giemsa stain. The nuclei are 1.5–2 RBCs in diameter with densely stained chromocenters that encircle multiple largely central nucleoli. The nuclei of intermediate size have a similar chromatin pattern with multiple nucleoli that suggest these are part of the same neoplastic population. There are a number of small (benign) lymphocytes present that have densely stained nuclei similar in diameter or slightly larger than RBCs. The cytoplasm is relatively abundant and highly basophilic. There is a cell in mitosis at the center right margin.

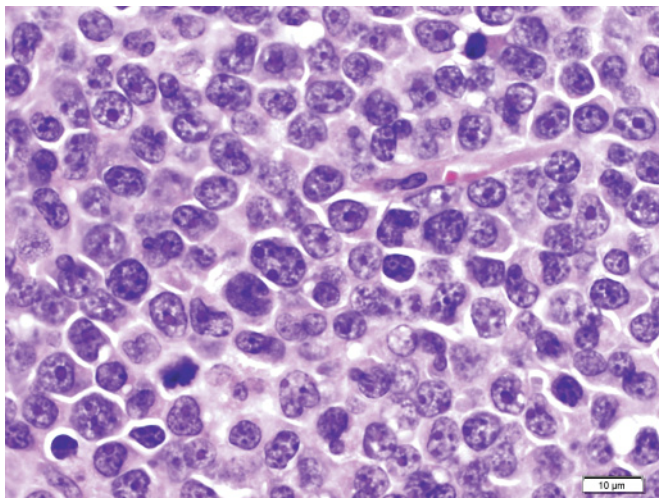

FIGURE 69.19 Lymph node from a dog with diffuse large B cell lymphoma. The large oval nucleus in the center with peripheralized nucleoli is a typical centroblastic nuclear type with mild parachromatin clearing. There is a mitotic cell in the lower left and an apoptotic cell in the upper right. There is more anisokaryosis in this field than is typically present with this subtype of lymphoma. Wright-Giemsa stain.

in which the mitotic rate was determined to be 12.13 per 400× field while in the same study 55 cases of IB-type had a mean mitotic rate of 8.7 mitoses per 400× field. These differences were statistically significant, suggesting that this distinction might relate to biological behavior.

Cytologically, both the immunoblastic and centroblastic cell types tends to have round to oval nuclei 2–2.5 RBCs in diameter and coarse granular or branched chromatin patterns with mild parachromatin clearing. The cytoplasm is almost always moderate in volume and staining density with cell boundaries irregularly distinct. There are usually about the same number of apoptotic nuclei and mitoses as is seen in Burkitt-type lymphoma but not as many tingible body macrophages.

The plasmablastic variant of large B cell lymphoma occurs in dogs, cats, and horses. The distribution of the tumor can vary widely and involve almost all tissues including lungs and skin. Major distinguishing features of this type of lymphoma are large nuclei (>2.0 RBC diameters), marked variation in chromatin distribution, and very abundant eccentrically placed and highly amphophilic cytoplasm. A major difference between plasmablastic lymphoma and plasmacytoma is the presence of nucleoli and a higher mitotic rate in the plasmablastic subtype. There are some differences in homing patterns with the plasmablastic-type of lymphomas tending to mimic plasma cells in homing to medullary cords where they may be mistaken for benign plasma cell expansion if not examined in detail.

The intravascular variant of large B cell lymphoma is rare. It may be found in any tissue but is most frequent in the central nervous system. Animals with this form of lymphoma usually present in good condition with a rapid onset of nervous signs that begins with caudal paresis and rapidly ascends to convulsions and collapse with death occurring in 1–2 days after onset. Histologically, there is dilation of veins in the cerebral meninges and subdural vessels of the spinal cord. Oddly, the cells appear in clusters that distend vessels but do not appear to be attached to vessel walls; however, the tumor is not apparently leukemic. There is marked anisokaryosis with multinucleated and binucleated cells present. The nuclei are vesicular with peripheralized and branched chromatin patterns and multiple prominent nucleoli. The cytoplasm is moderate in volume and staining, and cell boundaries are generally distinct. Similar intravascular lymphomas may be found in the heart and lungs.

Mediastinal large B cell lymphomas are rarely encountered or described but occur in dogs very similarly to what is described in humans. These lymphomas also occur in the cat and perhaps other species. In humans, the disease occurs in young adults with a female to male ratio of 3:1. Specific identification of the neoplasm is important because mediastinal large B cell lymphoma rapidly invades surrounding tissues. This disease is usually identified by ultrasound-guided fine needle aspiration and Tru-cut biopsy. Cytologically, the cells vary markedly in size and shape and are supported by a dense fine fibrovascular network that surrounds cells down to groups of two or three. Binucleated forms are occasionally present.

The primary effusion-type large B cell lymphoma is rare in humans and has recently had a single report in animals. The disease is defined as an effusion of fluid containing neoplastic large B cells in serous cavities including the pleura, pericardium, or peritoneum in the absence of solid tumors in the underlying tissues. In humans, the disease is seen more frequently in immunosuppressed and post-transplant patients.

Involvement of the spleen in large B cell lymphoma is initially multifocal and rapidly becomes coalescing. The multifocal involvement may occur as 1–2 mm foci grossly termed "sago spleen", or the tumor may be a single large isolated mass. Focal large cell splenic lymphoma is an entity in the horse and the tumor may obtain a mass of 11.3–15.9 kg (25–35 lb). Diffuse involvement of the spleen is prominent in cows with lymphoma and rupture of the capsule may be the first indication that the tumor is present with the cow becoming recumbent due to anemia. In general, the larger the tumor the more likely it is to be associated with hemorrhage and infarction. Large B cell lymphoma frequently also involves the liver and kidney, but almost any other tissue in the body may be affected including uterus, skeletal muscle, tonsil and rarely bone.

Large B cell lymphoma of domestic animals labels positively with CD79a and CD20 and is negative for CD3. Most large B cell lymphomas can be shown to have surface or cytoplasmic immunoglobulin and most are clonal for lambda light chain. For some subsets of lymphoma, CD20 is a more useful reagent than CD79a, particularly for plasmablastic lymphoma and T cell-rich large B cell lymphoma.

Studies are now underway to specifically define the changes in B cell lymphoma of dogs that are unique to different breeds and subtypes of lymphoma.[11] Remarkably, after years of comparing animal lymphomas to those in humans there is now interest in studying large cell lymphoma in the dog in order to gain information of comparative value in treating human lymphoma. This interest arises because it is easier to define a single nucleotide polymorphism (SNP) in relatively inbred purebred dogs than in outbred human species. In large cell lymphoma there are frequent chromosomal alterations involving the 3q27 band that apparently is a translocation involving regions of other chromosomes within the sites of immunoglobulin genes.

The cell of origin is not known in animals but it can be assumed that this is roughly similar to humans where in large B cell lymphoma there is usually hypermutation of the IgH region compatible with origin from a post-germinal center cell. Clonality is now determined by polymerase chain reaction (PCR) application of the VDJ region in dogs and cats, and this is now routinely carried out in a number of institutions.

Clinical Features

Of 50 cases of large cell lymphoma described in dogs, the topography included generalized lymphadenopathy in 18, enteric or abdominal in nine, a single enlarged node in seven, multicentric in four, skin in four, tonsillar in three, spleen in two, mediastinum in two, and central nervous system in one. In 314 cats with large cell lymphoma, there were 85 cases with gastrointestinal involvement, 68 multicentric, 56 mediastinal, 35 in small intestine only, 25 renal, 20 with one or two nodes only, seven in nasal cavity, six with subcutaneous mass, three in skin, three in heart, two in urinary bladder, and one in liver. In 118 cases of equine lymphoma, there were 25 cases of large cell lymphoma with 20 of large centroblastic-type, four of immunoblastic-type, and one diffuse large cleaved-type. Presentation was not known in most of the horses, but one had generalized lymphadenopathy, one had splenic only, and four had enteric involvement. There was little information relating clinical signs to topography in these cases. About one-third of human patients with large B cell lymphoma have symptoms that include recurrent fever and weight loss.

Large B cell lymphoma must be distinguished from lymphomas of similar type and T cell phenotype, with the variation in T cell types bridging most of the cytologic descriptions previously given. Large B cell lymphoma must also be distinguished from indolent lymphomas of intermediate subtypes like MZL. One of the most difficult diagnostic decisions is the distinction between large B cell lymphoma and Burkitt-type lymphoma that is of intermediate size and characterized by a very high mitotic rate and presence of numerous tingible body macrophages. One of the reasons this distinction is difficult is that there is a large variation in nuclear size in both large B cell lymphoma and in intermediate type Burkitt's lymphoma, so that in morphometric comparisons there is overlap in nuclear volume but not in mean volume or cell size.

Large B cell lymphomas generally progress with no change in cell morphology. There appears to be progression of changes at the molecular level that may relate to the progression and aggressiveness of tumor with time. Unlike benign B cells, where somatic hypermutation permits antibody diversity, in large B cell lymphoma, dysfunction of this process drives disease progression. Changes in the immunoglobulin genes appear to affect both non-translated as well as coding regions leading to changes in amino acid sequence and ultimately malignant transformation.

Treated animals need to be restaged for subsequent management planning. In human cases, doxorubricin-based therapies are frequently used followed by radiation therapy. Even late-stage disseminated large B cell lymphoma in human patients has been followed by apparently long-term remission using combination chemotherapy, with CHOP being the most common initial regimen. Advancing age is considered an important negative factor in treatment of human patients with large B cell lymphoma; gene activation profiling of human lymphomas suggests that patients who have gene expression that mimics reactive germinal centers have a better survival profile than those whose gene profile reflects the pattern of activated blood lymphocytes.

Treatment and survival is currently under study in animals without firm data. One-third of human patients with large B cell lymphoma have night sweats and irregular fever with weight loss at the time of diagnosis. An international prognostic index developed for large B cell lymphoma, divides human cases into stage 0–1 (35%), stage 2–3 (45%)and stage 4–5 (20%). The 5-year survival for stage 0–1 was 73% and for stage 4–5 was 26%. An almost equivalent estimate of survival was determined by measuring only serum lactate dehydrogenase and β-2 microglobulin levels. The rapidity of achieving complete response on first cycles of treatment is prognostically favorable in humans and apparently has equal value in animals. In humans, a high proliferative rate of the tumor cells tends to correlate with poor survival, while retention of a normally functioning immune system is correlated with longer survival. In humans, over expression of the bcl-2 protein is associated with more frequent relapse but not the presence of BCL-2 gene rearrangement.

Burkitt's Lymphoma

Burkitt's lymphoma is a high grade and multicentric B cell lymphoma characterized by diffuse architecture, heavy tingible body infiltration (starry sky appearance) at low magnification.[8,16,22,25] Cytologically, cells are of intermediate size with vesicular nuclei, multiple nucleoli, moderate parachromatin clearing, and high mitotic rates. Burkitt's lymphoma was the first human tumor shown to be curable by chemotherapy and the first shown to be associated with the Epstein-Barr virus

(EBV). Burkitt's lymphoma was also the first solid tumor to be associated with a non-random chromosomal translocation and also the first in which genetic deregulation was shown to be associated with an oncogene (c-*myc*). It was also recognized that the geographic distribution of Burkitt's lymphoma in Africa was associated with both the presence of endemic malaria and the mosquito vector. Later the association of chronic immune stimulation related to malaria infection was shown to increase susceptibility to chromosomal injury by EBV.

There are two forms of the Burkitt's lymphoma. The classic type has very uniform cells, described as being of monotonous type (i.e. like "peas in a pod"): this form is very rare in animals. In contrast, the variant type (i.e. Burkitt-like lymphoma), also known as small non-cleaved cell lymphoma, is very common in animals, particularly in dogs.

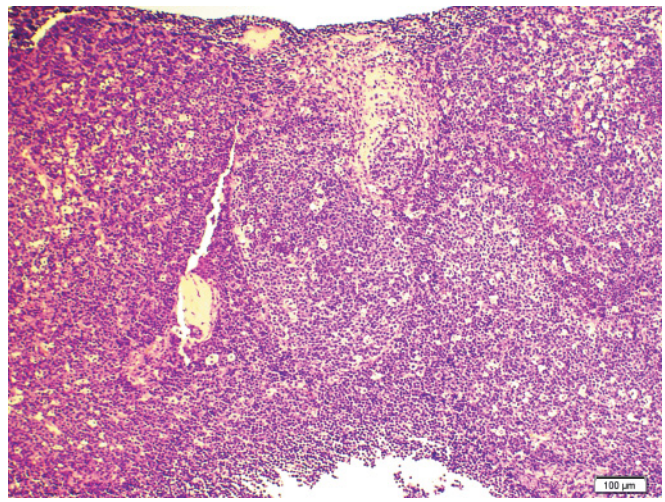

FIGURE 69.20 Lymph node with Burkitt's-like lymphoma. Note the "starry sky" appearance. Wright-Giemsa stain.

Pathologic Features

Because the cells of Burkitt's lymphoma are of intermediate type, the only abnormality that is likely to be noticed in the blood is lymphocytes of intermediate size that have nucleoli, and these may be interpreted as reactive.

The typical architecture of lymph nodes in Burkitt-like lymphoma in dogs is of a multifocal proliferation that compresses normal cells between them.[36] Benign areas are identified by more darkly stained cells, usually of smaller type, and with a higher number of RBCs present. The foci of proliferation are irregularly coalescing and are characterized by many tingible body macrophages in areas of apparent homogeneous cell proliferation. Cytologically, the cells are of intermediate type with round to oval nuclei 1.5 RBCs in diameter. There are irregular areas of chromatin distribution with parachromatin clearing and 1–4 small but prominent nucleoli. Cytoplasm is moderate in volume and staining density, with cell boundaries generally indistinct. There are usually more than 10 mitoses per 400× field. The numbers of apoptotic cells will almost always equal or exceed the number of mitoses with the number of tingible body macrophages usually 2–3 times the number of mitoses (Fig. 69.20). Nuclei can be oval but are not indented. This relates to this same population of cells being identified in the older working formulation as "small non-cleaved cells." If excisional or incisional biopsy tissue is examined, there are fading germinal centers, usually only with a mantle cell cuff remaining in the subcapsular areas. The cortex appears diffuse with compression of medulla, and medullary sclerosis is not present.

In the classical form of Burkitt's lymphoma, the cells are of monotonously uniform-type lacking the mild anisokaryosis of the Burkitt-like lymphoma. The interface of the cells in fixed and processed tissues usually results in separation of cytoplasmic membranes along hexagonal lines, which is known as the "squaring-off" phenomenon typically seen in human Burkitt-type lymphomas. Architectural characteristics are similar, although the Burkitt-type usually presents with solid tumor involvement with high tingible body macrophage infiltration, whereas the Burkitt-like lymphoma is more typical of the multifocal areas of proliferation with foci of coalescing tumor cells. The mitotic rate is similar in both tumor types.

Other organs likely to be involved in the dog include the liver, mesenteric lymph nodes, and intestinal wall. Although the spleen may be involved, the histopathology has not been extensively described.

Burkitt-type and Burkitt-like lymphomas stain strongly with CD79a and CD20, and are negative with CD3.[1,15,26] Currently, specific information on molecular or chromosonal changes in Burkitt-type lymphoma in animals is lacking. Burkitt-type lymphoma in humans has the c-*myc* translocation, whereas the Burkitt-like variant in humans has variable staining for CD10 and Bcl-6 that is strongly positive in Burkitt-type lymphoma and stains positive for Bcl-2 which is not expressed in the classical form.

Burkitt-type lymphoma and Burkitt-like lymphoma must be distinguished from acute lymphoblastic leukemia and lymphoblastic lymphoma.[34,35] This is largely based on the presence of aggregated chromatin with parachromatin clearing and prominent small nucleoli in Burkitt's tumors rather than the uniformly dispersed chromatin and obscured nucleoli of acute lymphoblastic leukemia and lymphoblastic lymphoma. The Burkitt-type lymphoma is distinguished from Burkitt-like lymphoma on the basis of very uniform cell type in Burkitt-type lymphoma with mild anisokaryosis in the Burkitt-like subtype.

Clinical Features

About 20% of human Burkitt's lymphoma cases have bone marrow involvement and oncologists are now finding that dogs also have early involvement of bone marrow. The general presentation of dogs with Burkitt's

lymphoma is of an animal in good condition that suddenly has reduced appetite and is noticed to have one or more enlarged peripheral lymph nodes. Unlike diffuse large B cell lymphoma, Burkitt-like lymphoma tends to present in dogs less than 10 years of age and generally 5–7 years old with no gender preference.

Burkitt-like lymphoma, as well as Burkitt-type lymphoma, tends to be widespread and extranodal at the time of diagnosis. Careful staging is important to determine all sites of involvement. Restaging is essential to determine new or recurrent sites of tumor involvement. That is usually done by x-ray of the chest and ultrasound examination of the abdomen as well as digital palpation. In human cases, serum lactate dehydrogenase and IL-2 receptor levels correlate well with tumor burden and progressively rise in concert with increasing tumor cell volume. Bone marrow aspirate and core biopsy are indicated if the animals have a nonregenerative anemia and the anemia is not likely to be due to prior treatment.

Treatment of Burkitt-like lymphoma appears to be one of the areas where veterinary oncology is making progress, with long-term survival exceeding 2 years in some cases. Human cases that present in early stages of the disease can be confidently cured with current treatments, and even cases that present as advanced have only slightly less probability of long-term survival.

Waldenström's Macroglobulinemia

Acronyms and Abbreviations

BM, bone marrow; BMSC, bone marrow stromal cell; CCNU, 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (Lomustine); CD, cluster of differentiation; CEMP, cutaneous extramedullary plasmacytoma; CT, computed tomography; EMP, extramedullary plasmacytoma; FELV, feline leukemia virus; FIV, feline immunodeficiency virus; HVS, hyperviscosity syndrome; IFE, immunofixation electrophoresis; IFN, interferon; Ig, immunoglobulin; IL, interleukin; IRF, interferon receptor factor; IRF4, interferon receptor factor 4; MGUS, monoclonal gammopathy of unknown significance; MM, multiple myeloma; MRD, myeloma related disorders; MRI, magnetic resonance imaging; NCEMP, non-cutaneous extramedullar plasmacytoma; NFκB, nuclear factor kappa B; OAF, osteoclast activating factor; PBSC, peripheral blood derived stem cell; PET, positron emission tomography; PT, prothrombin; PTT, partial thromboplastin; RANK, receptor activator nuclear factor Kappa B; RANKL, receptor activator nuclear factor kappa B ligand; RBC, red blood cell; SOP, solitary osseous plasmacytoma; SPB, solitary plasmacytoma of bone; SSA, sulfosalicylic acid; TNF-α, tumor necrosis factor-α; VAD, vincristine adriamycin (doxorubicin) prednisone; VBAP, vincristine BCNU adriamycin (doxorubicin) prednisone; VBMCP, vincristine BCNU melphalan cyclophosphamide prednisone; VEGF, vascular endothelial growth factor; VEGF-R1, vascular endothelial growth factor receptor 1; WM, Waldenström's macroglobulinemia.

Plasma cell tumors represent a spectrum of diseases characterized by clonal (predominantly monoclonal) proliferation of immunoglobulin (Ig)-producing plasma cells or B cells.[21] They encompass clinically indolent conditions such as monoclonal gammopathy of unknown significance (MGUS) and Waldenström's macroglobulinemia (WM) as well as malignant processes, including multiple myeloma (MM) and solitary plasmacytoma (solitary osseous plasmacytoma and extramedullary plasmacytoma). All these disorders share common cytomorphologic features, Ig production patterns, and immune dysfunction.

Five major classes of Ig: IgG, IgA, IgM, IgD, and IgE, are synthesized by normal B cells and plasma cells, whereas atypical plasma cells secrete one of these molecules or, occasionally, only light chain molecules. When the production of heavy and light chain molecules is unbalanced, the excess of light chain proteins is excreted in the urine (i.e. Bence Jones proteinuria; see Chapter 145). In non-secretory-type myeloma, plasma cells do not secrete these proteins.

MULTIPLE MYELOMA

Epidemiology

Multiple myeloma (MM) is estimated to account for <1% of all malignant tumors occurring in domestic animals and approximately 8% of all hematopoietic malignancies in dogs.[20,29] The true incidence of MM in cats is unknown, but it appears to be less common in

this species, and it is extremely rare in other domestic animals.[6,36] In humans, more than 50% of MM patients are older than 70 years. Likewise, older dogs (average 8–9 years)[29,36] and cats (average 12–14 years)[14,36] are most commonly affected.

Etiology

Factors associated with the development of MM in companion animals have not been clearly identified. In humans, exposure to ionizing radiation is consistently linked to MM development. Genetic and hereditary factors may play a role in myeloma development. Recurrent infections or antigenic stimulation have been proposed as predisposing factors, although epidemiologic studies have not confirmed this association.

A link between MM and feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV) infections has not been identified, but the diagnosis of disease among siblings suggests a familial association.[14] The role of oncogenes, tumor-suppressor genes, cytokines, and their interaction with the bone marrow microenvironment in the etio-pathogenesis of the disease are currently being investigated in animal models. Overexpression of cell cycle regulators such as cyclin D1 and dysregulation of receptor tyrosine kinase have been implicated in the pathogenesis of plasma cell tumors and MM.[2] Progression of B cell lymphoma to MM in one dog and of solitary plasma cell tumors to MM in both dogs and cats have been reported.[38] MGUS, described as a premalignant condition, rarely progresses to MM.

Pathogenesis and Disease Evolution

Multiple myeloma is characterized by the proliferation of malignant plasma cells or their precursors, arising as a clone from a single cell. It is a germinal center-derived tumor with a B cell phenotype and Ig gene hypermutation and rearrangement. MM is associated with a dysregulation of genes responsible for controlling cell growth and survival, resulting in a multistep process that involves alterations in oncogenes and tumor suppressor genes.

Like other lymphocytes, B cells do not have multilineage potential, but they have the ability to self-renew at multiple steps of development. These properties may be co-opted by malignant plasma cells to maintain a "stem cell" phenotype. Multiple myeloma stem cells also may possess or acquire drug resistance: (1) by maintaining quiescence; (2) by increasing intracellular detoxifying enzymes; or (3) by expression of drug transporters on the surface membrane, as has been demonstrated for brain tumors and leukemic stem cells. Stem cell signaling pathways also may support cancer stem cells; for example, aberrant activation of the Hedgehog signaling pathway has been associated with the development of MM, and its inhibition induces plasma cell proliferation.

It has been hypothesized that a subset of MM may derive from MGUS. Furthermore, monosomy 13 seems to be implicated in the transition of MGUS to MM.[1] Interactions between cancer cells and microenvironment (bone marrow stromal cells and extracellular matrix) are mediated by myeloma cell-derived adhesion molecules, which are essential for tumor cell localization, growth, and survival. Moreover, increased microvessel density has been demonstrated in human patients with MM compared to patients with MGUS and immunohistochemical studies also have shown vascular endothelial growth factor (VEGF) expression by myeloma cells, thus implying the potential role and clinical relevance of angiogenesis in MM.

While VEGF does not appear to have considerable proliferative effects on myeloma cells, it plays an important role in cancer cell migration and angiogenesis. Indeed, myeloma cells have been shown to express the vascular endothelial growth factor receptor 1 (VEGF-R1), which may provide an interesting therapeutic target for emerging anti-angiogenic strategies.

The secretion of tumor necrosis factor-α (TNF-α) by myeloma cells not only stimulates the production by bone marrow stromal cells (BMSCs) of interleukin-6 (IL-6), an essential growth and survival factor for these cancer cells, but also induces nuclear factor kappa B (NFκB) activation leading to the up-regulation of adhesion molecules.

Clinical Manifestations of Disease

The infiltration of various organ systems by neoplastic cells, the production of cytokines by the tumor or the bone marrow microenvironment, and the high circulating level of a single type of immunoglobulin (M-component), lead to a wide array of clinical manifestations. Multiple myeloma patients are usually immunocompromised and thus highly susceptible to infections. This occurs due to suppression of normal Ig and albumin secondary to a variety of factors, including a direct effect of the monoclonal Ig, bone marrow crowding, decreased T helper cell function, and macrophage-related factors influencing the progression of B cells to plasma cells.

A variety of pathologic conditions are associated with MM, including bleeding diathesis, hyperviscosity syndrome (HVS), renal disease, cardiac disease, skeletal lesions, hypercalcemia, bone marrow hypoplasia, and hypercholesterolemia. The pathogenesis of bleeding diathesis is likely multifactorial. The M-component may interfere with normal coagulation and lead to hemostatic defects by various mechanisms that include: (1) inhibition of platelet aggregation and release of platelet factor 3; (2) adsorption of minor clotting factors; (3) induction of abnormal fibrin polymerization; and (4) functional decrease in calcium. Clinically, hemorrhages occur in approximately one-third of dogs and one-fourth of cats affected by MM.[14,29,36] In instances where myelophthisis is present due to profound bone marrow infiltration, thrombocytopenia may develop and contribute to hemorrhagic events. Approximately 50% of dogs affected by MM have abnormal prothrombin (PT) and partial thromboplastin (PTT) times. In a recent ret-

rospective study of MM in 16 cats, thrombocytopenia was identified in just over 50% of the cats and one had evidence of a prolonged PT.[36]

Hyperviscosity syndrome is characterized by clinicopathologic abnormalities that occur secondarily to increased serum viscosity, which is associated with the M-component. Hyperviscosity syndrome is most commonly associated with IgM macroglobulinemia due to the high molecular weight of IgM.[10] However, it also can occur in presence of IgA and rarely with IgG.[29] Hyperviscosity syndrome leads to bleeding diathesis, neurologic signs (such as seizures, depression, coma), congestive heart failure, renal failure, and ophthalmic abnormalities, including tortuous and dilated retinal vessels, retinal hemorrhages, and retinal detachment, sludging of blood within small vessels, and impaired delivery of nutrients and oxygen to tissues. Approximately 20% of dogs with MM develop HVS and it has been reported in cats.[36]

Renal disease occurs in approximately 30–50% of dogs and about 30% of cats with MM.[29,36] The pathogenesis of renal disease is commonly multifactorial and implicated mechanisms include: (1) tumor infiltration within the renal parenchyma; (2) hypercalcemia; (3) amyloidosis; (4) decreased renal perfusion due to HVS; (5) dehydration; (6) ascending urinary tract infections; (7) Bence Jones proteinuria; and (8) development of light-chain casts causing interstitial nephritis.[29] Light chain proteins have a low relative molecular mass and are normally filtered through the renal glomerulus. In MM, however, an imbalance between heavy and light chain proteins occurs, which leads to an excess of light chains that can precipitate and cause renal tubular obstruction and injury. In the absence of a concurrent monoclonal spike, light chain proteinuria is most likely indicative of light chain disease. Bence Jones proteinuria has been estimated to occur in approximately 25–40% of dogs and approximately 65% of cats with MM.[29,36] Urine protein electrophoresis remains the preferred diagnostic modality to detect monoclonal light chain proteinuria.

Heart failure may occur as a result of hyperviscosity-related myocardial hypoxia and increased cardiac workload. In addition, amyloid deposition in the myocardium and anemia may exacerbate the severity of this condition. Approximately 50% of cats with MM in one study had an idiopathic heart murmur.[36]

Skeletal lesions can be either solitary (well-circumscribed, "punched-out" area of osteolysis) or multiple (diffuse osteopenias) and occur in approximately 50–56% of dogs with MM.[29] Rarely, pathologic fractures are seen. Skeletal lesions are typically identified in bones involved in active hematopoiesis (e.g. ribs, vertebrae, pelvis, and proximal and distal aspects of long bones).

Hypercalcemia has been reported in approximately 15–20% of dogs and 20–25% of cats affected by MM.[14,36,40] It is thought to result from the release of an osteoclast-activating factor (OAF) by either the bone marrow microenvironment or by cancer cells locally in bone.[29] Parathyroid hormone-related peptide also may contribute to the pathogenesis of MM-related hypercalcemia.[39] In humans, interleukin-1 (IL-1), IL-6, tumor necrosis factor-α (TNF-α) and the receptor activator of the nuclear factor kappa B ligand (RANKL) all modulate osteoclast activity and may contribute to hypercalcemia. Because binding of calcium by the M-component increases the total calcium concentration, determination of ionized calcium is necessary to confirm a true hypercalcemia.

Approximately 30% of dogs and 75% of cats have a normocytic normochromic nonregenerative anemia associated with anemia of inflammatory disease, myelophthisis, hemostatic abnormalities resulting in blood loss, or increased red blood cell (RBC) destruction induced by HVS.[29] In humans with MM, decreased erythropoietin responsiveness has been documented. Multiple myeloma-related thrombocytopenia and neutropenia can also be observed in cats and dogs.[14,36]

Hypocholesterolemia was noted in approximately 69% of affected cats in one study.[36] This finding was inversely correlated with globulin concentration and was suspected to be related to down-regulation of hepatic cholesterol production in the attempt to maintain adequate oncotic pressure despite the presence of hyperglobulinemia.

Diagnosis

Symptoms suggestive of MM include the onset of bone pain or back pain, renal failure, anemia, and a history of recurrent infections. Patients exhibiting these signs should be evaluated with a complete blood count, serum biochemical profile, and urinalysis. Serum and urine protein electrophoresis should be performed in the presence of hyperglobulinemia and proteinuria, respectively, to confirm the presence of a monoclonal gammopathy and identify the class of Ig involved in the disease process (see Chapter 145). In patients experiencing bleeding, a hemostatic profile should also be performed and serum viscosity measurements considered (see Chapters 138 and 145). In dogs affected by MM, the incidence of IgA and IgG is comparable, whereas in cats, IgG is most commonly involved.[29,39,40] Rarely, occurrences of biclonal gammopathies have been reported and, on occasions, cryoglobulinemia has been described in dogs.[6]

Screening for Bence Jones proteinuria should not be based solely upon urine dipstick because this modality primarily detects albuminuria (see Chapter 145). The sulfosalicylic acid (SSA) test provides greater sensitivity for globulin detection but specificity is low due to the concomitant detection of albumin, globulin, Bence Jones proteins, proteases, and polypeptides. In people, false positive results for Bence Jones proteins detected by means of heat precipitation can occur due to excessive amount of polyclonal light chain proteins in patients affected by a variety of conditions, including nonplasmacytic tumors and chronic renal failure. Therefore, urine protein electrophoresis remains the preferred diagnostic modality for the detection of Bence Jones proteins.

Bone marrow infiltration by MM can be quite variable, with the vast majority of patients having an amount of plasma cells greater than 5%. The appearance of malignant plasma cells can range from normal plasma cells, to mildly differentiated cells, to bizarre atypical forms. Plasma cell morphology can be an important predictor of severity of disease (Fig. 70.1).[8] In humans, histopathologic grade is correlated with disease progression, with grade I disease being slow-growing in contrast to grade III disease (plasmablastic-type) characterized by an aggressive behavior.

Survey radiographs are typically recommended to screen for skeletal lesions. These vary from areas of osteopenia observed in early stages of diseases to lytic, "punched-out" lesions typical of later stages. Biopsy and histopathology of a lytic lesion may sometimes be necessary for a definitive diagnosis. Skeletal lesions are rare in patients with Waldenström macroglobulinemia where cancer cells more commonly infiltrate other organs, including liver, spleen, and lymph nodes.[10,16]

In cats, the frequent identification of abdominal organ neoplasia (85% of organs with an imaging abnormality) underscores the need to incorporate abdominal imaging as part of the routine staging (Fig. 70.2).[32] A funduscopic examination should be performed to rule out ocular lesions, such as retinal hemorrhages, retinal detachment, venous tortuosity, dilation, sacculation, and blindness.

Other conditions associated with monoclonal gammopathies that should be considered as differential diagnoses include lymphoproliferative disorders, chronic infections (e.g. ehrlichiosis and leishmaniasis in dogs, and feline infectious peritonitis in cats), immune-mediated disorders, and other neoplastic conditions.

Treatment

Treatment of MM with oral melphalan and prednisone is the standard of therapy due to its dual ability to reduce the bulk of the tumor and the symptoms of disease. Although complete eradication of disease is only rarely achieved, chemotherapy is often effective in decreasing tumor burden, reducing serum Ig levels, promoting bone remodeling, and providing symptomatic relief. Overall this leads to improved quality and possibly duration of life.[29,30]

Melphalan is an alkylating agent whose oral absorption is unpredictable, requiring administration to be made preferably on an empty stomach. In dogs, melphalan is initially administered at 0.1 mg/kg orally once a day for 10 days, and then at 0.05 mg/kg orally every other day. Prednisone is generally administered at 1.0 mg/kg for the first 10 days of therapy, and then decreased to 0.5 mg/kg every other day. Treatment is continued indefinitely, until relapse or myelosuppression occurs. Possible myelosuppression is generally monitored via serial complete blood counts performed biweekly for 2 months and monthly thereafter. A pulse-dosing regimen, where melphalan is administered at 7 mg/m^2 orally for five consecutive days every 3 weeks, has been used successfully in patients experiencing dose-limiting thrombocytopenia with the more conventional low-dose treatment described above.

Other alkylating agents including cyclophosphamide (Cytoxan), chlorambucil (Leukeran), and 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (CCNU or Lomustine) also have been used to treat MM in dogs and cats.[7] The addition of cyclophosphamide to a prednisone/melphalan regimen may be beneficial to patients with severe clinical signs and/or hypercalcemia. Due to its platelet-sparing effect, cyclophosphamide may be used in place of melphalan in thrombocytopenic patients, although this drug can have severe suppressive effects on other bone marrow lineages. Chlorambucil, administered at 0.2 mg/kg orally once daily has been used successfully for the treatment of IgM macroglobulinemia in dogs. CCNU has been used in cats at 50 mg/m^2 orally every 21 days, resulting in one partial response.[41] Combination chemotherapy protocols incorporating vincristine, carmustine (BCNU), melphalan, cyclophosphamide, and prednisone (VBMCP) or vincristine, melphalan, cyclophosphamide, and prednisone/vincristine, BCNU, doxorubicin, and prednisone (VMCP/VBAP) have been extensively utilized in people, but outcomes are essentially comparable to those of patients treated with prednisone and melphalan alone.

Glucocorticoids have been shown to induce apoptosis in vitro via inhibition of IκB activation and decreased NFκB activity. The administration of high-dose dexamethasone in conjunction with vincristine and doxorubicin (VAD) was investigated in humans with refractory myeloma and resulted in a response rate greater than 50%. Rapid tumor response, alleviation of bone pain, resolution of hypercalcemia, and absence of cumulative damage to bone marrow stem cells were remarkable advantages of this treatment combination.

Anecdotally, in dogs, responses of a few months duration have been achieved with a combination of doxorubicin (30 mg/m^2 intravenously every 21 days), vincristine (0.7 mg/m^2 intravenously on days 8 and 15), and prednisone (1 mg/kg orally daily). Rescue approaches have been taken in dogs with refractory myeloma with high-dose cyclophosphamide (limited success), and liposome-encapsulated doxorubicin, which resulted in a durable remission in one dog.[18]

The efficacy of interferon (IFN) for the treatment of MM is controversial. While a response rate of approximately 20% was reported in humans with relapsed myeloma, the addition of IFN to standard chemotherapy approaches failed to provide a significant benefit to the overall survival time in a meta-analysis of 2,286 patients.[27]

High-dose chemotherapy in association with autologous transplantation using bone marrow (BM) or blood-derived stem cells (PBSCs) is now widely used for the treatment of hematological malignancies including MM (see Chapter 102). This approach yielded complete remissions in refractory human patients, but mortality rate due to bone marrow suppression was high. Contamination of most bone marrow and blood stem cell samples with neoplastic cells has been shown in MM even after high-dose chemotherapy. The presence of tumor cells within the autograft has resulted in recurrence of disease, emphasizing the need to optimize purging techniques.

In humans with indolent myeloma, treatment is generally withheld until disease progression, symptomatic manifestations, or new lytic bone lesions develop. However, bisphosphonates such as pamidronate have been used to prevent or delay the onset of bone lesions and associated bone pain.

Treatment of patients affected by indolent myeloma with the anti-angiogenic agent thalidomide resulted in a 66% response rate and the drug appeared to have potential to delay the onset of clinical signs associated with the disease. The efficacy of thalidomide for the treatment of refractory relapsed MM has also been confirmed. The combination of thalidomide and dexamethasone has yielded response rates greater than 50% in patients with relapsed myeloma and 70% in newly diagnosed patients.[35] Studies evaluating the role and possible efficacy of thalidomide for the treatment of MM in pet animals are lacking, in part because federal regulations in the United States prohibit dispensing thalidomide for veterinary patients.

Bortezomib, a proteasome inhibitor, induces apoptosis of MM cells and inhibits their binding to BMSCs, which otherwise would trigger the transcription of IL-6 via an NFκB-dependent pathway.[15] In a multicenter phase II trial of bortezomib, a 35% response rate was achieved with a median duration of remission of 12 months and an overall survival time of 16 months. Addition of dexamethasone to the treatment regimen improved responses in 19% of treated patients.

Response to therapy is assessed based on amelioration of clinical signs as well as improvement in the radiographic appearance of skeletal lesions and clinicopathologic abnormalities.[29] Because complete resolution of MM is extremely rare, a ≥50% reduction in the pre-treatment M-component (Bence Jones proteins or Ig) is considered a good response to therapy.

Patients experiencing severe clinical signs secondary to hypercalcemia and renal impairment, HVS, or pathologic fractures may require additional therapy specifically directed to the clinical complications of disease. For example, fluid therapy and diuretics may need to be instituted for patients with severe hypercalcemia. Similarly, plasmapheresis may be beneficial in minimizing clinical signs of hyperviscosity, while aggressive fluid therapy may be necessary for patients with renal failure.

Prognosis

In humans with MM, the course of disease is extremely variable, with survival times ranging from less than 1 year with aggressive forms to more than a decade in indolent forms. Prognostic variables in people include: (1) tumor burden (serum calcium, immunoglobulin, albumin, α_2-microglobulin, number of lytic bone lesions, percentage of bone marrow plasmacytosis); (2) tumor biology (mitotic rate, IgA myeloma, plasma cell labeling index); (3) tumor microenvironment (bone marrow microvessel density and matrix metalloproteinase 9 level, among others); (4) treatment (12 months or less of prior treatment, achievement of complete remission, tandem transplantation, second transplantation within 6 months); and (5) patient (performance status, albumin level, other unrelated conditions).

α_2-Microglobulin has been consistently identified as a predictor of survival in MM. It is a light-chain protein belonging to the class I of histocompatibility antigens expressed on the surface of nucleated cells and released into the blood. Because α_2-microglobulin is excreted by the kidneys its level reflects tumor burden as well as renal function.

In humans, a nodular pattern of bone marrow infiltration appears to be associated with a worse prognosis compared to a diffuse pattern. In addition, severity of disease has been correlated with cell morphology. For example, plasmablastic disease has been associated with a more aggressive behavior of the cancer.

In dogs with MM, the short-term prognosis is good in respect to initial tumor control and improvement of quality of life. However, the long-term prognosis is generally poor due to high likelihood of tumor relapse and recurrence of clinical signs as well as development of resistance to chemotherapeutic agents. In a study of 60 dogs with MM treated with melphalan/prednisone combination chemotherapy: 8% did not respond to therapy; 43% achieved complete remission (defined as normalization of serum Ig); and 49% achieved a partial remission (defined as less than 50% decrease in the pre-treatment Ig level). The median survival time was 540 days. Negative prognostic factors identified in this study include presence of hypercalcemia, extensive bone lysis, and evidence of Bence Jones proteinuria.[29]

Short-term prognosis is unfortunately not as good in cats as it is in dogs. Although the majority of cats initially respond to melphalan/prednisone or cyclophosphamide-based chemotherapy regimens, responses are often partial and short-lasting. The median survival of cats is approximately 4 months, but survival times greater than 1 year have been reported.[5,14,29,40]

IgM macroglobulinemia has been identified and treated only in a small number of dogs. In nine dogs treated with chlorambucil, 77% achieved remission and the reported median survival time was 11 months.

SOLITARY AND EXTRAMEDULLARY PLASMACYTIC TUMORS

Extramedullary plasmacytoma (EMP) is a neoplastic plasma cell tumor originating from soft tissues in the absence of primary bone marrow disease; both cutaneous (CEMP) and non-cutaneous (NCEMP) forms have been described.[24,27] Solitary osseous plasmacytoma (SOP or SPB) is an isolated lesion of bone origin with potential to progress to systemic MM.[23,31] Plasma cell tumors account for approximately 2.4% of all canine tumors and most commonly occur at cutaneous sites (86% of cases), followed by mucous membranes of lips and oral cavity (9%), colon, and rectum (8%). Approximately 22–28% of EMPs in dogs are located within the oral cavity.[4] Feline EMPs have been reported to occur in skin, upper lip, gingiva, orbit, gastrointestinal tract, brain, and retroperitoneal space, and their incidence appears to be low.[3,12,22,25,26,33]

The median age of dogs affected by plasmacytomas is 9–10 years and breed predispositions include American cocker spaniel, English cocker spaniel, and West Highland White terrier. The median age of affected cats is 10.6 years and the European short-haired cat is overrepresented.[22,37] Individual cases have been reported in Abyssinian, Persian, and Burmese breeds.

Historically, EMP carries a better prognosis than MM. However, the biological behavior of EMP highly depends upon its anatomic location. For example, EMPs in cutaneous and oral cavity locations are generally associated with a low metastatic rate, and thus are curable by means of surgery alone. Progression of cutaneous EMPs to systemic disease has been documented in two cats, one of which developed MM, the other nodal and distant metastatic disease.[3,38] Non-cutaneous and non-oral forms of EMPs typically have a more aggressive behavior. Gastrointestinal EMPs, affecting esophagus,[13] stomach,[24] small intestine,[17] and large intestine[17,19,24] are frequently associated with lymph node metastases, although monoclonal gammopathies and bone marrow involvement are rare.

Solitary osseous plasmacytoma has been reported to occur in ribs and zygomatic arch of dogs. Solitary osseous plasmacytoma frequently progresses to MM, although this may take months to years to occur.[24,31]

Clinical Manifestations of Disease

Clinical manifestations are dependent on the anatomic location of the tumor. Cutaneous forms generally manifest as a solitary, raised, alopecic, smooth nodule 1–10 cm in diameter, and clinical signs of illness are typically absent. Bleeding from the mouth was the chief complaint in canine oral EMP. Gastrointestinal EMP is associated with nonspecific signs, whereas colorectal EMP often results in tenesmus, rectal prolapse, rectal bleeding, and hematochezia.[19] Pain, lameness, and neurologic signs may be observed in dogs with SOP affecting the appendicular or the axial skeleton.

Diagnosis

Fine needle aspiration or biopsy is needed to confirm a diagnosis of SOP or EMP. Reclassification of reticulum cell sarcomas as plasmacytomas has resulted in an increased incidence of this type of tumor in veterinary medicine.[4]

Plasmacytomas are generally characterized by a monomorphic population of plasma cells with occasional binucleate or multinucleate cell present. A polymorphic blastic plasma cell that appears to be associated with a more aggressive behavior in the dog has also been described.[2,19] Immunohistochemical detection of cytoplasmic Igs with predominant clonality for κ- or λ-chains is a common finding and 97–100% of EMPs are positive for λ-chain reactivity.[24] Moreover, monoclonal light-chain reactivity is helpful in differentiating plasmacytomas from other round cell tumors. However, Ig heavy chains (IgG and IgA chains) have been confirmed in other feline tumor cells; which often contain amyloid deposits.[3,22,26,37] Canine plasmacytomas stain positively for IgG, A, or M as well as CD45, CD18, CD45RA, and CD79a (Mb-1) leukocyte antigens. While the Cyclin-D1 marker has been identified in MM, no association has been found that relates Cyclin-D1 to plasmacytomas. Interestingly, the identification of this marker in EMPs has been postulated to be a possible indicator of a highly-aggressive malignancy or a metastatic lesion from MM.[2]

A complete staging should be performed before initiation of therapy to rule out systemic involvement, which, if present, would alter treatment recommendations and prognosis. Diagnostic modalities should include serum protein electrophoresis, skeletal survey radiographs, bone marrow aspiration, and cytology, particularly for SOPs and gastrointestinal EMPs due to their higher metastatic potential.

Treatment

Surgery is considered the treatment of choice for cutaneous plasmacytomas and, on rare occasions, melphalan and prednisone therapy has been successfully utilized in canine and feline cases where surgery resulted in incomplete tumor margins or local tumor recurrence. Surgery is also recommended in patients with SOPs associated with a pathologic fracture or with neurologic compromise. Spinal cord decompression combined with removal of the primary tumor and spinal cord stabilization may need to be performed in selected patients. The efficacy of radiation therapy in palliating bone pain associated with the tumor itself and/or the presence of pathologic fractures has been reported; however, the majority of patients eventually developed MM.[23,31]

In patients with SOPs and no evidence of systemic involvement, it is debatable as to whether chemotherapy should be instituted at the same time as local therapy. Likewise, gastrointestinal EMPs are managed solely with surgery, unless systemic disease is documented, in which case the incorporation of chemotherapy would be warranted. Mandibulectomy or maxillectomy is recommended for treatment of oral plasmacytomas accompanied by boney infiltration.[4,] All dogs with oral plasmacytomas excised with incomplete surgical margins experienced local tumor regrowth in one study.[41] Periodic monitoring and restaging are pivotal in allowing early detection of tumor regrowth and metastatic disease.

Prognosis

Oral, cutaneous and mucocutaneous plasmacytomas are associated with a good prognosis and can be cured by means of surgery alone, provided complete surgical margins are achieved.[2,41] Anecdotally, multiple plasmacytomas that eventually resulted in death of affected dogs have been reported. Tumor cell proliferation rate (based on Ki-67 staining) and histopathologic grade have not been found to hold prognostic significance in dogs or cats, although a more aggressive behavior has been attributed to a polymorphic blastic type of canine plasmacytoma.[2,25] Cyclin-D1 expression and presence of amyloid also do not seem to have clinical significance.[2]

Radiation therapy is the preferred treatment option for solitary plasmacytomas. In fact, local recurrence rates less than 10% and long-term survival in 30% and 70% of patients with SOPs and EMPs, respectively, are expected in patients treated with definitive courses of radiation therapy. This is most likely due to the high-grade nature of round cell tumors that makes them susceptible to therapy.

Long-term survival times have also been reported for dogs with gastrointestinal EMPs or EMPs affecting liver, uterus, or other abdominal organs, undergoing surgery and/or chemotherapy.[19,23,24] The median survival time of nine dogs with colorectal plasmacytomas was 15 months;[19] two dogs treated with surgery alone experienced tumor regrowth 5 and 8 months postoperatively. DNA aneuploidy and c-myc oncoprotein content of canine plasmacytomas were analyzed by means of flow cytometry and found to be predictive for survival; however, findings strongly correlated with non-cutaneous forms of disease, suggesting that location of the tumor is a prognostic indicator of equivalent importance.[9]

In cats, prognostic information is limited mostly due to the rarity of these tumors and the related paucity of

cases reported in the literature. In general, principles of therapy that apply to dogs should be also applied to feline patients.

WALDENSTRÖM'S MACROGLOBULINEMIA

Waldenström's macroglobulinemia (WM) is a rare lymphoproliferative, immunosecretory disorder occurring in dogs, cats, and humans. According to the WHO classification scheme, it is considered a form of lymphoplasmacytic lymphoma that involves spleen, bone marrow, and lymph nodes and can manifest with IgM-related signs of cryoglobulinemia or hyperviscosity. This description corresponds to the lymphoplasmacytic type of immunocytoma incorporated into the Kiel classification and to the REAL lymphoplasmacytoid lymphoma/immunocytoma. A consensus has not yet been reached among pathologists in regard to the new classification, most likely due to the subjectivity involved in the distinction between small or plasmacytoid lymphocytes and plasma cells.

Waldenström's macroglobulinemia is characterized by bleeding tendencies, anemia, lymphadenopathy, high-serum viscosity with a high molecular mass M-component, and is associated with a monoclonal expansion of B cells infiltrating the bone marrow or other lymphoid organs producing an IgM serum paraprotein. IgM consists of high-relative molecular mass, positively charged proteins that can bind to RBCs leading to rouleaux formation. Waldenström's macroglobulinemia differs from MM in that bone lysis is generally absent and hepatosplenomegaly, lymphadenopathy, or both are frequently encountered clinical findings. Peripheral neuropathy, hyperviscosity syndrome (HVS), and HVS-associated complications that include retinal hemorrhage, epistaxis, cardiac and renal damage, and central nervous system abnormalities can occur. In addition, IgM can cause immune-mediated disorders such as cryoglobulinemia, cold agglutinin hemolytic anemia, and peripheral neuropathies secondarily to autoantibody activity.[11,34] Bleeding diathesis has been reported to occur in approximately 33% of affected dogs and it is suspected to derive from the interference of IgM with clotting factors and/or platelet aggregation. Possible laboratory findings in both humans and dogs include anemia, pancytopenia, leukocytosis or leukopenia, hypercalcemia, IgM hypergammaglobulinemia, and Bence Jones proteinuria.[11] In addition to WM, the production of IgM paraproteins has been reported in association with MM, chronic lymphocytic leukemia, splenic marginal zone lymphoma, extranodal marginal zone lymphoma, plasmacytoid lymphoma, and non-neoplastic conditions such as leishmaniosis.

In human patients, findings that may aid in differentiating WM from other non-neoplastic monoclonal gammopathies or MGUS include the degree of bone marrow infiltration and the amount of M-component, and it has been suggested that the minimum threshold of IgM level is 30 g/L and the percentage of plasma cells in bone marrow is 20%.[20] Diagnostic features of this disease in dogs are still a matter of debate. Immunophenotyping and serum immunofixation electrophoresis (IFE) are often necessary to more definitively diagnose lymphoproliferative disorders in pet animals.

Treatment of WM is unlikely to provide a cure; rather, it is directed at diminishing tumor burden and alleviating clinical signs associated with the disease. Approximately 77% of dogs with IgM macroglobulinemia respond favorably to prednisone therapy combined with alkylating agent-based chemotherapy, and median survival times range from 11 months to 14 months.[28] Chlorambucil is most frequently used in conjunction with prednisone, but melphalan and cyclophosphamide have also been shown to have activity against IgM macroglobulinemia.[11,20]

DEFINITION

Hodgkin's lymphoma is a disease in humans with a number of subtypes all of which require the presence of the iconic Reed-Sternberg cells which themselves vary between the subtypes of this neoplasm. Briefly stated, the World Health Organization (WHO) classification for Hodgkin's lymphoma includes four subtypes: (1) nodular lymphocyte predominance; (2) lymphocyte-rich classic; (3) nodular sclerosis grades I and II; (4) mixed cellularity and lymphocyte depletion.

CLASSIFICATION OF HODGKIN'S LYMPHOMA

Like the non-Hodgkin's lymphoma, the classification of Hodgkin's type of lymphoid neoplasms has been the subject of continuous variation based on new developments and increased understanding of the underlying neoplastic processes (see Chapter 64). Reed-Sternberg (RS) cells are derived from B cells that have a rearranged variable region of the immunoglobulin gene. In type 3 Hodgkin's disease, Reed-Sternberg cells are clonal, whereas in the lymphocyte predominance type, the variable region of the immunoglobulin gene continues to mutate: this is now identified as the lymphocyte-rich classic type. This situation is even more complex with a small proportion of human cases having apparent Reed-Sternberg cells that appear to be dendritic cells or natural killer (NK) cells. Therefore, the definition of Hodgkin's lymphoma in humans is neither entirely a specific or exclusive designation and it becomes more likely that there are types of neoplasms in animals that have characteristics similar to human Hodgkin's lymphoma without being exact replicas of human Hodgkin's lymphoma.[1–7]

T cell-rich large B cell lymphoma in the cat is biologically similar to Hodgkin's disease. Feline T cell-rich large B cell lymphoma characteristically appears first in the nodes in the cervical region, frequently on the right side. Spread from that area will be to a node immediately beneath the initially involved node and secondly either to the prescapsular node or down the neck to the mediastinal node.

A further complication is that Reed-Sternberg-type cells in animals with lymphoma differ from those described in humans. Human Reed-Sternberg cells are described as having peripheralized chromatin with a hyperdistended central nucleolus in a binucleated cell arising within "an appropriate cellular background". Most cases of putative Reed-Sternberg cells in animals do not have peripheralized chromatin or hyperdistended nucleoli, even if they are binucleated. Despite that, there are sufficient similarities occurring in the feline type of Hodgkin's-like lymphoma that the designation appears appropriate when considered along with the similarities in biology of the disease.

PATHOLOGIC FEATURES

Lymphocyte Predominant Type

About 5% of human cases of Hodgkin's lymphoma are of the lymphocyte predominant type. Most cases are nodular in type while a small subset is diffuse lymphocytic or diffuse histiocytic in type (Fig. 71.1). The disease is most common in men in the fourth decade of life who present with persistent nodal enlargement in the early stages of the disease, which tends to run a relatively long and indolent course. Most of the cells are small lymphocytes with some histiocytes and in the nodular forms about half of the small lymphocytes are B cells. This subtype of lymphoma is characterized by multinucleated Reed-Sternberg cells known as popcorn-type cells. A consistent feature of this disease is the small lymphocytes ringing the popcorn-type Reed-Sternberg cells referred to as a rosetting pattern. The absence of mononuclear-type Reed-Sternberg cells is considered an important diagnostic criterion.

Lymphocyte-Rich Classic Hodgkin's Lymphoma

The classic-type of lymphocyte-rich Hodgkin's lymphoma now includes all other types that are linked by having the same phenotype of constituent cells, with the differences occurring in topographical areas involved and levels of fibrosis. Lymphocyte-rich classic Hodgkin's lymphoma is defined as a diffuse lymphoid proliferation with infrequent Reed-Sternberg cells (classic-type with very large nucleoli). The accompanying population of small lymphocytes and occasional eosinophils and plasma cells mean the main differential diagnosis is the T cell-rich large B cell lymphoma.

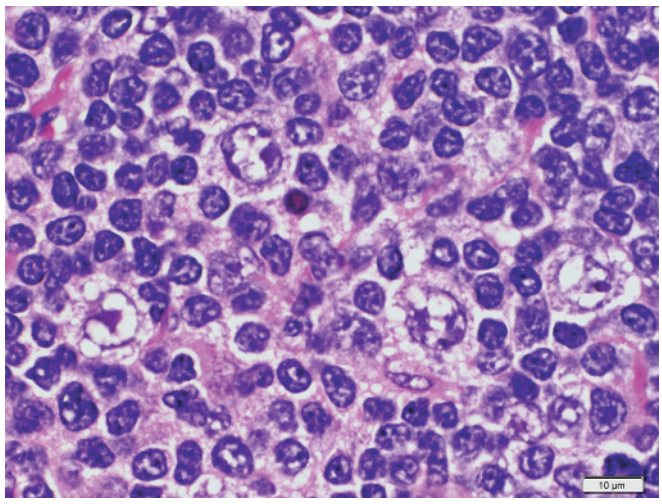

FIGURE 71.1 Human lymph node with Hodgkin's lymphoma: lymphocyte predominance type. The lymphocytes are of small and intermediate type with a predominance of "popcorn-type" Reed-Sternberg cells. The tissues are supported by a fine sclerosis. H&E stain. (Slides from Cornell tutorial.)

Nodular Sclerosis Hodgkin's Lymphoma

This is the most common type of lymphoma in humans, constituting more than 60% of cases, and has the highest level of agreement on review by different diagnosticians. This type of lymphoma is more common in women (generally less than 50 years old) and tends to present in lower cervical, superclavicular, and mediastinal lymph nodes. These incidentally are the comparative age, gender, and sites of presentation of T cell-rich large B cell lymphoma of cats. The dominant factors in diagnosis are broad bands of collagenous connective tissue separating areas of lymphoid proliferation (Fig. 71.2). The background cell population is variable and mixed with small and medium lymphocytes with relatively numerous eosinophils, neutrophils and a fine supporting fibrovascular network. The Reed-Sternberg cells are relatively numerous and are of the lacunar-type, so named because in formalin-fixed tissues the broad cytoplasm of these cells separates from the surrounding tissues leaving the cells in isolated lacunae. These cells frequently have eosinophilic cytoplasm as the cells undergo necrosis. A similar process is seen in cats with T cell-rich large B cell lymphoma.

In the recent WHO classification the nodular sclerosis-type of Hodgkin's lymphoma was divided into two types with type 1 having the majority of cases and type 2 having focal areas of lymphocyte depletion and foci of anaplastic lacunar cells. Patients with type 2 nodular sclerosis Hodgkin's lymphoma have poor response to treatment, increased relapse rate, and shortened survival times.

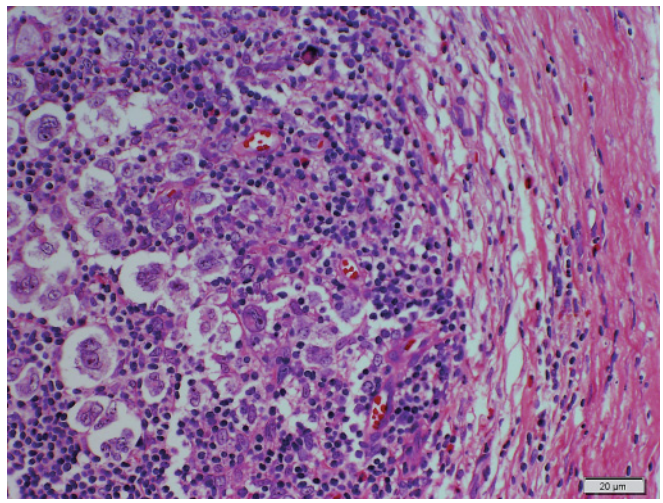

FIGURE 71.2 Human lymph node with Hodgkin's lymphoma: nodular sclerosis type. Foci of lymphoid proliferation are accompanied by large numbers of lacunar-type Reed-Sternberg cells (left center; note areas of peripheral clearing). Note the prominent nucleoli in several of the Reed-Sternberg cells. The right side of the image is made up of broad bands of dense mature collagen separating the lymphoid nodules. H&E stain. (Slides from Cornell tutorial.)

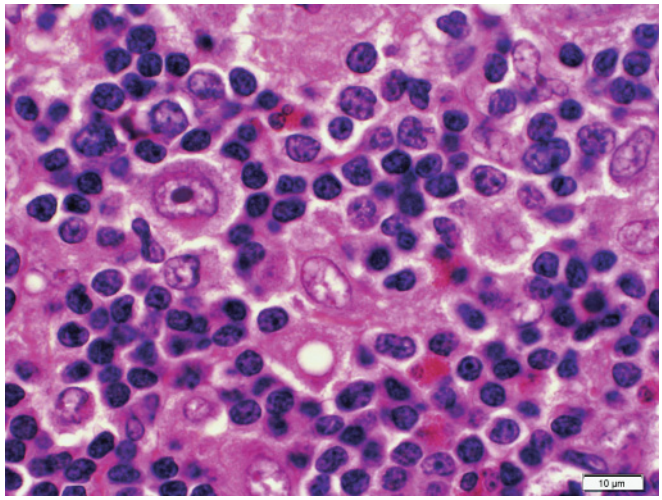

FIGURE 71.3 Human lymph node with Hodgkin's lymphoma: mixed cellularity type. The background population is composed of small lymphocytes with dense nuclei that generally lack nucleoli and appear morphologically and biologically normal. Notice the numerous eosinophils in lower right. The Reed-Sternberg cells are of the classic type with hyperdistended nucleoli and frequent binucleation. H&E stain. (Slides from Cornell tutorial.)

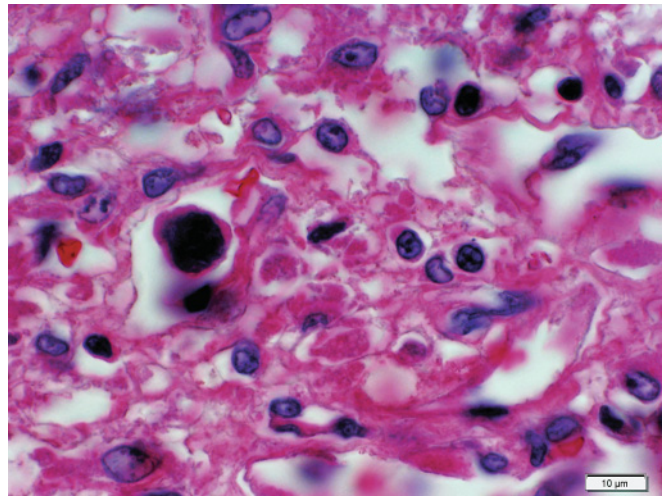

FIGURE 71.4 Human lymph node with Hodgkin's lymphoma: lymphocyte depletion with diffuse fibrosis type. There is marked sclerosis with most of the cells present of connective tissue type and only a few lymphocytes remaining in right center. A moderate number of lacunar-type Reed-Sternberg cells (left center) are atypical with a hyperchromatic nucleus that obscures internal detail. H&E stain. (Slides from Cornell tutorial.)

Mixed Cellularity Hodgkin's Lymphoma

This subtype is the second most common type of Hodgkin's lymphoma in humans and is the most common type in males. The condition presents with systemic signs and diagnostically is considered to lie between lymphocyte predominance-type and lymphocyte depletion-type. As the name implies, the background cells are a mixture of small lymphocytes with variable numbers of neutrophils, eosinophils, plasma cells, and macrophages often in clusters (Fig. 71.3). Small lymphocytes have round nuclei with compact chromatin, lack nucleoli, and appear morphologically benign. There is only fine fibrosis but foci of necrosis are frequently present. The differential diagnosis for this type of Hodgkin's lymphoma is broad because many other neoplastic and benign conditions share the general features of mixed cellularity. The Reed-Sternberg cells of the mixed cellularity Hodgkin's lymphoma tend to be of the classic type with binucleation and prominent nucleoli.

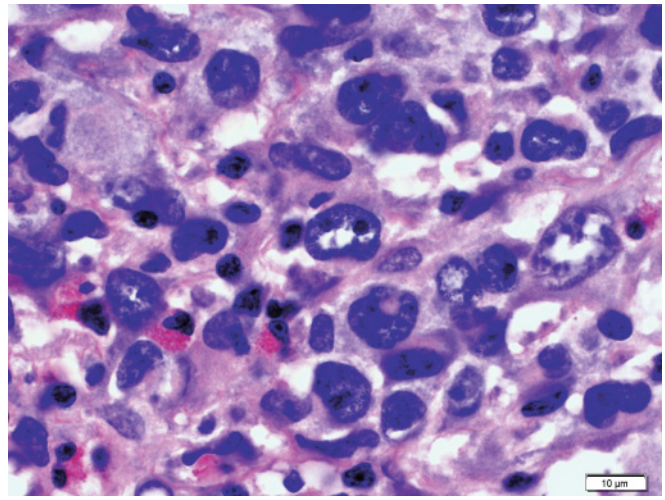

FIGURE 71.5 Human lymph node with Hodgkin's lymphoma: lymphocyte depletion of reticular type. There is a low level of lymphocytes with numerous eosinophils and many atypical Reed-Sternberg cells. The elongated nuclei in the background make up the connective tissue component. H&E stain. (Slides from Cornell tutorial.)

Lymphocyte Depletion Hodgkin's Lymphoma

This is the least common type of Hodgkin's lymphoma affecting humans and comprises about 1% of cases. The condition affects older individuals that present with systemic signs and are usually in stage 3 or 4 disease progression. These patients frequently have fever and have suffered marked loss of body mass due to hepatic dysfunction, but generally do not have peripheral lymphadenopathy. The disease tends to be extensive below the diaphragm, involving liver, spleen, retroperitoneal nodes, and bone marrow. This form of Hodgkin's lymphoma has the shortest survival and survival is poorest in patients that have atypical Reed-Sternberg cells known as reticular type (previously termed Hodgkin's sarcoma; Figs. 71.4 and 71.5). Architecturally, the tissues are characterized by diffuse fibrosis of non-mature collagenous connective tissue with cell depletion mainly involving small lymphocytes. The Reed-Sternberg cells may occur in clusters of the more common type or the anaplastic type.

HODGKIN'S-LIKE LYMPHOMA IN ANIMALS

The most obvious counterpart of Hodgkin's lymphoma in animals in the T cell-rich large B cell lymphoma most common in horses and cats, with that in the cat being best described and understood. In the cat, T cell-rich large B cell lymphoma tends to present with an enlarged node in the cervical area that may be as long as 4 cm, half that in width and 1 cm in depth. A consistent characteristic of these tumors is that they are very cohesive with a fine dense fibrovascular supporting structure and with the nodes remaining mobile beneath the skin except when they become very large. As a consequence these tumors can be effectively removed in their entirety.

The architecture may be uniform throughout the entire nodal profile or there may be focal areas with apparent tumor involvement and other areas with fading germinal centers. The lesions are very slow growing and the animals tend to retain normal appetite and activity. The tumor may recur in exactly the same place 6 months or more after initial removal. This is due to another small node in the same region having become involved.

The cytologic appearance of the nodes is variable but always of mixed cell type with the absence of a homogeneous population of cells that would normally be required for diagnosis of lymphoma. The cells present are small, intermediate, and large lymphocytes that make up the atypical population (Fig. 71.6). Lymphocytes may be as low as 5–10% of the total cells present having round to oval nuclei 2–4 red blood cells (RBCs) in diameter with fine dense, often peripheralized, chromatin and with a prominent single central nucleolus. Like the human lacunar cells, feline large neoplastic cells frequently contract from the surrounding tissues which also makes them visible on low power examination. In addition, the cytoplasm is frequently deeply basophilic due to the cells undergoing necrosis.

Immunologic Features

In the cat, only 5–10% of the large atypical cells stain with CD79a (i.e. B cell marker) but most of the cells stain with CD20 (i.e. B cell marker; Figs. 71.7 and 71.8). Background cells stain with CD3 (pan T cell marker)

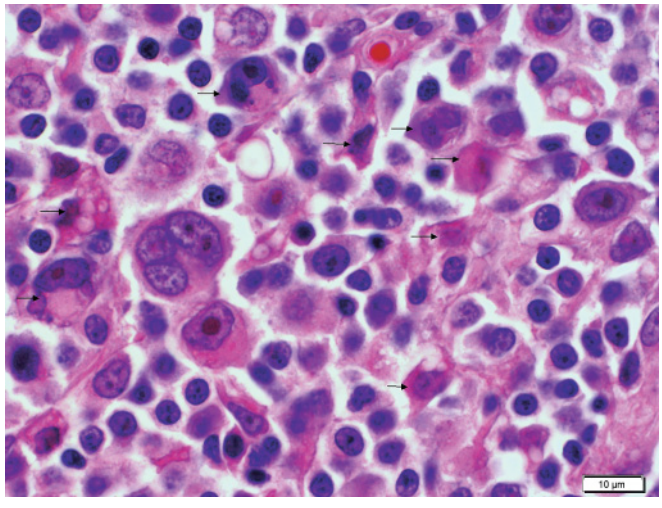

FIGURE 71.6 Cat lymph node with T cell-rich large B cell lymphoma. The predominant population is small lymphocytes with some intermediate-sized lymphocytes. The atypical cells have large nuclei with prominent nucleoli and are occasionally multinucleated. Many of the atypical cells (arrows) have eosinophilic cytoplasm and are undergoing single cell necrosis typical of Reed-Sternberg cells in this type of lymphoma. H&E stain.

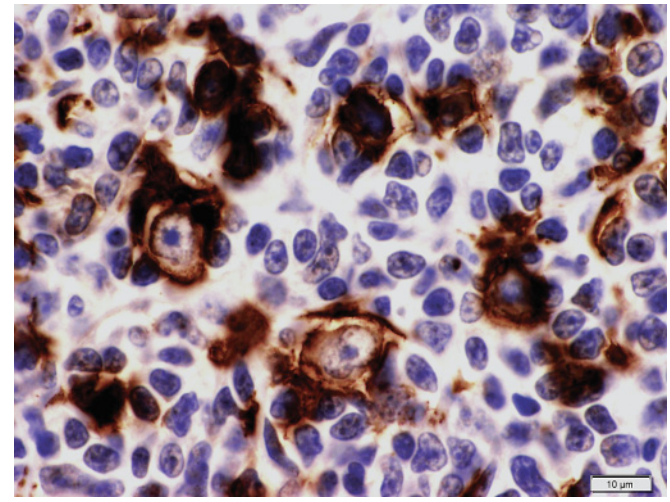

FIGURE 71.7 Cat lymph node with T cell-rich large B cell lymphoma. The atypical cells are strongly positive with the background of small and intermediate size lymphocytes unlabeled. CD20 immunostaining.

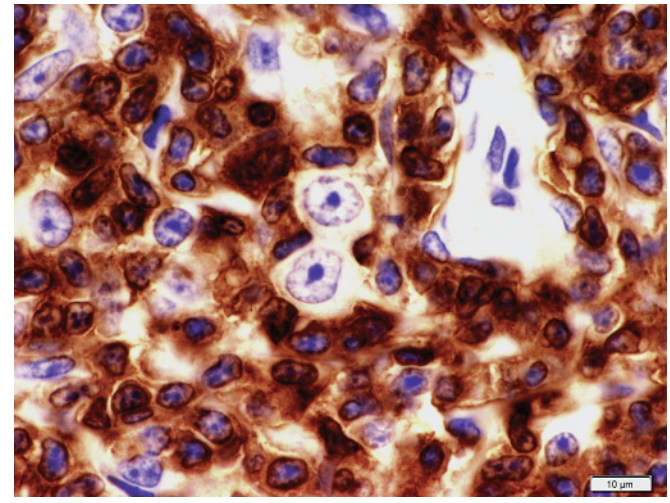

FIGURE 71.8 Cat lymph node with T cell-rich large B cell lymphoma (same case as Figure 71.7). The atypical cells (center) are unlabeled with the background T cells being strongly and uniformly labeled. CD3 immunostaining.

and on gross inspection of immunophenotypic stains it may appear that the tissues are positive for both B and T cell markers. The dense but fine background connective tissue population is unobtrusive but becomes very apparent in nodes stained with reticulin stains.

Differential Diagnosis

A major differential diagnosis in cats with T cell-rich large B cell lymphoma is benign hyperplasia. Cats with benign hyperplasia usually have a more uniform distribution of cells or an inflammatory gradient that indicates the presence of an infectious agent or other cause of inflammation. The presence of the large cells with very prominent nucleoli in a background of small and intermediate lymphocytes with a sclerotic background gives this type of lymphoma a specific identity in both the cat and horse, and less commonly in dogs. Spreading by contiguity is only well defined in the cat and is not known to occur in dogs and horses.

Transformation and Prognosis

T-cell rich large B-cell lymphoma in cats is an indolent disease in which affected cats survive for several years and may succumb to other diseases. It appears that with progression the proportion of large cells increases. This change is generally not apparent unless serial biopsies are performed. The actual cytomorphology of individual cells does not appear to change with progression of the disease.

Treatment and Survival

T cell-rich large B cell type tumors respond poorly to aggressive therapy. This finding is logical due to the high level of connective tissue within the enlarged nodes. Animals tend to do best with conservative treatment involving brief cycles of aggressive therapy, recognizing that neoplastic B cells may be removed by this process without an appreciable decrease in node size.

Finally it should be recognized that there is not a defined difference between what has been called the Hodgkin's-like lymphoma in the cat and T cell-rich large B cell lymphoma. These appear to be one and the same disease and it is best termed T cell-rich large B cell lymphoma.

T cell lymphomas are a heterogeneous group of tumors whose common features include clonal rearrangements of T cell antigen receptor genes (TCRα, β, γ, or δ) and expression of CD3 complex proteins. In many cases, these tumors fail to express functional TCR, either because productive rearrangements do not occur in complementary matched genes that form TCR (α/β or γ/δ), or because one or more chains in the CD3 complex are absent. This prevents proper transport and assembly of the complex at the cell membrane. In most cases CD3 proteins will accumulate in the cytoplasm, and one or both of these findings (i.e. rearranged T cell receptor genes and accumulation of CD3 proteins) are useful for a preliminary classification of T cell lymphomas.

Compared to B cell lymphomas, relatively little information exists about the biology of T cell lymphomas. In people, these malignancies are estimated to account only for 12–15% of all lymphoproliferative diseases.[7,154,186] However, there are geographical differences. T cell lymphomas are significantly more common in Asian populations, due at least in part to the endemic nature of human T lymphotropic virus-I (HTLV-I) and Epstein Barr virus (EBV), both of which are associated with specific T cell lymphoma subtypes.

T cell tumors also are incompletely understood in domestic animals. Recent efforts have allowed for classification of these tumors in the dog,[200] and while most of these tumors are assumed to occur in other species,

peer reviewed reports are limited. The relative frequency and the overall incidence of T cell lymphomas in dogs might be higher than those observed in Western populations, although they may be lower than those observed in certain Asian countries such as Japan. Contemporary data suggest that T cell tumors account for approximately 30% of all lymphoproliferative malignancies in dogs.[62,63,69,97,146,184,192] There appear to be heritable factors that predispose dogs to develop lymphoproliferative disorders in general. A high prevalence of T cell tumors in Boxers was found in several independent studies.[97,121,146] Other breeds that are highly predisposed include Spitz breeds and small Asian lapdogs.[97,133]

In cats, the relative frequency of T cell tumors seems to be in flux, evolving with the waning of the feline leukemia virus (FeLV) epidemic.[120] A heritable component also may exist in cats; several reports indicate that Siamese cats are predisposed to mediastinal lymphoma, a disease subtype that most commonly originates from malignant T cells.[30,66,67,191] The relative frequency of T cell lymphoma in other domestic animals is unknown. While extranodal lymphomas, especially in the skin often originate from T cells, nodal T cell lymphomas also may be common in horses. In one study, 26 of 37 cases of equine lymphoma were of T cell origin and 25 had multicentric distribution with frequent mediastinal involvement.[130]

APPLICATION OF THE WHO CLASSIFICATION TO T CELL TUMORS IN DOMESTIC ANIMALS

In 1994, the International Lymphoma Study Group proposed a revised World Health Organization (WHO) classification for human lymphoid neoplasms that combined morphologic, immunologic, and genetic assessments.[85] Modifications to the 2001 WHO classification scheme incorporated clinical features, further improving its prognostic and predictive accuracy (see Chapter 64).[26,93]

The WHO classification scheme also was recently adapted to lymphoma in domestic animals,[60,63,97,184,201,202] but studies are lacking to define the precise incidence and relative frequency of T cell lymphoma subtypes in these species. It is possible that this classification is artificial, as the concordance between the ontogeny and biology of lymphoma subtypes in humans and domestic animal has not been fully established. Indeed, the apparent high prevalence of T cell tumors in dogs might be due to differences in the underlying molecular mechanisms of lymphomagenesis between dogs and humans, although it also could reflect the relative importance of gene-environment interactions. For example, dogs are the only domestic species where neither a clinically important retrovirus nor a gamma-herpes virus has been identified. Nevertheless, the WHO system provides a useful scheme to guide comparative studies that will establish unique and shared properties of these diseases in different species, and so improve our understanding of lymphomagenesis.[16]

Here, we describe T cell lymphomas according to the modified WHO classification[200,201] with special emphasis on those tumors that are most relevant to domestic animals. Specifically, we will describe tumors derived from precursor T cells, including acute lymphoblastic leukemia (ALL) and lymphoblastic lymphoma, and tumors derived from mature cells, including large granular lymphoma (LGL), chronic lymphocytic leukemia (CLL), intestinal lymphoma, cutaneous lymphoma, T zone lymphoma (TZL), nasal lymphoma, hepatosplenic lymphoma, peripheral T cell lymphomas not otherwise specified (PTCL-NOS), natural killer (NK) cell tumors, and a recently described high-grade plasmacytoid type lymphoma. We refer the reader to other exceptional textbooks for a more complete description of rare T cell lymphomas in animals,[200] and for a thorough overview of T cell malignancies in humans.[47,49,103,188] We have chosen to retain TZL as a specific descriptor because this condition is common in at least some breeds of dogs,[60,200] and we included NK cell tumors in a separate category, owing to the scarcity of reagents to identify these cells in domestic animals and the consequent paucity of information.

PRECURSOR T CELL NEOPLASMS

Both T cell ALL and lymphoblastic T cell lymphoma (LBTL) are included in the precursor T cell neoplasm category. The considerable overlap of morphologic, clinical and immunologic features between these diseases has led some to suggest that these two conditions may represent different manifestations of the same disease.[190] Presently, the classification is largely based on where the largest burden of disease is present (blood or bone marrow for ALL and solid tissues for LBTL).

T Cell Acute Lymphoblastic Leukemia

As is true for most other acute leukemias, T cell ALL cannot be diagnosed based on cellular morphology alone. Instead immunophenotyping and assays to establish the presence of a clonal TCR rearrangement are needed to reach this diagnosis (see Chapter 142). Surface CD3 expression can be absent, making detection of cytoplasmic CD3 necessary for accurate classification. Most acute leukemias express CD34,[206,216] but there are few published studies examining the distribution of this antigen on different leukemic subtypes. Efforts to define phenotypic subtypes of acute leukemia in domestic animals are mostly restricted to dogs. Among ALL cases, the observed frequency of T cell leukemias in dogs seems to mirror the overall frequency of all T cell tumors.[166,197,205]

Various recurrent genetic abnormalities have been defined in humans that probably contribute to the pathogenesis of T cell ALL, including translocations and fusions that juxtapose transcription factors with promoters or enhancers within the TCR, aberrant expression of

genes that disrupt thymocyte development, inactivation of cell cycle regulatory genes, and constitutive activation of non-receptor protein tyrosine kinases that provide a survival advantage for immature T cells.[44]

The clinical features of T cell ALL are largely related to infiltrative bone marrow disease, which causes peripheral cytopenias that lead to fever, increased risk for infection, and bleeding tendencies. However, ALL cells can also infiltrate visceral organs, disrupting architecture and leading to severe dysfunction or failure (see Chapter 65).[214] While chemotherapy protocols have improved survival of some types of B cell ALL in people, especially children, the same cannot be said for T cell ALL where 5 year survival rates remain below 60%.[6,28] Cell counts and expression of various maturation-associated antigens can be prognostic in people. A threshold of >100,000 cells/μL at presentation is associated with inferior survival,[88] and early precursor phenotypes are indicators of poor prognosis.[31,35]

Lymphoblastic T Cell Lymphoma

Lymphoblastic T cell lymphomas are highly aggressive tumors of immature T cells that are seen more commonly in children and young adults. Almost all lymphoblastic lymphomas in humans are LBTL.[75] Anterior (cranial) mediastinal lymphoma appears to be a relatively common, unique entity within the T cell ALL/LBTL complex.

Lymphoblastic T cell lymphoma originates from a precursor cell and can, therefore, have CD4/CD8 double negative or double positive phenotypes.[63,84] Similar to T cell ALL, surface CD3 expression can be absent, making the detection of cytoplasmic CD3 necessary. The tumors show diffuse effacement of nodal architecture, invasion into the subcapsular sinus and often extension into perinodal tissues by a cytologically bland population (Fig. 72.1). Despite their description as blasts, cells are of intermediate size, have round to indented euchromatic nuclei with indistinct nucleoli, and scant to modest amounts of lightly basophilic cytoplasm (Fig. 72.2). Unlike low-grade T cell lymphomas, these tumors can exhibit high mitotic activity and prominent staining with proliferation-specific markers such as Ki-67.

A recent study showed that the CDKN2 locus that encodes the cyclin kinase inhibitors p16 and p15, and the p53 regulator p14/ARF, was deleted in 10/10 high-grade canine T cell lymphomas, including 7/7 LBTL.[60] In contrast, this abnormality was not present in any of 11 low-grade T cell lymphomas (T zone lymphoma [TZL] or small lymphocytic lymphomas) or 26 high-grade and low-grade B cell lymphomas. These tumors also are genetically unstable, harboring numerous additional cytogenetic abnormalities.[110,193] The mechanisms that account for genetic instability in these tumors are unknown, but recent gene expression profiling experiments suggest canine LBTL resembles other high-grade tumors, showing enrichment of genes that control metabolism, proliferation, and survival at the expense of genes that comprise functional ontogenetic pathways (A. Frantz, T.L. Phang, J.F. Modiano, unpublished data).

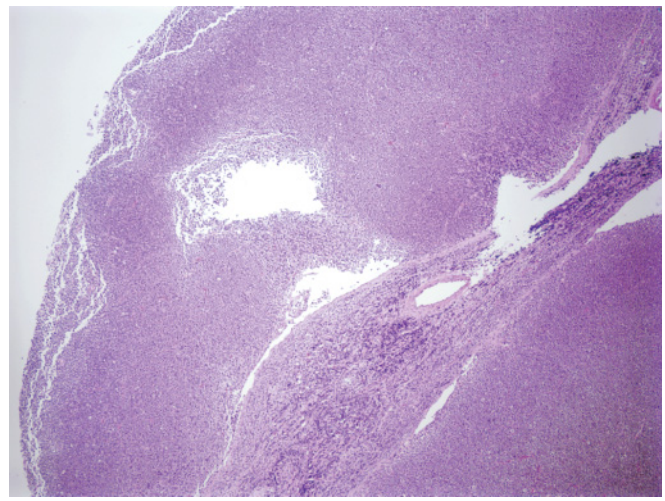

FIGURE 72.1 Lymphoblastic T cell lymphoma in a lymph node from a dog. Notice diffuse effacement of nodal architecture and invasion into the subcapsular sinus by a monomorphic population of lymphocytes. H&E stain; original magnification 40×.

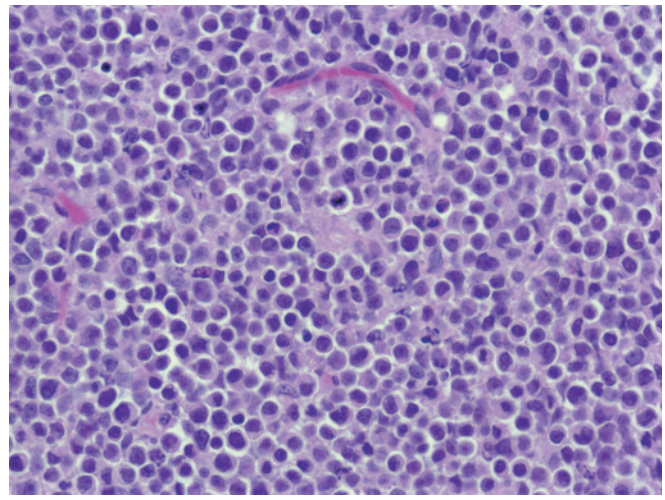

FIGURE 72.2 Lymphoblastic T cell lymphoma in a lymph node from a dog. Notice pleomorphic cells, generally of intermediate size with indented euchromatic nuclei, and modest amounts of lightly basophilic cytoplasm. In this case, nucleoli are apparent in many cells, a rare feature in these tumors. H&E stain; original magnification 500×.

Therapy for LBTL in dogs is generally unrewarding unless it is confined to the mediastinal space. The median survival with cyclophosphamide, vincristine, doxorubicin, prednisone (CHOP)-based chemotherapy for the dogs described above with LBTL and CDKN2 deletion was less than 4 months, and none of the dogs survived 1 year.[60]

Cranial Mediastinal Lymphoma

In humans, LBTL of the mediastinum is a defined subtype of precursor T cell lymphoma that usually

presents as an anterior mediastinal mass with or without blood and bone marrow involvement.[53,117] In domestic animals, primary mediastinal lymphoma (also known as thymic lymphoma) has been reported in the dog, cat, horse, cow, ferret, and pig, most commonly as a T cell disease,[29,63,66,99,112,113,140,141,217] although this diagnosis may include a more heterogeneous group of diseases.

Incidence data are not published in all species, but cranial mediastinal lymphoma is considered, respectively, as the most common cause of thymic pathology in the cat and the second most common cause of thymic pathology in the dog.[41] This is also the most common thoracic neoplasm in the horse.[122,187] There may be heritable predisposition in the Boxer breed,[121] in Siamese cats (specifically as a form of juvenile thymic lymphoma not associated with FeLV infection),[67,120] and perhaps in golden retrievers.

Most cases of mediastinal LBTL in humans occur in adolescents and young males, and they are the most common mediastinal tumors in children.[8,185,199] Mediastinal lymphoma does not have an age predilection in dogs,[41] but it is most commonly seen in younger cats.[41,120] In cows, mediastinal LBTL is one of three forms of sporadic bovine lymphoma (not associated with BLV infection), and is most common in animals between 6 months and 2 years of age.[217]

As is noted for other peripheral lymphomas outside the gut, primary mediastinal lymphoma has become less common in cats as the prevalence of FeLV infection has decreased. Prior to 1980, mediastinal lymphoma was reported to account for up to 40% of feline lymphoma in the United States, 50% in the UK, and 70% in Japan.[33,81,177,189] More recently, mediastinal lymphoma was reported to represent less than 12% of cases in the United States and approximately 25% of cases in Australia.[30,67,120,198]

In people, there can be immunophenotypic overlap between cells from LBTL and cells from other non-lymphomatous lesions in the mediastinum, most notably those from cases of thymoma and thymic hyperplasia. As such, a diagnosis of LBTL requires the identification of a thymocyte-like (i.e. CD4/CD8-double positive) population demonstrating loss of one or more of the normal thymocyte cell surface antigens (CD2, CD3, CD5, CD7, and/or CD45), disproportionately high numbers of CD4/CD8-double negative, CD4-single positive, or CD8-single positive cells, or expression of CD34 by an atypical population of mature thymocytes.[78,117] Flow cytometric light scatter also can help distinguish neoplastic LBTL cells from normal thymic components.[78,117]

The diagnostic challenge of mediastinal LBTL is magnified in animals. Imaging alone is insufficient to distinguish lymphoma from other mediastinal lesions such as thymoma, carcinoma, chemodectoma, and sarcoma.[157,218] Fine needle aspirate (FNA) cytology is useful as an adjunct to diagnosis, but distinguishing thymic lymphoma from thymoma in FNA samples from dogs is difficult because of the large number of non-neoplastic lymphocytes present in the latter.[9,112]

Lymphoblastic T cell lymphoma cells in mediastinal lymphomas of domestic animals can also show phenotypic heterogeneity, although they frequently have a single positive CD3, CD4 phenotype in dogs.[63,112,121,134] In cats, the majority of cases of feline anterior mediastinal lymphoma consist of CD3, CD5, CD8-positive T cells.[66,116,148,177,198] In cows, anterior mediastinal lymphoma is a CD2, CD3, and/or CD5-positive T cell disease, most commonly of CD4/CD8-double negative cells.[4,169,217] Similar characterization is lacking in other species.

MATURE T CELL NEOPLASMS

T cell Large Granular Lymphocytic Leukemia

T cell large granular lymphocytic (LGL) leukemias account for 2–3% of small lymphocytic leukemias in people.[144] It is typically a disease of older adults (median age 61 years) with equal gender distribution.[50] Autoimmune diseases including rheumatoid arthritis and Sjogren's syndrome, and detection of anti-nuclear antibodies are reported as common co-morbidities with T-cell LGL leukemia.[50,144] Anti-platelet antibodies, anti-neutrophil antibodies, and positive Coombs' tests have been reported in subsets of people with LGL leukemia.[50] T cell LGL leukemia is typically an indolent disease in people, and a significant proportion of affected patients do not require therapy at diagnosis. With treatment, median survivals of 161 months have been reported.[50]

T cell LGL leukemia has been reported in the dog, cat, horse, and cow, with much of the published literature focusing on the first two species.[107,109,163,167] Large granular lymphocytic leukemia of the dog and cat is most commonly a T cell disease, as more than 90% of cells in lesions from each are of CD3-positive T cell origin.[163] In the dog, T cell LGL leukemia is reported to be a common form of CLL, representing 54% (39/73) of cases in one study. It is a clinically heterogeneous disease in dogs with a broad spectrum of presentations and outcomes.[126] In canine LGL leukemia, neoplastic cells are commonly seen in the blood.[126] Infection with *Ehrlichia canis* needs to be excluded as it can result in a selective increase in circulating LGLs.[210] In contrast, feline LGL malignancies are typically aggressive. Gastrointestinal tract-associated conditions are frequent with fewer than 10% of cats presenting with a leukemic component.[109] Median survival time in treated cats has been reported to be 57 days.[109]

Clinical features in the dog are variable; splenomegaly (12 of 20 dogs) is reported as the most common physical examination finding.[127] In contrast, feline LGL is typically characterized by anorexia, lethargy, weight loss, and vomiting, with an abdominal mass, described in 52% of cases, reported as the most common physical examination finding.[109,163]

A diagnosis of LGL leukemia in the dog and cat is generally made through the cytologic detection of the characteristic neoplastic cell in blood or tissue. These cells are typically large (10–35 μm) and pleomorphic

with nuclear variability and a variable number of irregularly shaped and sized magenta, intracytoplasmic granules. The majority of feline cases of LGL disease are composed of CD18 (21/21), CD3 (19/21), homodimeric CD8 (13/21), and CD103 (11/19)-positive cells, consistent with intestinal origin.[163] Rare, CD4 single positive, and CD4, CD8 double-positive cases have been reported.[163] In the dog, T cell LGL is described as a phenotypically heterogeneous disease in which CD3, leukointegrin $\alpha_d\beta_2$-positive cells predominate (>90% of cases), with variable TCR expression. The leukointegrin expression has been proposed to indicate that canine LGL leukemia originates in the splenic red pulp with bone marrow involvement only seen in the advanced stages.

An etiology has not been demonstrated for domestic animal T cell LGL leukemia, as the vast majority of affected cats are negative for FeLV and FIV infection.[109,163] In dogs, a single report describes the presence of retroviral particles, although the significance of this remains uncertain.[72]

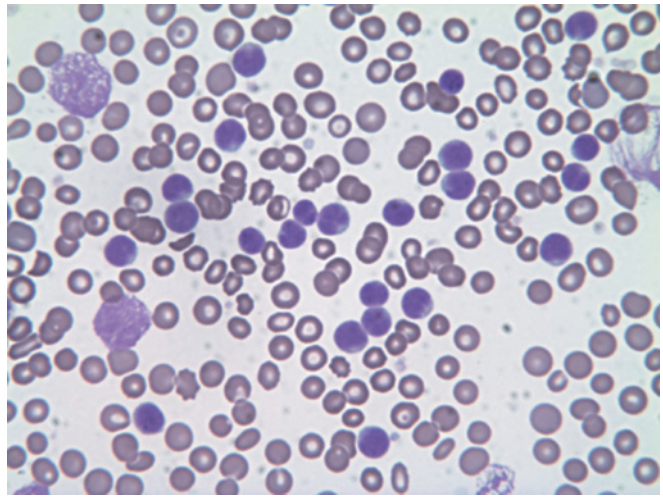

FIGURE 72.3 Chronic lymphocytic leukemia (CLL) in a blood smear from a dog. Notice an expanded population of small lymphocytes characterized by round to convoluted nuclei without nucleoli and scant light cytoplasm. In this case, cells are agranular, but azurophilic granules are commonly seen in CLL cells. Diff-Quik stain; original magnification ×560.

T Cell Chronic Lymphocytic Leukemia/ Prolymphocytic Leukemia and Small Lymphocytic Lymphoma

In the late 1980s, the French-American-British (FAB) classification system subdivided mature T cell leukemias into four categories; T cell chronic lymphocytic leukemia (CLL); T cell prolymphocytic leukemia; human T lymphotropic virus type 1-positive (HTLV-1) adult T cell leukemia/lymphoma; and Sézary syndrome.[13] The original category of T cell CLL was updated in 2001 to T cell prolymphocytic leukemia (TPLL) where leukemias with small, mature-appearing lymphocytes are now considered as a small cell variant of prolymphocytic leukemia. There is no consensus for the use of prolymphocytic leukemia versus CLL in domestic animals, and CLL is used mostly by convention to describe an expanded population of small lymphocytes in the circulation. When the disease is confined to lymphoid organs, it is called small lymphocytic lymphoma (SLL).

The characteristic cell in human TPLL is described as a small to medium sized prolymphocyte with a prominent single nucleolus and basophilic cytoplasm. In domestic animals, T cell CLL is characterized by small to medium sized cells with round to oval nuclei, smooth chromatin, and scant to moderate clear to lightly basophilic cytoplasm that may contain azurophilic granules (Fig. 72.3).

In humans, the median age at diagnosis of TPLL is 63 years.[46] In contrast to the more common B cell CLL, TPLL commonly presents with peripheral lymphadenopathy, splenomegaly, and peripheral lymphocyte counts greater than 10,000/μL; a subset of patients will present with cutaneous involvement, particularly of the head and neck.[34,125] In animals, T cell CLL manifests as an indolent disease that is often diagnosed incidentally. Unlike acute leukemias, bone marrow infiltration is inconsistent and peripheral cytopenias are rare, although splenomegaly and lymphadenopathy are reported in up to 30% of affected dogs.[115,126,213]

The phenotypic characteristics of TPLL in humans and T cell CLL in dogs are consistent with post-thymic origin. In humans, TPLL is most often associated with a helper/inducer phenotype (CD4),[46] and while it is possible some of these tumors arise from CD4/CD25/FoxP3 regulatory T cells, this manifestation may be more common in the Sézary syndrome (see below). In dogs and cats, CLL is most often a disease of T cells, including large granular lymphocytes.[197,205,216] Canine T cell CLL usually involves expansion of a CD8 clone, whereas in cats and horses, CLL often comprises CD4 T cells.[37,130,158,216]

A peculiar feature of TPLL in humans and CLL in dogs and cats, is aberrant expression of cell surface markers.[94] For example, in a study of 87 T cell tumors, Gorczyca et al. found that complete loss of any T cell antigen (CD2, CD5, CD7) or the pan-leukocyte antigen CD45 was diagnostic for malignancy.[79] Loss of CD45 appears to be the most common form of aberrant antigen expression in canine T cell CLL, and loss of CD4 and CD8 also may occur in some cases of canine and feline T cell CLL (Anne Avery, personal communication).[205,213]

Management strategies for CLL are discussed in Chapter 63. Recent data suggest that the phenotype and number of circulating cells are prognostic in dogs. In one study, dogs with less than 30,000 lymphocytes/μL in the peripheral circulation had significantly longer survival (mean = 1,098 days) than dogs with more than 30,000 lymphocytes/μL (mean = 131 days).[213]

Enteropathy-type T Cell Lymphoma/Intestinal T Cell Lymphoma

Enteropathy-type T cell lymphoma (ETTCL) is a relatively rare condition that accounts for approximately 5–10% of NHL and 1–4% of all gastrointestinal tumors in people.[51] In 2001, the WHO classification of intestinal T cell lymphoma was modified to include ETTCL because it was deemed more specific, although ETTCL can occasionally arise from extra-intestinal sites.[26] O'Farrelly originally coined the term enteropathy-associated T-cell lymphoma to denote the association of this lymphoma with jejunal mucosal atrophy.[144] Enteropathy-type T cell lymphoma is now recognized as a tumor that affects the gastrointestinal tract causing villous atrophy and crypt hyperplasia, with involvement of the regional lymph nodes, and potentially the spleen and liver. The small intestine is the primary affected site, but this form of lymphoma also can involve stomach and colon. Males tend to be overrepresented, and the disease has a worse prognosis than intestinal lymphomas arising from B cells.[104]

Most ETTLs are believed to originate from intraepithelial CD8 (CD103-negative) T cells with large anaplastic morphology; however, about 20% arise from small, atypical, cytotoxic lymphocytes or NK T cells that express CD3, CD8, CD56, and CD103, and that do not cause enteropathy-related lesions.[219] While these tumors may have distinct clinicopathologic features,[139] they are both characterized by aggressive biological behavior.[3]

Enteropathy-type T cell lymphoma has not been described as a specific entity in animals, although intestinal T cell lymphoma is relatively common in both epitheliotropic (lymphocytes infiltrate the epithelial layer) and non-epitheliotropic (lymphocytes do not cross the basement membrane) forms that also can involve one or more areas in the gut, regional lymph nodes, spleen, and liver. In the dog, intestinal T cell lymphoma accounts for more than 70% of intestinal lymphoid tumors and is frequently epitheliotropic, but the immunophenotype of these tumors (T cell versus B cell) was not prognostically significant in the small number of cases examined to date.[64]

In cats, the reduced incidence of retroviral-induced lymphomas has led to an apparent increase in the frequency of alimentary lymphoma. Almost 40% of feline lymphomas from a retrospective study spanning 20 years affected the gastrointestinal tract, and the authors noted an increase in the incidence of intestinal lymphoma in the last 10 years of the study.[120] However, these data should be interpreted cautiously given the limitations of case-control and retrospective studies. The majority of alimentary lymphomas in cats have been described as having a B cell phenotype; yet, recent reports indicate tumors likely to have originated in the small intestine are more commonly T cell lymphomas.[66,91,147,149,208] Epitheliotropism is seen in most low-grade feline tumors.[24,108] When cats with increased large granular lymphocytes in the circulation or in aspirates of abdominal organs were examined, they uniformly had T cell intestinal lymphoma arising from CD8-single positive cells, consistent with their putative intraepithelial lymphocyte origin.[162]

The pathogenesis of ETTCL in humans and intestinal T cell lymphoma in animals is incompletely understood. There seems to be a spectrum of infiltrative, lymphoplasmacytic infiltrative lesions that range from mild inflammation with a diagnosis of inflammatory bowel disease (IBD) to effacement of intestinal architecture by monomorphic populations that are undoubtedly lymphoma. There may be a progression from antigen driven lymphocytic inflammation to lymphoma. For example, 5–10% of patients with an inflammatory enteropathy called celiac disease ("gluten allergy") are refractory to gluten withdrawal therapy, and patients with refractory celiac disease are at high risk to develop intestinal T cell lymphoma, suggesting these tumors may originate from intraepithelial lymphocytes expanded as part of the inflammatory response.[204] A similar progression of IBD to intestinal lymphoma has been hypothesized to occur in cats.[24,155] For example, one cat diagnosed with alimentary lymphoma survived 28 months with conservative management using prednisone and a novel protein diet.[24]

Clinical signs associated with ETTCL are referable to gastrointestinal dysfunction and depend on the anatomical site and extent of infiltration. Although morphologically the cells are "bland" in appearance, the disease is highly aggressive in people, with one study reporting less than 20% 5 year survival and another study reporting less than 30% 2 year survival.[38,68] Clinical signs of intestinal lymphoma in animals also are referable to the anatomic site and extent of infiltration. Paraneoplastic eosinophilia and eosinophil infiltration of the tumor have been reported in canine, feline, and equine T cell intestinal lymphoma. In humans, eosinophil production and recruitment are associated with tumor production of interleukin-5 (IL-5),[11,18] but such association remains to be documented in veterinary species.

Diagnosis of ETTCL or intestinal lymphoma requires complementary use of clinical signs, imaging, and microscopic pathology. Aspiration cytology of thickened bowel or enlarged mesenteric lymph nodes often can lead to a diagnosis if a uniform, atypical population of lymphocytes is seen. The cytomorphology of human ETTCL is highly variable. The cells are generally medium-sized to large but in a subset of cases, they can be anaplastic and express surface CD30, a characteristic of anaplastic large cell lymphoma (ALCL).[56]

Morphologic distinction between lymphocytic inflammation and lymphoma of the gut can be challenging, underscoring the utility of immunophenotyping and clonality assays.[39,208] High-grade alimentary lymphomas are poorly responsive to therapy, especially because gastrointestinal signs can be intractable. Indolent intestinal T cell lymphomas in dogs and cats can be successfully managed with low-intensity chemotherapy, but lack of prognostic indicators makes this disease a therapeutic challenge.

Cutaneous T Cell Lymphoma

Cutaneous lymphoma (LPD) are relatively uncommon peripheral neoplastic diseases that are, in both humans and veterinary patients, characterized by a widely heterogeneous clinical presentation. Cutaneous lymphomas represent 1% and 2.8% of all canine and feline skin tumors, respectively.[76] Cutaneous lymphoma is predominantly a disease of older animals, with a mean age of 9–12 years in the dog, 8–17 years in the cat, and 3–19 years in the horse.[40,43,54,70,87,136,137,153,173,195,215] In cattle, cutaneous lymphoma most commonly develops in animals between 2 and 3 years of age. In no species has a sex predilection been identified.

In veterinary medicine, cutaneous LPD is most commonly subdivided into epitheliotropic and non-epitheliotropic forms, based on the presence or absence of invasion of the epithelium of the epidermis and/or adnexae.[129,172] In contrast, cutaneous lymphoma in humans comprises a broader spectrum of conditions including T cell, NK cell, and B cell neoplasms as well as immature hematopoietic malignancies and Hodgkin's lymphomas.[21] The WHO classification scheme considers these as independent entities, and the presence or absence of epitheliotropism is only one part of a multifaceted diagnostic algorithm that includes clinical presentation, histology, immunophenotyping, and molecular analysis.[21]

Despite these classification differences, there are many similarities between the cutaneous LPDs of humans and domestic animals. Most notably is the observation that most arise from T cells, and are therefore denoted as cutaneous T-cell lymphomas (CTCLs).[40,137] Here, we have used the WHO classification scheme as a framework to organize the descriptive properties of CTCL in animals, recognizing that not all of the current veterinary literature fits neatly into this scheme. Those entities within veterinary medicine with WHO counterparts are: mycosis fungoides (MF), pagetoid reticulosis, and Sézary syndrome (SS).

Mycosis Fungoides

Mycosis fungoides (MF), in both humans and most domestic species, is the most common form of CTCL.[19,21,40,137] It is characterized by invasion and effacement of the epidermal and/or adnexal epithelium by neoplastic cells, a property which has led to its more descriptive designation, epitheliotropic cutaneous lymphoma (ECL). Mycosis fungoides is reported in dogs, cats, horses, ferrets, cows, hamsters, squirrels, and a coati.[87,89,129,137,164,171,175,180,195] It is the most common cutaneous LPD in the dog and cow.[19,40] Briards, English cocker spaniels, bulldogs, Scottish terriers, and golden retrievers may be predisposed to develop cutaneous lymphoma.[76]

In both humans and domestic animals, an underlying etiology for MF remains to be identified. In humans, retroviruses, environmental exposures, genetic mutations and infection with *Staphylococcus aureus* and *Chlamydia* spp. have been implicated, but studies have yielded inconsistent results.[1,73,90] In the cat, attempts to link retroviral infection to MF have been unsuccessful.[23,57,136,142,173,195] An infectious cause of MF also has not been identified in dogs, although retroviral particles have been described in a cell line.[71] In the cow, the majority of cases of MF are manifestations of sporadic bovine lymphoma, which is not associated with BLV infection.

In addition to infectious, environmental, and genetic causes, a link between atopic dermatitis and MF has been proposed in humans based on the common phenotype of the infiltrating lymphocytes in both diseases (CD3/CD4/CD45RO- TCRαβ-positive and CD8/CD30-negative memory T cells), an overlap in their cytokine profiles, and increased circulating levels of IgE in patients with MF.[127,156,174] Although the results of such human studies are mixed, work in dogs supports a similar hypothesis. In addition to the phenotypic similarities between the lymphoid population in canine atopic dermatitis and MF, canine MF predominantly develops in anatomic areas affected with allergic disease.[52] Moreover, a retrospective study of canine MF and atopic dermatitis suggests that there is an incidence association between the two diseases.[127,168] The clinical presentation of MF is heterogeneous, and has been described in detail elsewhere.[80,176] Generally, it involves an exfoliative dermatitis that is refractory to therapy. In humans, MF is most commonly a disease of mature, memory helper T cells (a CD2, CD3, CD4, TCRαβ, CD5, CD45RO-positive phenotype), while only rare cases of CD8 and TCRαβ MF have been reported.[21] Although particularly aggressive cases might originate from regulatory T cells.[83] In contrast, MF in dogs is predominantly a disease of cytotoxic CD8, TCRαβ-positive T cells, with few CD4-positive or CD4/CD8-double negative cases reported.[58,137] A high-grade variant of CTCL in humans originates from anaplastic large cells that express CD30. The authors have yet to encounter a homologous CD30-positive T cell-derived ALCL but the morphological features of cutaneous ALCL have been described.[200] Intriguingly, the majority of MF cases in the dog do not express CD5.[135]

Information about feline MF is limited, but this also appears to be primarily a disease of CD3-positive T cells.[22,23,96,142,173,195] Expression of perforin, a cytotoxic protein stored in the cytoplasm of cytotoxic T cells and NK cells, was documented in one case,[118,142] but others state that CD4-, CD8-double negative cells predominate in this disease.[80] Mycosis fungoides in horses and cows is also poorly defined.[19,36,87,100,153,170,181]

Skin biopsy with histopathology is required to diagnose MF in people and domestic animals, although neoplastic lymphoid cells that merit including MF in a differential list can be identified in fine needle aspiration samples. The pathognomonic features of MF include the presence of a population of neoplastic round cells demonstrating selective tropism for the epidermal, mucosal, and/or adnexal epithelium. Additionally, small aggregates of intraepithelial lymphocytes (i.e.

Pautrier's microabscesses) can occasionally be identified throughout the epidermis.[80] In early lesions, light microscopic diagnosis may be difficult due to the presence of an infiltrate that contains relatively few overt neoplastic cells. As the disease progresses, the cellular infiltrate becomes more homogeneous, with small cells that resemble those seen in T zone lymphomas. Adjunctive diagnostic modalities such as immunohistochemistry and molecular analysis may be necessary to diagnose MF.[59]

Pagetoid Reticulosis

Pagetoid reticulosis is a low-grade variant of MF with characteristic histomorphologic appearance.[21] Microscopically, pagetoid reticulosis is characterized by prominent epitheliotropism of vacuolated neoplastic cells into a thickened epithelium.[21] In contrast to MF, pagetoid reticulosis has been described as a form of epitheliotropic lymphoma in which the neoplastic population is confined almost completely to the epidermal layer and in which the underlying dermis is infiltrated by a pleocellular, inflammatory infiltrate.[80] A single case of pagetoid reticulosis is reported in a dog.[95]

Non-epitheliotropic Lymphoma

In the WHO classification, non-epitheliotropic cutaneous lymphoma (NECL) is not recognized as a specific entity, but rather, the lack of significant epidermal invasion is a histologic feature of various diseases such as subcutaneous panniculitis-like T cell lymphoma and other forms of primary, cutaneous T cell lymphoma.[21]

NECL has been reported in dogs, cats, horses, and cows, and it appears to be the least common form of cutaneous lymphoma in the dog and the most common form in the cat and cow.[43,48,77,106,159,178,196] The etiology of NECL is unknown,[23,57] and the clinical features resemble other types of CTCL. The cellular phenotypes in NECL also are similar to those of MF and other CTCL, consisting primarily of CD3-positive T cells, which in the case of the dog can be CD8-single positive or CD4/CD8-double negative cells.[40,136] In the cat, most published cases described CD3-positive neoplastic cells.[40,106] In the cow and horse, limited data also indicate that NECL is a T cell neoplasm.[19,43,175]

Microscopically, this disease is characterized by infiltration of the dermis and subcutis by a population of neoplastic round cells with relative sparing of the epithelium of the epidermal and adnexal structures.[80] As is true for ECL, histopathology is necessary to demonstrate the presence or absence of epitheliotropism.[9]

Sézary Syndrome

In the WHO-European Organization for Treatment and Research of Cancer (EORTC) classification scheme, Sézary syndrome (SS) is described as the leukemic form of CTCL.[21] The disease is characterized by the presence of neoplastic T cells (Sézary cells) in the blood and lymph nodes (Fig. 72.4). It is a very rare manifestation of CTCL and, in domestic animals, has been reported in dogs, cats, and horses.[16,150,160,173,194,215]

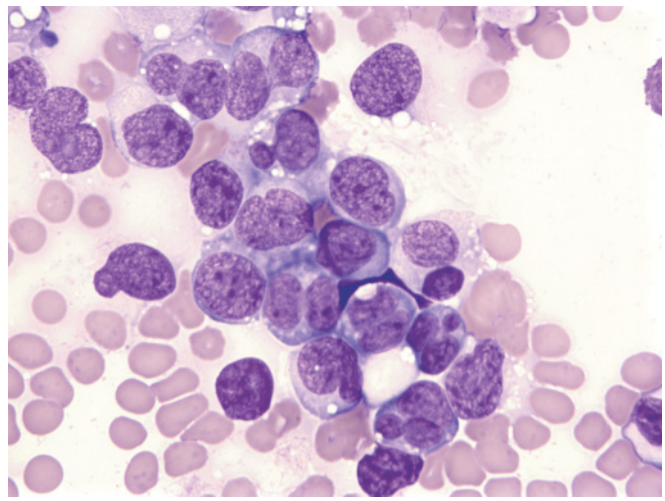

FIGURE 72.4 Sézary cells in a blood smear from a dog. Notice a population of pleomorphic lymphocytes characterized by round, lobulated, or complex nuclei with coarsely stippled to reticular chromatin and moderate amounts of vacuolated, lightly basophilic cytoplasm. Sézary cells in blood tend to show significantly greater pleomorphism than MF cells in the skin. Diff-Quik stain; original magnification ×500.

The clinical presentation of human SS includes generalized reddening and scaling of the skin (erythroderma) with lymphadenopathy. In animals, SS causes exfoliative, erythematous dermatitis that can cause severe pruritus and lymphadenopathy.[61,80,173,215] In humans, the cellular infiltrate arises from mature helper T cells with the same phenotype reported for MF.[21] There is limited information on the immunophenotype in animals, but two reports in dogs suggest either a prototypical MF phenotype (i.e. CD3, CD8-positive) or NK-like phenotype (CD3, CD4, CD8, TCR-negative).[71,215] In cats, there is a single case report where cells in the circulation were CD3+, CD8+, CD4– T cells.[215]

In humans, the International Society for Cutaneous Lymphoma criteria for a diagnosis of SS are: an absolute Sézary cell count of at least 1,000 cells/μL; an expanded CD4+ T cell count resulting in a CD4/CD8 ratio of more than 10 where the cells may lack expression of CD2, CD3, CD4, or CD5; or the demonstration of a T cell clone in the blood by molecular or cytogenetic studies.[209] Explicit criteria have yet to be established in veterinary hematopathology; thus, a diagnosis of SS in domestic animals relies on the identification of: (1) cutaneous lesions consistent with MF, and (2) circulating neoplastic T cells.

T Zone Lymphoma

T zone lymphoma as a distinct disease entity was introduced in the Kiel classification of 1974, but abandoned in the most recent WHO classifications because of

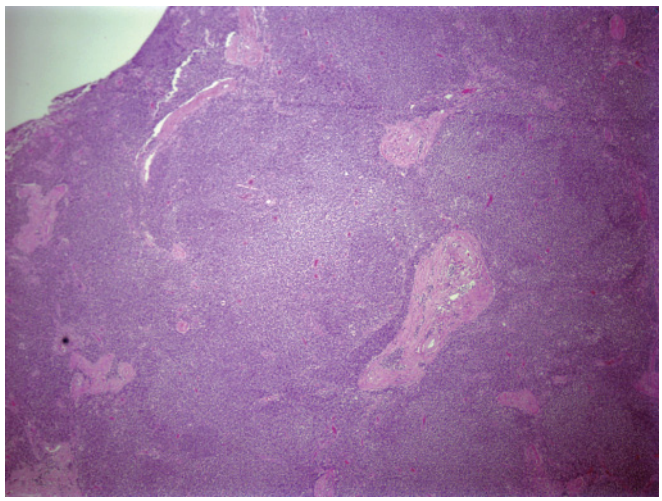

FIGURE 72.5 T-zone lymphoma in a lymph node from dog. Notice an expansion of lymphocytes in the parafollicular zone, residual follicular structures, and compression of the peripheral sinus. Also notice the prominent small vessels interlaced within the tumor. H&E stain; original magnification ×40.

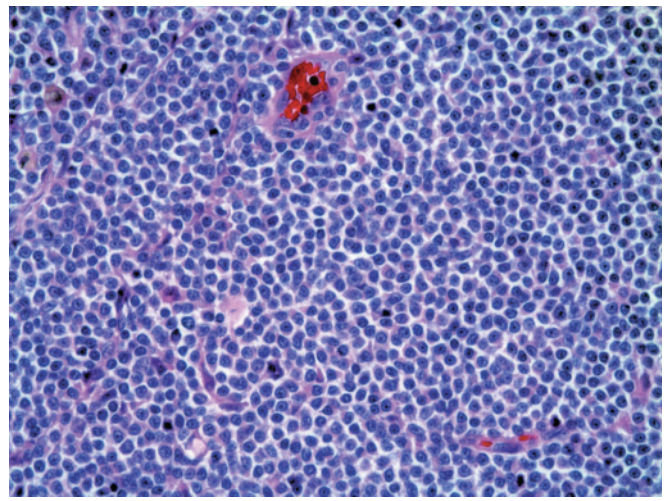

FIGURE 72.6 T-zone lymphoma in a lymph node from a dog. Notice the typical monomorphic appearance of the cells, which are small in size, have round nuclei with occasional indentations, smooth to stippled chromatin, prominent chromocenters, no apparent nucleoli, and modest amphophilic cytoplasm. Also notice the low mitotic activity and prominent association with a vascular network, suggestive of angioimmunoblastic lymphoma. H&E stain; original magnification ×500.

significant morphologic and biologic overlap with angioimmunoblastic T cell lymphomas (AITL) and other indolent T cell lymphomas. Retaining this category in the classification of domestic animal lymphomas appears to have merit in the case of the dog, as TZL may be the most common indolent lymphoma at least in some breeds.[60,200] The disease is characterized by expansion of small to intermediate lymphocytes in the parafollicular zone, leading to follicular collapse (i.e. fading follicles), compression of the peripheral sinus and some degree of medullary sclerosis (Fig. 72.5). In contrast to indolent B cell lymphomas arising from the marginal zone, the cellular population responsible for TZL is eccentric to the follicles, rather than surrounding them. The main distinction between the TZL and AITL is the prominent vascular component in AITL, although these two diagnoses may represent a spectrum of the same disease. Morphologically, TZL cells have few distinguishing characteristics: they tend to have nuclear clefts or indentations, smooth to stippled chromatin that may form prominent chromocenters, indistinct nucleoli, scant, clear to amphophilic cytoplasm, and low mitotic activity (Fig. 72.6).

T zone lymphomas generally have a helper (CD4) phenotype and seem to display slow clinical progression, but controlled studies are lacking to determine the most appropriate therapy for this disease. It is clear that TZL does not have the same poor duration of response and short patient survival commonly associated with high-grade T cell lymphoma. In fact, a recent study showed that, among 40 canine lymphomas, these tumors had by far the best response to standard care.[60] Furthermore, these tumors may respond even better to conservative management with low intensity chemotherapy, although data to support this are only anecdotal.

Extranodal NK/T Cell Lymphoma, Nasal Type

Extranodal NK/T cell lymphoma (ENKL) is a rare form of human lymphoma, although the incidence is higher in East Asia and Latin America where the majority of cases are associated with EBV infection.[186] Most cases of ENKL in humans arise from NK cells,[118] although both the NK cell and T cell variants are considered as a single disease entity that share clinical and prognostic features.

Nasal lymphoma is rare in dogs, but it is the most common tumor of the nasal cavity in cats, with increased incidence since the inception of routine FeLV vaccination.[5,86,120,131,138] Common clinical signs in dogs and cats include sneezing, upper respiratory stridor, and nasal discharge that can be purulent, serous, and bloody; facial pain and/or deformity are rare.[109,196] The association of nasal lymphoma with systemic lymphadenopathy or spread to other distant sites is unclear. A recent publication reported 10 of 22 cats with multi-organ involvement of brain, gut, liver, lung, kidney, eye, and bone marrow.[109]

Two independent case reports in dogs supported T cell ontogeny.[102,196] Nasal lymphoma in the cat is predominantly a B cell tumor (70–90% of the cases).[42,109,138]

Histology is preferred for diagnosis of nasal lymphoma, but brush cytology of the nasal passages can provide diagnostic samples if there is minimal inflammation and hemorrhage.[109] Squash preparations from endoscopic biopsies are also a reliable source of tissue for cytologic assessment, although it can be difficult to distinguish between lymphoma and lymphoid hyperplasia.[45]

Hepatosplenic Gamma-Delta T Cell Lymphoma

In humans, hepatosplenic T cell lymphoma (HSTCL) is a clinically aggressive neoplasm that was first described as an entity in 1981.[98] It is characterized by hepatosplenic involvement, sinusoidal tropism, and an infiltrating population of αβTCR-positive T cells that also express CD2, CD3, and CD56.[93,122,165,183,203] Although selected cases of TCRαβ have been identified, the gamma-delta variant of the disease is recognized as a distinct clinicopathologic entity in the WHO classification system.[93,122,183] As TCRαβ HSTCL has not been reported in the veterinary literature, it will not be discussed.

In both the human and veterinary literature, HSTCL is considered to be rare. In humans, approximately 200 cases of HSTCL have been reported, which represents less than 1% of all human lymphomas. The incidence of HSTCL in veterinary medicine is uncertain, but the small number of published reports since its initial description in 2003 suggests that it is similarly rare. HSTCL has been described in three reports, encompassing four dogs and one horse.[27,65,161] Although a definitive diagnosis of HSTCL in the cat has yet to be published, a report of erythrophagocytic T cell lymphoma, which shares clinical and clinicopathologic features of HSTCL has been published.[25]

HSTCL in humans may be associated with immunodeficiency, particularly in patients undergoing long-term immunosuppression associated with organ transplantation or inflammatory bowel disease.[12] Approximately one-third of human cases have been associated with organ transplantation and other conditions that require immune-modifying agents. The mechanism is unknown, but may be related to disruption of T cell negative regulation.

Human patients with HSTCL typically present with marked hepatomegaly, splenomegaly, or both, in the absence of lymphadenopathy.[12,27,92,209] They also have cytopenias of more than one lineage.[12,209,212] In animals with HSTCL, the clinical features include lethargy, fever, splenomegaly, anorexia, diarrhea, and pancytopenia.

The diagnosis of human HSTCL generally requires histological and immunohistologic evaluation of bone marrow and spleen, tissues in which the vascular tropism characteristic of the neoplastic cells can be identified.[12,165,209] Infiltration by atypical cells within marrow sinusoids is common, but cellular identification is often difficult, because the infiltrating population is often subtle and requires immunohistochemistry. In humans, the neoplastic cells in HSTCL are most commonly CD2, CD3, CD38, CD56-positive cells with variable expression of CD7 and CD16.[165,203] According to the limited veterinary patient phenotype data, the cells in four cases of canine HSTCL are described as CD3, CD11d, and TCR γδ-positive.[27,65] Additionally, activated hemophagocytic histiocytes may be admixed with the neoplastic T cells.[12] Despite its common involvement, evaluation of liver is not recommended to diagnose HSTCL in people because the histologic pattern is more commonly consistent with an inflammatory rather than a neoplastic process.

Given the limited number of cases in animals, an algorithm to diagnose veterinary patients with this disease remains to be constructed. Despite this, features similar to human HSTCL (prominent sinusoidal tropism in liver, spleen and bone marrow, and neoplastic cell CD3-positivity) have been reported in cases of canine HSTCL. However, in contrast to the humans, the antemortem evaluation of bone marrow through aspiration cytology, was not helpful in the two dogs in which it was performed.[27,65]

The prognosis of HSTCL is poor; most human patients die within 16 months of diagnosis irrespective of therapy, and three of the five animals with this disease (two dogs and the horse) survived less than 5 days after diagnosis.[12,27,65,161,209]

Peripheral T Cell Lymphoma, Not Otherwise Specified

PTCL-NOS is a WHO category created to encompass those peripheral T cell malignancies that cannot be readily classified into another defined group based on morphology, phenotype, or molecular characteristics. As such, the diagnosis of PTCL-NOS encompasses a heterogeneous group that includes 40–50% of all human T cell lymphomas, representing some of the most aggressive cases of NHL that often present as advanced disease in middle-aged to older people with involvement of lymph nodes, skin, liver, spleen, and bone marrow or blood.[2,74,101] This disease is commonly associated with paraneoplastic syndromes including hypercalcemia, skin rashes, vasculitis, eosinophilia, and hemophagocytosis.[17]

The morphology of PTCL-NOS cells can range from uniform small nondescript lymphoid cells with indistinct nucleoli, to large anaplastic cells, to combinations of the two, but there is no correlation between cytological atypia and biological behavior.[105] Often, there are prominent reactive infiltrates admixed with the tumor cells, and not surprisingly, the latter have variable phenotypes, with expression of CD3 being the only consistent finding.[211] PTCL-NOS in people is most commonly a nodal disease of CD4 cells; however, extranodal tumors, generally of CD8 origin, also are seen.[105]

The heterogeneous nature of this NHL subgroup is reinforced by their gene expression profiles, although these clearly distinguish PTCL-NOS from the two next most common human T cell lymphomas, AITL and ALCL.[2] Treatment for this disease is generally unrewarding, and intensification of chemotherapy does not seem to improve outcomes over treatment with standard CHOP-based protocols.[55]

Given the paucity of immunolabeling reagents and the absence of large-scale studies describing precise subcategories of lymphoma in domestic animals, it would be tempting to include many T cell tumors in this category. However, dogs are the only species where some rigor has been applied to reach this diagnosis.[60,63] PTCL-NOS appears to affect middle-aged to older dogs,

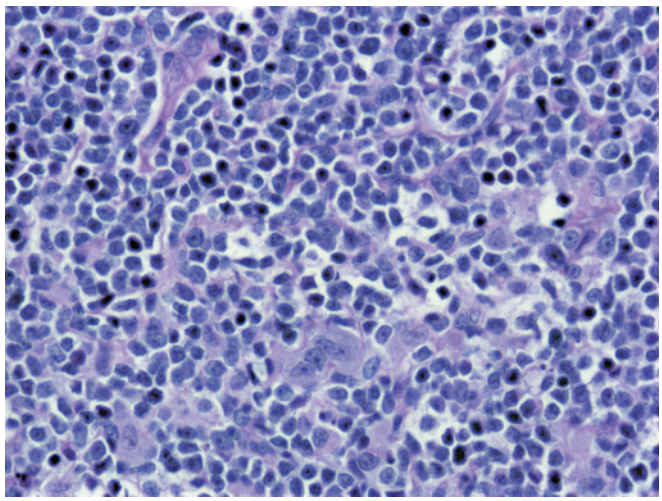

FIGURE 72.7 Peripheral T cell lymphoma, not otherwise specified in a lymph node from a dog. Notice the large, pleomorphic cells with prominent irregular nuclear contours and variable amounts of pale, foamy cytoplasm. Nucleoli are generally indistinct, although in this case they are apparent in some cells. Features that distinguish them from diffuse large B cell lymphomas (DLBCL) and LBTL, are that PTCL has only occasional macrophages (these are a prominent feature of DLBCL and very rare in LBTL) and it can have a prominent vascular network. H&E stain; original magnification ×500.

causing regional or generalized lymphadenopathy. Morphologically, the tumor cells are pleomorphic, have prominent nuclear contour irregularity, indistinct nucleoli, and variable amounts of pale cytoplasm (Fig. 72.7). They mostly arise from CD4 T cells,[63] and in the authors' experience, they are frequently associated with paraneoplastic syndromes such as hypercalcemia. Like LBTL, these tumors are cytogenetically unstable, seem to harbor deletions of the CDKN2 locus, and respond poorly to multi-agent chemotherapy.[60]

Natural Killer Cell Neoplasms

Natural killer cells are incompletely characterized in domestic animals other than the cow because there is a paucity of useful reagents that define their phenotype in humans and mice. Until now, a diagnosis of NK leukemia or lymphoma has been based on absence of T or B cell markers, and undetectable clonal rearrangements of lymphocyte antigen receptors. Yet, cells with morphologic characteristics and functions of NK cells can be isolated from canine blood,[82] and the recent characterization of canine and feline CD56 may help to confirm the incidence of NK malignancies in these species.[179]

Unclassifiable, High-grade Plasmacytoid Type Lymphoma

This subcategory of canine lymphoma was only recently described and is of particular interest given the disparity between its cytologic features and immunophenotype. The tumor cells resemble plasma cells; yet, they consistently express T cell markers. There is no category of human T cell lymphoma with comparable features, so this tumor may warrant classification in a separate category in dogs.[63]

High-grade plasmacytoid T cell lymphoma appears to affect younger dogs and displays aggressive clinical behavior.[152] Dogs have regional or generalized lymphadenopathy along with hepatosplenomegaly, mediastinal involvement, and bone marrow infiltration with infrequent atypical cells in the circulation.[63,151] In one study, hypercalcemia was present in four out of nine cases and response to multi-agent chemotherapy was unrewarding, with a median disease-free survival of 3 months.[151]

High-grade plasmacytoid T cell lymphoma has a diffuse histological appearance with high mitotic index and frequent tingible body macrophages that create the typical starry sky appearance associated with diffuse B cell lymphomas.[63,151] The malignant lymphocytes are of intermediate size, occasionally binucleate with variably clumped chromatin and abundant basophilic cytoplasm with perinuclear clearing, all morphologic features consistent with plasma cells. They express CD3 and CD8, but some cases may co-express CD4.[63,151] The presence of nuclei with irregular, flower-shaped contours consistent with T cell origin in a tumor with plasmacytoid morphology is one feature that should encourage the pathologist to perform additional tests to reach a definitive diagnosis.

Acronyms and Abbreviations

APC, antigen-presenting cell; CCNU, 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (Lomustine); CH, cutaneous histiocytosis; CNS, central nervous system; DC, dendritic cell; EMH, extramedullary hemopoiesis; FPH, feline progressive histiocytosis; HHS, hemophagocytic histiocytic sarcoma; HS, histiocytic sarcoma; IHC, immunohistochemistry; LC, Langerhans cell; LCH, Langerhans cell histiocytosis; MF, mycosis fungoides; MH, malignant histiocytosis; NECL, non-epidermotropic cutaneous lymphoma; PCR, polymerase chain reaction; PLCH, feline pulmonary Langerhans cell histiocytosis; SH, systemic histiocytosis.

OVERVIEW

There are at least four well-defined histiocytic proliferative diseases that have been recognized in dogs. They are a frustrating group of diseases because it may be difficult to differentiate them from granulomatous, reactive, inflammatory, or lymphoproliferative diseases by examination of regular paraffin sections. The clinical presentation and behavior and responsiveness to therapy vary between the syndromes observed (Table 73.1). Clinical and pathological images of canine histiocytic diseases, and details of histiocytic lineages are available on a web site maintained by the authors (http://www.histiocytosis.ucdavis.edu).

Canine cutaneous histiocytoma usually occurs as a single lesion in young dogs and spontaneously regresses. Metastatic histiocytoma is a rare example of aggressive behavior of this solitary tumor. *Langerhans cell histiocytosis* covers a spectrum of disease from multiple cutaneous lesions, which individually resemble solitary histiocytomas, to multiple cutaneous lesions with progressive systemic involvement. *Cutaneous histiocytosis* (CH) presents with single or multiple lesions, which tend to wax and wane, and may even spontaneously regress. Few cases respond to corticosteroids, the remainder persist and may require more aggressive immunosuppressive therapy. *Systemic histiocytosis* (SH) is a familial disease of Bernese mountain dogs and also occurs sporadically in other breeds. Systemic histiocytosis presents with prominent skin manifestations identical to those seen in CH, but mucous membranes (ocular and nasal) and a variety of other organ systems, including lymphoid organs, lung, and bone marrow may also be involved. Although the lesions may wax

TABLE 73.1 Canine Histiocytic Disease Classification

Disease Group	Disease	Cell of Origin	Disease Progression
Histiocytoma complex	Histiocytoma	Epidermal LC	Spontaneous regression
	Langerhans cell histiocytosis	Epidermal LC	Widespread cutaneous/systemic disease. Spread beyond skin poor prognostic indicator
Reactive histiocytosis	Cutaneous histiocytosis	Interstitial DC (dermal DC)	Immunoregulatory disorder – limited to skin and lymph node. Responds to immunosuppression
	Systemic histiocytosis	Interstitial DC	Immunoregulatory disorder – skin, lymph node, mucous membranes, internal organs. Responds to immunosuppression
Histiocytic sarcoma complex	Localized histiocytic sarcoma	Interstitial DC	Initial solitary site – rapid dissemination
	Disseminated histiocytic sarcoma	Interstitial DC	Progression of localized disease; multicentric origin (equivalent to malignant histiocytosis)
	Hemopohagocytic histiocytic sarcoma	Macrophage – splenic red pulp and bone marrow	Originates in spleen (± bone marrow); rapid spread to liver and lung

and wane, SH is a progressive disease that often requires continuous immunosuppressive therapy. *Histiocytic sarcoma* (HS) and *malignant histiocytosis* (MH) occur with high incidence in Bernese mountain dogs, Rottweilers, Flat Coat Retrievers, Golden Retrievers and sporadically in many other breeds. Histiocytic sarcomas occur as localized lesions in spleen, lymph nodes, lung, bone marrow, skin and subcutis, brain, and periarticular tissue of large appendicular joints. Histiocytic sarcomas can also occur as multiple lesions in single organs (especially spleen). Localized HS lesions rapidly disseminate to involve multiple organs. Hence, disseminated HS is difficult to distinguish from MH, which is a multisystem, rapidly progressive disease in which there is simultaneous involvement of multiple organs such as spleen, lymph nodes, lung, bone marrow, skin and subcutis. Response of HS and MH to chemotherapy is at best brief.

HISTIOCYTIC DIFFERENTIATION AND CANINE HISTIOCYTOSIS

The development of canine specific monoclonal antibodies for many of the functionally important molecules of macrophages and dendritic antigen-presenting cells (DCs) has enabled the identification of cell lineages involved in canine histiocytic disorders.[1,3,14,19] The majority of histiocytic disorders involve proliferation of various DC lineages.

Histiocytes differentiate from CD34+ committed stem cell precursors into macrophages and several DC lineages, which include epitheliotropic DCs or Langerhans cells (LCs), interstitial DCs in many organs (e.g. dermal DCs in skin), and interdigitating DCs of T cell domains in peripheral lymphoid organs (see Chapter 8). Dendritic cells are the most potent antigen-presenting cells (APCs) for induction of immune responses in naïve T cells. Canine DCs have been best defined in canine skin. They occur in two major locations: within the epidermis LCs, and within the dermis, especially adjacent to post-capillary venules (i.e. interstitial DCs or dermal DCs). Canine DCs abundantly express CD1 molecules,[12,14,19] which together with MHC class I and MHC class II molecules, are responsible for presentation of peptides, lipids and glycolipids to T cells. Hence, DCs are best defined by their abundant expression of molecules essential to their function as APCs. Of these, the family of CD1 proteins is largely restricted in expression to dendritic APCs in skin,[12] while MHC classes I and II are more broadly expressed.

The beta-2 integrins (CD11/CD18) comprise the major family of adhesion molecules on leukocytes, and as such are useful markers of leukocytic differentiation. CD11/CD18 expression is highly regulated in normal canine macrophages and DCs. CD11c is frequently expressed by DCs, while macrophages predominately express CD11b (or CD11d in the splenic red pulp and bone marrow).[5,6] In diseased tissues, these beta-2 integrin expression patterns may be diversified.

Langerhans cells (intraepithelial DCs) and interstitial DCs are distinguishable by their differential expression of E-cadherin (LC+) and Thy-1 (CD90) (interstitial DC+). Lineage distinctions among histiocytes are best made via immunohistochemistry (IHC) performed on frozen sections (CD1, CD11b, CD11c, CD11d, CD18, CD90, MHC II, and E-cadherin expression). Less definitive, but useful distinctions can also be attained via IHC on formalin-fixed paraffin-embedded sections with panels of leukocytic markers developed for use in this format (CD3, CD11d, CD18, CD45, CD45RA, CD79a, and E-cadherin).

Successful interaction of dendritic APCs and T cells in response to antigenic challenge also involves the orderly appearance of costimulatory molecules (B7 family – CD80 and CD86) on dendritic APC, and their ligands (CD28 and CTLA-4) on T cells. Defective interaction of dendritic APC and T cells appears to contribute to the development of reactive cutaneous histiocytic proliferative diseases (cutaneous and systemic histiocytosis), which are related DC disorders arising out of disordered immune regulation (see below).

CANINE CUTANEOUS HISTIOCYTOMA COMPLEX

Solitary Cutaneous Histiocytoma

Histocytoma is a common, benign, cutaneous neoplasm of the dog. Histiocytomas usually occur as solitary lesions, which undergo spontaneous regression. The age-specific incidence rate for histiocytomas drops precipitously after 3 years, although histiocytomas do occur in dogs of all ages.[24] Recurrence of histiocytomas at the same or other sites is uncommon. The occurrence of multiple tumors is also uncommon. Epidermal invasion by cells of histiocytoma frequently occurs (incidence about 60%) and intra-epidermal nests of histiocytes resemble Pautrier's aggregates, characteristically found in epidermotropic cutaneous T cell lymphoma (mycosis fungoides or MF; Fig. 73.1). Epidermal invasion in histiocytoma, or presence of simultaneous multiple histiocytomas, especially in aged dogs, can present a diagnostic dilemma and distinction from MF and non-epidermotropic cutaneous lymphoma (NECL) is difficult without immunostaining for CD3 (T cell lymphoma) and CD18 (histiocytoma).[17–19]

Multiple histiocytomas are also readily confused with cutaneous histiocytosis on clinical appearance, although morphologically, histiocytomas are consistently epidermotropic and commonly epidermally invasive; these are not features of cutaneous histiocytosis, which is not focused on the epidermis. Instead the bulk of the lesion is formed by coalescence of perivascular infiltrates in the deep dermis and subcutis.

Immunophenotypic Studies

Immunohistochemistry is best performed on frozen sections of tumor or cytological preparations (not formalin-fixed material). Histiocytoma is readily distinguished from other histiocytic disorders and cutaneous lymphoma with the aid of IHC. Histiocytomas have the phenotype of epidermal LC.[19] They express CD1a, MHC class II, CD11c/CD18, and often E-cadherin. In formalin-fixed tissue, histiocytomas consistently express CD18 and commonly E-cadherin (Fig. 73.2). Among skin leukocytes, E-cadherin expression is unique to LCs. Langerhans cells utilize E-cadherin to localize in the epidermis via homotypic interaction with E-cadherin expressed by keratinocytes. E-cadherin expression has only rarely been observed in HS in canine skin and subcutis. Histiocytomas lack expression of CD4 and Thy-1, which are consistently expressed by histiocytes in CH and SH.

Regression of Histiocytomas

The factors that determine the onset of regression in canine histiocytomas are unknown. Evidence of regression is usually observed in lesions that have been present for only a few weeks, although regression can be delayed for many months. Regardless, regression is mediated by CD8+ αβ T cells; only scant numbers of CD4+ T cells are observed in histiocytoma lesions. Migration of tumor histiocytes and/or tumor infiltrating reactive DC to draining lymph nodes could activate CD4+ T cells, which would assist in CD8+ cytotoxic T cell recruitment. Because massive CD8+ T cell infiltration is observed in all instances of histiocytoma regression, therapeutic intervention with the aim of immunosuppression should be avoided once a definitive diagnosis of histiocytoma has been reached, to allow unfettered cytotoxic T cell function.

Metastatic Histiocytoma

We have observed several dogs with solitary histiocytomas in which neoplastic histiocytes had migrated to draining lymph nodes resulting in complete oblitera-

tion. In three of four instances regression of these lesions occurred spontaneously within 3–4 weeks.[19]

Langerhans Cell Histiocytosis

If histiocytomas occur in multiple cutaneous sites, there is a spectrum of clinical disease ranging from skin involvement only to skin, lymph node, and internal organ involvement. This spectrum of disease best fits under the umbrella of LCH.

Multiple histiocytomas, limited to skin or skin and draining lymph nodes, are best classified as cutaneous LCH. Multiple histiocytomas limited to skin appear to be more common in Shar Pei dogs, but can occur in any breed. Delayed regression of multiple histiocytomas can occur and lesions can persist for up to 10 months before onset of regression. In about 50% of instances, dogs with multiple histiocytomas are euthanized due to lack of regression of lesions and complications in management of the extensive ulcerated lesions that are frequently present. Multiple histiocytomas with lymph node metastasis have a poor prognosis, because spontaneous regression has not been encountered, and all affected dogs have been euthanized.

Multiple cutaneous histiocytomas with progression to lymph node and internal organ involvement are best classified as systemic LCH. Clinically, the lesions may be almost confluent in affected skin regions. Affected animals have all been euthanized and the time course is shorter than cutaneous LCH. There is one published account of a similar case without necropsy to verify internal lesions,[20] and the author has data on nine dogs with a similar presentation. Langerhans cell histicytosis is also recognized as a rare disease of humans, in which marked variation in clinical behavior is recognized.[7,22]

Treatment of Histiocytoma Complex

Solitary histiocytomas are either surgically removed or undergo spontaneous regression. Cutaneous LCH and systemic LCH are refractory to therapeutic intervention. Treatment with CCNU (Lomustine), which is commonly used to treat HS, has not been effective in LCH. Corticosteroids are contraindicated for reasons alluded to above. Spontaneous remission is possible in cutaneous LCH and this occurs in about half of the cases, unless lymph node involvement occurs. In one published report, response of cutaneous LCH to immunomodulatory therapy with griseofulvin was reported.[20] Others have tried immunomodulation with levamisole without success in cutaneous LCH.

CANINE HISTIOCYTIC SARCOMA COMPLEX

Localized and Disseminated HS

The HS complex encompasses a number of distinctive clinical entities. Histiocytic neoplasia, which originates at a single site, is called localized HS. This form of histiocytic sarcoma, which is often encountered on the extremities, has the best prognosis if treated early by surgical excision or by amputation of a limb. When spread to sites beyond the local lymph node occurs, the disease is then termed disseminated HS; this is more likely to occur unnoticed when primary lesions occur in cryptic sites (e.g. spleen, lung, and bone marrow). This latter form of HS is most like MH. Malignant histiocytosis is an aggressive, histiocytic neoplasm, which arises in multiple sites simultaneously. Most lesions previously defined as MH are probably more correctly termed disseminated HS. The occurrence of true MH is difficult to establish because the lesions often occur in cryptic sites, and the existence of histiocytic neoplasia is only recognized after clinical signs have appeared and disease progression is advanced. HS and MH are capable of widespread metastasis; hence in time the two syndromes merge clinically and it is not always possible to differentiate true multicentric origin (MH) from widespread metastasis of disseminated HS. Also, it is never possible to know exactly how long the disease process has been operative. Hence, the perception is that both disseminated HS and MH follow a rapid clinical progression despite therapeutic intervention. This is certainly true once clinical signs are apparent, but the sub-clinical period is of unknown duration.

The HS complex of diseases is best recognized in the Bernese Mountain Dog, in which a familial association is apparent. Other breeds are predisposed to HS complex diseases and include Rottweilers, Golden Retrievers, and Flat-coated Retrievers.[3] HS complex is not limited to these breeds and can occur sporadically in any breed. Primary lesions of HS occur in spleen, lymph node, lung, bone marrow, skin, and subcutis especially of extremities, and in periarticular tissues of the limbs. Secondary sites are widespread, but consistently include liver and lung when the spleen is the primary site, and hilar lymph node when lung is the primary site. Clinical signs include anorexia, weight loss, and lethargy. Other signs depend on the organs involved and are a consequence of destructive mass formation. Accordingly, pulmonary symptoms such as cough and dyspnea have been seen. Central nervous system (CNS) involvement (primary or secondary) can lead to seizures, incoordination, and paralysis. Lameness is often observed in periarticular HS. Regenerative anemia, thrombocytopenia, hypoalbuminemia and hypocholesterolemia have been consistently documented in hemophagocytic HS.[16] Many of the cases have been mistaken for Evans' syndrome despite the lack of demonstrable IgG on the surface of red blood cells (RBCs).

Morphological Features of HS

Lesions of HS are typically destructive mass lesions with a uniform, smooth cut surface and are white/cream to tan in color. Lesions have a soft consistency and may contain discolored areas (typically yellow), which indicate area of necrosis. Lesions can be solitary or multiple within an organ (especially spleen). Periarticular HS has a distinctive appearance: it occurs

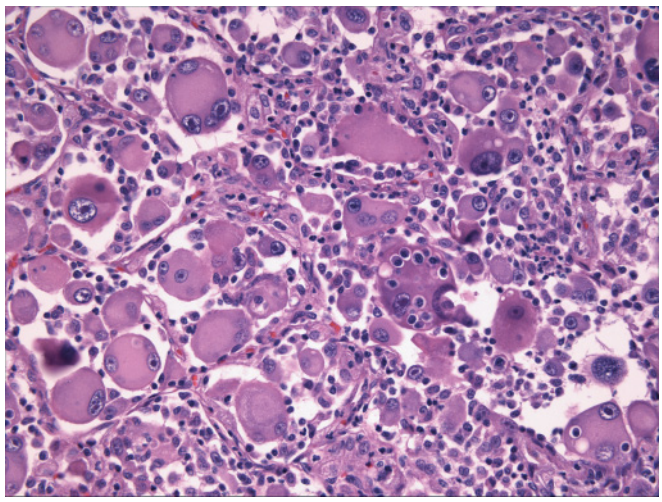

FIGURE 73.3 Histiocytic sarcoma. Cytologically atypical mononuclear and multinucleated giant cells in HS. Many cells are phagocytic. Hematoxylin & Eosin stain.

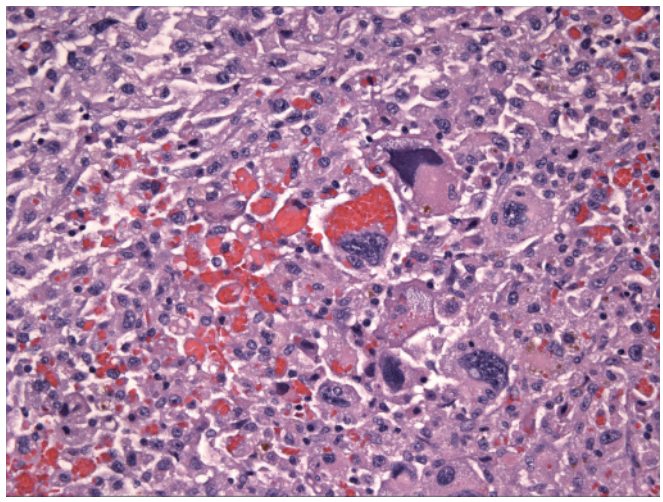

FIGURE 73.4 Hemophagocytic HS. Prominent erythrophagocytosis by cytologically atypical histiocytes in the splenic red pulp. Hematoxylin & Eosin stain.

as multiple tan nodules located in the sub-synovium. These lesions may encircle the affected joint. Hemophagocytic HS does not initially form mass lesions in the primary sites (spleen and bone marrow). Typically, diffuse splenomegaly and ill-defined mass lesions are observed; the cut surface is dark red and the consistency is firm. The liver is usually bile stained (jaundice) and disruption of the lobular pattern due to metastasis is observed: marked liver involvement can occur in the absence of destructive liver masses.

The histological appearance of HS lesions is consistent regardless of location. Lesions are most frequently composed of sheets of large, pleomorphic, mononuclear cells and multi-nucleated giant cells, which show marked cytological atypia and numerous bizarre mitotic figures (Fig. 73.3). Some lesions may include spindle cell forms either alone, or mixed with the mononuclear cells and multinucleated giant cells. Pure spindle cell lesions resemble spindle cell sarcomas of diverse cell lineage. Confirmation of histiocytic lineage can only be achieved with IHC in these instances. Phagocytosis of RBCs, leukocytes and tumor cells occurs, but is not prevalent in most forms of HS. However, in hemophagocytic HS this behavior is amplified. Neoplastic histiocytes manifest marked erythrophagocytosis and the infiltrates obliterate the splenic red pulp and invade red pulp sinuses (Fig. 73.4). Foci of extramedullary hemopoiesis (EMH) occur within and adjacent to the tumor infiltrates in the splenic red pulp. Simultaneous involvement of bone marrow is frequent, and erythrophagia is observed here as well; these cases are probably equivalent to hemophagocytic MH in recognition of the simultaneous involvement of multiple sites. In some instances, the neoplastic infiltrates can be deceptively cytologically bland. The cytological appearance can be asynchronous between sites (e.g. spleen and bone marrow), which can contribute to diagnostic ambivalence if only one site is evaluated. Invasion of splenic red pulp sinuses portends invasion of the hepatic sinusoids. In the early stages, liver metastases can easily be overlooked grossly and histologically, because histiocytic infiltrates creep along sinusoids and do not form discrete masses. Neoplastic histiocytes in hemophagocytic HS express a distinctive surface antigen profile much like that expressed by macrophages in splenic red pulp and bone marrow (see below).

In some instances, a secondary hemophagocytic syndrome can be confused with hemophagocytic HS. This has occurred most frequently with hepatosplenic T cell lymphoma, which is frequently accompanied by responsive anemia and thrombocytopenia. Demonstration of proliferative foci of CD3+ neoplastic T cells in spleen and liver in association with cytologically normal, hemophagocytic macrophages is necessary to resolve these cases.[9]

Immunophenotypic Studies

Histiocytic sarcoma lesions express leukocyte surface molecules characteristic of DC (CD1, CD11c/CD18 and MHC II) (Fig. 73.5). Diffuse expression of E-cadherin, Thy-1, and CD4 has not been observed in HS or MH in any site; this together with cytomorphology assists in the distinction of MH and HS from histiocytoma and reactive histiocytosis (SH and CH).[1,3] In histiocytoma, the phenotype is quite similar to that of HS except for the expression of E-cadherin, which occurs in histiocytoma especially in the cellular infiltrate immediately adjacent to the epidermis. However, E-cadherin expression is often visibly weaker in tumor cells in the deep dermis. In reactive histiocytosis, the activated interstitial (dermal) DCs (CD1+, CD11c+, MHC II+, E-cadherin-), consistently express CD4, and Thy-1 expression occurs.

In hemophagocytic HS, histiocytes express CD11d instead of CD11c, and MHC II (Fig. 73.6). Expression of CD1 molecules is uniformly low, or occasionally moderate but with a patchy distribution. This phenotype is

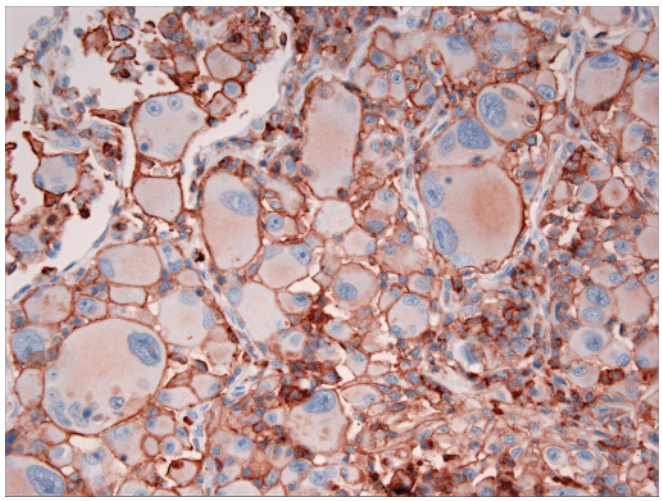

FIGURE 73.5 Histiocytic sarcoma. CD18 expression by atypical histiocytes. This most likely represents expression of CD11c/CD18.

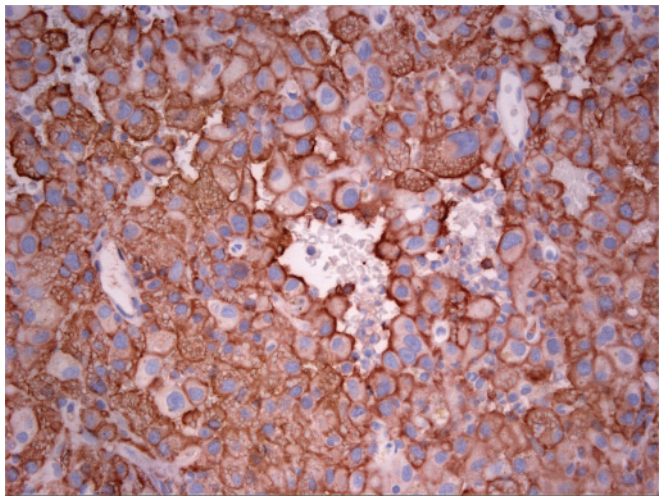

FIGURE 73.6 Hemophagocytic HS. CD11d expression by atypical histiocytes in the splenic red pulp – reflects expression of CD11d/CD18.

consistent with macrophage differentiation rather than DC differentiation, in which abundant expression of CD1 and CD11c is expected.[16]

The exact sublineages of DC involved in HS have not been determined in most instances. The most likely candidates include interdigitating DC in lymphoid tissues and perivascular interstitial DC in other involved tissues. Immunophenotyping and careful morphological assessment should also avoid confusion of HS and MH with the large cell form of T cell lymphoma (CD3+), and poorly differentiated mast cell tumors (CD18+ variable, CD45+, CD45RA+, Tryptase+, c-kit+).

Treatment of HS Complex

Localized HS affecting skin and subcutis has been cured by early surgical excision, which in some instances, has been apparently successfully supplemented by local radiation therapy. In the case of periarticular HS, which occurs in the sub-synovial tissues of the extremities, amputation of the affected limb is necessitated by the inoperable nature of the primary lesions. It is important to establish that evidence of metastasis is absent via thoracic radiographs, abdominal ultrasound, and draining lymph node aspiration cytology before embarking on limb amputation. Disseminated HS (including MH) is not readily treated surgically, because even in the splenic form, early metastasis to the liver has often occurred. Chemotherapy with CCNU has been reported; the success depended on disease load. A small number of dogs with minimal residual disease had prolonged survival (>431 days); however, the median survival for all dogs was only 106 days. The authors identified hypoalbuminemia and thrombocytopenia as negative prognostic variables; dogs with these features survived less than 1 month.[23] The latter group of dogs may have included dogs with hemophagocytic HS.[16]

CANINE REACTIVE HISTIOCYTOSES

Systemic Histiocytosis

Systemic histiocytosis was originally recognized in related Bernese mountain dogs.[15] Systemic histiocytosis is a generalized histiocytic proliferative disease with a marked tendency to involve skin, ocular and nasal mucosae, and peripheral lymph nodes. The disease predominately affects young to middle aged dogs (2–8 years old). Systemic histiocytosis has been observed less frequently in other breeds (Irish wolfhounds, Basset hounds and others). Clinical signs vary with the severity and extent of disease and include anorexia, marked weight loss, stertorous respiration, and conjunctivitis with marked chemosis. Multiple cutaneous nodules may be distributed over the entire body, but are especially prevalent in the scrotum, nasal apex, nasal planum, and eyelids. Ulceration of the skin overlying the nodules is common. Peripheral lymph nodes are often palpably enlarged. The disease course may be punctuated by remissions and relapses, which may occur spontaneously especially early in the disease course. In severe disease, lesions become persistent and do not respond to immunosuppressive doses of corticosteroids.

Cutaneous Histiocytosis

Cutaneous histiocytosis is a histiocytic proliferative disorder that primarily involves skin and subcutis and does not extend beyond the local draining lymph nodes.[13] Cutaneous histiocytosis occurs in a number of breeds. Evidence of spread beyond the skin would invoke the diagnosis of SH, a closely related disorder. Lymphadenopathy has not been emphasized in published reports, and has only been documented in a small number of our cases. The lesions occur as multiple cutaneous and subcutaneous nodules up to 4 cm in

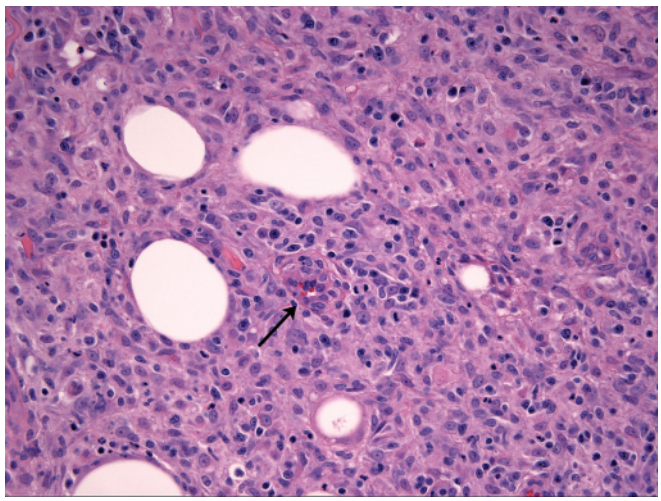

FIGURE 73.7 Cutaneous histiocytosis. Cohesive infiltrates of well differentiated histiocytes and fewer lymphocytes in the subcutis. Lymphocytes and histiocytes infiltrate a vessel wall (arrow). Hematoxylin & Eosin stain.

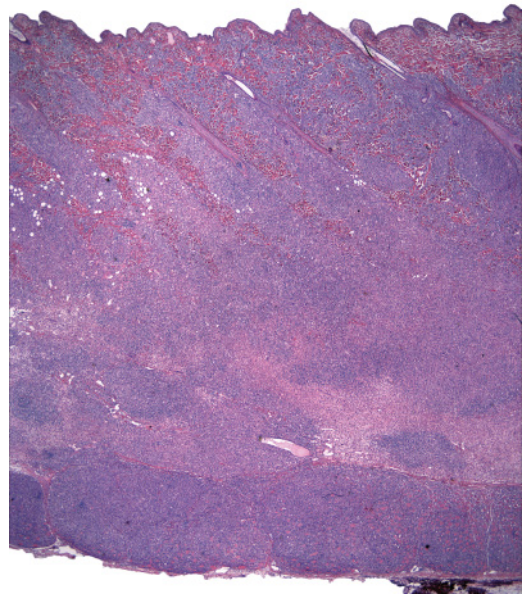

FIGURE 73.8 Cutaneous histiocytosis. Histiocytic infiltrates spare the superficial dermis and coalesce in the deep dermis and subcutis. Hematoxylin & Eosin stain.

diameter. Overlying skin ulceration is common. Lesions may disappear spontaneously, or regress and appear at new sites simultaneously. Topographically, lesions may be found on the face, ears, nose, neck, trunk, extremities (including foot pads), perineum. and scrotum.

Morphological Features of SH and CH

The lesions of SH in most tissues consist of perivascular infiltrates of large histiocytes and variable populations of lymphocytes, neutrophils, and eosinophils (Fig. 73.7). The histiocytes frequently invade vessel walls and this may lead to vascular compromise and infarction of surrounding tissues, which contributes to ulceration of the cutaneous lesions. The widespread distribution of lesions of SH is only fully appreciated at necropsy. Histiocytic lesions have been observed in skin, lung, liver, bone marrow, spleen, peripheral and visceral lymph nodes, kidneys, testes, orbital tissues, nasal mucosa and other sites. In skin, the lesions of SH and CH are virtually identical. The lesions usually involve the deep dermis and subcutis. Involvement of the superficial dermis is inconsistent and epidermotropism of the histiocytes is not observed (Fig. 73.8). In CH the lesions are limited to the skin, but may involve the draining lymph nodes. It is important to note that the lesion topography of SH and CH are the inverse of histiocytoma, and this is an often overlooked feature in diagnostic decision-making.

Immunophenotypic Studies

Histiocytes in SH and CH express markers expected of DCs, including CD1, C11c, and MHC II. However, lack of E-cadherin expression, and expression of Thy-1 (expressed by dermal DCs) and CD4 (a marker of DC activation) are consistent with an activated interstitial type DC phenotype.[1] In skin, dermal DCs are mostly of interstitial DC type. In contrast, histiocytomas express an epidermal LC phenotype. Langerhans cells are intraepithelial DCs; they express CD1, CD11c, MHC II and E-cadherin. Langerhans cells lack expression of Thy-1, and do not express CD4 in the non-activated state.

Pathogenesis

The clinical behavior and consistent clinical response to immunosuppressive therapy with agents capable of profoundly inhibiting T cell activation has reinforced the concept that SH and CH occur in the context of disordered immune regulation. This may arise from defective interaction of DC and T cells in the resolution phase of an immune response. The end result of this dysregulated immune interaction is chronic proliferation of DC and T cells. The initiation of the process is probably antigen-driven, although studies to identify the nature of antigens involved have not been exhaustively conducted. Hence, it is important to perform tests to rule out infectious agents in the workup of a reactive histiocytosis case (culture and/or special stains for microorganisms in tissue). The lesions can wax and wane over time and spontaneous regression without therapy has been observed. The lymphoid component of the lesion consists of predominately CD8+ αβT cells, whose numbers can vary markedly between lesions. These T cells can comprise up to 50% of the cells in some instances. The role played by T cells is unknown. T cells may be involved in a key way in the exaggerated proliferation and activation of DC via T cell derived cytokines such as GM-CSF and TNFα, which are known to influence the proliferation and differentiation of DC.

The author believes that the continued distinction of SH and CH as separate entities is no longer justifiable.

It would be preferable to consider them within the spectrum of reactive histiocytoses of interstitial DC origin, in which clinical outcome is predictable more by the distant migratory potential of proliferating histiocytes beyond the skin. In this view, CH and SH would be regarded as skin limited and systemic interstitial DC proliferations, respectively. A wide range of clinical behavior is to be expected within each grouping, with SH usually exhibiting more aggressive disease. Cutaneous histiocytosis and SH should not be confused with malignant DC disorders (HS and MH), which can occur in the same topographical locations, and in littermates in genetically susceptible breeds. Cytological and immunophenotypic differences can distinguish these diseases in most instances. There has been very little direct evidence of progression of reactive histiocytosis to HS. On a cautionary note, inflamed T cell lymphoma of skin can look very much like reactive histiocytosis. In such cases, polymerase chain reaction (PCR)-based analysis of the T cell receptor gamma locus will identify clonal T cell expansion in the lesion with good sensitivity (about 80%).[25]

Treatment Options in SH and CH

Systemic histiocytosis has proven to be a difficult and frustrating condition to treat. Consequently, many of the early cases were euthanized. Originally we treated dogs with thymosin (derived from bovine thymus) because of reports of its effectiveness in human LCH cases.[21] Some dogs appeared to respond to thymosin, but not consistently. The original rationale for using thymosin was that SH was likely an immunoregulatory disorder and not cancer.[15] Once modern immunosuppressive drugs became available, we abandoned the use of thymosin. In the majority of instances corticosteroid treatment is ineffective, although steroids are effective in 10% or more of cases in controlling lesions. Hence, steroids are worth trying given the expense of alternative treatments.

Intractable cases are best treated with immunosuppressive doses of cyclosporine A (Neoral, Novartis, East Hanover, NJ) or leflunomide (Arava, Aventis Pharmaceuticals, Bridgewater, NJ). These drugs are potent inhibitors of T cell activation, and their ability to abrogate clinical disease supports the hypothesis that SH and CH are disorders of immune regulation. Treatment with these drugs is expensive and may be needed for life in dogs with continuously active disease. It is preferable not to invoke such powerful immunosuppressive therapy until disease progression is evident or troublesome sites are involved, since in some cases of CH (and even SH) spontaneous regression of lesions or episodic disease activation can occur. Cost of treatment can be substantially reduced by co-administration of cyclosporine A and ketaconazole. It is imperative to measure 12 hour plasma trough levels of cyclosporine A (with twice daily dosing); this is especially important if ketaconazole is co-administered. The 12 hour plasma trough target for cyclosporine A is 500–600 ng/mL. Neoral is the preferred cyclosporine A drug, because it is a microemulsion preconcentrate with superior gastrointestinal absorption compared to Sandimmune oral concentrate (Novartis), which consists of cyclosporine A in an olive oil base. Hence, Neoral can be used at a lower dose.[10] Neoral is marketed as Atopica (Novartis) for treatment of dogs with atopic dermatitis; its main advantage over Neoral is the convenient capsule sizes optimized for veterinary use.

FELINE HISTIOCYTIC PROLIFERATIONS

True histiocytic proliferative diseases in cats have not been extensively documented in the veterinary literature. At least three different histiocytic proliferative diseases have been recognized in cats; these include progressive histiocytosis, pulmonary LCH, and HS/MH.

Feline Progressive Histiocytosis

Feline progressive histiocytosis (FPH) behaves as a low-grade histiocytic sarcoma, which originates in skin from resident DCs.[2] The initial clinical course is indolent and morphologically the histiocytes are cytologically bland. However, in time, the lesions become more troublesome and morphologically there is a higher frequency of cytological atypia more consistent with HS. The lesions have been considered an analogue of canine histiocytoma, although spontaneous regression is not observed, unlike canine histiocytoma. Canine histiocytoma is a LC proliferation, but the cell of origin in FPH has features in common with dermal DCs, which are interstitial DCs. The initial presentation of FPH many be a solitary skin nodule, although usually multiple papules, nodules or plaques develop, measuring up to 1.5 cm in diameter. The nodules are firm, non-pruritic and non-painful. The surface is often alopecic and may be ulcerated. The lesions are mostly located on the head, lower extremities or trunk. Occasionally, the lesions are limited to one extremity. Feline progressive histiocytosis is a disease of middle-aged to older cats, the age ranging from 7 to 17 years. Sex or breed predilection has not been seen. The lesions may wax and wane but spontaneous regression does not occur. In general, the nodules progress in size and may coalesce to large plaques. In addition, new lesions may develop. Some cats develop lesions in lymph nodes and internal organs including the lungs, kidneys, spleen, and liver. Additional clinical signs vary depending on the internal organ systems involved. Feline progressive histiocytosis has a poor long-term prognosis as no successful treatment has been recognized to date.

Lesions consist of diffuse dermal histiocytic infiltrates, which may extend into the subcutis. The overlying epidermis is either intact or ulcerated. Histiocytes have irregular, vesicular nuclei and finely dispersed chromatin. Cytological atypia is present in a minority of lesions early in the course. Biopsies of later lesions reveal a higher incidence of multinucleated tumor cells, and occasional intra-lymphatic tumor cell aggregates

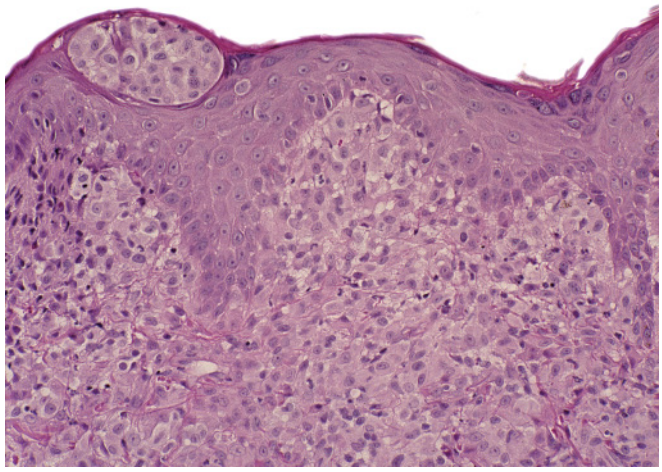

FIGURE 73.9 Feline progressive histiocytosis. Cohesive sheets of immature histiocytes infiltrate the superficial dermis and extend into the epidermis as a solitary focus. Hematoxylin & Eosin stain.

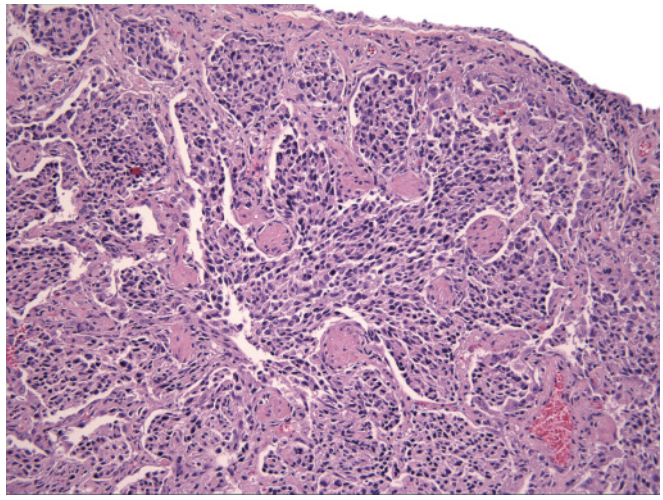

FIGURE 73.10 Feline pulmonary LCH. Cohesive sheets of histiocytes fill the alveolar duct and extend to the alveoli and pleura. Hematoxylin & Eosin stain.

may be present. The mitotic activity varies and atypical mitoses are seen. Some cases are epitheliotropic, characterized by intra-epidermal single cells or cell aggregates; other cases lack epithelial involvement (Fig. 73.9). As lesions progress, cells may exhibit numerous cytoplasmic vacuoles and hence have a foamy appearance. The extent of reactive infiltrates, composed of dispersed lymphocytes and fewer neutrophils, varies between cases. Feline progressive histiocytosis has to be differentiated from xanthoma as well as multicentric round cell tumors, such as lymphoma and mast cell proliferation.

Immunophenotypic Studies

Histiocytes of FPH consistently express CD18, CD1, and MHC II. This immunophenotype is consistent with a DC origin.[14] However, both the epitheliotropic and non-epitheliotropic lesions mostly lack expression of E-cadherin, and Birbeck's granules could not be found in the only case evaluated by electron microscopy. These features indicate that FPH is not composed of LCs, despite the existence of epitheliotropic infiltrates. The DCs are most likely of interstitial (dermal) type. The reactive lymphocytes are CD8+ cytotoxic T cells.

Feline Pulmonary Langerhans Cell Histiocytosis

Pulmonary Langerhans cell histiocytosis (PLCH) is a disease of aged cats (10–15 years old), which causes progressive respiratory failure leading to euthanasia.[4] The cats have severe respiratory distress characterized by tachypnea and open mouth breathing. The symptoms can be acute or present for several months. Thoracic radiographs reveal a diffuse broncho-interstitial pattern of miliary to nodular opacities throughout all lung lobes. The original report described PLCH in three cats. Since then, the author has encountered two more cases. All have been diagnosed at necropsy. An

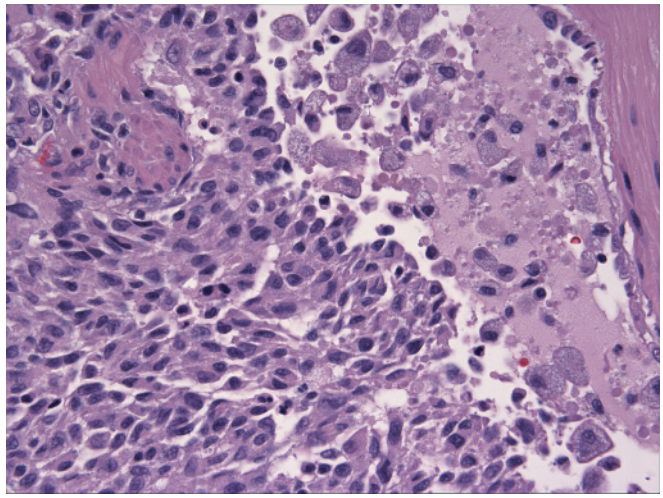

FIGURE 73.11 Feline pulmonary LCH. Moderately pleomorphic histiocytes with complex nuclear membranes invade the bronchial lumen, which is filled with foamy macrophages. Hematoxylin & Eosin stain.

infiltrative process involved all lung lobes, which were diffusely firm and entirely effaced by ill-defined, coalescing nodular masses (2–5 mm maximum dimension). Extra-pulmonary spread to pancreas and kidney was variably observed. Draining lymph nodes were also effaced.

Pulmonary lesions are characterized by histiocytic infiltrates within terminal and respiratory bronchioles. The infiltrates partially obliterate the airway walls and fill the lumens. Extension of the infiltrates into adjacent alveolar ducts and alveoli occurs (Fig. 73.10). Histiocytes form cohesive infiltrates with indistinct cell borders. They are moderately pleomorphic in cell size and nuclear morphology, which is often complex (Fig. 73.11). Transmission electron microscopy was used to

demonstrate characteristic Birbeck's granules in the cytoplasm of lesional histiocytes; these structures are only present in LCs and are formed in an endocytic process involving the C-type lectin, langerin.

Immunophenotypic Studies

The lesional histiocytes expressed CD18 and E-cadherin. E-cadherin is expressed by LCs, which use it to localize within epithelia.

Feline Histiocytic Sarcoma Complex

Localized HSs have been observed in cats. The poorly demarcated tumor masses were located in the subcutis of the ventral abdomen or extremities. Metastasis to draining lymph nodes occurs. These lesions may be the end stage of FPH, which would be indistinguishable from HS. Alternatively, primary HS may occur in the spleen.[11] Two of the cats in this study had lesions quite similar to those in canine HHS.[16] Cats presented with anemia, thrombocytopenia, and hypoalbuminemia and splenomegaly like the canine cases, but studies of the cell of origin were limited due to lack of discriminating cell markers. We have seen similar cases in which erythrophagocytosis by bizarre histiocytes was the dominant feature, and the diagnosis was HHS. Investigation of cell lineage was conducted in a recent feline HHS case and a macrophage lineage was indicated based on lack of CD1 expression.[8] Expression of CD11d by hemophagocytic histiocytes in feline HHS has not been evaluated; hence it is not known if feline HHS originates in splenic red pulp macrophages. Feline HS complex resembles the canine counterpart in terms of location of lesions and disease progression, but the incidence of feline HS is much lower. Feline HSs have a poor prognosis and most cats have been euthanized.

Feline HS shares morphological features with canine HS, including variable cytology encompassing mononuclear and multinucleated round cells, and discrete to aggregated spindle cells. Anisocytosis and anisokaryosis exist in tumor cells of all types. A moderate to high mitotic rate with bizarre mitotic figures is common. Prominent erythrophagocytosis is observed in feline HHS. Immunohistochemistry is required to differentiate histiocytic sarcomas from vaccine-induced sarcomas or anaplastic sarcomas with giant cells (incorrectly referred to as "malignant fibrous histiocytoma").

Immunophenotypic Studies

The round and spindle-shaped tumor cells in feline HS express CD18, CD1, and MHC II. This immunophenotype is consistent with a DC origin, although the precise sublineage of DC has yet to be determined. The tumor cells lack expression of E-cadherin and hence, are not of LC origin. Feline HHS is reported to lack CD1 expression, which supports a macrophage origin.[8]

Acronyms and Abbreviations

Ad5, Adenovirus serotype 5; APC, antigen presenting cell; CAV2, canine adenovirus 2; CRAd, conditionally replicative adenoviruses; CTL, cytotoxic T-lymphocyte; IACUC, Institutional Animal Care and Use Committee; IBC, Institutional Biosafety Committee; IFN, interferon; IL, interleukin; MHC, major histocompatibility complex; NK, natural killer cell; PEG-3, progression elevated gene-3; SCFV, single-chain Fv fragment; TAAs, tumor-associated antigens; TGF, transforming growth factor; TNF, tumor necrosis factor; Treg, regulatory T-lymphocyte.

GENERAL APPROACHES TO GENE THERAPY IN HEMATOLOGIC NEOPLASIA

Therapy for disease based on the introduction of novel genetic material has been discussed since the early 1980s. Initially, the concept of gene therapy was limited to replacement therapy in inherited metabolic diseases. However, that concept has been greatly expanded to include therapies for acquired diseases, including cancer. Now a maturing field, gene therapy has progressed into the clinics, with both human and animal patients enrolled in trials. Many innovative approaches have been identified including genetic vaccination, oncolytic replication competent viruses, and vector delivery of toxins or toxin converting genes. Much of the research that has been undertaken in the field of cancer gene therapy has focused on human cancers and a large amount of the preliminary evaluation of these strategies has been performed in the laboratory mouse. These approaches have also been applied to a number of species of veterinary interest. The therapeutic application of genes in a variety of cancers in domestic animal species serves both to provide intermediate animal models in the evolution of these therapies for humans and to develop applicable gene therapies in these species themselves.

VECTOR STRUCTURES AND STRATEGIES

Gene therapy strategies are built around the delivery of genes to target tissues and cells. In most cases, this requires some further components in addition to the nucleic acids. These components are collectively known as vectors. Some common gene therapy vectors are shown in Table 74.1 and will not be discussed in detail here. Ideally, a vector should be able to survive the

TABLE 74.1 Gene Therapy Vectors

Vector	Insert Size (kb)	Target	Tropism	Comments
Retrovirus	~7	Depends on envelope used	Dividing cells	Integrates into host chromosome
Lentivirus	~7	CD4 (can be altered by using other env genes)	Quiescent and dividing cells	Integrates into host chromosome
Adenovirus	~7	CAR	Many cell types including liver, not tumor	Remains episomal, can be retargeted
"Gutted" Adenovirus	~30	CAR	Same as Adenovirus	Requires helper virus, can be retargeted
Adeno-associated virus	~4–5	Variable	Depends on serotype	Integrates in mouse, episomal in other species
Alpha herpes virus	~75	Unknown	Neurons	Highly pathogenic – requires significant attenuation for use
Plasmid (naked DNA)	~12	Variable	Depends on site of injection and any carrier molecules	Extremely stable long-term

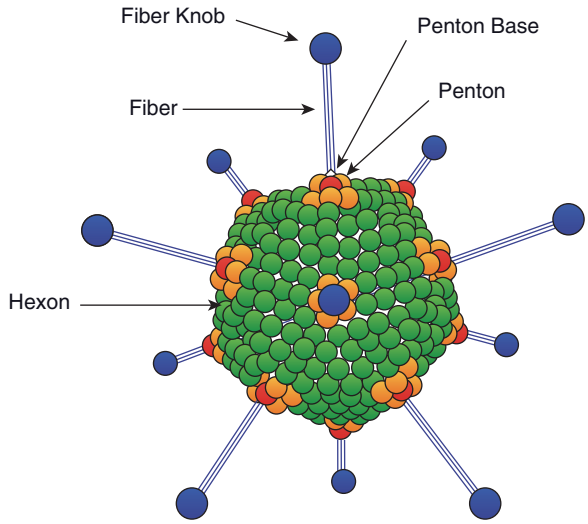

FIGURE 74.1 Structure of a typical adenovirus. The virus coat is an icosahedron consisting primarily of Hexon protein. At each vertex are five Penton and one Penton base proteins. The Penton base serves as the insertion site for the trimeric fiber protein, which forms a rod and a knob. Fiber knob is the binding site of CAR (cocksackie adenovirus receptor).

physiologic milieu, effect entry of the target cell across the plasma membrane and deliver its payload of nucleic acids to the nucleus, where gene expression occurs. A variety of different vectors have been identified, with most based on known viruses, which are essentially highly evolved gene delivery machines. These vector systems typically use engineered viruses, where critical genes for viral replication have been removed, rendering the virus replication incompetent (Fig. 74.1). In order to produce infectious virus particles, these genes must be provided in *trans*, by engineered packaging cell lines. As will be discussed in more detail below, subtle variations in these lines can result in innovative changes in vector targeting.

TUMOR TARGETING

The need to specifically target tumor cells within the body is obvious. Because of the nature of gene therapy, it presents unique opportunities to target tumor cells on a systemic basis, promoting tumor killing without affecting intervening cells. This can be particularly useful in treating widely disseminated metastases which might not be practical to approach either surgically, or with radiation. In gene therapy, targeting can be accomplished at several levels by combining targeting modalities, including vector detargeting, ligand based targeting and the use of expression targeting. Ideally, targeting of gene therapy for cancer patients consists of a combination of approaches, with each approach adding a layer of specificity and therefore safety and efficacy to the eventual therapy (Fig. 74.2).

Vector Detargeting

Many vectors have specific endogenous affinities that may or may not be appropriate for therapy. For example, Adenovirus serotype 5 (Ad5) may infect a wide variety of cell types through the CAR receptor; however, this receptor is often poorly expressed in many tumors. To assure cell-specific uptake of the vector, this receptor binding can be ablated to "detarget" non-tumor cells. There are several approaches to accomplish this. Antibodies to the cell-specific portion of the vector can be used to mask the binding site. For viral vectors, the viral site that binds to the target cell may either be modified to change binding or ablated to eliminate binding.

Cell Specific Targeting

There are multiple ways to achieve cell-specific targeting of gene therapy vectors including physical restriction of the vector, pseudotyping, genetic modification

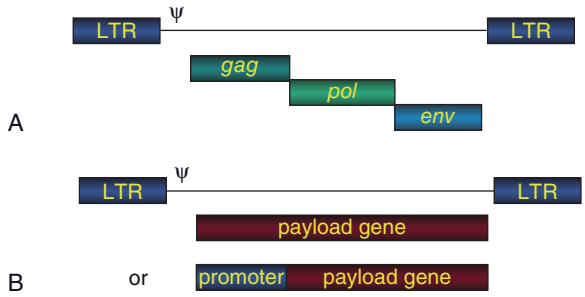

FIGURE 74.2 Genome structure and map of a typical mammalian retrovirus and a derived gene therapy vector. (**A**) A typical retrovirus encodes three major genes including *gag*, encoding the membrane glycoprotein, *pol*, encoding the reverse transcriptase (RNA-dependent DNA polymerase) and *env*, encoding the viral capsid protein. The retroviral genome also includes two long terminal repeats (LTRs) which encode the enhancer/promoter complex regulating viral gene expression and which are responsible for viral genome integration into the host genome. The bidirectional enhancer component of the LTR is also responsible for the insertional oncogenic activations associated with retroviral genome insertion events observed in gene therapy trials. (**B**) In gene therapy vectors derived from such viruses, the three major viral genes can be replaced with a gene therapy payload gene as long as the LTRs and the packaging sequence (ψ) are included and the viral particles are assembled in a packaging cell line that contains a helper retrovirus to provide the *gag*, *pol*, and *env* gene products. Expression of the payload gene may be driven off either the intrinsic LTR promoter (top) or an exogenous promoter can be inserted (bottom).

and redirection with antibodies to cell surface markers. Depending on their mode of action, vectors can be injected into specific and restricted body compartments that will limit their spread. These include direct injection into the tumor. In many tumors, direct injection requires multiple injections at numerous locations to treat the entire mass. A regional administration approach may also be used. Commonly, this method isolates the vasculature to a single limb and allows intravascular administration to the limb. Briefly increasing intravascular pressure in the isolated limb may allow vectors to freely cross the vascular endothelium and enter tissue beds. When perfusion is re-established, there may be some washout of vector into the general circulation.

Vectors may also be administered systemically and targeted to specific cells using cell surface markers. This approach requires that markers be identified that are restricted to a particular cell type, or a limited subset of other cells. In the case of tumor cells, these may be tumor-associated antigens (TAAs), which are typically cell surface proteins that are normally expressed during development. Given the variety in natural tissue tropism among virus families, it may be possible to exploit the tissue specificity of a particular virus, either through using that virus, or through pseudotyping, a process whereby one virus is given the "coat" proteins of another virus. For example, the tropism of human Ad5, which has an extensive range of target tissues that express CAR, can be restricted to a different subset of cells if the Ad5 fiber is replaced by the Ad3 fiber protein.[30]

Receptors that are not specifically viral receptors may be used to target cells through ligand-receptor interactions. These interactions are often highly specific, and will only target those cells expressing the receptor. This approach may also result in activation of the cellular signaling pathway that is normally the target of the receptor. Depending upon the receptor, cell type and pathway, this may be beneficial, or it may prove detrimental. If the target is not a receptor, or activation of a receptor is undesirable, antibodies may be used to target those cells. Conjugation strategies to attach the antibody to the vector can also add complications. It is also possible to identify peptides with targeting efficacy without any prior knowledge of the target cell's protein inventory. Phage display libraries can be used to screen millions of potential peptides for their capacity to bind to specific cell types. These libraries can be screened in vitro with cultured cells or in vivo by injecting the library and then harvesting the appropriate tissues or cells. By screening for several rounds in the target tissue, it is possible to enrich for peptides or families of peptides with similar sequences and enhanced affinity for target tissue.

Targeting molecules, including peptides, ligands, and antibodies, can by used to target in several ways. Viral vectors can be engineered so that these moieties are expressed in an appropriate location that both detargets the vector and retargets it at the same time. Care must be taken though that the added targeting molecule does not alter or destroy the ability of the virus to assemble, bind, infect or replicate.

Non-genetic approaches to targeting vectors usually include "biphasic" adapters of some type. These adapters are often engineered fusion proteins that consist of two binding moieties, one to bind the vector and the other to bind the target cell. This approach has been demonstrated using Ad5 vectors. In this case, the adapter was created from an SCFV (single-chain Fv fragment) that binds to the Ad5 fiber knob region, blocking CAR binding and therefore detargeting the vector, and either a second SCFV, or a receptor ligand, such as CD40L. These adapters have the advantage of allowing the vector to be produced as a generic reagent using the common packaging lines or techniques, and then mixed at the bedside with the targeting adapter to allow customized targeting of the vector for each patient.

Expression Targeting

Targeting may also be achieved at the level of gene expression through the use of specific promoters. These may consist of tumor or tissue specific promoters such as the tyrosinase promoter in pigmented epithelium and melanoma. The ideal promoter for use in tumor cells is one that is normally active early in development and is therefore not active in normal adult cells. One example of this is the progression elevated gene-3

(PEG-3) which is active in many different tumor cells.[27] One disadvantage to these promoters is that they cannot be controlled. Conditional promoters are promoters that can be either induced or suppressed by the addition of another substance. Among the most frequently used are the Tet-on and Tet-off promoters, that are engineered bacterial promoters that have been adapted for use in eukaryotic cells. These promoters are regulated by the antibiotic tetracycline and can either deactivate or induce gene expression in the presence of the antibiotic. Such constructs permit the expression of the therapeutic gene in a temporally controlled fashion, either providing the needed protein at the correct time, or allowing protein synthesis to be disabled as a safety measure should toxicity occur. These promoters do not offer any tissue specificity.

TUMOR CELL KILLING

Ultimately, the goal of any genetic therapy is to kill cancer cells while sparing normal tissues. There are many different approaches to achieve this including the use of toxins, the induction of apoptosis, lysis of tumor cells with replication competent viruses and activation of an antitumor immune response.

Suicide Gene Therapy

Perhaps the most classical approach is known as "suicide gene therapy." This method consists of transferring a prodrug converting enzyme gene to the tumor cells, followed by the administration of the prodrug. Expression of the gene results in the presence of the enzyme, which converts the prodrug to a toxic drug, in turn killing the target cell. An example of an enzyme/prodrug combination is herpes simplex virus thymidine kinase (HSV-TK) and the anti-herpetic "X"-cyclovir prodrugs (e.g. gancyclovir). HSV-TK metabolizes the prodrug into a nucleotide analog, that is then incorporated into the cell's DNA during replication of the genome. The drug may also pass to neighboring cells through gap junctions resulting in a "bystander effect." This results in killing greater numbers of cells than actually express the transferred enzyme. Killing is usually confined to tumor cells.[24]

Oncolytic Viruses

Oncolytic virotherapy consists of the administration of replication competent viruses to tumor cells. These viruses are selected or engineered to specifically replicate in tumor cells, resulting in the eventual lysis of tumor cells. When the cell lyses, new viral particles are released to circulate and potentially infect additional tumor cells. The most commonly used oncolytic viruses are conditionally replicative adenoviruses (CRAd). In general, because of the species-specificity of viral replication, the CRAd must be derived from a virus that infects the target species. In humans, this is typically Ad5. In dogs, canine adenovirus 2 (CAV2) has been adapted for use as a CRAd.[13] Normally, this virus causes a mild respiratory disease in dogs, when inhaled, and is used as a vaccine for CAV1, which causes canine hepatitis. In this case, the E1 gene, an early gene product of the virus that is critical for replication, was placed under the control of the osteocalcin promoter to restrict replication to osteosarcoma cells. CRAds can be injected either intra-tumorally or intravenously. Intravenously injected CRAd has been shown to remain in the circulation longer than 48 hours, even in the face of pre-existing immunity.[25] Because the virus circulates, CRAds are considered to be an excellent method to target multiple distant metastases.

Tumor Vaccination

Tumor vaccines have been used with varying success for many years. These vaccines may consist of tumor cells or pieces, typically killed or fixed, that are injected back into the patient. In a refinement of this approach, specific tumor antigens, such as tyrosinase (or P100) in melanoma have been identified in a few tumors and have been used as antigens for tumor vaccines. The first DNA vaccine conditionally licensed for any species in the United States employs P100 as an antigen in an attempt to create an immune response to melanoma cells in the dog.[1] The type of immune response may also be critical to the success of this approach. A predominantly T-helper 2 (Th2) response with a high level of circulating IgG1 antibody, may not have any effect on tumor cells, while a predominantly T-helper 1 (Th1) response, with IgG2 and activation of cytotoxic T-lymphocytes (CTLs) may produce significant cell killing. For this reason, antigen presentation and adjuvants have critical effects on the ability of a tumor vaccine to raise a therapeutic response.

IMMUNE MODULATION

Several different approaches to immune modulation have been developed including enhanced antigen presentation strategies where tumor-specific antigens are introduced for presentation on antigen presenting cells or in which existing antigen recognition is enhanced to promote the breaking of immune tolerance. Systemic or local administration of antigen complexes, or nucleotides encoding them, has been attempted as have strategies whereby immune system components which suppress immunity are themselves suppressed. Gene therapy promoting the local expression of cytokines has also been adopted.

Gene therapy by introducing a foreign gene, such as green-fluorescent protein (GFP), has been used in a variety of species to promote immune targeting of neoplasias. This approach has been shown to promote immune responses to both the foreign gene target as well as tumor-associated antigens. Both cytotoxic T lymphocytes (CTLs) and antibody-based reactions have been promoted by this approach.

Enhanced Antigen Presentation

There is an abundance of data suggesting that tumors express specific antigens recognized by the immune system and in some instances these antigens induced immune responses to cause natural remission. A therapeutic strategy that could stimulate or enhance the effectiveness of immune recognition and induction of an effective immune response would be of immense value in the treatment of neoplastic disease, particularly in those cases of dissemination which are not surgically manageable. The basic strategy for forcing an immune response has involved different means of promoting or forcing tumor antigen presentation by antigen presenting cells (APCs). Such strategies have involved technologies such as protein antigen feeding to APC populations or transfection of DNA expression constructs or even tumor cell-derived mRNA population loading into APCs. Various APC populations, including allogeneic and autologous dendritic cells or even CD40 activated B cell populations have been antigen loaded.[15] Another approach, designed to improve immune recognition, is based on creation of hybrid-cell vaccines through fusion of APCs with tumor cells.[4] Hybrid-cell fusion constructs express both tumor-specific antigens and the necessary machinery needed for antigen presentation. Additionally, if they are MHC matched, T cell activation is also possible. Because dendritic cells are able to transport presented antigens to activate effector T cells in lymph nodes they have been suggested as promising candidates for the APC component of such hybrid-cell vaccines.[4,5,10] Such experiments have been performed in normal healthy laboratory dogs providing proof-of-principle for successful development of tumor-specific immunity in this species.[4,5]

Enhanced T-Helper Activity

Approaches to modify the T cell response to cancer have been attempted in dogs for a variety of cancers or to demonstrate proof-of-principle for strategies designed to enhance immune recognition of pan-tumor associated antigens associated with canine melanoma and mammary cancer.[5] Application of such strategies to hematopoietic cancers is in a more formative stage; however, successful antigen loading of canine CD40-activated B cells has been demonstrated.[21] Specific T cell responses were detected to model antigens and the intent is to apply this technology to spontaneous canine lymphoma.

Modulation of Peripheral Tolerance and Regulatory T Cells

The importance of regulatory T (Treg) cells in the recognition and development of a killing immune response to cancer has only recently been recognized, especially their contributions to suppression of the immune response to what would be otherwise considered self-antigens.[2] However, lack of appropriate antibodies to Treg antigens such as CD25 have inhibited investigations in species other than mouse and human until recently. A murine anti-FoxP3 antibody, which identifies this Treg-enriched transcription factor, has recently been shown to cross-react with canine FoxP3 putatively identifying canine Tregs.[3] Such studies should provide the means to investigate the role of Tregs in canine intermediate models developed to investigate immunomodulatory strategies for treatment of cancer.

Cytokine/Chemokine and Antibody Modulation

The use of gene therapy to alter immune recognition through modification of cytokine, chemokine, or antibody expression has been an early approach attempted in a variety of cancer treatment strategies.[19] Relevance has been demonstrated as canine lymphomas have been shown to express interleukin (IL)-2 receptors.[12] However, the toxicity and the prohibitive costs associated with systemic treatment with cytokines and other immunomodulatory molecules in intermediate and larger species has driven efforts to find technical solutions designed to force localized expression from inserted genes only at desired locations or tissues. Interferon (IFN)-gamma has been shown to modify major histocompatibility complex (MHC) and tumor-associated antigen expression and to induce antigen specific T cell responses. Interferon-gamma also appears to synergize with effects of interleukins, such as IL-6, and growth factors, such as transforming growth factor (TGF)-beta 1. There is also evidence that regression of canine Langerhans (dendritic) cell tumors are associated with expression of several cytokines including IL-2, tumor necrosis factor (TNF)-alpha and IFN-gamma.[17] These investigations have suggested that such molecules have the potential to improve immune recognition, particularly if they are used in conjunction with other strategies designed to force presentation of tumor associated antigens.

There are also indications that IL-6 can antagonize TGF-beta 1-dependent inhibition of T cell activation. Canine tumor-infiltrative lymphocytes also synthesize IL-6 and may be recruitable to promote an antitumor activity.

Transplantation Therapy

There is a well developed history of immune modulation in dogs associated with a variety of transplant models as well as those approaches specifically designed to improve management of canine cancer. This has resulted in the development of a new transplantation approach to treatment of canine T cell lymphoma based on aggressive chemotherapy to induce remission followed by transplantation of hematopoietic cell lineages supported by subcutaneous injections of canine granulocyte colony-stimulating factor.[11,20] This approach has also been demonstrated following radiation ablation.[16] Although based on transplantation of related and at least partially DLA-matched hematopoietic populations, such approaches have been shown to promote disease-free survival of such patients for more than a

year. Additionally, the chimeric nature of the transplant was maintained in a stable form.

Non-Specific Immune Stimulation

Some effort has been applied to investigating the nature of nonspecific immune stimulation after the application of Toll-like receptor 9 ligands such as CpG containing oligonucleotides in primates, rodents, and dogs. Such nonspecific immunostimulants have a measurable effect on the innate immune system including natural killer (NK) cell activity. They also tend to promote Th1 type responses from the immune system and have been promoted for use as adjuvants.

NEOPLASTIC OUTCOMES RESULTING FROM HEMATOLOGIC GENE THERAPY

Gene therapy is a potent tool to alter the genomes of the target cell and organism, and it can be an extremely useful tool in the treatment of neoplasia. However, gene therapy has also been linked to the induction of tumors. In a clinical trial using retroviral vectors to treat X-linked severe combined immunodeficiency (X-SCID), at least four of ten boys developed leukemia. The therapeutic aspects were extremely successful, resulting in lifesaving immune reconstitution in nine of the ten patients. However, integration of the retrovirus in or near several proto-oncogenes, including LM02 in two patients, perhaps combined with expression of the transferred gene product, a cytokine, caused proliferation of those cells and subsequently, leukemia.[31] A similar serious adverse event has been reported in a patient in an X-SCID gene therapy trial in England.[14]

GENE THERAPY FOR SPECIFIC VETERINARY HEMATOLOGIC NEOPLASIAS

The instances of successful treatment of veterinary hematologic neoplasias are few, but attempts have been made with varying degrees of success and notable problems with unanticipated side effects. Although many strategies have been investigated in cell culture in vitro, few have been translated to preclinical laboratory animal models or clinical cases. Among non-human and non-murine animal species, these neoplasias include leukemias of both the spontaneous and induced forms, and the more distantly associated osteosarcomas.

Leukemias and Lymphomas

Although few attempts to directly treat canine lymphoma using a gene therapy approach have been reported, there have been several investigations identifying gene targets that appear to play a causative role in development of canine non-Hodgkin's lymphoma and may be amenable to a gene therapy strategy based on genetic complementation in *trans*. The cyclin-dependent kinase inhibitor p16/INK4A has been identified as a defective tumor suppressor gene in many of these canine lymphomas and could be amenable to repair by genetic complementation.[9,23] Such an approach would seek to restore cyclin/CDK modulating activity to G1 phase of the cell cycle with the aim of providing the cell with the means to arrest or exit cell cycle via the p16/INK4A and retinoblastoma pathway. These cells appear also to harbor p53 defects making it likely that p53-dependent apoptosis is also defective.[26] Additionally, the IL-2 receptor has been identified as dysfunctional in canine lymphoma and may provide a surface marker for targeting or an additional target for gene therapy.[8] Canine distemper virus is known to infect such lymphoma cells and has the potential to be used as a gene therapy vector if safety considerations can be addressed.[28] Although at a more formative stage than dogs, investigation of these tumors in cats has revealed some oncogene targets associated with feline lymphomas.[18]

Experimental treatment of leukemias has been attempted in dogs with mixed results owing to the nature of the side effects encountered. This strategy was based on a retroviral vector system and the introduction of a gene involved in imposing pattern formation on phenotype in developing animals. Homeobox (*HOX*) genes are a clustered family of genes involved in higher order developmental pattern regulation in multicellular animals. As such, these *HOX* genes play a critical role in the regulation of normal differentiation and appear to guide cells through an ever narrowing range of cellular fates or outcomes. The corollary for such an effect is thought to be a lack of control over phenotype should such genes become dysfunctional. Recent evidence has shown the potential of gamma-retroviral vectors in delivering *HOXB4* genes to hematopoietic stem cells and the expansion of repopulating cells.[33] The strategy was designed to replace neoplastic populations with genetically modified cells in which *HOXB4* cDNA constructs were inserted in an effort to impose such differentiated phenotypes on expanded populations of stem cells. This effect can be demonstrated in a variety of species and includes expanded proliferative potential and perhaps immortalization in some species, a trait only recently attributed to the *HOX* genes.[33] Control of aging appears to be highly homologous among mammals as the canine SIRT2 gene (a gene silencing regulator), an important regulator of lifespan in most multicellular species, has been identified and appears to be aberrant in function in spontaneous canine mammary tumor-derived cell lines.[7]

Transfer of *HOXB4* to hematopoietic stem cells using a *gamma*-retroviral vector in both dogs and macaques has revealed clear potential for leukemogenesis due to the presence of the genetic construct.[32] All of the dogs transplanted (two survived transplantation) and half the non-human primates (1 of 2 macaques) developed leukemias related to the presence of the construct within 2 years of transplantation. There was clearly a difference among species as this effect had not been detected in prior mouse investigations and the potential for leukemia development was not predicted from these

FIGURE 74.3 Gene therapy clinical trial patient. A 10-year-old female spayed Rottweiler with osteosarcoma is shown receiving an oncolytic canine adenovirus intravenously following amputation of her affected forelimb. The high titer CRAd vector is administered slowly to reduce the potential of anaphylaxis.

experiments, although other experimental gene therapy trials in humans have uncovered such potential when using retroviral vectors. Innovative vector constructs have recently been reported for the investigation of ways to mitigate the predisposition for insertional mutagenesis of viral vectors in a mouse model.[6] These vector constructs incorporated suicide genes to enhance drug sensitivity for transduced cells providing a means to eliminate leukemic cells.

Osteosarcomas

Osteosarcoma is among the most frequently occurring bone malignancies in dogs and has been promoted as a model application for the development of new conditionally replicative adenoviral gene therapy vectors.[13,25] These adenoviral vectors have been targeted to deliver gene payloads to canine osteosarcoma cells in osteosarcoma patients. Although early in its development, preclinical trials in normal dogs have been conducted to determine dosage, safety, and levels of viral vector tolerance. To facilitate delivery but suppress uncontrolled spread, conditionally replication competent (CRAd) constructs have been developed. Measurable replication in several serial but diminishing peaks of the viral vector have been detected following treatment of tumor bearing canine patient animals (Dr. B.F. Smith, personal communication). Figure 74.3 shows the initial clinical patient to receive this vector.[5,29] Trials using replication defective adenoviral vectors to deliver pro-apoptotic and immunomodulatory therapies also are in early phase clinical trials in dogs with osteosarcoma.[22]

FUTURE DIRECTIONS IN VETERINARY HEMATOLOGIC GENE THERAPY

Gene therapy as a field is rapidly approaching its 25th anniversary. As such, the approaches being used are maturing and gaining sophistication. Is gene therapy a magic bullet? Unquestionably, it is not. As with other therapeutic approaches to cancer, it will, in the end, be a combination of approaches, tailored to the specific tumor in the patient and designed to maximize tumor cell killing that will provide the most successful cancer management strategies.

Novel vectors are continually being introduced. In the next 5–10 years, vector development will focus on issues of enhancement of function. In particular, camouflaging vectors against immediate immune recognition and creation of vectors with novel tumor cell ligands are likely developments. In veterinary medicine, cost will drive the use of targeting molecules with the broadest possible application, especially if that is to treat multiple tumor types. To that end, cocktails of vectors with multiple and different targeting molecules may be developed to allow a single preparation to be used in all patients with a given tumor type. Targeting at the level of transcription may also become more broadly applicable with the use of promoters that are expressed in multiple tumors.

Vectors are also likely to undergo significant development in the coming years. Novel fusion proteins with enhanced specificities for prodrug conversion are currently being evaluated. In addition, payloads focused on inciting immune responses or activating cellular apoptotic pathways are gaining favor.

Clinical Trials in Veterinary Species

At the point that it becomes possible to conduct a "clinical trial," that is an experimental administration of a novel therapeutic in client-owned animals, there is a critical need to interact with multiple constituencies. Depending on the organization, experiments in client-owned animals may be covered by the Institutional Animal Care and Use Committee (IACUC) which by law is required to review experiments with institutionally-owned animals, but which may expand its jurisdiction to client-owned animals. Alternatively or in addition to the IACUC, it may be necessary to satisfy a specific clinical trials committee, or other hospital-based quality assurance and patient safety regulatory bodies. Additionally, in the case of many biologics and certainly in the case of any vector using recombinant DNA, it is necessary to secure the approval of an Institutional Biosafety Committee (IBC). Once institutional approvals are in place, most trials proceed in a manner similar to human trials.

Initially, a Phase 1 trial is conducted, which is designed specifically to address safety. Some data may be generated in healthy animals in the preclinical phase; however, since these animals do not have tumors, it is necessary to evaluate safety in tumor bearing animals as well, as there can be important differences in physiologic response and immune status. In many cases, Phase 1 trials involve dose escalation to determine the maximum tolerable dose. If the Phase 1 trial is successful, then a Phase 2 trial may commence. Typically, this is a larger study designed to continue to gather safety

and dosing data, and to examine therapeutic efficacy. Some studies may combine Phase 1 and 2 trials to obtain efficacy data at an earlier time point. Following successful completion of the phase 2 trial, a larger, typically multi-center trial, known as a phase 3 trial, is undertaken to gather more definitive efficacy data, and to compare the experimental therapy to the current standard of care in a larger patient population.

In pet animals, the ability to perform clinical trials has been bolstered by the creation of the National Cancer Institute's (NCI) Comparative Oncology Trial Consortium. As of 2008, 16 veterinary schools were members of the consortium. When a party is interested in performing a large-scale clinical trial, they negotiate directly with NCI, which then coordinates the trial with the consortium members that would like to participate. This approach can either identify large numbers of cases for a major trial, or it can help accumulate rare cases where an investigator may not have sufficient caseload at their own institution.

Acronyms and Abbreviations

Arp, actin-related protein; DTS, dense tubular system; GMP140, granule membrane protein 140; GP, glycoprotein; LAMP, lysosomal-associated membrane protein; LIMP, lysosomal integral membrane protein; OCS, open canalicular system; PADGEM, platelet-activated derived granule external membrane protein; PMCA, plasma membrane calcium ATPase; PtdIns, phosphatidylinositol; SERCA, sarco/endoplasmic reticulum calcium ATPase; VWF, von Willebrand factor; WASp, Wiskott-Aldrich syndrome protein.

MEMBRANE STRUCTURE

Microdomain Lipid Rafts

Mammalian platelets are derived from the cytoplasm of megakaryocytes. Platelet membranes are similar to those of other cells and are characterized by phospholipids arranged in a bilayer forming a hydrophobic core. Interspersed within the fluid lipid matrix are densely compacted microdomain lipid rafts primarily composed of sphingolipid and cholesterol molecules, and fewer numbers of protein molecules. These microdomain lipid rafts are capable of lateral mobility and enhance signaling in initial phases of platelet activation as well as enhance cytoskeletal reorganization events critical for normal clot retraction.[9]

Receptors

Proteins and glycoproteins, serving as specialized receptors important in platelet responses are present both within and outside the lipid rafts. Glycoprotein (GP) Ib-IX-V and GPVI, receptors involved in von Willebrand factor (VWF) and collagen binding, respectively, are examples of proteins primarily located within lipid rafts. Glycoprotein complex IIb-IIIa (GPIIb-IIIa), also known as integrin $\alpha_{IIb}\beta_3$,[3] is the most prevalent glycoprotein complex on the surface of platelets and is located outside of lipid rafts.[25] Although GPIIb-IIIa is not located within lipid raft microdomains, the complex does up-regulate phosphatidylinositols, in particular phosphatidylinositol(4,5)bisphosphate (PtdIns(4,5)P2), as part of the outside-in signaling cascade. This process may be facilitated by interaction with tetraspanins located within microdomains distinct from lipid rafts.[33] PtdIns(4,5)P2 induces the recruitment of several actin-modulating proteins resulting in the interaction of the cytoskeleton with the microdomains. The interaction of the cytoskeleton with lipid raft microdomains is necessary for sustaining the forces necessary for mediating clot retraction.[9] GPIIb-IIIa receptors are important for mediating platelet aggregation by binding fibrinogen, although these complexes can also bind VWF and assist with early stages of platelet adhesion to the subendothelium. The major receptors present on the surface of platelets are summarized in Table 75.1.

CYTOPLASMIC STRUCTURAL AND MEMBRANOUS ELEMENTS

Microtubules

Just beneath the platelet membrane is a circumferential band of microtubules.[35] Microtubules are hollow, cylindrical structures composed of protofilaments formed by

TABLE 75.1 Classification and Function of Major Platelet Membrane Receptors[a]

Classification	Function	References
Integrins		
$\alpha_{IIb}\beta_3$ (GPIIb-IIIa;CD41/CD61)	Known as the fibrinogen receptor. 50,000–80,000 receptors per platelet. Primarily mediates platelet aggregation; platelet activation is required to induce a conformational change resulting in ligand binding. Ligands include several RGD containing proteins including fibrinogen, VWF, thrombospondin, fibronectin, and vitronectin. Glanzmann thrombasthenia (GT) is due to mutations involving genes encoding α_{IIb} or β_3	60
$\alpha_v\beta_3$ (CD51/CD61)	Known as the vitronectin receptor. 200–300 receptors per platelet. Platelet activation is required to induce a conformational change resulting in ligand binding. Ligands include RGD containing proteins such as vitronectin, fibrinogen, and osteopontin	4, 62
$\alpha_2\beta_1$ (GPIa-IIa;CD49b/CD29)	Known as VLA2 on lymphocytes. 2000–3000 receptors per platelet. Major collagen adhesion receptor; platelet activation required for collagen binding via this receptor	47
$\alpha_5\beta_1$ (CD49e/CD29)	Known as the fibronectin receptor. Functions to supplement platelet adhesion; platelet activation is not required for fibronectin binding	56
$\alpha_6\beta_1$ (CD49f/CD29)	Known as the laminin receptor. Functions to supplement platelet adhesion; platelet activation is not required for laminin binding	29, 74
Leucine-Rich Repeat		
GPIb-IX-V	Known as the VWF receptor; also binds Mac-1 and P-selectin. Functions in platelet adhesion under high shear. 60,000 receptors per platelet. Bernard-Soulier syndrome is due to mutations in genes encoding GPIb or GPIX	2
Seven Transmembrane		
Protease activated receptors (PAR)	Function as thrombin receptors. Platelets have 3 PAR receptor types; types vary with species. Human and dog platelets primarily have functional PAR1 and PAR4 types. Mouse platelets have functional PAR3 and PAR4 types	10, 16
ADP receptors	P2Y1 and P2Y12 have been identified on platelets. P2Y1 is coupled to Gq and initiates calcium mobilization resulting in shape change and reversible platelet aggregation. P2Y12 is coupled to Gi resulting in inhibition of adenylate cyclase and lowering of cAMP levels. P2Y12 activation is associated with irreversible platelet aggregation	61
Thromboxane receptor (TXA_2/PGH_2)	Platelets possess two types of receptors, TPα and TPβ, which are coupled to G proteins; TPα is coupled to Gs while TPβ is coupled to Gi. TXA_2 and PGH_2 interact with both receptor types. While genomic studies suggest both types of receptors are present on platelets from cattle, horses, and cats, there is no genomic evidence for TPβ receptors on dog platelets	79, MK Boudreaux, unpublished observations
Prostacyclin receptor (PGI_2)	PGI_2 receptors are coupled to Gs. Prostacyclin binding results in activation of adenylate cyclase, enhanced cAMP production, and inhibition of platelet activation	75
Platelet activating factor (PAF) receptor	PAF mediates platelet shape change and aggregation. PAF receptors are coupled to Gi and Gq. PAF can also initiate signal-dependent translation pathways in human platelets	85
Adenosine receptor	3 receptor subtypes have been detected on platelets. Adenosine receptor activation results in cAMP elevation and inhibition of platelet aggregation	1, 31
Adrenergic receptor	alpha2A-adrenergic receptors are present on platelets which are coupled to Gi. Epinephrine binding results in reduction of cAMP and potentiation of platelet activation. May play a role in enhancing thrombus stability	66
Serotonin receptor	Coupled to G-proteins leading to calcium mobilization and enhancement of platelet activation. Two subtypes have been detected on human platelets	1
Immunoglobulin/ITAM/ITIM		
GPVI-FcRγ	Major collagen receptor. Composed of two immunoglobulin C2 loops which bind collagen. Is complexed with FcRγ which contains an ITAM which is tyrosine phosphorylated during platelet activation	34
FcγRIIA	Immune receptor expressed on human but not mouse platelets. Binds IgG. Plays a role in heparin-induced thrombocytopenia	13
FcεRI	IgE immune receptor. Activation induces release of serotonin and RANTES and thus may play a role in allergic inflammatory responses	36
ICAM-2	Present on the surface of activated and non-activated platelets. The only β2 integrin ligand on platelets; may play a role in leukocyte-platelet interactions	24

TABLE 75.1 *Continued*

Classification	Function	References
PECAM-1 (CD31)	Composed of six C2 immunoglobulin domains, a transmembrane domain, and a short cytoplasmic tail containing two ITIM domains. Plays dual roles as an inhibitor and enhancer of platelet activation. Has an inhibitory effect on ITAM-based collagen responses and also promotes $\alpha_{IIb}\beta_3$ mediated outside-in signaling	46, 80
CD47	Thrombospondin receptor; also known as integrin-associated protein (IAP). TSP binding results in enhanced platelet activation via inhibition of nitric oxide/cGMP signaling	40
Tetraspanins		
CD9	Present on resting platelet plasma membrane in association with $\alpha_{IIb}\beta_3$. May be involved in recruiting phosphatidylinositol kinase activity, specifically PI4K, to integrin-based signaling complexes	39
CD82	Studies in lymphocytes suggest a role in linking signaling through raft microdomains with the actin cytoskeleton. Presence on platelets not clear	21
CD151 (PETA-3)	Present on resting platelet plasma membrane in association with $\alpha_{IIb}\beta_3$, $\alpha_5\beta_1$, and $\alpha_6\beta_1$. May play a role in integrin-mediated signaling	29
TSSC6	Associated with $\alpha_{IIb}\beta_3$ in resting platelets. As with other tetraspanins are associated with distinct microdomains that associate with lipid rafts during platelet activation, thus facilitating signal transduction events, including outside-in integrin signaling	33
Others		
P2X1	ATP receptor that enhances calcium entry. Plays a role in reinforcing and amplifying platelet activation	61
CD36 (GPIV, GPIIIb)	Ligands include thrombospondin, modified phospholipids, and long-chain fatty acids. Contributes to thrombus formation by binding to phosphatidylserine exposed on endothelial cell-derived micro-particles resulting in enhanced platelet activation	32
C1q	May play a role in classical complement pathway activation on platelet surfaces, particularly under high-shear induced platelet activation situations	63
Serotonin reuptake	Receptor is distinct from serotonin activation receptor. Responsible for serotonin transport across the platelet plasma membrane. Selective serotonin reuptake inhibitors inhibit platelet reactivity	72
Glycosyl phosphatidylinositol (GPI) anchored proteins	Platelets contain at least 5 GPI anchored glycoproteins on their surface. These include CD55, CD59, CD109, and prion protein. Platelets contain >96% of prion protein in human blood. Prion proteins are primarily present within alpha granule membranes and become expressed with platelet activation. Prion proteins are associated with platelet-derived microparticles and exosomes following thrombin-induced platelet activation	68
Thrombopoietin receptor	A member of the tyrosine kinase receptor family. Important for regulating platelet production. Receptors are internalized when bound by TPO. TPO binding does not activate platelets but does enhance platelet activation and may contribute to the adverse prothrombotic events observed in unstable angina in people	53

[a]ITAM, immunoreceptor tyrosine-based activation motif; ITIM, immunoreceptor tyrosine-based inhibitory domains; PETA-3, platelet and endothelial cell tetraspan antigen; RANTES, regulated on activation, normal T expressed, and presumably secreted; PI4K, phosphatidylinositol 4 kinase; TPO,thrombopoietin.

alpha-beta tubulin dimers arranged in a helical head-to-tail fashion. Microtubules are responsible for the maintenance of the disc-shaped form of the circulating platelet.[43] Under normal physiologic conditions, β1-tubulin is solely expressed as a component of microtubules within megakaryocytes and plays a role in the orderly fragmentation of platelets from the megakaryocyte cytoplasm.[70]

Open Canalicular System (OCS)

Connected to the surface of the platelet and extending deep within its cytoplasm is an extremely tortuous maze of open interconnecting channels called the surface connected canalicular system or open canalicular system (OCS).[81] This system was thought to be a remnant of the demarcation membrane system of megakaryocytes but the absence of the OCS in some mammals[86] and the presence of the OCS in thrombocytes of birds[77] and fish[18,52] has cast some doubt as to its origin. The OCS can act as a conduit for the uptake of particles and for the release of granule contents by activated platelets. Particles such as viruses or bacteria can be taken up by the OCS; this activity usually results in platelet activation. Alpha and lysosomal granules have been documented to fuse and evacuate their contents

into the OCS around engulfed bacteria or viruses, but communication with the outside is always maintained, unlike phagocytic vacuoles of leukocytes. Thus, platelets are not considered to be true phagocytes.[82] The OCS is everted to some extent during platelet activation and can thus serve to increase the number of surface receptors available for ligand binding since many of the same receptors found on the platelet surface also line the OCS.[27] Ruminant and equine platelets do not possess an OCS[30] although their megakaryocytes do possess a demarcation membrane system.[78] Platelets from these species do not enhance their surface area during activation, do not have a mechanism for uptake of particles, and release their granule contents by fusion of granules directly to the outer membrane. Figures 75.1 and 75.2 are electron micrographs of platelets obtained from several species for comparison of overall appearance.

Dense Tubular System (DTS)

Another specialized cytoplasmic organelle is the dense tubular system (DTS). The DTS is a remnant of the smooth endoplasmic reticulum of the megakaryocyte and is located near the microtubules. Unlike the OCS, it does not communicate with plasma or granule membranes. DTS membranes contain cyclooxygenase and thromboxane synthase and thus participate in prostaglandin synthesis. The DTS is also a site for calcium sequestration by the platelet; calcium movement is facilitated by ATPase pumps termed SERCAs (sarco/endoplasmic reticulum calcium ATPases) which are

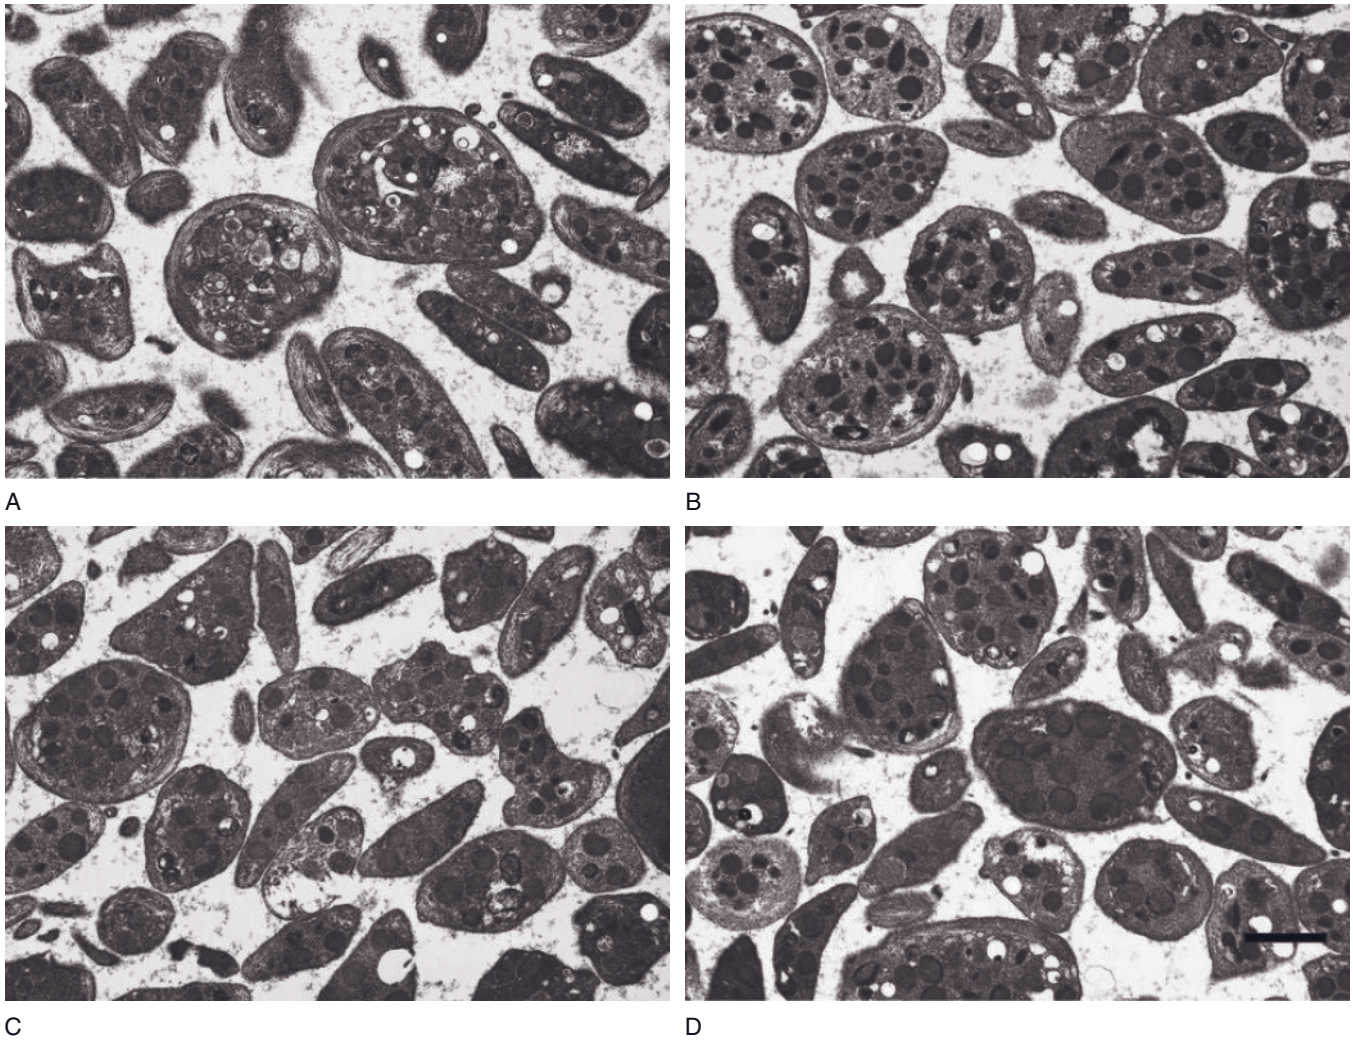

FIGURE 75.1 Electron micrographs of platelets obtained from alpaca (A), cow (B), goat (C), and sheep (D) for overall comparison of platelet morphology. Alpha granules appear light to dark gray and are prevalent and variably sized and shaped in these species. The electron dense content of most of the dense granules has been lost leaving vacuolar-like spaces. Microtubules can be observed in the periphery of some platelets. An open canalicular system is not present in these species. Bar = 2μm. (Courtesy of Dr. Maria Toivio-Kinnucan, Auburn University.)

FIGURE 75.2 Electron micrographs of platelets obtained from cat (A), dog (B), and horse (C). Alpha granules are numerous and variable in size and shape as seen with ruminant platelets. An open canalicular system is present in cat and dog platelets but absent in horse platelets. Bar = 2μm. (Courtesy of Dr. Maria Toivio-Kinnucan, Auburn University.)

tightly coupled to plasma membrane calcium ATPases (PMCAs). Plasma membrane calcium ATPases function to move calcium ions to the extracellular medium while SERCAs pump calcium ions into the DTS. Calcium stores in addition to the DTS also exist in platelets but their specific location is poorly defined.[50]

Mitochondria

Platelets have mitochondria important for maintaining energy and providing metabolic energy requirements during aggregation and secretion events. Mitochondrial membrane potential collapse is associated with platelet aging in circulation.[64]

CYTOSKELETON

Platelets possess a cytoskeleton on the cytoplasmic side of the plasma membrane composed of actin, spectrin (fodrin), adducin, filamin, and glycoprotein Ib-IX-V (the VWF receptor). The membrane cytoskeleton interacts with an extensive cytoplasmic actin network. Adducin links the ends of cytoplasmic actin filaments to membrane associated spectrin strands. Filamin subunits bind to actin and to the cytoplasmic tails of the GPIbα subunits resulting in strengthening of the interaction of the spectrin/actin network with the plasma membrane.[35] During platelet activation adducin molecules dissociate from the ends of actin filaments allowing disassembly and reorganization of actin. Actin disassembly is promoted by gelsolin and cofilin. Gelsolin undergoes a conformational change in response to increased cytoplasmic calcium allowing the protein to interdigitate and disrupt actin filaments. Cofilin becomes activated as a result of dephosphorylation during platelet activation and functions to sever and promote actin disassembly along with gelsolin. Actin reassembly during the formation of filopodia and lamellipodia by activated platelets is mediated by the actin-related protein (Arp) 2/3 complex. Proteins involved in activation of the Arp 2/3 complex include cortactin and Wiskott-Aldrich syndrome (WASp) family proteins. Actin reassembly and myosin II binding and activation are critical for platelet spreading, granule movement, granule release, and clot retraction.

GRANULES

Platelets have three main types of storage granules, dense, alpha, and lysosomal, and they are heterogeneous in content and morphology.[49] Alpha and dense granules are thought to be derived from a common multivesicular body intermediate, and thus their membranes share several common components.[84] (Table 75.2).

Dense Granules

The dense granules or dense bodies, as their name implies, are electron dense when viewed using an elec-

tron microscope, and serve as storage sites for adenine nucleotides, serotonin, calcium, and inorganic phosphates.[57,67] The adenine nucleotide (ADP/ATP) ratio is roughly 1.5 within dense granules. The pool is metabolically inert and not available as an energy source. Serotonin is actively transported from plasma into dense granule cores and the serotonin concentration within dense granules is 1000 times higher than plasma concentrations. Dense granules contain 70% of the total calcium within platelets. This calcium pool is not mobilized during platelet activation, unlike the calcium pool within the DTS. Inorganic phosphates, calcium, serotonin, and adenine nucleotides are held together tightly within dense granules as a result of intermolecular forces, thus contributing to their stability and density.[73] Human and pig platelet dense granules contain high levels of lysolecithin;[23] however, lysolecithin was not detectable in the dense granules of rabbit platelets.[19] Dense granules also contain ganglioside GM3 and phospholipids including phosphatidylethanolamine, phosphatidylinositol, phosphatidylcholine, and sphingosine.[14] Organelle proteomics has led to the discovery of 40 proteins within dense granules, many of which had not been known to be present within this organelle. Dense granule protein categories include cell signaling proteins, molecular chaperones, cytoskeletal proteins, proteins involved in glycolysis, and proteins involved in platelet function.[38] Dense granule membranes contain several receptors that become expressed on the plasma membrane as a result of dense granule fusion with the surface during the platelet release reaction. Some of these receptors are shared with other granule membranes and with the plasma membrane (Table 75.2).

Alpha Granules

The alpha granules, the largest and most numerous of the platelet granules, correspond to the azurophilic granules viewed by light microscopy. They are unique in terms of structure and packaging function. Structurally, alpha granules are composed of two major compartments, a dark centrally located nucleoid region and a peripherally located electron-lucent gray matrix region, that can be viewed at the electron microscopic level. The nucleoid region contains proteoglycans which confer stability to the granules. The nucleoid region is where beta-thromboglobulin and platelet factor 4 as well as other proteins are localized. Von Willebrand factor, multimerin, and factor V colocalize within tubular structures located in the outer part of the gray matrix region. Fibrinogen, thrombospondin, and fibronectin are primarily located in the gray matrix region in an area between the nucleoid and outer gray matrix region. Compartmentalization of VWF and fibrinogen within alpha granules has been documented in mouse, human, and porcine platelets.[69] Compartmentalization of proteins may serve to allow platelets to differentially release proteins in response to activation.[71] Mouse alpha granules are more heterogeneous in terms of shape, size, and distribution compared to human alpha granules.[69] Alpha granules contain proteins that are synthesized by megakaryocytes as well as proteins that are endocytosed as platelets circulate in blood. Alpha granule proteins that are synthesized by megakaryocytes fall into two categories, those that are megakaryocyte-specific (such as beta-thromboglobulin and platelet factor 4) and those that are synthesized by other cells but are concentrated within platelet alpha granules (such as factor V and PDGF).[76] The latter proteins are sometimes referred to as platelet-selective proteins. The most well-recognized protein endocytosed by platelets is fibrinogen with uptake being mediated by the glycoprotein IIb-IIIa (integrin $\alpha_{IIb}\beta_3$) receptor. Proteins present in low levels within alpha granules such as albumin and immunoglobulin are passively taken up by platelets and do not require specific receptors. A proteomic analysis of human platelet alpha granule proteins has been recently published and provides a list of 284 proteins, 44 of which have not been previously identified within platelet alpha granules.[55] Alpha granule membrane proteins, much like dense granule membrane proteins, become expressed on the platelet surface after platelet secretion as a result of fusion of granules with the OCS or outer platelet membrane. The most well known alpha granule membrane protein expressed on the surface of activated platelets is P-selectin or CD62P (formerly known as granule membrane protein 140 (GMP140)[45] and as platelet-activated derived granule external membrane

protein (PADGEM)).[51] Since its discovery, P-selectin has also been detected on the membranes of dense granules.[41] Monoclonal antibodies have been developed to detect the presence of P-selectin on the surface of activated platelets in dogs.[26] Other proteins present within alpha granule membranes include GPIb-IX-V, GPIIb-IIIa, PECAM-1, vitronectin receptor, and GPIV (Table 75.2). Some of these membrane proteins have also been detected within the membranes of dense granules.[83]

Lysosomal Granules

Lysosomal granules contain acid-dependent hydrolases including glycosidases, proteases, and lipases.[22] Lysosomal granules can be identified in platelets and megakaryocytes using specific cytochemical stains.[5] Secondary lysosomes have been detected in bovine megakaryocytes and platelets.[58] Lysosomal membranes also contain proteins that become exteriorized during the platelet release reaction (Table 75.2). Membrane proteins, which include lysosomal integral membrane protein (LIMP or CD63) and lysosomal-associated membrane proteins 1 and 2 (LAMP-1 and LAMP-2),[28] are heavily glycosylated to protect them from hydrolytic enzymes stored within these granules.[59] While initially LAMPs were thought to be solely present within lysosomal granule membranes, LAMP-2 and LAMP-3 have been detected within dense granule membranes as well.[42] Lysosomal membrane proteins which mediate transport of ions and amino acids across the membrane necessary for maintenance of an acidic luminal pH are also present.

AA, arachidonic acid; CalDAG-GEFI, calcium diacylglycerol guanine nucleotide exchange factor I; CCL2, chemokine ligand-2; cPLA2, cytoplasmic phospholipase A2; CXCL8, chemokine IL-8; DAG, 1,2 diacylglycerol; DTS, dense tubular system; GIRK, G protein-gated inwardly rectifying potassium channel; GP, glycoprotein; ICAM-1, intercellular adhesion molecule–1; IP3, inositol triphosphate; ITAM, immunoreceptor tyrosine-based activation motif; LAT, linker for activation of T cells; LFA-1, lymphocyte function associate antigen-1; MLC, myosin light chain; NHE1, Na/H exchanger; PAK, p21-activated kinase; PAR, protease activated receptor; PE, phosphatidylethanolamine; PI3K, phosphoinositide-3-kinase; PIP, phosphatidylinositol; PIP3, phosphatidyl-inositol(3,4,5) trisphosphate; PIP2, phosphatidylinositol 4,5-bisphosphate; PKC, protein kinase C; PLC, phospholipase C; PS, phosphatidylserine; PSGL-1, P-selectin glycoprotein ligand; ROCK, Rho associated coiled-coil-containing kinase; SLP-76, Src homology domain-containing leukocyte phosphoprotein of 76 kDa; TF, tissue factor; TP, thromboxane receptor; TRAP, thrombin receptor activation peptide; TXA, Thromboxane A2; VCAM-1, vascular cell adhesion molecule–1.

OVERVIEW OF PLATELET FUNCTION

Platelets are the first line of defense against bleeding at sites of vascular injury and are major contributors to thrombosis, inflammation and neoplasia. Platelets have cell surface receptors that recognize signals from their environment and communicate those signals to a complex network of biomolecules that include ions, proteins, nucleotides and phospholipids. While the details of many key networking pathways that elicit platelet responses are known, others remain to be elucidated. Platelet reactions orchestrated via these complex signaling networks include adhesion, aggregation, granule release, and procoagulant expression.

When molecules specifically recognized by platelets (agonists) bind to platelet receptors, they induce inside-out signaling resulting in structural changes in glycoproteins on the platelet membrane surface that then allow binding of proteins that mediate platelet adhesion and aggregation (Fig. 76.1; see also Chapter 81, Fig. 81.1). In turn, binding of adhesive proteins to receptors results in outside-in signaling events that promote and enhance platelet granule release, platelet aggregate and fibrin formation, and clot retraction.

This chapter reviews platelet signaling events communicated through the major activation receptors present on platelets as well as pathways and receptors involved in platelet-leukocyte interactions and expression of procoagulant activity.

Cross-talk between platelet receptors and signaling molecules is a key component of platelet activation, and much is still to be learned about the players involved in these events. Added to the complexity of understanding platelet signaling events is the recognition that platelets are capable of synthesizing proteins.[68] This capability, referred to as signal-dependent translation, will likely change current viewpoints of platelet involvement in many events including hemostasis, thrombosis, inflammation, and neoplasia.

PLATELET RECEPTORS AND ACTIVATION PATHWAYS

ADP/ATP Receptors

Platelets have three distinct P2 purinergic receptors, P2Y1, P2Y12, and P2X1.[16] P2Y1 and P2Y12 are G

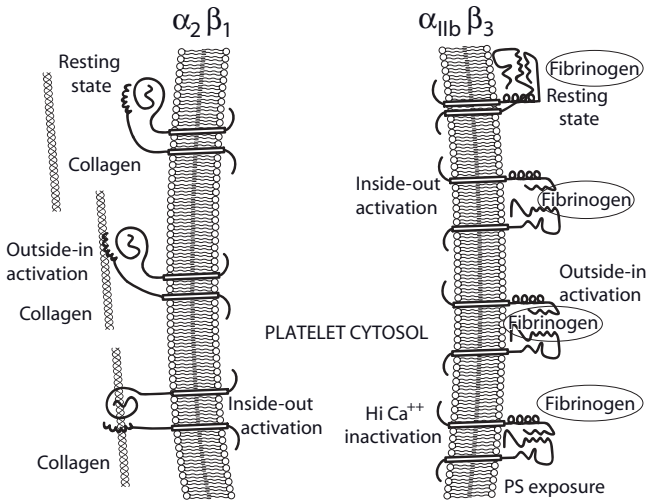

FIGURE 76.1 Platelet activation transforms the resting state of platelet membrane adhesion receptors for collagen (α2β1) and fibrinogen (αIIbβ3) by altering their conformation states. Effector molecules generated by various signaling pathways in response to outside-in or inside-out signaling control the strength, reversibility or irreversibility of collagen or fibrinogen binding. Formation of tight and irreversible complexes consolidates platelet adhesion and aggregation. When platelet ionized Ca^{2+} is elevated for prolonged periods αIIbβ3 becomes secondarily inactivated and can no longer bind fibrinogen.

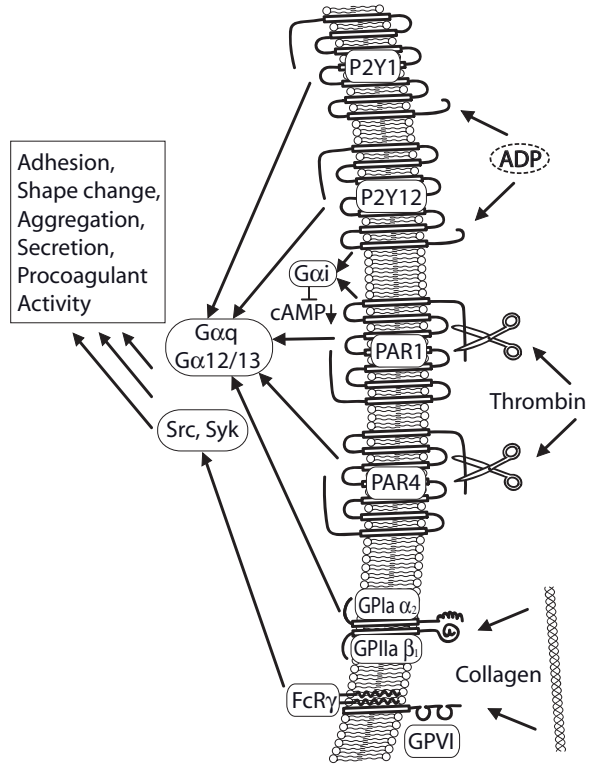

FIGURE 76.2 G protein-coupled receptors (GPCRs) link platelet-signaling pathways. The extracellular domains of paired receptors for ADP (P2Y1 and P2Y12), thrombin (PAR1 and PAR4) and collagen (α2β1 and GPVI) interact with their specific ligands to mediate outside-in signaling pathways. The thrombin receptor is activated when thrombin binds to and cleaves the extracellular *N*-terminal domain unmasking a new tethered *N* terminus that binds to the second extracellular loop of the receptor. In contrast to α2β1 which is a GPCR, GPVI signals collagen-initiated platelet activation through sequential activation of Src and Syk family tyrosine kinases.

protein-coupled ADP receptors, mediating platelet shape change and aggregation responses, while P2X1 is a ligand-gated cation channel ATP receptor responsible for fast calcium entry and may play a role in collagen- and shear-induced platelet activation (Fig. 76.2).[33,43,44]

P2Y1 is coupled to a Gαq protein subunit; signaling via Gαq results in activation of phospholipase C β2 (PLCβ2), Rho A, Rac, and Src family kinases.[25] PLCβ2 mediates intracellular calcium mobilization and protein kinase C (PKC) activation via hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP2) within platelet membranes, to inositol triphosphate (IP3) and 1,2 diacylglycerol (DAG).[30,44] IP3 mediates calcium mobilization from intraplatelet stores sequestered within the dense tubular system (DTS). DAG and ionized calcium activate diacylglycerol guanine nucleotide exchange factor I (CalDAG-GEFI) which in turn facilitates the displacement of GDP and loading of GTP within Rap1b. GTP-bound Rap 1b plays an important role in mediating the change in conformation of αIIbβ3 necessary for fibrinogen binding and platelet aggregation. The importance of CalDAG-GEFI downstream of PLC β2 in mediating inside-out signaling events leading to activation of αIIbβ3 is illustrated in mice, dogs, and cattle with mutations in *CalDAG-GEFI*.[5,6,14] All of these animals have a bleeding diathesis and impaired platelet responses to ADP and collagen.

P2Y1 activation results in platelet shape change as well as a reversible wave of platelet aggregation. Platelet shape change occurs as a result of both calcium-sensitive and calcium-insensitive pathways contributing to phosphorylation of myosin light chain (MLC).[45] The calcium-sensitive pathway is mediated by calcium-calmodulin. The calcium-insensitive pathway is mediated by Rho A/p160ROCK downstream of Gαq. Rho associated coiled-coil-containing kinase (p160ROCK) is a serine/threonine protein kinase that is directly targeted by Rho A. p160ROCK activation alters the balance between MLC phosphatases and MLC kinases in favor of MLC kinases, resulting in MLC kinase mediated phosphorylation of MLC necessary for platelet shape change.[15] The RhoA/p160ROCK pathway is important in mediating the disruption of the microtubule ring necessary for transformation of platelets from discs to spheres and is also critical for maintaining the change in shape once shape change has occurred.[46] Rac, a Rho family GTPase that is activated by P2Y1, is thought to be important in mediating platelet spreading and anchoring via activation of a p21-activated kinase (PAK).[4] Activated PAK is thought to activate the serine/threonine kinase LIM which targets and phosphorylates cofilin, inhibiting cofilin's ability to depolymerize actin.[3]

Rac activation by P2Y1 is potentiated by P2Y12 signaling.[58] In contrast, P2Y1 signals Src kinase

activation and the inhibition of the phosphoinositide-3-kinase(PI3K)-dependent phase of P2Y12 signaling. This inhibition is thought to be an important negative feedback mechanism regulating platelet activation mediated by ADP.[25]

P2Y12 activation does not contribute to platelet shape change but is associated with platelet aggregation and granule release, thromboxane generation, expression of procoagulant activity and inhibition of adenylyl cyclase.[59] Engagement of the P2Y12 is also required for amplification of platelet activation induced by ADP and low concentrations of other platelet agonists including TXA2, collagen and thrombin. P2Y12 is coupled to the heterotrimeric G protein complex Gαi2βγ.[66] ADP binding to P2Y12 results in uncoupling of Gαi2 and Gβγ which act as separate signaling molecules. Gαi2 inhibits adenylate cyclase resulting in lowering of cAMP levels. Gβγ dimers activate PI3K, Akt/protein kinase B, Rap1b, and G protein-gated inwardly rectifying potassium channels (GIRKs).[33]

The PI3K isoforms that function downstream of Gβγ in platelets are PI3Kγ and PI3Kβ. The two isoforms seem to function in distinct but complementary roles leading to platelet aggregation and release. PI3Kγ plays a role in enhancing granule secretion while PI3Kβ is necessary for sustaining platelet aggregation and formation of stable thrombi.[29] Akt/protein kinase B activation is thought to be mediated via PI3Kγ. Deficiency of Akt/protein kinase B in mice results in impaired platelet aggregation and release, and like PI3Kβ, it is required for formation of stable thrombi.[65] PI3Kγ and PI3Kβ, via generation of phosphatidyl-inositol (3,4,5) trisphosphate (PIP3), activate Rap1b, a critically important step in mediating the αIIbβ3 conformational change required for fibrinogen binding and platelet aggregation.[37]

GIRK channels containing GIRK1 and GIRK4 subunits are involved in the activation of Src kinases. Channel activation is coupled to Gβγ and ADP occupancy of the P2Y12 receptor. Src kinases in turn phosphorylate and activate cytoplasmic phospholipase A2 (cPLA2).[56] P2Y1 activation and signaling via Gq as well as signaling through αIIbβ3 are also necessary for cPLA2 activation.[31] When phosphorylated, cPLA2 is translocated from the cytoplasm to membranes where it functions to release membrane-bound arachidonic acid leading to the generation of thromboxane. Human patients with congenital P2Y12 deficiency and P2Y12 knock-out mice have prolonged bleeding times and exhibit bleeding, illustrating the importance of this receptor in hemostasis. The absent aggregation response of P2Y12 deficient platelets can be restored if platelets are activated concomitantly with ADP and epinephrine, presumably due to epinephrine being negatively coupled to adenylate cyclase in a manner similar to P2Y12.[10]

The P2X1 receptor is an ATP receptor that is antagonized by ADP; early studies demonstrating P2X1 receptor responses to ADP were later shown to be a result of ATP contamination of ADP preparations.[38] P2X1 activation is associated with the change in conformation of platelets from discs to spheres with the rapidly reversible formation of multiple short pseudopodia.[50,51] ATP binding to P2X1 is associated with a rapid, reversible calcium influx followed by rapid desensitization of the receptor.[42] Calcium influx is thought to activate MLC-kinase which is responsible for mediating the shape change response. P2X1 activation also results in centralization of granules without granule release and formation of platelet microaggregates.[21,61] Microaggregate formation is likely a result of calcium influx coupled with protein kinase C activation leading to Erk2 activation.[33] Like the P2Y12 receptor, P2X1 also participates in amplification of platelet responses to low concentrations of other agonists, including ADP, collagen, thrombin, and thromboxane.[21,22,42] Dense granule release of ATP induced by low concentrations of agonists triggers P2X1-mediated calcium influx resulting in reinforcement and amplification of platelet activation. P2X1 also seems to be essential in thrombus formation and growth at sites of injury in vessels where high shear forces are generated.[26]

Collagen Receptors

Platelets have two receptors that are primarily responsible for direct response to collagen; glycoprotein VI (GPVI) and integrin α2β1.[49] (Fig. 76.2) The platelet glycoprotein Ib-IX-V complex, which interacts with collagen indirectly, is critically important in initiating platelet contact with collagen under high shear rate conditions. The glycoprotein Ib-IX-V complex mediates transient arrest of platelets from flowing blood and weak tethering of platelets on exposed subendothelial surfaces through the binding of von Willebrand factor (VWF) A1 domain to the GPIbα region of the receptor complex. As tethered platelets roll along exposed subendothelium they encounter collagen fibrils, which bind to glycoprotein VI. This leads to inside-out signaling and activation of integrins α2β1 and αIIbβ3 and the release of ADP and thromboxane formation which in turn reinforce GPVI interactions.[41] Activated α2β1, transformed to a high affinity state, binds tightly to specific sequences in collagen, allowing firm platelet adhesion and spreading.[34] Activated αIIbβ3, also transformed to a high affinity state, reinforces firm platelet adhesion and supports platelet aggregation.[53]

Integrin α2β1 and GPVI are thought to signal through a shared network of signal transduction proteins. The shared signaling pathway possibly explains why the absence of either GPVI or integrin α2β1 does not result in a significant bleeding diathesis.

Glycoprotein VI is a member of the immunoglobulin superfamily Type I transmembrane proteins; it is noncovalently associated with the Fc receptor gamma-chain (FcR γ-chain). The FcR γ-chain has an immunoreceptor tyrosine-based activation motif (ITAM). When stimulated with collagen, the FcRγ-chain is tyrosine phosphorylated by the Src kinases, Lyn and Fyn.[23] This leads to the recruitment and activation of Syk tyrosine kinases which lead to the phosphorylation and activation of other signaling molecules.

Adaptor molecules such as linker for activation of T cells (LAT) and Src homology domain-containing

leukocyte phosphoprotein of 76 kDa (SLP-76) coordinate assembly of a multiprotein signaling complex necessary for activation of phospholipase Cγ2 (PLCγ2) and phosphoinositide-3-kinase (PI3K). LAT is a membrane associated adapter molecule that is anchored to lipid rafts in platelet membranes.[47] Activation of PLCγ2 leads to cleavage of phosphatidylinositol 4,5 bisphosphate into inositol 1,4,5-triphosphate (IP3) and 1,2 diacylglycerol (DAG). IP3 mediates the release of calcium from stores within the dense tubular system. DAG and calcium bind to calcium diacylglycerol guanine nucleotide exchange factor I (CalDAG-GEFI) resulting in activation of PKC and activation of Rap1b. Rap1b activation plays a role in inducing the change in conformation of αIIbβ3 to a high affinity state necessary for binding of fibrinogen and platelet aggregation. Although GPIb-IX-V also stimulates PLCγ2 activation, the tyrosine phosphorylation pattern is distinct from that occurring via GPVI, resulting in weaker PLCγ2 activation and diminished phospholipase activity.[60]

Collagen induced platelet aggregation is largely dependent on ADP signaling through P2Y12. Thromboxane A2 (TXA) generation and resulting platelet aggregation and release result in signaling through the P2Y12 receptor by secreted ADP and a positive feedback on platelet secretion through the PI3K pathway.[44]

Thromboxane Receptors

Thromboxane A2 (TXA) and prostaglandin H2 interact with the same receptors. Human platelets have two distinct thromboxane A2-prostaglandin H2 receptors, TPα and TPβ, that are products of alternative splicing. These receptors differ only in their C-terminal or tail domains.[28] TPα is a high-affinity binding site for thromboxane and mediates platelet shape change and intracellular calcium movement. TPα couples positively to adenylate cyclase via Gq and activates PLCβ which hydrolyzes PIP2, resulting in generation of IP3 and DAG. TPβ is a low-affinity binding site and mediates platelet aggregation and secretion. TPβ couples negatively to adenylate cyclase via Gi and inhibits cAMP formation. Platelets obtained from most dogs have a weak arachidonic acid (AA) response characterized by shape change and reversible platelet aggregation without granule release.[32] Addition of epinephrine prior to AA corrects the impaired aggregation and release response.[20] Canine platelets likely only possess TPα receptors based on the absence within the dog genome of the coding region necessary for synthesizing the alternative C-terminal domain for TPβ. This may partially explain the minimal response of the majority of canine platelets to AA stimulation in vitro. Epinephrine, by linking to Gi, may mimic the effects of TPβ thus allowing for full platelet aggregation and release. A bovine TPα receptor has been cloned and characterized.[39]

Platelets generate TXA from AA. AA is liberated from dense tubular membrane phospholipids by the action of phospholipase A2 in response to agonist stimulation. Cytosolic phospholipase A2 (cPLA2) is phosphorylated during thrombin, ADP, and collagen induced platelet activation. Phosphorylation of cPLA2, in combination with a rise in intracellular calcium, results in cPLA2 translocation to the membrane where it releases arachidonic acid from the sn-2 position of membrane-bound phospholipids. Arachidonic acid is converted sequentially to prostaglandin G2 (PGG2), prostaglandin H2 (PGH2), and TXA via cyclooxygenase-1, prostaglandin hydroperoxidase, and thromboxane synthetase. The resulting thromboxane generation results in platelet aggregation and dense granule release.

TXA synthase inhibitors do not inhibit platelet reactivity due to the enhanced production of prostaglandin H2 under these conditions and the ability of prostaglandin H2 to activate the receptor.[63]

Thrombin Receptors

Platelet thrombin receptors include the glycoprotein complex Ib-IX-V and protease activated receptors (PARs). The Ibα subunit of the Ib-IX-V complex has a thrombin binding site that overlaps with the binding site for VWF.[48] The GP V subunit is cleaved and removed from the complex by thrombin during platelet activation. GP V is thought to negatively modulate platelet activation; cleavage of GP V is a necessary first step prior to binding of thrombin to Ibα. Thrombin binding to Ibα mediates platelet activation via induction of ADP release and signaling through P2Y12. Ibα is also thought to act as a cofactor in the activation of PAR1 by thrombin.[17] Thrombin bound to Ibα is protected from inactivation by antithrombin.[18]

Protease activated receptors (PARs) are G-protein coupled receptors that are characterized by the presence of a tethered ligand (Fig. 76.2). Protease activated receptors are activated when enzymes cleave at a specific site near the N-terminal exodomain resulting in formation of a tethered peptide sequence that can in turn bind to a G-protein coupled receptor on the same molecule. Peptide sequences that match the tethered ligands generated by thrombin cleavage, thrombin receptor activation peptides or TRAPs, have been used with varying success in vitro to activate platelets.[9,11] In most species, TRAPs are not as effective as the comparable tethered ligand in inducing platelet aggregation or release. Mammalian platelets contain three PAR types that vary with species. Human platelets have PAR1 and PAR4 while mouse platelets signal through PAR3 and PAR4. PAR1 couplings to Gq, G13, and Giz are thought to be of most importance in mediating thrombin effects on platelets.[12]

The PI3 kinase pathway is considered to be of importance in stabilizing thrombin-induced platelet aggregates, although thrombin can activate platelets independently of Gi activation. On human platelets PAR1 binding results in a rapid spike in calcium influx while PAR4 binding is associated with a slower and sustained calcium influx that is considered vital to eliciting secondary signals necessary for complete platelet activation.[13] Canine platelet PARs have not been fully

evaluated; however, it is likely that canine platelets are similar to human platelets and possess PAR1 and PAR4 receptor subtypes.[5] Canine platelets do not respond to TRAPs designed from human or canine sequence[19] (M.K. Boudreaux, personal observation). There is genomic evidence for PAR3 receptor subtypes on both human and canine platelets; however, PAR1 and PAR4 receptors are considered to be of primary importance in mediating thrombin-induced platelet activation. Mouse platelets do not possess PAR1. PAR3 on mouse platelets acts as a cofactor in supporting cleavage and activation of PAR4. PAR3 alone is unable to mediate signaling leading to platelet activation but rather acts as a cofactor for promoting PAR4 cleavage in the presence of low thrombin concentrations.[40]

PLATELET-LEUKOCYTE INTERACTIONS

The GPIbα subunit of platelet glycoprotein complex Ib-IX-V is a ligand for endothelial P-selectin, as well as VWF, both of which translocate from Weibel-Palade bodies to endothelial surfaces in response to stimuli such as thrombin and histamine.[2,52,67] The binding site on GPIbα for P-selectin is very similar to the binding site of P-selectin glycoprotein ligand (PSGL-1) which allows leukocytes to roll along the vascular endothelium. Both GPIbα and PSGL-1 are membrane mucins and possess a heavily *O*-glycosylated region that separates the ligand-binding region from the plasma membrane.[36] Both receptors also contain an acidic region immediately amino-terminal to the mucin-like region that is important for ligand binding.[35] Unlike PSGL-1, which requires extensive post-translational modification, including fucosylation of side chains in order to interact with P-selectin, GPIbα is capable of binding to endothelial P-selectin without modifications.

GPIbα can also bind to integrin αMβ2 (Mac-1)[57] likely via the I domain within the αM subunit which closely resembles the A1 domain of VWF. This interaction, which requires conversion of Mac-1 to the ligand-binding competent form, may contribute to neutrophil attachment to the endothelium or subendothelium at sites of endothelial activation or injury. Platelet P-selectin can bind to PSGL-1 on neutrophils, monocytes, and T-cells providing a mechanism for initial adhesion of leukocytes to platelets. Firm platelet-leukocyte adhesion is mediated by binding of Mac-1 to fibrinogen bound to the surface of activated platelets.

Firm leukocyte-platelet interactions can also be mediated by intracellular adhesion molecule 2 (ICAM-2) on platelets which can bind to αLβ2 (LFA-1; CD11a/CD18) on leukocytes. Platelets can also release CD40L which binds to CD40 on vascular endothelial cells resulting in chemokine secretion and up-regulation of adhesion molecules.[27] Platelets also secrete IL-1β which can induce endothelial cell secretion of IL-6, CXCL8, and CCL2 and up-regulation of adhesion molecules such as E-selectin, VCAM-1, ICAM-1, and αvβ3.[24] All of these events link platelets to the inflammatory process.

PROCOAGULANT ACTIVITY

Platelet activation triggers significant remodeling of the platelet cell surface. This is associated with the activation and clustering of receptors for adhesion molecules, receptor mediated outside-in signaling, relocation and binding of proteins and other biomolecules from the cytosol to membrane surfaces, secretory organelle movement and fusion, and a dramatic redistribution of membrane phospholipids and formation and release of platelet membrane derived microparticles.

Mammalian cells including platelets exhibit an asymmetric distribution of aminophospholipids. In non-activated platelets, negatively charged aminophospholipids phosphatidylserine (PS) and phosphatidylethanolamine (PE) are located primarily on the inner leaflet of the plasma membrane. An aminophospholipid translocase is responsible for transporting PS and PE to the inner membrane leaflet and maintaining asymmetry. When platelets are activated by collagen or thrombin alone or in combination, PS is rapidly externalized and maintained on the outer leaflet of the membrane (Fig. 76.3). This redistribution is also accompanied by the release of PS-enriched procoagulant microparticles. Phosphatidylserine is also externalized in cells exposed to apoptotic triggers.

Activation of the lipid transporter protein referred to as "scramblase" functions to move phospholipids regardless of charge in a bidirectional fashion resulting in loss of membrane asymmetry and rapid externalization of PS. Phosphatidylserine remains externalized due to the inhibition of aminophospholipid translocase when "scramblase" is activated.

The presence of PS on the surface of platelets is essential for expression of platelet procoagulant activity. Rare bleeding disorders associated with a deficiency of platelet procoagulant activity have been reported in humans and dogs.[7,62] Phosphatidylserine facilitates the binding of coagulation proteins, which when anchored to PS and the activated platelet surface form procoagulant reaction complexes. These include the extrinsic tenase (factor VIIa + tissue factor (TF) + factor X), intrinsic tenase (factor X + factor IXa + factor VIIIa) complexes and the prothrombinase complex (factor Va + factor Xa and factor II). Once assembled the complexes allow for protein associations, which improve catalytic efficiency of the reactions. For example the prothrombinase complex is about 300,000 times more efficient than Xa alone in generation of thrombin from prothrombin, and the intrinsic tenase complex is more than 100,000 times more active than factor IXa alone as an activator of factor X.

The assembly of reaction complexes on the PS enriched surface of activated platelets serves to localize and concentrate procoagulant reaction products at sites of injury. Since AT preferentially targets uncomplexed reaction products for neutralization, the anchored reaction products, including FXa and thrombin, are protected from neutralization and inhibition by AT.

Lipid scrambling is associated with formation of PS-enriched procoagulant membrane microparticles which

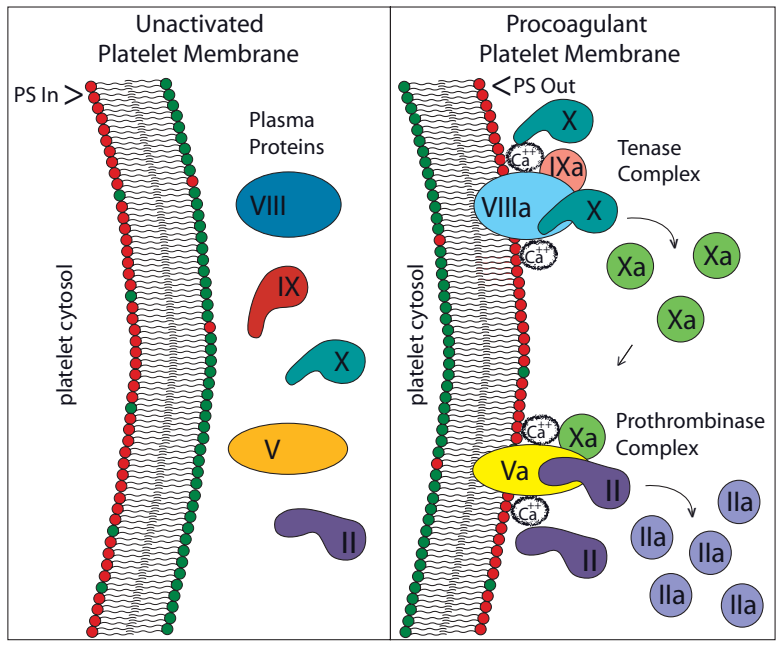

FIGURE 76.3 Signaling pathways activated by collagen and thrombin trigger externalization of phosphatidylserine (PS). When PS is externalized, specific coagulation proteins can bind to the platelet surface. The platelet then acts as a scaffold for assembly of the tenase and prothrombinase complexes, which accelerate thrombin (II_a) generation and clot formation at the site of vessel injury.

are shed from the plasma membrane. High cytoplasmic calcium concentrations are thought to activate lipid scramblase and inhibit aminophospholipid translocase, thus leading to expression of PS on the surface of activated platelets. Other studies have shown that expression of procoagulant activity is dependent on a change in intracellular pH and Na influx which occurs with activation of the Na/H exchanger (NHE1), and potentially other mechanisms, in human and porcine platelets.[54] NHE1 can be phosphorylated and activated by PKC. NHE1 also has two PIP2-binding domains which are required for optimal activation, suggesting that PIP2 may play a role in mediating PS exposure in activated platelets.[1,8] Studies have shown that only small populations of platelets express PS upon activation with thrombin or collagen. Combining the two agonists results in an increase in this fraction of platelets and an overall increased PS signal when assessed by flow cytometry.[64]

Activated platelets have been shown to be capable of synthesizing and expressing tissue factor on their surface which contributes to the prothrombinase function of platelets. Platelets possess pre-mRNA transcripts which are spliced and translated into protein upon platelet activation. Cdc2-like kinase dependent splicing is thought to play a role in this mechanism.[55]

Acronyms and Abbreviations

APTT, activated partial thromboplastin time; BFU-Meg, burst forming unit megakaryocyte; CBC, complete blood count; CFU-Meg, colony forming unit megakaryocyte; CMP, common myeloid progenitor cell; DIC, disseminated intravascular coagulation; DMS, demarcation membrane system; EDTA, ethylenediaminetetraacetic acid; ELISA, enzyme-linked immunosorbent assay; FDP, fibrin-fibrinogen degradation product; FXII, factor XII; GM-CSF, granulocyte-monocyte colony stimulating factor; HUS, hemolytic uremic syndrome; IL, interleukin; MPC, mean platelet component concentration; MPV, mean platelet volume; OSPT, one-stage prothrombin time; PCDW, platelet component concentration distribution width; PCT, plateletcrit; PDW, platelet distribution width; PT, prothrombin time; SDF-1, stromal cell-derived factor-1; TTP, thrombocytopenic thrombotic purpura; VWF, von Willebrand factor.

PLATELET KINETICS

Megakaryocytopoiesis and Platelet Production

Platelets are the second most numerous circulating cell in blood and are essential for coagulation, maintenance of vascular integrity, and control of hemostasis. In mammals, these small, anucleated cells originate in the bone marrow from megakaryocytes.

Megakaryocytopoiesis progresses through many stages starting with a pluripotential stem cell and proceeds through subsequent development of committed precursors. The hematopoietic pluripotential stem cells and early megakaryocyte progenitor cells are positive for CD34 and have low expressions of CD41.[42,49] Cells that become committed to the megakaryocyte lineage acquire the expression of CD61 and CD42, and expression of CD41 increases.[42,49] From the hematopoietic stem cell, megakaryocytopoiesis progresses through the common myeloid progenitor cell (CMP), followed by a bipotential progenitor cell for erythroid and megakaryocytic cells.[20,41,58] The next stage, a primitive megakaryocytic burst-forming unit (BFU-Meg), has a high proliferative capacity and can produce anywhere from 100 to 500 megakaryocytes per colony in a 1 week time period.[11,42] Following the BFU-Meg, the more mature megakaryocytic colony-forming unit (CFU-Meg) gives rise to approximately 3–50 megakaryocytes per colony. The BFU-Meg and CFU-Meg stages express CD34, CD33, and CD41. Later stages gain CD61 expression

followed by CD42 and CD36. The first morphologically recognizable cell of the megakaryocyte lineage in marrow is the promegakaryoblast. Before this stage, the morphology of the earlier progenitors resembles a small lymphocyte. The promegakaryoblast has a high N:C ratio, dark blue cytoplasm, and is approximately 10 μm in diameter.[42,103] The megakaryoblast has a kidney-bean shaped nucleus, dark blue cytoplasm and is approximately 15–50 μm in diameter. As the later stages of megakaryocyte precursors undergo endomitosis, the cells lose CD34 expression, and increase ploidy, cell size and volume. Megakaryocytes undergo DNA duplication as low as 2N and can attain ploidy as high as 128N, with the modal ploidy in most mammals being 16N.[13] Mature megakaryocytes are the largest hematopoietic cells in marrow, reaching diameters as high as 150 μm. The higher ploidy corresponds to an increased cell volume, and as a result, a higher number of platelets that are produced.[13]

Each megakaryocyte is capable of generating several thousand platelets. In humans, daily platelet production is estimated to be approximately 35,000 ± 4,300 platelets/μL or 1×10^{11} total platelets.[13,45,49] It takes 4–5 days to complete the sequence of megakaryocyte development to the release of new platelets.[45] Mature megakaryocytes produce platelets by cytoplasmic fragmentation through regulated and dynamic processes that involve the invagination of the megakaryocyte plasma membrane which forms the demarcation membrane system (DMS) and the association of the DMS with microtubules and an actin/myosin complex.[69,74] The association with microtubules causes evagination of the DMS and elongation of pseudopodal extensions that result in proplatelet formation.[13,69] The actin/myosin complex is thought to be important in proplatelet formation and the separation of platelets from proplatelets.[82] In marrow, mature megakaryocytes migrate so that they are closely positioned near endothelial cells. This allows the long proplatelet pseudopods from the megakaryocyte to extend into marrow sinusoids and also allows the megakaryocyte to enter the peripheral circulation. The final process of platelet shedding has to occur in the circulation to prevent platelet trapping within the marrow.[13,95] This latter observation may explain, in part, why megakaryocytes are often found in pulmonary circulation where significant platelet shedding occurs.[98]

Thrombopoietin is the major cytokine that regulates all stages of megakaryocyte and platelet production. In addition to thrombopoietin, megakaryocytes and platelet production are regulated by several growth factors and cytokines. Many of these affect hematopoiesis in general, or work synergistically with thrombopoietin. Megakaryocyte progenitors are stimulated by interleukin (IL)-3, IL-6, IL-11, IL-12, granulocyte-monocyte colony stimulating factor (GM-CSF), and erythropoietin.[32] Additional factors important in thrombopoiesis include IL-1, stem cell factor, and leukemia inhibitory factor.[13,32] Stromal cell-derived factor 1 (SDF-1) is thought to play a role in megakaryocyte migration.[34]

Platelet production is regulated by total platelet mass rather than platelet numbers. In situations of increased demand, platelet production can increase as much as 20-fold or higher.[49] In health, platelet numbers are relatively stable and constant, and the thrombopoietin-thrombopoietin receptor system is responsible for maintaining platelet mass. Thrombopoietin is secreted constitutively from the liver and to a lesser extent from the kidney. High affinity thrombopoietin receptors, present on platelet surfaces, bind thrombopoietin, which is then internalized and degraded.[48,52] In thrombocytopenic states, a higher level of free thrombopoietin is available to stimulate platelet production.

Circulating Lifespan and Senescence

Platelet numbers remain fairly constant within a species, but platelet numbers vary widely between different species. In addition, approximately 30% of the platelet circulating mass is transiently compartmentalized in the spleen for a short period of time in a resting individual. In health, there is a steady state between the number of platelets produced and platelets destroyed. Platelets circulate for approximately 5–9 days in most mammalian species. As platelets age, they are removed from circulation by macrophages in the spleen and liver. Signals involving platelet senescence are not completely characterized.[59] Exposure of phosphatidylserine on the outer platelet membrane, damaged or denatured platelet glycoproteins and proteoglycans, and gradual loss of platelet fragments or microparticles are thought to play important roles in platelet attrition.[59] Phosphatidylserine may induce macrophage phagocytosis directly or through bridging proteins that bind macrophage and phosphatidylserine receptors.[39,59] Similar to erythrocyte senescence, glycoproteins on the platelet surface may become denatured or damaged through changes in glycosylation or through the exposure of neoepitopes that are recognized by naturally occurring antibodies.[59] A smaller percentage of platelets are continually removed from circulation because of their role in the maintenance of endothelial integrity.[30,59]

Non-mammalian Species

The cellular equivalent of platelets in birds, reptiles, amphibians, and fish is the thrombocyte, which is a small, round, oval, or spindled nucleated cell. Similar to mammals, the primary function of thrombocytes is hemostasis and coagulation, and thrombocytes are the second most prevalent circulating cell in blood after erythrocytes. Avian thrombocytes may also be important in innate immunity since these cells have phagocytic capability and can remove foreign material from blood.[33] In addition to hemostasis, reptilian thrombocytes play a role in wound healing.[93]

Thrombopoiesis is similar in avian and reptilian species in that thrombocytes originate in the bone marrow from a distinct mononuclear cell. The stages in thrombopoiesis include thromboblasts, immature

thrombocytes (early, mid, and late stages), and mature thrombocytes. In general, as thrombocytes develop, they decrease in size, the cytoplasm changes from basophilic to pale blue or colorless, and the cell and nuclear shape change from round to oval.

Thrombocyte numbers in most avian species range between 20,000 and 30,000/µL or approximately 10–15 thrombocytes per 1000 erythrocytes; 1–2 thrombocytes per monolayer area under oil immersion (100×) is considered normal or adequate in most birds.[10,25] In normal reptiles, thrombocyte numbers in blood range between 25 and 350 thrombocytes per 100 leukocytes.[93] Numbers of thrombocytes in fish blood range from 60,000 to 70,000/µL.[78] Manual counts for thrombocytes in fish can be performed using a hemacytometer, but given the tendency to clump, accurate counts are difficult to obtain. Thrombocytes of certain fish species do not appear to have phagocytic ability.[78]

BASIC MECHANISMS OF THROMBOCYTOPENIA

Thrombocytopenia is defined as a decrease in circulating platelets and is the most common acquired hemostatic disorder in veterinary and human medicine. Thrombocytopenia results from one or a combination of the following basic mechanisms: decreased or defective platelet production, increased peripheral platelet loss or consumption, increased platelet destruction, or abnormal distribution. To understand a diagnostic approach (Fig. 77.1) to thrombocytopenia, a basic understanding of the mechanisms leading to thrombocytopenia is useful, and an overview is discussed below. The pathogenesis of thrombocytopenia is covered in more detail in Chapters 78 and 79.

Decreased or Defective Platelet Production

Platelets originate from megakaryocytes found in the bone marrow and to a lesser extent in the lung. Causes of decreased platelet production that result in thrombocytopenia can specifically target the megakaryocyte, but more frequently, other hematopoietic cells are also affected.

Although rare, acquired megakaryocyte hypoplasia or aplasia has been reported in dogs and cats, and probably has an immune-mediated component.[27,54,65] General etiologies for bone marrow disease leading to hypopla-

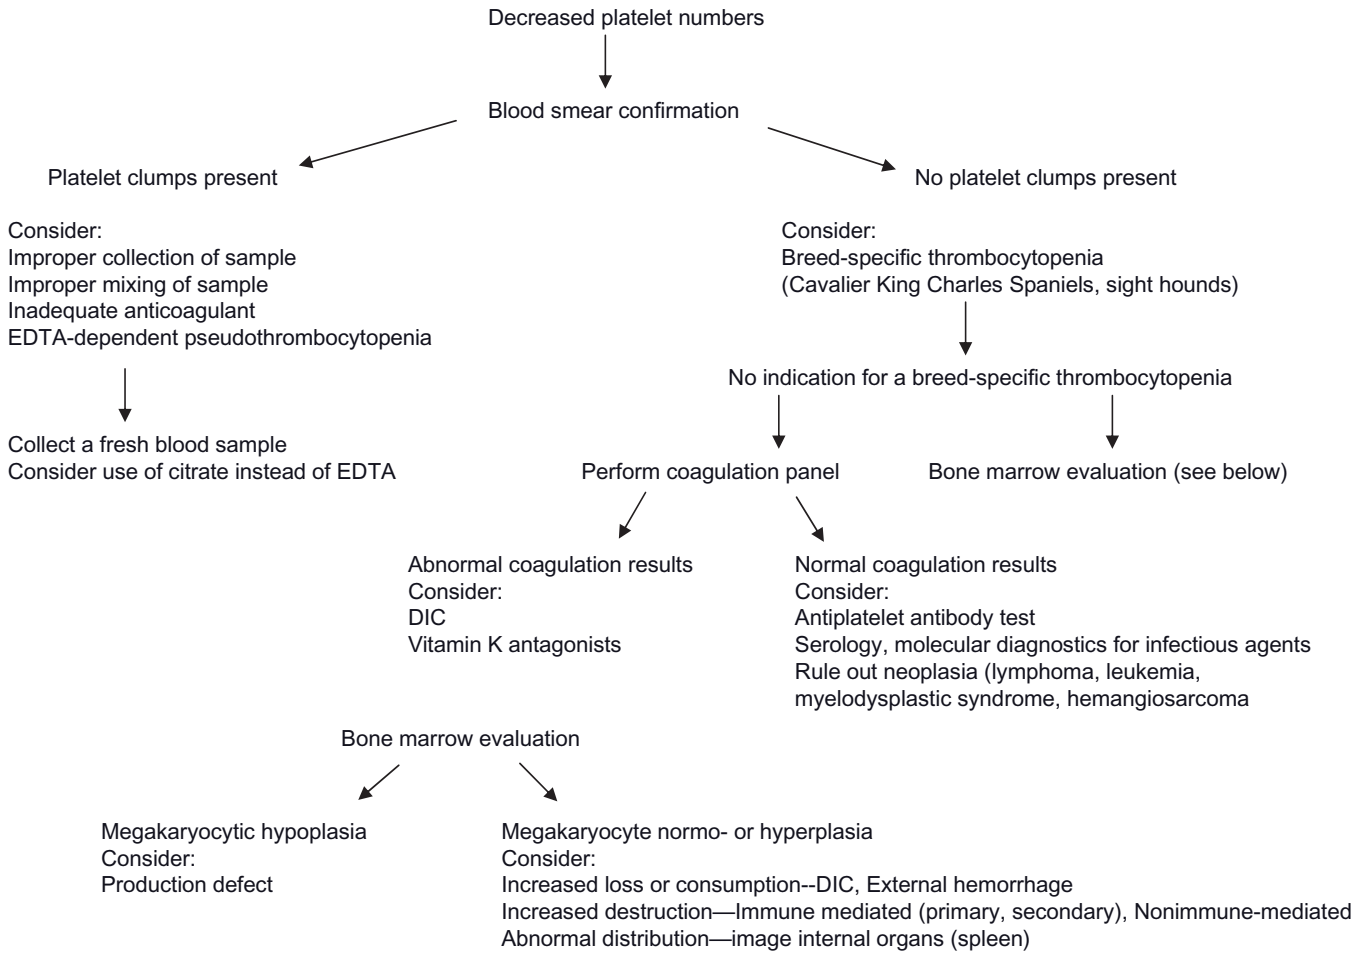

FIGURE 77.1 Diagnostic approach to thrombocytopenia.

sia of one or more hematopoietic cell lines include drugs, chemicals, or toxins that have cytotoxic effects or produce idiosyncratic reactions; irradiation resulting in cell death and marrow suppression; infection with certain viruses (canine parvovirus, feline leukemia virus, feline immunodeficiency virus, equine infectious anemia virus, bovine viral diarrhea virus, African swine fever virus) or rickettsial agents; myelophthisis from primary or metastatic neoplasia or myelofibrosis; or myelonecrosis.

Increased Platelet Loss or Consumption

Thrombocytopenia secondary to rapid, increased loss of platelets may occur with massive trauma, extensive external hemorrhage, or exchange blood transfusion. In situations of trauma or external hemorrhage, thrombocytopenia is generally mild to moderate, transient, and usually reversible without specific treatment.[85]

Accelerated consumption of platelets can be brought on by widespread activation of the coagulation system or endothelial damage. Disseminated intravascular coagulation (DIC), thrombocytopenic thrombotic purpura (TTP) and hemolytic uremic syndrome (HUS) are complex syndromes characterized by widespread consumption of platelets, resulting in moderate to significant thrombocytopenia. Disseminated intravascular coagulation is a common complication seen in both veterinary and human medicine. Thrombocytopenic thrombotic purpura and HUS occur in humans but are rare in veterinary species. A syndrome resembling HUS has been reported in dogs, cats, horses and a heifer.[2,14,21,22,40,56,63,79] Animal models of TTP and HUS have been described.[77,81,102]

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation occurs secondarily to a wide variety of insults and diseases; DIC can be acute, subacute, or chronic and is characterized clinically by hemorrhage and microthrombosis. The pathophysiology of DIC is discussed in more detail in Chapter 88.

Common disorders associated with DIC include vascular damage, septicemia with release of bacterial endotoxins, release of tissue thromboplastin from necrotic or malignant tissue, or release of other procoagulant proteins. Approximately 65% of DIC cases in humans occur secondarily to infection; bacterial infection is the most common.[107] In Gram-negative infections, bacterial release of endotoxin (lipopolysaccharide) causes simultaneous activation of the coagulation system and inhibition of coagulation control mechanisms. Endotoxin stimulates intrinsic coagulation directly by activation of factor XII (FXII) or indirectly by activation of FXII via endothelial damage. Endotoxin stimulates the extrinsic coagulation pathway by causing generation and increased surface expression of thromboplastins or tissue factor by inflammatory cells, primarily monocytes. Activated monocytes release IL-1 and tumor necrosis factor alpha (TNF-α), which decreases endothelial expression of thrombomodulin and prevents activation of protein C, thus impairing an important coagulation inhibitory pathway.

Thrombocytopenic Thrombotic Purpura and Hemolytic Uremic Syndrome

In humans, the thrombotic microangiopathies are exemplified by two syndromes, TTP and HUS. The pathogenesis of both is heterogeneous and often the origin is unknown; many consider them to be different expressions of the same disease mechanism. Thrombocytopenic thrombotic purpura and HUS may occur either as a primary condition or as a secondary complication. Most cases of HUS occur in childhood after bloody diarrhea caused by *Shigella dysenteriae* serotype I or various *Escherichia coli* serotypes. The classical triad of TTP is characterized by severe thrombocytopenia, intravascular hemolysis with schistocytes, and neurologic symptoms. Severe renal dysfunction is also a prominent feature of HUS.

The thrombotic microangiopathies are characterized by endothelial damage and platelet aggregation with resultant thrombocytopenia, hemolytic anemia, and thrombosis. High plasma concentrations of thrombomodulin, tissue plasminogen activator, and von Willebrand factor (VWF) are observed in many TTP patients.[94] Plasminogen activator inhibitor type I and urine endothelin concentrations are increased in HUS patients.[5,87] Concentrations return to normal when patients enter remissions.

Platelet aggregation may be caused by the presence in plasma of abnormally large VWF molecules that bind platelets and cause aggregation and activation much more actively than smaller VWF molecules. In TTP, endothelial damage may cause leakage of stored large VWF multimers into subendothelial tissue and plasma. Normal cleavage and clearance of these large VWF multimers is limited, causing increased concentrations and extensive platelet aggregation.[61] This extensive, systemic platelet aggregation causes platelet consumption and moderate to significant thrombocytopenia. Hemolytic uremic syndrome and TTP are discussed in more detail in Chapter 79.

Platelet Destruction: Immune Mediated, Non-immune Mediated, and Complex Mechanisms

Immune-mediated thrombocytopenia is covered in Chapter 78. Briefly, immune-mediated destruction of platelets may be primary (idiopathic) or may occur in association with infectious agents, neoplasia, drugs, autoimmune, isoimmune, or neonatal-immune diseases. A diagnosis of idiopathic or primary immune-mediated thrombocytopenia is made after all other potential causes have been eliminated.

Immune destruction of platelet occurs when circulating platelets coated with antibody, antigen-antibody complexes or complement are phagocytized by macrophages in the spleen, liver, and bone marrow. The result

is decreased platelet survival and lifespan. The spleen is the largest lymphoid organ, the major site of antibody production and platelet removal.

Platelet aggregation, phagocytosis, or lysis resulting in platelet destruction and thrombocytopenia can occur independently of immune-mediated events. Non-immune-mediated platelet destruction occurs in some acute bacterial and viral infections and in cardiovascular disease. Thrombocytopenia occurring from venomous snakebites may be secondary to DIC or may result from direct aggregation of platelets. Platelet activation with thrombocytopenia is associated with severe and extensive burns.

Platelet destruction in bacterial infections can occur as a result of platelet adherence or aggregation to activated monocytes or neutrophils. In Gram-negative infections, monocytes stimulated by endotoxin express tissue factor on their surface and generate thrombin.[83] Thrombin, a potent platelet agonist, causes platelet activation and aggregation. Platelets adhere to monocytes and are phagocytized. Neutrophil stimulation is not believed to be a major cause of platelet removal and is probably more important with regard to platelet function and thrombus formation.[36] Exotoxins released from Gram-positive bacteria may directly damage platelets and contribute to thrombocytopenia.[31,47,76,97]

The pathogenesis of thrombocytopenia associated with acute viral infections is often multifactorial, even though one mechanism may predominate. Direct platelet damage or lysis is one proposed mechanism of viral-associated thrombocytopenia. Myxovirus infections, including those due to Newcastle disease virus and influenza, decrease platelet survival by removal of platelet membrane sialic acid residues by viral neuraminidase.[96,99] Other viruses in which platelet damage is suspected include bovine viral diarrhea virus and hog cholera virus.[16,104]

In humans, platelets can be damaged and destroyed by mechanical means in arterial disease with roughened endothelial surfaces and narrowed microcirculation, stenotic or prosthetic heart valves, or cardiac by-pass surgery.[6,17,29] Turbulent circulation causes membrane damage and microparticle formation.[28] Interactions of platelets with altered or damaged endothelial surfaces cause extensive platelet activation, clumping, and removal of platelets by the mononuclear phagocyte system.[6] This may also occur in viral infections that infect or alter endothelial cells. In vitro, virally transformed endothelial cells show a significant increase in platelet adherence.[18]

Many of the rickettsial diseases are associated with thrombocytopenia. Several mechanisms contribute to thrombocytopenia, including immune-mediated platelet destruction, direct damage, vasculitis, and platelet production deficits. Disseminated intravascular coagulation may occur as a secondary complication.

Abnormal Platelet Distribution

In health approximately 30–40% of the total circulating platelet pool may be stored in the spleen, which is referred to as physiologic platelet sequestration. The liver and bone marrow are additional tissue sites of platelet sequestration.[3] Hypersplenism is a pathologic condition in which as much as 90% of circulating platelets become sequestered predominately in the spleen. Hypersplenism is characterized by the presence of one or more cytopenias with corresponding bone marrow hyperplasia and significant splenomegaly. Splenic size is probably the most important factor that determines the degree of thrombocytopenia; the spleen must be significantly enlarged to cause a severe decrease in circulating platelets.[71] Although hypersplenism is characterized by splenomegaly, the presence of splenomegaly does not always signify hypersplenism.

Thrombocytopenia that results from hypersplenism can be thought of as a displacement of the majority of platelets from peripheral circulation into a reversible, but slowly exchanging, splenic pool.[29] Thrombocytopenia secondary to splenic pooling is different from that seen with idiopathic thrombocytopenic purpura in which there is active removal of platelets by the splenic macrophages.[29] In hypersplenism, thrombocytopenia is evident on a complete blood count (CBC), but the total numbers of platelets and platelet mass are actually normal. Platelet survival is usually normal, as is platelet production.[3,37]

Hypersplenism is rare in animals but a few suspected cases have been described.[44,51] All other causes of splenomegaly should be ruled out before a diagnosis of primary hypersplenism is made. Recommended treatment in these cases is splenectomy.

Severe hypothermia adversely affects platelet morphology and can cause a mild transient thrombocytopenia owing to pooling of platelets in the spleen.[44] Transient thrombocytopenia can also occur with endotoxemia and hypotension.

Pseudothrombocytopenia

Pseudothrombocytopenia (artifactual or spurious thrombocytopenia) is an in vitro phenomenon resulting from platelet clumping secondary to poor or difficult venipuncture and subsequent platelet activation or exposure of the blood to certain anticoagulants. Feline platelets are especially prone to activation during blood collection. Pseudothrombocytopenia can occur with overfilling of a blood collection vacutainer tube and subsequent improper or inadequate sample mixing.[72]

Uncommonly, in vitro clumping occurs in certain individuals when blood is collected into anticoagulants. This has been seen most commonly with ethylenediaminetetraacetic acid (EDTA) and rarely with other anticoagulants. EDTA-dependent pseudothrombocytopenia has been reported in humans, a horse, a miniature pig, and a dog.[30,38,75,105] Although there may be several factors, the leading mechanism for EDTA-dependent pseudothrombocytopenia involves autoantibody-mediated platelet agglutination. Hidden epitopes become exposed within the platelet IIb-IIIa complexes as a result of complex destabilization occurring with calcium removal from calcium binding domains.[8,12,23]

Rarely, platelet clumping can occur with exposure to anticoagulants containing citrate, oxalate, or heparin.[68,70,86]

Accurate automated platelet counts in cats are often difficult to obtain due to clumping. Feline platelets are more reactive than those of other species. Several factors unique to feline platelets may be involved, including a larger platelet size, a higher concentration of serotonin, irreversible aggregation and granule release when exposed to serotonin, and irreversible aggregation in response to low concentrations of ADP.[9,57,73] Because of their nature and small size and the fact that many cats resist handling and restraint in unfamiliar settings, venipuncture is often challenging, which may increase the likelihood of platelet activation in vitro.[66]

CLINICAL SIGNS OF THROMBOCYTOPENIA AND RISK OF HEMORRHAGE

Clinical signs leading one to suspect thrombocytopenia include petechiation or ecchymosis in tissues or mucosal membranes, epistaxis, melena, hematochezia, hematuria, prolonged bleeding after venipuncture, or retinal hemorrhage or hyphema. However, clinical signs of bleeding are infrequently seen. More commonly, thrombocytopenia is usually identified on a routine CBC. Animals having a low platelet count may exhibit no clinical signs or present for lethargy, weakness, fever or other signs related to an underlying disease process. Despite the observation that hemorrhage is not a consistent feature, thrombocytopenic animals are at an increased risk of bleeding.

Hemorrhage solely caused by thrombocytopenia does not usually occur until peripheral platelet numbers are severely decreased (<50,000 platelets/μL). Animals that have platelet counts of ≤10,000/μL are at a much greater increased risk of hemorrhage. Abnormal or compromised platelet function or vascular disease in a thrombocytopenic animal can increase the risk of hemorrhage.

LABORATORY EVALUATION OF THROMBOCYTOPENIA

See Figure 77.1.

Complete Blood Count

The first indication that an animal is thrombocytopenic may come from a CBC. Likewise, a CBC should be the first test performed in any animal that is suspected of having a bleeding disorder. Generally EDTA-anticoagulated blood is acceptable for platelet counts for 5 hours after collection when kept at 20 °C and 24 hours when kept at 4 °C; however, certain platelet parameters are affected by anticoagulant, time or refrigeration.[64] Specific platelet parameters available on most automated CBCs include platelet count, mean platelet volume, and platelet distribution width. Additional parameters available on some hematology analyzers may include plateletcrit, mean platelet component concentration, and platelet component concentration distribution width. Many of these platelet indices may provide helpful information about the underlying cause of thrombocytopenia; however, there is a paucity of studies in veterinary species, especially in those with thrombocytopenia. In addition to these automated parameters, microscopic examination of the blood smear for platelet morphology and size, and evidence of platelet clumping or adherence to leukocytes should be performed. Although manual methods are less accurate and precise compared to automated methods for platelet enumeration, they become necessary when platelet counts fall below the limit of sensitivity or linearity (usually 5,000–20,000 platelets/μL) of a hematology analyzer. Errors in manual platelet counts are less when performed by those who are experienced with the method and perform it regularly. If the platelet count is normal in an animal that has abnormal bleeding, petechiation, or ecchymosis, an abnormality in platelet function or a coagulopathy should be considered.

Platelet Parameters on Automated Hematology Analyzers

Mean platelet volume (MPV) estimates platelet size and is inversely proportional to platelet number in some species. Increases in MPV may be associated with response to thrombocytopenia, with some myeloproliferative diseases, and with hyperthyroidism.[24,88] Decreases in MPV have been reported in some dogs that have early manifestations of immune-mediated thrombocytopenia.[67] Decreases in MPV are more often associated with bone marrow failure. Artifactual increases in MPV arise when platelets are exposed to EDTA for prolonged periods of time, cooled to room temperature (25 °C), or refrigerated (4 °C), or if there is delayed exposure to an anticoagulant. Minimal changes in MPV occur when blood is collected in an anticoagulant containing citrate and is kept at 37 °C.[35,64]

Platelet distribution width (PDW) is a value given by some automated particle counters and represents an index of variation in platelet size. PDW may be useful in laboratories that do not routinely perform smear evaluation. In humans, PDW was increased in patients with immune-mediated thrombocytopenia compared to patients with thrombocytopenia due to aplastic anemia; therefore PDW may be useful in differentiating between hyperdestructive thrombocytopenia (immune-mediated thrombocytopenia) and hypoproductive thrombocytopenia due to aplastic anemia.[46]

The plateletcrit (PCT or thrombocrit) is used to assess total circulating platelet mass and is the percentage of the blood volume that is composed of platelets. It is determined by certain analyzers or calculated using platelet count and MPV. Expected values are usually less than 1%. In dogs with experimentally-induced endotoxemia and thrombocytopenia, the platelet count and the PCT were significantly decreased, and the MPV and PDW were increased.[106] Because the PCT

represents total platelet mass, this parameter may be more representative of the functional potential and thrombopoietic stimulus than the platelet count.[53] PCT was found to be a better parameter than platelet count for assessing the platelet status in Cavalier King Charles Spaniels, a breed which can have a hereditary macrothrombocytopenia.[100]

Mean platelet component concentration (MPC) estimates the average platelet density by two-angle light scatter and is used to assess platelet activation.[15] MPC was found to be sensitive to the activation state of feline platelets.[108] MPC was decreased in several groups of horses including septic foals, foals with DIC and adult horses with inflammation, gastrointestinal obstruction, enteritis, ischemia, or thrombocytopenia, leading the authors to suggest that the parameter may be of value in detecting platelet activation in horses.[84] MPC is influenced by several factors including anticoagulant, sample age, storage temperature and time, so these should be considered when interpreting MPC results.[26,92,101]

Platelet component concentration distribution width (PCDW) is a measure of the variability of platelet density, and values decrease with platelet activation and platelet shape change from discoid to spherical as platelets become activated. PCDW also decreases with increasing storage time and may be useful for documenting the platelet storage lesion.[55] Although studies in thrombocytopenic animals have not yet been done, PCDW may help elucidate potential causes of thrombocytopenia secondary to platelet activation.

Microscopic Evaluation of the Blood Smear

Microscopic examination of a blood film is necessary to evaluate platelet morphology and to ensure accuracy of automated platelet counts. Furthermore, decreased platelet counts should always be confirmed by microscopic examination of a blood smear, and if necessary, the platelet count should be repeated on a freshly drawn blood sample. It is also imperative that the venipuncture is carefully performed to prevent platelet activation resulting in artifactual changes on the CBC, making platelet parameters unreliable. Delayed time of exposure to anticoagulation, improper mixing, or improper collection can all contribute to falsely low platelet counts. EDTA-dependent pseudothrombocytopenia can be ruled out by restoration of normal platelet numbers and elimination of platelet clumps observed on blood smears when samples are drawn into citrate anticoagulant.

Evaluation of the blood smear should begin on low magnification to look for the presence of large platelet clumps. Often clumps are found on the feathered edge of the smear. If large clumps are found, this likely means that the number of platelets indicated by the hematology analyzer is falsely low. A general guideline for estimating platelet numbers on a blood smear is to determine the average number of platelets in 10 oil immersion fields using a 100× objective and multiply the average by 15×10^3 to obtain the estimated number of platelets per microliter.

Additional Diagnostic Tests

Once an animal is found to be thrombocytopenic, additional diagnostic testing is often necessary to elucidate the cause. Additional tests that should be considered include a coagulation panel, bone marrow analysis, serology or DNA analysis for infectious agents, and bacterial cultures. In thrombocytopenic horses, an agar gel immunodiffusion test (Coggins test) or an enzyme-linked immunosorbent assay (ELISA) to rule out equine infectious anemia is indicated.

Antiplatelet or antimegakarocytic antibody assays, reticulated platelet analyses, and platelet function studies are additional tests that may be considered for the evaluation of platelet disorders. Antiplatelet antibody assays measure platelet-associated antibodies and may help to confirm an immune component but do not distinguish between primary and secondary immune-mediated thrombocytopenia. Reticulated platelets are young platelets recently released from bone marrow and contain increased RNA concentrations.[4,19] In cases of peripheral platelet destruction, the percentage of reticulated platelets is increased in circulation. Thrombocytopenic patients who have compromised platelet production have decreased percentages of reticulated platelets in circulation.[50] The percentage of reticulated platelets was increased in two horses that had DIC and several ponies experimentally infected with equine infectious anemia virus.[80] In dogs, reticulated platelets may be a useful parameter for assessing platelet production.[60,89] Many platelet function assays are only available at specialized or institutional laboratories and may not be readily available or practical.

Coagulation Panel

Performing a coagulation screen is suggested in any animal where a coagulopathy is suspected. A coagulation panel generally includes some combination of the following tests: activated partial thromboplastin time (APTT), one-stage prothrombin time (OSPT; also referred to as prothrombin time or PT), fibrinogen concentration, fibrinogen and fibrinogen-fibrin degradation products (FDP), antithrombin, and D-dimer concentration. Depending on the underlying pathology, animals may be thrombocytopenic without additional abnormalities on a coagulation panel or they may have abnormalities on a coagulation panel and not have thrombocytopenia. DIC secondary to a large variety of disorders and rodenticide toxicity are two conditions that can be seen in animals that are thrombocytopenic and have abnormal coagulation results.

Bone Marrow Evaluation

Bone marrow evaluation of megakaryocytes may be necessary to determine if thrombocytopenia is secondary to a platelet production defect or is caused by peripheral platelet destruction or consumption. The typical finding in cases of diminished or defective platelet production is the absence of or the decreased

numbers of megakaryocytes. Abnormal morphology and size may also be observed. In most cases of peripheral platelet destruction, megakaryocyte numbers are normal to increased. Often megakaryocytes are increased in size and ploidy as well. Both aspiration and core biopsies of bone marrow should be taken since both approaches offer certain advantages. Cellular morphology is superior with aspiration biopsies, whereas core biopsies are more useful for evaluation of overall megakaryocyte numbers, myelofibrosis, or necrosis. For proper and complete bone marrow interpretation, a blood sample should be taken for a CBC at the time of bone marrow sampling.

Bone marrow is collected by sterile technique, usually under sedation, but sometimes under general anesthesia. Sites for marrow collection can depend on personal preference and experience. The site is clipped and surgically prepared. A local anesthetic agent should be used in non-anesthetized animals. Use of a bone marrow needle with stylet (usually 15 gauge) is recommended. The needle with stylet is seeded into the bone and advanced a few more millimeters. The stylet is removed and a syringe (usually 10 or 20 mL) containing an anticoagulant (usually EDTA or citrate) is attached. If marrow is collected by this method, then the sample can be put into a Petri dish and grossly examined for particles. These appear as small flecks of whitish-gray material. Slides for cytology are made by picking these flecks up with a pipette and making squash preparations. Often, a bone marrow core biopsy can be taken when an aspirate is collected. After marrow has been aspirated, the needle is left in the bone and rotated 360° and advanced for another several millimeters and then pulled straight out. The stylet can then be used to push the core biopsy out of the needle so that it can be placed into formalin and processed.

LABORATORY CONFIRMATION OF CONSUMPTIVE THROMBOCYTOPENIAS

Thrombocytopenia and microangiopathic anemia with schistocytes are typical laboratory findings in DIC and TTP-HUS. Differentiation can often be made with the help of coagulation screening tests, including fibrinogen, FDP, D-dimer concentration, antithrombin levels, OSPT, and APTT. In DIC the classical laboratory findings are three or more of the following: thrombocytopenia, decreased plasma fibrinogen concentration, increased plasma FDP concentration, and prolonged APTT and OSPT. More recently, D-dimer testing has been introduced to many laboratories. D-dimers form from the degradation of cross-linked fibrin, whereas FDPs reflect either fibrinogen and/or fibrin breakdown. With DIC, elevations in D-dimers are often markedly increased, whereas low to moderately increased concentrations may be associated with a variety of disorders. One study in dogs reported that D-dimer concentration below 1000 ng/mL excluded most dogs that did not have DIC.[90] In foals where DIC was detected using clinicopathological criteria, D-dimer concentrations were higher compared to non-DIC groups and controls.[1] In cats, D-dimer concentrations may not be a useful test for diagnosing DIC.[7,91] Antithrombin is a molecule that binds thrombin to form a complex which is subsequently removed from circulation by hepatocytes. In DIC, antithrombin activity is usually decreased because of accelerated consumption. In contrast to DIC, coagulation tests (APTT, OSPT, fibrinogen concentration) are usually normal, FDP concentrations may be mildly increased, and D-dimer concentrations are increased in patients with TTP and HUS.[43,62]

Acronyms and Abbreviations

ANA, antinuclear antibodies; CBC, complete blood count; D-MIFA, direct megakaryocyte immunofluorescence assay; EIA, equine infectious anemia; FeLV, feline leukemia virus; FIP, feline infectious peritonitis; FIV, feline immunodeficiency virus; IMHA, immune-mediated hemolytic anemia; IMT, immune-mediated thrombocytopenia; LE, lupus erythematosus; MLV, modified live virus; MPV, mean platelet volume; PDW, platelet distribution width; PF3, platelet factor 3; PSAIg, platelet surface-associated immunoglobulin; RBC, red blood cell; SLE, systemic lupus erythematosus.

PRIMARY IMT IN DOGS

Signalment

Dogs of any age, gender, or breed can suffer from primary IMT. The age of dogs with IMT has ranged from 3 months to 17 years, with reported mean or median ages of 4–8 years.[25,31,42,49,52,56,57,69] In most studies, females have outnumbered males 2:1 to 3:1.[25,30,31,33,42,52,69] Some investigators have found no breed predisposition, while others have reported predispositions in cocker spaniels, toy poodles, miniature poodles, standard poodles, old English sheepdogs, and German shepherds.[25,31,41,42,57,69]

History and Physical Exam

Most dogs with primary IMT are presented because of hemorrhage involving skin and mucosal surfaces.[52,69] Hemorrhage may arise spontaneously or it may be a pathologic prolongation of bleeding following estrus, whelping, surgery, dentistry, grooming, or venipuncture. Other nonspecific signs include lethargy, anorexia, stiffness, collapse, or weakness.[4,30,69] Thrombocytopenia may also be discovered incidentally during routine health checks, preoperative testing, or medical evaluation of unrelated problems.[52,57] Even dogs with platelet concentrations of less than 10,000/μL may be bright and alert with no clinical signs of disease (M.A. Scott, L.A. Jutkowitz, personal observations).

Physical examination of most affected dogs reveals petechiae, ecchymoses, epistaxis, gastrointestinal hemorrhage (melena, hematemesis, hematochezia), oral bleeding, vaginal bleeding, hemoptysis, and/or hematuria.[31,33,52,69] Hemorrhages are especially common on the oral mucosae, ventral abdomen (Fig. 78.1), inner limbs, and pinnae, where they may be mistaken for a rash. Ocular lesions are also common and vary from mild conjunctival, scleral (Fig. 78.2), iridal, or retinal hemorrhage to hyphema, severe retinal hemorrhage, retinal detachment, and blindness.[30,52,59] When hemorrhage is severe enough to cause anemia, other signs such as pallor, exercise intolerance, tachycardia, systolic ejection murmur, bounding pulses, and shock may

FIGURE 78.1 Abdominal petechiae and ecchymoses in a 7-year-old spayed German shepherd with primary immune-mediated thrombocytopenia.

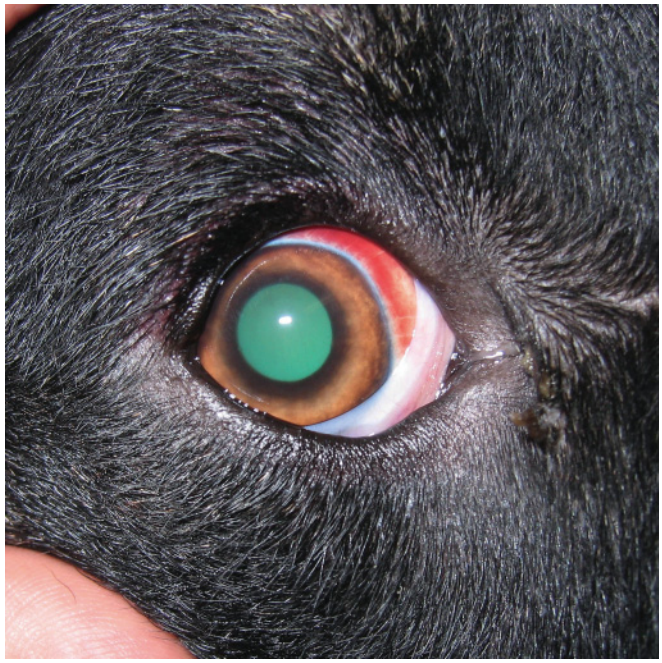

FIGURE 78.2 Scleral hemorrhage (present bilaterally) in a young dog with immune-mediated thrombocytopenia and 7,000 platelets/μL.

develop. Severe hemorrhage is most commonly attributed to gastrointestinal bleeding,[46] but it has also been reported secondary to epistaxis, hematuria, and vulvar bleeding.[69] Fever has been reported in many dogs with IMT, but it may be less common in dogs with primary IMT than in dogs with secondary IMT.[31,33,52,69] Splenomegaly and lymphadenomegaly have been reported. Intracranial and spinal cord hemorrhage are uncommon but life-threatening complications of IMT that should be suspected with decreasing levels of consciousness or acute onset of neurologic signs.

Pathogenesis

Primary IMT is an autoimmune disorder, unassociated with known predisposing conditions or multi-system autoimmune disease, in which the immune system causes thrombocytopenia through autoreactive mechanisms. It may be considered idiopathic to the extent that the root causes of autoreactivity are unknown. In human medicine, acute and chronic forms have been described. Human chronic IMT appears to be caused by varying degrees of accelerated platelet destruction and impaired platelet production mediated by humoral and cellular immune responses. T lymphocytes are reportedly resistant to apoptosis, suggesting that there is defective clearance of autoreactive T cells.[48] These autoreactive T cell clones appear to proliferate in response to platelet or megakaryocyte autoantigens and stimulate B cells to produce autoantibodies that mediate platelet destruction and impair megakaryocyte maturation and thrombopoiesis. Evidence also supports a role for cytotoxic T cells in platelet lysis and possibly in megakaryocyte damage. In acute childhood IMT, immune stimulation of an immature immune system may enable previously suppressed autoreactive B cells to escape thymic deletion because of cross-reactivity with other antigens (e.g. viral epitopes). As in chronic IMT, resultant autoantibodies may bind to platelets and megakaryocytes.

Early case reports describing idiopathic thrombocytopenia in dogs were likely reports of primary IMT.[23] The first laboratory evidence for this was positive results of the platelet factor 3 (PF3) assay in which globulin fractions from affected thrombocytopenic dogs accelerated coagulation, thus implicating the presence of antiplatelet antibodies. Later, direct assays for canine platelet surface-associated immunoglobulin (PSAIg) supported the presence of immunoglobulins, usually IgG, on the platelets of dogs with clinical diagnoses of primary IMT.[42,52,57] Acid eluates of platelets from some affected dogs were shown to contain immunoglobulins that immunoprecipitated the integrin $\alpha_{IIb}\beta_3$ from allogeneic platelets.[41] Other canine IMT plasma has been shown to immunoprecipitate glycoprotein Ib/IX,[57] further documenting antibody binding to platelet glycoproteins.

Many human antiplatelet antibodies also bind to shared epitopes on megakaryocytes, and some appear to interfere with megakaryocyte maturation and thrombopoiesis despite normal to increased megakaryocyte numbers.[13] Therefore, megakaryocytic hyperplasia should be interpreted only as increased megakaryopoiesis, not as evidence of increased thrombopoiesis. As expected, canine platelets and megakaryocytes have been documented to share some reactive sites, including epitopes on glycoprotein IIIa.[17] Dogs with IMT or those made thrombocytopenic by injections of rabbit

anti-canine platelet antiserum have developed marked thrombocytopenia associated with megakaryocyte cytoplasmic vacuolation, foaminess, basophilia, and decreased granularity.[33] These microscopic changes may be indicative of immune-mediated megakaryocyte damage and impaired thrombopoiesis.

Rarely, autoantibodies to hematopoietic cytokines have been documented to induce IMT in people through impaired platelet production.[27] Similarly, injections of a recombinant human thrombopoietin product into dogs caused thrombocytopenia and megakaryocytic hypoplasia in association with increased titers of antibodies that were presumed to cross-react with canine thrombopoietin.[16]

Diagnosis

The diagnosis of primary IMT is one of exclusion, requiring clinical and laboratory evaluation (see Chapter 77) for all other causes of thrombocytopenia (Table 78.1).[51] One must exclude non-immune causes of decreased platelet production, non-immune platelet consumption, abnormal platelet distribution, alloimmune IMT, and secondary IMT. Patient history should include exposure to drugs or toxicants, recent vaccinations, recent trips, recent contact with other dogs, previous transfusions, previous and current medical conditions, and tick exposure. Physical examination should include assessment of other causes of thrombocytopenia. Underlying infections may be suggested by lymphadenomegaly, ticks, arthritis, or fever. Neoplasia may be suggested by the presence of lymphadenomegaly, splenomegaly, other masses, or cachexia. Systemic immune-mediated disease may be suggested by polyarthritis or certain forms of dermatitis.

The extent and type of diagnostic testing varies with clinical information and geographic location, but typically includes: CBC, chemistry profile, and urinalysis; hemostasis profile for evidence of consumptive coagulation; abdominal and thoracic radiography and abdominal ultrasonography for organomegaly and occult neoplasia; and assessment for infectious agents by blood culture, serology, or molecular testing, as indicated. Bone marrow examination may be indicated, as well as tests for antinuclear antibodies (ANA), rheumatoid factor, lupus erythematosus (LE) cells, and red blood cell (RBC)- or neutrophil-associated immunoglobulin if systemic immune-mediated disease is suspected. Blood smears should be evaluated to confirm automated platelet concentrations and to exclude pseudothrombocytopenia. Pseudothrombocytopenia usually occurs when platelets are clumped because of platelet activation during or after venipuncture. Platelet clumps indicate the need for a new sample to be collected with a nontraumatic venipuncture. If anticoagulant-induced clumping is suspected, a new sample should be tested promptly after collection into a citrate tube. Pseudothrombocytopenia may also occur if many platelets are larger than the high threshold setting of automated hematology analyzers, in which case platelet concentrations should be measured using a hemocytometer. Clinically normal cavalier King Charles spaniels with platelet microtubule instability have many large platelets and thrombocytopenia,[18] requiring careful microscopic assessment of the platelet appearance and concentration before exploring other reasons for thrombocytopenia in this breed. Similarly, many healthy greyhounds have platelet concentrations below typical canine reference intervals (e.g. near 100,000/μL).[61]

In primary IMT, platelet concentrations are usually lower than 50,000/μL,[23,30,46,57] and frequently lower than 10,000/μL.[52,57] Overall, platelet concentrations in dogs with IMT have been significantly lower than those of dogs with presumed non-immune thrombocytopenias.[25,46,57] Most reports associate bleeding with platelet concentrations lower than 30,000/μL or even 10,000/μL,[52,69] but bleeding may occur at higher concentrations.[52] Inconsistent bleeding tendencies among dogs

TABLE 78.1 Causes of Thrombocytopenia

- Decreased platelet production
  - Acquired amegakaryocytic thrombocytopenia (may be immune-mediated)
  - Bone marrow replacement (hemic or metastatic neoplasia, myelofibrosis, osteopetrosis)
  - Hereditary disorders of hematopoiesis (e.g. β1-tubulin gene mutation)
  - Infections (hemic cell infection, cytokine suppression, myelonecrosis; usually multifactorial)
  - Irradiation, whole body or extensive
  - Megakaryocytic leukemia
  - Myelonecrosis (infections, neoplasia, toxicants)
  - Myelosuppressive toxicants
    - Predictable (e.g. chemotherapeutics, estrogens in dogs, bracken fern in ruminants, tricothecene mycotoxins)
    - Idiosyncratic (e.g. phenylbutazone, meclofenamic acid, trimethoprim-sulfamethoxazole, griseofulvin)
- Decreased platelet survival
  - Immune-mediated destruction
    - Primary (idiopathic, autoimmune)
    - Secondary
      - Drugs (may be multifactorial)
      - Infections (usually multifactorial)
      - Neoplasia (usually multifactorial)
      - Systemic autoimmune disease (e.g. lupus erythematosus)
    - Alloimmune
      - Neonatal alloimmune thrombocytopenia
      - Post-transfusion purpura
  - Non-immune consumption
    - Disseminated consumptive coagulation (envenomations, hepatic disease, infections, necrosis, neoplasia, overheating, pancreatitis, septicemia)
    - Hemorrhage, acute and widespread (e.g. anticoagulant rodenticides)
    - Localized intravascular coagulation (thrombosis, hemangiosarcoma)
    - Vasculitis/endocarditis (infectious vasculitides, hemolytic uremic syndrome)
- Abnormal platelet distribution (splenic sequestration)
- Hemodilution by massive infusion of platelet-poor fluids

with similar platelet concentrations may relate to variations in vascular stability, trauma, the rapidity with which thrombocytopenia develops, the age and metabolic activity of the circulating platelets, or the antigenic specificities of antiplatelet antibodies.

Decreased mean platelet volume (MPV) has been associated with immune-mediated platelet destruction.[46,69] In one study, low MPV appeared to be a specific indicator of primary IMT in dogs.[46] However, MPV results for dogs with non-immune thrombocytopenias of similar severity were not reported. In another retrospective canine study, MPV and platelet distribution width (PDW) were not useful in differentiating causes of thrombocytopenia.[6]

Regenerative or nonregenerative anemias are common at presentation and are usually associated with blood loss.[25,30,31,52,69] Leukogram abnormalities are inconsistent and not useful in diagnosing primary IMT,[25,30,52] but they may suggest underlying or concurrent disease. Complete blood count abnormalities suggesting secondary IMT or non-immune thrombocytopenia include: bicytopenia, pancytopenia, leukemia, a severe inflammatory leukogram, granular lymphocytosis, marked hyperproteinemia, intracellular organisms (e.g. fungi, ehrlichia, distemper inclusions), extracellular parasites such as microfilaria, and RBC abnormalities (e.g. spherocytes, schistocytes, dacryocytes).

Bone marrow evaluation is not necessary in most dogs suspected of having primary IMT. Megakaryocyte findings are not specific for primary IMT, and non-megakaryocytic abnormalities are uncommon in dogs for which primary IMT is the major diagnostic consideration.[45] Bone marrow assessment may be indicated initially to detect other causes of thrombocytopenia or after treatment in those dogs that do not respond well to routine therapy. Indications for bone marrow evaluation include suspicion of leukemia, multiple myeloma, or other hemic neoplasia. Other causes of production failure that may be identified include myelofibrosis, bone marrow necrosis, metastatic cancer, and granulomatous infections. If bone marrow hypoplasia or aplasia is suspected, a core biopsy should be done in addition to an aspirate. Thrombocytopenia should not be considered a contraindication to bone marrow sampling in thrombocytopenic dogs,[69] although prolonged pressure may be required to achieve hemostasis.

Estimation of marrow megakaryocyte numbers is subjective and dependent on sample quality. Reliable estimates should be attainable with either representative core samples or aspirate samples containing many marrow particles. However, megakaryocyte numbers can be underestimated in aspirate samples with few or no particles because megakaryocytes tend to be associated with particles. Compared to aspirate smears, core sections allow better differentiation of megakaryocyte numbers. In primary IMT, megakaryocytes are usually present in normal or increased numbers (Fig. 78.3).[33,52,69] However, rare dogs have absent or markedly reduced numbers of megakaryocytes.[9,33,39,69]

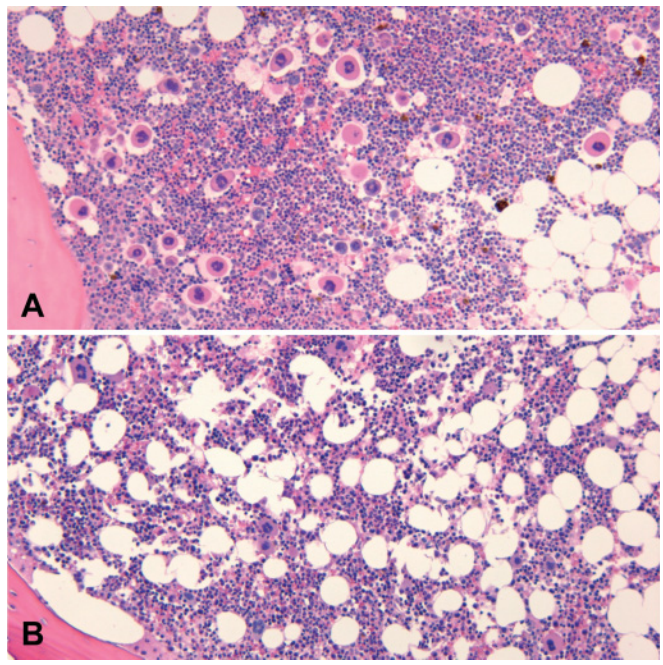

FIGURE 78.3 Bone marrow core biopsy samples. (**A**) Megakaryocytic hyperplasia and erythroid hyperplasia in an 8-year-old castrated mixed breed dog with primary immune-mediated thrombocytopenia, a platelet concentration of 4,000/μL, and secondary hemorrhage. (**B**) In contrast, normal megakaryocyte density in an 8-year old castrated boxer with unexplained hypercalcemia. Megakaryocytes are large cells with multilobulated nuclei and eosinophilic cytoplasm. H&E stain.

IMT Assays

The diagnosis of primary IMT remains a diagnosis of exclusion because assays have insufficient diagnostic sensitivity and specificity for routine clinical utility.[51] Early assays, such as the PF3 test, were insensitive and nonspecific indirect functional assays that cannot be recommended.[12,31,33,69] Current assays have more analytical sensitivity and specificity for antibodies to platelets or megakaryocytes. The presence of increased PSAIg or other positive test results is evidence of an immune component to the thrombocytopenia. However, positive results do not differentiate primary IMT from secondary IMT, and PSAIg has been increased in human patients with presumed non-immune thrombocytopenias.[51] Although patients with negative results need to be evaluated further for non-immune causes of thrombocytopenia, negative results may occur in primary IMT. Therefore, all causes of thrombocytopenia must be considered despite assay results.

Most assays developed to diagnose IMT in dogs have used labeled antiglobulin reagents to detect platelet- or megakaryocyte-reactive immunoglobulins, and none are glycoprotein specific. These assays include the megakaryocyte immunofluorescence assays D-MIFA,[31,33,37] enzyme-linked immunosorbent assays,[12,42,44] platelet immunoradiometric assays,[57] and microscopic and flow cytometric platelet immunofluorescence assays.[37,52]

Flow cytometric assays are currently used most frequently. Assays have been designed either as direct assays that assess for antibodies on patient platelets or megakaryocytes, or as indirect assays that assess for antibodies in patient plasma or serum that bind to platelets or megakaryocytes from healthy individuals (see Chapter 140).

Direct assays are generally superior to indirect assays in assessing primary IMT. Indirect assays cannot differentiate plasma or serum autoantibodies from confounding circulating immune complexes, aggregates of IgG formed in heated or stored sera, or acquired and naturally-occurring alloantibodies to common or platelet-specific antigens. However, transport and storage of samples may profoundly and unpredictably affect the results of some direct assays.[57] D-MIFAs are little affected by sample transport, but D-MIFA positivity may not mirror PSAIg positivity.

Therapy

When treating dogs with IMT, aspirin and other antiplatelet drugs should be avoided. Medications that may cause or contribute to thrombocytopenia should be discontinued whenever possible. Trauma (including intramuscular injections) should be minimized, jugular venipuncture avoided, and concurrent problems treated appropriately. Other therapy should be aimed at raising platelet concentrations enough to protect against clinical hemorrhage, though some dogs may do well despite low platelet concentrations and no medical management.[31] Platelet concentrations within the reference interval are the preferred target and may be achieved in the majority of patients.[52] However, some patients may be refractory to therapy or intolerant of treatment side effects. In such patients, reaching platelet concentrations of 50,000–100,000/μL is probably adequate in the absence of platelet dysfunction.[52]

Immunosuppressive doses of corticosteroid are the mainstay of therapy in dogs, reportedly stabilizing vascular endothelium, decreasing macrophage phagocytosis of opsonized platelets, increasing platelet production, and diminishing antibody production.[52] Prednisone or prednisolone is generally started at a dose of 1–2 mg/kg every 12 hours; an equivalent dose of dexamethasone may be calculated by dividing the prednisone dose by seven.[7] There is currently no evidence to suggest that the higher end of the immunosuppressive range is more effective than the lower end, or that dexamethasone is more effective than prednisone in dogs. In many dogs, hemorrhage may resolve prior to increases in platelet concentration.[30,69] The glucocorticoid dose is gradually tapered over several months until being withdrawn or maintained at the minimal effective dose as directed by platelet concentrations. Side effects or inadequate response justify other therapeutic approaches.

Numerous adjunct immunosuppressive agents have been used in dogs with IMT. Decisions regarding the selection of these drugs are frequently based upon clinical bias, as randomized, controlled, clinical trials in dogs with IMT are lacking. However, beneficial effects of adjunct agents cannot be excluded, and combination therapy with reduced doses of individual drugs may reduce unwanted side effects. Azathioprine, cyclophosphamide, danazol, cyclosporine, mycophenolate, vincristine, and human gamma globulin have all been used.[4,30,31,52,56,69]

In one prospective, controlled, but non-randomized study, combined therapy with prednisone and vincristine (0.02 mg/kg once intravenously) was associated with a more rapid increase in platelet concentration and shortened duration of hospitalization compared to treatment with prednisone alone.[56]

In dogs, splenectomy has had variable results.[30,69] It remains to be seen if response to splenectomy can be predicted. Hemotropic mycoplasmosis is a recognized complication of splenectomy and immunosuppression in dogs but long-term studies of this problem in clinical cases of IMT are lacking.[2]

There is little evidence to support the prophylactic administration of platelet products to dogs with IMT. Studies to date addressing this issue failed to find a benefit in dogs that received platelet-rich plasma or fresh whole blood. Transfused platelets are rapidly consumed or destroyed by circulating antiplatelet antibodies. However, significant transient increments may occur, and, as in human patients, they justify platelet transfusions when dogs with IMT require surgery or when there is severe, life-threatening hemorrhage. Multiple units of platelet concentrates are usually required for an appreciable effect. Additionally, an estimated 30% of dogs with IMT require packed RBC transfusions to address acute blood loss.[52,56]

Rituximab, a monoclonal antibody that targets the CD20 antigen on B cells, has been used successfully in human patients to treat lymphoma as well as IMT.[53] The goal of this and other antibodies evaluated for therapy of human IMT is to disrupt the immune dysregulation driving autoantibody production. However, the monoclonal antibody to human CD20 does not appear to bind canine B cells.[29] With increasing evidence that platelet production may be impaired in IMT, treatments that promote megakaryopoiesis may also be helpful. Romiplostim (Amgen Inc., Thousand Oaks, CA), a thrombopoietin receptor ligand, has recently received approval for the treatment of chronic IMT in people. In a phase 3 clinical trial, 87% of patients given Romiplostim were able to discontinue or decrease concurrent therapy, compared to 38% in the placebo group.[38] During preclinical development, Romiplostim was studied in mice, rats, rabbits, dogs, and monkeys and was reported to increase platelet concentrations in the majority of species investigated.[68]

Outcome

The prognosis for dogs with primary IMT is generally favorable, with initial response rates of 80–95%.[4,30,52,56] Most dogs achieve hemostatic platelet concentrations (>50,000/μL) within 5–7 days, but recovery times of up to 35 days have been reported.[4,30,52,56] Dogs that do not

respond to initial therapy may still have a favorable outcome given more time or alternative strategies, such as splenectomy. Reported mortality rates have ranged from 10% to 43%, with the lower rate[52] more in line with the authors' experience. Both acute and chronic forms of the disease are seen in dogs, perhaps analogous to the human conditions. Over 50% of dogs with IMT experience a single, acute bout of thrombocytopenia followed by recovery.[30,52,69] However, a substantial percentage of dogs respond initially but relapse and require re-treatment or chronic therapy with low dose steroids or other immunosuppressive agents.[30,52,69] There is currently no way to predict which outcome a particular dog will have.

PRIMARY IMT IN CATS

Signalment

Primary IMT appears to be a rare condition in cats, with only a few probable cases reported.[5,22,32,34,36,63] The ages of affected cats ranged from 18 months to 12 years with a median age of 6 years. A gender bias is not apparent. Affected cats have been domestic shorthairs and single cats of the following breeds: Abyssinian, Somali, and British shorthair.

History and Physical Exam

Presenting complaints and physical exam findings include epistaxis, petechiae, ecchymoses, hematochezia, hematuria, and hemoptysis.[5,22,32,34,36,63] Decreased appetite and weight loss have also been present.[5]

Pathogenesis

An immunologic pathogenesis for reported cases of feline idiopathic thrombocytopenia has been supported by exclusion of other identifiable disorders, response to immunosuppressive therapy, or increased PSAIg.[36] The presence of megakaryocytic hyperplasia in most reported cases supports a decrease in platelet survival with responsive megakaryopoiesis.

Diagnosis

The diagnosis of IMT in cats is one of exclusion. Most affected cats have severe thrombocytopenia (<15,000/μL) and mucocutaneous hemorrhage. Low automated platelet concentrations should be confirmed by evaluation of a blood film or by determining the platelet concentration with a hemocytometer. Pseudothrombocytopenia is common in cats, secondary to platelet clumping and/or large platelets that may not be counted as platelets by automated analyzers. Once true thrombocytopenia is confirmed, all causes of thrombocytopenia should be considered, including decreased platelet production, increased platelet consumption, abnormal platelet distribution, and accelerated platelet destruction by immune or non-immune mechanisms (Table 78.1).[32] Acquisition of historical information, physical examination, and diagnostic testing should generally mirror those for the thrombocytopenic dog (see page 588). In the cat, additional consideration should be given to certain drug exposures (e.g. methimazole)[50] and to infection with FIV or FeLV.[36] In one retrospective study, thrombocytopenia was associated most commonly with viral infections, especially by FeLV, and with neoplasia, particularly hemic in origin.[32] Therefore, bone marrow examination is indicated. Regenerative and nonregenerative anemias have been reported in cats with primary IMT, and they are not unexpected with blood loss.[5] However, anemia may occur with concurrent IMHA (i.e. Evans' syndrome)[36] or other illness resulting in anemia and a non-immune or secondary immune-mediated thrombocytopenia.

Relatively little work has been done to develop and validate feline assays for PSAIg,[34,36,63] and, as in dogs and people, these tests will likely play a limited role in the clinical diagnosis of primary IMT. Antiplatelet antibodies may support an immunologic component to the thrombocytopenia if the assays are reliable, but current assays cannot differentiate primary IMT from secondary IMT. Increased PSAIg has been reported in cats with a wide array of disorders including fat necrosis, feline infectious peritonitis (FIP), FeLV infection, FIV infection, lymphoma, leukemia, hepatitis, pyelonephritis, and hyperthyroidism.[36]

When no underlying condition is found in a severely thrombocytopenic cat with megakaryocytic hyperplasia and a thorough diagnostic work-up, idiopathic IMT is a reasonable working diagnosis, particularly if a reliable assay indicates the presence of increased PSAIg. Positive response to immunosuppressive therapy may lend further support to the conclusion.

Treatment

Therapy for cats with idiopathic IMT is similar to that of dogs. Prednisolone may be initiated at a dose of 2 mg/kg orally twice daily, or an equivalent dose of dexamethasone (approximately 0.3 mg/kg) may be given intravenously at the same frequency. Prednisone may be inferior to prednisolone in cats as it appears to have marked variability in bioavailability and activity in this species.[24] Cyclosporine, azathioprine, and vincristine have been used in cats with IMT, with variable success.[5,22,63] Intravenous immunoglobulins may be used in cats with refractory disease.[70]

Outcome

The prognosis for cats with primary IMT is similar to that for dogs, with over 80% of the reported cats surviving 15 months to greater than 5 years from the time of diagnosis.[5,22,32,34,36,63] Median recovery time to hemostatic platelet concentrations (>50,000/μL) has been 7 days, ranging from three days to 144.[5,22,36,63] All reported cats with IMT required long-term therapy, and some never achieved normal platelet concentrations.[5,22,36,63] Relapses were reported in cats weaned from therapy.

PRIMARY IMT IN HORSES

Immune-mediated thrombocytopenia is uncommon in horses, but it may occur as idiopathic thrombocytopenia (likely primary),[11,28,43] neonatal alloimmune thrombocytopenia, or in association with infections, drugs, neoplasia, or IMHA.

As in other species, the diagnosis of primary IMT is based on exclusion of other causes of thrombocytopenia. Thrombocytopenia may be suspected because of the presence of mucocutaneous hemorrhage (e.g. petechiae, epistaxis) and prolongation of bleeding from sites of trauma, including venipuncture. Complete blood count, chemistry, urinalysis, and hemostasis profiles should be performed to document thrombocytopenia and screen for underlying disorders. Thrombocytopenia is typically severe and associated with hemorrhage, but it should be confirmed with microscopic examination of a blood film to exclude pseudothrombocytopenia. Equine platelets tend to be pale staining and together with the relatively low numbers of platelets in horses, when compared to other species, blood film evaluation may yield a false impression of thrombocytopenia to the untrained eye. History and physical examination should be thoroughly assessed for known causes of thrombocytopenia (see Table 78.1). Bone marrow assessment may be useful to detect underlying diseases. Molecular or serologic diagnostics for infections with equine infectious anemia virus and *Anaplasma phagocytophilum* may also be indicated. A platelet antibody assay may be used to provide evidence of PSAIg.[43]

Most horses with idiopathic IMT respond favorably to corticosteroids, but azathioprine has been added in refractory cases with apparent benefit.[28,43] Dexamethasone may be instituted intravenously at 0.1–0.2 mg/kg every 24 hours. It may be continued with tapering doses over several weeks, or therapy may be switched to tapering doses of oral prednisolone. Prednisone should not be used because it has limited absorption in horses.[49] Some horses experience only a single episode of thrombocytopenia while others may have recurrent bouts. Platelet-rich plasma may be used for life-threatening bleeding.

SECONDARY IMT

Secondary IMT refers to IMT that is part of a more widespread autoimmune disease or that is associated with known predisposing neoplastic, infectious, or drug-induced conditions. Classification as secondary IMT is justified when there is a clear association between thrombocytopenia and the underlying condition, and when there is strong evidence that immune mechanisms are responsible for the thrombocytopenia. Increased PSAIg in a patient with a particular disorder supports an immunologic component to the thrombocytopenia, but it would be insufficient evidence to conclude that the underlying disorder should be considered a definite cause of secondary IMT.

In patients with secondary IMT, PSAIg may be bound specifically to platelet autoantigens as antiplatelet autoantibodies (e.g. systemic lupus erythematosus) or it may be bound to adsorbed non-autoantigens associated with infectious agents, drugs, or neoplasia (Fig. 78.4). PSAIg may also be in the form of immune complexes bound to platelets by: (1) complement-mediated immune adherence; (2) Fc receptors for IgG in species with platelet Fcγ receptors; or (3) nonspecific interactions. Circulating immune complexes may arise from infectious diseases, vaccinations, drugs, neoplasia, or systemic autoimmune diseases. Therefore, secondary IMT may or may not be autoimmune. In veterinary medicine, the type of interaction between antibody and platelet surface is typically unknown for any particular patient with a positive platelet antibody result.

Systemic Autoimmune Diseases

Primary IMT is but one clinical presentation in a spectrum of somewhat indistinct autoimmune disorders with different antibody specificities. Systemic lupus erythematosus (SLE) associated with presumed IMT has been reported in dogs, cats, and horses (see Chapter 54). An immune-mediated pathogenesis of the thrombocytopenia in dogs with SLE has been supported by PSAIg positivity and positive results with D-MIFAs or indirect assays. Thrombocytopenia may accompany IMHA because of consumption or immune-mediated destruction (Evans' syndrome) (see Chapters 33 and 34).

Immune-mediated thrombocytopenia has been suspected in association with several other targets of the immune system. Positive indirect results for platelet-bindable immunoglobulin have been reported in a dog with steroid responsive idiopathic neutropenia and thrombocytopenia, and in a dog with thrombocytopenia and red cell aplasia.[37] Similarly, a syndrome of concurrent neutropenia, splenomegaly, and severe thrombocytopenia has been described in giant schnauzers.[65] IMT has been clinically diagnosed or suspected in dogs with rheumatoid arthritis and pemphigus, and thrombocytopenia has accompanied juvenile-onset polyarthritis syndrome in Akitas.[21,25] Although possible IMT was reported in association with canine inflammatory bowel disease, thrombocytopenia was severe in only one dog and moderate in one dog.[55]

Neoplasia

Thrombocytopenia frequently occurs in association with neoplasia, and although its pathogenesis is multifactorial, immune-mediated platelet destruction may contribute. This would explain the documented shortened platelet survivals without concurrent decreases in fibrinogen survivals in dogs with multicentric or metastatic neoplasms.[47] Lymphoma and other hemic and non-hemic tumors have been associated with IMT in dogs, and this is supported by results of D-MIFAs and indirect assays for platelet-bindable immunoglobulin.[31,35,37] IMT also has been diagnosed in horses with lymphoma.

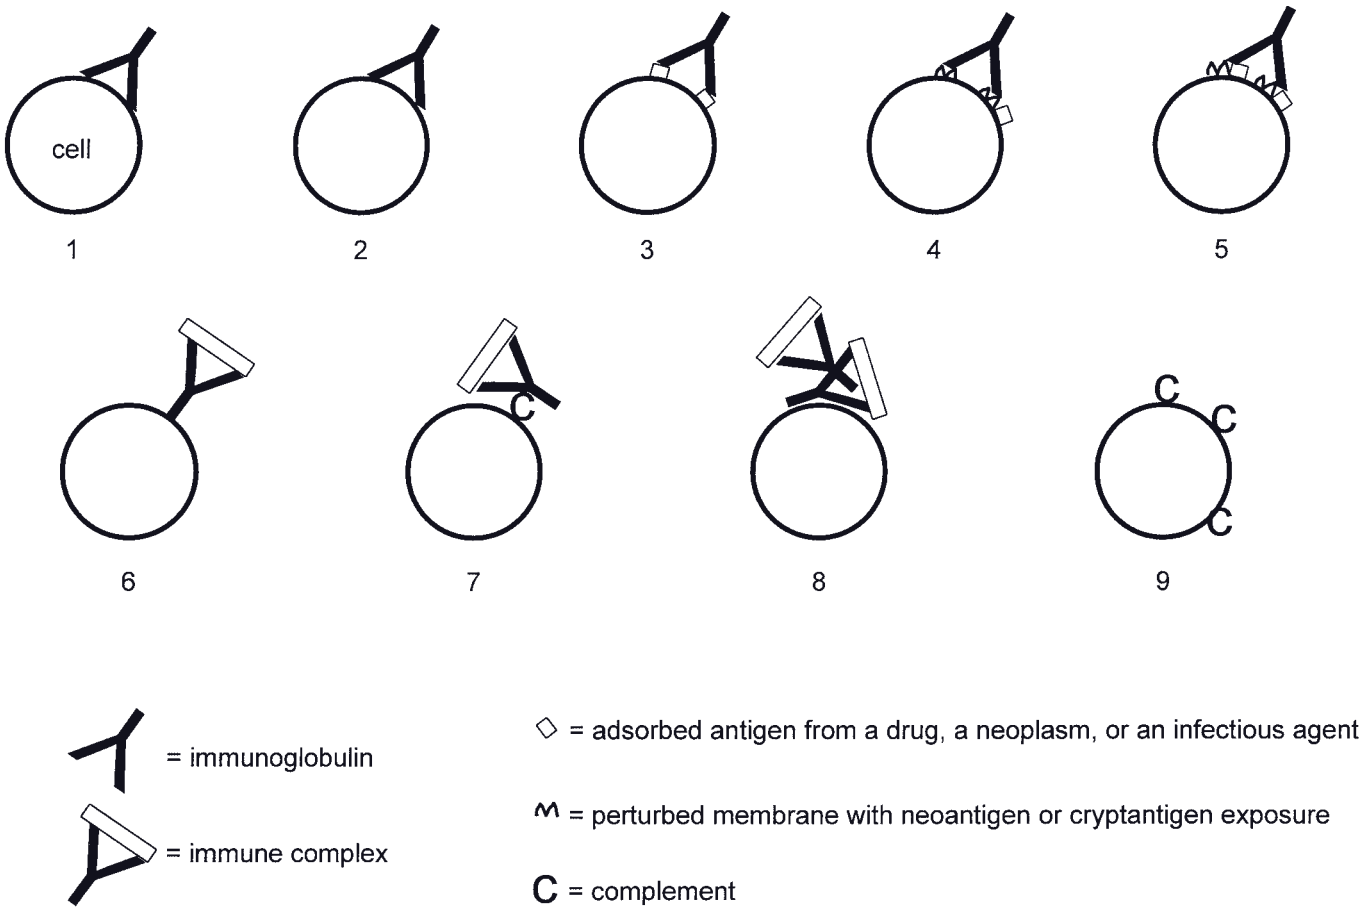

FIGURE 78.4 Schematic diagram of mechanisms by which immunoglobulins and complement may bind to and opsonize platelets or other hemic cells. Note that platelet surface-associated immunoglobulin (PSAIg) is not necessarily caused by autoantibodies. **1.** Autoantibody binding to specific autoantigens is Fab mediated; this occurs in primary immune-mediated thrombocytopenia (IMT). **2.** Alloantibody binding is also Fab mediated, but antibodies bind to specific cell alloantigens; this occurs in transfusion reactions and neonatal alloimmune thrombocytopenia. **3–5**. In secondary IMT, Fab-mediated binding may occur to adsorbed antigens from infectious agents, drugs, or neoplasms (**3**), to surface sites perturbed by other molecules (**4**), or to a combination of adsorbed antigen and perturbed membrane (**5**). **6.** In secondary IMT, PSAIg may also be bound as immune complexes via Fc receptors in some species (e.g. primates). **7.** Immunoglobulin may bind via complement-mediated immune adherence in species with platelet complement receptors. **8.** With in vitro indirect assays of serum or plasma, increased PSAIg may be a storage artifact resulting from nonspecific binding of immunoglobulins that have aggregated during freezing. **9.** Complement deposition may occur as an innocent bystander phenomenon, with cold-reacting antibodies that dissociate from the cells before testing, or along with any complement-activating PSAIg.

Infectious Diseases

Thrombocytopenia is commonly associated with infections caused by viruses, bacteria (especially the rickettsials), protozoa, fungi, and nematodes.[6,25,32,58] As with neoplasia, the pathogeneses of these infectious thrombocytopenias may be complicated, involving various combinations of suppressed platelet production, altered platelet distribution, increased consumption, or immune-mediated and non-immune platelet destruction.

Rickettsial diseases are common infectious causes of thrombocytopenia in endemic areas, but the pathogeneses of the thrombocytopenias are poorly understood. Immune-mediated platelet destruction is thought to contribute to the thrombocytopenia of acute ehrlichiosis caused by *Ehrlichia canis*,[67] and positive Coombs' tests have suggested that immune-mediated disease may not be restricted to platelets.[66] PSAIg or serum platelet-bindable immunoglobulins have been increased in some naturally and experimentally infected dogs.[41,67] Immune mechanisms may contribute to thrombocytopenias in other rickettsial infections, including infection with *Anaplasma phagocytophilum*[3] and *Rickettsia rickettsii*.[26]

Cats with FIV and FeLV infections may develop thrombocytopenias with immune components (see Chapters 55 and 62). Immune-mediated platelet destruction appears to contribute to the thrombocytopenia associated with equine infectious anemia (EIA), but thrombocytopenia in EIA is likely multifactorial and caused partly due to impaired platelet production.[15] Puppies experimentally infected with canine distemper virus develop marked thrombocytopenia and increased PSAIgG.[1] A complement-independent, immune

complex-induced destruction of platelets appeared to contribute to thrombocytopenia. Dogs[60] and other species[20] vaccinated with modified live virus (MLV) distemper vaccines may develop mild to occasionally marked transient decreases in platelet concentrations. While clinical purpura has reportedly followed 1–21 days after routine clinical MLV vaccinations,[20] further studies of these clinical observations have not been published.

Immune-mediated platelet destruction likely contributes to the thrombocytopenia occurring commonly in dogs with histoplasmosis, babesiosis, and leishmaniasis, and it may play a role in thrombocytopenic dogs with other fungal or nematode infections.[8,14,42,62] Serum from dogs with leishmaniasis contains platelet-bindable IgM and sometimes IgG, suggesting a role for immune-mediated platelet clearance, but the nature of the platelet-immunoglobulin interaction is not known and may involve immune complexes and immune adherence.[64]

Drugs

Drugs produce thrombocytopenia by many mechanisms, including immune-mediated platelet destruction by drug-induced antibodies that may be detectable by indirect assays of serum or plasma (see Chapters 14–16). Drug-induced antibodies may be drug-dependent, requiring the presence of the drug or its metabolite for platelet binding, or they may occasionally be drug-independent, behaving like autoantibodies that bind in the absence of drug. Some drug-dependent antibodies bind to cells in the form of drug-antibody complexes. Others bind directly to either membrane cryptantigen exposed by the presence of the drug or to drug-protein neoantigens on the cell surface. Drug-induced IMT has been suspected with several drugs, most notably sulfonamides in dogs,[40,42] methimazole in cats,[50] and penicillin or trimethoprim-sulfadoxine in horses.[43]

ALLOIMMUNE THROMBOCYTOPENIAS

Although alloimmune thrombocytopenias can be classified as types of secondary IMT, they are considered separately here because of their distinct pathogeneses. They result from the production of alloantibodies that target platelet alloantigens and cause platelet destruction, primarily by phagocytosis of the opsonized platelets. Exposure to foreign platelet alloantigens may occur with pregnancy or blood transfusion, causing neonatal alloimmune thrombocytopenia or post-transfusion purpura, respectively.

Neonatal alloimmune thrombocytopenia occurs when maternal antibodies to paternal epitopes on neonatal platelets are passively transferred through the placenta or colostrum. These antibodies circulate in the blood where they bind to neonatal platelets and lead to their premature destruction. The disorder is self-limiting because of the inherent lifespan and amounts of transferred immunoglobulins. Neonatal alloimmune thrombocytopenia is uncommon, but has been described in pigs, horses, and possibly mules.[10,19,54] The diagnosis of neonatal alloimmune thrombocytopenia is mostly one of exclusion, bacterial or viral infections being the most common differential. Where available, antibody assays may be applied to support a diagnosis of alloimmune thrombocytopenia by documenting the presence of PSAIg in the neonate, the absence of maternal PSAIg, and the presence of maternal antibody reactivity with paternal and neonatal, but not maternal, platelets. Specific therapy may not be required for this self-limiting condition, but glucocorticoids may be useful in severely affected newborns. Platelet transfusions are indicated if hemorrhage is severe or if central nervous system hemorrhage is suspected. Compatible platelets can be obtained from the dam, but they should be washed to remove plasma antibodies. Future offspring from the same mating pair are at risk of developing the same disease.

Post-transfusion purpura is characterized by severe thrombocytopenia developing several days after transfusion of a patient previously sensitized to a platelet alloantigen by pregnancy or transfusion. Re-exposure to the platelet alloantigen induces a high titer of antibodies targeting the transfused platelets. Severe thrombocytopenia occurs because the patient's own platelets are also destroyed, despite being negative for the target alloantigen when tested after recovery. Proposed mechanisms include epitope spreading, the development of an oligoclonal immune response that targets non-polymorphic autoepitopes in addition to the inciting alloepitope. Development of thrombocytopenia within 1–2 weeks of a blood transfusion should prompt consideration of this clinical entity in veterinary species (see Chapter 100).[42]

Acronyms and Abbreviations

APTT, activated partial thromboplastin time; AT, antithrombin; CBC, complete blood count; CDV, canine distemper virus; DIC, disseminated intravascular coagulation; EDTA, ethylenediaminetetraacetic acid; FDP, fibrin/fibrinogen degradation product; GPIIb-IIIa, glycoprotein IIb-IIIa; HUS, hemolytic uremic syndrome; IMT, immune mediated thrombocytopenia; MPC, mean platelet component; MPS, mononuclear phagocytic system; MPV, mean platelet volume; PCR, polymerase chain reaction; PSAIg, platelet surface associated immunoglobulin; PT, prothrombin time; TPO, thrombopoietin; TTP, thrombocytopenic thrombotic purpura; VWF, von Willebrand factor.

Thrombocytopenia is generally an acquired pathologic process that accompanies an underlying disease or disorder and is a common finding in many species.[22,27,64] Uncomplicated, mild to moderate thrombocytopenia is usually subclinical and affected animals are either asymptomatic or have clinical signs (e.g. fever, lethargy, anorexia) that are related to the underlying condition. Thrombocytopenia is often first recognized when a decreased platelet concentration is identified following review of a blood smear or a complete blood count (CBC). Spontaneous bleeding disorders due to uncomplicated thrombocytopenia are rare when platelet concentrations are greater than 20,000–30,000/µL.[2,27]

Animals with severe thrombocytopenia or thrombocytopenia complicated by a coagulopathy, vascular disorder, or functional platelet defect often present with clinical findings typical of a defect in primary hemostasis. Findings may include petechiae or ecchymoses (often on the ventral abdomen, inner thighs, or mucous membranes), epistaxis, gastrointestinal bleeding, gingival bleeding, hematuria, vaginal bleeding, or ocular hemorrhage. Excess hemorrhage following trauma, surgery, and venipuncture is sometimes noted.[56,66]

PLATELETS AND NORMAL HEMOSTASIS

Platelet Function

Platelets play a central role in thrombus formation and maintenance of vascular integrity. Initially, platelets are recruited and help to form the primary hemostatic plug which can repair small lesions in the vascular wall. Subsequently, platelets play a role in fibrin production and formation of the more stable secondary hemostatic plug.[66]

When a blood vessel is injured, platelets initially adhere to the defect in a von Willebrand factor (VWF)-dependent manner, particularly under high shear con-

ditions. Following adhesion, platelets become activated and expose fibrinogen binding sites on membrane integrin $\alpha_{IIb}\beta_3$, also known as glycoprotein IIb-IIIa (GPIIb-IIIa). Adhesive proteins, such as fibrinogen and VWF, bind to $\alpha_{IIb}\beta_3$ on adjacent platelets and form a bridge to support platelet aggregation. Activated platelets release a variety of agonists that activate other platelets (e.g. thromboxane, adenosine diphosphate), promote vessel healing (e.g. platelet derived growth factor), or play a role in coagulation (e.g. fibrinogen, factor V). Activated platelets shift negatively charged phospholipids (e.g. phosphatidylserine) from the inner membrane surface to the outer membrane where they provide binding sites for coagulation enzymes and cofactors.[28,38] Finally, platelets facilitate wound closure by undergoing contractile processes that lead to clot retraction.[66]

Platelet Kinetics

Platelet concentration in the blood reflects a balance between platelet production and platelet consumption, destruction or redistribution to the vasculature of organs. In most healthy animals, platelet lifespans are approximately 5–10 days.[66] Platelets are continually consumed during repair of small vascular defects. Aged platelets are removed by macrophages. The spleen appears to play a major role in determining platelet survival. Platelet lifespans are significantly longer in splenectomized dogs when compared to healthy dogs with spleens.[11]

Studies in people have shown that 10^{11} platelets are produced every day and platelet population turnover occurs every 8–9 days. Platelets are produced by cytoplasmic fragmentation of megakaryocytes, with each megakaryocyte producing thousands of platelets.[14] In response to increased demand, platelet production can increase 20 fold or more.[30] Platelet production is affected by a number of growth factors (see Chapter 9); however, thrombopoietin (TPO) plays the primary role in regulating megakaryopoiesis and thrombopoiesis.[30] Thrombopoietin is primarily produced by hepatocytes, stromal cells in the bone marrow, and renal epithelial cells. In healthy animals, TPO is constituitively produced and the blood concentration is generally inversely related to platelet mass.[14] Thrombopoietin is bound to receptors on platelets and megakaryocytes. When circulating platelet mass is decreased, the concentration of unbound TPO available to stimulate megakaryopoiesis and thrombopoiesis is increased. Production of TPO is increased in some disease states. In inflammation, interleukin 6 has been shown to induce TPO production by the liver.[14]

DIAGNOSTIC ASSAYS FOR THROMBOCYTOPENIA

The laboratory evaluation of thrombocytopenia is covered in greater depth in Chapter 77. A list of common diagnostic assays is found in Table 79.1. When thrombocytopenia is detected by an automated hematology analyzer, it is important to first examine a blood smear to check for platelet clumps, estimate platelet concentration to confirm the accuracy of an automated platelet count, and evaluate platelet morphology. If clumps are present then the automated platelet concentration is of minimal value. Collection of a fresh blood sample without clumping would be required to determine an accurate platelet concentration.

TABLE 79.1 Diagnostic Tests for Thrombocytopenia

Assay	Comments[a]
Complete blood count	
Platelet concentration	Automated or manual Confirm and track thrombocytopenia
Mean platelet volume	Increase suggests enhanced thrombopoiesis
Mean platelet component	Decrease suggests platelet activation
Blood smear examination	Detect platelet clumps Estimate platelet concentration Detect organisms or neoplastic cells Detect large platelets – suggests increased production Evaluate for inflammatory leukogram
Hemostasis profile	Evaluate for DIC
Bone marrow examination	Assess megakaryocyte density and morphology Detect organisms, neoplastic cells, necrosis, inflammation, myelofibrosis
Serology	Detect exposure to infectious agents
PCR	Detect infectious agents
Flow cytometry	Detect PSAIg Measure reticulated platelets to assess platelet production Detect activation markers

[a]DIC, disseminated intravascular coagulation; PSAIg, platelet surface-associated immunoglobulin.

Once thrombocytopenia is confirmed, additional qualitative and quantitative data are available from a routine CBC and provide useful diagnostic information. Identification of increased numbers of large platelets, also known as megaplatelets, on a blood smear suggests increased thrombopoiesis and may be associated with an increased mean platelet volume (MPV).[66] Increased MPV in an animal with thrombocytopenia suggests adequate to increased platelet production in the bone marrow.[29,69] Decreased mean platelet component (MPC) suggests in vivo platelet activation.[48,62]

Additional diagnostic tests are often required to determine the underlying cause of the thrombocytopenia. The decision of which tests to perform depends on clinical presentation and results of other diagnostic findings. A complete hemostasis profile (prothrombin time [PT], activated partial thromboplastin time [APTT], fibrinogen concentration, fibrin degradation products [FDPs], D-dimer, and antithrombin [AT] activity) is

used to detect disseminated intravascular coagulation (DIC). Examination of blood smears, cytology smears, or bone marrow samples may reveal infectious organisms or neoplastic cells. Serology or polymerase chain reaction (PCR) testing is indicated to identify an infectious process. Flow cytometry is used to detect reticulated platelets, platelet surface-associated immunoglobulin (PSAIg), or activated platelets.[75] Reticulated platelets are immature platelets with increased amounts of RNA. Measurement of reticulated platelets may help differentiate thrombocytopenia due to shortened platelet survival from thrombocytopenia due to platelet production disorders. Reticulated platelets were increased in dogs and horses with destructive or consumptive thrombocytopenia.[57,78] Identification of PSAIg may support a diagnosis of immune-mediated disease but these assays do not differentiate primary from secondary immune-mediated thrombocytopenia (IMT).[31,78] Detection of activated platelets may identify animals that are in a prothrombotic state or in DIC.[48,62]

Bone marrow examination may be useful if a platelet production problem is suspected. If thrombocytopenia is due to a production disorder, megakaryocytes should be decreased or totally absent. Neoplastic cells or etiologic agents may be identified. If thrombocytopenia is due to platelet destruction or consumption, megakaryocytes should be normal or increased in number. The value of bone marrow examination as an initial diagnostic assay in animals with thrombocytopenia is debatable. A recent study in thrombocytopenic dogs reported that bone marrow cytology provided useful diagnostic or prognostic information in a minority of cases, suggesting that bone marrow aspiration was most likely to be useful in animals with thrombocytopenia that was unresponsive to therapy or was accompanied by bicytopenia or pancytopenia.[46] Immunofluorescence assays may be used to detect anti-megakaryocyte antibodies on bone marrow cytology preparations; however, the sensitivity and specificity of these assays are low.[66]

BASIC MECHANISMS FOR THROMBOCYTOPENIA

Thrombocytopenia occurs when platelets are removed from circulation faster than they are replaced from the bone marrow. This occurs because of decreased platelet survival or decreased platelet production. Basic mechanisms for decreased platelet survival include loss, distribution disorders, consumption with excessive thrombi formation, or destruction. Decreased platelet production results from impaired megakaryopoiesis or thrombopoiesis. Often multiple mechanisms are involved in the pathogenesis of thrombocytopenia in an animal.

Platelet Loss

Thrombocytopenia, usually mild to moderate in severity, may follow external hemorrhage. Platelet concentration decreased by up to 50% in dogs with experimental acute, severe blood loss.[66] Thrombocytopenia due to blood loss is usually self-limiting and resolves when the hemorrhage resolves. When severe thrombocytopenia occurs in conjunction with hemorrhage, it is likely that the hemorrhage is due to thrombocytopenia and not that the thrombocytopenia is due to hemorrhage.

Dogs that have anticoagulant rodenticide toxicity frequently have thrombocytopenia and the thrombocytopenia may be severe.[39] Likely mechanisms for thrombocytopenia include loss associated with hemorrhage and platelet consumption during formation of hemostatic plugs at sites of hemorrhage.[66]

Platelet Consumption

Accelerated platelet consumption occurs with disorders that cause widespread damage to endothelial cells or trigger massive activation of coagulation via other mechanisms. In people, well characterized platelet consumptive disorders include DIC and thrombotic microangiopathies such as thrombocytopenic thrombotic purpura (TTP) and hemolytic uremic syndrome (HUS).

Thrombotic Microangiopathies

Thrombotic microangiopathies are uncommon, life-threatening conditions characterized by disseminated thrombosis in the microvasculature, secondary ischemic organ damage, microangiopathic hemolytic anemia with schistocytes, and thrombocytopenia. Laboratory evidence of abnormalities in coagulation and fibrinolysis pathways is generally lacking.[42] Thrombotic microangiopathies are associated with inherited or acquired disorders and the underlying pathogenesis is often heterogeneous.[80]

Some people consider HUS and TTP to be variants of the same condition and differentiation of the two disorders is challenging.[42,80] Based upon clinical presentation, HUS is associated with more severe renal insufficiency. The most common form of HUS occurs primarily in children and follows a period of infectious diarrhea, particularly involving enterohemorrhagic *Escherichia coli*. The atypical form of HUS in humans is often associated with inherited or acquired defects in complement regulation.[26,49,80] Although rare, HUS syndromes have been described in dogs, cats, cattle, and horses.[3,13,15,55]

When compared to HUS, the clinical presentation of TTP is associated with frequent neurologic dysfunction, less severe renal insufficiency, and evidence of microthrombi that are rich in platelets and VWF. Recent findings indicate that many people with TTP have inherited or acquired deficiency of ADAMTS13, a metalloprotease that cleaves VWF and prevents accumulation of the most thrombogenic, high relative molecular mass forms of VWF in the blood.[49,80] TTP has not been well-documented in veterinary species; however, spontaneous TTP has been reported in pigs and there are animal models of experimentally induced TTP.[43,59]

Disseminated Intravascular Coagulation

Unlike HUS and TTP, DIC is commonly diagnosed in veterinary species. Disseminated intravascular coagulation differs from HUS and TTP in that patients with DIC typically have laboratory evidence of abnormalities in coagulation and fibrinolytic pathways.[42] DIC is never a primary condition; it occurs secondary to a wide variety of disorders that are characterized by excessive and unregulated coagulation. DIC varies from overt or uncompensated to non-overt or compensated. In non-overt DIC, excess thrombin is generated but is balanced by inhibitory pathways. In overt DIC, there is widespread microthrombi formation and bleeding may result from consumption of coagulation factors and platelets.[37,67] Clinical signs vary from subclinical in non-overt DIC to signs of severe, life threatening hemorrhage, shock or multiorgan failure in overt DIC. Clinical signs referable to the underlying condition are often present.[66] The consequences of hemorrhage are easily recognized; however, clinical signs and death are often attributable to organ dysfunction resulting from microthrombi formation and resulting tissue hypoxia.[37,67]

The pathogenesis of DIC is further discussed in Chapter 88. Briefly, DIC is characterized by overwhelming activation of coagulation and subsequent disruption of the normal regulatory mechanisms. Widespread fibrin deposition results due to excessive thrombin generation, loss or inhibition of physiologic anticoagulants, impaired fibrinolysis, and release of proinflammatory cytokines.[19] Triggers for thrombin generation generally include extensive vascular disruption or massive release of tissue factor from damaged tissue.[66] Snake venoms may directly activate coagulation factors. Specific disorders associated with DIC include infections (e.g. septicemia, endotoxemia), malignant neoplasia, severe tissue injury (e.g. trauma, surgery, burns), immune-mediated disorders (e.g. immune-mediated hemolytic anemia), conditions that cause blood stasis (e.g. shock, severe dehydration), heatstroke, systemic hypersensitivity reactions, pancreatitis, snakebites or hepatic failure.[37,56,66]

Thrombocytopenia due to DIC varies from mild to severe. Unfortunately, no single test is diagnostic for DIC. Tests that detect markers of thrombin activation (e.g. prothrombin fragments 1+2, thrombin-antithrombin complexes) or fibrin generation (e.g. fibrinopeptide A) are sensitive; however, they are difficult to run and lack specificity.[67] The International Society on Thrombosis and Haemostasis proposed a diagnostic algorithm to diagnose overt DIC in people using platelet concentration, PT, fibrinogen concentration, and FDP or D-dimer. A more complex diagnostic algorithm adding evaluation of abnormal trends in coagulation screening data, AT activity and protein C activity has been proposed to detect non-overt DIC.[70]

The diagnosis of DIC in veterinary species usually relies on identifying abnormalities involving multiple hemostatic pathways. Laboratory findings include evidence of thrombocytopenia, coagulation defects (prolonged APTT or PT, hypofibrinogenemia), enhanced fibrinolysis (increased FDPs or D-dimer), and loss of natural anticoagulants (e.g. decreased AT activity). Identification of schistocytes or keratocytes on a blood smear is also supportive.[66]

Platelet Destruction

Immune-mediated Platelet Destruction

Immune mediated thrombocytopenia (IMT) is commonly diagnosed in dogs and sporadically recognized in other species. IMT occurs when antibodies bind to platelets and cause shortened platelet lifespan due to complement-mediated lysis or platelet removal by the mononuclear phagocytic system (MPS). Direct T cell mediated cytotoxicity as well as impaired megakaryopoiesis and thrombopoiesis are implicated in the pathogenesis of IMT.[65,81]

With primary IMT, the immune response is directed against autoantigens and no underlying disease is identified. In people with primary IMT, the most common target antigens are located on integrin $\alpha_{IIb}\beta_3$.[81] Target antigens are rarely identified in animals with primary IMT. Antibodies directed against $\alpha_{IIb}\beta_3$ and GPIb were detected in dogs with primary IMT.[40] With secondary IMT, the immune response is associated with an underlying disorder such as systemic immune-mediated diseases (e.g. immune-mediated hemolytic anemia), neoplasia (e.g. lymphoma, hemic neoplasia, various solid tumors), drug administration, and infections.[40,66]

The diagnosis of IMT generally relies on exclusion of other causes of thrombocytopenia and response to immunosuppressive therapy. Detection of PSAIg is supportive but testing is not frequently performed in veterinary species.[66]

The pathogenesis and diagnosis of IMT is covered in more depth in Chapter 78.

Non-immune-mediated Platelet Destruction

Non-immune platelet destruction occurs in disorders that cause platelet aggregation, phagocytosis, or lysis independent of antibody or complement. Non-immune platelet destruction is often a feature of thrombocytopenia due to infections, drugs, or neoplasia. These are disorders with complex mechanisms and are discussed separately below. Potential mechanisms for non-immune destruction include direct damage to platelets causing lysis or premature removal, release of substances that directly activate platelets, cytokine-mediated activation of the MPS leading to enhanced phagocytosis of platelets, hemophagocytic syndrome, or phagocytosis by neoplastic cells.[1,66,76] Hemophagocytic syndrome is characterized by a non-neoplastic proliferation of activated macrophages and is associated with multiple cytopenias in the blood. Hemophagocytic syndrome occurs secondary to immune-mediated disorders, infections, and neoplasia. In some cases, an underlying condition cannot be identified.[76]

Platelet Distribution Disorders

The total platelet mass in any animal consists of platelets freely circulating in the blood and platelets reversibly distributed in the vascular systems of tissues, particularly the spleen, liver and bone marrow. In some healthy animals, 30% or more of total platelet mass is stored in the spleen.[8] Redistribution thrombocytopenia occurs when platelets become reversibly sequestered in tissues. Total platelet mass is not affected so increased thrombopoiesis is not expected. Disorders associated with increased platelet destruction are not considered redistribution disorders. Platelet pooling has been reported in the liver and spleen of dogs with hypothermia and in the lungs of dogs with endotoxemia.[66] Mild to moderate thrombocytopenia may result from sequestration in animals with any condition associated with splenomegaly or hepatomegaly and increased blood pooling.[8]

Clinical hemorrhage is not expected with platelet sequestration unless the underlying disorder is complicated by platelet dysfunction or a coagulation disorder. Clinical signs are generally limited to those associated with the underlying disorder. Diagnosis of redistribution thrombocytopenia relies on discovering the cause for organomegaly and ruling out other potential causes of thrombocytopenia.

Platelet Production Disorders

Bone marrow production disorders are covered in Chapters 16–19. Decreased platelet production may result from disorders that specifically target megakaryocytes or from diseases that have more generalized effects to impact production of multiple hematopoietic cell lines directly or by altering the microenvironment in the bone marrow. Bicytopenia or pancytopenia in the blood suggests generalized bone marrow disease.[66]

Selective megakaryocytic hypoplasia is uncommon. Acquired immune-mediated amegakaryocytic thrombocytopenia has been reported in dogs and cats.[35,83] Megakaryocytic hypoplasia can be associated with drugs, infections or neoplasia. Neoplasia may be metastatic to the bone marrow or hemic in origin, causing replacement of the normal hematopoietic cells. Other causes of hypoplasia include irradiation and myelonecrosis.[66] Hereditary causes of megakaryocytic hypoplasia are documented in people but have been rarely reported in veterinary species.[5,32]

High quality bone marrow samples are required to adequately assess bone marrow production. Decreased megakaryocytes should be interpreted with caution in an aspirate, and core biopsy samples are recommended for definitive diagnosis of megakaryocytic hypoplasia.[63]

Disorders with Complex Mechanisms

Thrombocytopenia has been frequently associated with infection, neoplasia and drug therapy in veterinary species.[22,27,64] In many cases, the pathogenesis of the thrombocytopenia is unclear and likely multifactorial in origin.

Infectious Thrombocytopenia

Thrombocytopenia frequently accompanies infections. [22,25,27,64] Some of the organisms associated with thrombocytopenia are listed in Table 79.2. Many organisms impair platelet production in the bone marrow by direct infection of megakaryocytes, stimulation of an immune response targeting megakaryocytes, or stimulation of an inflammatory response in the bone marrow and production of myelosuppressive cytokines. Platelet survival is often decreased. Proposed pathophysiologic mechanisms include increased platelet consumption due to platelet activation and associated DIC, direct infection of platelets causing destruction or removal by the MPS, secondary IMT, or platelet sequestration in the spleen or other tissues.[56,66]

With endotoxemia or some bacterial infections, platelets are activated due to a direct effect of endotoxins or inflammatory cytokines.[61] Inflammation leads to production of platelet stimuli (e.g. thrombin, platelet activating factor) by activated endothelial cells, neutrophils, monocytes and platelets.[61,72] Activated platelets enhance tissue factor expression by monocytes, leading to activation of the coagulation cascade.[54,61] Endothelial cells become injured and consequently decrease production of inhibitory substances such as prostaglandin I_2. Activated platelets express P selectin which plays a role in platelet adhesion to neutrophils and monocytes.[77] Inflammatory cytokines mediate activation of the MPS which may further enhance phagocytosis of platelets.[1]

Rickettsial bacteria are commonly associated with thrombocytopenia. Acute infection with *Ehrlichia canis* is associated with immune-mediated and non-immune platelet destruction in dogs.[74] Chronic infection is associated with bone marrow hypoplasia.[66] Other rickettsial bacteria associated with thrombocytopenia include *Anaplasma platys* in dogs, *Rickettsia rickettsii* in dogs, *Neorickettsia risticii* in horses, and *Anaplasma phagocytophilum* in several species.[18,41] *A. phagocytophilum*, the cause of granulocytic anaplasmosis (granulocytic ehrlichiosis), was reported to directly infect megakaryocytes but to not alter platelet production. Immune responses were implicated in the pathogenesis of the thrombocytopenia.[21] The pathogenesis of thrombocytopenia in *A. platys* infection is unknown but may involve sequestration or removal of infected platelets by macrophages. In experimentally infected dogs, PCR testing was positive for the organism in the spleen and bone marrow.[16] Vasculitis and platelet consumption occur in *R. rickettsii* infection and may be the primary causes for thrombocytopenia. The cause of thrombocytopenia in *N. risticii* infection is unclear but likely involves consumption due to DIC.[56] Other bacterial infections (e.g. leptospirosis, salmonellosis, borreliosis, bartonellosis) are sporadically associated with thrombocytopenia.[6,18,56,66]

Viral infections are well-recognized causes of thrombocytopenia in animals. In dogs, thrombocytopenia

TABLE 79.2 Reported Causes of Thrombocytopenia in Dogs, Cats, Horses and Cattle

Species	General Category	Specific examples[a]
Dog	Infectious	Viruses: distemper, herpes virus, infectious hepatitis, parvovirus Bacteria: septicemia, endotoxemia, *Anaplasma phagocytophilum, A. platys, Ehrlichia canis, Rickettsia rickettsii,* leptospirosis, salmonellosis, bartonellosis, borreliosis Fungi: histoplasmosis, candidiasis Protozoa: babesiosis, leishmaniasis Parasites: heartworm disease
	Neoplasia	Hemangiosarcoma, lymphoproliferative and myeloproliferative neoplasia, various solid tissue neoplasms
	Drugs/toxins	Antibiotics (e.g. sulfonamides, cephalosporin); chemotherapeutic drugs (e.g. cyclophosphamide, doxorubicin), anti-inflammatory drugs (e.g. phenylbutazone, carprofen), phenobarbital, thiacetarsamide, estrogen, snakebites
	Miscellaneous	IMT, DIC, distribution disorders
Cat	Infectious	Viruses: FeLV, FIV, FIP, parvovirus Bacteria: septicemia, endotoxemia, *A. phagocytophilum, Mycoplasma* sp., salmonellosis, bartonellosis Fungi: histoplasmosis Protozoa: cytauxzoonosis, toxoplasmosis Parasites: heartworm disease
	Neoplasia	Lymphoproliferative and myeloproliferative neoplasia, various solid tissue neoplasms
	Drugs/toxins	Chemotherapeutic drugs, griseofulvin, methimazole, propylthiouracil
	Miscellaneous	IMT, DIC, distribution disorders
Horse	Infectious	Viruses: EIA, EVA, VEE Bacteria: septicemia, endotoxemia, *A. phagocytophilum, Neorickettsia risticii,* salmonellosis
	Neoplasia	Lymphoproliferative and myeloproliferative neoplasia, various solid tissue neoplasms
	Drugs/toxins	Phenylbutazone, trimethoprim, penicillin, trichothecene mycotoxin, snakebites
	Miscellaneous	IMT, neonatal alloimmune thrombocytopenia, DIC, gastrointestinal disorders, distribution disorders
Cattle	Infectious	Viruses: BVD Bacteria: septic metritis/mastitis, septicemia, endotoxemia, salmonellosis Protozoa: babesiosis, theileriosis
	Drugs/toxins	Bracken fern toxicity, trichothecene mycotoxin
	Miscellaneous	IMT, DIC, distribution disorders, displaced abomasums

[a]BVD, bovine viral diarrhea; DIC, disseminated intravascular coagulation; EIA, equine infectious anemia; EVA, equine viral arteritis; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; FIP, feline infectious peritonitis; IMT, immune-mediated thrombocytopenia; VEE, Venezuelan equine encephalitis.

occurs with canine distemper virus (CDV), herpes virus, infectious hepatitis, or parvovirus infection. The thrombocytopenia in CDV infection results from viral damage to platelets, secondary IMT, and decreased production due to direct infection of megakaryocytes.[4] Thrombocytopenia associated with herpes virus or infectious hepatitis virus infection results from endothelial damage and DIC.[6] In cats, thrombocytopenia is associated with feline infectious peritonitis (FIP), feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), and parvovirus infection. Thrombocytopenia in FIP is multifactorial and results from vasculitis, secondary IMT, direct viral damage to platelets, and DIC.[7] In horses, thrombocytopenia occurs with equine infectious anemia (EIA), equine viral arteritis, and Venezuelan encephalitis virus infection. Thrombocytopenia in EIA results from cytokine mediated impairment of platelet production, secondary IMT, and non-immune platelet destruction.[10,58] In cattle, thrombocytopenia is associated with bovine viral diarrhea virus and primarily results from megakaryocyte damage and subsequent decreased platelet production.[73] In pigs, thrombocytopenia follows infection with African swine fever or classical swine fever (hog cholera). In classical swine fever, thrombocytopenia results from direct damage to platelets, platelet activation and removal by the MPS, DIC, and impaired megakaryopoiesis.[20,52]

Other agents associated with thrombocytopenia include protozoa (e.g. babesiosis, cytauxzoonosis, leishmaniasis, theileriosis, and toxoplasmosis), fungi (e.g. disseminated candidiasis, histoplasmosis), and metazoan parasites (e.g. heartworm infection in dogs and cats).[6,22,27,56,66]

Infection-induced thrombocytopenia is often suspected based upon history and clinical findings. Thrombocytopenia varies from mild to severe. Microscopic examination of blood, bone marrow or cytology smears may identify infectious agents. If organisms are not visible microscopically, serology, culture, or molecular (e.g. PCR) techniques may be diagnostic.

Drug-induced Thrombocytopenia

Thrombocytopenia is often suspected following exposure to drugs or toxins. Some drugs associated with thrombocytopenia in veterinary species are included in Table 79.2. Drug-induced blood cell disorders are covered in Chapter 16 and only a brief summary is provided here. With some drugs (e.g. chemotherapeutic drugs), thrombocytopenia is dose-dependent and predictable.[23,66] Chemotherapeutic-induced thrombocytopenia is usually transient and resolves when the drug is withdrawn or dosage is altered. With other drugs (e.g. potentiated sulfas), thrombocytopenia is an idiosyncratic and unpredictable result.[71]

Many drugs are known to have myelosuppressive effects. Secondary IMT, targeting either platelets or megakaryocytes, is frequently implicated as a mechanism for drug-induced thrombocytopenia. In most cases, the immune response occurs only when the drug or drug metabolite is present.[82] Antibodies may target the drug or metabolite adsorbed to the platelet membrane, a complex formed between the drug and a platelet antigen, or a hidden antigen exposed on the platelet membrane.[66,82] Subsequent binding of antibody targets the platelet for removal by the MPS. Rarely, drugs cause IMT that is drug-independent and persists after the drug is removed. These types of drugs appear to stimulate an immune response that targets unaltered platelet antigens.[66,82] Drug-induced IMT is often difficult to prove in these situations. PSAIg has been detected in dogs following administration of sulfonamides and in horses following administration of trimethoprim and penicillin.[36,45]

Some drugs directly activate platelets causing increased consumption, or injure platelets causing removal by the MPS. Snake venoms may either directly activate platelets or may cause the production of substances such as thrombin that cause platelets to aggregate.[24]

Diagnosis of drug associated thrombocytopenia generally relies on a history of thrombocytopenia occurring following drug administration and normalization of platelet concentration following cessation of drug therapy.

Neoplasia Associated Thrombocytopenia

Thrombocytopenia is commonly attributed to neoplasia.[22,23,27,63] In dogs with neoplasia, thrombocytopenia was detected in 10–36% of affected animals.[8] Lymphoma, carcinoma, hemangiosarcoma, and hematopoietic neoplasia comprised the majority of cases. Thrombocytopenia was frequently attributed to chemotherapy, decreased platelet production, or DIC.[23]

Decreased platelet production may result from myelophthisis, secretion of estrogen by neoplastic cells or myelosuppressive chemotherapeutic drugs.[8] Disseminated intravascular coagulation is a frequent complication of neoplasia. In one study, over 10% of dogs with malignant neoplasia had DIC. Hemangiosarcoma, mammary carcinoma and adenocarcinoma of the lung were at greatest risk.[44] Neoplasia is the most commonly recognized cause of DIC in cats.[17]

Secondary IMT has been implicated as a mechanism for thrombocytopenia in a variety of hemic and nonhemic neoplasias.[8,34,63] Other proposed mechanisms for neoplasia-induced thrombocytopenia include distribution disorders with platelet pooling (particularly with large vascular tumors), platelet loss with tumor associated hemorrhage, or platelet destruction by neoplastic cells.[8,66] Thrombocytopenia was identified in 88% of dogs with hemophagocytic histiocytic sarcoma and phagocytosis of platelets by neoplastic cells was believed to play a role.[47]

Clinical signs are often related to the underlying neoplasm; thrombocytopenia may or may not be severe enough to cause a defect in primary hemostasis. Diagnosis is based upon cytologic or histopathologic identification of neoplastic cells. If the neoplasia is hemic in origin, then abnormal cells may be present in the blood.

Miscellaneous Causes of Thrombocytopenia

Breed Associated Thrombocytopenia

Thrombocytopenia is an incidental finding in certain dog breeds. Affected dogs are healthy and do not have evidence of a bleeding disorder. Greyhounds often have thrombocytopenia when compared to non-breed specific reference intervals. Platelet concentrations are typically greater than 100,000/μL. In one study, none of the samples tested had detectable PSAIg, suggesting that the thrombocytopenia is not immune-mediated in origin.[60] An inherited thrombocytopenia occurs in approximately 50% of Cavalier King Charles Spaniels (see Chapter 82). Macrothrombocytes are present in many dogs, making automated platelet counts unreliable.[9] Recent studies suggest that there is a mutation in the gene encoding beta1-tubulin, leading to unstable microtubule formation in megakaryocytes and altered proplatelet formation.[12]

Pseudothrombocytopenia

Pseudothrombocytopenia occurs when platelets in a sample are excluded from counting for any reason. Decreased automated platelet concentration should always be confirmed by microscopic examination of a blood smear. Small clumps may not be detected by automated analyzers and still falsely lower measured platelet concentrations.[68] A recent study in cats reported that platelet concentrations determined with an impedance hematology analyzer were decreased in a majority of animals tested; however, examination of a blood smear confirmed thrombocytopenia in only 3.1% of cats. The disparity was attributed to the presence of platelet clumps and inability to separate platelets and erythrocytes based upon size.[51] When clumps are detected in a sample, the measured platelet concentration is of minimal value and collection of a new blood sample without clumping is required to obtain an accu-

rate platelet concentration. Platelet concentration determined by analyzers that use a buffy coat technique appear to be less affected by platelet clumping than impedance hematology analyzers.[33]

Proper blood collection and handling are critical to minimize the clumping that occurs when platelets become activated and form aggregates. Clumping can be minimized by atraumatic venipuncture or addition of platelet inhibitors to the sample.[50] Platelet clumps may form in vitro in an EDTA-dependent manner. In people, EDTA causes a conformational change in $\alpha_{IIb}\beta_3$ that exposes normally hidden epitopes that bind to circulating antibodies. EDTA-dependent pseudothrombocytopenia has rarely been reported in dogs, horses and pigs; however, the underlying mechanism has not been determined.[79]

Samples with increased megaplatelets may have falsely low platelet concentrations because large platelets are excluded by some automated hematology analyzers. In these animals, manual platelet counts using a hemocytometer and microscope may provide a more accurate platelet concentration.[53]

Acronyms and Abbreviations

CIMF, Chronic idiopathic myelofibrosis; CML, chronic myeloid leukemia; CMPD, chronic myeloproliferative disease; ECMP, European clinical, molecular and pathological criteria; ET, essential thrombocythemia; GM-CSF, Granulocyte monocyte colony stimulating factor; IL, interleukin; JAK2, Janus kinase 2; MCV, mean cell volume; PV, Polycythemia vera; PVSG, Polycythemia Vera Study Group; SD, standard deviation; SDF-1, stromal cell-derived factor-1; STAT, signal transducer and activator of transcription; TPO, thrombopoietin; WHO, World Health Organization.

Thrombocytosis, or thrombocythemia, is defined as a high platelet count or, more specifically, a count that is above a reference interval established for the species. Various methods are available for measuring platelet counts, including estimates from stained peripheral blood smears, manual hemocytometer counts, quantitative buffy coat analysis, and automated methods based on impedance or laser-induced light scatter. These vary in precision and accuracy and results from the same animal may differ between methods.[31,59] Therefore, most veterinary laboratories establish reference intervals specific for their own equipment for routinely analyzed species. For those animals in which laboratory-specific intervals are unavailable, interpretation of the platelet count is more difficult. Knowledge of the normal physiology of the animal, combined with published reference intervals, can be used as a guide to data interpretation. Platelet counts in healthy animals vary markedly between species. For instance, small rodents normally have very high counts, whereas horses have relatively low counts (Table 80.1). Thus, a normal platelet count in a mouse would be regarded as an extreme thrombocytosis in a dog or horse.

A potentially misleading consequence of thrombocytosis is a pseudohyperkalemia that occurs in serum samples. This is due to release of intracellular potassium during clotting and has been most thoroughly evaluated in the dog.[13,49] Potassium concentrations can be 0.63 ± 0.17 mEq/L (mean ± SD) higher in serum than plasma in dogs with platelet counts between 150,000–600,000/μL.[49] This difference increases in dogs with higher counts (1.55 ± 0.73 mEq/L) and can be quite marked (up to 5 mEq/L) in dogs with extreme thrombocytosis (>1,000,000 platelets/μL).[3,13,25,39,49] To avoid this artifact, heparinized plasma is the preferred sample for potassium measurement.

Thrombocytosis can be due to an artifact (pseudothrombocytosis), altered trafficking of platelets (i.e. release from storage pools; also called physiologic) and increased platelet production (enhanced thrombopoiesis). Enhanced thrombopoiesis can be secondary to drugs, cytokines (also called reactive), clonal hematopoietic disorders, or familial/inherited megakaryocyte disorders (Table 80.2).

To understand the pathophysiology of thrombocytosis, the factors governing thrombopoiesis are briefly reviewed below (see Chapter 9 for more details).

THROMBOPOIESIS: A BRIEF REVIEW

Platelets are produced from megakaryocytes in the bone marrow, by a unique process that involves fragmentation of long cytoplasmic extensions (proplatelets) that the megakaryocyte inserts between bone marrow sinusoidal endothelial cells. The precise mechanisms controlling platelet release from proplatelets are largely unknown, however this process does require adhesion of megakaryocytes to subendothelial matrix components (particularly fibronectin and thrombospondin), cytoskeletal elements (actin, microtubules), pro-apoptotic enzymes,[12] matrix metalloproteinases[33] and shear forces (which facilitate proplatelet fragmentation). To date, the only known soluble mediator of platelet release is the chemokine, stromal cell-derived factor-1 (SDF-1);[33] none of the known thrombopoietic cytokines, including thrombopoietin (TPO), appear to stimulate this process.[35] It has been estimated that approximately 2,000–3,000 platelets are produced from each megakaryocyte, with the residual megakaryocyte nucleus being degraded by phagocytes within the bone marrow.[35]

Thrombopoietin is the main thrombopoietic cytokine and is produced primarily in the liver and kidney. TPO binds to its receptor, MPL (a product of the proto-oncogene, *c-mpl*) to mediate downstream responses through the non-receptor tyrosine kinase, Janus kinase 2 (JAK2), which in turn activates the transcription factors signal transducer and activator of transcription (STAT 3 and 5).[29,35] MPL is highly expressed on megakaryocytes and platelets, but is also expressed on other cell types, including hematopoietic stem cells. TPO levels in serum are thought to be regulated by binding to MPL, with subsequent internalization and degradation. TPO mainly acts as a differentiation factor, stimulating stem cells to differentiate along the megakaryocytic lineage and preventing apoptosis through the protein Bcl-XL.[32] It is also required for complete megakaryocyte maturation. TPO acts in concert (additively or synergistically) with other hematopoietic cytokines, including stem cell factor, interleukin-3 (IL-3) and erythropoietin, to promote megakaryocyte proliferation and polyploidy.

TABLE 80.1 Reference Intervals for Platelet Counts from Various Animal Species

Species	Reference Interval (range or mean ± SD) ($\times 10^3/\mu L$)
Canine	186–545[a]
Feline	195–624[a]
Equine	94–246[a]
Bovine	252–724[a]
Alpaca	220–947[a]
Caprine	245–975[b]
Ovine	250–750[c]
Porcine	520 ± 195[c]
Mice	1163 ± 382[c,d]
Long Evans Rats (13–15 months)	993 ± 183[c,d]

[a]Intervals established for the 2120 ADVIA hematology analyzer at Cornell University (2008).
[b]Intervals established for the 120 ADVIA hematology analyzer at Cornell University (2000).

TABLE 80.2 Causes and Associated Mechanisms of Thrombocytosis[23,51,54,56]

Cause	Mechanism
Pseudothrombocytosis	
Red cell ghosts or fragments, fragile leukocytes	Non-platelet cell fragments are counted as platelets
Physiologic	
Epinephrine (trauma, exercise, excitement)	Splenic contraction
Post-splenectomy	Lack of sequestration
Drug-induced	
Epinephrine	Splenic contraction
Vincristine	Enhanced megakaryopoiesis
Reactive	
Inflammation, infection, neoplasia (hematopoietic and non-hematopoietic), trauma, rebound from thrombocytopenia	Cytokine-mediated (directly or indirectly through TPO production) enhanced megakaryopoiesis
Iron deficiency-related	Unknown
Neoplasia involving megakaryocytes	
Chronic myeloproliferative disease: essential thrombocythemia, chronic myeloid leukemia, chronic basophilic leukemia, polycythemia vera, chronic idiopathic myelofibrosis	Acquired or inherited genetic mutations causing TPO-independent proliferation, e.g. JAK2 signaling mutations
Acute megakaryocytic leukemia	Acquired or inherited genetic mutations
Hereditary/familial[a]	Inherited genetic mutations

[a]Not reported in animals.

Other thrombopoietic cytokines are SDF-1,[38] IL-6 superfamily members (IL-6, IL-11, leukemia inhibitory factor), GM-CSF, IL-1α and IL-9.[29,35]

Thus, potential mechanisms that would result in thrombocytosis due to megakaryopoiesis are increased concentrations of thrombopoietic cytokines, ligand-independent MPL activation, and abnormal activation of the JAK2/STAT signaling pathway.

CAUSES OF THROMBOCYTOSIS

Pseudothrombocytosis

Pseudothrombocytosis can occur when small, fragmented or hemolyzed erythrocytes, leukocyte fragments (from normal or leukemic cells), or particulate cellular debris are erroneously counted as platelets (Fig. 80.1). Although this artifact can be analyzer-dependent, it can potentially occur with any counting method. Thus, it is important to always verify platelet counts by estimating numbers from stained blood smears.[21,58] Although estimates are of questionable accuracy, smear examination can quickly confirm an elevated platelet count, identify morphologic defects in platelets and potentially reveal abnormalities that may cause a pseudothrombocytosis.

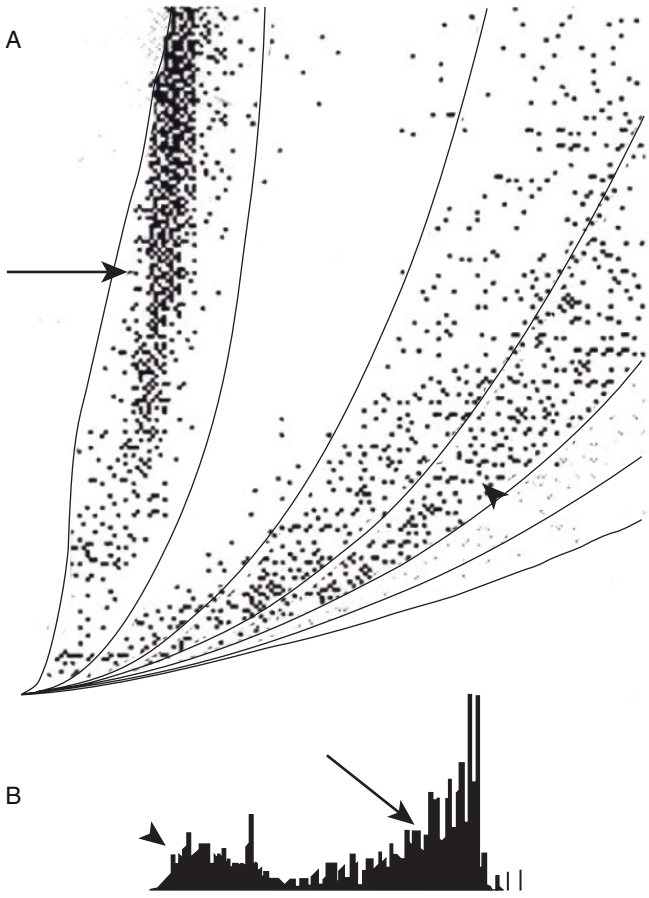

FIGURE 80.1 Pseudothrombocytosis in a hemolyzed sample from a dog with immune-mediated hemolytic anemia. (**A**) Hemolyzed red cells (arrow) can be seen entering the upper left portion of the platelet cytogram (forward scatter versus side scatter dotplot) and are counted as platelets on the ADVIA 120 hematology analyzer (laser light scatter-based system). (**B**) The hemolyzed erythrocytes can also be visualized as a second population of macrocytic cells (arrow) in the platelet histogram (cell number versus cell volume) and will artifactually increase the mean platelet volume and platelet distribution width. The "true" platelet clusters are identified by the arrowhead in both cytograms.

Physiologic Thrombocytosis

Up to one-third of the platelet mass is normally sequestered in the splenic red pulp. These stores can be released upon splenic contraction, which is mediated by epinephrine.[34,65] A transient or persistent thrombocytosis may occur post-splenectomy in humans,[53] however this is not a consistent finding in dogs.[50] Although some authors have suggested the presence of an adrenaline-responsive, platelet pool in the lungs,[20] there is no definitive evidence for this.[34]

Drug-induced Thrombocytosis

Two retrospective studies have made associations between various drugs and thrombocytosis in dogs and cats, however a direct cause and effect has not been established.[23,56] It is possible that the thrombocytosis documented in animals on drug therapy is secondary to their underlying disease or a rebound from thrombocytopenia, rather than a drug response per se. Drugs documented to cause a thrombocytosis in animals are vincristine and epinephrine.[34,37] Vincristine likely functions through enhanced megakaryopoiesis, whereas epinephrine induces a rapid (within a few minutes), transient (less than 60 minutes) thrombocytosis in dogs through splenic contraction, although there is large inter-animal variability in the response.[20,34] Data for glucocorticoids are conflicting. Although hyperadrenocorticism is associated with thrombocytosis in dogs,[19] two studies have not shown a consistent increase in platelet counts in healthy dogs given daily doses of up to 2 mg/kg prednisolone.[37,46]

Reactive Thrombocytosis

Reactive thrombocytosis (or secondary thrombocytosis) is due to cytokine stimulation of thrombopoiesis. It is the most common cause of thrombocytosis in humans and animals and occurs secondary to various disorders (Table 80.2).[6,22,23,51,54,56] Several retrospective studies in animals have shown that inflammation and neoplasia are the most common diseases associated with a thrombocytosis, although different platelet counts were used to define a thrombocytosis in these studies.[23,51,54,56] A recent unpublished study at Cornell University further showed that 61% of 42 cats with a thrombocytosis (>750,000 platelets/μL) had a primary inflammatory or infectious disorder. Reactive thrombocytosis can be transient or persistent, depending on the underlying cause, so documenting a thrombocytosis more than

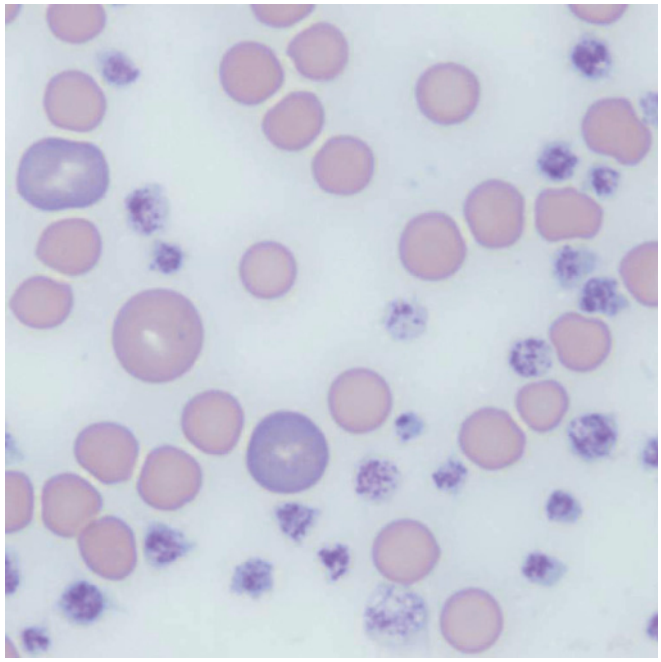

FIGURE 80.2 Peripheral blood smear from a 12 week old kitten with iron deficiency anemia secondary to flea infestation. Many platelets, which vary markedly in size, are seen in the smear. The kitten had an extreme thrombocytosis (platelet count = $1.9 \times 10^6/\mu L$), which was presumably reactive. Wright's stain; 1000× magnification.

once (particularly if done less than 1–2 months apart) does not exclude a reactive condition.[52] Also, the increase in platelet count can be quite marked in reactive conditions (>1,000,000/μL) (Fig. 80.2).

There are a plethora of cytokines potentially responsible for a reactive thrombocytosis, including TPO, IL-6, GM-CSF, IL-3, IL-11 and erythropoietin. These can be constitutively secreted by tumors[26,43] or secretion can be induced from host-derived cells as a result of inflammation, infection or neoplasia.[5] The inflammatory cytokine IL-6 is considered one of the main mediators of a reactive thrombocytosis. IL-6 levels are increased in patients with thrombocytosis due to inflammation and neoplasia[5,8,61] and persistently high levels are supportive of a reactive thrombocytosis.[1,61] Rather than acting directly on megakaryocytes, IL-6 is thought to stimulate platelet production indirectly through induction of TPO production from hepatocytes.[30] Unfortunately, in some disorders typically associated with thrombocytosis (e.g. iron deficiency), the precise mechanism for the thrombocytosis is unknown.[11]

The main differential diagnosis for reactive thrombocytosis in animals is essential thrombocythemia (ET). However, there are only a handful of reported cases of ET in dogs and cats, indicating that thrombocytosis in most animals (like humans) is likely reactive.

Essential Thrombocythemia in Humans

Essential thrombocythemia (also known as primary thrombophilia, hemorrhagic thrombocythemia/thrombocytosis, primary thrombocythemia and idiopathic thrombocythemia), is a clonal disorder of hematopoiesis, that primarily affects megakaryocytes. It is classified as a chronic myeloproliferative disease (CMPD), along with chronic myeloid leukemia (CML), polycythemia vera (PV), and chronic idiopathic myelofibrosis (CIMF), by the World Health Organization (WHO).[27] ET is the most frequently diagnosed CMPD[22,27,52] and usually affects the elderly (>50 years), with no sex predilection. There is a second peak of incidence in females around 30 years old.[27,52] Most patients (up to two-thirds) are asymptomatic at diagnosis, but affected individuals can paradoxically suffer from microvascular thrombosis (which is more common) or hemorrhage. Thrombi predominantly occur in arteries supplying the brain, heart, and extremities.[27,52] The duration, but not degree, of thrombocytosis has been linked to a higher risk of thrombosis. The mechanism for thrombosis is largely unknown, but may involve interactions between activated platelets and leukocytes.[2] In contrast to thrombosis, hemorrhage is associated with an extreme thrombocytosis (>1,000,000 platelets/μL), although hemorrhage can occur in patients with lower counts.[52,63] Hemorrhage is typically from the skin or mucosa and has been attributed to acquired type II von Willebrand disease (VWD), with a selective loss of the high molecular weight multimers of von Willebrand factor (due to their preferential adsorption to platelets or enhanced proteolysis).[41,52]

Essential thrombocythemia is characterized by a marked thrombocytosis in peripheral blood and a megakaryocytic hyperplasia in the bone marrow.[27] Leukocyte and erythrocyte counts are generally within normal limits. Platelets can vary markedly in size, but are usually not dysplastic. A histologic hallmark of ET is the presence of giant hyperlobulated megakaryocytes, found diffusely or in small loose clusters, within a normo- to slightly hypercellular marrow. Other evidence of dysplasia is lacking and there is no to minimal reticulin fibrosis.[27,63] The main differential diagnoses for ET are reactive thrombocytosis (which is far more common) and other CMPDs (see below).

The discovery of a mutation in the JAK2 gene has advanced our understanding of the pathogenesis of ET and related CMPDs (PV and CIMF). JAK2 is a non-receptor tyrosine kinase that has a critical role in megakaryocyte and other hematopoietic cell signaling. JAK2 upregulates anti-apoptotic proteins, is required for efficient trafficking of MPL, and induces hematopoietic cytokine (e.g. IL-3, TPO) production.[15,52] The mutation causes a phenylalanine for valine substitution at residue 617 (V617F) of the autoinhibitory domain and results in constitutive activation of JAK2.[52,63,64] The V617F mutation is not specific for ET and also occurs in PV (up to 90% incidence) and CIMF, perhaps explaining the phenotypic and biologic similarities between these CMPDs.[42,63,64] Constitutive JAK2 activation may explain the demonstrated hypersensitivity of megakaryocyte colonies derived from ET patients to thrombopoietic cytokines and to their autonomous growth in vitro.[15,63,64] Testing for the JAK2 V617F mutation has

TABLE 80.3 Diagnostic Criteria for Essential Thrombocythemia in Humans

	PVSG[a]	WHO[b]	Revised WHO[c]
Positive criteria	Platelet count ≥600,000/μL	Sustained platelet count ≥600,000/μL[d]	Sustained platelet count ≥450,000/μL,[e] large or giant platelets
		Megakaryocytic hyperplasia (enlarged, mature)	Megakaryocytic hyperplasia (enlarged, mature), no significant increase or left shifted neutrophil granulopoiesis or erythropoiesis, JAK2 mutations or other clonal markers
Exclusions			
Reactive thrombocytosis	No underlying disease	No underlying disease or prior splenectomy	No underlying disease
Iron deficiency	Stainable iron in marrow, failure of 1 month iron trial (to raise red cell mass)	Stainable marrow iron, normal ferritin, normal MCV (if these criteria not met, failure of iron trial)	Failure of iron trial in presence of decreased ferritin
Polycythemia vera	Normal red cell mass or hemoglobin	Normal red cell mass or hemoglobin	Normal hematocrit or hemoglobin
Chronic myeloid leukemia	No Philadelphia chromosome	No Philadelphia chromosome or BCR/ABL fusion	No Philadelphia chromosome or BCR/ABL fusion
Chronic idiopathic myelofibrosis	Collagen fibrosis absent or <1/3 biopsy No splenomegaly No leukoerythroblastic reaction	Collagen fibrosis absent, reticulin fibrosis minimal or absent, no dysplasia	No leukoerythroblastic reaction, absence of relevant reticulin or collagen fibrosis, no abnormal megakaryocyte morphology or clusters
Myelodysplastic syndrome		No dysplasia No MDS-related gene defects	No dysplasia

[a]Ref. 47.

[d]Sustained not defined. One recommendation is more than two occasions at least 2 months apart.[52]
[e]Sustained defined as during the work-up period.

been added to a proposed diagnostic scheme for ET[42] (Table 80.3). However, since the mutation is only identified in up to 57% of patients with ET, non-JAK2 mutations are likely also involved in ET pathogenesis.[15,48]

Essential thrombocythemia is considered an indolent disease, with affected patients having normal to slightly reduced lifespan. Unlike CML, ET rarely evolves into acute leukemia, but can transform into CIMF.[42,52,63,64] Thrombohemorrhagic symptoms contribute to morbidity and mortality in ET patients and, consequently, cytoreductive therapy is recommended for patients likely to develop these complications. Such therapy includes platelet apheresis, hydroxyurea, anagrelide (a quinazoline derivative that inhibits megakaryocyte proliferation and differentiation) and interferon-α. Aspirin is frequently concurrently administered to patients at risk for thrombosis.[40,60] Newer drugs targeting generic or JAK2 kinases may have promise in treating ET.[40]

Differentiating Essential Thrombocythemia from Reactive Thrombocytosis

In humans, various laboratory and clinical criteria have been developed to try and distinguish reactive thrombocytosis from ET (Table 80.4). Although platelet counts trend higher in ET, there is substantial overlap between these two conditions and the degree of increase in the platelet count cannot be relied upon to distinguish between them.[22,53] A diagnosis of ET over reactive thrombocytosis is favored by a history of thrombohemorrhagic events, mild to moderate non-progressive splenomegaly (due to extramedullary hematopoiesis), no evidence of inflammation, abnormally large megakaryocytes in the bone marrow, and identification of JAK2 or MPL mutations.[42,52]

Differentiating Essential Thrombocythemia from other Chronic Myeloproliferative Disorders

Thrombocytosis is a common feature of all CMPDs, although the incidence and degree of increase differs between them.[63] Furthermore, there is a substantial overlap in clinical presentation, biology, and laboratory features between these diseases. In 1986, the Polycythemia Vera Study Group (PVSG) developed diagnostic criteria for ET. The diagnosis was one of exclusion; i.e. ruling out reactive thrombocytosis (particularly due to iron deficiency), PV and CML

TABLE 80.4 Criteria for Differentiating Between Reactive Thrombocytosis and Essential Thrombocythemia in Humans[52,63]

Criteria	Reactive Thrombocytosis	Essential Thrombocythemia
Clinical		
Underlying disease	Yes	No
Thrombosis or hemorrhage	No[a]	Yes
Splenomegaly	No	Mild to moderate (due to extramedullary hematopoiesis)
Laboratory		
Platelet morphology	Normal	Normal, may see hypogranular/giant platelets
Bone marrow[b]	Normo- to hypercellular (concurrent granulocytic hyperplasia) Megakaryocytic hyperplasia (normal size, morphology)	Normocellular megakaryocytic hyperplasia (large cells, hyperlobulated or "staghorn" nuclei seen in loose clusters)[b]
Inflammatory markers (IL-6, fibrinogen, C-reactive protein)	High (may be normal)	Normal (may be high)
TPO levels	High or normal	High or normal[c]
Platelet aggregation	Normal	Abnormal (particularly to epinephrine) in 63–100%

[a]May occur if initiated by underlying disease.
[b]Although these bone marrow changes are emphasized in the WHO classification scheme for ET, they may be quite subtle and are not present in all patients.
[c]High TPO levels in ET have been attributed to down-regulation of MPL on platelets and megakaryocytes.

(Table 80.3).[47] In 2001, the WHO established a diagnostic scheme for ET. Like the PVSG criteria, this emphasized ET as a diagnosis of exclusion, but added bone marrow histopathology to exclude early or prefibrotic CIMF.[27,63] However, it is now recognized that the WHO scheme excludes approximately 30% of ET patients with platelet counts below the designated cut-off (600,000/μL).[42,63] For this reason, a new revised WHO has been proposed (Table 80.3). This uses a lower platelet cut-off and incorporates testing for JAK2 and MPL mutations.[62] It remains to be seen whether this new scheme has any advantages over currently used criteria. Indeed, questions have been raised about the validity of the revised scheme, emphasizing the difficulty in differentiating the various CMPDs.[57]

Essential Thrombocythemia in Animals

There are only a handful of case reports of ET in animals, primarily affecting dogs[3,14,16–18,25,45,55] and cats.[17,24] However, after careful scrutiny, many of these cases were probably not ET (as currently defined in humans) and were more likely reactive thrombocytosis,[16–18] acute megakaryoblastic leukemia[55] or CML.[14,16,25,45] In the two cases of what may be true ET (in a dog and a cat), PVSG criteria (Table 80.3) were used for diagnosis.[3,24] Both animals had a marked persistent thrombocytosis (>600,000 platelets/μL for >1 month), megakaryocytic hyperplasia, normal TPO levels, and no evidence of dysplasia, iron deficiency, or underlying inflammation. It is possible that ET is a different disorder in animals than in humans and diagnostic criteria for humans (including genetic mutations) may not be valid in animals.

The main differential diagnosis for ET in animals is a reactive or cytokine-driven thrombocytosis, which is far more common (regardless of the platelet count). Essential thrombocythemia is an extremely rare diagnosis in animals and, as in humans, remains one of exclusion. It is very difficult to differentiate ET from other CMPDs (e.g. CML), which are also quite rare. A diagnosis of ET should only be entertained in animals with a sustained (more than 1–2 months) and unexplained thrombocytosis and no evidence of CML (low numbers of myeloblasts, and no dysplasia, leukocytosis or severe anemia). It is possible that the increased availability of sensitive markers of inflammation (e.g. acute phase reactant proteins[9]) will help distinguish between reactive thrombocytosis and ET in animals.

Thrombocytosis has also been reported with acute megakaryoblastic leukemia[7,10,44] and other CMPDs, including basophilic leukemia and PV in animals.[36,51]

Familial/Inherited Thrombocytosis

This has been attributed to germline mutations in genes involved in thrombopoiesis (MPL, TPO, JAK2), resulting in non-neoplastic polyclonal thrombopoiesis. High platelet counts are observed at birth or an early age. Affected individuals may be asymptomatic or suffer from thrombohemorrhagic complications.[4,52,53]

Acronyms and Abbreviations

AVWS, acquired von Willebrand syndrome; ADAMTS13, a disinintegrin and metalloprotease with thrombospondin repeats; DDAVP, deamino 8-D-arginine vasopressin; ELISA, enzyme-linked immunosorbent assay; FVIII, coagulation factor VIII; LIA, latex immunoassay; OMIM, on-line inheritance in man; PFA, platelet function analyzer; MW, molecular weight; VWD, von Willebrand disease; VWF, von Willebrand factor; VWF:Ag, von Willebrand factor antigen; VWF:CB, von Willebrand factor collagen binding; VWF:RCo, von Willebrand factor ristocetin cofactor activity.

Von Willebrand disease (VWD) is the most common hereditary bleeding disorder in dogs[10] and people,[21] and the trait has been reported in many other species. The disease is heterogeneous, caused by a variety of defects in von Willebrand factor protein (VWF) that influence clinical severity and complicate disease diagnosis and management.[6,9,10,19–21]

DISEASE MECHANISM

The bleeding tendency of VWD is caused by quantitative and functional deficiencies of VWF, a large plasma glycoprotein required for platelet adhesion at sites of vessel injury (Fig. 81.1).[21]

Endothelial cells are the major site of VWF synthesis and storage. Platelets provide a secondary pool of VWF in some species; however, canine platelets contain only trace amounts of VWF. Mature VWF circulates as linear strings of subunits (multimers) assembled within the endoplasmic reticulum and Golgi apparatus. Initially, two VWF subunits join to form dimers, followed by the association of dimers into variably-sized multimers. Multimers may be composed of more than 100 subunits, ranging in molecular weight (MW) from 500 to 20,000 kDa. Endothelial cells secrete VWF via steady-state constitutive pathways, and release the protein from storage organelles in response to stimuli such as thrombin and epinephrine. VWF acts as a carrier for coagulation factor VIII (FVIII), circulating with FVIII in a noncovalent complex. Upon vascular injury, VWF binds to subendothelial collagen and undergoes a conformation change that facilitates its interaction with platelet glycoprotein lb. VWF also mediates intraplatelet bridging via platelet glycoprotein IIbIIIa. High MW VWF multimers are most effective in supporting platelet adhesion. Deficiency of VWF, or loss of high MW forms, results in failure of platelet plug assembly, especially under high shear in the microvasculature. After secretion, ultra-high MW multimers are catabolized to smaller forms by a disintegrin and metalloprotease with thrombospondin repeats (ADAMTS13) (Fig. 81.1).[21] This conversion takes place slowly in plasma under static conditions (12 hour half-life); however, ADAMTS13 more rapidly cleaves platelet-bound VWF under conditions of high shear.[5,21]

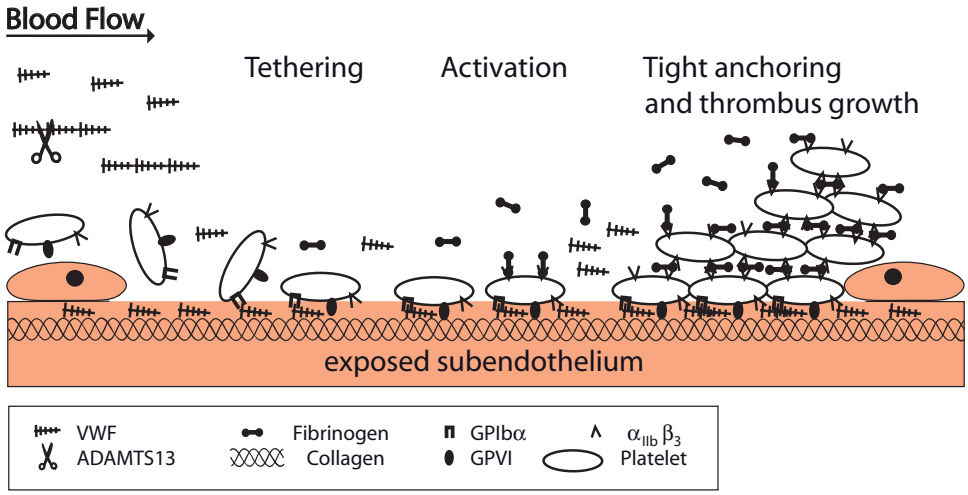

FIGURE 81.1 Schematic diagram illustrating the role of VWF in platelet adhesion, aggregation, and thrombus growth. At the site of blood vessel injury, platelets transiently adhere to subendothelial VWF via platelet GP1bα receptors. This slows platelet movement and triggers the engagement of platelet receptors, including the collagen receptor. Receptor engagement results in platelet activation and stable attachment. Activated platelets secrete additional prostimulatory molecules and bind to plasma fibrinogen and VWF to form a tight anchoring matrix for platelet recruitment and ultimately thrombus formation. Upon release from endothelial cells, ultra large VWF multimers are rapidly cleaved by ADAMTS13.

TABLE 81.1 Classification of von Willebrand Disease

Type	VWF Defect	Affected Species (Breeds)
1	Partial quantitative deficiency, residual VWF has normal structure and function	Dog (Airedale, Akita, Bernese mountain dog, Dachshund, Doberman pinscher, German shepherd, Golden retriever, Greyhound, Irish wolfhound, Kerry blue terrier, Manchester terrier, Miniature pinscher, Papillon, Pembroke Welsh Corgi, Poodles, Schnauzer, other purebreeds and mixed breed dogs) Horse (Arabian) Mouse (RIIIS/J)
2A	Selective loss of large VWF multimers, decreased VWF-platelet & collagen interactions	Dog (German shorthaired pointer, German wirehaired pointer) Cow (Simmental) Horse (Quarter Horse, Thoroughbred)
2B	Increased VWF affinity for platelet glycoprotein Ib	No animal cases
2M	Impaired VWF binding to platelet glycoprotein Ib, normal multimer structure	No animal cases
2N	Decreased VWF binding to factor VIII	No animal cases
3	Complete VWF deficiency	Dog (Dutch Kooiker, Scottish terrier, Shetland sheepdog; sporadic cases Border collie, Chesapeake Bay retriever, Cocker spaniel, Eskimo dog, Labrador retriever, Maltese, Pitbull, and mixed breed) Cat (Himalayan) Pig (Poland, China) Primate (Rhesus monkey)

DISEASE CLASSIFICATION

VWD Subtypes

Von Willebrand disease in people is classified into one of three categories based on plasma VWF concentration, function, and multimer structure (see Table 81.1).[6,21] This classification scheme is broadly applicable for VWD in animals. Type 1 VWD is a partial quantitative deficiency. Plasma VWF concentration is low (<50% of normal), but the protein consists of a full complement of functional multimers. In this form, clinical severity generally correlates with reduction in VWF concentration.[3,19,21]

Type 2 VWD refers to a group of VWF functional variants. Although four distinct subtypes are found in people, type 2A VWD is the only subtype described in animals to date.[2,16,24] In this form, preferential loss of high MW multimers accompanies low plasma VWF concentration. The residual VWF's ability to support

platelet adhesion is greatly reduced. Defects that enhance the binding affinity of the platelet VWF receptor (glycoprotein 1bα) produce a disease phenotype similar to type 2B VWD. This rare bleeding disorder, referred to as platelet-type VWD, has not been identified in animals.

Type 3 VWD refers to a complete absence of plasma VWF. Lack of VWF, in many species, is associated with concomitant reduction in FVIII. However, dogs affected with type 3 VWD have at most mild reduction in FVIII, presumably due to species-differences in FVIII stability.[22]

Affected Species and Breeds

Clinical expression of VWD is best characterized in dogs;[1–3,10,12,17,26] however, family studies and case reports describe VWD in horses,[16] non-human primates,[15] cats,[7] cows,[24] and laboratory strains of pigs[8] and mice[13] (Table 81.1). Type 1 VWD is the most common form in dogs, with cases identified in many purebreds and in mixed breed dogs (Table 81.1). Type 2 VWD represents 10–20% of human cases;[19,21] however, this subtype has been found only in two related canine breeds (German wirehaired and shorthaired pointers) in addition to horses and cattle. The most severe form, type 3 VWD, has been described as a familial trait in several breeds (Kooiker, Scottish terrier, Shetland sheepdog), and there are many sporadic cases in other breeds and species (Table 81.1). The true prevalence of VWD within affected breeds is difficult to determine. In the absence of random surveys, diagnosis bias favors screening affected individuals and their relatives. Selection may eliminate the trait within a certain family, in spite of relatively high overall breed prevalence. The breed-variants listed in Table 81.1 include published reports and recent case submissions to the authors' laboratory; however, new cases may develop in previously unaffected species and breeds.

INHERITANCE AND EXPRESSION PATTERNS

Molecular characterization of VWD reveals a variety of mutation-types and numerous distinct mutations throughout the VWF gene (*VWF*).[9,17,21,26] In general, mutations causative for type 2 VWD are clustered in *VWF* regions required for multimer assembly and stability, or VWF-platelet interactions. Common mutations in type 3 patients include frameshift, nonsense, and large deletions that disrupt VWF synthesis. Mutations causative for type 1 VWD are found throughout *VWF* and in some variants, described in mice and people, mutations unlinked to the *VWF* locus influence VWF protein stability or rate of synthesis.[9,13,21]

Hereditary VWD

Hereditary VWD is an autosomal trait. In this form of inheritance, males and females transmit and express the trait with equal frequency. Most type 2 VWD kindreds and all type 3 VWD families demonstrate recessive expression patterns. Homozygotes inherit mutant *VWF* alleles from both parents and invariably express a bleeding tendency, whereas heterozygotes have one normal and one mutant *VWF* allele and are clinically normal (see Table 81.2).

TABLE 81.2 Transmission and Expression of Recessive von Willebrand Disease

Parental Status	Offspring Status: Predicted Ratios[a]
Clear (VV) × Clear (VV)	All Clear (VV)
Clear (VV) × Carrier (VV^m)	½ Clear (VV) & ½ Carrier (VV^m)
Carrier (VV^m) × Carrier (VV^m)	¼ Clear (VV) & ½ Carrier (VV^m) & ¼ Affected (V^mV^m)
Clear (VV) × Affected (V^mV^m)	All Carrier (VV^m)
Carrier (VV^m) × Affected (V^mV^m)	½ Carrier (VV^m) & ½ Affected (V^mV^m)
Affected (V^mV^m) × Affected (V^mV^m)	All Affected (V^mV^m)

[a](VV) = VWD Clear, male or female, no signs of bleeding; (VV^m) = VWD Carrier, male or female, no signs of bleeding; (V^mV^m) = VWD Affected, male or female, clinical bleeding due to abnormal primary hemostasis.

Two distinct mutations have been described in canine breed-variants of type 3 VWD.[17,26] A deletion mutation within exon 4 and a splice site mutation at the boundary of exon 16 are causative for type 3 VWD in Scottish terriers and Dutch Kooikers, respectively. Direct DNA tests are commercially available (Vetgen) to detect these mutations, and other mutations believed to be causative for breed-variants of type 2 or type 3 (Shetland sheepdog) VWD. Heterozygous carriers of types 2 and 3 VWD have low plasma VWF concentration, with values generally less than 50% of normal. Carrier status may be ambiguous for some individuals, however, due to overlap in VWF values at the low end of normal range.[2,9,10]

Type 1 VWD is typically a dominant trait, or dominant with incomplete penetrance.[9,19,20] The causative mutations underlying this phenotype in people are often classified as "dominant-negative," where an abnormal gene product affects VWF processing or clearance. Incomplete penetrance refers to a variability of disease expression among individuals carrying the same mutation. A range of clinical severity is also a common feature within canine breed-variants of type 1 VWD.[3,10,18] While low plasma VWF concentration is a primary risk factor for expression of type 1 VWD, molecular genetic and biochemical analyses have not fully defined additional factors that influence disease penetrance.[9,13,21] A commercial test (Vetgen) is offered to detect a *VWF* splice site mutation common to many canine breeds affected with type 1 VWD. The relationship of homozygosity or heterozygosity for this mutation to expression of a bleeding tendency has not been described; however, association studies in types 1 and 2 VWD have shown that the canine *VWF* locus has a major influence on plasma VWF concentration.[3,12]

Acquired VWD

Acquired von Willebrand syndrome (AVWS) refers to VWF quantitative and functional defects that develop as a consequence of other primary disease conditions.[21] The pathogenesis of AVWS in people includes antibody-mediated clearance secondary to immune disorders, shear-induced proteolysis due to cardiac disease, and increased VWF-platelet binding in thrombotic and neoplastic syndromes. In addition to these defined mechanisms, AVWS has been described in people (and animals) in association with hypothyroidism and treatment with plasma expanders (e.g. hydroxyethyl starch, dextran). An AVWS, characterized by loss of high MW VWF multimers, has been reported recently in dogs with cardiac valvular lesions causing turbulent flow.[25] Screening to detect VWF defects is therefore warranted in animals with signs of mucosal hemorrhage and primary diseases associated with AVWS. Similarly, correction of acquired disorders that reduce VWF plasma half-life or impair its function may prevent exacerbation of hereditary VWD.

VON WILLEBRAND FACTOR ASSAYS

Definitive diagnosis of VWD is based on specific assay of plasma VWF.[6] Species differences in VWF antigenic structure and function require species-specific assays, or validation of human assays, for veterinary applications. Valid results also depend on collection techniques that prevent platelet activation and clot formation, conditions that deplete and degrade VWF in the sample specimen.

Quantitative VWF Assays

VWF antigen (VWF:Ag) refers to the immunologic quantitation of VWF concentration. Determination of VWF:Ag is the initial step in characterizing VWD. The most sensitive and accurate assay methods in current use are enzyme-linked immunosorbant assay (ELISA) and automated latex immunoassay (LIA).[6] Test results of VWF (and clotting factors) are conventionally reported as percentage of "normal." The VWF content of each test sample is compared with that of a reference standard having an assigned value of 100% or 100 units per deciliter (U/dL). Assay standards and reference intervals for animal VWF:Ag must be established by each testing laboratory. In general, plasma VWF:Ag below 50% (<50 U/dL) indicates VWF deficiency.

Functional and Structural VWF Assays

Functional VWF assays measure various aspects of VWF interaction with platelets, collagen, or FVIII. The ristocetin cofactor assay (VWF:RCo) is a traditional test that measures VWF-dependent platelet agglutination. This property of VWF depends on the presence of high MW multimers and that VWF:RCo values are disproportionately decreased compared to VWF:Ag in people with type 2A, 2B, and 2M VWD.[6,21] VWF:RCo assays are difficult to standardize for clinical diagnosis in people and require modification for use in animals. Collagen binding assays (VWF:CB) measure a different function of VWF that also depends on the presence of high MW VWF multimers. VWF:CB assays have begun to replace VWF:RCo for initial screening to detect type 2 VWD. These newer assays are more readily standardized among laboratories, and have been adapted for clinical assessment of VWD subtypes in dogs.[11,20]

VWF multimers are visualized using protein electrophoresis for size separation, followed by direct hybridization with anti-VWF probes, or transfer to a membrane (western blot) before antibody labeling. Multimer analyses are generally performed in research settings for detailed VWF characterization and VWD subtype classification of newly diagnosed breed or species-variants.[2,4,10]

Point-of-Care Analyses

Bleeding time tests are in vivo measures of primary hemostasis performed by making a superficial incision in a capillary bed and monitoring the time to cessation of blood flow. Prolongation of bleeding time is compatible with severe forms of VWD (and platelet function defects); however, the bleeding time endpoint is also influenced by platelet count, hematocrit, and other conditions affecting blood viscosity.[6] In addition to nonspecificity, bleeding time tests have fallen out of use in human medicine because of high inter-operator variability, patient discomfort, and poor predictive values.

The Platelet Function Analyzer (PFA-100®, Dade Behring) is a table-top instrument that measures platelet plug formation in whole blood under high shear flow.[6,14] The test endpoint (closure time) refers to occlusion of an aperture coated with collagen and ADP or epinephrine. The instrument was developed as a noninvasive test of platelet and VWF function and has been evaluated in dogs and horses. The PFA-100® ADP/collagen closure time is sensitive to VWF deficiency and dysfunction in dogs, with reports of prolonged closure times in dogs with types 1, 2, and 3 VWD.[4,14] Many of the nonspecific conditions that influence bleeding time (e.g. thrombocytopenia, anemia) also affect the closure time endpoint, thereby limiting its use as a screening test in some clinical situations.

CLINICAL MANAGEMENT OF VWD

Clinical Diagnosis

Clinical Signs

Clinical signs of VWD in all species include mucosal hemorrhage, cutaneous bruising, and prolonged bleeding after surgery or trauma. Specific sites of mucosal hemorrhage in VWD case series include epistaxis, hematuria, gastrointestinal hemorrhage, prolonged

estral bleeding, and gingival bleeding at deciduous teeth.[1] These signs are typical of primary hemostatic defects, commonly seen in patients with thrombocytopenia, platelet dysfunction, and VWD. Petechiae, however, represent specific signs of platelet defects and are rarely seen in VWD patients. The bleeding tendency of type 1 VWD ranges from mild to severe. Mildly affected patients infrequently develop spontaneous hemorrhage, but typically experience abnormal bleeding after surgery or trauma. Types 2 and 3 VWD are invariably severe bleeding disorders. Neonatal deaths caused by hemorrhage may occur, but many animals survive to adulthood, albeit with transfusion support. The anatomic site of tissue injury influences the consequences of hemorrhage. Minor hemorrhage into critical sites such as the central nervous system or respiratory tract may produce severe morbidity and mortality. Oronasal and urinary tract tissues are rich in fibrinolysins, and injuries to these tissues often cause more prolonged bleeding than superficial wounds.

Diagnostic Evaluation

Thrombocytopenia and coagulation factor deficiencies are common causes of hemorrhage; therefore the initial evaluation of any patient suspected of having a bleeding diathesis should include platelet count and coagulation screening tests (see Fig. 81.2).

Bleeding scores derived from standardized questionnaires have been proposed to improve the diagnostic utility of VWD screening in people.[19] A brief hemostasis questionnaire is also useful as a screening tool to identify veterinary patients with hereditary or drug-induced bleeding disorders (see Table 81.3). If preliminary results reveal normal platelet count and coagulation panel results, then point-of-care tests of primary hemostasis and/or VWF:Ag should be performed to screen for VWD (see Fig. 81.2). Prolongation of in vivo bleeding time (beyond 4–6 minutes) and PFA-100® collagen/ADP closure time (beyond 2 minutes) is compatible

TABLE 81.3 Screening Questionnaire to Aid in the Diagnosis of Bleeding Disorders

1	Has this animal ever had spontaneous bleeding from nose, mouth, urinary tract, or noticeable bleeding at teething?
2	Has this animal ever had a surgical procedure, dentistry, or traumatic injury – did bleeding complications occur?
3	Has this animal ever required a transfusion because of anemia or hemorrhage?
4	Is this animal receiving medication or dietary supplements?
5	Are you aware of any bleeding problems in relatives or in this breed?

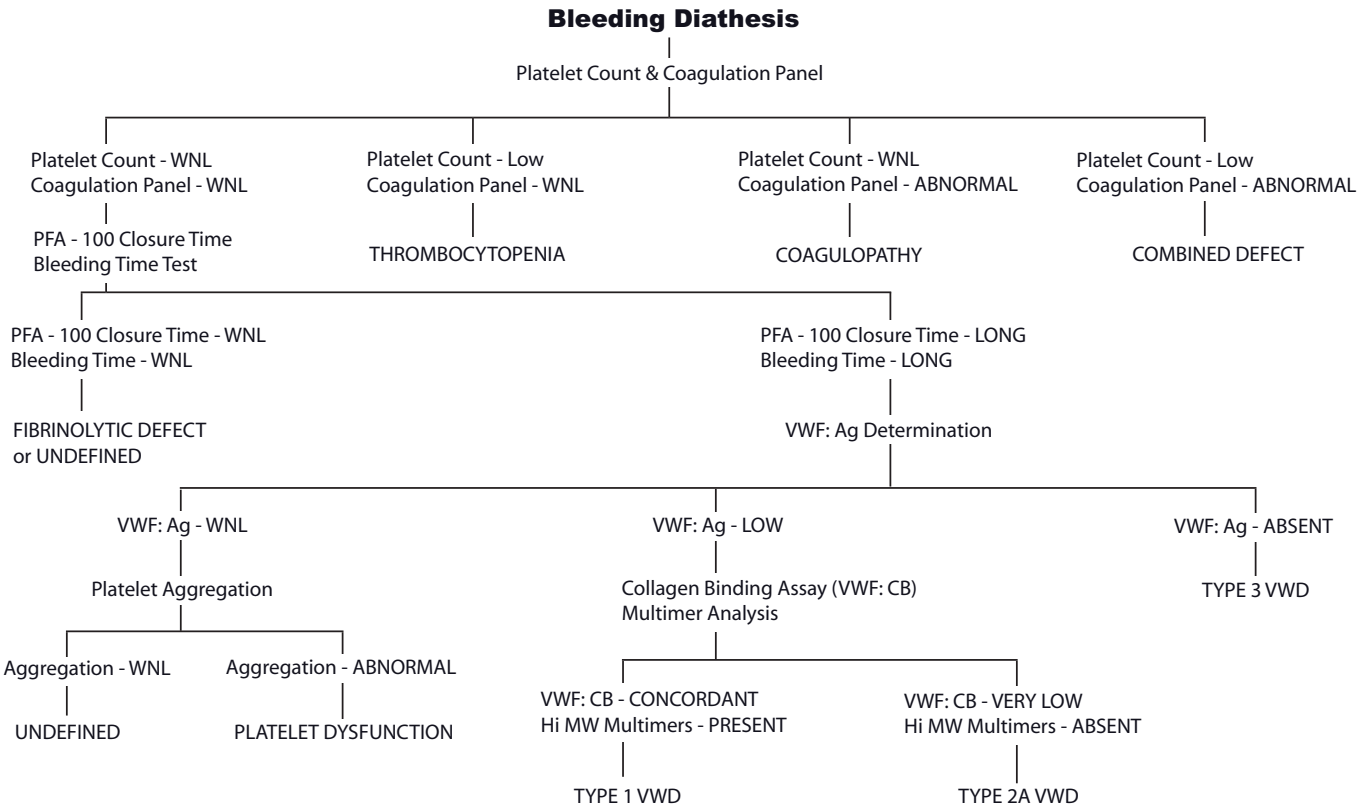

FIGURE 81.2 Diagnostic algorithm for assessment of VWD and other bleeding disorders.

with VWD, and the finding of low plasma VWF (VWF:Ag < 50%) confirms VWF deficiency. A complete lack of plasma VWF (VWF:Ag < 0.1%) is definitive for severe, type 3 VWD. Diagnosis of type 2 VWD is based on quantitative deficiency, combined with additional structural and functional abnormalities (see Fig. 81.2 and Table 81.1). In particular, a disproportionate defect of collagen binding (ratio of VWF:Ag/VWF:CB > 2) provides evidence of type 2A VWD. In patients with low, but functional VWF, the risk of abnormal hemorrhage ranges along the continuum of VWF:Ag values. In dogs and people, clinical expression of a bleeding tendency is typically associated with VWF:Ag < 25%, whereas VWF:Ag close to 50% is often clinically inapparent.[1,3,9,19] The current management strategy for type 1 VWD in people considers VWF deficiency as a biomarker for hemostatic risk. Ongoing studies aim to relate clinical outcomes to defined VWF protein levels, mutation types, and other parameters of intrinsic platelet function.[9,21]

Treatment of VWD

Management of VWD is directed at controlling hemorrhage in patients with active bleeds and preventing hemorrhagic complications in case of surgery or trauma. The clinical heterogeneity of VWD requires an individualized approach to account for disease classification and underlying conditions that might influence disease expression.

Transfusion Therapy

Transfusion is the mainstay of emergency treatment and prophylaxis of VWD (see Chapter 90 and Section VIII). The most successful strategy is early, high-dose transfusion to rapidly increase plasma VWF to levels capable of supporting platelet adhesion. Patients with types 2 and 3 VWD almost invariably require transfusion to undergo invasive procedures or stop an active bleed. Transfusion for type 1 VWD can be assessed based on clinical history, severity of VWF deficiency, any underlying disease, and the nature of the hemostatic stress. Patients with blood-loss anemia or requiring major surgical procedures should be transfused, whereas those with normal hematocrits or minor, cutaneous injuries may be successfully managed with limited or no transfusion. Severely affected patients may require repeated transfusion, with lower dosages at longer intervals to sustain hemostasis for 24–48 hours after initial control of bleeding. Stabilization of hematocrit and cessation of active hemorrhage are signs that hemostatic levels of VWF have been attained.

Plasma cryoprecipitate is the most specific component for rapid VWF replacement therapy, with fresh frozen plasma an acceptable alternative (see Chapter 96).[23] The use of plasma components, rather than whole blood, prevents sensitization to red cell antigens, eliminates the need for type-matched donors, and minimizes risk of volume overload. The unit definition of cryoprecipitate varies for different suppliers; however, transfusion of 1 unit/10 kg cryoprecipitate (1 unit defined as cryoprecipitate from 200 mL fresh frozen plasma) or transfusion of 10–15 ml/kg fresh frozen plasma provides adequate VWF to support hemostasis. The plasma half-life of VWF is approximately 12 hours, necessitating q8–12 hour transfusion for severe hemostatic stress.

Non-transfusion Therapy

Hereditary VWD causes a life-long bleeding tendency; therefore invasive procedures are best avoided. In case of injury or non-elective surgery, local wound care may help reduce transfusion requirements (see Chapter 90). Cautery, topical tissue adhesive, multilayer closure, and pressure wraps help to reduce blood loss at focal injury sites. Anti-platelet and anticoagulant drugs (e.g. sulfa drugs, non-steroidal anti-inflammatory agents, heparin, dextran, and other plasma expanders) should be given cautiously, if at all.

Signs of VWD can be exacerbated by concurrent thrombocytopenia and other disease conditions that affect hemostasis. Uremia, hyperproteinemia, anemia, hypothyroidism, and liver disease are among the more common disease conditions associated with primary hemostatic failure. Medical therapy to correct these disorders, and primary diseases associated with AVWS, is therefore important in the general management of VWD.

Desmopressin acetate (deamino 8-d-arginine vasopressin [DDAVP]) is a synthetic vasopressin analog used as a specific pharmacologic agent for type 1 VWD in people. The drug is believed to act by stimulating endothelial V2 vasopressin receptors, resulting in release of VWF intracellular stores. Repeated infusions of desmopressin at closely spaced intervals fail to elicit VWF release (tachyphylaxis), thereby limiting its ability to maintain hemostasis to periods of hours, rather than days. Desmopressin has been recommended as preoperative prophylaxis for type 1 VWD-affected dogs, although experimental studies reveal relatively small increases in plasma VWF concentration compared to the human response.[4,11] To support surgical hemostasis, desmopressin (1 µg/kg) is given subcutaneously one-half hour before surgery. Close monitoring is required, with transfusion available if desmopressin response is inadequate.

CHAPTER 82

Inherited Intrinsic Platelet Disorders

MARY K. BOUDREAUX

Overview – Intrinsic vs Extrinsic Platelet Disorders
Inherited Macrothrombocytopenia
Membrane Receptor Disorders
  Glanzmann Thrombasthenia (GT)
  P2Y12 Receptor Disorder
Storage Pool Disorders
  Cyclic Hematopoiesis
  Chediak-Higashi Syndrome (CHS)
  Dense Granule Defect
Signal Transduction Disorders
  Calcium Diacylglycerol Guanine Nucleotide Exchange Factor I (CalDAG-GEFI) Thrombopathias
  Kindlin-3
Procoagulant Expression Disorders
  Scott Syndrome
Diagnosis
Case Management

Acronyms and Abbreviations

ADAMTS13, a disintegrin and metalloprotease with thrombospondin repeats; AP3β1, adaptor protein complex 3 beta 1; CalDAG-GEFI, calcium diacylglycerol guanine nucleotide exchange factor I; CAP-1, canine activated platelet-1; CHS, Chediak-Higashi Syndrome; CKCS, Cavalier King Charles Spaniel; DDAVP, 1-desamino-8-D-arginine vasopressin; guanine nucleotide exchange factor (GEF GT, Glanzmann thrombasthenia; RIBS, receptor-induced binding site; VWD, von Willebrand Disease.

OVERVIEW – INTRINSIC VS EXTRINSIC PLATELET DISORDERS

Intrinsic platelet disorders are characterized by defects involving membrane receptor glycoproteins, secretory organelles, signal transduction proteins, or structural proteins that result in either platelet dysfunction (thrombopathia) or thrombocytopenia. Several inherited intrinsic platelet disorders have been documented in veterinary medicine at the functional, biochemical, and molecular level. Extrinsic platelet disorders are characterized by abnormalities in plasma or subendothelial proteins that are essential for platelet adhesion or aggregation. Extrinsic platelet disorders include von Willebrand Disease (VWD) and hypo- or dysfibrinogenemia, the latter of which are rare in veterinary medicine. Intrinsic and extrinsic platelet disorders are indistinguishable at the clinical level. Buccal mucosa bleeding times are usually prolonged in both types of disorders while coagulation screening tests are normal. Petechial and ecchymotic hemorrhages and mucosal bleeding such as gingival bleeding, epistaxis, and urinary and gastrointestinal hemorrhage can be observed with both types of disorders. Internal bleeding within organs such as kidney, spinal cord, and brain can also occur. Excessive bleeding during permanent tooth eruption is commonly observed and may be the first indication of the existence of a bleeding diathesis. Clinical signs in affected animals can vary considerably; signs may be overt or very subtle or nonspecific. Periodic bruising or petechial hemorrhages may be the only clinical signs. Internal hemorrhage within the brain or spinal cord may result in seizures or paralysis. Unilateral or bilateral epistaxis occurs in some affected animals and may be either spontaneous or associated with treatment with platelet-inhibitory medications. Trauma or surgery can result in severe hemorrhage with either intrinsic or extrinsic platelet disorders. Transfusion products required for treatment of intrinsic and extrinsic platelet disorders differ; therefore correct classification is necessary prior to development of an appropriate treatment regimen for a bleeding patient.

INHERITED MACROTHROMBOCYTOPENIA

Cavalier King Charles Spaniels (CKCS) have an autosomally recessive inherited macrothrombocytopenia that is not associated with clinical bleeding.[21,25,41,46,48] Platelet counts can range between 30,000 and 100,000/μL and large platelets are frequently observed. Platelets in affected CKCS have been reported as being both hypo- and hyper-responsive; discrepancies are likely due to variations in methodology and in the CKCS population

TABLE 82.1 Genetic Basis for Inherited Intrinsic Platelet Disorders Reported in Dogs, Cattle, and Horses

Disorder/Breed	Gene[a]	Mutation[b]
Macrothrombocytopenia		
Cavalier King Charles Spaniel	*β1-Tubulin*	Exon 4, G>A, D>N
Glanzmann thrombasthenia		
Great Pyrenees	*αIIb*	Exon 13, 14-base duplication
Otterhound	*αIIb*	Exon 12, G>C, D>H
Thoroughbred (England)	*αIIb*	Exon 2, G>C, R>P
Quarter Horse (Alabama)[c]	*αIIb*	Exon/Intron 11, 10-base deletion; Exon 2, G>C, R>P
Peruvian Paso (Idaho)	*αIIb*	Exon/Intron 11, 10-base deletion
Oldenbourg (Canada)	*αIIb*	Exon 2, G>C, R>P
Cyclic hematopoiesis		
Gray collie	*AP3β1*	Exon 20, 1-base duplication
ADP Receptor		
Greater Swiss Mountain Dog	*P2Y12*	Exon 2, 3-base deletion
Chediak-Higashi		
Japanese Black cattle	*LYST/CHS1*	6065A>G, H>R
Selective ADP deficiency		
American Cocker Spaniel		Not known
Signal transduction		
Basset hound	*CalDAG-GEFI*	Exon 5, 3-base deletion
Spitz	*CalDAG-GEFI*	Exon 5, 1-base duplication
Landseer-ECT	*CalDAG-GEFI*	Exon 8, C>T, R>STOP
Simmental cattle	*CalDAG-GEFI*	Exon 7, T>C, L>P
Arabian horse	*CalDAG-GEFI*	Exon 6, C>G, H>Q
German Shepherd	*Kindlin-3*	Exon 12, 12-base insertion
Procoagulant expression		
German Shepherd		Not known

[c]Compound heterozygote.

evaluated. The prolonged PFA-100 closure times reported in some CKCS are likely secondary to acquired VWD in dogs with concomitant mitral valve regurgitation and are not related to the inherited macrothrombocytopenia.[51] The high shear conditions generated with mitral valve regurgitation and other types of heart valve disorders can result in enhanced cleavage of von Willebrand Factor (VWF) by ADAMTS13 (a disintegrin and metalloprotease with thrombospondin repeats), an enzyme that cleaves VWF under high shear conditions.[52] Evaluation of plasma VWF antigen concentration and VWF collagen binding activity should be included in the diagnostic profile. The large platelets in affected CKCS can be equal in size or larger than erythrocytes and tend to be spherical to oval in shape with prominent alpha granule staining. A mis-sense mutation at coding nucleotide 745 (c.745G>A) in the gene encoding β1-tubulin correlates with the inherited macrothrombocytopenia in CKCS.[22] The mutation is predicted to result in the substitution of an asparagine for aspartic acid at amino acid position 249 (D249N) (Tables 82.1 and 82.2). Aspartic acid 249 is part of a microtubule intraprotofilament binding site and the change in charge at this position is thought to impair microtubule assembly necessary for normal proplatelet formation and platelet production by megakaryocytes. The prevalence of the mutation in United States CKCS is high; in the study by Davis et al., 90% of the CKCS were found to be either homozygous or heterozygous for the mutation. In the same study 65% of CKCS in Ireland were either heterozygous or homozygous for the mutation. Treatment is not necessary for this disorder; affected dogs do not have clinical signs.

Recently two non-CKCS dogs were documented to be heterozygous for the β1-tubulin gene mutation described in CKCS (M.K. Boudreaux, personal observation). Mutations in β1-tubulin should be considered as part of the differential diagnosis in dogs with persistent thrombocytopenia in the absence of clinical signs.

MEMBRANE RECEPTOR DISORDERS

Glanzmann Thrombasthenia (GT)

Glanzmann thrombasthenia is characterized by absence or marked reduction in platelet glycoprotein complex IIb-IIIa, also known as integrin αIIb-β3 and as the fibrinogen receptor.[39] In people, GT is categorized into three main types: Type I, Type II, and Variant. In Type I less than 5% of the receptor is detectable on platelet surfaces and clot retraction is absent. In Type II 10–20% of the receptor is present on platelet surfaces and clot retraction is detectable but reduced. In Variant GT the receptor is present but dysfunctional; clot retraction may or may not be detectable. In veterinary medicine, Type I GT has been documented in horses and dogs.[5,24,33,36] The αIIb-β3 complex primarily binds fibrin-

TABLE 82.2 Comprehensive Description of Reported Mutations Causing Animal Platelet Disorders

Macrothrombocytopenia	
Cavalier King Charles Spaniel	There is a substitution of an A for a G in the gene encoding β1-tubulin at coding nucleotide 745 (c.745G>A) resulting in the substitution of an asparagine for aspartic acid at amino acid 249 (D249N). Microtubule stability is impaired resulting in aberrant proplatelet formation and platelet release. Affected dogs do not have clinical signs
Glanzmann thrombasthenia	
Great Pyrenees	A 14-base duplication near the end of exon 13 of the gene segment encoding for the fourth calcium binding domain of αIIb results in defective splicing of intron 13 and appearance of a premature stop codon
Otterhound	A single nucleotide change at coding nucleotide 1100 (c.1100G>C) in exon 12 of the gene encoding for αIIb results in the substitution of a histidine for an aspartic acid in the third calcium binding domain of αIIb (D367H). This results in a charge change in a highly conserved region of the protein. Similar mutations in humans resulted in destabilization of the αIIb-β3 complex resulting in lack of expression of the complex on the platelet surface
Thoroughbred-cross (England) and Oldenbourg (Canada)	A single nucleotide change at coding nucleotide 122 (c.122G>C) in exon 2 of the gene encoding αIIb results in the substitution of a proline for an arginine (R41P) in a highly conserved region of the protein
Quarter Horse (Alabama)	This horse is a compound heterozygote with the same mutation described in the Thoroughbred in England as well as a 10-base deletion encompassing the splice site at the end of exon 11 in the gene encoding for αIIb. This second mutation likely results in lack of synthesis of the protein due to the appearance of a premature stop codon leading to nonsense-mediated decay
Peruvian Paso (Idaho)	This horse is homozygous for the 10-base deletion in the gene encoding αIIb described in the Quarter horse in Alabama
Cyclic hematopoiesis	
Gray collie	There is a 1-base duplication (A) in a tract of 9 adenine nucleotides in exon 20 of the gene encoding the beta subunit of adaptor protein complex 3. The mutation and resulting frameshift cause the appearance of a premature stop codon. The protein is part of a complex that directs trans-Golgi export of transmembrane cargo proteins to granules
Chediak-Higashi syndrome	
Japanese Black cattle	There is a single nucleotide change (c.6065A>G) resulting in the substitution of an arginine for a histidine (H2015R) in the gene encoding a lysosomal trafficking regulator protein referred to as LYST or CHS1
CalDAG-GEFI disorder	
Basset hounds	There is a deletion in coding nucleotides 509, 510, and 511 (c.509–511delTCT) of the gene encoding CalDAG-GEFI resulting in deletion of a phenylalanine at position 170 (p.F170del) in structurally conserved region 1 (SCR1) of the catalytic domain of the protein. This mutation results in a qualitative disorder; the protein can be detected in western blots
Eskimo Spitz	There is a duplication of coding nucleotides 452 (c.452dupA) of the gene encoding CalDAG-GEFI resulting in a frame shift starting at the codon encoding aspartic acid 151 (D151) near the beginning of SCR1. This frame shift results in the appearance of a premature stop codon at nucleotide 796.
Landseers-ECT	There is a premature stop codon at the codon encoding arginine at position 328 (R328Stop) of the gene encoding CalDAG-GEFI due to a substitution at coding nucleotide 982 (c.982C>T) at the beginning of the sequence encoding SCR4. The protein is not synthesized likely due to nonsense mediated decay of mRNA.
Simmental cattle	There is a substitution at coding nucleotide position 701 (c.701T>C) in the gene encoding CalDAG-GEFI resulting in the change of a leucine to a proline in SCR2 at amino acid 234 (L234P).
Arabian horse	There is a single nucleotide change at coding nucleotide 687 (c.687C>G) predicted to result in the change of a histidine to a glutamine at position 229 (H229Q) in SCR2. Although this mutation is within a SCR, the platelet function phenotype is mild compared to CalDAG-GEFI disorders described in dogs and cattle.

ogen; however, it can also bind other RGD-containing adhesive proteins, including von Willebrand factor. Glanzmann thrombasthenia is inherited as an autosomal recessive trait and is characterized by the inability of platelets to aggregate in response to all agonists, including thrombin. The alpha and beta subunits of the receptor are encoded by separate genes; both subunits are necessary for the formation of a stable complex on the platelet surface. All cases of GT described in domestic animals have been due to mutations in the gene encoding the αIIb subunit; mutations in the gene encoding β3 have not yet been identified.[7,8,17,18,32] Most mutations are in areas of the gene encoding for calcium binding domains within αIIb (Tables 82.1 and 82.2). αIIb subunits are not detected in flow cytometric assays using antibodies specific to the αIIb subunit. Flow

cytometric studies using antibodies to the β3 subunit or to the αIIb-β3 complex may detect β3 subunits associated with vitronectin receptors (αv-β3) which share the β3 subunit and may be increased in these patients.[38] Platelets isolated from dogs with GT do not bind CAP-1, a monoclonal antibody specific for a receptor-induced binding site (RIBS) epitope on canine fibrinogen, when activated by strong agonists.[6]

Glanzmann thrombasthenia (formerly known as thrombasthenic thrombopathia) has been reported in Otterhounds and Great Pyrenees dogs, and in horses in England, Australia, Canada, Japan, and the United States. The prevalence of carriers for the mutation in Otterhounds is between 25% and 30% based on genetic testing done at Auburn University. The prevalence of the mutation in Great Pyrenees dogs is not known; only sporadic testing is being conducted by owners and breeders. Great Pyrenees dogs that are carriers for the mutation have been detected in several states, including Mississippi, Alabama, Florida, Missouri, Minnesota, Indiana, Illinois, Oklahoma, and Washington. The horses described in Australia and Japan have not been documented at the molecular level.[37,50] The Quarter Horse described at Auburn University was a compound heterozygote and had two distinct mutations in the gene encoding αIIb. One mutation was identical to that described in the horse in England. The other mutation was a 10-base deletion encompassing the exon 11–intron 11 splice site (Tables 82.1 and 82.2). Recently, a 10 year-old horse in Idaho with GT was documented to be homozygous for the same 10-base deletion (M.K. Boudreaux, personal observation). The prevalence of mutations causing GT in horses is unknown.

P2Y12 Receptor Disorder

Recently a Greater Swiss Mountain dog in Calgary, Alberta, Canada was identified with a mutation in the gene encoding P2Y12. The dog experienced excessive bleeding after a routine spay. No other clinical signs were noted. (MK Boudreaux, personal observation).

STORAGE POOL DISORDERS

Cyclic Hematopoiesis

Cyclic hematopoiesis is an autosomal recessive disorder described in gray collies characterized by cyclic fluctuations in the number of circulating neutrophils, reticulocytes, and platelets.[16,23,34] Melanocytes are also affected in this disorder resulting in the gray color of affected animals. A bone marrow stem cell defect results in neutropenic episodes occurring approximately every 12 days. Mortality is high; most puppies die prior to 6 months of age due to fulminating infection. Thrombocytopenia does not occur and platelet numbers fluctuate between 300,000 and 700,000/μL. Platelet dense granules are absent. Platelet reactivity to several agonists is defective; clot retraction and platelet adhesiveness are impaired. A mutation in the gene encoding adaptor protein complex 3 beta-subunit (AP3β1) has been linked to this disorder.[2] AP3 directs trans-Golgi export of transmembrane cargo proteins to granules.

Chediak-Higashi Syndrome (CHS)

Chediak-Higashi syndrome is an autosomal recessive genetic disorder characterized by abnormal leukocyte, melanocyte and platelet granulation. Affected animals have partial oculocutaneous albinism, increased susceptibility to infection, and a bleeding diathesis as a result of impaired platelet function. Platelets of affected animals lack discernable dense granules and are deficient in granule storage pools of adenine nucleotides, serotonin, and divalent cations. Platelet aggregation in response to collagen, which is largely dependent on thromboxane generation and granule release of ADP, is markedly reduced in affected animals.[28] The disease was identified in a line of Persian cats: all of the affected animals exhibited a "blue smoke" hair color and pale irises with the development of bilateral nuclear cataracts in several animals as early as 3 months of age.[30] Affected cats experienced prolonged bleeding at incision sites and the development of hematomas following venipuncture. Chediak-Higashi syndrome has also been diagnosed in Aleutian mink,[40] three breeds of cattle,[1,40,53] blue foxes,[47] killer whales,[44] and mice.[35] CHS in Japanese Black cattle, mice, and people has been linked to mutations in the lysosomal trafficking regulator (LYST) gene which encodes a 425 kDa cytoplasmic protein that may be involved with incorporation of proteins into lysosomal membranes.[31] Molecular studies have not been reported in Brangus or Hereford cattle or other species affected with CHS.

Dense Granule Defect

A dense granule defect has been described in a family of American Cocker Spaniels.[13] Affected dogs had a moderate to severe bleeding diathesis, particularly after trauma or surgery. Three of five affected dogs had impaired platelet aggregation responses to ADP and collagen. Platelet ^{14}C-serotonin uptake and retention were normal; ATP content was also normal. ADP content was low resulting in an increased ATP/ADP ratio. Platelet morphology at the electron microscopic level was normal suggesting a functional dense granule defect. The disorder has not been recognized in Cocker Spaniels since the initial report. Molecular studies have not been conducted.

SIGNAL TRANSDUCTION DISORDERS

Calcium Diacylglycerol Guanine Nucleotide Exchange Factor I (CalDAG-GEFI) Thrombopathias

Basset hounds, Eskimo Spitz, Landseers of European Continental Type (ECT) and Simmental cattle have been identified with inherited signal-transduction platelet disorders that are virtually identical in presentation at

the clinical and functional level.[4,15,26,27,29,45,49] Terms describing these disorders in the literature include canine thrombopathia, Basset hound thrombopathia, Spitz thrombopathia, Landseer thrombopathia, Bovine thrombopathia, and Simmental thrombopathia. Platelet aggregation responses to ADP and collagen are minimal to absent in affected animals. Platelet aggregation in response to thrombin is rate-impaired and is characterized by a lag phase, lengthening the time to complete aggregation to 4–6 minutes (normal dog platelets aggregate fully within 3 minutes). Because thrombopathic platelets do respond to thrombin, clot retraction assays are normal. Flow cytometric assays using antibodies to αIIb or β3 show normal receptor density. CAP-1 binding is absent on ADP or PAF-activated thrombopathic canine platelets indicating that affected platelets either fail to bind fibrinogen or the αIIb-β3 receptor fails to induce changes in the conformation of fibrinogen necessary for detection by this RIBS antibody.[9] Platelet function disorders, likely due to problems with signal transduction, have been described in other breeds, including mixed-breed dogs.[14] These disorders have not been evaluated at the molecular level. As observed in people,[43] signal-transduction disorders are probably the most common cause of inherited intrinsic platelet disorders in dogs and possibly other species. The molecular basis for the signal transduction-related platelet disorders in Basset hounds, Spitz, Landseers-ECT and Simmental cattle is due to distinct mutations in the gene encoding calcium diacylglycerol guanine nucleotide exchange factor I (CalDAG-GEFI).[9,10] All of the mutations are within areas encoding structurally conserved regions (SCRs) of the catalytic domain (Tables 82.1, 82.2, and 82.3). CalDAG-GEFI is a signal transduction protein that functions as a guanine nucleotide exchange factor (GEF) and facilitates GDP/GTP switching by Rap1b. Rap-1b is a Ras-related low molecular mass guanine nucleotide binding protein (GTPase) that is activated by the binding of GTP. Activated Rap-1b is critically involved in activation and change of conformation of integrin αIIb-β3 necessary for fibrinogen binding and ensuing platelet aggregation.[3] The ability of thrombin to activate mutant platelets is thought to be attributable to the ability of PAR4 signaling to bypass CalDAG-GEFI and activate Rap1b directly or act via a pathway independent of Rap1b.[9,20]

The mutation in Basset hounds is believed to be widespread; results of DNA testing at Auburn University indicate that between 25% and 30% of Basset hounds are carriers for the mutation. The mutation is more prevalent in Basset hound lines used for show rather than for hunting. Landseer-ECT is a distinct breed recognized in Europe since 1960. Breeders within several European countries have tested their breeding stock for the CalDAG-GEFI mutation. The prevalence of the carrier state in Landseers-ECT, based on testing at Auburn University, is around 25%. Other than the original two Eskimo Spitz reported in 1994, no other affected or heterozygous Eskimo Spitz have been identified. Whether this small number results from a very low prevalence or lack of recognition of the disorder is not known. The prevalence of the CalDAG-GEFI gene mutation in Simmental cattle is also unknown; testing for the disorder has not been mandated by breed organizations. A mutation in CalDAG-GEFI was identified in an Arabian horse that presented with hemoabdomen and enlarged spleen at Auburn University (M.K. Boudreaux, personal observation). The mutation was a single nucleotide change in Exon 6 at coding nucleotide 687 (c.687C>G) and is predicted to result in the change of a histidine to a glutamine at position 229 (H229Q) in SCR2 (Table 82.3). Although this mutation was in an area encoding a highly conserved region and would be predicted to affect the structure of SCR2, platelet aggregation in response to ADP and collagen was only mildly diminished. The presence of this mutation may result in enhanced susceptibility of affected horses for abnormal hemorrhage, particularly if given platelet inhibitory medications or subjected to trauma.

To eliminate confusion in the literature and to more precisely describe the nature of the platelet disorders described in Basset hounds, Spitz, Landseers-ECT, and Simmental cattle they should be referred to as CalDAG-GEFI platelet disorders. Although CalDAG-GEFI is also expressed in brain, neurological signs in people or animals with CalDAG-GEFI disorders have not been reported. CalDAG-GEFI may play a role in signal transduction events in other hematopoietic cells, including neutrophils. Redundant pathways, however, are likely responsible for preventing significant impairment of neutrophil function in animals with CalDAG-GEFI mutations.

Kindlin-3

Recently a mutation in the gene encoding Kindlin-3 was identified in a German Shepherd dog referred to Washington State University (MK Boudreaux, personal observation). The dog had a history of prolonged bleeding, persistently high leukocyte counts, and susceptibility to infections. Kindlin-3 is a signal transduction

protein shared by all hematopoietic cells that plays an essential role in integrin activation.

PROCOAGULANT EXPRESSION DISORDERS

Scott Syndrome

A family of German shepherd dogs has been described with a bleeding disorder resulting from lack of procoagulant expression on the surface of platelets, similar to Scott syndrome described in people.[11,12] Affected dogs experienced intramuscular hemorrhage, epistaxis, and hyphema. Platelet morphology at the light microscopic level and platelet numbers were normal. Platelet aggregation and release, clot retraction, and buccal mucosa bleeding times were also normal. Affected platelets were markedly impaired in their ability to externalize membrane phosphatidylserine or generate platelet prothrombinase activity in response to collagen, thrombin, or combinations of collagen and thrombin. Platelet microvesicle generation was also impaired in response to calcium ionophore, thrombin, and collagen. In flow cytometric experiments, Annexin V binding by affected platelets activated by calcium ionophore was markedly reduced, supporting the inability of platelets to express phosphatidylserine. Although this is a platelet disorder, the clinical signs are more typical of a coagulopathy due to the inability of the platelets to generate and support a surface for coagulation protein activation. The molecular basis for this disorder is not known in dogs or in people.

DIAGNOSIS

The existence of inherited thrombocytopenia should be considered in dogs, particularly in CKCS, with persistent macrothrombocytopenia in the absence of clinical signs. Documentation of a mutation in the gene encoding β1-tubulin is recommended to avoid subjecting these animals to unnecessary and potentially harmful drug treatments.

The existence of a qualitative intrinsic platelet disorder should be considered in animals with platelet-type bleeding (mucosal bleeding, epistaxis, petechial/ecchymotic hemorrhages) in the absence of thrombocytopenia (platelet numbers greater than 50,000/μL) and in the presence of normal coagulation screening assays and VWF factor antigen levels of greater than 15%. Diagnosis of novel intrinsic platelet disorders requires specialized testing which may include platelet aggregation and release, flow cytometry, and electron microscopy. Some of these techniques are not readily available and several require that the affected animal be on the premises of the testing facility for sample collection and processing. As a consequence, novel intrinsic platelet disorders are often diagnosed based on exclusion. In recent years the molecular basis for several of the documented inherited intrinsic platelet disorders in animals has been determined, not only facilitating diagnosis of affected animals but also providing a means of identifying heterozygous individuals.

CASE MANAGEMENT

Clinical signs in animals with inherited intrinsic platelet disorders can vary considerably, even in animals with the same type of disorder. On a day to day basis hemorrhages are typically mild and sporadic, and tend to be self-limiting. Transfusions are usually only required in animals scheduled for surgery or subjected to major trauma. Minor procedures such as ear and teeth cleaning should be performed with extreme care. Hemorrhage into the ear canal can result in a vicious cycle of trauma and hemorrhage as a consequence of head shaking and scratching that can be difficult to curtail. Bleeding in the oral cavity may initially be missed if the animal swallows the blood; melena may be the first indication of this type of bleeding. Bloating can occur with excessive swallowing of blood and air. Gingival bleeding can be controlled using topical thrombin in animals with CalDAG-GEFI thrombopathias; however, repeated use of thrombin may result in immune reactions to thrombin and should be avoided. Surgical adhesive can also be used for any of the inherited platelet disorders to control bleeding from small skin lesions. Irritants present in cedar shavings, harsh detergents, cigarettes, or solvents, may elicit epistaxis and exposure should be avoided. Oral or topical medications that inhibit platelet reactivity or result in thrombocytopenia should also be avoided. Blood loss through the gastrointestinal or urinary tracts can be insidious and can result in iron deficiency anemia. Iron levels should be monitored in affected dogs less than a year old with chronic insidious bleeding. The animals should also be evaluated for intestinal parasites. It may be necessary to supplement iron using oral supplements and if oral iron is not sufficient to restore iron levels then injections should be considered using the smallest gauge needle to minimize risk of bleeding at injection sites. Affected dogs should be evaluated by a veterinarian at least every 6 months, even in the absence of apparent clinical signs. Owners can be taught to periodically assess mucous membranes for lightening in color as an indication of anemia.

Animals scheduled for surgery or subjected to trauma may require transfusion of multiple units of platelet-rich plasma or platelet concentrates. These products, which can be difficult and costly to obtain, cannot be stored for longer than 5 days and should be maintained at room temperature with gentle rocking to avoid platelet activation. Whole blood transfusions can be administered, but when given in volumes designed to prevent circulatory overload they may not provide enough functional platelets to produce effective hemostasis.

Repeated transfusions in animals with GT may result in an immune response against αIIb-β3 on transfused platelets. In people with inherited platelet disorders alternative treatments have been evaluated including administration of 1-desamino-8-D-arginine vasopressin (DDAVP) and recombinant human factor VIIa.[19,42] The

mechanism of action of DDAVP in shortening of bleeding times in people with inherited platelet disorders is thought to entail more than enhanced release of VWF from Weibel-Palade bodies; however, those mechanisms remain unclear. DDAVP was found to be more useful in people with platelet signal transduction and granule disorders than in people with GT; recombinant human factor VIIa was found to be more useful in the latter group. The use of non-plasma-derived reagents and species compatible purified plasma products in veterinary medicine is largely unexplored but may be attractive as an alternative method of treatment, particularly in dogs.

Acronyms and Abbreviations

ADP, adenosine diphosphate; BMBT, buccal mucosal bleeding time; BVDV, bovine viral diarrhea virus; CCL5, chemokine L5; CKCS, Cavalier King Charles Spaniel; COX, cyclooxygenase; DIC, disseminated intravascular coagulopathy; EPO, erythropoietin; FDP, fibrin degradation products; FeLV, feline leukemia virus; IMT, immune-mediated thrombocytopenia; MR, mitral regurgitation; MVP, mitral valve prolapse; NSAIDs, non-steroidal anti-inflammatory agents; OHE, ovariohysterectomy; PAF, platelet activating factor; PFA-100, platelet function analyzer-100; PRP, platelet-rich plasma; TEG, thromboelastography; TXA_2, thromboxane A_2; VWD, von Willebrand disease; VWF, von Willebrand factor.

INTRODUCTION

Impaired platelet function should be considered in any patient with a bleeding tendency in the absence of thrombocytopenia, low von Willebrand factor (VWF) levels, or laboratory evidence of coagulopathy (e.g. prolonged prothrombin time, activated partial thromboplastin time, or activated clotting time).

Abnormal platelet function, also known as thrombopathia, thrombopathy, or thrombocytopathy, may be primary (congenital, usually inherited) or secondary (acquired). Inherited intrinsic platelet disorders and von Willebrand Disease (VWD) are discussed in other chapters in this text (see Chapters 81 and 82). Acquired disorders occur most commonly due to underlying disease or treatment with drugs or other exogenous agents. These conditions may be subcategorized into hypofunctional and hyperfunctional disorders, which may cause bleeding tendencies and thrombotic tendencies, respectively. Clinical manifestations of acquired thrombopathies are highly variable. Ideally, therapy should be directed toward removing or managing the underlying disease process or exogenous stimulus causing secondary platelet dysfunction. Specific etiologies and mechanisms of acquired platelet dysfunction are discussed in more detail below.

ACQUIRED PLATELET HYPOFUNCTION

Acquired platelet hypofunction may occur secondary to underlying disease or treatment with drugs or other exogenous agents.

Underlying Disease

Many pathologic conditions are recognized as potential causes of impaired platelet function, including renal failure, anti-platelet antibodies, infections, malignancies, increased fibrinolytic products, and others.

Uremia

Uremia is recognized as a cause of platelet dysfunction in people and animals.[29,34,61] Many molecules and pathways affecting platelet adhesion, aggregation, and secretion have been implicated.[1] An experimental model of renal failure in dogs resulted in prolonged buccal mucosal bleeding time and markedly impaired platelet glass bead retention, but did not significantly affect platelet concentration, volume, or aggregation in response to several agonists, or coagulation assays (prothrombin time and activated partial thromboplastin time), findings consistent with defective platelet adhesion.[15] Neither quantitative nor qualitative abnormalities in VWF have been shown consistently in people with uremia, suggesting that the impaired adhesion in the uremic dogs was due to abnormal platelet function.[1]

Anti-platelet Antibodies

Anti-platelet antibodies not only may cause immune-mediated thrombocytopenia (IMT), but are also recognized as a cause of platelet dysfunction. Specifically, antibodies against GPIIb-IIIa ($\alpha_{IIb}\beta_3$) and other key platelet surface receptors such as Ib-IX-V have been implicated in people.[1] Experimental work in dogs and equids suggests a similar phenomenon. A study in which serum from normal dogs or dogs with IMT was added to platelet-rich plasma (PRP) from a normal dog found the serum from dogs with IMT to cause impaired aggregation to several platelet agonists.[52] In another study, serum from dogs experimentally infected with *Ehrlichia canis* inhibited aggregation of platelets from a normal dog.[43] Serum from mule foals with experimentally-induced neonatal alloimmune thrombocytopenia had evidence of higher concentration of platelet-associated IgG than serum from control mule foals, and addition of serum from affected foals to donkey PRP caused impaired aggregation in response to collagen.[77] Exogenous anti-platelet antibodies also comprise a group of drugs designed to inhibit platelet function (see "Platelet Inhibitors", below).

Infection, Inflammation, and Neoplasia

There is evidence that type II bovine viral diarrhea virus (BVDV), in addition to causing thrombocytopenia, may also impair platelet function. Experimental work in neonatal calves showed impaired platelet aggregation in affected animals.[93,95] In contrast, work by the same research group found no evidence of altered platelet function in cattle persistently infected with BVDV.[94]

Feline leukemia virus (FeLV) can infect megakaryocytes and, in addition to causing many other hematologic abnormalities, may cause platelet abnormalities potentially associated with impaired function.[81] Clear evidence of a causal relationship between FeLV and platelet hypofunction is lacking. However, abnormal platelet or megakaryocyte morphology is a feature of many FeLV-related conditions, both neoplastic and non-neoplastic, and it is plausible that this has a functional correlate.[6,13]

There is conflicting information about the effects of endotoxin or sepsis on platelet function, with data to suggest both decreased and heightened reactivity.[92] Lipoteichoic acid from *Staphylococcus aureus* has been shown to impair intracellular calcium mobilization and aggregation in human platelets.[82] *Yersinia pestis* expresses a surface protein, YopM, that is structurally similar to the VWF- and thrombin-binding domain of the platelet GPIb receptor, and has been shown to inhibit aggregation of human platelets, possibly via competitive binding with thrombin.[54] The clinical significance of these findings is not clear.

Studies of experimentally-induced pancreatitis in dogs have found evidence of both platelet hypofunction and hyperfunction. In one study, pancreatitis caused impaired platelet aggregation in response to several agonists and reduced ATP release in response to collagen.[46] Another study found platelets to have increased sensitivity to ADP and PAF within the first hour after the insult to the pancreas, but diminished or normal sensitivity thereafter.[56]

Hyperglobulinemia, either due to antigenic stimulation (e.g. ehrlichial) or neoplasia (e.g. multiple myeloma), is commonly recognized in veterinary medicine as a potential cause of impaired platelet function, possibly by "coating" the platelet surface and impairing adhesion and aggregation.[29,87,91] Platelet dysfunction is a recognized complication of IgA and IgG myeloma and Waldenström macroglobulinemia in people, and some in vitro experiments have shown paraprotein to be capable of interfering with platelet function.[1] A dog with IgA myeloma had a mildly prolonged bleeding time but more specific platelet function assays were not performed.[79]

Increased Fibrinolytic Products and Liver Disease

It is not clear how often or to what degree increased plasma concentration of fibrin degradation products (FDPs) causes platelet inhibition in the clinical setting. Purified low molecular mass fibrinogen degradation products have been shown to inhibit platelet aggregation in vitro, but may not occur in high enough concentrations in vivo to produce this effect, and patients with disseminated intravascular coagulopathy (DIC) or other conditions may have decreased in vitro platelet aggregation due to in vivo platelet activation.[74,86] Nevertheless, increased plasma concentration of FDPs is commonly cited as a potential cause of impaired platelet function in animals.[29,87,91] Increased FDPs may occur due to increased fibrinolysis (e.g. in DIC) or decreased clearance (with liver insufficiency). Certainly, factors other than FDPs contribute to a bleeding tendency in patients with DIC. A study of dogs with liver disease found impaired platelet aggregation in response to some agonists, and bleeding tendencies consistent with thrombopathy, but FDPs were not shown to be the causative agent, and experimentally-induced hyperammonemia

has been shown to inhibit platelet aggregation in rats.[83,106]

Snake Envenomation

Snake venoms contain complex mixtures of bioactive molecules (e.g. proteases, phospholipases, disintegrins, lectins) that can affect hemostasis in many ways, including interference with platelet function via interaction with receptors, modulation of ADP release or TXA_2 formation, and production of reactive oxygen species.[23,69] Experimental work in animals has shown species-dependent platelet sensitivity to some snake venom proteins.[55]

Drugs and Other Exogenous Agents

Many drugs and other exogenous agents have been shown to have inhibitory effects on platelet function. Some of these agents have platelet inhibition as their main clinical application, while others cause platelet inhibition as a side-effect.

Platelet Inhibitors

Some drugs are designed to inhibit platelet function. Most of these are platelet receptor antagonists. Examples that have been used in animals include peptides or antibodies that inhibit GPIIb/IIIa ($\alpha_{IIb}\beta_3$ integrin) and agents that inhibit the ADP receptor.[4,5,9,16,17,24,25,27,33,45,98,100,103,109] New platelet inhibitors continue to be developed for use in people.[2,3]

Anti-inflammatory Agents

Many anti-inflammatory agents inhibit platelet function. The main inhibitory mechanism is inactivation of the cyclooxygenase (COX) enzyme, which results in decreased production of the potent platelet agonist, thromboxane A_2 (TXA_2). Aspirin, which irreversibly inactivates both COX-1 (expressed by both newly formed and mature platelets) and COX-2 (expressed only by immature platelets) isoenzymes, has been shown to inhibit platelet function in many animal models.[8,14,48,63,64,75] Platelet responses to aspirin evidently are species-dependent. In some species, aspirin impairs platelet aggregation in response to collagen and ADP. In cattle, however, treatment with oral aspirin resulted in decreased TXA_2 production but did not impair platelet aggregation in response to collagen, ADP, or PAF.[37] Aspirin also does not inhibit ADP-induced platelet aggregation in most dogs. This is likely because platelet release is not a necessary co-component of ADP-induced irreversible platelet aggregation in most dogs.[7,8,10] Aspirin will inhibit ADP-induced aggregation responses in the small subset of dogs in which ADP-induced platelet aggregation is accompanied by dense granule release.

Other non-steroidal anti-inflammatory agents (NSAIDs) inactivate COX reversibly, and some of them selectively inhibit COX-2. Phenylbutazone has been shown to inhibit platelet aggregation in horses for a short time after administration, without causing a prolongation in BMBT.[62] A recent study evaluating effects of several non-aspirin NSAIDs in dogs found that carprofen inhibited platelet aggregation, and caused thromboelastography (TEG) changes suggesting hypocoagulability, but deracoxib and meloxicam did not; in fact, deracoxib caused TEG changes consistent with increased clot strength.[14] However, information on effects of carprofen on platelet function in dogs is conflicting: other studies found no evidence of carprofen causing impaired aggregation or prolonged PFA-100 closure time.[35,42] Ketoprofen has been found to impair platelet aggregation and prolong PFA-100 closure time in dogs.[35,42] The clinical implications of this effect are likely to be mild. In another study, dogs given ketoprofen before ovariohysterectomy (OHE) had inhibited platelet aggregation but did not have prolonged BMBT; the authors concluded that ketoprofen was safe to give to healthy dogs pre-OHE, but any such dogs should be screened preoperatively for bleeding problems and closely monitored after surgery.[53]

Other Drugs and Exogenous Agents

There is a long list of other drugs or exogenous agents found to inhibit platelet function in animals or people. A partial list includes antibiotics (penicillins and cephalosporins); antihistamines; barbiturates; calcium channel blockers; chondroprotective agents; dextran 70; diethylcarbamazine; dipyridamole; fibrinolytic and anti-fibrinolytic agents; halothane; heparin; hydroxyethyl starch; local anesthetics; marine fatty acids; mycotoxins; propanolol; psychotropic drugs; radiographic contrast agents; and wine or grape juice.[1,8,19,20,26,28,30,36,39,48,49,51,58,60,65,70,72,105]

ACQUIRED PLATELET HYPERFUNCTION

Underlying disease or drug treatment may result in secondary platelet hyperfunction as well as hypofunction. Some studies in animals have found an association between underlying pathology or strenuous exercise and platelet activation, without demonstrating that the platelet response to the stimulus is abnormal.[67,68,80,97,99,102] This section will be limited to conditions shown to result in abnormally enhanced platelet reactivity.

Underlying Disease

Many pathologic conditions are recognized as potential causes of enhanced platelet reactivity, including infectious and inflammatory diseases, neoplasia, and others.

Infection, Inflammation, and Neoplasia

Several infectious diseases are associated with increased platelet reactivity in animals, including heartworm disease and Rocky Mountain spotted fever in dogs,

feline infectious peritonitis in cats, and pasteurellosis in cattle.[7–12,22,41,71] Platelets from experimentally infected animals have been found to be hyperaggregable in response to some agonists, although the mechanisms responsible for this enhanced reactivity are not well understood. There is conflicting data in the scientific literature about the effects of sepsis on platelet function in people, with evidence to suggest both inhibition and activation.[92]

Interleukin-6, in addition to stimulating thrombopoiesis, increases the sensitivity of canine platelets to activation by some agonists.[18,76] Ponies with experimentally-induced laminitis from excess dietary carbohydrate had increased platelet aggregation and formation of platelet-neutrophil aggregates.[100,101] However, there is evidence indicating that inflammation may impair as well as enhance platelet reactivity. As noted above, studies of dogs with experimentally-induced pancreatitis have found evidence of both platelet hypofunction and hyperfunction. Moreover, a study using bovine samples found that addition of C-reactive protein to platelets suspended in homologous plasma impaired aggregation in response to some agonists.[21]

Cancer may be a cause of acquired platelet hyperfunction. Platelet hyperaggregability was detected in two dogs with probable essential thrombocythemia.[31] A study in dogs found that platelets from dogs with cancer (not all of which were hematologic malignancies) were more sensitive to some agonists, compared to platelets from control animals.[59]

Taurine Deficiency in Cats

The effect of taurine deficiency on platelet function in cats has been the subject of investigation, at least in part because of the tendency for cats with cardiomyopathy associated with taurine deficiency to develop thromboembolic disease. One aggregometry study using collagen as an agonist found platelets from taurine-depleted cats to be hyperaggregable compared to platelets from cats receiving taurine, and platelets from people supplemented with taurine to be hypoaggregable compared to platelets from people with normal taurine status.[44] However, another similar study in cats did not confirm these findings, showing mildly increased collagen-induced serotonin release but no difference in collagen-induced platelet aggregation between taurine-deficient and taurine-replete cats; moreover, in this study there was evidence of decreased ADP-induced platelet aggregation and serotonin release.[104] A recent study using the PFA-100 instrument showed no evidence of shorter closure times in cats with hypertrophic cardiomyopathy, compared to normal cats.[47]

Heart Disease

Mitral valve disease is associated with increased reactivity and decreased survival of platelets in humans, and a possible association between mitral valve disease and platelet dysfunction has been the subject of investigation in dogs, particularly in Cavalier King Charles Spaniels (CKCS).[73] Congenital platelet abnormalities in CKCS, as discussed in more detail in Chapter 82, complicate interpretation of platelet function testing results in this breed. One study in CKCS found no correlation between degree of mitral valve prolapse (MVP) and platelet aggregation responses.[73] Another study found CKCS with MVP had enhanced aggregation responses regardless of mitral regurgitation (MR) status, but platelets did not appear to circulate in an activated state. In that study, CKCS with MR and dogs with subaortic stenosis had prolonged PFA-100 closure times but also had lower proportions of large VWF multimers, likely secondary to consumption under high shear conditions, suggesting a mechanism of impaired primary hemostasis other than platelet hypofunction.[90]

Nephrotic Syndrome

Enhanced platelet responsiveness to some agonists has been described in people and dogs with nephrotic syndrome, and may increase the risk of thromboembolic complications in these patients.[40,57,78,84] The basis of the enhanced sensitivity is probably multifactorial; one study found that hyperaggregability can be inhibited in vitro by increasing plasma albumin concentration.[40]

Asthma

A study of people with asthma found increased sensitivity of platelets to some agonists, as evidenced by increased intracellular free calcium concentration, increased CD62P expression, and increased plasma concentration of the RANTES or CCL5 cytokine.[66] This enhanced response was inhibited in people with asthma who were taking oral theophylline. It is not clear whether allergic respiratory disease in animals causes similar platelet hyperfunction.

Diabetes Mellitus

Diabetes is a risk factor for atherosclerosis in people, likely due in part to altered platelet function.[32,89,96] Platelet hyperreactivity in people with diabetes probably occurs due to multiple mechanisms, including glycation of proteins, oxidative damage to lipids, increased GP Ib-IX receptor expression, and altered signal transduction pathways.[32,85] Effects of diabetes on platelet function are evident in the laboratory by enhanced sensitivity to agonists. In one study, platelets from people with diabetes had increased adhesion to an extracellular matrix substrate composed of collagen, adhesive glycoproteins, and proteoglycans, but not VWF.[50] Rats with streptozotocin-induced diabetes had markedly increased release of arachidonic acid in response to thrombin in one study, and enhanced aggregation to ADP and thrombin and increased release of serotonin in response to thrombin in another study.[38,107] The prevalence and clinical significance of altered platelet function in domestic animals with diabetes is not known.

Drugs and Other Exogenous Agents

In dogs, administration of erythropoietin (EPO) increased platelet responsiveness to thrombin and increased the proportion of reticulated platelets.[108] A study in humans found that EPO increased platelet reactivity but did not change the numbers of reticulated platelets.[88,108] Platelet reactivity was increased after thiacetarsamide treatment of Beagles experimentally implanted with adult heartworms, but not after treatment of dogs with naturally occurring heartworm infections.[7]

Hemostasis is a vital protective mechanism that prevents blood loss by sealing sites of injury in the vascular system. Hemostasis must be controlled, however, so that blood does not coagulate within the vasculature. Such uncontrolled coagulation restricts normal blood flow, resulting in tissue hypoxia.

Hemostasis consists of a tightly controlled and well-balanced interplay among a large number of cellular and protein participants. Endothelial cells lining the vasculature, cells outside the vasculature, and platelets all play important roles. Hemostatic proteins include inactive precursors (zymogens) that are converted to active enzymes, regulatory proteins (cofactors) that enhance the functionality of their corresponding coenzymes, and inhibitors that interfere with protein function through a variety of mechanisms (see Table 84.1).

Normally, coagulation does not occur within the vasculature because properties of the resting cellular participants render them inactive, and because the majority of protein participants circulate in their inert, zymogen form. The initiation of coagulation in response to injury depends on the exposure of extravascular components that are not present within the bloodstream under physiologic conditions. Exposure of these extravascular participants initiates an explosive cascade of cellular activation, changes in cell-surface properties, and generation of active enzymes that produce a stable clot. Some of the cells and enzymes also trigger vascular wall responses, inflammatory pathways, and immune-defense mechanisms. Coagulation also initiates fibrinolysis, the process by which the clot is removed to restore blood flow. Ultimately, coagulation triggers the cell migration and proliferation that promote healing.

ENZYME BIOCHEMISTRY

The Nature of Enzymatic Cascades

The clotting cascade consists of a series of enzymatic reactions. Protein participants circulate in the blood mostly as inert precursors, or zymogens. These zymogens are activated by limited proteolysis to form active enzymes. With the exception of thrombin, all of these enzymes have limited activity unless they bind to their protein cofactor and a procoagulant membrane surface. Once the complete enzymatic complex has assembled on a suitable membrane surface, the activity of the enzyme is markedly exaggerated, by as much as several hundred-thousand fold.

Each cascade reaction is initiated when the active enzyme complex binds to its substrate, resulting in cleavage of the substrate to generate the next enzyme in the series. In many cases, positive feedback occurs because a downstream enzyme is able to back-activate an upstream zymogen, thereby markedly amplifying the generation of downstream enzymes from minimal amounts of upstream enzymes. Negative feedback is also a common feature in the coagulation cascade, with downstream enzymes generating inhibitors that down-regulate activity of upstream enzymes. The generation of a blood clot is carefully controlled through the complex interplay of the initial trigger, amplification, and inhibition.

Enzymatic Complexes (Cofactors and Enzymes)

The majority of enzymes participating in coagulation are serine proteases with homology to trypsin, the prototype enzyme of this class. Serine proteases cleave after arginine residues. Other coagulation proteins have no enzymatic capabilities, but rather play regulatory roles in enhancing enzymatic activity. These proteins circulate in inactive forms, called procofactors. A procofactor must be cleaved by the appropriate enzyme to result in a fully active cofactor. Proteolytic activation of zymogens to enzymes and procofactors to cofactors can take several forms (Fig. 84.1).

Many of these proteins contain disulfide bonds between two cysteine residues within the protein. Enzymatic cleavage of an activation site that lies between the cysteine residues will convert the protein from a single chain protein to a two chain protein of identical molecular weight, without removing any of the amino acid sequence.

When the activation site does not lie between disulfide bound cysteine residues, cleavage of a single site will result in two different fragments of the initial protein. The smaller non-functional fragment is the activation peptide, while the remaining fragment is the fully activated enzyme or cofactor.

Some of the proteins contain multiple activation sites. If both lie between disulfide-bridged cysteine residues, then an activation peptide is released and a two-chain enzyme is produced. The order in which the target sites are cleaved may result in inactive intermediates, or partially or fully active intermediate enzymes. Complete cleavage of all of the sites will generally result in multiple fragments.

Fully functional enzymatic complexes often consist of both an enzymatic subunit (the serine protease) and a regulatory subunit (the cofactor).

Inhibition of Enzymatic Activity

Coagulation and fibrinolysis enzymes may be inhibited through several general mechanisms: cleavage of the

TABLE 84.1 Hemostatic Proteins, Factors, Cofactors, and Inhibitors

Functional Classification	Abbreviation	Common Use Name	Previous Names	Characterization
Extrinsic pathway	TF	Tissue Factor	Thromboplastin	Cofactor
	FVII	Factor VII	Proconvertin	Zymogen
	FVIIa	Factor VIIa		Enzyme
Contact pathway	FXII	Factor XII	Hageman factor	Zymogen
	FXIIa	Factor XIIa		Enzyme
	PK	Prekallikrein	Fletcher factor	Zymogen
	K	Kallikrein		Enzyme
	HK	High molecular weight kininogen	Williams-Fitzgerald-Flaujeac factor	Cofactor
Intrinsic pathway	FXI	Factor XI	Plasma thromboplastin antecedent	Zymogen
	FXIa	Factor XIa		Enzyme
	FIX	Factor IX	Christmas factor	Zymogen
	FIXa	Factor IXa		Enzyme
	FVIII	Factor VIII	Antihemophilic factor	Procofactor
	FVIIIa	Factor VIIa		Cofactor
Common	FX	Factor X	Stuart-Prower factor	Zymogen
	FXa	Factor Xa		Enzyme
	FV	Factor V	Labile factor	Procofactor
	FVa	Factor Va		Cofactor
	Pro	Prothrombin	Factor II	Zymogen
	Fg	Fibrinogen	Factor I	Substrate
	Fb	Fibrin		Final product
	FXIII	Factor XIII		Zymogen
	FXIIIa	Factor XIIIa		Enzyme
Coagulation inhibitors	α_1PI	α_1-Protease inhibitor	α_1-Antitrypsin	
	AT	Antithrombin	Antithrombin III	Serpin
	HC	Heparin Cofactor II		Serpin
	TFPI	Tissue factor pathway inhibitor	Extrinsic pathway inhibitor	Kunitz inhibitor
	PC	Protein C		Zymogen
	APC	Activated protein C		Enzyme, inhibitor
	PS	Protein S		Cofactor
	TM	Thrombomodulin		Cofactor
	PZ	Protein Z		Cofactor
	ZPI	Protein Z dependent protease inhibitor		Enzyme
Fibrinolysis	PLG	Plasminogen		Zymogen
	PLM	Plasmin		Enzyme
	scUPA	Single chain urokinase plasminogen activator	Prourokinase	Zymogen (slight enzyme)
	tcUPA (uPA)	Two-chain urokinase plasminogen activator	Urokinase	Enzyme
	sctPA	Single chain tissue-type plasminogen activator		Enzyme
	tctPA (tPA)	Two-chain tissue-type plasminogen activator		Enzyme
Fibrinolysis inhibitors	α_2-AP	α_2-Antiplasmin	Plasmin inhibitor	Serpin
	PAI-1	Plasminogen activator inhibitor-1		Serpin
	TAFIa	Thrombin activatable fibrinolysis inhibitor	Carboxypeptidase U, B, or R	Enzyme
Nonspecific inhibitors	C1-INH	C1 inhibitor		Inhibitor
	α_2-MG	α_2-Macroglobulin		Inhibitor
	PN1	Protease nexin 1		Inhibitor
	PCI	Protein C inhibitor	Plasminogen activator inhibitor 3	Serpin

enzyme, blockage of the active site, formation of stable complexes, and modification of the substrate (Fig. 84.2).[39]

Some inhibitors are enzymes that act by cleaving the target protein, cutting it into pieces that are no longer functional. An example of this kind of inhibition is the cleavage of activated factor V (FVa) by activated protein C (APC).

Blockage of the active site is an inhibitory mechanism that is commonly employed by the pharmaceutical

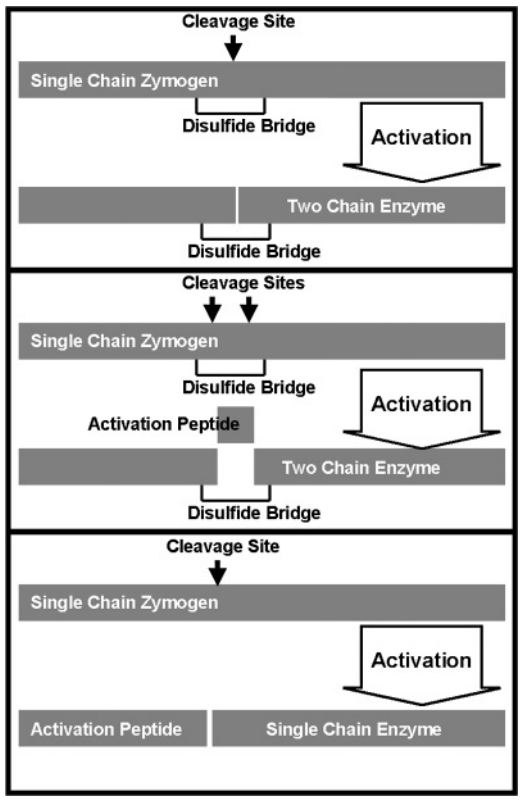

FIGURE 84.1 Enzymatic activation of coagulation proteins. Most coagulation proteins circulate as inactive, single chain polypeptides containing disulfide bridges between nonadjacent cysteine residues. Depending on the location of the disulfide bridges and the cleavage site (or sites), enzymatic cleavage may result in a two-chain activated protein of identical size to the precursor, a two-chain activated protein (smaller than the precursor) and a released activation peptide, or a single chain activated protein (smaller than the precursor) and a released activation peptide.

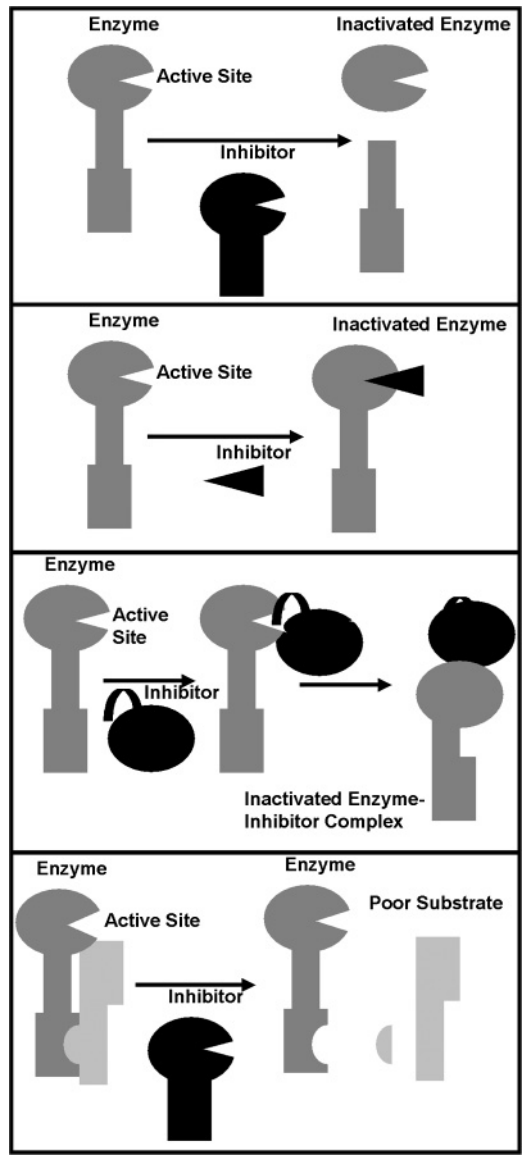

FIGURE 84.2 Coagulation enzyme and cofactor inhibition. Inhibitors work through a variety of different mechanisms: (**1**) Activated coagulation proteins can be inhibited by enzymes that cleave the target protein, damaging the structure and resulting in an inactivated protein. (**2**) Active site inhibitors bind the enzymatic site of the target enzyme, preventing the protease from cleaving its target protein. (**3**) Other inhibitors, such as serpins, display a "bait" peptide that looks like a substrate for the target enzyme. When the enzyme binds to and attempts to cleave the bait, the inhibitor changes in structure, resulting in a shift in position and structure of the target enzyme, which inactivates the enzyme into a stable complex with the inhibitor. (**4**) Some inhibitors modify the substrate rather than the target enzyme. These changes usually decrease binding interactions between the enzyme and the substrate, slowing or eliminating the ability of the enzyme to cleave its substrate.

industry and by some naturally occurring inhibitors. Small molecule inhibitors may fit directly into the enzymatic site, limiting the access of the substrate.

Other inhibitors act by binding to the enzyme and altering it so it can't be released. As a result, the target enzyme and inhibitor form a stable complex that permanently inactivates the enzyme. An example of this mechanism is inhibition of thrombin by antithrombin-heparin. Antithrombin (AT) is a member of the serpin (serine protease inhibitor) class of inhibitors. These inhibitors employ a "suicide-substrate" mechanism. They contain a small peptide loop that acts as "bait" that mimics substrates of the target enzyme. However, binding of the target enzyme to the bait results in serpin structural modifications that shift the position and conformation of the enzyme.

A few inhibitors work by changing the nature of the substrate, so that the enzyme cannot bind effectively to its target site. The thrombin activatable fibrinolysis inhibitor (TAFI) acts via this mechanism by cleaving fibrin to limit plasmin-mediated fibrinolysis.

Membrane Surface Interactions

The rate of coagulation is profoundly affected by the presence of appropriate membrane surfaces for enzymatic reactions. Membrane-binding enhances enzyme

activity because localization to a membrane surface helps properly align the participating proteins. Tissue factor (TF) is the only coagulation protein that is permanently attached to the membrane surface.[36]

Some coagulation proteins (factors VII, IX, X [FVII, FIX, FX]), prothrombin, proteins C, S, Z [PC, PS, PZ]) contain gammacarboxyglutamic acid (Gla) residues that enable protein binding to a membrane surface via interaction with calcium and negatively charged phospholipids. Calcium-binding of the Gla domains of these proteins requires that the glutamic acid residues are carboxylated via intra-hepatic post-translational modifications involving the vitamin K cycle (Fig. 84.3).

Incompletely carboxylated Gla proteins do not properly bind calcium and are unable to assemble on an activated membrane surface. The importance of carboxylation in membrane binding is dramatically illustrated by the profound adverse impact of vitamin K antagonists such as warfarin (See Chapter 85). The requirement of calcium for membrane-binding explains the ability of calcium chelators (e.g. citrate and EDTA) to prevent activation of many coagulation enzymes.

Some cofactors (factors V and VIII [FV and FVIII]) also have regions that interact with phospholipids, allowing fully functional enzymatic complexes to assemble on a membrane surface. The mechanism of membrane binding is less well described than that for Gla proteins, but involves the stereochemical configuration of the phosphatidylserine (PSer) head group.[21,23]

COAGULATION PROTEINS THAT GENERATE THROMBIN

Previous coagulation models divided coagulation into the extrinsic, intrinsic and common pathways (Table 84.1, Fig. 84.4). The extrinsic pathway consisted of generation of active factor X (FXa) by the complex of TF

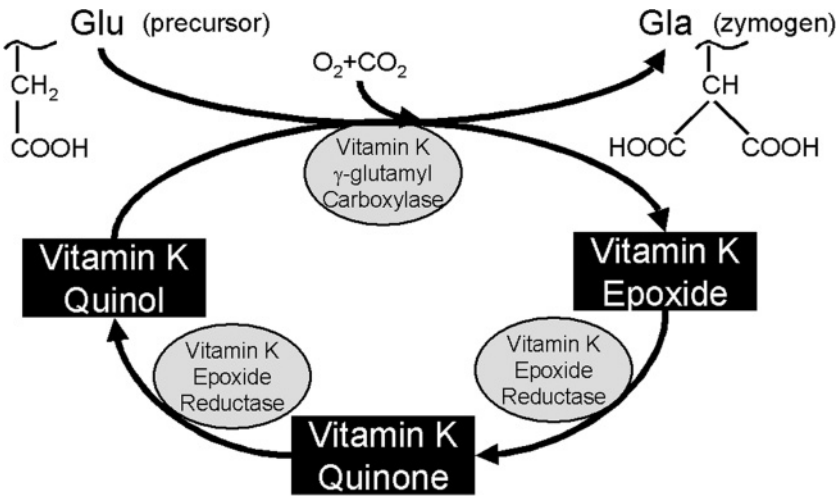

FIGURE 84.3 The vitamin K cycle. In hepatocytes this cycle is necessary for production of fully functional vitamin K dependent coagulation proteins. These proteins (prothrombin, FVII, FIX, FX, protein C, protein S, protein Z) are produced as precursors containing glutamic acid residues. The enzyme vitamin K γ-glutamyl carboxylase modifies these residues to γ-carboxyglutamic acid (Gla), producing zymogens containing Gla residues which are capable of binding Ca^{2+} and mediating membrane interactions. As a result of this enzymatic action, the vitamin K is converted to an epoxide, and must be regenerated via the activity of vitamin K epoxide reductase. Warfarin (and its derivatives) interfere with vitamin K epoxide reductase, preventing recycling of vitamin K epoxide to vitamin K quinol.

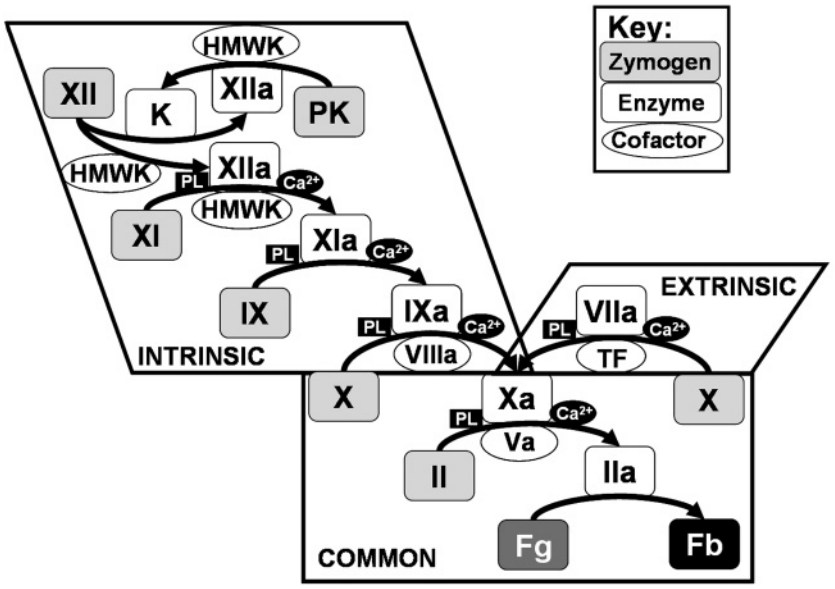

FIGURE 84.4 The cascade model of fibrin formation. This outdated model divides the coagulation system into separate, seemingly redundant pathways (extrinsic and intrinsic) either of which can result in the generation of FXa. The common pathway consists of formation of the prothrombinase complex (FXa-FVa) and results in generation of thrombin, followed by cleavage of fibrinogen to form fibrin. Many of the enzymes and enzymatic complexes require calcium (Ca^{2+}) and binding to active membrane surfaces (PL) for full activity. For simplicity, inhibitors of the various enzymes and feedback activation of procofactors to cofactors have been omitted. See Table 84.1 for abbreviations.

and activated factor VII (TF-FVIIa). The terminology "extrinsic" pathway arose from the requirement for TF (an extravascular, cell-bound protein) as a clotting trigger. The intrinsic pathway consisted of contact activation of factor XII (FXII), followed by a cascade consisting of activation of the downstream proteases factor XI (FXI) then FIXa-FVIIIa, ultimately resulting in FXa generation. This pathway was termed the "intrinsic" pathway due to the fact that it appeared to be intrinsic to blood, not requiring the addition of any extravascular trigger. The downstream portion of this cascade is still referred to as the intrinsic pathway, even though it is not truly intrinsic to blood. The common pathway consisted of the formation of the FXa-FVa complex, which generates thrombin. Thrombin then cleaves fibrinogen to fibrin, which spontaneously polymerizes into an insoluble fibrin gel.[9] These classifications have been useful for in vitro laboratory evaluation, but such divisions do not occur in vivo.

Contact Pathway (Kallikrein-Kinin Pathway)

The contact pathway consists of the zymogens FXII (Hageman factor) and prekallikrein (PK), and the cofactor high molecular weight kininogen (HK; see Table 84.1). Activation of the two zymogens occurs spontaneously (auto-activation) upon assembly of the proteins on a suitable negatively charged surface.[7] Because FXIIa can cleave downstream coagulation proteases, contact activation ultimately results in generation of thrombin and therefore formation of a fibrin clot. Consequently, contact activation (i.e. creation of the enzymes FXIIa and kallikrein) occurs whenever blood comes in contact with an artificial surface. Contact activation always occurs, to some extent, when blood is removed from the vascular system. The contact pathway is the source of blood's apparent "intrinsic" clotting potential, and the reason blood coagulates when collected into a syringe or tube in the absence of anticoagulants. The amount of FXIIa and kallikrein generated depends on the negative charge of the artificial surface. Therefore, blood clots relatively slowly in plastic, more quickly in glass, and most rapidly when in contact with a strong negative charge. Note that contact activation is *not* calcium dependent, and consequently is not abolished by collection of blood into calcium chelators such as citrate or EDTA.

Traditional coagulation cascade models often depict the contact pathway and the extrinsic pathway as independent and redundant generators of FXa, and subsequent thrombin and fibrin production (see Fig. 84.4). Recent advances clearly indicate that the contact pathway, while an important feature of in vitro coagulation, is irrelevant for in vivo hemostasis. The evidence to support this concept includes comparative genomics that reveal a complete absence of the FXII gene in cetaceans and non-mammalian vertebrates (see Chapter 91). In addition, many mammalian species (e.g. humans, mice, cats, and dogs) with inactivating FXII or PK mutations have no bleeding tendency.[37]

Recent work suggests that the contact pathway plays a role in pathologic thrombus formation.[16,37] The physiologically relevant negatively charged surface that allows contact activation to influence coagulation in vivo has not been identified, although RNA,[22] polyphosphate,[46] and misfolded proteins[26] have been proposed to serve this function.

Contact activation has a defined role, however, in several physiologic processes. Contact activation on negatively charged phospholipid cell membranes is primarily responsible for bradykinin generation. The contact pathway has additional anti-adhesive, profibrinolytic, proinflammatory, and antithrombotic properties, and it is involved in angiogenesis (Fig. 84.5).[7]

Factor XII

Factor XII is produced in the liver and circulates as a single chain molecule with molecular weight of about 80 kDa. Cleavage by either kallikrein or plasmin generates a two-chain active enzyme (FXIIa) composed of a light and heavy chain. The heavy chain contains two sites that bind to negatively charged surfaces, and the light chain is a serine protease. Autoactivation to FXIIa may occur when FXII binds to a negatively charged

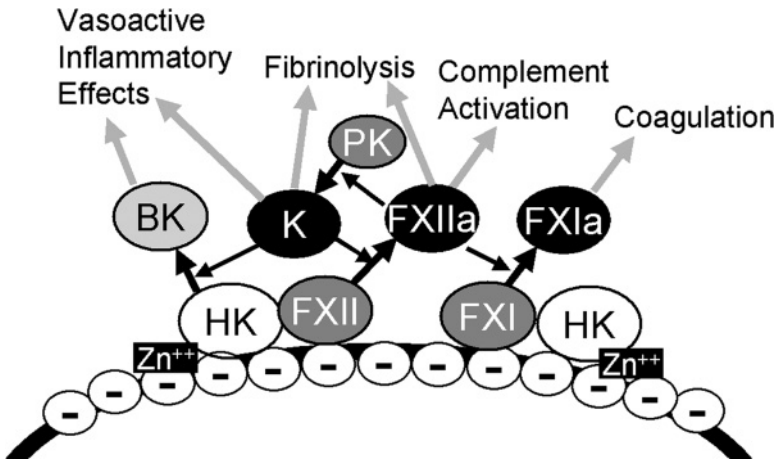

FIGURE 84.5 The contact pathway. This involves the assembly of FXII and K on a negatively charged surface, resulting in autoactivation of zymogen FXII to the enzyme FXIIa. FXIIa can then activate PK to K, and K can back activate more FXII to FXIIa. K also cleaves HK to generate BK while FXIIa can activate FXI to FXIa. The major products of contact activation have important roles unrelated to coagulation, in inflammation, vasoactive regulation, and fibrinolysis. See Table 84.1 for abbreviations.

surface, especially in the presence of Zn^{2+}. Prekallikrein, HK, and FXI are FXIIa's primary coagulation substrates; however, it also activates the complement pathway and cleaves single chain urokinase plasminogen activator (scuPA) into its two chain form. C1-inhibitor (C1-INH) is the major inhibitor of FXIIa.[7,44]

Prekallikrein

Prekallikrein is a single chain molecule of about 86 kDa expressed in many tissues, with highest levels in the liver. Approximately 75% of PK circulates bound to HK. Conversion of PK to kallikrein by FXIIa occurs on a negatively charged surface when HK is also bound. This generates a light chain (containing the serine protease) and a heavy chain. Autoactivation of PK at a different cleavage site results in a less active enzyme, β-kallikrein. Kallikrein's primary substrates are FXII and HK. Like FXIIa, kallikrein also cleaves scuPA. Kallikrein is primarily inhibited by C1-INH and α_2-macroglobulin (α_2-MG). Kallikrein is also inhibited by protein C inhibitor (PCI) and, when bound to HK, by heparin-AT.[7]

Kininogens

High molecular weight kininogen and low molecular weight kininogen are multi-domain, distinct protein products of the same gene produced by alternative splicing. Both proteins contain an identical heavy chain (domains 1, 2, and 3) and domain 4. The light chain of HK contains domains 5 and 6, while the light chain of its low molecular weight form contains a different domain 5 and no domain 6.

Kininogens have a multitude of functions unrelated to coagulation. Domains 1, 2, and 3, respectively, inhibit atrial natriuretic peptide, prevent calpain-mediated platelet aggregation, and prevent thrombin binding to platelets. Upon cleavage by kallikrein, domain 4 releases the critical vasoactive peptide bradykinin. Domain 5 of HK contains the binding site for charged-surfaces, has anti-adhesive properties affecting protein and cell-binding to neutrophils and endothelial cells, and also influences apoptosis. Domain 6 is the binding site for kallikrein and affects neutrophil activation. Endothelial cells, granulocytes, and platelets contain HK and express binding sites for HK on their resting membrane surface. Platelet activation results in dramatic increase in surface HK, due to release and increased expression of HK binding sites. Zn^{2+} is absolutely required for binding of HK to membrane surfaces.[7]

Extrinsic (Tissue Factor) Pathway

Tissue Factor

Tissue factor, also known as thromboplastin, CD142, and factor III, is a glycosylated single polypeptide chain of approximately 29.5 kDa. It is synthesized in a variety of cells, and expressed on the cell surface as an integral membrane protein. The extracellular portion of the molecule is responsible for interaction with coagulation proteins. The transmembrane domain anchors TF to the cell surface and is required for procoagulant activity. A small cytosolic domain is dispensable for coagulation functions, but is involved with intracellular signaling in TF's role as a cell-surface receptor.[34,36]

In physiologic circumstances, TF is expressed by adventitial cells surrounding blood vessels larger than capillaries, differentiating skin keratinocytes, and by other epithelial cells, particularly in mucous membranes and organ capsules. This distribution is consistent with TF's function as a protective "hemostatic envelope" whose role is instant initiation of coagulation. Under pathologic conditions, TF expression can be upregulated in other cell types by cytokines and other inflammatory mediators. Endothelial cells, vascular smooth muscle cells, monocytes, and granulocytes may express TF in disease states. Tissue factor is found in atherosclerotic plaques and is expressed by some malignant cells. Based on the lack of reports of TF deficiency in humans or animals, and the lack of viability of mice when the TF gene is deleted, TF expression appears to be essential for life.[36]

Tissue factor serves as the regulatory subunit of the TF-FVIIa enzymatic complex. Cell-surface TF, unlike most cofactors, fully functions as a cofactor without proteolysis. Although FVIIa is a weak enzyme alone, the TF-FVIIa enzyme complex is the most potent activator of coagulation. Consequently, TF-FVIIa is the first enzyme in the clotting cascade.

Tissue factor is primarily sequestered outside the vasculature to prevent intravascular coagulation; however, TF antigen has been detected at low levels in blood. The source and role of this "blood-borne" TF are currently a matter of intense investigation. Blood-borne TF is thought to be associated primarily with microparticles and monocytes. It appears to accumulate in thrombi and may play a role in thrombus propagation. Circulating TF appears to be of limited procoagulant activity under normal circumstances. Some investigators believe that circulating TF is "encrypted" and must be cleaved by an enzyme for activity. Others believe that circulating TF is not fully active because the membrane surface on which it resides is not an appropriate procoagulant membrane.[34,36]

Factor VII

Factor VII is a glycosylated single chain polypeptide with a molecular weight of approximately 50 kDa. It is a vitamin K-dependent protein produced in the liver and contains 10 Gla residues. It has the shortest half-life of the Gla proteins, so that FVII levels decrease rapidly if the vitamin K cycle or liver function is impaired. Factor VII binding to TF and to membrane surfaces via its Gla domain are calcium-dependent interactions. The FVII zymogen is converted to active FVIIa by proteolysis of a single peptide bond resulting in a two-chain molecule of identical size. Factor VIIa can be generated by a variety of downstream proteases, including FIXa, FXa, FXIIa, FVII activating protease, thrombin, and

plasmin. Factor VII bound to TF can also be autoactivated by TF-FVIIa. The most important physiologic FVIIa activator has yet to be definitively determined.[36]

Factor VIIa is unique among coagulation enzymes in that some of it circulates with a long plasma half-life of approximately 2 hours (as compared to other serine proteases whose enzyme half-lives are measured in seconds). Approximately 1% of total circulating FVII antigen is active FVIIa, although inter-individual FVIIa levels vary considerably.[35] The intriguing question of how and where circulating FVIIa is generated remains unanswered at this time. Factor IXa may be an important contributor of FVIIa generation, as patients deficient in FIX (hemophilia B) have very low levels of FVIIa.[50] Factor VIIa levels are higher in lymph than plasma, suggesting that some FVIIa may be generated outside the vasculature and returned to the bloodstream via lymphatic circulation.[32]

Because some FVII circulates as FVIIa, exposure of blood to TF as a result of injury leads to formation of both TF-FVII complexes and TF-FVIIa complexes. The initial TF-FVIIa formation and autoactivation of TF-FVII to additional TF-FVIIa is believed to generate sufficient enzymatic activity to trigger the clotting cascade via cleavage of the primary TF-FVIIa substrates, FIX and FX.[36] The TF-FVIIa complex is often referred to as extrinsic tenase when its target substrate is FX. Deficiency of FVII is associated with a highly variable, but potentially severe bleeding tendency.[29]

Free plasma FVIIa is not inactivated by any plasma protease inhibitor, hence its long half-life. The TF-FVIIa complex is inhibited by the tissue factor pathway inhibitor (TFPI)-FXa complex, and by heparin-AT (albeit very slowly).[36] The inhibition of TF-FVIIa by heparin-AT is unique, in that heparin-AT binding to FVIIa releases a stable FVIIa-AT complex and regenerates fully functional TF. Consequently, FVIIa-AT levels may be an indicator of systemic TF exposure.[29]

Intrinsic Pathway

The intrinsic cascade primarily occurs on the activated platelet surface. Platelet activation is a critical component of the function of the intrinsic tenase complex (FIXa-FVIIIa). Upon activation, platelets expose many (approximately 6000 per platelet) binding sites for FIXa as well as 1000–2000 each for the cofactor, FVIIIa, and the substrate FX. It is unclear whether these binding sites are simply the negatively-charged membrane surface, or whether a specific protein receptor is also involved. Regardless, co-localization of FIXa, FVIIIa, and FX on the platelet surface increases the rate of FXa generation by many million fold.

Factor XI

Factor XI is an approximately 160 kDa protein that is produced in the liver. Its structure is unique among coagulation proteins as a disulfide-linked dimer of two identical polypeptide chains. Factor XI circulates in plasma complexed with HK, which is required for FXI binding to negatively charged surfaces. Prothrombin can substitute for HK as a cofactor for binding to platelet surfaces.

Factor XI can be activated by FXIIa, FXIa, and thrombin in calcium-dependent reactions. Cleavage results in a 160 kDa enzyme with two disulfide linked heavy chains and two active site-containing light chains. Because FXII deficiency does not cause a bleeding tendency, it is likely that thrombin (rather than FXIIa) is the physiologically relevant enzyme generating FXIa. The GP Ibα subunit of the platelet GP Ib/IX/V complex binds FXI, localizing it and thrombin on the platelet for efficient cleavage. After activation, FXIa remains surface-bound where it cleaves its substrates, FXI and FIX. Factor IX is FXIa's preferred substrate.

Inhibition of FXIa depends on its localization. Plasma inhibitors include its major inhibitor, α_1 protease inhibitor (α_1-PI), and C1-INH, α_2-antiplasmin (α_2-AP), AT, protease nexin 1, plasminogen activator inhibitor 1 (PAI-1), and PCI. Platelet-bound FXIa is protected from α_1-PI inactivation. When bound to the endothelial cell surface, protease nexin 2, in concert with surface heparan sulfate proteoglycans (HSPGs), strongly inhibits FXIa. This differential inhibition may serve to restrict FXIa mediated cleavage of FIX to the platelet surface.

Factor IX

Factor IX's structure and size (about 55 kDa) are similar to those of FVII. Factor IX is a glycosylated single-chain polypeptide, produced in the liver. Post-translational carboxylation of 12 residues by the vitamin K cycle is required for normal Gla domain function and consequently for full-membrane binding capability.[2]

Tissue factor-FVIIa or FXIa activate FIX bound (in the presence of calcium) to a procoagulant membrane surface. Cleavage of two FIX sites releases a 35-residue activation peptide, resulting in a two-chain enzyme of about 45 kDa. The catalytic domain is in the heavy chain portion of the molecule. The presence of detectable levels of the FIX activation peptide in blood suggests that coagulation is ongoing, but controlled by inhibitory pathways.[2]

The primary substrate for FIXa is FX. The FIXa-FVIIIa complex on a suitable membrane surface (usually the platelet surface) in the presence of calcium is a powerful generator of FXa. Either FIX or FIXa may bind to endothelial cells, via specific receptors (collagen IV). Binding to the endothelial surface supports activation of FX by FIXa-FVIIIa in the absence of platelets. Factor IXa alone (without its cofactor FVIIIa) is able to activate FVII in the absence of TF.

FIXa is primarily inhibited by AT-HSPG, although at a relatively slow rate compared to AT's inhibition of FXa or thrombin.

Factor VIII

Factor VIII synthesis and secretion are extremely complex. Two distinct interactions involving metal ions (copper and calcium/manganese) are vital for normal FVIII structure and function. The primary site of FVIII

production is unclear, although the liver and the reticuloendothelial system are strongly implicated. Factor VIII is synthesized as a single chain protein containing three A domains, a B domain, and two C domains, with multiple free cysteine residues and disulfide bonds. After translation, FVIII is translocated to the endothelial reticulum (ER), for modification. Factor VIII is retained within the ER by two protein chaperone systems, immunoglobulin-binding protein and calnexin/calreticulin. Improperly folded FVIII is extracted from the ER and degraded. Factor VIII then transits to the Golgi apparatus for further processing, which includes cleavage at two sites. The resulting protein consists of a heavy chain (160 or 200 kDa) and a light chain (80 kDa) which are not connected to one another unless von Willebrand factor (VWF) is also bound.[23]

Binding to VWF enables proper association of the two FVIII chains and markedly improves its intracellular and plasma stability. The ratio of the two proteins is maintained at one molecule of FVIII to 50–100 subunits of VWF. Although somewhat species-dependent, VWF deficiency is associated with lower levels of circulating FVIII, and infusion of desamino-8-D-arginine vasopressin (DDAVP) to increase circulating VWF levels elicits a concomitant increase in FVIII. Some FVIII is stored with VWF in storage granules, such as Weibel-Palade bodies of endothelial cells and α granules of platelets.

Factor VIII can be dissociated from VWF by exposure to negatively-charged phospholipids. Thrombin cleavage of FVIII at multiple sites activates FVIII to FVIIIa and releases it from VWF. Factor VIII can be activated by FXa, although the maximal activation by thrombin is greater than FXa. Factor VIIIa interacts with PSer on membrane surfaces by stereo-selective recognition of the PSer head group via a phospholipid-binding site in the light chain. Factor VIIIa also interacts with two platelet receptors, GP Ib and $\alpha_{IIb}\beta_3$. Platelet binding of FVIII is inhibited by VWF. The FIXa-FVIIIa enzyme/cofactor complex assembles in a calcium-dependent manner on procoagulant phospholipid surfaces, and is referred to as intrinsic tenase, because its target substrate is FX.

Factor VIIIa is inherently labile due to spontaneous dissociation of its subunits; however, FIXa binding stabilizes FVIIIa and delays decay. Factor VIIIa is cleared from the circulation by low density lipoprotein receptor-related protein (LRP), a common cell-surface receptor found on a variety of cell types. Proteolytic cleavage by activated protein C (APC) and FXa also inactivates FVIIIa.[23]

Common Pathway

Factor X

Factor X is a Gla protein of approximately 59 kDa. It is a glycosylated single-chain polypeptide requiring post-translational carboxylation of 11 glutamic acid residues. Factor X is activated to FXa by either extrinsic tenase (TF-FVIIa) or intrinsic tenase (FIXa-FVIIIa) on a suitable membrane surface in the presence of calcium. The activation is due to a single cleavage site and results in a 46 kDa enzyme.

Factor Xa forms the prothrombinase complex with its cofactor FVa. Factor Xa is strongly inhibited by AT-HSPG and by TFPI. It is also inhibited by the enzyme/cofactor protein Z-dependent protease inhibitor (ZPI)/PZ. Inhibition by ZPI/PZ is calcium and phospholipid dependent.

Factor V

Factor V circulates in plasma as a glycoprotein of approximately 300 kDa. Portions of the molecule are very similar in structure to FVIII. Like FVIII, FV contains a copper ion, and requires post-translational modifications and molecular chaperones for successful cellular trafficking. Approximately 20% of FV in blood is contained within platelet α granules. The plasma half-life of FV in man is fairly long (approximately 13 hours).[21]

Factor V is activated to FVa by cleavage at two sites that releases a large activation peptide, and a resultant two-chain cofactor of about 160 kDa. Activation is primarily due to thrombin cleavage, but FXa can also activate FV when both are bound to a procoagulant membrane surface. Activation by FXa is less efficient than activation by thrombin; however, FV released from platelets is somewhat more susceptible to FXa activation than plasma FV.[21]

Factor Xa and FVa form an enzyme/cofactor complex, referred to as the prothrombinase complex, in the presence of calcium on PSer-containing membrane surfaces. While FVa binding to the membrane is not calcium dependent, the binding of FX and prothrombin to the membrane is calcium dependent, but of low affinity. Binding of FVa to a negatively charged membrane surface markedly increases the affinity of FXa for FVa, and enhances formation of the complex. Platelets and microparticles primarily provide this membrane surface in vivo.[21]

Proteolysis of FVa by APC results in its inability to bind prothrombin, and therefore loss of function of the prothrombinase complex. Inactivation of FVa by APC occurs more rapidly on endothelial cells than on activated platelet surfaces.[12,21]

Prothrombin

Prothrombin is a 72 kDa glycoprotein synthesized in the liver that (like other Gla proteins), undergoes vitamin K-dependent post-translational carboxylation of 10 glutamic acid residues. Prothrombin is the second most abundant coagulation protein in plasma, after fibrinogen.[20]

In addition to the Gla domain, prothrombin contains two kringle domains and a serine protease precursor domain. Prothrombin cleavage at two distinct sites by prothrombinase generates its most abundant active form, α thrombin. The first in vivo cleavage site is generally between the A and B chains of its serine protease domain to form the important intermediate, meizothrombin. Meizothrombin contains all the domains of

the prothrombin molecule, with a fully active enzyme site, but it is less active toward fibrinogen and platelets than α thrombin. After the second cleavage, prothrombin fragments 1 (containing the Gla domain and kringle 1) and 2 (containing kringle 2 domain) are removed. The A and B chains of the much smaller (36.7 kDa) α-thrombin molecule remain. Under some conditions the order of cleavage is reversed, releasing the membrane binding Gla domain prior to activation of the protease.[20]

Coagulation Inhibitors

Tissue Factor Pathway Inhibitor

Tissue factor pathway inhibitor is the key regulator of the extrinsic pathway. It is a Kunitz type inhibitor synthesized by endothelial cells and expressed on their surface. Alternative splicing creates two forms: TFPIα and TFPIβ. Both forms are bound to the cell surface: TFPIα via a not yet identified glycosylphosphatidylinositol (GPI)-linked protein, and TFPIβ via interactions between the C terminal region and an identified GPI anchor.[41] Cell surface associated heparan sulfates also play a role in the binding of TFPI to the endothelial cell.[1,30]

The majority (80–85%) of TFPI is attached to the endothelial cell surface. A small amount (10%) of TFPI circulates in plasma associated with lipoproteins, and platelet α granules also contain TFPI.[1] Intravenous heparin administration causes release of TFPI from the endothelial cell-surface and a marked increase in plasma TFPI.[30] Free TFPI is cleared from the circulation primarily by the liver and kidneys.

Both TF-FVIIa and FXa are susceptible to TFPI inhibition. In the absence of FXa, TFPI is only a weak inhibitor of TF-FVIIa. The second Kunitz domain of TFPI binds to FXa; however, the FXa-FVa complex is protected from inhibition by TFPI, particularly if the substrate prothrombin also binds.[31] Recent work indicates that PS serves as a TFPI cofactor, enhancing its inhibitory function,[43] and that polyphosphate released from platelet dense granules profoundly abrogates TFPI inhibition.[46]

The TFPI-FXa complex is a strong inhibitor of TF-FVIIa, binding via the first Kunitz domain. Endocytosis and degradation of the quarternary complex (TFPI-FXa-TF-FVIIa) is mediated by cell-surface associated LRP.[1]

Inherited deficiency of TFPI has not been described, suggesting that complete lack of this inhibitor is incompatible with life.

C1-Inhibitor

C1-Inhibitor is the largest member of the serpin family. It has an unusual structure for this class of proteins, containing a typical serpin domain and an additional N-terminal domain of ill-defined structure and function. It is a relatively slow inhibitor of its target proteases, but C1-INH inhibition is potentiated by glycosaminoglycans such as heparin and heparan sulfates.[49]

The C1-INH is the major inhibitor of the contact pathway, acting on FXIIa and kallikrein, and the downstream protease FXIa. Hereditary deficiency of C1-INH has no impact on hemostasis. Rather, it causes excess episodic production of bradykinin, producing the disease phenotype hereditary angioedema.[49]

Antithrombin

Antithrombin is the prototype serpin; however, it is a relatively inefficient inhibitor of its target enzymes. The "bait" portion of the AT molecule is available only if AT binds to its cofactor. This cofactor is a specific pentasaccharide sequence that is found on approximately 30% of pharmaceutical heparin molecules and on endothelial-bound HSPG molecules. Upon AT-pentasaccharide binding, the bait loop becomes available as a target for the enzyme to be inhibited. Antithrombin's inhibitory activity is enhanced up to several thousand-fold by interaction with heparins, but the impact varies with heparin structure and the target protease. Pentasaccharide alone is sufficient for AT inhibition of some enzymes, while longer heparin molecules are required for inhibition of others. In particular, AT inhibition of thrombin requires, in addition to the specific pentasaccharide sequence, heparin molecules of at least 18 sugar units to interact with thrombin.

Antithrombin molecules in circulation have limited inhibitory capabilities in the absence of the necessary pentasaccharide. Endogenous activation of AT occurs when it binds to heparans on the surface of the endothelial cell. Additionally, endothelial cell surface thrombomodulin (TM) can also bind AT, which enhances AT inhibition of thrombin approximately 8-fold.[4,48]

In addition to inhibiting thrombin, AT-heparin has broad inhibitory activity against a variety of serine proteases. These include FXIIa, FXIa, kallikrein, FIXa, and FVIIa. The primary targets are FXa and thrombin. Platelet-bound thrombin (via GP Ib_{α}) and thrombin bound to the fibrin clot or fibrin degradation products are refractory to AT-heparin inhibition. In contrast, inhibition of FVIIa requires that the enzyme be bound to its cofactor (TF) on a cell surface, and kallikrein is more readily inhibited when bound to HK on a cell surface.

Antithrombin bound to a target protease forms a stable complex with long half-life. The complexes are primarily cleared in the liver by LRP. Inherited or acquired AT deficiency is associated with development of pathologic thrombosis.[4]

Protein C Pathway

The PC pathway involves a complex interplay among endothelial cell-surface molecules, thrombin, PC, and PS. Activated PC is an essential regulator of thrombin generation due to its inactivation of the critical cofactors, FVa and FVIIIa. The thrombotic disorders in people attributed to inherited and acquired PC deficiency demonstrate its important anticoagulant action.

Protein C is an approximately 62 kDa vitamin K-dependent protein, synthesized in the liver, containing a Gla domain with nine glutamic acid residues. It circulates as a two-chain zymogen that is activated by thrombin (or meizothrombin) to APC. Cleavage at two sites results in removal of a 12-residue activation peptide and formation of an approximately 56 kDa two-chain enzyme, APC. Plasmin activation also produces limited amounts of APC. As a Gla containing protein, PC activation is calcium dependent and markedly enhanced by negatively charged phospholipid surfaces, in particular phosphatidylethanolamine (PEth). Thrombin alone is a poor activator of PC unless it is bound to TM.[12]

Thrombomodulin is an endothelial transmembrane molecule that interacts with thrombin to influence its substrate specificity. Thrombomodulin inhibits thrombin's interaction with fibrinogen and protease activated receptors, and markedly enhances the ability of thrombin to cleave PC. Cellular expression of TM is modulated by a large number of factors. It is up-regulated in response to cyclic AMP, thrombin, vascular endothelial growth factor, and platelet factor 4. It is down-regulated by inflammatory mediators (e.g. tumor necrosis factor, interleukin 1, endotoxin), hypoxia, transforming growth factor β, and neutrophil activation.[12]

Protein S is an approximately 69 kDa vitamin K dependent protein with a Gla domain that interacts with membranes. Protein S is the cofactor for APC mediated cleavage of FVa and FVIIIa, and for TFPI's inhibition of FXa.[43] Approximately 60% of circulating PS is bound to a large (540 kDa) member of the complement system, C4 binding protein (C4BP). C4 binding protein is an acute phase reactant and therefore increases in inflammatory conditions. Protein S complexed with C4BP is unable to provide APC cofactor activity. Activated platelets and neutrophils contain proteases that cleave and inactivate PS.[11,12]

Endothelial protein C receptor (EPCR) is a transmembrane protein found primarily on arterial endothelium. The EPCR can substitute for negatively-charged phospholipids in promoting activation of PC. It binds directly to PC via the Gla domain, anchoring it to the cell surface. The APC-EPCR complex is unable to bind PS and does not have anticoagulant activity, but may interact with other receptors, potentially contributing to the anti-inflammatory effects of APC.[12,13] Once APC is produced and dissociates from thrombin-TM or EPCR, it assembles with PS on a procoagulant membrane surface and rapidly inactivates FVa and FVIIIa. A mutation at one of the APC cleavage sites on FV ("FV Leiden") confers resistance to APC inactivation, and is a common hereditary prothrombotic disorder in people. Activated PC cleaves FVa more efficiently on endothelial surfaces than on platelets,[38] and FVIIIa is resistant to APC inactivation when bound to VWF. The anticoagulant activity of APC is highly species-specific.[12]

The PC pathway appears to have a major role in linking inflammation and coagulation, in part due to the ability of APC to down-regulate thrombin generation. Additionally, APC alters gene expression in endothelial cells via activation of membrane surface protease activated receptors (PARs), resulting in anti-apoptotic and anti-inflammatory effects. Activated PC-PS also inactivates an important inhibitor of fibrinolysis (PAI-1).[12] Activated PC has a relatively long half-life of about 15 minutes. It is inhibited by α_1-PI, PCI, and α_2-MG.

Miscellaneous Inhibitors

Heparin cofactor II (HC) is a 66 kDa serpin with some similarities to AT. It requires binding to proteoglycans for full function, but the mechanism differs from that of AT. Heparin cofactor II is strongly activated by binding to dermatan sulfate and has a narrow spectrum of activity restricted to thrombin inhibition. Although HC-thrombin complexes are detectable in vivo, HC deficiency is not associated with increased risk of thrombosis. Roles for HC in inflammation and wound healing, rather than in regulation of coagulation, have been suggested.[4]

Protein Z-dependent protease inhibitor is a 72 kDa serpin that strongly inhibits FXa when bound with its cofactor, PZ, on a phospholipid surface in the presence of calcium. Protein Z is a 62 kDa vitamin K-dependent protein that binds to the membrane via its Gla domain. Thrombomodulin also acts as a cofactor for ZPI. Factor XIa is also susceptible to ZPI inactivation, in a heparin-dependent reaction that does not require calcium or phospholipids.

α_1-Protease inhibitor, PCI, and α_2-MG are inhibitors that act on a variety of serine proteases in coagulation and other systems. α_1-Protease inhibitor is a 52 kDa molecule, synthesized primarily in the liver, whose major physiologic role is the protection of alveolar tissue from proteolytic damage by enzymes like neutrophil elastase. It is an acute phase reactant, and is up-regulated by inflammatory mediators.[14]

Protein C inhibitor is a 53 kDa serpin that inhibits APC, FXa, FXIa, kallikrein, thrombin, thrombin-TM, urokinase plasminogen activator (uPA), and tissue plasminogen activator (tPA). Its inhibitory activity is enhanced by heparin and it is involved in modulating vascular permeability, tissue regeneration, proteolysis in the kidney, and tumor cell invasion.[47]

α_2-Macroglobulin is a large, 725 kDa inhibitor of matrix metalloproteinases that works through a unique mechanism. The target enzyme cleaves an α_2-MG "bait" region to produce a conformational change that provides sites for covalent enzyme attachment. The enzyme binds and is entrapped by the inhibitor, with resultant α_2-MG-enzyme complexes internalized and degraded via LRP binding.

CELLS THAT PARTICPATE IN HEMOSTASIS

Endothelial Cells

The endothelium, once considered an inactive barrier between the blood and the subendothelial tissues, is now recognized as a highly active organ. The endothe-

lium has a variety of functions including regulation of coagulation and fibrinolysis, local control of vascular tone, systemic regulation of blood pressure, interaction with lipoprotein metabolism, production of angiotensin converting enzyme, presentation of histocompatibility antigens, and interaction with leukocytes. The majority of endothelial cells are in capillary beds due to the surface area distribution of the vascular system, and most interactions between the endothelium and flowing blood occur in capillaries where the ratio of endothelial cell surface to blood volume is high.

Antithrombotic Properties of Endothelium

The prevention of coagulation in flowing blood is normal endothelium's primary role in hemostasis (Fig. 84.6).

Non-activated, resting endothelial cells have anticoagulant properties, in part due to proteins expressed on their surface and via a neutral membrane charge that is incapable of supporting coagulation reactions. Heparan sulfate proteoglycans are glycosaminoglycans expressed by endothelial cells on the luminal surface, in contact with flowing blood. Much larger abluminal stores of HSPG act as a reservoir. Antithrombin bound to HSPGs (at pentasaccharide sequences) is then able to inactivate its serine protease targets (e.g. thrombin, FXa). Resting endothelial cells also express TM. Thrombin, once bound to TM, demonstrates anticoagulant rather than procoagulant properties. Thrombomodulin-bound thrombin is unable to cleave fibrinogen or activate PARs, and the TM-thrombin complex rapidly activates PC. Expression of TM is 100-fold higher in capillary endothelium compared to endothelium in the major vessels. Thrombin circulating in large vessels is therefore quickly extracted when the blood passes through capillaries. Lastly, TFPI on the endothelial cell surface prevents thrombin generation by acting as an upstream inhibitor of FXa and TF-FVIIa.

Prothrombotic Properties of Endothelium

Endothelial cells store VWF in granules called Weibel-Palade Bodies. This protein has important roles in FVIII biology, and in mediating platelet adhesion and aggregation (Chapter 81). Endothelial cells express a specific G protein coupled receptor for thrombin. Thrombin binding to this receptor initiates a number of procoagulant and proinflammatory events. Intracellular signaling initiates endothelial secretion of VWF and P-selectin from Weibel-Palade bodies, nitric oxide (NO) release, and phospholipase A_2 activation that results in platelet activating factor (PAF) production. Activated endothelial cells express intracellular adhesion molecule 1, generate interleukin 1, and secrete both plasminogen activators and PAI-1.

Other Properties of Endothelial Cells

Endothelial cells synthesize NO in response to a variety of stimuli including thrombin, histamine, ATP, bradykinin, and acetylcholine. Nitric oxide inhibits platelet activation and causes vasodilation. Thrombin and other stimuli also induce endothelial cell synthesis of prostacyclin (PGI_2), a platelet inhibitor that also maintains vascular relaxation.[8]

Platelets

Platelets are a fundamental requirement for normal hemostasis. Activated platelets adhere to the site of injury, secrete molecules necessary for coagulation and for wound healing, and form platelet aggregates that obstruct the site of injury, preventing further blood loss. Platelets provide the primary membrane surface for thrombin generation, allowing for formation of a platelet-fibrin clot (Chapter 76).

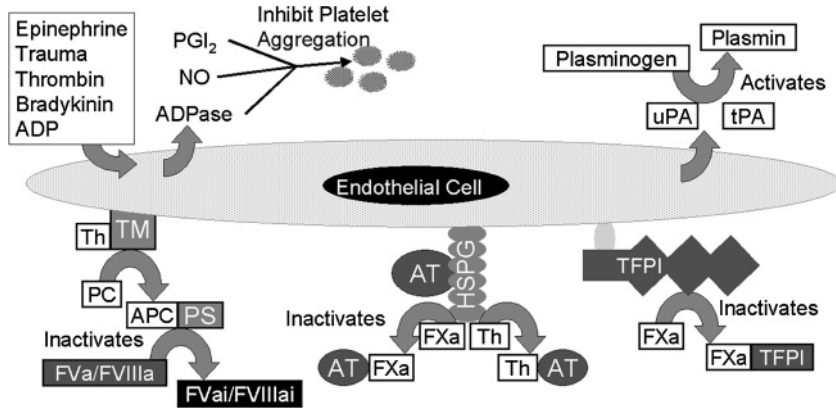

FIGURE 84.6 Anticoagulant properties of endothelial cells. Endothelial cells are thromboresistant under normal physiologic conditions. They express adenosine diphosphatase (ADPase) and synthesize and release prostacyclin (PGI_2) and nitric oxide (NO), leading to inhibition of platelet aggregation. They also produce urokinase (uPA) and tissue-type (tPA) plasminogen activators which activate plasminogen to plasmin, the enzyme that lyses fibrin clots. Endothelial cells express thrombomodulin (TM), heparan sulfate proteoglycans (HSPG) and tissue factor pathway inhibitor (TFPI) on their membrane surface, which collectively inhibit generation of thrombin (Th). TM acts as a cofactor for Th-mediated activation of the protein C (PC) pathway; HSPG acts as a cofactor for antithrombin (AT) inhibition of FXa; TFPI inhibits FXa and TF-FVIIa.

Tissue Factor Bearing Cells

As previously discussed, exposure of TF on a TF-bearing cell is the physiologically relevant trigger for in vivo coagulation. Tissue factor-bearing cells are primarily outside the vasculature, particularly in the adventitia, skin, mucous membranes, and organ capsules. Under pathologic conditions leukocytes, endothelial cells, and neoplastic cells may also express TF.

Microparticles

Microparticles (MPs) are intact vesicles surrounded by membranes. They range in size from 2–20% of the size of a red blood cell (i.e. 0.1–1 μm diameter) and arise when activated or apoptotic cells shed bits of membrane. Cytokines (such as tumor necrosis factor and interleukin-6), thrombin, shear stress, and hypoxia can stimulate MP formation. Under normal conditions, MPs are primarily derived from endothelial cells, platelets, and monocytes, but in certain disease states, MPs may arise from granulocytes and erythrocytes. The quantity of circulating MPs is increased in certain illnesses such as diabetes mellitus, sepsis, and cardiovascular disease and may contribute to pathologic coagulation in a variety of disorders.[33]

Microparticles contain cell surface proteins similar to those found on their parent cell (e.g. ultra-large VWF monomers on endothelial cell-derived MPs, TF on monocyte-derived MPs) that can participate in coagulation reactions, especially when the MP expresses a procoagulant surface. The contribution of MPs to normal hemostasis is currently under active investigation.[24,33,40]

The Role of Cell Surface Membranes

All cells are surrounded by a lipid membrane bilayer which contains a large number of membrane surface proteins. In most mammalian cells, membrane bilayers consist primarily of cholesterol and phospholipids with neutral head-groups such as phosphatidylcholine (PChol), sphingomyelin, sugar-linked sphingolipids and PEth. The membranes also contain phospholipids with negatively charged-head groups, primarily PSer. In the resting state, PEth and PSer are sequestered on the membrane's inner surface. This membrane asymmetry is essential and tightly controlled by lipid transporters. Flippase actively transports PSer from the external to the internal leaflet while floppase transports PChol in the opposite direction. These ATP-dependent enzymes maintain cell membrane asymmetry in the resting state.

Cell-injury or activation stimuli that produce a sustained increase in intracellular calcium induce a poorly characterized "scramblase" that shuffles phospholipids between the membrane leaflets. This results in the appearance of PSer and PEth on the external membrane surface.[40,51] Although the mechanisms of coagulation on activated membrane surfaces are not fully understood, it is known that membrane-surface PSer markedly (often by a factor of thousands to hundreds of thousands) increases the rate of coagulation reactions. The presence of PEth enhances the properties of PSer-expressing membranes, so that less PSer is required for maximum speed when PEth is present. It has been proposed that PEth aids in grouping PSer into clusters that support preferential binding of coagulation proteins.[36,53] Under normal physiologic conditions, cells do not express these procoagulant phospholipids on their outer membrane. As a consequence, thrombin production is limited to cell surfaces in an injured area that have been triggered to externalize PSer (and PEth). The ability of cells to control the composition of their membrane surface constitutes a powerful method of localizing coagulation reactions.[53]

CELL BASED MODEL OF THROMBIN GENERATION

Our new understanding of hemostasis incorporates the role of cells. This model suggests that in vivo coagulation occurs in distinct overlapping phases that require the participation of two different cell types: TF-bearing cells and platelets.

Initiation

All evidence to date indicates that TF is the sole relevant initiator of coagulation in vivo. Cells expressing TF are generally localized outside the vasculature, which prevents initiation of coagulation under normal flow circumstances with an intact endothelium. Some circulating cells (e.g. monocytes) and MPs may express TF on their membrane surface, but this TF under normal conditions is thought to be inactive or "encrypted".[27,36]

Upon injury, flowing blood is exposed to a TF-bearing cell and FVIIa rapidly binds to TF.[35,36] The TF-FVIIa complex then activates additional TF-FVII to TF-FVIIa, which generates small amounts of FIXa and FXa. Although it occurs slowly, FV can be activated directly by FXa. The resultant enzyme and cofactor (FXa, FVa) form the prothrombinase complex, which subsequently cleaves prothrombin to generate a small amount of thrombin on the surface of TF-bearing cells. Any FXa that dissociates from the membrane surface is rapidly inactivated by either TFPI or AT-HSPG. Factor Xa, therefore, is effectively restricted to the surface of the TF-bearing cell on which it was generated. However, FIXa is not inhibited by TFPI, and much more slowly inhibited by AT than FXa. Consequently, trace amounts of generated FIXa can dissociate and move to the surface of nearby platelets or other cells.[19,42]

Since TF is always expressed in the perivascular space, any FVIIa that leaves the vasculature will bind to TF and potentially initiate coagulation. The gaps in the physiologic endothelial envelope under normal conditions are very small. Most of the upstream coagulation proteins are relatively small, whereas some of the downstream proteins are much larger. These downstream substrates, as well as platelets, are sequestered from the extravascular space. Coagulation progresses beyond initiation (and its generation of trace amounts

of thrombin) only when the injury allows platelets and larger proteins to leave the vascular space and adhere to extravascular TF-bearing cells (Fig. 84.7A).[19,42]

Amplification

Once a small amount of thrombin has been generated in the initiation phase, it is available to activate platelets that have leaked from the vasculature at the site of injury. Thrombin binding to platelet surface receptors causes extreme changes in the surface of the platelet, resulting in shape change, shuffling of membrane phospholipids to create a procoagulant membrane surface, and release of granule contents that provide additional "fuel for the fire." Platelet granules contain a large number of proteins and other substances which include raw materials for clotting reactions, agonists to induce further platelet activation, and calcium. Calcium may induce membrane externalization and clustering of PSer, and promotes binding of coagulation proteins to the activated membrane surface. In addition to activating platelets, thrombin generated in the initiation phase cleaves FXI to FXIa and activates FV to FVa on the platelet surface. Thrombin also cleaves VWF from FVIII and activates FVIII to FVIIIa (Fig. 84.7B).[19,42]

Propagation

The release of platelet granule contents recruits additional platelets to the site of injury. The propagation phase occurs on the surface of these platelets. Expression of ligands on their surface results in cell-cell interactions that lead to platelet aggregation. Factor IXa generated by TF-FVIIa in the initiation phase can bind to FVIIIa (generated in the amplification phase) on the platelet surface. Additional FIXa is generated due to cleavage of FIX by FXIa (generated during amplification on the platelet surface). Once the intrinsic tenase complex forms (FIXa-FVIIIa) on the activated platelet surface, it rapidly begins to generate FXa on the platelet. Since FXa generated on TF-bearing cells is rapidly inhibited if it moves away from the cell surface, it cannot easily reach the platelet surface. The majority of FXa in the propagation phase, therefore, must be generated directly on the platelet surface by the intrinsic tenase complex. This generated FXa then rapidly binds to FVa (generated by thrombin in the amplification phase) and cleaves prothrombin to thrombin. This prothrombinase activity results in a burst of thrombin. When enough thrombin is generated with enough speed to cleave fibrinogen, a clot forms (Fig. 84.7C).[19,42]

THROMBIN

Thrombin is generated from prothrombin by cleavage at two activation sites. Thrombin is the terminal coagulation protease responsible for fibrin formation. Thrombin generation, however, is not the end of coagulation. Many steps vital to normal hemostasis occur temporally *after* generation of a fibrin gel. Approximately 5% of the

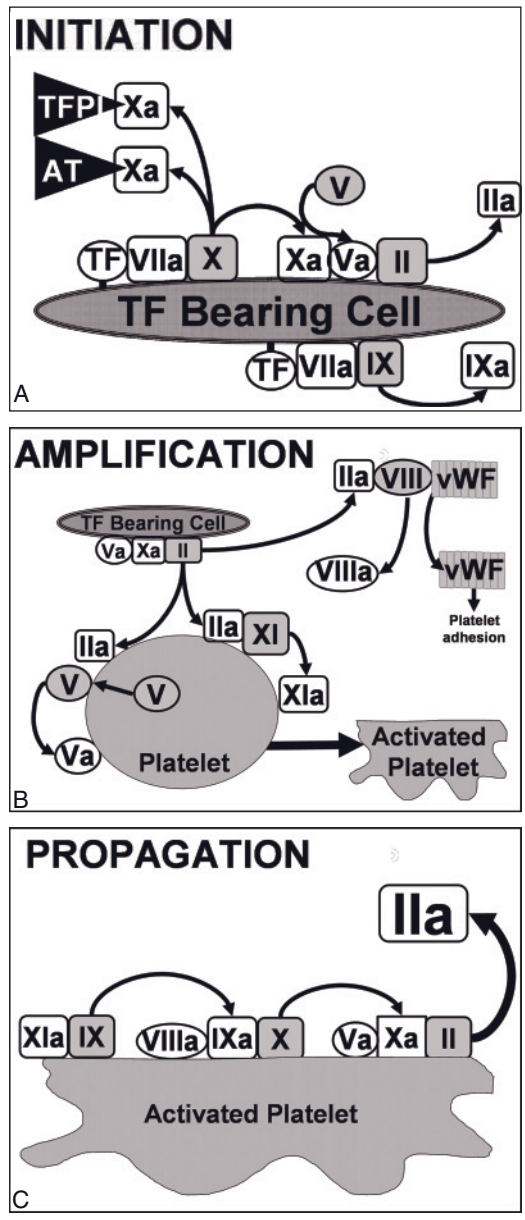

FIGURE 84.7 Cell-based model of fibrin formation. In this model thrombin generation occurs in overlapping phases. (**A**) Initiation phase: This phase occurs on the TF-bearing cell and is initiated when injury exposes the TF-bearing cell to the flowing blood. It results in the generation of a small amount of FIXa and thrombin that diffuse away from the surface of the TF-bearing cell to the platelet. (**B**) Amplification phase: In the second phase, the small amount of thrombin generated on the TF-bearing cell activates platelets, releases VWF and leads to generation of activated forms of FV, FVIII, and FXI. (**C**) Propagation phase. In the third phase the various enzymes generated in earlier phases assemble on the procoagulant membrane surface of the activated platelet to form intrinsic tenase, resulting in FXa generation directly on the platelet surface. Prothrombinase complex forms and results in a burst of thrombin generation directly on the platelet. See Table 84.1 for abbreviations. (Reproduced from Smith S, The cell-based coagulation model. J Vet Emerg Crit Care 19:3–10, with permission.)

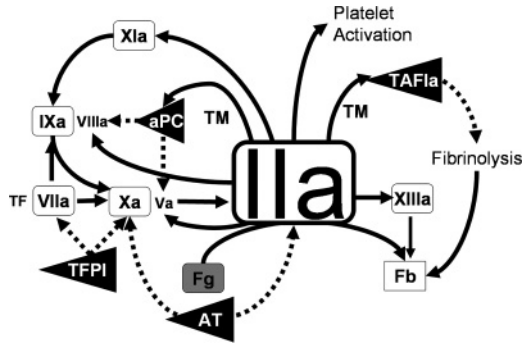

FIGURE 84.8 Central role of thrombin. Thrombin plays a central role in hemostasis, acting as both a procoagulant and an anticoagulant. Procoagulant thrombin is generated in small quantities during the initiation phase (which occurs on the TF-bearing cell), then in larger quantities on the platelet surface in the propagation phase. Thrombin is responsible for platelet activation which provides the procoagulant surface needed for the burst of thrombin generation during propagation. Thrombin cleaves fibrinogen to fibrin, resulting in clot formation. Thrombin also impacts clot structure through activation of cross-linker FXIII, and fibrinolysis inhibitor TAFI. Thrombin becomes anticoagulant via thrombomodulin-mediated activation of the protein C system. See Table 84.1 for abbreviations. (Reproduced from Smith S, The cell-based coagulation model. J Vet Emerg Crit Care 19:3–10, with permission.)

prothrombin that will be cleaved has been converted to thrombin at the time of fibrin gel formation, as detected in routine plasma-based clotting assays.[28]

Free thrombin has an extremely short plasma half-life of less than 15 seconds due to rapid inhibition by AT-HSPG.[10] Thrombin bound to the fibrin clot, however, is both enzymatically active and protected from inhibition. In addition to its function in cleavage of fibrinogen to fibrin, thrombin has many additional roles in coagulation and fibrinolysis, as well as functions in cell regulation (Fig. 84.8).[28]

Feedback Regulation of Coagulation

Thrombin provides positive feedback to the process of coagulation by back-activating a number of upstream proteases and cofactors. These include FVII, FXI, FVIII, and FV. Thrombin bound to endothelial surface TM acts primarily to inhibit coagulation via activation of the PC anticoagulant pathways. Moreover, TM-binding inhibits the interactions between thrombin and fibrinogen, limits thrombin activation of platelet PARs, and promotes activation of the fibrinolytic mediators, TAFI and scuPA. Through these feedback mechanisms, thrombin influences the quantity and speed of its own generation, and the amount of fibrin deposition and degradation.

Platelet Activation

Thrombin, along with many other serine proteases, can bind and cleave PARs. These cell-surface associated G-coupled proteins are found on platelets, endothelial cells, smooth muscle cells, leukocytes, and other cell types. Cleavage by thrombin untethers a portion of the PAR molecule that self inserts into the receptor, thereby initiating intracellular signalling. This PAR-mediated signaling is the major mechanism by which thrombin activates platelets. Thrombin also binds to the platelet GP Ib/IX/V complex via a binding site in GP Ibα, although how this binding mediates platelet activation is not clearly understood.[10]

Fibrin Formation

The primary function of thrombin is conversion of fibrinogen to fibrin. Thrombin cleaves two short peptides from the fibrinogen molecule, fibrinopeptide A (FpA) and fibrinopeptide B (FpB), thus exposing binding sites that interact with pre-existing sites on other fibrin molecules. The interaction between multiple fibrin molecules results in spontaneous polymerization into an insoluble fibrin gel.

Activation of Factor XIII

Factor XIII (FXIII) is a 320 kDa protein that consists of five chains arising from transcription of two different genes. Half of the circulating pool of functional FXIII is free in plasma, and the remainder is released from platelet α granules. Factor XIII cleavage by thrombin releases an activation peptide, resulting in a 312 kDa active enzyme. Thrombin cleavage of free FXIII is slow; however, polymerized fibrin acts as a cofactor, markedly increasing the rate of FXIIIa generation. Consequently, FXIIIa is generated primarily after a critical weight of fibrin has polymerized.

Factor XIIIa is a transglutaminase whose primary function is crosslinkage of fibrin fibrils. This activity is calcium dependent, and critical for normal clot strength and stability. Factor XIIIa also crosslinks fibronectin to fibrin and to collagen, which influences anchoring of the clot to the vessel wall. Additionally, FXIIIa has roles in cell adhesion, angiogenesis, and tissue repair.

FIBRINOGEN AND FIBRIN CLOT STRUCTURE

Fibrinogen is a soluble 340 kDa dimer consisting of three pairs of disulfide-bridge linked polypeptides. It is the most abundant coagulation protein in plasma and is abundant in platelet α granules. In addition to the role of fibrinogen as a precursor to fibrin, fibrinogen mediates intracellular interactions between platelets in conjunction with thrombospondin (Chapter 76).

Thrombin cleaves fibrinogen at two sites, releasing FpA and FpB. Upon FpA release, soluble fibrin monomer spontaneously assembles into an insoluble dimer. This polymerization occurs because removal of FpA exposes a binding site "A knob" that interacts with a complementary binding "hole" on separate fibrin molecules. Initial polymerization produces a dimer with a half-staggered structure. Dimers continue to associate to form longer, two-fibrin-wide strands, called protofibrils.[3,18] Subsequent removal of FpB allows for lateral

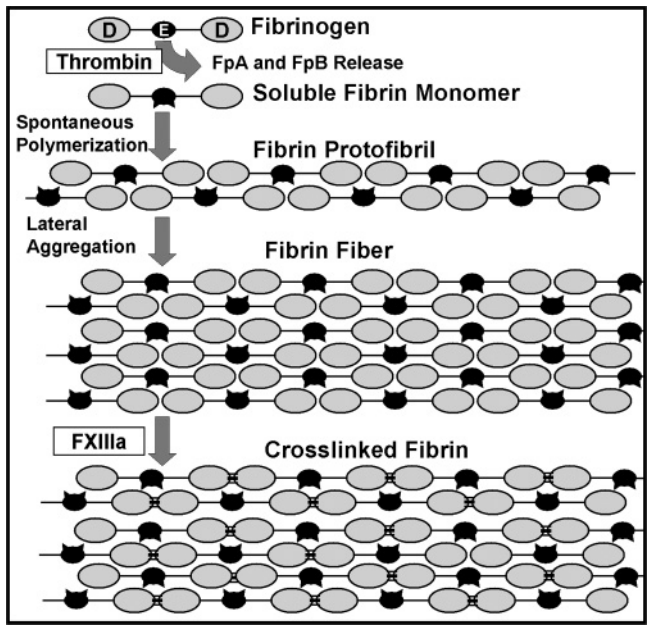

FIGURE 84.9 Fibrin formation. Fibrinogen consists of a central E domain connected by coiled chains to two lateral D domains. Thrombin cleaves fibrinogen to fibrin monomer by removing two short peptides from the E domain (fibrinopeptides A and B) exposing binding sites in the E domain. These exposed sites then interact with corresponding binding sites on the D domains of other fibrin molecules, resulting in spontaneous polymerization into a fibrin protofibril. Multiple protofibrils laterally polymerize, forming a fibrin fiber. FXIII is activated to FXIIIa by thrombin. FXIIIa creates cross-links between D domains of contiguous fibrin monomers.

aggregation of protofibrils of increasing width via the "B knob" interacting with its complementary binding site. Protofibrils are stabilized by the same A-a and B-b knob-hole interactions that allowed for initial dimer association. Protofibril growth continues, with branch points developing where multiple fibrin monomers interact laterally. The resulting fibrin polymer is a mesh-like network (Fig. 84.9).[3,18]

Thrombin mediated release of fibrinopeptides from fibrinogen is neither calcium nor membrane dependent. However, fibrinogen contains several calcium binding sites. Calcium influences fibrin assembly, enhancing the rate and extent of lateral protofibril association. Consequently, calcium influences the structure of the mature fibrin clot.[3,18] As the fibrin network forms, some thrombin is bound into the developing mesh via specific binding sites on the two molecules. Fibrin binding is important in activation of FXIII, and clot-bound thrombin also acts as a cofactor that accelerates fibrin assembly.[3,17,18]

FIBRINOLYSIS

Fibrin clot formation prevents hemorrhage, but the clot must be removed eventually for restoration of blood flow. Clot dissolution is referred to as fibrinolysis. The fibrinolytic system is normally quiescent due to the relative abundance of fibrinolysis inhibitors, and the requirement for fibrin as a cofactor for many of its processes. Although the primary function of fibrinolysis is removal of fibrin, many components of the system are involved in tissue repair processes, such as cell adhesion, migration, and proliferation.

Plasminogen

Plasminogen (PLG) is a single chain 92 kDa glycoprotein synthesized primarily in the liver. It circulates in plasma with a long half-life of approximately 2 days. Its complex structure consists of five kringle domains and a protease domain. Several of the kringle domains bind aminocarboxylic acids (such as α_2-aminocaproic acid and tranexamic acid) that are used as pharmacologic fibrinolysis inhibitors (see Chapter 90).

Plasminogen activators transform plasminogen to plasmin by cleavage at a single site, resulting in a two-chain molecule with an N-terminal glutamic acid residue (Glu-plasmin). *In vitro*, plasmin cleaves other plasmin molecules to remove part of the N-terminus, leaving an N-terminal lysine residue (Lys-plasmin). This additional cleavage probably does not occur *in vivo* due to rapid neutralization of free plasmin by inhibitors. The half-life of free plasmin is extremely short (0.1 seconds). Fibrin is a strong modulator of PLG activation. It enhances PLG activation due to binding and colocalization of PLG and its activators to the terminal lysine residues of fibrin monomers. Partially degraded fibrin exposes additional lysine sites, enhancing PLG activation through a positive feedback loop. Aminocarboxylic acids interfere with PLG binding to the lysine residues of fibrin. The fibrinolysis inhibitor, TAFI acts by removing lysine residues, thereby limiting available PLG binding sites.

The PLG molecule contains within its kringle domains the anti-proliferative protein angiostatin. Tumor mediated proteolysis or proteolysis by macrophages releases this fragment from plasmin. Angiostatin also inhibits endothelial cell and smooth muscle proliferation and migration, and induces apoptosis.[5]

Plasmin degrades polymerized fibrin to form heterogeneous fragments referred to collectively as fibrin degradation products (FDP). The D-dimer fragment is produced by degradation of the linked region between D domains of adjacent fibrin molecules. This linkage is created exclusively by FXIIIa; therefore the presence of D-dimers indicates that polymerized fibrin was subject to crosslinking.

Plasminogen Activators

Mammals produce two physiologic PLG activators, tPA and uPA, named for the source from which they were originally isolated (tissue and urine). Some bacteria and vampire bats also produce plasminogen activators.[5]

Tissue-type Plasminogen Activator

Tissue-type plasminogen activator is a 68 kDa serine protease glycoprotein produced and secreted by endothelial cells in response to a variety of triggers,

including bradykinin, histamine, acetylcholine, α-adrenergic agents, and PAF. Very little tPA circulates in the bloodstream and most is bound to its major inhibitor, PAI-1. Free tPA and tPA-PAI-1 complexes are rapidly removed from circulation by binding to endothelial cell and hepatocyte receptors. The α_2-MG-LRP interaction is a major clearance mechanism.

Endothelial cells secrete tPA as a single chain molecule (sctPA) that is *not* a zymogen; however, its enzymatic activity is weak in the absence of fibrin. Plasmin cleaves sctPA to form the two chain mature enzyme form (tPA). Fibrin binds to either single chain or two chain tPA. The protease activity of fibrin-tPA is strong and highly specific for cleavage of PLG to form plasmin.[5]

Urokinase Plasminogen Activator

Urokinase plasminogen activator is a 54 kDa serine protease glycoprotein synthesized by fibroblast-like cells, epithelial cells, monocytes, and endothelial cells. It is secreted as a single chain molecule (scuPA) with less than 1% protease activity of the two-chain mature enzyme, uPA. Plasmin, FXIIa, and kallikrein cleave scuPA to form uPA.[5] Monocytes express an important cellular receptor for scuPA (uPAR). Colocalization of scuPA and uPAR on cell surfaces enhances PLG activation.

Unlike tPA, uPA can activate PLG in the absence of fibrin. It appears that tPA is the major PLG activator within the vasculature, whereas uPA is the major extravascular PLG activator. Consequently uPA's primary roles include degradation of extracellular matrix in the processes of cell migration, and healing.[5]

Fibrinolysis Inhibitors

Plasminogen Activator Inhibitor 1

Plasminogen activator inhibitor 1, a 52 kDa serpin, is the major inhibitor of PLG activators. The primary source of plasma PAI-1 is unknown; however, many cell types, including megakaryocytes, endothelial cells, and hepatocytes, synthesize PAI-1. It is produced as an unstable, active form found primarily in blood and tissues, and a more stable latent form present in platelets. Most of the circulating PAI-1 is complexed with vitronectin, which stabilizes PAI-1's active conformation.[52]

The target enzymes of PAI-1 are sctPA, and the two chain forms of tPA and uPA. When bound to a PLG activator, PAI-1 loses its affinity for vitronectin, but gains affinity for cell-surface LRP. This shift results in rapid clearance of PAI-1 by internalization, mediated by LRP. Vitronectin-bound PAI-1 also inhibits thrombin, an activity enhanced by HSPG.[52] In addition to its protease inhibitory activities, PAI-1 mediates vitronectin's adhesive properties and its role in tissue remodeling.[5,52]

α_2-Antiplasmin

α_2-Antiplasmin is a single chain, 70 kDa serpin that is the primary plasmin inhibitor. It is synthesized in the liver, circulating with a long half-life of approximately 3 days. It also binds to PLG, which interferes with PLG activation due to impaired PLG-fibrin interaction. Plasmin-bound fibrin is relatively resistant to α_2-AP inhibition. Factor XIIIa cross-links some forms of α_2-AP to fibrin, thereby making the fibrin more resistant to lysis.[5]

Thrombin Activatable Fibrinolysis Inhibitor

Thrombin activatable fibrinolysis inhibitor is a 60 kDa protein synthesized in the liver and released as a zymogen.[6] Thrombin and plasmin activate TAFI by cleavage at a single site; however, activation is extremely slow. Thrombomodulin-bound thrombin, however, increases the TAFI activation rate more than 1000-fold. Activated TAFI inhibits fibrinolysis by removing the C-terminal lysines of polymerized fibrin. These residues are the primary binding site on fibrin for both PLG and its activators; therefore modification of fibrin by TAFIa makes the fibrin clot resistant to fibrinolysis. Complement cascade proteins and adhesive proteins are secondary targets of TAFIa.

No TAFIa inhibitors have been identified, rather TAFIa appears to be regulated via spontaneous loss of activity. This inherent lability is temperature dependent. At body temperature TAFIa has a half-life of about 10 minutes.

Miscellaneous Inhibitors

As a non-specific protease inhibitor, α_2-MG acts to inhibit plasmin (especially in the absence of free α_2-AP) and also binds to tPA and uPA. Protein C inhibitor and protease nexin 1 also inhibit tPA.

HEMOSTASIS AND INFLAMMATION

Recent discoveries demonstrate apparent "cross-talk" between the inflammatory and hemostatic systems. This communication plays important roles in the healing processes necessary for tissue repair, and in the inflammatory and innate immune response required when infection develops as a consequence of tissue injury. Cross-talk may be responsible for inappropriate activation of hemostasis associated with systemic inflammation (Chapter 88).

Effects of Hemostasis on Inflammation

Contact pathway activation produces two enzymes (kallikrein and FXIIa) that activate complement and induce neutrophil activation, and stimulate monocytes to down-regulate Fc receptors and release inflammatory cytokines. Additionally, cleavage products of HK have effects on cellular adhesion, cellular proliferation, and apoptosis.[13,25,45]

The TF-FVIIa complex expressed on monocytes and endothelial cells activates cell surface PARs. This stimulation induces PAR-mediated signaling and increased expression of inflammatory cytokines (e.g. interleukins 1 and 6, tumor necrosis factor) and expression of chemotaxis proteins.[13,25,45]

Thrombin is chemotactic for macrophages and neutrophils, stimulates selectin expression that promotes neutrophil adhesion to endothelial cells, and activates endothelial cells to produce PAF, a potent neutrophil agonist. Thrombin activation of platelets releases CD40 ligand which can induce TF formation and increase cytokine production. Thrombin also increases endothelial permeability.[13,25,45]

The inflammatory response is attenuated by APC's enzymatic action on PAR-1, which down-regulates TF expression. Soluble EPCR, released by metalloproteinases from the endothelial cell surface, inhibits neutrophil adhesion. Down-regulation of TM expression increases endothelial intracellular signaling pathways responsible for production of proinflammatory cytokines, and limits activation of TAFI, adversely affecting clearance of some complement proteins.[13,25,45]

Fibrin can directly stimulate production of proinflammatory cytokines by monocytes, and release of chemokines by endothelial cells and fibroblasts.[13,25,45]

Effects of Inflammation on Hemostasis

Inflammatory mediators, especially components of the complement system, induce transmembrane phospholipid movement, resulting in expression of a procoagulant surface. The acute phase response results in a shift in the balance of protein synthesis. Proteins whose synthesis increases include fibrinogen, PLG, tPA, uPA, C1-INH, C4BP PS, vitronectin, PAI-1, and α_1-PI. Proteins whose synthesis is decreased include FXII, AT, and PC.[15,25]

Inflammatory cytokines down-regulate the expression of EPCR and TM on the endothelial cell surface. This results in less activation of APC, and consequently less inactivation of FVa and FVIIIa. Proinflammatory cytokines also induce expression of TF by cell-types that do not express this antigen under resting conditions. Proinflammtory cytokines also down-regulate expression of HSPG on the endothelial cell surface, which decreases the anticoagulant activity of AT.[13] Neutrophil elastase cleaves a variety of coagulation and fibrinolysis proteins, including AT, PC, and TM.[25]

    Heparin overdose

Acronyms and Abbreviations

ACT, activated clotting time; APLA, antiphospholipid-protein antibody; APS, antiphospholipid syndrome; aPTT, activated partial thromboplastin time; AT, antithrombin; DIC, disseminated intravascular coagulation; FDP, fibrin degradation product; KH_2, vitamin K hydroquinone; KO, vitamin K epoxide; PIVKA, proteins induced by vitamin K absence/antagonism; PT, prothrombin time; TCT, thrombin clotting time; TEG, thromboelastography; t-PA, tissue plasminogen activator; UFH, unfractionated heparin.

Clinical signs of hemorrhage are usually the result of a breach in vascular integrity that overwhelms an individual's normal hemostatic response. For these cases, diagnosis and management is directed at defining the site and cause of blood vessel injury. A subset of patients, however, have abnormal bleeding due to impaired hemostatic plug formation. Thrombocytopenia (see Chapters 78 and 79) and acquired coagulopathies are the most common hemostatic defects encountered in clinical practice. An index of suspicion and consistent use of screening tests early in the diagnostic work-up are key to recognition and effective management of acquired coagulopathies.

PATHOGENETIC CLASSIFICATION OF ACQUIRED COAGULOPATHIES

Acquired coagulopathies discussed in this chapter include disease processes that delay or prevent fibrin clot formation or increase the rate of fibrinolysis (Table 85.1).

Coagulation Factor Deficiencies

Coagulation factor activation generates a local burst of thrombin that transforms soluble plasma fibrinogen into an insoluble fibrin clot. Quantitative and/or functional deficiencies of coagulation factors influence the rate and amount of thrombin produced. (see Chapter 84). The common acquired factor deficiencies, unlike hereditary coagulopathies, are characterized by combined deficiencies of multiple clotting factors.

Synthetic Failure

The liver is the sole or primary source of all the serine protease coagulation factors and anticoagulants (i.e. factors II, VII, IX, X, XI, XII, proteins C and S) and other critical hemostatic proteins including factors V, XIII, antithrombin, and plasminogen. Liver disease is associated with complex abnormalities, with combined and variable deficiencies of procoagulant and anticoagulant proteins.[1,25] Liver failure, however, typically manifests as a hemorrhagic diathesis. A lack of hepatic synthetic

TABLE 85.1 Pathogenesis of Acquired Coagulopathies

Mechanism	Disease Syndromes	Associated Factor Defects
Synthetic failure	Liver disease: severe failure and markedly reduced functional hepatic mass	Most coagulation factors low but relative retention of factor VIII activity Hypofibrinogenemia and dysfibrinogenemia Antithrombin and protein C low
	Portosystemic shunting	Protein C low
Vitamin K dependent activation defect	Cholestasis, intestinal malabsorption, Vitamin K antagonists, neonates	Factors II, VII, IX, and X low Protein C low
Excessive rate of consumption	Overt (hemorrhagic) disseminated intravascular coagulation	Complex pattern of increased and decreased factor activities, hypofibrinogenemia Antithrombin low
	Envenomation	Hypofibrinogenemia, variable deficiency of other factors
Coagulation inhibitors	Alloimmune and autoimmune factor inhibitors	Single factor deficiency (factor VIII deficiency most common)
	Phospholipid-protein antibodies (associated with thrombosis)	Coagulation factor activities normal
	Heparin overdose	Serine protease factors neutralized (especially factor X, factor II)
Hyperfibrinolysis	Disseminated intravascular coagulation, neoplasia, infectious agents, prostate surgery	Complex factor deficiencies High plasminogen activators Hypofibrinogenemia

capacity results in quantitative coagulation factor deficiencies, first detectable by decreased activities of factors with short plasma half-lives (e.g. factor VII, half-life of 6 hours). Plasma fibrinogen, as an acute phase reactant, is often normal or elevated in patients with inflammatory and cholestatic liver disease. Diseased hepatocytes, however, may produce a dysfunctional, "nonclottable" fibrinogen due to abnormal alpha chain conformation and high sialic acid content that impairs fibrin formation and polymerization. The development of hypofibrinogenemia in patients with liver disease is an indicator of severely compromised synthetic functional reserve, associated with poor prognosis.[1]

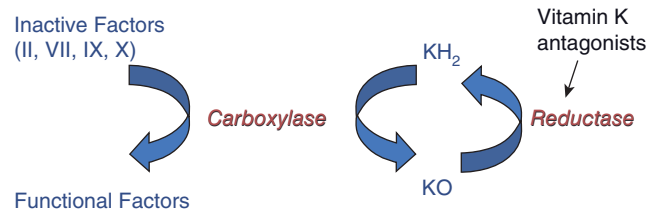

FIGURE 85.1 Vitamin K cycle. A vitamin K-dependent carboxylase simultaneously converts vitamin K quinol (KH_2) to vitamin K 2,3 epoxide (KO) as it transforms glutamate to functional gamma carboxyglutamate residues on factors II, VII, IX, and X. Vitamin K 2,3 epoxide is then reduced back to a quinol by vitamin K epoxide reductase. This enzyme is inhibited by coumarin-type anticoagulants.

Activation Defects

Vitamin K is essential for the post-translational processing of the prothrombin group of coagulation factors (factors II, VII, IX, X) and the anticoagulants, proteins C and S. All of these factors require the addition of gamma-carboxyglutamic acid residues in order to interact with calcium, bind to membrane surfaces, and form active enzyme complexes (see Chapter 84). Vitamin K participates in the carboxylation reaction through oxidation of vitamin K hydroquinone (KH_2) to vitamin K epoxide (KO). The epoxide form of vitamin K is continually recycled to replenish KH_2 by the enzyme vitamin K epoxide reductase (Fig. 85.1).

Coagulation factors synthesized in the absence of vitamin K circulate in plasma as inactive, descarboxy precursors referred to as proteins induced by vitamin K absence or antagonism (PIVKA).

Factor Consumption and Dilutional Coagulopathies

Acute or chronic hemorrhage does not result in coagulation factor deficiency in animals with normal liver function. Factor consumption outpaces hepatic synthesis, however, in animals with overt disseminated intravascular coagulation (DIC). The resultant coagulation factor depletion causes clinical signs of hemorrhage (see Chapter 88). Systemic amyloidosis in people is associ-

ated with variable factor X deficiency, although the phenomenon has not been described in animals. Amyloid fibrils are believed to adsorb factor X and facilitate its rapid plasma clearance in some patients.[7] The bleeding tendency of amyloidosis is multifactorial; due to amyloid tissue infiltration and deposition in the microvasculature, and potentially exacerbated by severe factor X deficiency (e.g. values below 25%). Many snake venoms contain proteases that activate clotting factors and/or directly cleave fibrinogen, resulting in systemic factor depletion and defibrination in a consumptive process.[13]

Dilutional hemostatic defects are common after aggressive fluid resuscitation or massive transfusion, commonly defined as replacement of more than one blood volume within a 24 hour time interval.[21] Factor dilution develops secondary to fluid shifts from the interstitial and intracellular space into the intravascular space. These shifts are triggered by reduced intravascular hydrostatic pressure and are compounded by administration of large volumes of intravenous fluids. Activation of coagulation secondary to trauma-induced tissue factor expression also leads to factor consumption. Thrombocytopenia, acidosis, hypothermia and hypocalcemia (due to citrate-based anticoagulants in blood products) further contribute to hemostatic compromise.[8,10]

Coagulation Inhibitors

The classification of coagulation inhibitors includes antibodies (usually IgG) directed against specific coagulation factors.[19] The antibodies bind to and directly inhibit factor activity and/or speed the rate of factor clearance. Inhibitory alloantibodies develop in patients with hereditary factor deficiencies after transfusion exposure to the "foreign" antigen. Factor VIII inhibitory antibodies develop in approximately 20% of people with severe hemophilia A (factor VIII deficiency).[19,20] Alloimmunization and development of factor VIII and IX inhibitors has also been described in dogs with hemophilia A and B, respectively.[18] Autoantibodies directed against coagulation factors represent a loss of tolerance and can also develop in patients without hereditary factor defects, regardless of prior transfusion.[9] Factor VIII is the most commonly implicated factor and the resultant coagulopathy is referred to as "acquired hemophilia." The epitope specificity of factor VIII alloantibodies and autoantibodies generally overlap, with most binding to the protein's light chain C domain. Recently, acquired factor V inhibitors have been recognized in people exposed perioperatively to topical bovine thrombin and fibrin glues.[12] These products contain trace amounts of bovine factor V, sufficient to induce cross-reactive antibody production, especially in multiply exposed patients.

The term "lupus anticoagulant" was formerly used to describe antibodies that prolong in vitro clotting times by blocking the interaction of coagulation factors with phospholipid reagents.[15] The immunogenic epitopes are actually phospholipid binding proteins and the current terminology for these inhibitors is antiphospholipid-protein antibodies (APLAs).[5] Paradoxically, people with APLA develop signs of thrombosis, rather than hemorrhage. Although their prothrombotic action is not fully defined, APLAs are believed to displace natural anticoagulants on cell surfaces and induce exposure of procoagulant phospholipids in the vascular space.

Additional classes of coagulation inhibitors include pharmacologic anticoagulants such as hirudin that act by directly impairing factor activity and heparin compounds that act indirectly to enhance antithrombin's ability to neutralize active factors (see Chapter 90). Finally, high plasma concentration of fibrin degradation products (FDPs) may act as coagulation inhibitors by interfering with normal fibrin polymerization.

Fibrinolysis Defects

Accelerated fibrinolysis causes hemorrhage by degrading fibrin clots before vascular repair is complete. Disease syndromes that induce increased plasminogen activators, decreased plasminogen inhibitors, or these factors combined, produce a hyperfibrinolytic state.[29] Hyperfibrinolysis, mediated by high tissue plasminogen activator (t-PA), develops in people infected with the agents causing Rocky Mountain spotted fever, African swine fever, and dengue fever, and secondary to extensive tissue trauma.[8] Neoplasia is associated with hyperfibrinolysis due to specific elaboration of plasminogen activators by tumor cells (e.g. acute promyelocytic leukemia) or in the context of a DIC process (see Chapter 88). The prostate and uterus are rich in t-PA and urokinase plasminogen activators. Surgery on these organs risks hemorrhagic complications due to local hyperfibrinolysis and impaired intra- and postoperative hemostasis.

CLINICAL EVALUATION

The initial evaluation of animals with signs of hemorrhage should aim to differentiate blood loss caused by vessel injury or vascular disease from a systemic failure of normal hemostasis (i.e. bleeding diathesis). The location and nature of hemorrhage and prior history of abnormal hemorrhage or underlying disease conditions provide clues to guide subsequent laboratory evaluation. Some animals with acquired coagulopathies do not manifest overt hemorrhage at initial presentation. Detection of factor deficiency in these cases requires an index of suspicion and consistent inclusion of coagulation screening tests early in the diagnostic work-up.

History

A history of recurrent, episodic hemorrhage is suggestive of a hereditary hemostatic defect, rather than an acquired coagulopathy (see Chapters 81, 82, 86). Hemostasis questionnaires have been developed for medical studies with the goal of simplifying history gathering and generating bleeding "scores" for standard comparison among trials.[22] A brief questionnaire with specific questions on hemostasis is also useful

early in the clinical work-up of animals suspected of having a bleeding disorder. Pertinent questions include: Has this animal ever had spontaneous bleeding from the nose, mouth, urinary tract, or noticeable bleeding when teething? Has this animal ever had a surgical procedure, dentistry, or traumatic injury, and were there any bleeding complications? Are you aware of any bleeding problems in relatives or in this breed? Is this animal receiving any medication or dietary supplements? Does this animal have any ongoing medical problems? Additional questions regarding housing conditions and potential access to drugs and toxins are useful; however, a negative exposure history does not preclude toxicity.

Physical Examination

The physical examination should define focal or multifocal sites of hemorrhage and detect evidence of gross and subtle hemorrhage. Funduscopic examination and careful inspection of mucuous membranes and nonhaired skin may reveal petechiae and ecchymoses, suggestive of platelet or von Willebrand factor defects or vasculopathies. Large vessel (arterial/venous) injury typically causes obvious blood loss from localized sites of vessel injury. Animals with severe coagulopathies may develop spontaneous hemorrhage into any body cavity or potential space, producing effusion, mass effect, or hematoma formation. Simultaneous hemorrhage from several sites, including prolonged hemorrhage from venipuncture or catheter sites is evidence of severe coagulopathy. The possibility of an acquired coagulopathy should be included in the differential for any patient with unexplained hemorrhage, effusion or mass lesion, or disease conditions associated with factor deficiencies (see Table 85.1). Routine coagulation screening of these cases will minimize delays in instituting appropriate management.

Quick Assessment and Point-of-Care Tests

The initial assessment of any patient suspected of having a hemostatic defect should include platelet count or platelet estimate (see Chapter 77) and a point-of-care coagulation test. The activated clotting time (ACT) is the traditional, and simplest coagulation screening test (see Chapter 138). The ACT detects moderate to severe deficiencies of fibrinogen and all coagulation factors, with the exception of factor VII. The ACT is prolonged, therefore, in patients with active hemorrhage due to most acquired coagulopathies, including liver failure, anticoagulant rodenticide intoxication, DIC, and heparin overdose (see Table 85.1). More advanced instruments are now available to perform additional point-of-care clotting time tests using whole blood samples. A clinical study of coagulopathies in dogs found similar diagnostic utility comparing results of laboratory and point-of-care coagulation panels.[26] Recently, viscoelastic monitors have been developed with the goal of providing a global assessment of hemostasis that incorporates the contribution of cellular elements and procoagulant and anticoagulant plasma proteins.[6] The thromboelastography (TEG) analyzer is the viscoelastic instrument used most widely to study coagulopathies in dogs.[18,28] This instrument provides a visual tracing and numeric parameters reflecting the rate and strength of fibrin formation. Clinically significant coagulopathies are expected to cause prolonged initiation times and diminished tracing amplitude. Evidence of hypocoagulability, in either simple or sophisticated point-of-care tests, requires follow-up with specific coagulation panel assays (and possibly more detailed factor and anticoagulant assays) for definitive diagnosis of acquired coagulopathies.[6]

Coagulation Panel

The basic screening tests to detect coagulopathies include activated partial thromboplastin time (aPTT), prothrombin time (PT), thrombin clotting time (TCT) and fibrinogen concentration (see Chapter 138). The assays are functional tests, configured with specific reagents that sequentially activate distinct series of coagulation factors (i.e. aPTT and PT) or with a thrombin-containing reagent that directly transforms plasma fibrinogen to fibrin (i.e. TCT and fibrinogen). Factor deficiencies are detected by prolongation of clotting times. The pattern of abnormalities in screening test results depends on which factor(s) the patient lacks (see Fig. 85.2).

Coagulation panel results, combined with clinical presentation, are often sufficient for management of acquired coagulopathies. Complex cases may require specific analyses of individual coagulation factors, anticoagulant proteins, drugs, or measures of fibrinolysis, to better define pathogenesis or facilitate case management. Collection of pre-treatment samples is critical for timely and accurate diagnosis of coagulopathies, and clinicians must bear in mind that the validity of all hemostasis testing depends on appropriate sampling techniques (see Chapter 138).

SPECIFIC DISORDERS

Liver Disease

Animals with hepatobiliary disease demonstrate variable signs of coagulopathy, ranging from spontaneous bleeding to subclinical prolongation of in vitro clotting times.[2,14,24] Liver disease causes major alterations in many hemostatic mechanisms, including platelet and endothelial cell reactivity, procoagulant and anticoagulant protein production and function, dysregulation of fibrinolysis, and complications arising from portal hypertension and splenomegaly. These changes often act as opposing procoagulant and anticoagulant forces, resulting in variable net bleeding risk. Clinically severe hemorrhage is generally seen in animals with fulminant or end-stage hepatic failure, or those with concomitant DIC. Other forms of liver disease may cause relatively milder bleeding tendencies, albeit sufficient to impair surgical hemostasis for animals undergoing biopsy or hepatobiliary surgery.

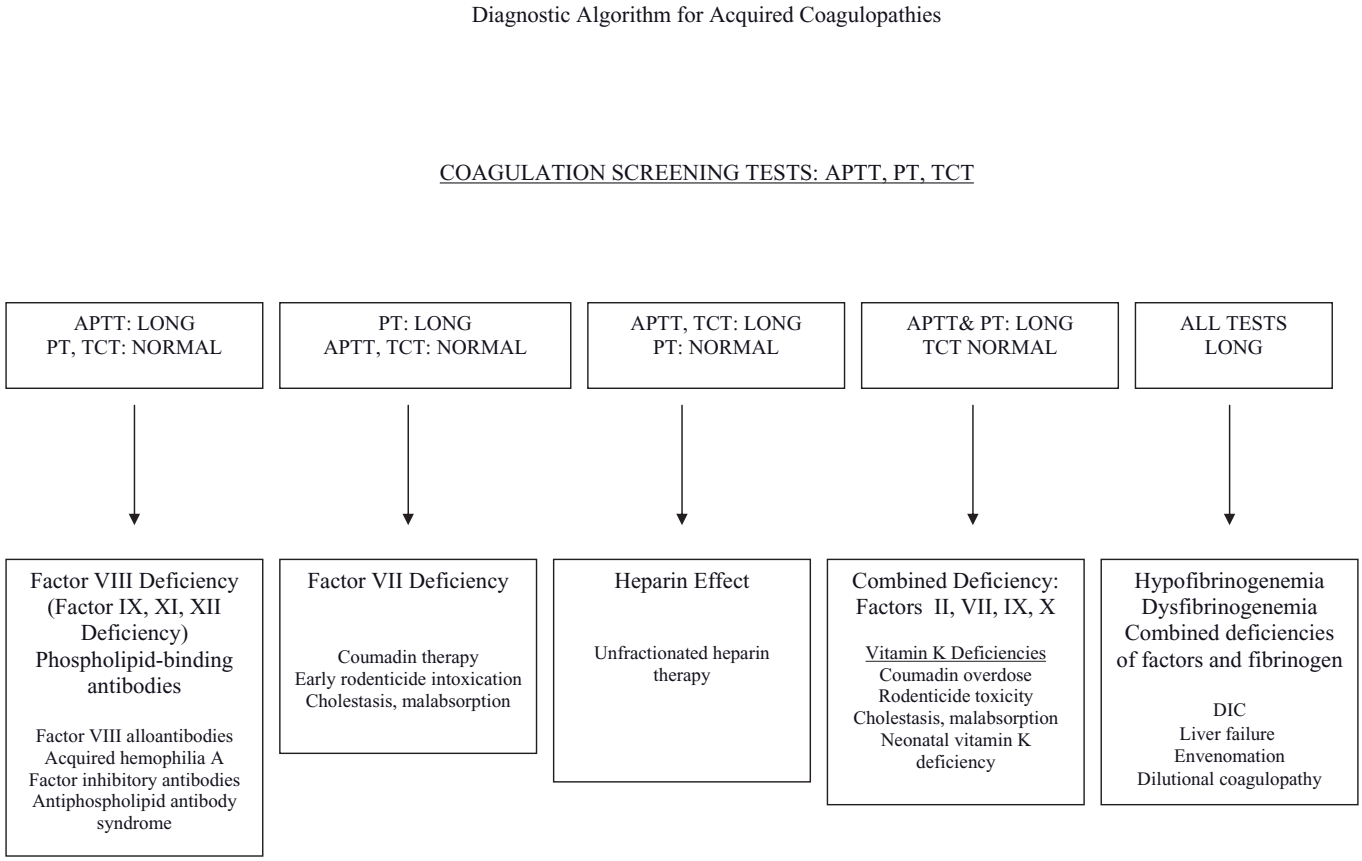

FIGURE 85.2 Coagulation screening test algorithm for acquired coagulopathies.

Marked prolongation of coagulation screening tests (aPTT, PT, TCT) and hypofibrinogenemia indicate high risk of spontaneous and post-surgical hemorrhage, and are overall poor prognostic signs. Mild prolongation or the absence of abnormal clotting times, however, does not rule out the risk of procedure-related bleeding. Newer hemostasis tests, such as endogenous thrombin potential and thromboelastography are designed to assess net procoagulant and anticoagulant forces. Their utility for predicting bleeding risk in patients with liver disease is currently under clinical investigation.[6] A preliminary study has shown that measurement of protein C activity may be useful as a biomarker of liver function and hepatoportal blood flow in dogs.[24] The finding of low protein C activity helps differentiate porto-systemic vascular anomalies from microvascular dysplasia, and is a useful predictor of clinical outcome when combined with traditional biochemical assays.

Management strategies for coagulopathy of liver disease include prophylactic and "rescue" therapies. Prophylactic administration of vitamin K_1 is often included with specific and supportive medical therapy for liver disease. Pre-operative vitamin K_1 administration is indicated for animals with cholestatic disorders and/or prolonged aPTT and PT (see Chapter 90). Current trends in human medicine favor more restrictive use of prophylactic transfusion therapy.[1] Fresh frozen plasma is transfused to patients with liver failure and signs of hemorrhage to supply active procoagulant and anticoagulant factors (see Chapters 90 and 96). The need for pre-operative transfusion is generally assessed on an individual patient basis in human and veterinary medicine. People undergoing liver transplantation invariably require transfusion and algorithms based on thromboelastographic parameters have been developed to guide the use of blood components in this patient population.[6]

Vitamin K Deficiency

Vitamin K deficiency is a common cause of coagulopathy, resulting from inadequate intestinal absorption or impaired intrahepatic recycling.[2,4,14,16] Biliary obstruction, intrahepatic cholestasis, chronic oral antibiotic administration, and infiltrative bowel disease may all reduce vitamin K absorption. Hemorrhagic disease of the newborn refers to vitamin K deficiency in infants within the first few days to weeks of life. Hemorrhage is attributed to inadequate placental transfer of vitamin K and inadequate hepatic recycling.[11] Coumadin (warfarin) and second-generation anticoagulant rodenticides (e.g. brodifacoum) act by irreversibly blocking the activity of epoxide reductase, the critical hepatic vitamin K recycling enzyme (see Fig. 85.1). Severe coagulopathies due to anticoagulant rodenticide toxicity are com-

monly encountered in small animal practice, have been reported in equine practice, and are increasingly recognized in wild birds (see Chapter 91). Factor deficiency and resultant signs of a bleeding diathesis develop over a period of several days post-ingestion of anticoagulant poisons as vitamin K stores become depleted. Signs of hemorrhage may be obvious as external blood loss, or may be nonspecifc as pleural or abdominal effusion or mass lesions anywhere in the body due to hematoma formation. Treatment delays often lead to death from hemorrhagic shock, or respiratory or central nervous system compromise.

Prolongation of both the aPTT and PT screening tests, with normal TCT, are the hallmarks of hemorrhage caused by severe vitamin K deficiency (see Fig. 85.2). Specific factor analyses reveal that severe deficiencies of factors II, VII, IX, and X but normal fibrinogen cause this characteristic coagulation profile. Therapeutic dosages of the anticoagulant Coumadin cause only mild deficiencies of the vitamin K-dependent factors that should not cause prolongation of the aPTT. Coumadin monitoring to ensure adequate, but not excessive dosage, is based on PT analyses (see Chapter 90).

Management of vitamin K deficiency requires replacement therapy with vitamin K_1 (phytonadione), rather than vitamin K_3 (menadione). Vitamin K therapy is often given empirically pending results of pre-treatment coagulation assays, because synthesis of sufficient active factors to correct the coagulopathy requires at least 12 hours from the start time of initiating vitamin K supplementation. Transfusion is also indicated for patients with severe signs at presentation (see Chapter 96).

Disseminated Intravascular Coagulation

Microvascular thrombosis is the characteristic feature of DIC; however, signs of a severe bleeding diathesis dominate some case presentations. Dogs with DIC secondary to neoplasia (e.g. hemangiosarcoma) often develop consumptive coagulopathies, with coagulation factor and fibrinogen depletion, and concomitant increase in FDP and D-dimer (see Chapter 88). Hemorrhagic, overt DIC is often transfusion resistant, requiring high volume plasma replacement to sustain hemostasis (see Chapter 96).

Dilutional Coagulopathy

The terms dilutional coagulopathy, or "traumatic coagulopathy" describe a hemostatic defect that develops after high volume fluid resuscitation. Traumatic coagulopathy occurs in up to 1 of 4 human trauma patients and is considered a negative prognostic indicator. Concomitant acidemia, hyperfibrinolysis, and hypothermia further exacerbate coagulopathy in these patients. The effect of crystalloids versus colloids in promoting a dilutional coagulopathy has been extensively studied, with colloids demonstrating a greater dilutional effect than crystalloids and a negative effect on clot stability.[8] Clinical studies in people also reveal that fibrinogen deficiency generally develops early in the course of hemodilution and signs of inadequate hemostasis manifest at fibrinogen concentration below 50–100 mg/dL (0.5–1.0 g/L).[21] Although traumatic coagulopathies are not as well-characterized clinically in animals, a retrospective study of massive transfusion in dogs noted prolonged aPTT and PT in half the cases.[10] Correction of hemostatic abnormalities is associated with improved survival in people, and factor replacement in the form of fresh frozen plasma is typically administered after recognition of coagulopathy.[8]

Coagulation Inhibitors

Factor VIII Inhibitory Antibodies

Antibodies that inhibit factor VIII are a well-recognized complication of factor replacement therapy for people with hemophilia A. This alloantibody formation is commonly, but not exclusively, found in patients with severe factor VIII deficiency (i.e. ≤1% factor VIII).[19] Consequently, mutation types that abolish protein synthesis appear to increase the risk of inhibitor formation. The development of coagulopathy due to factor VIII inhibitory antibodies also occurs as an autoimmune phenomenon.[9] Underlying conditions associated with acquired factor VIII inhibitor development include systemic lupus erythematosus, rheumatoid arthritis, drug hypersensitivity, inflammatory bowel disease, malignancy, and the post-partum state. Factor VIII inhibitors (alloantibodies and autoantibodies) often cause severe coagulopathies characterized by spontaneous hemorrhage refractory to standard replacement therapy.

Factor VIII inhibitors are detected by specific prolongation of the aPTT. This prolongation is not corrected by mixing patient plasma with normal plasma, in contrast to congenital factor VIII deficiency (in the absence of factor VIII inhibitors). The Bethesda unit assay (BU) is used to quantify the titer of inhibitory antibodies. Values below 5 BU/mL are considered low titers.[19,20] Active bleeding in patients with low BU titers often responds to transfusion of high dose factor VIII replacement therapy. In contrast, patients with high titer inhibitors often require "by-pass" therapy using recombinant activated human factor VII (see Chapter 96). Long-term management of high titer factor VIII inhibitors consists of specific therapy of underlying disorders (for autoantibody patients) and immune-modulating or immunosuppressive therapy.[20]

Antiphospholipid Syndrome Inhibitors

The antiphospholipid syndrome (APS) is recognized as a thrombotic risk factor in people. The syndrome typically develops in patients with autoimmune disorders and is characterized by the production of APLAs that prolong in vitro clotting time.[15] Long aPTT that fails to correct in a mixing study is compatible with the presence of APLA, and more specialized clotting time tests (e.g. dilute Russell's viper venom time) and quantitative immunoassays to detect antibodies directed against

lipid-binding proteins are used as confirmatory assays.[5] Inhibitory antibodies were proposed as the cause of long clotting times in a case report of canine immune-mediated hemolytic anemia (IMHA) and thrombosis; however, the prevalence and clinical relevance of APLA and APS in animals is not well-defined.[23]

Heparin Overdose

Unfractionated heparin (UFH) is widely used in veterinary medicine; however, few clinical studies have been performed to define effective dosage regimens. The pharmacokinetic profile of UFH is complex due to its extensive protein and cell binding and dose-dependent half-life (see Chapter 90).[3,17,27] Since hemorrhage is the major risk of high dose UFH therapy, individual patient monitoring is required to prevent excessive anticoagulant effect. The aPTT and TCT coagulation screening tests are both sensitive to UFH, whereas the PT is generally unaffected by therapeutic UFH levels. Adjustment of UFH dose to prolong aPTT to 1.5–2 times pretreatment values is the traditional means for guiding UFH therapy in people, and this strategy is applicable to prevent overdosage in animals. Clinical signs of hemorrhage or marked prolongation of aPTT (i.e. >2.5 times baseline) are indications for discontinuing UFH therapy. Due to its short (2–3 hour) plasma half-life, hemorrhage is usually transient. People with major hemorrhage due to UFH overdosage are infused with protamine sulfate, a basic polypeptide that binds tightly to UFH and immediately neutralizes its anticoagulant activity.[27] Protamine administration causes systemic hypotension in dogs; therefore transfusion therapy is used to control life-threatening hemorrhage caused by excessive UFH anticoagulant effect (see Chapter 96).

Acronyms and Abbreviations

ACT, activated clotting time; aPTT, activated partial thromboplastin time; coagulation factors: FII, factor II; FVII, factor VII; FVIII, factor VIII; FIX, factor IX; FX, factor X; FXI, factor XI; FXII, factor XII; FXIII, factor XIII; DIC, disseminated intravascular coagulation; HMWK, high molecular weight kininogen; PIVKA, proteins induced by vitamin K absence/antagonism; OMIA, on-line Mendelian inheritance in animals; OMIM, on-line Mendelian inheritance in man; PK, prekallikrein; PT, prothrombin time; RVVT, Russell's viper venom time; TCT, thrombin clotting time; VKOR, vitamin K epoxide reductase.

HEREDITARY COAGULATION FACTOR DEFICIENCIES

Hereditary coagulopathies arise from mutations within genes required for synthesis or processing of active coagulation factors. The bleeding tendency associated with each trait depends on the physiologic role of the deficient factors in fibrin clot formation and the degree of factor deficiency. Hemophilia A is the most common hereditary coagulopathy in human beings and animals, due in part to a high de novo mutation rate in the coagulation FVIII gene (*F8*).[11] In addition, new factor deficiencies continually arise within breed populations with variable frequencies that change over time. The general breeding strategies to limit propagation of hereditary factor defects include exclusion of individuals expressing a bleeding tendency, avoidance of repeat matings that produce affected individuals, and familial screening (especially dams, sires, siblings) of affected patients to identify others with quantitative or functional factor deficiencies. In addition to the review of defects presented in this chapter (Table 86.1), public access databases, such as Online Mendelian Inheritance in Man and Animals (OMIM, OMIA) hosted by the NIH, provide information on hereditary factor deficiencies in animals.

X-LINKED FACTOR DEFICIENCIES: HEMOPHILIA A AND B

Hemophilia A (OMIM 306700) and hemophilia B (OMIM 306900) are distinct X-linked bleeding disorders caused by functional or quantitative deficiencies of FVIII and FIX, respectively.[11] Although both genes map to the long arm of the X chromosome, they are inherited independently. Factor IX (a serine protease enzyme) and FVIII (its coenzyme) play critical roles in the amplification phase of coagulation by participating in formation of the "tenase" enzyme complex (see Chapter 84).

Clinical Diagnosis of Hemophilia

Hemophilia A and B are diagnosed primarily in males because of the sex-linked, recessive inheritance pattern of these traits. Carrier (heterozygous) females do not express a bleeding tendency. Signs of hemophilia include lameness due to hemarthrosis, intramuscular

TABLE 86.1 Hereditary Factor Deficiencies

Factor Deficiency	Screening Test Results		Species (Breeds)
	Abnormal	Normal	
Fibrinogen	TCT,[a] fibrinogen[a] All tests[b]	*aPTT, *PT	Dogs (Bichon Frise, Borzoi, collie), cats (DSH), goat (Saanen), sheep (Leicester)
Factor II (prothrombin)	aPTT, PT	TCT, fibrinogen	Boxer
Factor VII (proconvertin)	PT	aPTT, TCT, fibrinogen	Dogs (Alaskan Klee Kai, Beagle, Deerhound, Malamute, Schnauzer), cats (DSH)
Factor VIII (hemophilia A)	aPTT	PT, TCT, fibrinogen	Dogs (any breed, mixed breeds, German shepherd, Golden retriever), cats (any breed, DSH), horse, sheep
Factor IX (hemophilia B)	aPTT	PT, TCT, fibrinogen	Dogs (any breed, mixed breeds), cats (any breed, DSH), horse
Factor X (Stuart Prower factor)	aPTT, PT	TCT, fibrinogen	Dogs (Cocker spaniel, Jack Russell terrier), cats (DSH)
Factor XI (PTA deficiency, hemophilia C)	aPTT	PT, TCT, fibrinogen	Dogs (English springer spaniel, Kerry blue terrier), cats (DSH)
Factor XII (Hageman factor)	aPTT	PT, TCT, fibrinogen	Dogs (Miniature poodle, Shar Pei), cats (DSH, DLH, Siamese, Himalayan)

[a]Mild fibrinogen deficiency.
[b]Severe fibrinogen deficiency.

FIGURE 86.1 Clinical signs of hemophilia. Intramuscular hematoma formation in the lateral thigh muscles of a hemophiliac German shepherd. Note distal limb swelling due to edema, venous obstruction, and extravasated blood.

and subcutaneous hematoma formation, and prolonged hemorrhage from minor wounds and gingiva at tooth eruption sites (Fig. 86.1). Severe hemophilia typically manifests within the first few months of life. Severely affected patients are at risk for spontaneous and fatal hemorrhage, whereas milder hemophilia may become apparent only after surgery or trauma.

Hemophilia A is the more common form in all species, with an incidence of 1–2 cases per 10,000 male births (in human populations). Unlike many hereditary diseases in animals, hemophilia is not restricted to a single breed or inbred line. Cases of hemophilia A and B have been identified in mixed breed dogs and more than 50 different purebred lines.[2] Both traits have been reported in domestic and purebred cats[9,14] and horses,[6] and hemophilia A has been characterized in sheep.[1]

The laboratory diagnosis of hemophilia is based on results of coagulation assays. Both forms of hemophilia cause specific prolongation of intrinsic pathway screening tests (ACT and aPTT), but do not affect tests of the extrinsic/common pathways or fibrinogen (see Table 86.1). Definitive diagnosis and differentiation of hemophilia A from hemophilia B requires specific measurements of FVIII and FIX coagulant activities (FVIII:C, FIX:C). Clinical severity relates to residual factor activity. Severe hemophilia is characterized by FVIII:C or FIX:C < 2% of normal, whereas factor activities of 2–20% are associated with moderate to mild hemophilia. Factor assay values are derived from comparisons of patient plasma with the activity of plasma standards. Reaction kinetics vary among species; therefore animal factor activity assays are best performed using same-species plasma standards (see Chapter 138).

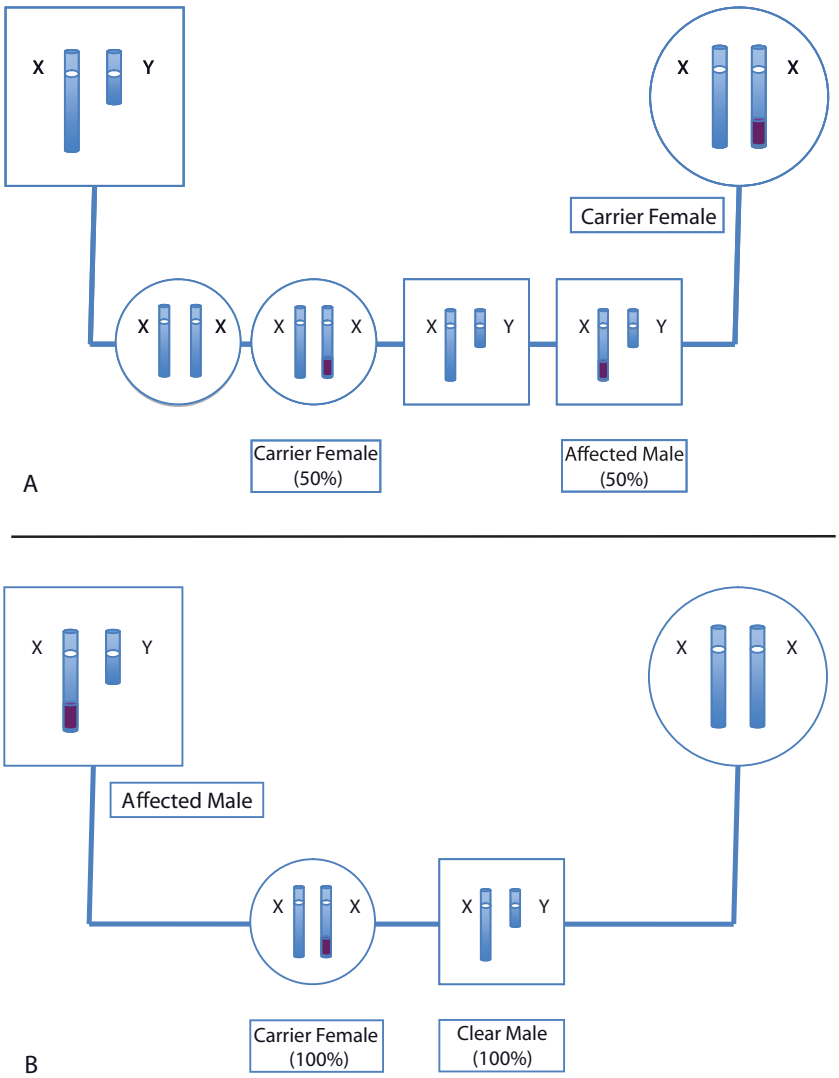

FIGURE 86.2 Inheritance of hemophilia A and B. (**A**) Propagation of hemophilia by a carrier female. If a carrier female is bred, on average one-half of her daughters and one-half of her sons will inherit her mutant gene (depicted as a purple bar on the X chromosome). (**B**) Propagation of hemophilia by an affected male. Males with mild forms of hemophilia may survive to reproduce. If bred, they transmit a mutation to all their daughters and none of their sons.

Treatment of Hemophilia

Transfusion is the primary means for controlling or preventing hemorrhage in animals affected with hemophilia A or B (see Chapters 88 and 96). Fresh frozen plasma supplies both FVIII and FIX, whereas cryoprecipitate is a more specific product for replacement of FVIII, and cryosupernatant supplies FIX. The transfusion interval for hemophiliacs varies depending on residual factor activity, and clinical features such as patient size, activity, and conditions that further impair hemostasis. Maintenance of patients with severe hemophilia (<2% FVIII:C, FIX:C) is difficult due to recurrent hemorrhage. Many severely affected animals are euthanized due to poor quality of life, or experience fatal bleeds before 1 year of age.

Genetics

New cases of hemophilia arise from frequent de novo mutation events in the FVIII and FIX genes. Once present, hemophilia mutations are typically transmitted by asymptomatic carrier dams; however, males with mild forms of hemophilia may survive to adulthood and widely propagate the trait if they are bred (Fig. 86.2). Males are accurately diagnosed as affected or clear of hemophilia based solely on FVIII and FIX assays. Obligate carrier females are then identified by pedigree review as the dams and daughters of the affected males. The status of suspect carrier females is difficult to classify with factor assays, however, because values overlap for carrier and clear females at the low end of the normal range. Molecular genetic analyses of hemophilia indicate that unique mutations within the FVIII and FIX genes are likely causative for hemophilia in different breeds and families.[2] In support of this prediction, distinct FIX mutations have been identified in different breed-variants of canine and feline hemophilia B.[3,14] The discovery of hemophilia A causative mutations is more challenging because of the large size and complexity of the FVIII gene. Direct mutation detection is the most accurate means of hemophilia carrier detec-

tion, providing the underlying mutation is known. An alternate, indirect strategy utilizing DNA markers linked to the FVIII gene has proven feasible for carrier detection of hemophilia A in sheep and dogs.[1,5]

AUTOSOMAL FACTOR DEFICIENCIES

All of the remaining factor deficiencies identified in animals (fibrinogen, FII, VII, X, XI, XII, and contact factor defects) are less common than hemophilia, and are typically restricted to a few breeds or families (Table 86.1). These autosomal defects are primarily recessive traits. In this form of inheritance, males and females express and transmit the traits with equal frequencies, affected individuals are homozygous for the disease-causing mutation, and heterozygous carriers do not express a bleeding tendency (Fig. 86.3).

Fibrinogen Deficiency

Fibrinogen is the plasma precursor of fibrin and also supports intra-platelet bridging in the process of aggregation. Fibrinogen consists of three polypeptide chains (A-α, B-β, and γ), coded for by three closely linked genes. Mutations in any of these genes can impair fibrinogen function or secretion.

Many distinct hereditary fibrinogen defects have been identified in people, broadly classified as quantitative deficiencies (i.e. afibrinogenemia and hypofibrinogenemia) and functional defects (dysfibrinogenemia and hypodysfibrinogenemia) (OMIM 202400). Afibrinogenemia is rare and causes a severe bleeding diathesis. Signs of dysfibrinogenemias are variable, ranging from severe hemorrhage to thrombosis. Hereditary fibrinogen defects have been identified in several breeds of dogs, and in cats, goats, and sheep (Table 86.1).[10,26] Reported manifestations include severe, spontaneous hemorrhage and hemarthrosis. Milder forms are characterized primarily by post-traumatic and post-surgical hemorrhage.

Fibrinogen deficiency affects formation of a fibrin clot endpoint in all clotting time tests (Table 86.1). The TCT is the most sensitive of these screening tests to detect mild fibrinogen deficiencies. A combination of functional (clottable) fibrinogen assays and quantitative methods, such as enzyme-linked immunosorbent assay (ELISA), are required for definitive diagnosis of hypo/dysfibrinogenemias and afibrinogenemia (see Chapter 138).

Hereditary fibrinogen defects are much less common than acquired hypofibrinogemia, which often develops secondary to hepatic synthetic failure or consumption in a DIC process (See Chapter 85). Unlike acquired disorders, hereditary fibrinogen deficiencies are rarely associated with concomitant thrombocytopenia, or deficiencies of other coagulation factors. The absence of clinical and laboratory signs of hepatic failure or DIC further aid in differentiating hereditary from acquired fibrinogen defects.

Cryoprecipitate is the treatment of choice for fibrinogen defects as it supplies high concentration fibrinogen in low volume transfusion. Fresh frozen plasma is an alternative product if cryoprecipitate is unavailable (see Chapter 96). Transfusion is indicated for patients with active hemorrhage, or for preoperative prophylaxis. The human dosage recommendation is transfusion to a target of 50–100 mg/dL fibrinogen.[21] The half-life of fibrinogen of 2–4 days is relatively long compared with most factors; thus fewer transfusions at longer intervals are often sufficient to support hemostasis for patients with fibrinogen defects.

Fibrinogen defects in people are mutationally heterogeneous and display autosomal dominant and recessive inheritance patterns. Afibrinogenemia is usually a recessive trait caused by mutations in the fibrinogen A-α chain. Hypo/dysfibrinogenemias have been described in patients with mutations in all three fibrinogen genes. Pending pedigree studies and molecular analyses, it is likely that animals will display the same variety of disease-gene, mutation location, and mutation-type found in human patients.

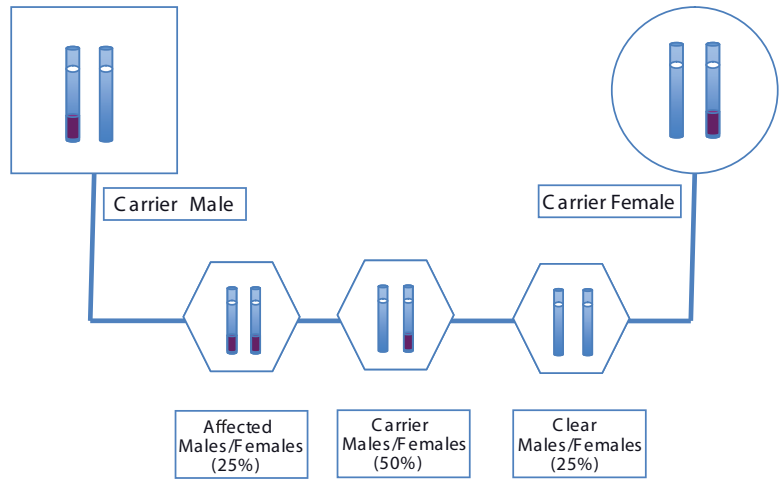

FIGURE 86.3 Inheritance of autosomal recessive factor deficiencies. Mutant genes (depicted as purple bars on an autosome) are transmitted from dam and sire to male and female offspring with equal frequencies. On average, one-quarter of the offspring will be homozygous (affected with the defect), one-half of the offspring will be asymptomatic heterozygous carriers, and one-quarter of offspring will inherit no mutant gene and therefore be clear of the trait.

Prothrombin Deficiency

Hereditary FII (prothrombin) deficiency is uncommon, with fewer than 100 cases reported in human beings and isolated cases in a few breeds of dog (OMIM 176930).[10] Prothrombin is the zymogen of thrombin, the serine protease factor that transforms fibrinogen to fibrin. Thrombin also plays a central role in platelet activation, inflammation, and wound healing. Knockout mice lacking the prothrombin gene are nonviable and all naturally occurring human (and animal) cases have some residual thrombin activity.

Clinical signs of hemarthrosis and post-traumatic hemorrhage are generally seen in patients with residual thrombin activities below 10% of normal. Prothrombin deficiency causes prolongation of the aPTT and PT (and PIVKA) screening tests, but does not affect the TCT or fibrinogen assay (Table 86.1). Differential diagnoses for this pattern of screening test abnormalities include deficiency of a single common pathway factor (FII, FV, FX) and combined deficiency of all vitamin K-dependent factors (FII, FVII, FIX, FX). The finding of specific deficiency of FII coagulant activity (FII:C), with normal activity of the other factors, provides definitive diagnosis of prothrombin deficiency (see Chapter 138).

Fresh frozen plasma and plasma cryosupernatant supply FII. The half-life of FII is approximately 3 days, and transfusion to attain target FII:C of 20–40% is the recommended guideline to maintain hemostasis in human patients.[21]

The expression of FII deficiency in people is autosomal recessive; affected patients are homozygous with residual FII:C ranging from 2% to 20%. Heterozygotes have FII:C of approximately 50% and are clinically asymptomatic. Although new mutations could arise, FII deficiency is uncommon and rarely recognized in any breed at this time.

Factor VII Deficiency

Trace amounts of activated FVII (FVIIa) bind to membrane-bound tissue factor at sites of vascular injury. This FVIIa/tissue factor complex plays a central role in the initiation phase of coagulation. Hereditary FVII deficiency is often associated with a clinically mild or inapparent bleeding diathesis, suggesting that sufficient residual FVII remains for active complex assembly. The trait has been identified in people and several different breeds of dog (OMIM 227500).[7]

Canine FVII deficiency is best characterized in Beagles.[7] Factor VII deficient Beagles rarely experience abnormal bleeding, even after surgery or trauma. In contrast, FVII deficiency in Malamutes is typically associated with more severe signs including hematoma formation, prolonged post-traumatic bleeding, and fatal hemorrhage.[2] Clinical severity may vary among individuals within a single breed. In a recent report of FVII deficient Alaskan Klee Kai, the index case experienced prolonged post-traumatic hemorrhage whereas other related dogs had undergone major surgery with no complications.[16]

Factor VII deficiency causes an isolated prolongation of the PT (and PIVKA) screening tests, with normal aPTT, TCT, and fibrinogen (Table 86.1). Hereditary FVII deficiency is differentiated from vitamin K-dependent coagulopathies as a single factor, rather than a combined multi-factor defect. In most canine and human kindreds, FVII deficient patients have some residual FVII activity with FVII coagulant activity (FVII:C) generally ranging from 1% to 10% of normal. More detailed laboratory characterization of residual FVII includes measurement of FVII antigen and levels of circulating FVIIa (see Chapter 138).

Most FVII deficient patients are transfusion-independent; however, those with severe forms and signs of hemorrhage can be transfused with fresh frozen plasma or cryosupernatant to supply FVII. Factor VII has a short plasma half-life of approximately 3–4 hours; therefore transfusion intervals of 8–12 hours may be needed to sustain hemostasis after initial stabilization (see Chapter 96).

Factor VII deficiency is a recessive trait. A mis-sense mutation in exon 5 of the FVII gene was first identified in FVII deficient Beagles, and subsequently found to cause FVII deficiency in Alaskan Klee Kai and Deerhounds.[7,16] Heterozygous carriers of the mutation generally have FVII:C values intermediate between affected and clear dogs. Direct mutation detection is preferable for carrier detection because factor activities overlap between carrier and clear individuals. Mutations causative for FVII deficiency in other breeds or species have not yet been identified.

Factor X Deficiency

Factor X and its cofactor, FV, play a central role in generating thrombin. The factors assemble on cell membrane surfaces to form the prothrombinase complex which rapidly converts prothrombin to the active enzyme, thrombin (see Chapter 84).

An absolute lack of FX is an apparently lethal trait; however, partial FX deficiency has been identified in human beings, dogs, and a DSH cat (Table 86.1; OMIM 227600).[8,10,13] The defect is a relatively severe bleeding diathesis in these species, with signs of spontaneous epistaxis, hematoma formation, and severe hemorrhage post-trauma or surgery.

Factor X deficiency causes prolongation of the aPTT, PT, PIVKA, and RVVT screening tests; however, TCT and fibrinogen are normal (see Chapter 138). Clotting time in the RVVT is initiated by direct activation of FX, independent of the intrinsic or extrinsic pathways. The differentials for this pattern of abnormalities include vitamin K-dependent coagulopathy, and isolated deficiencies of FX, FV, or FII. Definitive diagnosis is based on the specific finding of low FX coagulant activity (FX:C). Acquired FX deficiency has been reported in people with systemic amyloidosis, attributed to adsorption of FX onto amyloid fibrils. This phenomenon has not been documented in animals.

Fresh frozen plasma and cryosupernatant supply FX (see Chapter 96). After initial control of active hemor-

rhage, subsequent transfusions can be given at relatively long (q12–24 hours) interval due to the long half-life of FX of 40 hours.

Mis-sense and nonsense mutations are the most common mutation-type causing human FX deficiency; however, specific FX mutations have not yet been discovered in animals. The trait demonstrates a recessive inheritance pattern in people and animals. Familial testing in dogs and cats revealed severe deficiency (FX:C < 10%) in clinically affected patients and moderate factor deficiencies (20–50% FX:C) in obligate carrier parents.

Factor XI Deficiency

Thrombin activates FXI to form FXIa in the early initiation phase of coagulation. This reaction takes place most efficiently on the surface of activated platelets, where FXIa then generates FIXa and promotes assembly of the tenase coagulation complex (see Chapter 84).

Factor XI deficiency has been identified in people, dogs, cattle, and a DSH cat (Table 86.1; OMIM 264900).[18,19,24] The defect is clinically variable in all species, but typically causes a mild bleeding tendency. Spontaneous hemorrhage is rare and affected patients are often diagnosed because of prolonged hemorrhage or abnormal rebleeding after surgery or trauma. Clinical severity does not correlate as closely with residual factor activity as most other factor deficiencies; however, clinical expression of a bleeding tendency is more likely to occur in patients with FXI activities (FXI:C) below 30% of normal.

Factor XI deficiency causes specific prolongation of the aPTT, with normal PT, TCT and fibrinogen (Table 86.1). Hemophilia A and B cause the same pattern of screening test abnormalities; however, specific coagulation factor analyses define isolated FXI deficiency (see Chapter 138).

Fresh frozen plasma and cryosupernatant supply FXI (see Chapter 96). Transfusion is usually required only for support of surgical or post-traumatic hemostasis. After an initial preoperative or loading transfusion, FXI half-life of approximately 50 hours allows repeat transfusions to be given at 12–24 hour intervals. Although their use has not been reported in animals, antifibrinolytic agents and topical fibrin sealants have been used successfully in human FXI deficient patients (see Chapter 90).

An exonic SINE insertion has been identified in FXI deficient Kerry Blue terriers and insertions in exons 3 and 9 have been described in FXI deficient Holstein and Japanese cattle, respectively.[19,23] Homozygous cattle have marked FXI deficiency (FXI:C < 5%), whereas affected Kerry Blue terriers and DSH cats have relatively moderate reduction with FXI:C of approximately 2–15%.

Factor XII and Contact Factor Deficiencies

The contact group of coagulation factors includes FXII, prekallikrein (PK; Fletcher factor) and high molecular weight kininogen (HMWK). Contact factors interact in vitro to initiate coagulation on artificial surfaces through activation of FXI. However, these factors are not required for fibrin clot formation in vivo and deficiency of these factors does not cause a bleeding diathesis (see Chapter 84). The physiologic activities of the contact group factors are now believed to include regulation of blood pressure, cellular proliferation, angiogenesis, and inflammation. Early reports of FXII deficiency in people suggested an increased risk of systemic thrombosis; however, a causal relationship has not been confirmed.

In addition to human beings, deficiencies of the contact pathway factors have been identified in dogs, cats, and horses (Table 86.1; OMIM 234000,229000, 228960).[10,12,17,25] Factor XII deficiency, in particular, is a common factor deficiency found in DSH and purebred cats.[4]

Contact pathway deficiencies are characterized by markedly prolonged aPTT (often >120 seconds), with normal PT, TCT, and fibrinogen. A prolonged aPTT that shortens by increasing activation time is a common characteristic of PK-deficient plasmas. Specific deficiencies of the contact group factors can be diagnosed based on functional assays of FXII, PK, and HMWK (see Chapter 138). Due to its high prevalence, FXII deficiency should be considered a likely cause of specific prolongation of aPTT in cats. FXII deficient cats do not require specific therapy. Long aPTT is a persistent in vitro finding but is not an indication for transfusion of any contact factor deficient patients.

Contact factor deficiencies are recessive traits; however, causative mutations have not yet been identified in animals. Cats homozygous for FXII deficiency have residual FXII:C values of approximately 2–10%, whereas heterozygous carriers generally have moderate reduction in activity with residual FXII:C from 20% to 40%.[17]

Combined Deficiencies of the Vitamin K-Dependent Factors

Factors II, VII, IX, and X are serine protease enzymes that require post-translational γ-carboxylation in order to form active complexes with their coenzymes and substrates. Defects in the hepatic vitamin K reductase or carboxylase enzymes impair vitamin K recycling and cause coagulopathy due to a persistent vitamin K deficiency state (see Chapter 84).

Familial combined deficiency of FII, VII, IX, and X is a rare recessive trait in people and has been identified in cats, sheep, and recently in Labrador retrievers (Table 86.1; OMIM 277450 and 607473).[15,20,22] Clinical signs range from moderate to severe coagulopathy, with reports of spontaneous hematoma formation, prolonged hemorrhage after surgery, and some fatal hemorrhage.

Combined deficiency of the vitamin K-dependent factors causes prolongation of the aPTT and PT (and PIVKA) screening tests, but does not affect TCT and fibrinogen. Specific coagulation factor assays confirm deficiencies of FII, VII, IX, X, with normal activities of

the non-vitamin K-dependent factors. Acquired vitamin K-deficiency is common (see Chapter 85); therefore initial diagnostic work-up should rule out exposure to vitamin K antagonists, and liver disease or malabsorptive disorders. After exclusion of acquired disorders, specific analyses of hepatic microsomal vitamin K epoxide reductase (VKOR) and carboxylase enzyme activities further define a hereditary trait.

Patients with severe hemorrhage at presentation may require transfusion for rapid replacement of active factors (see Chapter 96). After an initial lag-time of 1–2 days, case reports describe normalization of aPTT and PT and control of clinical signs of hemorrhage in response to oral vitamin K_1 at approximately 2.5 mg/kg per day. Long-term maintenance of hemostasis has been reported at reduced daily dosages (e.g. 1 mg/kg/day) given at 3 day intervals.

Familial studies to date in all species reveal a recessive inheritance and expression pattern. The defective hepatic enzyme in cats and sheep is γ-glutamyl carboxylase; however, causative mutations in the corresponding genes have not yet been identified.

Unrecognized Factor Deficiencies

Hereditary deficiencies of FV, FXIII, and antiplasmin have been reported as rare hemorrhagic defects in people, with an estimated case incidence of <1 per million (OMIM 612309; 134570; 262850). The traits are autosomal recessive and cause clinically severe bleeding diatheses. Factor V deficiency causes prolongation of the aPTT and PT screening tests; however, identification of FXIII and antiplasmin deficiencies requires specific functional analyses of the corresponding proteins. While not yet recognized in animals, these defects should be included in the differential for severe hereditary coagulopathy after ruling out more common disorders.

Acronyms and Abbreviations

ADP, adenosine diphosphate; APC, activated protein C; aPTT, activated partial thromboplastin time; AT, antithrombin; ATE, aortic thromboembolism; CM, cardiomyopathy; COX, cyclo-oxygenase; CP, cancer procoagulant; CT, computerized tomography; DVT, deep vein thrombosis; ETP, endogenous thrombin potential; HAC, hyperadrenocorticism; HCM, hypertrophic cardiomyopathy; IMHA, immune-mediated hemolytic anemia; NO, nitric oxide; MPC, mean platelet component concentration; MPCDW, mean platelet component distribution width; PAF, platelet activating factor; PAI-1, plasminogen activator inhibitor-1; PGI_2, prostacyclin; PLE, protein-losing enteropathy; PLN, protein-losing nephropathy; PT, prothrombin time; PTE, pulmonary thromboembolism; TAT, thrombin-antithrombin complex; TE, thromboembolism; TEG, thromboelastography; TF, tissue factor; TFPI, tissue factor pathway inhibitor; TNF, tumor necrosis factor; TxA_2, thromboxane A_2; VEGF, vascular endothelial growth factor; VWF, von Willebrand factor.

Thrombosis is the partial or complete obstruction of a blood vessel by a thrombus, or blood clot. The term thromboembolism (TE) refers collectively to obstruction from local thrombus formation (primary thrombosis) or translocation from a distant site (embolism). These events are difficult to differentiate clinically and produce indistinguishable pathophysiologic consequences. In addition to mechanical obstruction, thrombi release humoral factors and stimulate neurogenic reflexes. The signs of TE range from clinically inapparent events to organ failure and death, depending on the site and extent of vascular occlusion, collateral circulation, and the compensatory reserves of affected organs.

In spite of growing veterinary awareness, current TE management guidelines are based on incomplete information. Most recommendations are extrapolated from human trials, experimental models, and results of small veterinary studies, case series, and anecdotal reports.

PATHOPHYSIOLOGY

Virchow's triad describes three major factors promoting TE: endothelial injury, blood flow abnormalities (turbulence or stasis), and hypercoagulability.[5] A single factor may predominate (Table 87.1); however, combined

abnormalities act synergistically to overcome hemostatic balance in most diseases. New models of cell-based hemostasis (see Chapter 84) and vascular bed-specific hemostasis[54] describe the complex interplay among cellular and plasma factors in various thrombotic syndromes.

In contrast to physiologic hemostasis where net forces favor blood flow, hypercoagulability refers to an imbalanced, prothrombotic state.[3,7] This imbalance can be mediated by platelet hyper-reactivity, excessive activation of coagulation, deficiencies of natural anticoagulants, and/or hypofibrinolysis (Table 87.1).

Platelet hyper-reactivity results from increased platelet agonist activity or decreased agonist modulation (see Section VI). Factors that promote platelet activation include direct stimulation by inflammatory cytokines and tumor cells, cytokine or cell-mediated release of platelet agonists, and hypoalbuminemia-mediated upregulation of thromboxane A_2 (TxA_2).[14,41] Platelet inhibition is attenuated by endothelial damage which decreases availability of prostacyclin (PGI_2), nitrous oxide (NO), and ADPase. Antiplatelet drugs may influence cyclo-oxygenase (COX) and membrane receptor activity.[46]

Excessive activation of coagulation generally results from increased expression and/or exposure of tissue factor (TF) (see Chapter 88). Endotoxin and inflammatory cytokines, particularly interleukin-6 (IL-6), induce TF expression on endothelial cells, macrophages, and cell-derived microparticles, and endothelial cell disruption exposes extravascular TF to the vascular space.[36] Some malignant cell-types express TF constitutively, and some produce a protease, cancer procoagulant (CP), that directly activates factor X.[7]

Lack of the physiologic anticoagulants antithrombin (AT), protein C, and tissue factor pathway inhibitor (TFPI) cause or contribute to hypercoagulability. Although numerous hereditary anticoagulant deficiency syndromes (thrombophilias) are recognized in people,[3,10] anticoagulant deficiencies in animals are acquired disorders. Acquired AT deficiency is recognized as a consequence of decreased hepatic synthesis, increased loss, or excess consumption. Hepatic failure rarely leads to thrombosis because concomitant coagulation factor deficiencies favor hemorrhage.[3,71] In contrast, increased glomerular permeability in protein-losing nephropathies (PLNs) permits selective loss of low molecular weight plasma proteins, such as albumin and AT, thereby producing a hypercoagulable state.[9,59] Pathologic AT consumption occurs in conditions of increased thrombin generation, such as disseminated intravascular coagulation (DIC) or massive TE. Drugs (e.g. l-asparaginase and estrogen) are also associated with low plasma AT.[30]

Protein C has a major anticoagulant effect at the endothelial cell surface and also modulates inflammation and endothelial cell apopotosis.[16] A mutation in the human factor V gene (Factor V_{Leiden}) renders the protein resistant to activated protein C (APC) inhibition.[3,10] This mutation is among the most common hereditary risk factors for deep vein thrombosis (DVT) in people of West European ancestry; however, a comparable syndrome has not been identified in animals. Acquired protein C deficiencies develop in association with sepsis, malignancy, hepatic or cardiac failure, pancreatitis, DIC, colic, laminitis and postoperatively.[2,12,16,65] Low protein C activity appears to be a biomarker of hepatic synthetic capacity and portosystemic shunting in dogs, albeit with no observed increase in TE.[67] In contrast, recurrent TE developed in a foal with primary protein C deficiency.[15]

Tissue factor pathway inhibitor, synthesized by endothelial cells and platelets, regulates initiation of coagulation by inhibiting the factor VIIa-TF complex. Acquired TFPI deficiency has been related to hypercholesterolemia, and may represent a risk factor for arterial and venous TE.[3]

Hypofibrinolysis, primarily mediated by upregulation of plasminogen activator inhibitor (PAI-1) has also been implicated in the pathogenesis of hypercoagulability.[3,10,25] As an acute phase protein, PAI-1 levels increase in association with inflammation and PAI-1 complexed with subendothelial fibronectin has inhibitory action on APC generation. High PAI-1 concentration has been associated with increased TE risk in people with atherosclerosis, sepsis, diabetes mellitus, post-trauma and surgery.[25] Although fibrinolytic defects

TABLE 87.1 Virchow's Triad Categorization of Prothrombotic Forces

Virchow's Triad Criteria	Forces
Vascular injury	Trauma Catheterization Inflammation Neoplastic invasion Parasitic damage Plaque deposition, atherosclerosis, amyloidosis
Stasis or turbulent flow	Hypoperfusion, hypovolemia, cardiac insufficiency, distributive Blood vessel compression Immobility Hyperviscosity, dehydration, polycythemia, leukemia, hyperglobulinemia, hyperfibrinogenemia Decreased RBC deformability, spherocytosis
Hypercoagulability	Platelet hyperaggregability, increased activation, decreased negative modulation Excessive activation of coagulation Decreased natural anticoagulant activity, antithrombin deficiency, (activated) protein C deficiency, TFPI deficiency[a] Hypofibrinolysis, decreased plasminogen activators, increased plasminogen activator inhibitors

[a]TFPI, tissue factor pathway inhibitor.

are relatively ill-defined in animals, hypoplasminogenemia has been reported in traumatized dogs and in horses with strangulating obstructions,[43,52] and increased PAI-1 and α2-antiplasmin activities have been reported in septic foals.[2]

The concept of vascular-bed-specific hemostasis explains the observed variability in sites of TE in patients with systemic hypercoagulability.[54] This model refers to the uneven expression and local regulation of endothelial cell-derived prothrombotic and antithrombotic activities. Regional vascular beds, therefore, are nonuniformly affected by hypercoagulability in different disease syndromes, which in turn produces a variable tissue distribution of thrombus formation.

THROMBOTIC DISORDERS

Thromboembolic disease, traditionally classified as arterial or venous based on vessel of origin, is the leading cause of death in industrialized societies.[1,3,71] Arterial TE is seen primarily in people with atherosclerosis, and manifests as acute coronary syndromes (myocardial infarction, angina) or cerebrovascular dysfunction (stroke, transient ischemic attack). Venous TE occurs secondary to congenital or systemic disease, and predominantly affects the deep veins in the extremities (DVT) and pulmonary vasculature (pulmonary thromboembolism; PTE).[64,71] In contrast, animal TE typically involves venous and/or arterial vessels with lower frequency than human TE.

Canine Thrombosis

Necropsy studies, case series, and case reports describe numerous conditions in dogs associated with TE.[8,26,34,50,69,70] The most commonly reported include PLN, neoplasia, immune-mediated hemolytic anemia (IMHA), necrotizing pancreatitis, hyperadrenocorticism (HAC), and corticosteroid therapy (Table 87.2). Approximately 60% of PTE cases in retrospective studies have multiple predisposing conditions, suggesting a cumulative risk of TE. Canine thrombotic syndromes typically cause arterial and venous TE, with multi-organ involvement. Notable exceptions include TE restricted to the arterial vasculature in dogs with atherosclerosis[27,69] and the propensity for PTE in dogs with IMHA.[8,34,51]

Feline Thrombosis

Although overall TE frequency appears lower, feline thrombotic disorders are similar to those of dogs and people (Table 87.3).[35,49,55,57] Aortic TE secondary to cardiomyopathy is by far the most common feline thrombotic syndrome (described in more detail below). Venous TE, albeit rare, has been reported in cats with neoplasia, cardiac disease, and complex, multisystemic disease.

TABLE 87.2 Canine Thrombotic Syndromes

	Sites of thromboembolism

Equine Thrombosis

Vascular injury is a defined (or presumptive) cause of equine large and small vessel thrombosis (Table 87.4). Jugular vein catheter thrombosis and thrombophlebitis are relatively common, and reported risk factors include endotoxemia, hypoproteinemia, salmonellosis, and anti-diarrheal and anti-ulcer therapy.[13] Parasite-induced intestinal vasculopathy and secondary TE are considered causes of acute and chronic colic, although the true incidence of this syndrome is not well-defined. Similarly, distal limb thrombosis in foals and aortic and iliac TE, manifested as hind limb lameness, are presumed sequelae of parasitic endovascular migration. Distal limb thrombosis has also been reported secondary to sepsis and gastrointestinal inflammation. Horses are susceptible to infectious agents causing small vessel TE, including panarteritis due to equine viral arteritis and mycotic vasculitis due to disseminated aspergillosis (see Chapter 89). Equine hypercoagulability syndromes, characterized by multiorgan TE, have also been reported. Severe gastrointestinal disease and resultant endotoxemia are

often associated with renal microvascular TE. Microvascular thrombosis in the dermal lamina may play a role in the etiopathogenesis of carbohydrate-induced laminitis. As in dogs and cats, PTE is likely underrecognized in horses and its incidence rate is unknown. In a small case series, endotoxemia-induced hypercoagulability was considered an underlying cause of equine PTE, and previous case reports describe toxin-induced hemolysis and pneumonia as primary disorders in horses with PTE.[48] Cardiac disease is a relatively uncommon cause of TE in horses.

Hypercoagulable Syndromes

Protein-losing Nephropathy

Nephrotic syndrome is a well-recognized hypercoagulable state, with reported systemic thrombosis rates of 40% in people.[59] Molecular markers of thrombin activation and platelet aggregation increase with even modest urinary protein loss. Hypoalbuminemia (i.e. serum albumin concentration below 2.0 g/dL) provides a surrogate measure for TE risk.[42] Protein-losing nephropathy is commonly associated with venous and arterial TE in dogs.[9,22–24,26,34,50,70] In one study, TE was documented in 26% of dogs with PLN that died or were euthanized;[9] however, relative TE risks have not been defined for specific renal disorders.

Urinary AT loss plays a major role in mediating the hypercoagulability of PLN.[23] Human patients experience thrombotic complications when plasma AT falls below 50–70%.[59] Concomitant hyperfibrinogenemia, hypercholesterolemia, high factor VIII, and hypofibrinolysis (due to high PAI-1) are believed to contribute to TE risk. Hypoalbuminemia is associated with enhanced platelet aggregability in dogs and people, and platelet reactivity correlates with proteinuria in people.[23,59] Volume depletion, venous stasis, and immune complex activation may also promote TE secondary to PLN.

Neoplasia

Thrombosis accounts for significant morbidity and mortality in human and veterinary cancer patients, with high incidence associated with some tumor types, e.g. acute leukemias and solid tumors.[7,22,33,34,49,53] Multiple mechanisms promote TE, including release of procoagulant substances and inflammatory cytokines by malignant cells, and direct interaction among tumor cells, endothelial cells, platelets, and monocytes (see Chapter 88).[7,14] Human and animal tumor tissues demonstrate constitutive TF expression and release of cancer procoagulant (CP). Acquired APC resistance and anticoagulant deficiencies further exacerbate prothrombotic forces in some neoplastic disorders. Nonspecific contributory factors include vascular invasion by tumor cells, immobility, venous catheterization, corticosteroid therapy, surgery and chemotherapy.[14]

Enhanced or impaired fibrinolysis may develop secondary to neoplasia, with resultant signs of hemorrhage or thrombosis. The balance between plasminogen activators and their inhibitors may also play a role in tumor metastasis. Tumor cell production of the proinflammatory cytokines tumor necrosis factor (TNF) and interleukin-1β induce endothelial cell TF and PAI-1 expression, and downregulate the expression of thrombomodulin. Tumor cells also release vascular endothelial growth factor (VEGF), which induces macrophage expression of TF, increases microvascular permeability, and promotes tumor angiogenesis. Tumor cells, cell extracts, and membrane fragments promote platelet aggregation *in vitro*, and tumor cell injections cause in vivo platelet aggregation in experimental animals.[7,14]

Immune-mediated Hemolytic Anemia

Venous TE is a major cause of canine IMHA mortality, with reported incidence at necropsy ranging from 30% to 80%.[8,39,58] Hyperbilirubinemia, hypoalbuminemia, and severe thrombocytopenia are consistently associated with TE; however, other factors such as transfusion have shown variable association across studies. Laboratory evidence of hypercoagulability is well documented in IMHA case series; the most common abnormalities include hyperfibrinogenemia, high plasma D-dimer concentration, and low AT.[58] Although inflammatory mediators likely activate coagulation,[36] the pathogenesis of IMHA-associated TE is not fully elucidated. Proposed mechanisms include hemolysis mediated platelet hyper-reactivity and the presence of antiphospholipid antibodies.[58,72]

Acute Pancreatic Necrosis

Thrombosis, correlated with disease severity, is common in people with acute pancreatitis.[28] Pancreatitis is also among the diseases associated with venous and arterial TE in dogs, and venous TE in cats.[34,53,57,69,70] Experimental studies of pancreatitis in animals demonstrate platelet hyperaggregability, hyperfibrinogenemia, increased PAI-1 activity, and decreased t-PA activity.[18] Pathogenic mechanisms of hypercoagulability include the release of TF and inflammatory cytokines from damaged pancreatic tissue.[28,44] Pancreatitis also induces phospholipase A_2, thereby increasing platelet activating factor (PAF) and the production of cytokines (e.g. IL-1, IL-6, and TNF). Platelet reactivity may be further enhanced by high plasma free fatty acids and hypoalbuminemia, which inhibit synthesis of PGI_2 and promote TxA_2 release, respectively.

Hypercortisolism

Hyperadrenocorticism and corticosteroid therapy are considered risk factors for TE in dogs.[6,34,69,70] Although systemic hypertension correlates with TE risk for people with Cushing's disease, the pathogenesis of TE in animals with hypercortisolism remains ill-defined, and a relationship between TE and dose or duration of corticosteroid therapy has not been established. Defining pathogenesis is difficult because Cushing's disease or steroid therapy are common in patients having other

potentially prothrombotic conditions, such as PLN, pancreatitis, diabetes mellitus, neoplasia, and IMHA. Postulated mechanisms for steroid-mediated hypercoagulability include hypercholesterolemia, hypofibrinolysis (due to increased PAI-1 and α-2 antiplasmin), hyperfibrinogenemia, and high coagulation factors.[17,30]

Cardiac Disease

Infective endocarditis and heartworm disease are the most common cardiac disorders associated with TE in dogs.[26,34,63] These disorders disrupt the endothelium and alter rheology, thereby promoting thrombus formation. In addition, exaggerated platelet aggregation and secretion response have been demonstrated in heartworm infected dogs.[4] Although overt TE is rarely reported in dogs with congestive heart failure or valvular disorders, plasma indices of hypercoagulabilty (i.e. hyperfibrinogenemia, high thrombin-antithrombin complex (TAT) concentrations, and low AT and APC activities) have been described in dogs with cardiac disease.[65]

Cardiomyopathy (CM), particularly hypertrophic CM (HCM), is the most common cause of arterial TE in cats. Reported incidence rates of TE secondary to CM range from 12% to 50%.[55,60] Thrombus formation typically occurs in the left atrium leading to aortic TE (ATE).[35,55,60] Cats with left atrial enlargement and/or echocardiographic "swirling" of blood are considered more likely to develop TE; however, relative risks associated with these findings are not defined. The pathogenesis of cardiomyopathy-induced TE is likely multifactorial. Possibilities include endothelial disruption, blood turbulence or stasis, platelet hyper-reactivity, and endothelial dysfunction secondary to metabolic imbalance.[40,60] Hemostatic abnormalities indicative of systemic hypercoagulabilty, including high TAT and D-dimer concentration have recently been reported in case series of HCM cats with and without TE.[62]

Atherosclerosis

Myocardial infarction and other arterial TE are well-recognized consequences of atherosclerosis in people. Although relatively uncommon in animals, atherosclerosis associated with aortic and cerebrovascular TE has been reported in hypothyroid dogs.[27,69] Mechanisms promoting TE include endothelial disruption by atherosclerotic plaques, hypercholesterolemia, and a prothrombotic lipoprotein profile (see Chapter 89).

Sepsis

Sepsis and the systemic inflammatory response syndrome (SIRS) are common triggers of microvascular thrombosis and DIC; however, macrothrombus formation with venous and arterial TE have also been reported in animals with inflammatory syndromes.[11,52,57,69,70] The pathogenesis of thrombosis in these disorders is complex, mediated by inflammatory cytokines, hemostatic proteins, leukocytes, platelets, and endothelial cells (see Chapter 88).[36]

Diabetes Mellitus

Thromboembolic disease is an uncommon complication of diabetes mellitus in dogs, and most cases have concomitant conditions that might exacerbate or induce a thrombotic tendency.[24,50,69] Platelet hyper-reactivity and refractoriness to inhibition are believed to play a role in diabetes-associated TE.[46] Loss of insulin's modulating effects on platelet activation and decreased endothelial synthesis of PGI_2 and NO combine to potentiate platelet response. Hyperglycemia also correlates with increased plasma PAI-1, resulting in decreased fibrinolysis.

LABORATORY TESTS OF HYPERCOAGULABILITY

The complex pathogenesis of hypercoagulability and its associated disease states complicates laboratory diagnosis of TE. Testing strategies include assays designed to measure "global" or net hemostatic forces and scoring systems based on routine tests and clinical parameters (see Chapter 88). The diagnostic utility of new and traditional tests is based on relating test results with clinical outcomes.

Coagulation Profile

The routine coagulogram (activated partial thromboplastin time [aPTT], prothrombin time [PT], and fibrinogen) screens for risk of hemorrhage due to coagulation factor deficiency (see Chapter 138). Although variable shortening or prolongation of aPTT and PT are often found in patients with TE, these changes are nonspecific and rarely aid in diagnosis or management. Hyperfibrinogenemia, however, is an independent risk factor for TE in people[71] and is a common finding in canine IMHA, feline CM, and sepsis.[2,52,58,62] The predictive value of fibrinogen determinations for animal TE has yet to be established.

Antithrombin

Antithrombin activity relates to TE risk in conditions such as PLN, where AT deficiency plays a major role in pathogenesis of hypercoagulability.[9] While risk of TE has been attributed to AT values below 60%,[23] there is little empiric data in animals at this time to define a specific AT threshold.

D-Dimer

D-Dimer is a distinct fibrin degradation product formed by plasmin proteolysis of cross-linked fibrin (see Chapter 138). Quantitative D-dimer assays are sensitive (but nonspecific) tests with proven diagnostic utility for ruling out PTE, and for predicting mortality in human thrombotic syndromes.[61,64] D-dimer assays are now used for screening animals, with studies in progress to better define their clinical utility (see Chapter 88).[47,62,65]

Thrombin-Antithrombin Complex

Free thrombin in plasma is neutralized by the formation of an irreversible, 1:1 complex with the anticoagulant protein, AT. The plasma concentration of the resultant thrombin-antithrombin complex (TAT) is an indirect measure of in vivo thrombin generation. The finding of high TAT is evidence of an active hypercoagulable state and TAT analyses have been used recently to characterize thrombotic syndromes in dogs, cats, and horses (see Chapter 88).[62,65]

Thrombin Generating Potential

The endogenous thrombin potential (ETP) is a new assay technique to directly measure the in vitro capacity of plasma to generate thrombin over time. The ETP is considered a "global test" whose parameters reflect the net effect of coagulation pathway activators and inhibitors. Studies of the diagnostic utility of ETP for various thrombotic syndromes in people are currently underway.[68]

Thromboelastography

Thromboelastography (TEG) measures the viscoelastic properties of a nascent fibrin clot in whole blood.[20] The point-of-care test generates qualitative tracings and numeric values depicting clot strength and stability, and the dynamics of clot formation and breakdown (Fig. 87.1). Thromboelastography has been used in human patients to test for hypo- and hypercoagulability, to monitor anticoagulant effects, to guide transfusion therapy, and to predict postoperative TE. Thromboelastographic features of hypercoagulability have been described in dogs with neoplasia, DIC, IMHA, parvoviral enteritis, and following deracoxib therapy.[32,43,73] Evaluation of the TEG and other viscoelastic monitors for clinical management of thrombotic syndromes in animals is currently underway.[11]

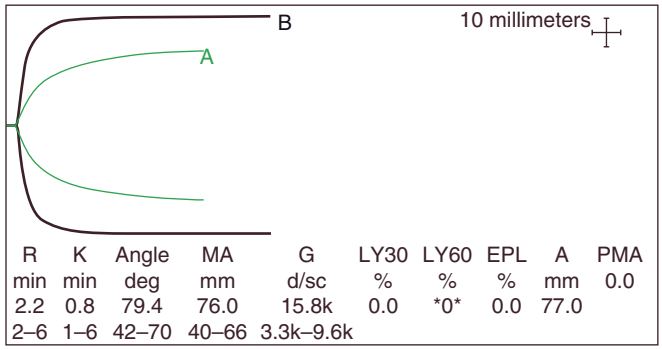

FIGURE 87.1 Tissue-factor activated TEG of a healthy dog and a dog with hyperadrenocorticism. (**A**) Healthy dog demonstrating normal TEG tracing. (**B**) Dog with hyperadrenocorticism demonstrating parameters of hypercoagulability: shortened clot formation time (K), increased angle (α), maximum amplitude (MA) and clot elasticity (G) values.

Platelet Function Analyses

Laboratory assessment of platelet function is complex, including measurements of platelet size, ability to aggregate, and expression of various activation markers. (see Chapter 142).

Platelet Aggregometry

Measurement of platelet aggregation response to agonists (e.g. ADP, collagen) is the traditional gold standard of in vitro platelet function testing.[41] While aggregometry has proven utility in the diagnosis of platelet "hyporeactivity" in people and animals, aggregation studies are generally not useful for clinical characterization of TE, and have limited research applications in gauging response to anti-platelet agents.

Flow Cytometry

Flow cytometry enables the detection of specific aspects of platelet function, including platelet size, granularity, expression of activation markers and presence of bound fibrinogen.[45,72] Exposure of P-selectin (an alpha granule protein) on the platelet outer membrane surface is an indicator of platelet degranulation and marker of platelet activation (see Chapter 137). High platelet P-selectin expression has been demonstrated in clinical studies of dogs with inflammatory disease and IMHA.[45,72]

Automated Platelet-sizing Parameters

Automated hematology analyzers measure several parameters of platelet function.[37,45] Mean platelet component concentration (MPC) is a measure of refractive index, which is linearly related to platelet density. Activated (i.e. degranulated) platelets have relatively low density compared to non-degranulated platelets. Mean platelet component distribution width (MPCDW) measures the uniformity in activation status. Mean platelet component correlated with P-selectin expression in dogs with inflammatory disease;[45] however, additional studies are needed to clarify diagnostic utility of MPC for TE.

CLINICAL DIAGNOSIS OF THROMBOSIS

Pulmonary Thromboembolism

The diagnosis of PTE is challenging because clinical signs mimic other conditions (e.g. pneumonia, cardiac disease), results of routine tests are often nonspecific, and definitive tests are invasive, expensive, and/or not widely available. An index of suspicion is critical; PTE should be considered for any patient with an acute onset of respiratory signs, particularly in the presence of underlying hypercoagulable states.

Initial Assessment

Clinical signs of PTE reflect the magnitude of respiratory and cardiac compromise.[34,48,49,64] Common signs

include acute dyspnea, tachypnea, and depression. Severe signs range from cough, hemoptysis, and cyanosis, to collapse, shock, and sudden death. Thoracic auscultation may reveal tachycardia, split heart sounds, and adventitious lung sounds. Patients in left heart failure have signs of hypoperfusion.

Diagnostic evaluation should include thoracic radiographs, arterial blood gas analyses, and routine hemogram and biochemistry profiles. Common radiographic abnormalities include pulmonary infiltrates (alveolar, interstitial, or mixed pattern) with indistinct borders in the right and caudal lobes.[19,26] Some cases have lobar radio-opacities and wedge-shaped densities with the apex toward the pulmonary hilus. Radiolucent vascular filling defects distal to the thrombotic occlusion are best visualized on ventrodorsal or dorsoventral views. (Fig. 87.2). Main pulmonary artery segment enlargement, attenuation of lobar vessels, generalized cardiomegaly, and pleural effusion may also occur.[19,34] Disproportionately severe respiratory signs with mild radiographic abnormalities are suggestive of PTE.

Arterial blood gas analyses, although non-pathognomonic, provide diagnostic and management information.[26,34,64] An increased alveolar-arterial oxygen tension gradient (A-a gradient) reflects ventilation-perfusion (V/Q) mismatch and is almost invariably present, whereas hypoxemia occurs in approximately 80% of dogs. Hypoxemia reflects the severity of vascular occlusion and usually responds to supplemental oxygen. Diminished oxygen response occurs with extreme V/Q mismatch and intrapulmonary shunting. Hypercapnia may occur with severe compromise.

Abnormal hemogram and biochemistry profiles generally reflect inflammation, hypoxemia, or stress. Test results may suggest additional work-up to identify hypercoagulable states. Hyperfibrinogenemia, low AT and TEG parameters consistent with hypercoagulability further support the presence of PTE and should prompt investigation for underlying disorders (Tables 87.1, 87.2, 87.3, 87.4).

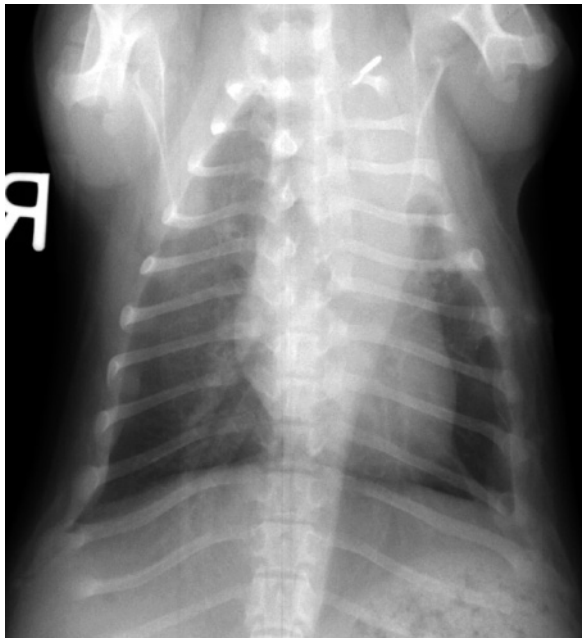

FIGURE 87.2 Ventro-dorsal survey thoracic radiograph of a dog with PTE. Note oligemia of the right caudal lung fields.

Ancillary and Definitive Diagnostic Tests

D-Dimer is used as an exclusionary test of PTE in people; low pretest PTE probability and low D-dimer values obviate the need for imaging studies.[61,64] Although test algorithms have not yet been validated for animals, case series have generally shown high sensitivity (80–90%) for D-dimer assays in veterinary patients with PTE and other thrombotic disorders.[47,62] High D-dimer is also found in animals with neoplasia, hepatic disease, renal or cardiac failure, internal hemorrhage, and after surgical procedures. Specificity for TE increases with markedly elevated D-dimer values (i.e. >1,000 ng/mL).[47]

Echocardiography is a valuable diagnostic tool for PTE in people, and is a rapid and non-invasive means to rule out primary cardiac disease in dyspneic patients.[21,64] Abnormalities typical of human PTE include right ventricular dilation and hypokinesis, pulmonary arterial hypertension, tricuspid regurgitation, and paradoxic septal wall motion. Regional hypokinesis sparing the ventricular apex (McConnell sign) is a specific finding.[38] Reported PTE-associated echocardiographic abnormalities in animals include dilation of the right atrium, ventricle, and pulmonary artery, pulmonary hypertension, paradoxic septal wall motion, and visualization of a thrombus.[29,33,49]

Pulmonary angiography, scintigraphy, and helical computerized tomography (CT) are definitive tests for PTE.[31,61] Selective pulmonary angiography, performed by direct injection of iodinated dye into the pulmonary artery was the early gold standard.[61,64] Intraluminal filling defects, abrupt termination of pulmonary arteries, and complete absence of arterial branches are diagnostic for PTE. Additional supportive findings include regional loss of vascularity, asymmetric blood flow, tortuous pulmonary arteries, and abrupt tapering of peripheral vessels. A negative selective arteriogram excludes clinically significant PTE. The invasive procedure requires general anesthesia, thus constituting a safety risk for compromised patients. Nonselective pulmonary angiography, performed by injecting contrast media into the jugular vein or right side of the heart, is a simpler and safer technique that does not require general anesthesia. Nonselective angiography, however, is relatively insensitive and difficult to interpret due to dilution of contrast medium by venous blood and the superimposition of vascular structures.

Pulmonary scintigraphy is a sensitive and specific test of PTE; however, its requirement for radiolabeling and specialized equipment limit its routine veterinary use.[31] The procedure involves sequential scans that assess pulmonary blood flow (perfusion scan) and air flow (ventilation scan) to identify regions of ventilated lung lacking perfusion (i.e. V/Q mismatch). Perfusion scans are performed by injecting technetium-labeled macroaggregated albumin (^{99m}Tc-MAA) into a central vein. Distribution is proportional to blood flow; inho-

mogeneous distribution is consistent with abnormal perfusion. Perfusion scanning is contraindicated in patients with severe pulmonary hypertension because ^{99m}Tc-MAA particles can occlude capillaries and cause right-sided heart failure. A normal perfusion scan excludes PTE; however, abnormal scans can result from nonthrombotic conditions (e.g. pneumonia, edema, contusions, obstructive pulmonary disease, atalectasis). In contrast to PTE, nonthrombotic conditions are associated with decreased regional ventilation. For this reason, interpretation of abnormal perfusion scans requires assessment of pulmonary ventilation. Ventilation scans are performed by the administration of a nontoxic radioactive gas, such as technetium-labeled diethylene-tiamene-penta-acetic acid (^{99m}Tc-DTPA), via closed ventilation circuit.[31] Hypoventilated lung regions appear photopenic. While PTE disrupts regional blood flow, ventilation scans are typically normal. Severely dyspneic animals may be unable to undergo ventilation scans. In these cases, an absence of radiographic abnormalities in regions of abnormal perfusion can be considered evidence of V/Q mismatch, compatible with PTE.

Helical, or spiral, computed tomographic angiography (CTPA) has largely replaced angiography and scintigraphy for the definitive diagnosis of PTE in people.[61,64,66] This rapid, noninvasive technique enables high resolution visualization of the pulmonary vasculature. Moreover, CTPA can define nonthrombotic pulmonary disease and is ideal for unstable patients. Advanced, "multislice" CTPA techniques enable quality images in awake or minimally sedated patients. The technique is extremely accurate in detecting thrombi in the main, lobar or segmental arteries. Recent studies describe CTPA to visualize the pulmonary vasculature and detect PTE in dogs.[66]

Aortic Thromboembolism

Feline Aortic Thromboembolism

Aortic TE is a common and devastating condition in cats, with reported survival-to-discharge rates of approximately 30%.[35,55,60] The inciting cause is usually HCM, with additional cases attributed to other cardiac disease, or rarely neoplasia.[57,60] Thrombi typically form in the left ventricle with embolization to the aortic trifurcation ("saddle thrombus") causing blood flow obstruction of both hind limbs. Less frequently, emboli lodge proximal to the renal arteries, or obstruct a single iliac or brachial vessel. Acute obstruction of the left ventricle or proximal aorta may cause sudden death. The consequences of ATE include physical occlusion of the vessel and embolus-induced vasoconstriction that disrupts collateral flow. Serotonin and TxA_2 have been implicated as mediators of this intense vasoconstriction.[56] Aortic occlusion increases left ventricular afterload, which may precipitate heart failure.

The diagnosis of ATE is usually based on characteristic history and clinical signs.[60] Affected cats develop acute pain, vocalization, and loss of motor function. Physical exam may reveal swollen, tense hind limb musculature, cool extremities, pale or dark purple pads and nailbeds, and weak or absent femoral pulses. Varying sites of occlusion produce variable signs such as paresis (or paralysis), loss of sensation, or renal dysfunction or failure. At presentation many cats are dyspneic due to heart failure, with heart murmurs and/or gallop rhythms. More specific assessment of limb perfusion can be performed with color flow Doppler imaging or by cutting a nail back to the "quick" and observing the presence or absence of normal blood color and flow. Angiographic and nuclear imaging are definitive PTE tests; however, the risks of these invasive procedures are rarely justified.

Cats with suspect or confirmed ATE should undergo cardiac evaluation (i.e. echocardiography, electrocardiography, thoracic radiography). Up to 90% of cats have cardiomegaly, and 50–70% have evidence of heart failure.[35] Electrocardiographic abnormalities include left ventricular enlargement and conduction abnormalities, left anterior fascicular block, and ventricular and supraventricular premature beats. Biochemical profiles often reveal hyperglycemia and other nonspecific abnormalities reflecting muscle ischemia and stress. Uremia may develop in patients with renal vascular TE. In the absence of cardiac disease, diagnostic efforts should be directed toward identification of other potential hypercoagulable states, especially neoplasia.

Canine Aortic Thromboembolism

Although canine ATE is relatively uncommon, it has been reported in association with cardiac disease (infective endocarditis, heartworm, cardiomyopathy, and valvular disorders), PLN, PLE, neoplasia, hyperadrenocorticism, atherosclerosis, and localized vascular injury (e.g. *Spirocerca lupi*).[29,63,69]

Clinical signs depend on TE site, the extent and rapidity of occlusion, and the degree of collateral circulation.[22] Dogs with underlying cardiac disease tend to have acute onset and severe signs resembling those of ATE in cats. Hypercoagulable syndromes generally cause local thrombosis with more insidious onset. In these cases, exercise intolerance, ill-defined pain and mild locomotor deficits or ataxia may develop. Femoral pulses may be absent, weak, or asymmetric. Prognosis generally depends on the underlying condition.

Definitive diagnosis of ATE is achieved via imaging.[29,33] Abdominal ultrasonography is most commonly employed and is usually reliable, especially when combined with color flow Doppler assessment. Additional diagnostic techniques include conventional and radionuclide angiography, magnetic resonance imaging, thermography, and Doppler device to assess blood flow to the affected limbs. Since canine ATE is rarely a primary disease, the diagnosis should always prompt a thorough evaluation for underlying disorders. Biochemical profiles of affected dogs often reveal high creatinine kinase and aspartate aminotransferase; however, other biochemical abnormalities may provide more specific indication of a primary disease process.

Acronyms and Abbreviations

APC, activated protein C; aPTT, activated partial thromboplastin time; AT, antithrombin; CT, computerized tomography; DIC, disseminated intravascular coagulation; EC, endothelial cells; FDP, fibrin(ogen) degradation product; FV/FVa, factor V/activated factor V; FVII/FVIIa, factor VII/activated factor VII; FVIII/FVIIIa, factor VIII/activated factor VIII; FIX/FIXa, factor IX/activated factor IX; FX/FXa, factor X/activated factor X; FXI/FXIa, factor XI/activated factor XI; FXIII, factor XIII; IMHA, immune-mediated hemolytic anemia; ISTH, International Society of Thrombosis and Hemostasis; MP, microparticle; PAR, protease-activated receptor; PCI, protein C inhibitor; PS, phosphatidylserine; PT, prothrombin time; RBC, red blood cell; TAFI, thrombin-activatable fibrinolysis inhibitor; TAT, thrombin-antithrombin complexes; TCT, thrombin clotting time; TF, tissue factor; TFPI, tissue factor pathway inhibitor.

Disseminated intravascular coagulation (DIC) describes a complex, dynamic state of hemostatic imbalance resulting in thrombus formation throughout the microvasculature. Many different primary disorders trigger DIC, and its clinical and laboratory manifestations vary among patients and change over time, complicating its recognition and treatment.[6] Hematologists have recently developed guidelines delineating distinct phases of overt and non-overt DIC, with the goals of standardizing terminology and improving clinical diagnosis (see Table 88.1).[54,57]

The International Society of Thrombosis and Hemostasis (ISTH) has proposed a consensus definition of DIC as follows: "An acquired syndrome characterized by the intravascular activation of coagulation with loss of localization resulting from different causes. It can originate from and cause damage to the microvasculature, which if sufficiently severe, can produce organ dysfunction."[54]

PRIMARY DISEASE CONDITIONS

An underlying disease process always initiates DIC; it is not a primary disorder (see Table 88.2).

DIC has been documented in most domestic animals, with the exception of camelids. In dogs and cats, neoplasia and systemic inflammation (e.g. sepsis, pancreatitis, immune-mediated hemolytic anemia [IMHA]) are the most common initiating diseases.[13,17,46,48,49,56] Endotoxemia (secondary to gastrointestinal disorders) and sepsis are the main causes of DIC in adult horses and neonatal foals, respectively.[3,15,50] Similarly, DIC is primarily due to endotoxemia or sepsis in ruminants.[26,39]

TABLE 88.1 Characterization of Overt and Non-Overt DIC

	Overt DIC	Non-Overt DIC
Alternate names and subtypes	Uncompensated DIC Acute DIC Fulminant DIC Consumptive coagulopathy Hypocoagulable DIC	Compensated DIC Chronic DIC Subclinical DIC Pre-DIC
Pathophysiology	Decompensated hemostasis with fibrin deposition throughout the microvasculature. Platelet and factor depletion may develop	Procoagulant excess opposed by coagulation inhibitors, partial compensation modulates fibrin deposition
Clinical features	Primary inciting disease Some or all of the following: Systemic thrombosis, PTE, MODS[a] Hemorrhage from multiple sites	Primary inciting disease Subclinical or tissue thrombosis
Screening test abnormalities	Some or all of the following: Thrombocytopenia, prolonged clotting times (aPTT, PT, TCT), hypofibrinogenemia, low AT, high FDP and D-dimer	No screening test abnormalities and/or progressive fall in platelet count and increase in clotting times, high FDP and D-dimer
Tests of pre-thrombotic state	Not applicable	Byproducts of thrombin generation or thrombin activity: Prothrombin fragment 1+2, TAT complex, APC-PCI complex, Fibrinopeptide A & B Kinetics of thrombin or fibrin generation: Endogenous thrombin potential Thromboelastography

[a]MODS, multiple organ dysfunction syndrome; PTE, pulmonary thromboembolism.

PATHOGENESIS

Over the past decade, our understanding of DIC has evolved from recognition of a severe hemorrhagic disorder to appreciation of DIC as a disease continuum. The process is initiated by inappropriate activation of hemostasis, at first kept in check by natural inhibitors. If regulatory mechanisms become overwhelmed, DIC progresses to a full-blown decompensated disorder characterized by systemic thrombosis and ultimately, a consumptive coagulopathy.[6,57] Much of the current knowledge of DIC pathogenesis is derived from experimental models of sepsis-induced DIC.[31,54] Although disease-dependent differences influence the initiation and clinical course of DIC, the consistent pathogenic mechanism remains the generation of excessive thrombin through dysregulated activation of coagulation.[54] For ease of understanding, the DIC continuum can be separated into three stages: initiation, progression/dissemination, and perpetuation.[19,54,57]

Initiation

Since DIC represents normal hemostasis gone awry, the same triggering event underlies DIC and physiologic hemostasis, i.e. exposure of tissue factor (see Chapter 84).[24] Tissue factor (TF, tissue thromboplastin, factor III) is a transmembrane protein whose expression is normally restricted to interstitial perivascular fibroblasts. Under physiologic conditions, exposure of TF to its plasma ligand, factor VII (FVII), occurs only at focal sites of endothelial cell injury.[23]

In DIC triggered by massive tissue trauma, widespread endothelial injury exposes supraphysiologic amounts of extravascular TF. In conditions such as viral infections, intravascular hemolysis, and vasculitis, generalized endothelial injury exposes extravascular TF and/or induces TF expression on damaged endothelium. Inflammatory cytokines also contribute to TF expression in these latter disorders (see Table 88.2).[19]

In the absence of endothelial injury, DIC may be initiated by aberrant expression of TF on the surface of intravascular cells, particularly monocytes and tumor cells (see Table 88.2). The pathogenesis of DIC in sepsis involves up-regulation of TF expression on monocytes (and possibly endothelial cells) by proinflammatory cytokines (Fig. 88.1).[19,25]

Although cancer cells have many ways of activating hemostasis, some types of neoplasms constitutively express high levels of TF thereby promoting cancer-associated DIC.[21] TF-independent mechanisms of initiating DIC also exist (see Table 88.2). For example, proteases identified in erythrocyte membranes, tumor cells, and snake venoms can directly activate coagulation factors.[28,47,63]

The development of DIC depends not only on the location and severity of the inciting stimulus, but on the ability of naturally occurring inhibitors to regulate the procoagulant hemostatic response. In physiologic hemostasis, the TF-FVIIa-FXa complex is rapidly neu-

TABLE 88.2 Inciting Diseases and Pathophysiologic Mechanisms of DIC in Animals

Disease Categories and Specific Disorders	Potential Mechanisms
Infections Sepsis (Gram positive and negative bacteria), viruses, protozoa (*Babesia*), parasites (*Angiostrongylus*), rickettsia (Rocky Mountain spotted fever)	Cytokine-induced TF expression on monocytes (and EC) Endothelial injury Exposure of extravascular TF or induction of TF on EC
Neoplasia Solid tumors (hemangiosarcoma, mammary cancer) Hematopoietic malignancy (lymphoma, acute leukemia)	Expression of TF on cancer cells Constitutive or induced by hypoxia, cytokines, or apoptosis Induction of TF expression Tumor-secreted cytokines act on monocytes, fibroblasts, and EC Shedding of TF-bearing microparticles from tumor cells, hematopoietic cells, other cell types Expression/secretion of procoagulants Cancer procoagulant (a vitamin K-dependent cysteine protease) mucin, up-regulation of factor V receptor, factor XIII-like activity, platelet activators Chemotherapy-induced changes Tumor lysis, myelotoxicity
Inflammation/necrosis Trauma, IMHA, pancreatitis, heat stroke, hepatitis, vasculitis, gastric dilatation-volvulus, strangulating obstructions and inflammatory gastrointestinal disorders	Inflammatory cytokines EC injury Tissue injury/necrosis/apoptosis Exposure of TF; shedding of PS-enriched MPs by apoptotic cells Release of procoagulant proteases (e.g. trypsin)
Intravascular hemolysis IMHA, acute transfusion reactions, insect/snake bites	EC injury Erythrocyte procoagulant activity RBC membrane-associated elastase, shedding of PS-enriched MPs
Envenomation	Snake venom proteases Direct coagulation factor activation and fibrinogen cleavage, phospholipase-induced tissue injury/cell lysis

tralized by tissue factor pathway inhibitor (TFPI). TFPI is primarily expressed on endothelial cells, with its activity enhanced by cell-surface heparin and heparin-like glycosaminoglycans.[32] In the process of DIC, TFPI is rendered ineffective through a number of mechanisms, including cleavage of TFPI by granulocytic elastases, cytokine-mediated suppression of TFPI expression, and generation of excess TF-FVIIa that overwhelms TFPI's inhibitory capacity.[22,43]

Progression/Dissemination

Amplification of Thrombin Production

Thrombin is pivotal to DIC progression (Figs. 88.1 and 88.2). In a positive feedback cycle, trace amounts of generated thrombin are amplified by intrinsic pathway reactions to produce a massive burst of thrombin.[24,57] The thrombin burst cleaves soluble fibrinogen to form fibrin polymers, and ultimately the cross-linked fibrin clot. Thrombin simultaneously inhibits fibrin degradation via thrombin-activatable fibrinolysis inhibitor (TAFI). In early DIC, as in physiologic hemostasis, the generation of thrombin and its actions are opposed by the plasma anticoagulants, antithrombin (AT) and protein C, and the endothelial cell surface receptor, thrombomodulin (see Fig. 88.2 and Chapter 84). This phase of systemically activated coagulation restrained by natural anticoagulants is referred to as "non-overt" DIC, a state of stressed, but compensated hemostasis (Table 88.1 and Fig. 88.1).[54,55] Patients with non-overt DIC are hypercoagulable, i.e. at risk for widespread microvascular fibrin deposition.

Role of Phosphatidylserine

Coagulation is a membrane-anchored process involving assembly of coagulation factor complexes on the surface of cells expressing the negatively charged phospholipid, phosphatidylserine (PS; see Chapter 84).[24] Resting cells restrict PS to the inner leaflet of their cell membrane; however, this asymmetry is lost when cells are activated, undergo apoptosis, or lyse.[30] During physiologic hemostasis, activated platelets provide the membrane-surface PS to support formation of coagulation complexes; hence PS is referred to as "platelet factor 3" or platelet phospholipid. In the course of DIC, cell-surface PS may be expressed by a variety of activated or injured cell types, by membrane-derived microparticles (MPs), and circulating lipoproteins (native very low density lipoproteins and oxidized low density lipoproteins).[14,20,45] Microparticles are tiny (<1 μm) PS-enriched membrane vesicles liberated from the surface of activated monocytes (Fig. 88.1), platelets, injured or activated endothelial cells, apoptotic cells, and cancer cells.[20] Monocyte-derived MPs also express TF. Microparticles bring various hemostatic components into close proximity and provide a large surface area for assembly of active coagulation complexes. Due to their small size, MPs are slowly cleared from the circulation and are believed to play a role in promoting systemic thrombin formation.

Dissemination of Coagulation

As the underlying disease progresses and natural coagulation inhibitors become overwhelmed, TF expression

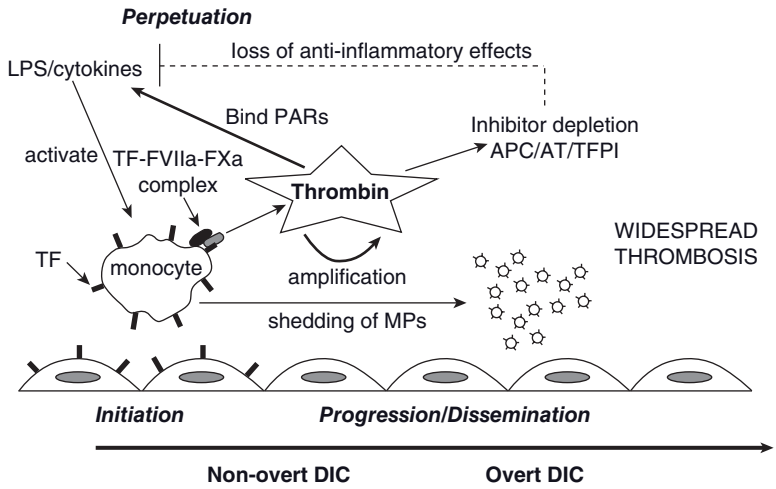

FIGURE 88.1 The DIC continuum in sepsis. Inflammatory cytokines initially induce TF expression on monocytes. Monocyte-surface TF, FVIIa, and FXa form an active complex which generates thrombin. In early, non-overt DIC, inhibitors control the activated hemostatic system. If inhibitory mechanisms become overwhelmed, then thrombin amplifies its own production, generating systemic thrombin. MPs shed from thrombin-activated cells provide a surface that supports systemic coagulation complex assembly. In the perpetuation phase, thrombin signaling through PARs activates monocytes and endothelial cells which potentiates the inflammatory response. The depletion of anti-inflammatory coagulation inhibitors further facilitates inflammation thereby maintaining the sepsis-DIC cycle.

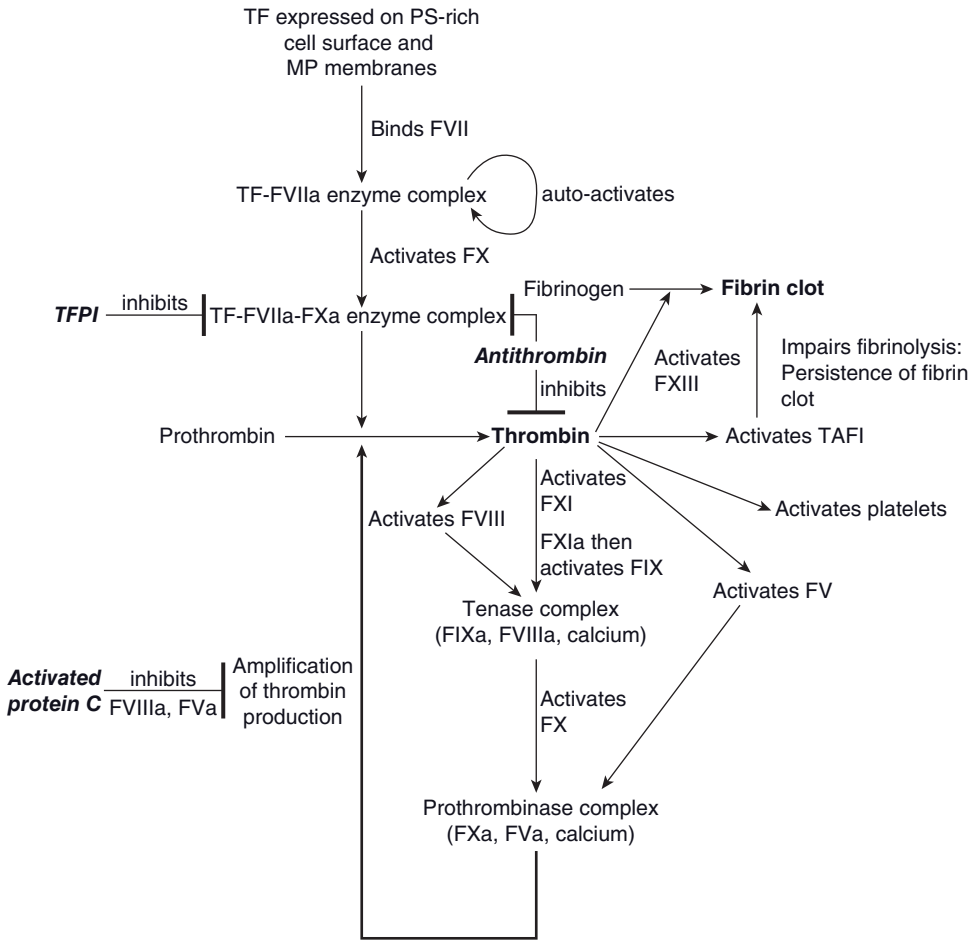

FIGURE 88.2 The pivotal role of thrombin in coagulation. Coagulation is triggered in DIC via the extrinsic pathway, when FVII binds TF, forming an autocatalytic complex. This binds to and activates FX; the TF-FVIIa-FXa complex then converts small amounts of prothrombin to thrombin. Thrombin amplifies its own production via the intrinsic pathway through FXI, which in turn activates FIX. Thrombin also activates the cofactors, FVIII and FV. Factor IXa forms a potent enzymatic ("tenase") complex with FVIIIa and calcium, which activates FX. FXa, with FVa as a cofactor and calcium ("prothrombinase" complex) generates an explosive burst of thrombin. Thrombin thus formed cleaves fibrinogen to fibrin and activates factor XIII (FXIII) (which cross-links fibrin), platelets, and TAFI. TAFI inhibits fibrinolysis, preventing clot breakdown. TFPI inhibits the TF-FVIIa-FXa complex, antithrombin inactivates thrombin and other proteases, and activated protein C inhibits FVIIIa and FVa (which decelerates thrombin generation). The entire series of enzymatic reactions occurs on the surface of PS-expressing cell or MP membranes.

TABLE 88.3 Mechanisms of Anticoagulant Deficiency in DIC

Mechanism	Primary Condition
Decreased hepatic synthesis AT, protein C, protein S	Hepatic disease, inflammatory cytokines
Decreased protein C activation	Down-regulation of thrombomodulin by inflammatory cytokines
Decreased activity TFPI, AT, protein C, protein S	Decreased free protein S (due to increased C4-binding protein, an acute phase reactant protein), down-regulation of heparin-like glycosaminoglycans on endothelial cells, cleavage of endothelial protein C receptor
Increased consumption AT, protein C	Rapid clearance of TAT and activated protein C-protein C inhibitor complexes
Loss TFPI, AT, protein C, protein S	Vascular leakage
Degradation TFPI, AT, protein C, protein S	Proteases, e.g. neutrophil elastases

persists and thrombin generation proceeds unopposed (Table 88.3).

Thrombin-mediated recruitment and activation of platelets provides additional PS-bearing surfaces to support coagulation. Tissue factor- and PS-enriched MPs help amplify and disseminate the coagulation process. The unchecked and systemic generation of thrombin produces diffuse microvascular fibrin thrombi, the hallmark of overt DIC (Table 88.1 and Fig. 88.1).

Fibrinolysis

Under conditions of physiologic hemostasis, plasmin-mediated fibrinolysis is stimulated by the release of tissue plasminogen activator from damaged endothelial cells (see Chapter 84). Fibrinolysis is also stimulated by inflammation, via activation of the contact pathway and through direct elaboration of proteases by granulocytes, neoplastic cells, and snake venoms.[10,31,36] Nevertheless, fibrinolysis is unable to maintain vascular patency in overt DIC, due in part to cytokine-induced endothelial cell secretion of plasminogen activator inhibitors, and activation of TAFI by thrombin.[9,19]

Perpetuation of DIC

Inflammatory Response

A self-perpetuating cycle develops in DIC triggered by sepsis or non-septic inflammation (Fig. 88.1).[31,57] Inflammation initiates coagulation via tissue injury, induced TF expression, and platelet and leukocyte activation and microvesiculation. Coagulation, in turn, fuels inflammation, through the proinflammatory properties of active coagulation factors (e.g. thrombin, FXa, FVIIa).[7,12,31] In addition to its central role in coagulation, thrombin binds to protease-activated receptors (PARs) on monocytes and endothelial cells, thereby stimulating cytokine secretion and adhesion molecule expression. Systemic depletion of anticoagulants results in the loss of the anti-inflammatory properties of coagulation inhibitors (particularly protein C and AT) and cell surface receptors (thrombomodulin and endothelial cell protein C receptor).[31,33,44,57] Experimental studies of TF-induced DIC indicate that in the absence of inflammation, TF alone does not sustain the positive feedback cycle.[42]

Endothelial Cell Dysfunction

Perturbed endothelial function (due to a primary disease or ensuing hypoxia) is another mechanism for perpetuating DIC.[6,31] Endothelial dysfunction causes a loss of inhibition and a gain of proinflammatory and procoagulant properties. Healthy endothelial cells secrete potent platelet inhibitors (e.g. prostacyclin) and express receptors that modulate coagulation and inflammation. Upon injury, these functions are lost and endothelial cells may secrete inflammatory cytokines and platelet activating compounds.

Other Factors

The release of vasoactive peptides (e.g. bradykinin, endothelin) from damaged or thrombin-stimulated cells induces hemodynamic changes that often decrease tissue perfusion, thereby contributing to hypoxic injury.[11,27] Ischemic and necrotic tissue injury, in turn, promotes inflammation and coagulation.[31] Secondary acidosis inhibits platelet function and coagulation factor activity, furthering development of hemorrhagic DIC.[35]

DIAGNOSIS OF DIC

Every animal with an inciting primary disease should be considered at risk for developing DIC (Table 88.2). Confirmation of DIC is challenging because animals may be examined at any point of the DIC continuum, clinical signs may be subtle or nonspecific, and individual laboratory tests are variably sensitive and specific for this syndrome. Histopathologic evidence of fibrin thrombi throughout the microvasculature in biopsy or necropsy specimens represents a "gold standard" test. Unfortunately, this test modality has low diagnostic utility because biopsy specimens are inconsistently obtained antemortem, and fibrin thrombi often lyse rapidly after death.[40,52]

Current trends in human medicine shift the emphasis toward early detection of both non-overt and overt DIC.[4,55,57] Studies of patients with sepsis reveal that antimicrobial therapy alone rarely halts progression of DIC, suggesting that improved clinical outcomes will require earlier and more directed therapeutic interventions.

The need for better strategies to diagnose early DIC is also recognized in veterinary medicine.[5,16,61]

Overt DIC

Clinical Diagnosis

Documentation of a primary initiating disease is the minimum requirement for diagnosis of DIC in all species (Table 88.2). The term overt DIC refers to an active thrombotic syndrome, with fibrin deposition throughout multiple organs (e.g. heart, lungs, liver, kidney, central nervous system). Widespread microvascular thrombosis decreases blood flow to vital tissues thereby causing hypoxic injury, cell death, and organ failure; factors ultimately responsible for the high morbidity and mortality of DIC.[5,6,15,57] Although large vessel thrombosis may be detected on physical examination, sophisticated imaging techniques such as helical computerized tomography (CT) and CT angiography are often the only means to identify medium and small vessel thrombosis and thromboembolism.[53] Since these imaging modalities are impractical for clinical veterinary practice, patients with primary inciting diseases should be monitored for the adverse effects of thrombosis on organ function, e.g. ventilation/perfusion mismatch, azotemia, hepatocellular injury or lactic acidosis. Indeed, azotemia and lactic acidosis were more severe in horses with acute colitis and laboratory criteria of DIC than those without these criteria. Furthermore, those horses in DIC were eight times more likely to die.[15] While differentiating the effects of primary disease from DIC can be difficult, signs of progressive organ dysfunction in critical care patients should be considered potential evidence of thrombosis associated with overt DIC.

A subset of overt DIC patients have a fulminant disease course characterized by signs of shock (from diffuse thrombosis and release of vasoactive peptides) and/or active hemorrhage. The bleeding diathesis often manifests as one or more of the following signs: epistaxis, petechiae, bruising, prolonged bleeding after venipuncture or minor surgical procedures, spontaneous hematoma formation and body cavity hemorrhage. Hemorrhagic DIC develops frequently in dogs, but appears to be uncommon in horses and cats.[3,15,17,50,56] Although severe signs at presentation often prompt laboratory investigation, screening tests to detect overt DIC should be performed in all patients with primary inciting disorders (Tables 88.1 and 88.2).

Laboratory Criteria of Overt DIC

Diagnosis of overt DIC relies upon identifying abnormalities in multiple tests, rather than a single pathognomonic sign or laboratory finding (Table 88.1).[6,19] Traditional criteria for diagnosis of overt DIC in animals include a combination of two or more test abnormalities, specifically thrombocytopenia, prolonged coagulation times (prothrombin time [PT], activated partial thromboplastin time [aPTT], thrombin clotting time [TCT]), hypofibrinogenemia, low AT, and high fibrin(ogen) degradation product (FDPs) or D-dimer.[3,13,15,17,48,50,56] The apparent diagnostic utility of these tests varies depending on species and stage at presentation.

Mild to moderate thrombocytopenia is a consistent finding in dogs with overt DIC (75–100% sensitivity),[5,48] but not in cats[17] or horses (0–64% sensitivity).[15,50] Overt DIC is therefore unlikely in dogs having stable platelet counts remaining within reference intervals. Of the routine coagulation screening tests, the aPTT appears to be more sensitive for detecting DIC in animals than the PT or TCT.[15,17,46,48,50] Hypofibrinogenemia is generally an insensitive indicator of DIC because fibrinogen is an acute phase reactant protein and likely to be upregulated secondary to underlying inflammatory disorders.[15,17,48,50] Indeed, the finding of normal fibrinogen values in a patient with active inflammation suggests ongoing consumption of fibrinogen in a DIC process. Low AT activity is one of the more sensitive tests for diagnosis of DIC in dogs (77–90%)[5,46,48] and horses (89–93%).[15,50] In cats with DIC, AT activities may acutely decrease; however, values rarely fall below reference intervals and may actually increase in some patients.[8,56] In most diagnostic laboratories, D-dimer assays have replaced FDP testing for detecting fibrinolysis in DIC. D-dimer is a sensitive test for DIC in dogs (75–100%)[41,46,49] but is less sensitive in horses (50%),[50] and has not been adequately evaluated in cats. Additional tests sometimes used to characterize DIC include blood smear examination for erythrocyte fragments, measurement of soluble fibrin monomer and individual coagulation factor activities (e.g. factor V).[18,48]

Scoring System for Overt DIC in Humans

The DIC subcommittee of the ISTH recently developed a practical system for consistent diagnosis of overt DIC in people.[54] The system is applied to patients with an underlying disorder associated with DIC and derives a summary score from results of four readily available laboratory tests: platelet count, PT, fibrinogen, and fibrin-related markers (soluble fibrin, FDP or D-dimer; Fig. 88.3).

These laboratory tests were deliberately chosen because they are widely available and suitable for serial monitoring and uniform comparisons among treatment trials. The ISTH also emphasized that clinical trials should include consistent and relevant outcome measures, such as decreased fatality rates, rather than relying solely on the DIC test score.[4,54] Following adoption of this recommendation, recent studies have used 28-day fatality rates as standard outcome measures to assess validity of the calculated DIC score.[4,29,58,59] Results of these studies demonstrate strong correlation between overt DIC (i.e. ISTH score ≥5) and patient mortality. Inclusion of fibrinogen in several trials did not increase prognostic power of the score. The ISTH scoring system is still undergoing validation to further refine its diagnostic utility.

Non-Overt DIC

Non-overt DIC is characterized by an activated, but not overwhelmed, hemostatic system.[19,55] Non-overt DIC

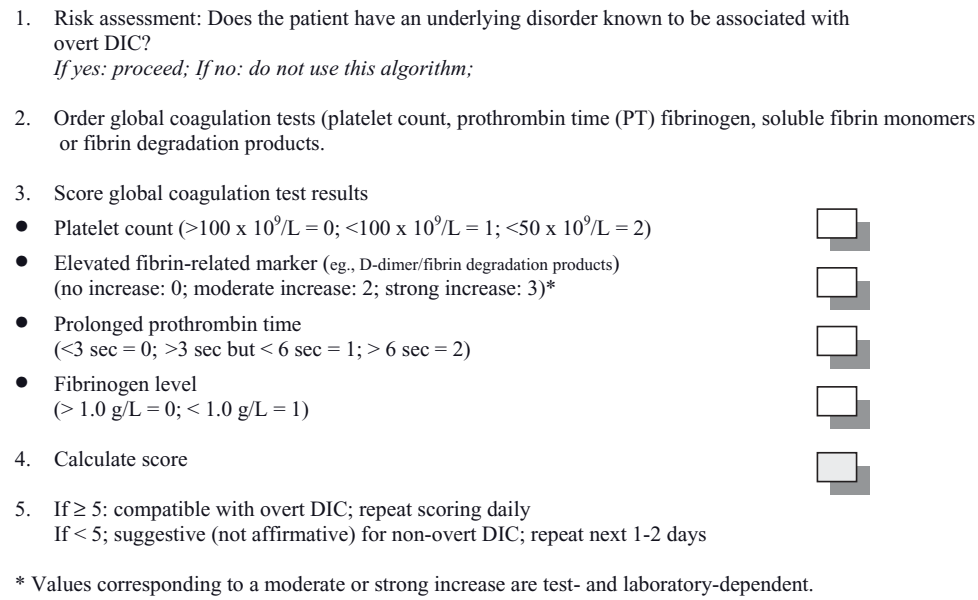

FIGURE 88.3 ISTH scoring system for overt DIC in man. (Adapted from Taylor FB, Jr., Toh CH, Hoots WK, et al. Towards definition, clinical and laboratory criteria, and a scoring system for disseminated intravascular coagulation. Thromb Haemostasis 2001;86:1327–1330, with permission.)

also applies to the clinical designation of hypercoagulability or "chronic DIC" reflecting continuous low grade, but compensated, activation of coagulation (Table 88.1 and Fig. 88.1). Routine coagulation screening tests are insensitive to this phase because they detect coagulation factor deficiencies, rather than accelerated coagulation. Technically sophisticated assays that measure the rate and byproducts of thrombin generation, coagulation inhibitor complexes, and kinetics of fibrin formation provide mechanistic and prognostic information on non-overt DIC (Table 88.1).[38,51,57] Unfortunately, these tests are not widely available for routine clinical diagnosis.

Thus, the ISTH has developed a second algorithm for the diagnosis of non-overt DIC primarily based on routine laboratory tests.[54] The scoring system requires serial testing to evaluate the dynamic nature of non-overt DIC and awards points for an underlying disease (Fig. 88.4).

The ISTH scheme for non-overt DIC has been modified and applied to critically ill dogs.[62] In a preliminary study, the sensitivity of the modified scheme for diagnosing non-overt DIC and predicting 28-day mortality rates was compared to that of traditional criteria for diagnosing DIC (i.e. three or more abnormalities in hemostatic tests). More dogs were diagnosed with DIC using traditional criteria; however, the classification of non-overt DIC was more closely related to mortality.[62] Further evaluation is needed to identify the optimum tests and test cut-offs to include in a DIC scoring scheme. Furthermore, due to species-differences in underlying diseases and diagnostic test sensitivity for DIC, it is unlikely that a single scoring system will apply across species. The strategy of serial monitoring of routine laboratory tests (e.g. platelet count, APTT, AT, D-dimer, fibrinogen) should be evaluated for clinical diagnosis of non-overt DIC. Trends toward abnormal values would indicate hemostatic system decompensation and progression of DIC, even if absolute values remain within assay reference intervals. Point-of-care "global tests of hemostasis" such as thromboelastography may also prove useful for identifying animals in hypercoagulable phases of DIC.[16,61]

Ultimately, there is a need to establish consensus guidelines for diagnosing non-overt and overt DIC in animals. This would serve as a basis for achieving consistency across studies to assess the impact of early diagnosis and various treatment protocols on defined clinical outcomes.

TREATMENT OF DIC

Affected animals should always be treated for their primary disease with the goal of breaking the DIC cycle. Supportive care aimed at alleviating metabolic/hemodynamic sequelae of DIC (shock, hypoperfusion and acidosis) helps minimize organ damage, inflammation, and continued activation of hemostasis. Effective treatment modalities beyond primary disease-specific and supportive care remain unproven. General treatment options include transfusion therapy and anticoagulant and anti-inflammatory drug therapy (see Chapters 90 and 96). Treatment recommendations are generally derived from the human literature and should be applied with the knowledge that they may not be suitable for animals, due to species-specific differences in hemostasis and drug pharmacokinetics and efficacy. Randomized, controlled clinical trials, with collaboration between multiple institutions or practices and consensus on testing criteria and a defined outcome (e.g. 28-day mortality), are urgently needed in veteri-

1. Risk assessment: Does the patient have an underlying disorder known to be associated with DIC? score

   Yes = 2, no = 0

2. Major criteria

Platelet count	>100 x 10^9/L = 0; <100 x 10^9/L = 1	+ rising = -1; stable = 0; falling = 1	
PT prolongation	<3 sec = 0; >3 sec = 1	+ falling = -1; stable = 0; rising = 1	
Soluble fibrin or FDPs*	normal = 0; raised = 1	+ falling = -1; stable = 0; rising = 1	

3. Specific criteria

Antithrombin	normal = -1; low = 1
Protein C	normal = -1; low = 1
TAT complexes	normal = -1; high = 1
Other**	normal = -1, abnormal = 1

4. Calculate score

5. If ≥ 5: compatible with non-overt DIC; repeat scoring 1-2 days
   If < 5: patient is not in DIC

* D-dimer can be used instead of soluble fibrin monomer or FDPs.
** Includes other specific markers of thrombin generation, e.g. fibrinopeptides

FIGURE 88.4 ISTH diagnostic algorithm for non-overt DIC in man. (Adapted from Taylor FB, Jr., Toh CH, Hoots WK, et al. Towards definition, clinical and laboratory criteria, and a scoring system for disseminated intravascular coagulation. Thromb Haemostasis 2001;86:1327–1330, with permission.)

nary medicine to identify safe and cost-effective DIC treatment strategies.

Replacement of Coagulation Factors and Platelets

The fear that transfusions "fuel the fire" of DIC is largely unfounded; however, transfusion therapy is generally restricted to actively bleeding patients in human studies. Component therapy, rather than whole blood, generally provides the most effective means of restoring adequate levels of factors or platelets to support hemostasis (see Chapters 96 and 97).

Anticoagulant Therapy

Although thrombosis underlies the morbidity and mortality of DIC, anticoagulant therapy, particularly heparin therapy, has not been proven to be a consistently effective therapy of overt DIC in people.[19] More specific case selection for heparin therapy may improve clinical outcomes;[34,37] however, pending new information on therapeutic efficacy, heparin should be used with caution for treating DIC in animals (see Chapter 90). Recommendations for unfractionated and low molecular weight heparin (LMWH) therapy in animals have been adopted from humans. Several recent studies have shown that currently used dosing regimes for LMWH do not attain therapeutic anti-FXa levels or are ineffective at inhibiting coagulation.[1,37]

Replacement of Inhibitors and Anti-inflammatory Therapy

Many human trials of the inhibitor concentrates, TFPI, AT and activated protein C (APC),[2,19,29,60] have been performed with the goal of preventing DIC progression. Of these, administration of AT (without concurrent heparin)[29] and APC[2,19] have shown some promise in reducing mortality in sepsis-associated DIC. Unfortunately, these concentrates are prohibitively expen-

sive, unavailable or unsuitable for use in animals.[25] With the recognition that many cases of DIC are initiated by inflammatory disorders, future studies will likely place greater emphasis on limiting inflammation in animals with DIC. It is possible that drug combinations (e.g. inhibitors with anticoagulants) or novel drugs aimed at modulating inflammation-coagulation interactions can ultimately improve clinical outcomes by breaking the DIC cycle.

Acronyms and Abbreviations

ADE, antibody dependent enhancement; AVF, arteriovenous fistula; CJPS, canine juvenile polyarteritis syndrome; DV, ductus venosus; EC, endothelial cell; EHV-1, equine herpesvirus-1; EVA, equine viral arteritis; FECV, feline enteric corona virus; FIPV, feline infectious peritonitis virus; FMD, fibromuscular dysplasia; IFN-γ, interferon-gamma; IL, interleukin; MCF, malignant catarrhal fever; PDA, persistent ductus arteriosus; SMC, smooth muscle cell; TNF-α, tumor necrosis factor-alpha.

Blood vessels contain three concentric layers: intima, media, and adventitia (Fig. 89.1). The intima is a single layer of endothelial cells (ECs) that rests on scant subendothelial connective tissue, separated from the media by the internal elastic membrane. The media is composed of smooth muscle cells (SMCs), collagen and elastin fibers, and fibroblasts. The outermost adventitia is a layer of dense fibroelastic connective tissue separated from the media of larger arteries by an external elastic membrane.

Hemodynamic stress evokes a variety of responses from all mural elements.[10,15] Vascular injury induces intimal migration and proliferation of SMCs. Smooth muscle contraction regulates regional blood flow and pressure. ECs have a myriad of functions, including the transfer of molecules across vessel walls and the modulation of blood flow, vascular resistance, hormone metabolism, SMC growth, and inflammatory and immune response. Moreover, the prothrombotic and antithrombotic properties of ECs play a critical role in regulating hemostasis.

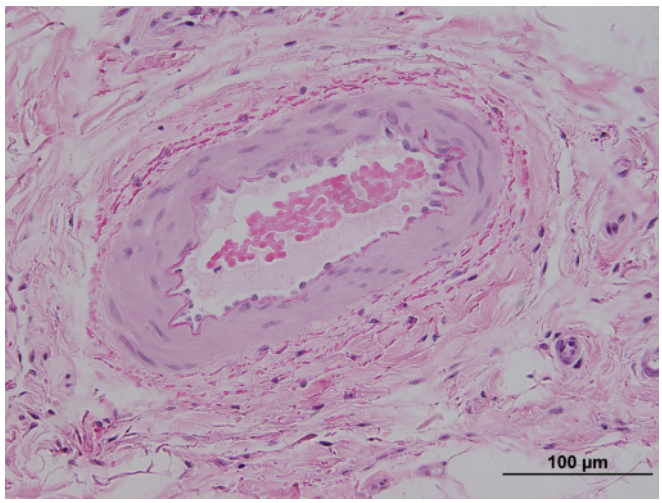

FIGURE 89.1 Cross section view of a normal muscular arteriole. A single layer of endothelial cells adjacent to the lumen is surrounded by smooth muscle cells and fibroblasts in the media, and an outermost loosely organized layer of adventitial cells. H&E stain; 40×.

CONGENITAL ANOMALIES AND MALFORMATIONS

Shunts

Persistent Ductus Arteriosus

The ductus arteriosus is the fetal vascular communication between the pulmonary artery and aorta. Hypoplasia or asymmetry of ductal SMCs and aorta-like elastic tissue in the ductus cause failure to contract properly after birth and persistence of a vascular lumen.[2] PDA occurs in all species, but is most common in dogs.

Persistent Ductus Venosus

The fetal ductus venosus (DV) allows umbilical and portal venous blood flow to bypass the liver.[32] An abrupt decrease in blood flow and pressure in the umbilical sinus shortly after birth causes retraction and narrowing of the DV orifice, resulting in functional shunt closure. Permanent closure via connective tissue deposition starts within days after birth and is complete by 15–18 days in the dog. Persistent DV may cause hepatic encephalopathy, with lobular atrophy, reduplication of the hepatic arterioles, and unapparent portal veins in the hepatic triads.

Arteriovenous Fistula

Arteriovenous fistulas (AVFs) are direct arterial-venous communications without intervening capillary beds. AVFs may be congenital defects or develop from penetrating wounds, rupture of arterial aneurysms into adjacent veins, or inflammatory necrosis of vessel walls. AVFs consist of enlarged congested vessels with disorganized arterial walls and thin walled, dilated venous channels. AVFs typically cause signs of recurrent hemorrhage; however, large AVFs may induce high output heart failure, and AVF in the CNS may cause neurologic signs and acute death.[11]

Telangiectasia

Telangiectasias are congenital or acquired exaggerations of preformed vessels. The condition is most common in the liver of cattle, characterized by increased deposition of basement membrane components and fibrosis resulting in hepatocyte atrophy and disruption of sinusoids.[13]

Varicose Veins

Varicosities, most common on the ovary and vulvar lips of horses, are dilated, tortuous veins produced by prolonged increased intraluminal pressure and loss of vessel wall support.

DEGENERATION OF ARTERIES

Atherosclerosis

Atherosclerosis is a chronic inflammatory response initiated by EC injury in the arterial wall, with progression mediated by macrophages, T-cells, SMCs, and the adjacent extracellular matrix.[34] Atherosclerosis is common in parrots and lesions occasionally develop in the coronary arteries of dogs with hypothyroidism or diabetes mellitus.[9] In early lesions, lipid-laden macrophages, T-cells, and small amounts of extracellular lipid accumulate in fatty streaks. Over time, macrophage derived IL-1 and TNF-α recruit more leukocytes, produce toxic oxygen species, and elaborate growth factors that stimulate medial SMCs to migrate to the intima, and to divide and deposit extracellular matrix. Fatty streaks may evolve into atherosclerotic plaques that protrude into the vessel lumen causing ischemic damage. Focal disruption of the plaque exposes a central necrotic mass composed of lipid, cholesterol clefts, cellular debris, foam cells, fibrin, variably organized thrombi, and other plasma proteins. These substances are highly thrombogenic, resulting in thrombosis and embolization. Atrophy of the media underlying atherosclerotic plaques may lead to aneurysmal dilation and arterial rupture.

Vascular Amyloid

Amyloid is a pathologic protein formed from precursors such as serum amyloid-associated protein, immunoglobulin light chain, and apolipoprotein A. Abnormal folding of precursors leads to the formation of oligomers and fibrils that are eventually deposited as β-pleated sheets. Histologically, amyloid is an amorphous, acellular eosinophilic extracellular deposit. Amyloid shows a characteristic apple green birefringence when stained with Congo red and examined under polarized light. Vascular amyloid deposition in the media of splenic and cardiac vessels is a common incidental finding in aged dogs, occasionally associated with EC necrosis and obliteration of the vascular lumen. Cerebral amyloid

angiopathy in cortical and leptomeningeal vessels is common in aged dogs and cats due to the deposition of β-amyloid produced by SMCs. Apolipoprotein AI-derived amyloid has been described in pulmonary vessels of old dogs, perhaps due to aberrant metabolism or mutant forms of apolipoprotein AI.

Mineralization

Uremic Gastropathy

Uremic gastropathy occurs most often in dogs with renal disease and occasionally in cats and horses. Vascular damage, presumably induced by a poorly characterized toxic peptide, results in gastric mucosal edema, congestion, and hemorrhage.[19] Medial necrosis, mineralization, and thrombosis of arterioles in the middle and deeper portions of the gastric mucosa may accompany EC injury. Despite the vasculopathy, gastric necrosis and ulceration rarely develop.

Medial Calcific Sclerosis

Medial calcific sclerosis (Monckeberg's arteriosclerosis) refers to flat plaques in the media of elastic arteries composed of calcium and phosphorus deposits. Osseous metaplasia with hematopoietic tissue in the intertrabecular spaces may develop at these sites.

Metastatic Mineralization

Metastatic mineralization, due to disturbance of calcium and phosphorus metabolism, occurs in vitamin D toxicity, secondary to chronic granulomatous diseases such as Johne's disease, and in herbivores that consume plants such as *Solanum malacoxylon* or *Cestrum diurnum* that contain 1,25-dihdroxycholecalciferol or a related compound.[16]

Arterial Ruptures

Trauma is the most common cause of arterial rupture in all species. Aortic rupture, from the level of the aortic valve to the brachiocephalic trunk, is best documented in horses[27] but the syndrome has been reported in camelids and woodchucks. Degenerative changes of the media, including cyst formation, fragmentation and mineralization of elastin fibers, and accumulation of myxomatous ground substance has been proposed as a risk factor for aortic rupture. Rapid death is usually due to hemopericardium; however, dissection into the myocardium may occur. Additional syndromes in horses include uterine artery rupture and mycotic ulceration of the internal carotid or maxillary artery. Experimental copper deficiency in pigs leads to rupture of the aorta due to deficiency of the copper-containing enzyme lysyl oxidase. Similarly, lathyrism due to β-aminopropionitrile inhibits lysyl oxidase.

Aneurysms

Aneurysms are localized abnormal dilations of a vessel. True aneurysms consist of multiple layers of the vessel wall, while false aneurysms are hematomas (surrounded by fibrous connective tissue) that communicate with the vessel lumen. Abdominal artery aneurysms are common in Holstein cattle in the northeastern United States.[12]

HYPERTROPHY OF ARTERIES

Chronic Hypoxic Pulmonary Hypertension

High-altitude disease refers to a syndrome of heart failure in cattle and pigs secondary to chronic hypoxic pulmonary hypertension. The pulmonary vasculature of cattle has distinctive, well-developed media in small arteries and veins. After initial vasoconstriction, chronic hypoxia induces medial hypertrophy of the small pulmonary arteries and a functional obstruction. Hypertrophy and dilation of the right ventricle eventually lead to right heart failure with ventral edema (brisket disease).[22] Some researchers propose that transforming growth factor-β1 mediates variation among individuals in the response to hypoxia. This growth factor, elaborated by perivascular neutrophils and mononuclear cells of small pulmonary arteries, appears to stimulate differentiation of vascular fibroblasts into myofibroblasts, a crucial step in hypoxia-induced vascular remodeling.[8]

Hypertension

Systemic Hypertension

Systemic hypertension is most often reported in dogs and cats with chronic renal failure, diabetes mellitus, hyperthyroidism, hyperadrenocorticism, and chronic anemia.[1] Systemic and local hypertension is reported in horses and cattle with laminitis. Chronic renal disease is typically associated with hyperplastic arteriosclerosis, as interlobular and intralobular renal arteries and afferent arterioles thicken due to medial hypertrophy and adventitial fibrosis. Hyaline arteriosclerosis refers to the deposition of a homogeneous, pale pink hyaline material that obscures mural elements. These vascular changes occur frequently in the nodular arterioles of the spleen of dogs and pigs, and in the uterine and ovarian arteries of pregnant and post-partum animals. Similar changes, but of unknown significance, occur in the intramural coronary arteries and small meningeal and cerebral vessels of dogs. Arteriolar hyaline degeneration is seen in the heart of pigs with vitamin E/selenium deficiency (mulberry heart disease)[21] and edema disease.

Pulmonary Hypertension

Pulmonary hypertension can either cause or result from pulmonary artery disease. Cardiac anomalies that lead to left to right shunting, hypoxic pulmonary vasoconstriction, and pulmonary thromboembolism may increase vascular resistance resulting in pulmonary arterial hypertension, whereas left-sided heart failure causes venous pulmonary hypertension and pulmonary edema. A secondary vasculitis, resulting from EC

degeneration and fibrinoid necrosis of the media, often accompanies the acute pulmonary hypertension of PDA. Chronic pulmonary hypertension leads to a spectrum of changes including isolated medial hypertrophy, medial hypertrophy with intimal thickening, and medial hypertrophy with intimal thickening and concurrent plexiform lesions (plexogenic pulmonary arteriopathy). Plexiform lesions, indicative of end-stage damage, consist of networks of small vessels spanning the lumen of thin-walled, dilated arteries.

Feline Pulmonary Artery Medial Hypertrophy

Pulmonary artery medial hypertrophy is a striking vascular lesion in cats.[23] The vascular changes, however, do not cause pulmonary hypertension or right ventricular hypertrophy. Medial changes range from mild thickening to marked hypertrophy and hyperplasia, with intimal proliferation and encroachment on the vascular lumen. Fibromuscular hyperplasia commonly develops in the adjacent pulmonary parenchyma and around alveolar ducts. The cat lungworm, *Aelurostrongylus abstrusus*, produces similar lesions, but most cats with medial hypertrophy are parasite-free.

Fibromuscular Dysplasia

Fibromuscular dysplasia (FMD) is an idiopathic, non-inflammatory, non-atherosclerotic segmental vascular wall thickening and central stenotic disease of arteries (and rarely veins).[28] Subtype classification is based on the layer of affected vessel wall, i.e. media, intima, or adventitia. Several studies in dogs have demonstrated intramyocardial coronary arterial changes similar to intimal FMD. These lesions are often clinically insignificant, but may develop secondary to pathologic conditions such as subaortic stenosis.[5] In the author's experience, segmental FMD characterized by stenosis, intimal thickening, and proliferation of SMC in coronary and atrial arteries may be associated with myocardial necrosis, fibrosis, and sudden cardiac death in dogs.

VASCULITIS

A wide variety of agents cause infectious vasculitis, including viruses, bacteria, chlamydia, rickettsia, fungi, protozoa, and helminths. These agents may directly injure ECs or act indirectly through the elaboration of toxins. Non-infectious vasculitides include hypersensitivity and drug reactions, toxins, and uremia. Although the etiology of vasculitis is often unknown, humoral and cell-mediated immunity are thought to play important roles.[3] Clinical significance varies depending on the number, size and type of affected vessels, and the presence of thrombosis, ischemia and infarction.

Vasculitis is characterized histologically by the accumulation of leukocytes within and around the vessel wall. Fibrinoid change refers to the deposition of a homogeneous or granular material composed of fibrin, immunoglobulins, complement, and platelets, with collagen and SMC degeneration. Inflammatory cells may consist primarily of neutrophils, lymphocytes, or macrophages. The presence of fragmented neutrophil nuclei is classified as leukocytoclastic vasculitis, whereas its absence is classified as nonleukocytoclastic vasculitis.

Viral Vasculitis

Equine Herpesvirus-1

Neurotropic strains of equine herpesvirus type 1 (EHV-1) cause an abrupt onset of neurological signs, often due to spinal cord lesions.[33] Grossly, hemorrhagic foci are scattered throughout the brain and spinal cord. Histologic lesions include lymphocytic infiltrates in the media and adventitia, and EC degeneration.

Canine Herpesvirus-1

Canine herpes virus-1 infection has been associated with keratitis, encephalitis, abortion, neonatal mortality, and infertility.[24] Serosanguinous pleural and peritoneal effusions are typically accompanied by petechial and ecchymotic hemorrhages scattered throughout the subserosal tissues. Small necrotic foci are found in many organs; however, inflammation and intranuclear inclusions are rare.

Malignant Catarrhal Fever

Malignant catarrhal fever (MCF) is an acute, fulminant disease of cattle, wild ruminants, and occasionally swine. A T-lymphotropic gamma herpes virus causes Wildebeest-associated MCF in exotic hoofstock, whereas ovine herpesvirus 2 causes sheep-associated MCF in cattle. Signs of MCF include generalized lymphoproliferation, vasculitis, and mucocutaneous and cutaneous ulceration. Characteristic vascular lesions consist of focal or segmental perivascular accumulation of herpesvirus infected CD8+ T-cells in many organs.[26] Fibrinoid necrosis may affect a single vascular layer or may be transmural. Although mortality rates are high, surviving cattle develop striking proliferative concentric fibrointimal plaques.

Equine Viral Arteritis

Equine viral arteritis (EVA) is caused by a non-arthropod borne enveloped positive stranded RNA virus in the order Nidovirales.[4] Panvasculitis develops in many organs, causing clinical signs of edema, congestion, hemorrhage, or abortion due to myometritis. Mild vascular changes consist of perivascular edema with EC hypertrophy and lymphocytic infiltrates, whereas severe lesions include fibrinoid necrosis with marked perivascular and vascular lymphocytic and occasional histiocytic infiltrates. Virus localizes to vascular EC, SMC and pericytes, but may be found in a variety of epithelial cell types.

Feline Infectious Peritonitis

Feline infectious peritonitis virus (FIPV) is a single-stranded, positive sense, linear RNA virus composed mainly of neucleocapsid, transmembrane, and spike proteins. FIPV evolves from feline enteric corona virus (FECV) in persistently infected cats in a multistep mutational process. FECV infection generally causes no signs, or mild enteritis. Transition of FECV to FIPV is accompanied by the acquisition of macrophage tropism due to mutations in the C-terminal domain of the spike protein. FIPV infects macrophages and efficiently disseminates when the virus complexes with antibodies against the spike protein, a process referred to as antibody dependent enhancement (ADE). Virus bound to spike protein-specific antibodies is taken up by Fc receptor-mediated endocytosis, with subsequent escape of the viral genome into the cytoplasm.[25,30] Most FIPV infected cats clear the virus, but fecal shedding may persist for several months. Cats that develop clinical signs are typically less than 2 years of age and mount an ineffective cell-mediated immune response characterized by low CD4+ T-cell counts, decreased levels of IL-12 and IFN-γ, and increased TNF-α and IL-1β.[17]

Effusive (wet) and noneffusive (dry) FIP represent extremes of a clinical continuum. Effusive vasculitis often manifests as abdominal effusion, with serosal surfaces covered by fibrin and perivascular necrosis and inflammation. Pleural and pericardial effusions are less common. Noneffusive FIP affects a variety of organs including eyes, CNS, kidneys, liver, pancreas and intestines. Microscopically, varying proportions of lymphocytes, macrophages, plasma cells and neutrophils accumulate in and around venules. Fibrin deposition correlates with severity of the vasculitis, while vascular degeneration and thrombosis lead to parenchymal necrosis. Noneffusive FIP clinically resembles lymphosarcoma, steatitis, mycotic infection and toxoplasmosis; however, histopathology provides the definitive diagnosis of FIP.

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever is caused by *Rickettsia rickettsii*, a Gram negative bacterium transmitted by regional tick vectors including *Dermacentor variablis*, *Dermacentor andersonii*, and *Amblyomma americanum*.[31] Rickettsia replicate within ECs of small blood vessels in a wide variety of mammals, but dogs most often develop disease. Clinical signs include myalgia/arthralgia, lymphadenopathy, dyspnea, conjunctivitis, edema, vomiting, diarrhea and petechial or hemorrhagic diathesis. Acute meningoencephalitis, often affecting the vestibular system, may be seen as well as inflammation of retinal vessels. Necrotizing vasculitis of small veins, capillaries and arteries is accompanied by predominantly perivascular lymphocytic infiltrates. EC necrosis and host inflammatory response lead to increased vascular permeability, edema, and multifocal hemorrhage and thrombosis.

Verminous Arteritis

Strongylus Vulgaris

Strongylus vulgaris is the most serious of the large and small strongyles that infect horses.[7] Larvae are unable to penetrate the internal elastic lamina and therefore migrate within the vascular intima. After reaching the cranial mesenteric artery, larvae undergo 3–4 months of development before molting and returning to the wall of the cecum and colon. Tortuous intimal tracks, consisting of fibrin, necrotic cellular debris, and mixed inflammatory cells are eventually covered by ECs and converted into fibroelastic thickenings. Clinical signs develop secondary to occlusive thrombi, often in the cranial mesenteric artery but also found in the aorta, renal arteries, and celiac artery. Affected vessels may develop saccular or fusiform aneurysms due to weakening of the wall. Cecal and colic artery thromboembolism, pressure on abdominal autonomic plexuses, and release of toxins from dead larvae induce colic.

Heartworm Disease

Heartworm disease caused by *Dirofilaria immitis* is common in dogs, but occurs in other mammals including domestic and wild felids, wild canids, ferrets, sea lions, muskrats, and horses. Mosquitoes of the genera *Aedes*, *Culex*, and *Anopheles* transmit infective third stage larvae that migrate through connective tissues to veins, ultimately reaching the heart 3–4 months later where they mature to adults. Adult worms reside primarily in the pulmonary arteries and right ventricle, but may extend into the right atrium and vena cava in heavy infestations. Pulmonary veins in the caudal lung lobes often develop fibromuscular intimal proliferation, resulting in pulmonary hypertension and right heart failure. Worm larvae, adults, and an intracellular bacteria *Wohlbachia*, induce eosinophilic and neutrophilic endoarteritis, and rugose myointimal proliferation in the host. Adulticide therapy may exacerbate thromboembolism, pulmonary hypertension, and induce granulomatous reactions.

Photosensitization Dermatitis

Photosensitization dermatitis occurs in animals that ingest plants containing photodynamic agents or drugs (type I), have an inherent inability to metabolize heme pigments (type II) or have liver disease that impairs excretion of phylloerythrin, a degradation product of chlorophyll (type III). Type III or hepatogenous photosensitization is associated primarily with cholestatic liver disease. Gross lesions occur in lightly colored areas of skin exposed to sunlight, with histopathologic findings of fibrinoid vascular degeneration, dermal edema, and epidermal coagulation necrosis.[14]

Immune-mediated Vasculitis

Among the various immune mechanisms causing vasculitis, antigen-antibody complexes formed in the cir-

culation (type II hypersensitivity) or locally (type III hypersensitivity) are most common. Complexes precipitate in vascular walls and bind to neutrophils via Fc or C3b receptors, thereby triggering inflammation, proinflammatory cytokine and lysosomal enzyme release, and generation of oxygen-derived free radicals. Complement cascade activation leads to neutrophil and monocyte recruitment and increased vascular permeability. Immune complex injury results in vascular wall necrosis and fibrinoid changes. Lesions may resolve as immune complexes are catabolized.

Equine Purpura Hemorrhagica

Equine purpura hemorrhagica occurs in 1–2% of horses after acute infection with *Streptococcus equi*.[20] Deposits of streptococcal M protein complexed with IgA or IgM damage ECs, and induce systemic leukocytoclastic vasculitis. Head and hind leg edema is accompanied by petechia on mucosal and serosal surfaces. Serious sequelae include immune complex glomerulonephritis and infarction of skeletal muscle, skin, gastrointestinal tract, pancreas and lungs, similar to the human syndrome Henoch-Schonlein purpura.

Canine Juvenile Polyarteritis Syndrome

Canine juvenile polyarteritis syndrome (CJPS) occurs primarily in young Beagles, but has been documented in a variety of breeds.[6,29] Affected dogs have sudden onset fever, anorexia, and a hunched stance, with frequent remissions and relapse. Small to medium muscular arteries in the dura mater and leptomeninges of the cervical spinal cord, extramural coronary arteries, and cranial mediastinum develop segmental vasculitis and perivasculitis. Lymphocytes, macrophages, and plasma cells encircle the vessel and often expand into an eccentric nodule, with neutrophils predominating in acute lesions. Fibrinoid change and rupture of the elastic lamina, and fibrin thrombi, hemorrhage, and necrosis of adjacent tissues characterize severe lesions. CJPS has many features of an immune complex syndrome of children, Kawasaki disease, including high serum IgA, low peripheral T-cells and high B-cells, mononuclear activation, antineutrophil cytoplasmic antibodies, and suppressed mitogenic response. Other causes of canine systemic vasculitis include leishmaniasis and drug toxicities.

Paraneoplastic Vasculitis

Paraneoplastic leukocytoclastic vasculitis with variable degrees of necrosis, is occasionally seen in association with lymphosarcoma.[18]

CHAPTER 90

Treatment of Hemostatic Defects

DANIEL F. HOGAN and MARJORY B. BROOKS

Treatment of Hemorrhagic Disorders
- Transfusion Therapy
  - Transfusion for platelet defects
  - Transfusion for coagulation and von Willebrand factor defects
- Non-Transfusion Therapy
  - Drug therapy
    - Vitamin K therapy
    - Desmopressin
    - Antifibrinolytic drugs
    - Recombinant FVIIa (rhVIIa)
  - Topical agents

Treatment of Thrombotic Disorders
- Clinical Thrombotic Disorders
- Anti-platelet Drugs
  - Aspirin
  - Thienopyridines
    - Ticlopidine
    - Clopidogrel
- Anticoagulant Drugs
  - Unfractionated heparin
  - Low molecular weight heparins
  - Warfarin
  - Synthetic Xa inhibitors
    - Fondaparinux
    - Idraparinux
- Fibrinolytic Drugs
  - Tissue plasminogen activator
  - Streptokinase
  - Urokinase

Acronyms and Abbreviations

ACT, activated clotting time; AT, antithrombin; aPTT, activated partial thromboplastin time; BSA, bovine serum albumen; CE, cardiogenic embolism; CNS, central nervous system; COX, cyclo oxygenase; DDAVP, desamino-8-D-arginine vasopressin (desmopressin); DIC, disseminated intravascular coagulation; EACA, ε-aminocaproic acid; Hct, hematocrit; HIT, heparin-induced thrombocytopenia; IM, intramuscular; IMHA, immune-mediated hemolytic anemia; IMT, immune-mediated thrombocytopenia; INR, international normalized ratio; IV, intravenous; LMWH, low molecular weight heparin; PIVKA, proteins induced by vitamin K absence/antagonism; PT, prothrombin time; PTE, pulmonary thromboembolism; SC, subcutaneous; TTP, thrombotic thrombocytopenic purpura; UH, unfractionated heparin; uPA, urokinase; VWD, von Willebrand disease; VWF, von Willebrand factor.

Hemostatic defects, arising from either inadequate or uncontrolled hemostatic plug formation, cause significant mortality if unrecognized or inappropriately treated. The hemorrhagic disorders discussed in this section include platelet defects (thrombocytopenia and platelet dysfunction) and plasma protein defects (coagulation and von Willebrand factor [VWF] deficiencies). Management of thrombosis arises in the context of primary immune, endocrine, cardiac, and neoplastic disorders. Although empiric use of blood components and antithrombotic agents is common in veterinary practice, evidence-based guidelines for defined disease syndromes have not yet been developed.

TREATMENT OF HEMORRHAGIC DISORDERS

Transfusion Therapy

Patients with hemorrhagic disorders are often transfused to control signs of active bleeding, prevent abnormal bleeding from invasive procedures, or correct signs of blood loss anemia. Blood component transfusion is usually the best means to provide sufficient cells or proteins to support hemostatic plug formation, while minimizing risk of volume overload and sensitization to foreign antigens[25] (see Section VIII). The blood components used to treat hemorrhagic disorders include

TABLE 90.1 Blood Products for Hemorrhagic Disorders

Products	Dosage Guidelines	Indications
Platelet rich plasma[a]	6–10 mL/kg	Thrombocytopenia, platelet dysfunction
Fresh frozen plasma	6–12 mL/kg	Coagulation factor and VWF deficiencies
Cryoprecipitate[b]	1 unit/10 kg	Fibrinogen, factor VIII, and VWF deficiencies
Cryo-poor plasma	6–12 mL/kg	Deficiencies of factors II, VII, IX, X, and XI
Fresh whole blood	12–20 mL/kg	Replacement of platelets and all factors

[a]Platelet rich plasma containing at least 200×10^6 platelets/mL.
[b]1 unit cryoprecipitate prepared from 200 mL fresh frozen plasma.

platelet rich plasma and cell-free plasma products (see Table 90.1).

Transfusion may transiently correct underlying deficiencies; therefore baseline samples (EDTA and citrate blood) for laboratory assays and point-of-care tests should be collected before transfusion. At minimum, platelet count and coagulation screening tests (e.g. activated clotting time [ACT], activated partial thromboplastin time [aPTT], prothrombin time [PT]) should be evaluated in any patient suspected of having a hemorrhagic disorder. Sophisticated viscoelastic coagulation analyzers are validated to guide transfusion for human patients undergoing liver transplantation and cardiac bypass.[14] Among these instruments, the thromboelastograph is most actively under investigation for veterinary patients.[7,49] In vitro assays, however, cannot replace careful patient monitoring. Cessation of hemorrhage and stabilization of hematocrit (Hct) are defined clinical endpoints for confirming appropriate response.[18,24]

Transfusion for Platelet Defects

Platelet defects include thrombocytopenia, and acquired and hereditary platelet dysfunction (see Section VI). Medical therapy is the primary means of managing most of these disorders. Platelet transfusion is rarely beneficial for immune-mediated thrombocytopenia (IMT) because transfused platelets are removed rapidly from circulation. Acquired platelet function defects typically cause mild to moderate bleeding tendencies that resolve after correction of the underlying disorder. Most patients with hereditary platelet dysfunction have sporadic bleeds, and require transfusion primarily for surgical prophylaxis (see Chapter 97). The goal of platelet transfusion is replacement of sufficient functional platelets to support hemostasis, rather than normalization of platelet count. In human medicine, threshold platelet counts as low as 5,000–10,000/μL are considered safe for patients with chronic thrombocytopenia, whereas counts of 50,000/μL up to 100,000/μL are used for active hemorrhage, including massive trauma and CNS injury.[18]

Transfusion for Coagulation and von Willebrand Factor Defects

Simultaneous deficiency of many coagulation factors develops in patients with severe liver disease, vitamin K deficiency, overt hemorrhagic disseminated intravascular coagulation (DIC), and massive transfusion (see Chapter 85). In contrast, most hereditary defects involve deficiency of a single factor (see Chapters 81 and 86). Unlike platelet defects, transfusion therapy is the primary means for controlling or preventing hemorrhage in patients with acquired and hereditary factor deficiencies. Plasma components, rather than whole blood, provide rapid replacement of hemostatic factors, while minimizing risks of sensitization and volume overload (Table 90.1 and Chapter 96). Measurement of in vitro clotting times and the use of newer point-of-care analyzers can aid in patient monitoring; however, clinical status is the most important parameter for determining adequate response to plasma (and platelet) transfusion. Clinical outcome variables to gauge response include the severity, site, and duration of hemorrhage, change in Hct, and transfusion intervals.[18,24]

Non-Transfusion Therapy

Drug Therapy

Pharmacologic agents may reduce or replace transfusion for some patients with hemorrhagic disorders. Non-transfusion therapy eliminates the risk of disease transmission and transfusion reaction, and promotes more efficient use of scarce blood supplies. Most drug therapies, with the exception of vitamin K, indirectly support hemostasis rather than reverse a primary hemorrhagic condition (see Table 90.2).

Vitamin K Therapy Vitamin K deficiency is a common acquired coagulopathy, often arising due to anticoagulant rodenticide toxicity or liver disease (see Chapter 85). Vitamin K replacement should be given in the form of vitamin K_1 (phytonadione), rather than vitamin K_3 (menadione). Oral administration is appropriate for patients with no gastrointestinal signs or malabsorptive disorders. The subcutaneous (SC) route is preferred for parenteral vitamin K_1, because IV administration may cause anaphylaxis, and intramuscular (IM) injection risks hematoma formation. Vitamin K_1 at an initial dose of 2–4 mg/kg, with maintenance dosage of 1.5 mg/kg q12–24 hours provides adequate replacement therapy, without risk of inducing Heinz body formation.[13] Factor synthesis to correct coagulopathy occurs over a lag

TABLE 90.2 Drug Therapy for Hemorrhagic Disorders

Drugs	Dosage Guidelines	Indications
Vitamin K_1	2 mg/kg/day PO[d] or SQ	Vitamin K-dependent coagulopathy
Desmopressin	1 µg/kg SQ[e]	Type 1 VWD, platelet dysfunction
EACA[a]	100 mg/kg PO or IV (loading); 30 mg/kg/h	Perioperative hemorrhage
Tranexamic acid[b]	10 mg/kg IV; 25 mg/kg PO q8 h	Perioperative hemorrhage
rhVIIa[c]	35–120 µg/kg IV	Coagulation inhibitors, refractory hemorrhage, surgical hemostasis

[a]Loading dose given as single bolus followed by hourly dose for up to 8 h.
[b]Maintain for up to 7 days post-operatively.
[c]Doses given q2 h until control of hemorrhage.
[d]Orally
[e]Subcutaneously

period of up to 12–24 hours from initiation of therapy. Transfusion is indicated, therefore, to immediately control hemorrhage in patients with signs of respiratory tract or CNS hemorrhage, or severe blood loss anemia. Prolonged vitamin K_1 therapy (up to 6 weeks) may be required to maintain hemostasis for long-acting anticoagulant rodenticide toxicities. Samples for coagulation testing should be drawn pre-treatment, because diagnostic laboratory findings of vitamin K deficiency (e.g. prolonged aPTT, PT, proteins induced by vitamin K absence/antagonism [PIVKA]) are corrected concomitantly with clinical reversal of the bleeding tendency (see Chapter 138).

Desmopressin Desmopressin (DDAVP) is a synthetic analogue of arginine vasopressin developed to produce antidiuresis without vasoactive side-effects.[27] Desmopressin promotes hemostasis by increasing plasma VWF concentration via release of intracellular stores. The drug also enhances platelet function via less-defined, non VWF-dependent mechanisms. It is most often used in human medicine to treat patients with mild to moderate forms of VWD and hemophilia A; however, it has shown some benefit for patients with hereditary and acquired platelet function defects.[27] The action of desmopressin varies among species. Dogs demonstrate relatively low qualitative and quantitative VWF release; nevertheless, desmopressin has been reported to shorten in vivo bleeding time and improve surgical hemostasis in dogs with type 1 VWD and platelet dysfunction.[9] The empiric dosage for this use is 1 µg/kg SC. The maximal increment in plasma VWF occurs by 1 hour post administration, with no additional benefit expected from repeated doses. Response varies among individuals; therefore blood products should be available if drug therapy fails to control hemostasis.

Antifibrinolytic Drugs The lysine analogues, ε–aminocaproic acid (EACA) and tranexamic acid, delay fibrinolysis by impairing plasminogen's interaction with fibrin. Both drugs are given systemically to reduce transfusion requirements for people undergoing surgery associated with large volume blood loss (e.g. liver transplantation, joint replacement, cardiac bypass; Table 90.2).[26] In addition, tranexamic acid is used as a topical solution for patients with hereditary and acquired coagulopathies undergoing oral surgery. Aprotinin, a serine protease inhibitor of plasminogen, has also proven effective for reducing perioperative blood loss and transfusion requirements in people; however, recent studies suggest that aprotinin therapy is associated with renal failure. The pharmacokinetics of EACA in horses has recently been described, and this drug has been used empirically in horses to control hemorrhage secondary to traumatic, surgical, and infiltrative disease.[38] The lysine analogues have few serious side-effects in people and their clinical use in veterinary medicine warrants further investigation.

Recombinant FVIIa Supraphysiologic levels of activated FVII (FVIIa) are capable of bypassing the role of factors VIII and IX in promoting thrombin formation. Recombinant FVIIa (rhFVIIa) was initially developed to treat hemorrhagic episodes in hemophiliacs with coagulation inhibitors. In addition to this approved use, rhFVIIa is undergoing trials for controlling hemorrhage in a variety of surgical procedures (e.g. spinal surgery, liver transplantation) and for severe intracranial and post-traumatic bleeds.[37] The approved dosage regimen involves intravenous bolus (90 µg/kg) at 2 hour intervals until cessation of bleeding (Table 90.2). While rhFVIIa appears safe and effective in hemophiliacs, its wider use has been associated with thrombotic complications. Efficacy studies have been performed in hemophilic and factor VII deficient dogs; however, the drug's expense and risk of sensitization will likely limit clinical veterinary use.

Topical Agents

A variety of topical agents, classified as hemostats, sealants, and adhesives, have been developed for direct application to control bleeding and/or close tissue surfaces at sites of surgical or traumatic injury (Table 90.3).[42]

Hemostats provide a mechanical barrier and matrix for fibrin clot formation and include products derived from porcine gelatin, bovine collagen, cellulose, and polysaccharide spheres. Thrombin, the enzyme that directly transforms fibrinogen to fibrin, is used in combination with hemostats to enhance their activity and in a two-component plasma-derived fibrinogen product, fibrin sealant. Synthetic products include cyanoacrylate adhesives for superficial skin closures and polyethylene glycol sealants approved for durotomy and abdominal procedures. A two-component adhesive consisting of bovine serum albumen (BSA) and glutaraldehyde is also approved for cardiac and vascular surgery. The

TABLE 90.3 Topical Hemostatic Agents

Category	Products (Tradename, Source)
Hemostats: Mechanical	Porcine gelatin (Gelfoam, Pharmacia) Bovine collagen (Avitine, Bard; Helistat, Integra; Instat, Johnson & Johnson) Cellulosic (Surgicel, Johnson & Johnson) Polysaccharide spheres (Arista, Medafor)
Hemostats: Flowable	Human thrombin with bovine gelatin (Floseal, Baxter) Porcine gelatin matrix (Surgiflo, Johnson & Johnson)
Thrombin products	Bovine thrombin (Thrombin-JMI, King Pharmaceuticals) Human-derived (Evithrom, Johnson & Johnson) Recombinant human (Recothrom, Zymogenetics)
Fibrin sealants	Human plasma derived fibrin plus thrombin (Tisseal, Baxter; Evicel, Johnson & Johnson)
Synthetic sealants	Polyethylene glycol polymers (Coseal, Baxter; Duraseal, Covidien)
Adhesives	Cyanoacrylate (Dermabond, Johnson & Johnson; Indermil, Covidien; Histoacryl, Tissueseal) Glutaraldehyde and albumen (Bioglue, Cryolife)

potential side-effects of the topical agents include allergic reactions, sensitization to heterologous proteins, embolization, wound infection, and delayed healing.

TREATMENT OF THROMBOTIC DISORDERS

Pathologic thrombosis reflects an imbalance between fibrin formation and fibrinolysis, arising from anticoagulant or fibrinolytic pathway dysfunction, and/or an overwhelming excess of procoagulant stimuli (see Chapters 87 and 88). Numerous hereditary thrombotic syndromes or "thrombophilias" have been identified in people. Among the best characterized are factor V_{Leiden} (a defect that renders factor V insensitive to protein C inactivation) and deficiencies of the anticoagulant proteins, antithrombin (AT) and protein C. To date, hereditary thrombophilias have not been identified in domestic animals.

Clinical Thrombotic Disorders

Thrombosis is recognized as a common complication of many common diseases in animals. Observational studies include immune-mediated hemolytic anemia (IMHA), hyperadrenocorticism, cardiac disease, and neoplastic and protein losing disorders as primary disease conditions often associated with systemic thrombosis and pulmonary thromboembolism (PTE) (see Chapter 87). Although hemostatic abnormalities are often described, the specific causal factors of thrombosis in animals with these conditions remain ill-defined. Regardless of underlying mechanisms, thrombosis increases morbidity and mortality beyond that of the primary disease and often prompts consideration of antithrombotic therapy.

Antiplatelet Drugs

Aspirin

Aspirin is the most used and studied antiplatelet agent.[12] It is an indirect agent that inhibits secondary platelet aggregation by irreversibly acetylating platelet cyclooxygenase (COX), thereby preventing the formation of the platelet agonist, thromboxane A_2. Aspirin also inhibits endothelial cell COX activity, resulting in decreased prostacyclin synthesis and loss of anti-aggregating and vasodilating properties. Unlike platelets, endothelial cell COX inhibition is reversible and therefore antithrombotic conditions predominate at sites of intact endothelium.

The prophylactic benefit of aspirin on arterial thrombosis in people is confirmed by large meta-analyses demonstrating reduced death, myocardial infarction, and stroke due to coronary syndromes.[2] Aspirin is relatively ineffective, however, in primary or secondary prevention of cardiogenic embolism (CE) in patients with prothrombotic conditions such as atrial fibrillation.

The pharmacologic, analgesic, and antiplatelet effects of aspirin have been well studied in dogs and cats.[5,7] Aspirin has been used in cats for over 30 years with the goal of preventing CE; however, retrospective studies reveal recurrence rates of CE from 17% to 75%.[31,34,39] Adverse gastrointestinal effects (e.g. anorexia and vomiting) are common in aspirin-treated cats, but can be ameliorated by low-dose therapy (5 mg/cat q72 hours).[39] Although few clinical reports describe aspirin antithrombotic therapy in dogs, a retrospective study of IMHA attributed improved clinical outcomes to the addition of low-dose aspirin to immunosuppressive therapy.[46] Healthy dogs receiving aspirin uniformly develop gastroduodenal erosions and submucosal hemorrhages; however, clinical signs are uncommon.[36]

Thienopyridines

Thienopyridines induce specific and irreversible antagonism of the platelet membrane ADP_{P2Y12} receptor.[3,28] These agents are more potent than aspirin and are classified as direct antiplatelet agents, inhibiting both primary and secondary platelet aggregation in response to multiple agonists. The parent compounds must undergo hepatic biotransformation to form active metabolites. Inhibition of the ADP_{P2Y12} receptor by the active compounds decreases platelet release of serotonin, ADP and thromboxane, thereby inhibiting the ADP-induced conformational change of platelet glycoprotein IIb/IIIa and reducing fibrinogen and VWF binding. Modulation of platelet-mediated vasoconstriction also occurs.[28]

Ticlopidine Ticlopidine (Ticlid®) is a first generation thienopyridine with a delayed, 4–6 day, onset of action. In spite of its demonstrated efficacy in people, its use is limited by adverse events such as gastrointestinal and dermatologic disturbances, bleeding, agranulocytosis, altered hepatic tests and thrombotic thrombocytopenic purpura (TTP).[28]

A pharmacodynamic study in normal cats demonstrated consistent antiplatelet effects of high-dose ticlopidine; however, gastrointestinal side-effects precluded its clinical use.[21] Similarly, gastrointestinal side-effects were found in heartworm infested dogs treated with ticlopidine.[6a]

Clopidogrel Clopidogrel (Plavix®) is a second-generation thienopyridine that has supplanted ticlopidine because of its equal or better clinical efficacy, and more favorable safety profile.[11] Clopidogrel's maximal antiplatelet effects are achieved by 3–5 days of daily administration and its action wanes by 5–7 days after discontinuation. Adverse effects of clopidogrel in people include diarrhea, skin rash, occasional minor bleeding, and a possible risk of TTP. Large clinical trials demonstrate that clopidogrel significantly reduces the risk of stroke, myocardial infarction and vascular death compared to aspirin.[10]

In a pharmacodynamic study in normal cats, clopidogrel induced a 95% inhibition in platelet aggregation in response to ADP, 92% inhibition in serotonin release and a 3.9-fold prolongation in mucosal bleeding time.[22] While no adverse effects were noted in this study, anecdotal reports describe vomiting in some cats that responds to administration of the drug in a gel capsule or with food. To date, there is no evidence of TTP in clopidogrel treated-cats. Clopidogrel administration improved collateral circulation and neurologic function in a feline model of aortic infarction.[23] A randomized controlled trial now in progress, the Feline Arterial Thromboembolism: Clopidogrel vs Aspirin Trial (FAT CAT; http://www.vin.com/fatcat/) is designed to evaluate the drug's clinical efficacy for feline CE. The pharmacodynamics of clopidogrel in dogs has been investigated, but clinical treatment trials have not been performed.[16]

Anticoagulant Drugs

Unfractionated Heparin

Unfractionated heparin (UH) is derived from porcine intestine or bovine lung and consists of heterogeneous molecules with a mean molecular weight of approximately 15,000 Da (range 3,000–30,000 Da).[20] This heterogeneity produces highly variable pharmacokinetic and anticoagulant properties. Heparin molecules contain a pentasaccharide sequence that binds to AT, thereby facilitating AT's inhibition of factors IIa (thrombin), Xa, and IXa, and reducing thrombin-catalyzed activation of factors V and VIII. The most common adverse effect of UH therapy is bleeding; however, a severe thrombotic syndrome of heparin-induced thrombocytopenia (HIT) develops in up to 10% of UH-treated people. UH has proven efficacy in people for prevention or treatment of venous thrombosis, PTE, acute coronary syndrome, cardiac surgery, and cardiovascular interventions.[20]

Unfractionated heparin has been used for many veterinary conditions including DIC, IMHA, PTE, and arterial thromboembolism. Treatment regimens are generally empiric, or extrapolated from the human literature. Because of its highly variable pharmacokinetics, UH therapy requires individual patient monitoring. The aPTT is typically used to monitor UH, with a therapeutic goal of prolongation to 1.5–2 times baseline values. In addition to the aPTT, UH monitoring can be based on measurement of factor Xa inhibitory activity (anti-Xa assays).[20]

Low Molecular Weight Heparins

The low molecular weight heparins (LMWHs) are smaller in size than UH (4,000–5,000 Da), but maintain the pentasaccharide sequence that binds to AT.[4,20] LMWHs inhibit factor IIa to a much lesser degree than factor Xa. Due to their smaller size, the LMWHs also have a higher bioavailability and longer plasma half-life than UH. At therapeutic levels, the LMWHs do not prolong aPTT; therefore anti-Xa assays are used for monitoring clinical studies.[45] Peak anti-Xa levels in people occur at 3–5 hours after SC injection, with decline to undetectable levels by 8 hours. Although anti-Xa activity does not directly correlate with in vivo anticoagulant effect, positive clinical outcomes have been associated with peak LMWH anti-Xa activities of 0.5–1.0 U/mL.[20] For clinical use, LMWHs are typically administered at a fixed dose with no laboratory monitoring. Numerous human trials have demonstrated that LMWH produce equivalent or improved outcomes versus UH for unstable angina, myocardial infarction, venous thrombosis, and PTE.[20] Bleeding is the most common adverse effect of LMWH, with reported frequencies of up to 27% (minor bleeding) and up to 6% (major bleeding).

The LMWHs have generated considerable interest in veterinary medicine. Pharmacokinetic studies of dalteparin (100 U/kg) and enoxaparin (1 mg/kg) given SC to healthy cats demonstrate attainment of peak anti-Xa activities by 4 hours, with decline to undetectable levels by 8 hours.[1] In a pharmacodynamic study in cats using a venous stasis model, enoxaparin (1 mg/kg q12 hours) induced 91.4% thrombus inhibition at 12 hours after drug administration, in the absence of measurable anti-Xa activity.[44] This dosage regimen may provide therapeutic anticoagulant levels; however, clinical trials are needed to confirm its efficacy. Retrospective studies of variable dosage dalteparin therapy in cats for secondary prevention of CE revealed comparable survival times to warfarin-treated cats, and relatively few side-effects.[40] The pharmacokinetics of enoxaparin and dalteparin have also been investigated in healthy dogs; however, clinical trials have not yet defined effective dosage regimens.[29]

Warfarin

Warfarin blocks vitamin K recycling which results in production of dysfunctional vitamin K-dependent coagulation factors (factors II, VII, IX and X), and anticoagulant proteins C and S. Warfarin remains the standard oral drug for thromboprophylaxis of various human conditions including venous thrombosis, atrial fibrillation, and prosthetic heart valves.[33] Bleeding is the most common complication, with major bleeding rates of approximately 1–2%, and up to 20% for minor bleeding. Warfarin metabolism is influenced by genetic factors and drug interactions that may increase or decrease its anticoagulant effect. Warfarin therapy is adjusted by transformation of PT assay results to international normalized ratio (INR) values. The INR allows standardization among testing laboratories and is derived from the following equation: [(patient PT/control PT)^{ISI}], where ISI is a measure of PT reagent sensitivity.[30] Although clinical trials based on dosage to target INR have not been performed in animals, INR values of 2–3 are associated with effective thromboprophylaxis in people and are recommended for most thrombotic syndromes.[33]

The pharmacokinetics and pharmacodynamics of warfarin have been evaluated in dogs and cats.[32,41] The human guidelines of PT prolongation to 1.3–1.6 times baseline, or an INR of 2–3 are empiric therapeutic targets for anticoagulation for animals. Retrospective studies of warfarin for secondary prevention of CE in cats reveal recurrence rates of 40–50%, with hemorrhage (including fatal hemorrhage) the most common complication. [31] Owners must be advised of the risks, expense, and dedication needed to undertake warfarin therapy in animals.

Synthetic Xa Inhibitors

Synthetic Xa inhibitors are a new class of drugs designed to selectively inhibit factor Xa through potentiation of AT.[4] These agents are homogeneous preparations of pentasaccharide units that bind exclusively to AT. These drugs also have complete bioavailability when administered subcutaneously, demonstrate less variability, and do not cause HIT. Drug monitoring is based on measurement of FXa inhibition in anti-Xa activity assays. The most common adverse effect is bleeding, occurring with a similar frequency as LMWH.

Fondaparinux

Fondaparinux (Arixtra®) is currently approved for medical use. The drug potentiates AT's anti-Xa activity by approximately 300-fold, has an elimination half-life of 17–21 hours and is given at 24 hour intervals.[15] Careful monitoring is required in patients with renal insufficiency because it is excreted unchanged in the urine. Numerous clinical trials have demonstrated fondaparinux equivalence or superiority to the LMWH, enoxaparin, for thromboprophylaxis in patients undergoing hip or knee replacement surgery, or for treatment of deep venous thrombosis or PTE.[8] A pharmacokinetic study of fondaparinux in cats demonstrated that dosage of 0.06 mg/kg SC q. 12 h results in peak and trough anti-Xa values that approximate human therapeutic levels (Hogan DF, unpublished data).

Idraparinux

Idraparinux is a second-generation synthetic pentasaccharide designed to replace warfarin for long-term thromboprophylaxis. Idraparinux binds to AT with high affinity, resulting in a plasma half-life equivalent to that of AT (80 hours).[19] Preliminary studies indicate that idraparinux is generally as effective as warfarin for patients with venous thrombosis and atrial fibrillation; however, its use is associated with higher rates of abnormal bleeding. The increased risk of bleeding and lack of specific antidote have slowed further development of idraparinux for clinical use.

Fibrinolytic Drugs

Supraphysiologic levels of plasminogen activators are administered intravenously to cause clot dissolution in patients with venous thrombosis, PTE, systemic arterial occlusive disease, ischemic stroke and acute myocardial infarction.[17,43] The most common complication of thrombolytic therapy in people is bleeding, which may be caused by thrombocytopenia, platelet dysfunction, hypofibrinogenemia, systemic fibrinolysis, or clot disruption. Reperfusion injury is another complication seen when metabolic waste and electrolytes are released from infarcted tissues. Leriche's syndrome refers to ischemia of the pelvic limb musculature caused by distal aortic infarction. Thrombolytic therapy in these patients often induces severe metabolic acidosis and hyperkalemia. An analogous condition develops in cats with aortic CE post-thrombolytic therapy.[34] Of the many thrombolytic agents approved for use in people, veterinary reports are limited to t-PA, urokinase, and streptokinase.

Tissue Plasminogen Activator

Plasminogen and tissue plasminogen activator (t-PA) both have a high affinity for fibrin, and t-PA interacts preferentially with fibrin-bound rather than free plasma plasminogen.[43] However, t-PA's fibrin specificity is relative and at high doses it induces a systemic proteolytic state and bleeding.[17] Isolated reports of dogs with arterial thromboembolism or vena caval thrombosis treated with bolus human recombinant t-PA (Activase®) describe variable response and hemorrhagic complications.[6] A clinical trial of t-PA therapy in six cats with CE revealed an acute survival rate of 50%, with deaths attributable to reperfusion injury and cardiogenic shock.[34] The survivors had perfusion restored within 36 hours and return to motor function within 48 hours.

Streptokinase

Streptokinase is considered a "nonspecific" plasminogen activator because it converts both circulating and fibrin-bound plasminogen to the active enzyme, plasmin.[43] Systemic plasminemia may predispose to bleeding from degradation and loss of fibrinogen and coagulation factors, and the inhibitory effects of fibrin breakdown products. Streptokinase is an immunogenic protein that can elicit allergic reactions and reduced drug efficacy, especially upon repeated administration. Streptokinase is rarely given to people at less than 4 year intervals. Streptokinase (Streptase®) has been administered to dogs and cats as an intravenous infusion of 90,000 IU intravenously (IV) over 1 hour followed by 45,000 IU/hour for up to 12 hours. Severe complications were seen in two retrospective studies of streptokinase therapy in cats with CE and aortic infarction, including acute respiratory distress, hemorrhage, reperfusion injury, and mortality rates of 100% and 67%, respectively.[31] In contrast, streptokinase therapy for thromboembolic disease is apparently well-tolerated in dogs. In a case series of four dogs, three experienced complete thrombus resolution and all had partial or complete resolution of signs with only rare, minor bleeding.[35]

Urokinase

Urokinase (uPA) is a serine protease plasminogen activator. Its active, low molecular mass form binds with great affinity to the lysine-plasminogen form of plasminogen, which preferentially accumulates within thrombi. This property confers some fibrin-specificity to uPA. Urokinase (Abbokinase®) is used clinically as a thrombolytic agent in people with venous thrombosis, PTE, and cardiac syndromes.[17] The drug has been administered to cats and dogs with arterial thromboembolism with a protocol of 4,400 IU/kg loading dose given over 10 minutes followed by 4,400 IU/kg/h for 12 hours.[47,48] In a small case series of cats with CE, uPA was generally well-tolerated and approximately half the cats regained some motor function and ultimately survived.[47] In contrast, none of four dogs treated with uPA survived.[48]

Treatment Guidelines

Acronyms and Abbreviations

ACT, activated clotting time; aPTT, activated partial thromboplastin time; DIC, disseminated intravascular coagulation; HPAI, highly pathogenic avian influenza; PK, prekallikrein; PT, prothrombin time.

Coagulation is a highly conserved vertebrate defense mechanism for controlling hemorrhage. Phylogenetic and comparative sequence analyses reveal that the key mammalian coagulation proteases (factors II, VII, IX, X) and cofactors (factors V and VIII) are present in birds and evolved from common ancestral genes.[4] However, differences between birds and mammals in coagulation protein structure and function affect the clinical assessment of avian hemostasis. Assay methods and reagents optimized for mammals are not directly applicable for the diagnosis of avian coagulopathies.[1,5,7,28] Although hemorrhagic disorders are recognized in poultry, pet birds, and wildlife, their clinical diagnosis is challenging due to relative unavailability of valid assay techniques.

COMPARATIVE AVIAN HEMOSTASIS

Coagulation in birds, as in mammals, culminates when a burst of thrombin (factor IIa) transforms soluble plasma fibrinogen into an insoluble fibrin clot.[9] Coagulation is initiated by tissue factor/factor VIIa and then amplified and propagated by factor complexes (factor VIIIa/IXa and factor Va/Xa). The major inhibitors of coagulation, Protein C and antithrombin, are also present in birds (see Chapter 84).[4,6]

Tissue Factor and Active Factor Complexes

In response to injury, the tissue factor/factor VIIa complex activates factors IX and X. These serine protease factors assemble on cell membrane phospholipids with their respective cofactors (factors VIII and V) to form active enzyme complexes. The corresponding avian factor and cofactor genes share extensive sequence homology with their mammalian counterparts.[4] For example, functional regions of ostrich prothrombin demonstrate 70–87% identity with the bovine and human genes. The encoded avian protein retains the overall domain structure of mammalian prothrombin and consists of an open reading frame of 607 amino acids compared to 608 amino acids for human prothrombin.[8] In addition, the enzymatic activities of human and avian thrombin and factor Xa are similar based on their cleavage of small peptide substrates.[9] Avian factors have relatively low activities, however, in clotting time assays configured with mammalian plasma and tissue thromboplastins.[4,9,28] In spite of functional similarities, avian and mammalian coagulation factors

have structural differences that influence their ability to form active enzyme complexes in heterologous (cross-species) systems.

Contact Factor Pathway

The contact pathway, found in most mammals, includes three serine protease factors: factor XI, factor XII, and prekallikrein (PK). These factors are required for surface-initiated in vitro fibrin formation in the activated partial thromboplastin time (aPTT) screening test. In vivo deficiencies of these factors, however, cause either mild (factor XI) or no signs of a bleeding diathesis. Comparative genomic studies have recently described their evolutionary development and clarified the cause of prolonged contact-activated clotting times of avian plasma.[19] These analyses indicate that a single prekallikrein-factor XI "predecessor" gene was retained in birds and did not undergo the duplication event leading to two distinct mammalian genes. In contrast, an ancestral vertebrate factor XII gene was lost from the lineage leading to birds. Consequently, aPTT screening tests and factor assays optimized for activation of the mammalian contact pathway are not directly applicable for assessing avian coagulation.[5,19] Further studies are needed to develop a comparable aPTT screening test method for birds.

Fibrinogen Formation and Fibrinolysis

Fibrinogen in birds, as in mammals, functions as a hemostatic protein and a positive acute phase reactant.[11,12] Avian plasma fibrinogen concentration is approximately 100–300 mg/dL (1–3 g/L).[11] The fibrinogen molecule in all species consists of three polypeptide chains. Although certain structural features differ between species, avian fibrinogen is susceptible to cleavage by mammalian thrombin. Factor XIII is also conserved in birds and acts to cross-link mature fibrin. Fibrinolysis is not fully characterized in birds; however, avian homologs have been identified for the fibrinolytic pathway serine proteases (i.e. urokinase, tissue plasminogen activator, and plasminogen).[19]

Thrombocytes

Thrombocytes in non-mammalian vertebrates fulfill the function of platelets as cellular matrices of the hemostatic plug, and have additional phagocytic activities not displayed by platelets. Thrombocyte counts of normal birds typically range from 20,000–30,000/µL but may extend up to 50,000/µL (Chapters 122–125). Thrombocytopenia should be ruled out by determining thrombocyte count in any bird suspected of having a hemostatic defect.

SAMPLE COLLECTION FOR COAGULATION TESTING

Blood collection from birds is an art, requiring careful, precise technique. Obtaining valid coagulation results depends on skillful venipuncture to minimize sample contamination with tissue fluid, collection of blood into citrate anticoagulant, and careful processing to prevent ex vivo factor activation (Chapter 138).

Venipuncture Technique

Venipuncture is performed with 25–27 gauge needles to minimize trauma and facilitate post-collection hemostasis. Forcing blood through small-bore needles causes hemolysis; therefore needles should be removed before blood transfer from syringes to processing tubes. The most useful syringe sizes are 3 mL, 1 mL, and 0.5 and 0.3 mL. Large syringes produce excessive negative pressure resulting in vascular collapse, endothelial damage, and hemolysis.

The right jugular, medial metatarsal, and basilic veins are the main vessels used for blood collection. When accessible, the jugular vein is preferred due to its relatively large size. The jugular vein is located dorsolaterally on the neck and is usually much larger on the right. In most birds, gently blowing to part the feathers on the neck exposes bare skin overlying the jugular vein (the jugular furrow or groove). In birds lacking a jugular furrow (e.g. waterfowl), wetting the feathers with alcohol aids in vessel localization. Columbiformes (e.g. pigeons) have a vascular plexus rather than distinct jugular vein, and air sac location in other species (e.g. hornbills) precludes blood collection from the jugular vein. Similarly, fat may obscure the jugular vein in obese birds, especially some Amazon parrot species.

The medial metatarsal vein is an alternate to the jugular; however, its localization may require plucking a few feathers, and venipuncture site hemorrhage may be difficult to control. The basilic (ulnar) vein is readily accessible, but a lack of overlying supportive tissue often results in hematoma formation after venipuncture and vessel immobilization may be impossible in awake birds. Blood collection from a clipped toe-nail is a painful and inappropriate technique that risks sample contamination with tissue fluid or uric acid, and uncontrollable hemorrhage.

Blood Collection and Processing

Approximately 10% of total blood volume (estimated as 0.8–1% of total body mass in grams) can be drawn safely from euvolemic, and nonanemic birds. Blood samples must be collected in sodium citrate anticoagulant; heparin-anticoagulated samples are *invalid* for coagulation testing. For optimal sample quality, blood is drawn into a syringe containing premeasured sodium citrate to obtain an exact ratio of 1 part citrate to 9 parts blood. The sample is then gently mixed, transferred to a tube for centrifugation, and the supernatant plasma removed for same-day assay, or stored frozen (–20 °C). Prolonged storage as whole blood or repeated freeze-thaw cycles may produce artifactually prolonged clotting times due to protease activation and factor/fibrinogen degradation.

TABLE 91.1 Avian Prothrombin Times

Subject	PT Range[a] (s)	Mean PT[a] (s)	Reference
Chicken	9–11	10	5
Chicken (24 weeks)	10–22	15	1
Chicken (8 weeks)	13–27	17	1

[a]PT, prothrombin time.

COAGULATION TESTING

Coagulation screening tests assess factor function based on rate of in vitro fibrin formation (see Chapter 138). Due to species and assay variables, evaluating results from paired same-species controls and/or same-species reference intervals facilitates test interpretation.

Prothrombin Time

The prothrombin time (PT) is the most commonly performed coagulation assay in birds.[1,6,15,25,26] The assay is configured with a thromboplastin/calcium reagent to initiate clotting and is a screening test of the extrinsic and common pathway (factors VII, V, X, prothrombin and fibrinogen). Prolonged PT is compatible with coagulopathy due to vitamin K deficiency, severe hepatic failure, or factor consumption. The source of tissue factor in thromboplastin reagents is a major assay variable affecting PT.[26,28] Optimized PT assays require avian-origin thromboplastins. Thromboplastins from the species of interest are ideal; however, a commercial chicken-brain extract (Innovative Research, Novi, Michigan, www.innov-research.com) has general use for avian PT. The reported values for avian PT (Table 91.1) reflect species differences, and variability in sample collection, plasma storage, and assay techniques.

Activated Clotting Time

The activated clotting time (ACT) is a point-of-care test that measures the time to clot formation for blood drawn into a particulate activator tube. The assay is an intrinsic and common pathway screening test that detects moderate to severe deficiencies of factors VIII, IX, V, X, prothrombin and fibrinogen. Although the use of PT is commonly reported, the ACT has potential as an in-house screening test.[1,5] In the authors' experience, quail ACT is less than 3 minutes, similar to human ACT. Whole blood clotting times have been reported for chickens; however, marked variability and wide range (<1–39 minutes) limit the clinical utility of this screening test.[25]

Fibrinogen

Heat precipitation techniques provide estimates of fibrinogen concentration to detect hyperfibrinogenemia. The Clauss technique, based on thrombin clotting time of plasma, is a more sensitive, quantitative measure to diagnose hypo- and hyperfibrinogenemia. Hypofibrinogemia has been described in birds with sepsis-induced disseminated intravascular coagulation (DIC) and hepatic failure.[6,22] Hyperfibrinogenemia secondary to bacterial infection has been reported in many species, including African gray parrots, cranes, flamingos, and penguins.[12]

AVIAN HEMORRHAGIC DISORDERS

Vitamin K Deficiency

The first reported coagulopathy in birds, characterized by intramuscular, subdural, and ecchymotic hemorrhage, was described in chicks fed a vitamin K-deficient diet.[3] Although dietary vitamin K deficiency and intestinal malabsorption due to sulfa drugs are now relatively infrequent,[21] anticoagulant rodenticide intoxication has become an important vitamin K deficiency syndrome in birds.[2,13,17,24] Due to high prevalence, rodenticide toxicity should be suspected in birds with hemorrhage, or less specific signs of anemia, hypoproteinemia, and shock. Granivorous birds directly ingest anticoagulants in baits, while predatory birds develop secondary toxicity through ingestion of anticoagulant-poisoned prey. Government agencies from New York to New Zealand have noted the adverse impact of rodenticide use on wild bird populations. Toxicities have occurred in free-ranging species, (e.g. barn owls, eastern screech-owls, great horned owls, red tailed hawks, seabirds) and in captive turkey vultures. Owls appear to be at high risk since small rodents are their primary food source.[24] Brodifacoum, a second-generation product with long half-life, is the most commonly implicated poison. The toxic dose of brodifacoum is not defined for most species; however, LD_{50} values of 0.31 mg/kg have been reported for mallard ducks and 4.5 mg/kg for chickens.[18]

Coagulopathy caused by vitamin K antagonists results in deficiency of factors VII, IX, X and prothrombin, which prolongs the PT (Chapter 85). Definitive diagnosis is based on identification of specific poisons in stomach contents, tissues, or bait samples.[24] The Louisiana Animal Disease Diagnostic Laboratory and other veterinary toxicology laboratories offer test panels to screen for anticoagulant rodenticides.

Hepatotoxins and Hepatic Disease

Severe liver disease in birds, as in mammals, causes synthetic failure of coagulation factors and fibrinogen.

Aflatoxin, produced by *Aspergillus* sp. fungi, is well-recognized as a potent hepatotoxin that causes fatty liver degeneration in birds and coagulopathy due to hepatic dysfunction.[5,7,20] Chickens dosed at 5 mg/kg aflatoxin had significantly prolonged PT with no clinical signs; however, species differences in susceptibility exist as turkeys and bobwhite quail are more susceptible than chickens and Japanese quail, respectively.[20] Other mycotoxins (e.g. fumonisin) and toxins in plants such as rapeseed may also induce hepatotoxicity and coagulopathy.[5,6] Metabolic and infectious disease (e.g. hepatic lipidosis, hemachromatosis, Gram negative bacterial infections, mycobacteriosis, chlamydophilosis, and biliary adenocarcinoma associated with viral disease) are additional causes of hepatic failure and coagulopathy in birds.

Fatty liver hemorrhagic syndrome is characterized by fat deposition in the liver and abdomen, and massive abdominal hemorrhage in laying hens consuming large amounts of high-energy diets.[27] The syndrome is associated with changes in plasma phospholipid composition, rather than factor deficiencies, and genetic factors are believed to influence susceptibility. Management practices (e.g. feeding nutritionally balanced layer diets and free-range production) appear to prevent the problem.

Infectious Disease

Numerous viral diseases are associated with hemorrhage, including circovirus, reovirus, herpesvirus, polyomavirus, and avian influenza.[10,16] Retroviral infection has also been proposed as a cause of Conure bleeding syndrome, an ill-defined syndrome characterized by oral or cloacal hemorrhage and regenerative anemia. The pathogenesis of coagulopathy in viral disease is likely multifactorial, including hepatic synthetic failure, vasculitis, and DIC.[10,12,16]

Pathogens capable of inducing DIC in birds include *Borrelia anserina*, *Salmonella pullorum*, *Escherichia coli*, *Erysipelothrix rhusiopathiae*, adenovirus, infectious bursal disease virus, laryngotracheitis virus, and avian influenza virus.[16,22,23] Recent studies of highly pathogenic avian influenza (HPAI) in chickens reveal clinical evidence of severe hemorrhage in multiple organs (lungs, gastrointestinal tract, musculature) and histologic evidence of fibrin thrombi in pulmonary arterioles.[16] Molecular analyses support a DIC process initiated by up-regulation of tissue factor expression, in addition to endothelial destruction and inflammatory cytokine release. As in mammals, clinico-pathologic abnormalities aid in antemortem diagnosis of DIC (Chapter 88). Findings supportive of overt DIC include prolonged PT, low thrombocyte count, and low fibrinogen.

TREATMENT GUIDELINES

Vitamin K_1 administration is indicated for vitamin K deficiencies caused by rodenticide toxicity, nutritional deficiency, antibiotic administration, and recommended prior to hepatic biopsy. Oral vitamin K_1 (phylloquinone; 0.13 mg/kg) is given to poultry as basic nutrition, with demonstrable shortening of PT.[14] Recommended dosages to reverse vitamin K-dependent coagulopathy range from 0.2 to 2.5 mg/kg SC q4–12 hours.[17] Due to the widespread use of long-acting rodenticides (e.g. brodifacoum), vitamin K replacement therapy is typically instituted for at least 1 month. Monitoring PT after discontinuing vitamin K_1 aids in detection of persistent anticoagulant effect, necessitating reinstitution of vitamin K therapy.

Birds with active or severe hemorrhage due to coagulopathy may require transfusion of whole blood to replace both red blood cells and clotting factors. Homologous transfusions are preferred due to risk of acute immune reactions and/or short survival time of heterologous red cells (Chapter 99).

Acronyms and Abbreviations

CMAH, cytidine monophospho-N-acetylneuraminic acid hydroxylase; DLH, domestic longhair; DSH, domestic shorthair; EA, erythrocyte antigen; FUT1, fucosyl-transferase 1; FUT2, fucosyl-transferase 2; NeuAc, N-acetylneuraminic acid; [NeuAc]2GD3, NeuAc-NeuAc-galactose-glucose-ceramide; NeuGc, N-glycolylneuraminic acid; [NeuGc]2GD3, NeuGc-NeuGc-galactose-glucose-ceramide; NI, neonatal isoerythrolysis; RBC, red blood cell.

Inherited cell surface antigens located on the red blood cell (RBC) membrane are referred to as blood group antigens. Their detection and description are based on polyclonal or monoclonal antibody serology. The antigens can vary in immunogenicity and, therefore, clinical significance. These antigens participate in recognition of self and in some cases can serve as markers of disease. In humans, for example, neoplastic cells sometimes express altered blood group antigens. In veterinary medicine the clinical significance of blood group antigens is usually in the areas of transfusion reactions and neonatal isoerythrolysis (NI). Blood group antigens are genetic markers and have in the past been used to resolve cases of disputed parentage. Though not yet proven in veterinary medicine, blood group antigens may play a role in immune-mediated hemolytic anemia and may serve as markers of disease. In this chapter our current understanding of the nomenclature, serology, biochemistry, inheritance, incidence, and transfusion significance of the dog, cat, cattle, horse, sheep, goat, pig, llama and alpaca blood groups is reviewed.

RED BLOOD CELL ANTIGENS AND BLOOD GROUPS IN THE DOG

Historical Background

The discovery of the human ABO blood group system in 1900 by Landsteiner stimulated the search for blood group systems in domestic animals. Canine blood groups were first recognized by Von Dungern and Hirszfeld in 1910, who defined four different blood groups based on immune isoagglutinins.[95] Swisher and coworkers at the University of Rochester, NY, used dogs as animal models to study in vivo mechanisms of RBC destruction. In a series of reports they described antigens A, B, C, D, E, F, and G, determined the frequencies of the antigens in a random population of dogs, and characterized the in vivo and in vitro behavior of the isoantibody systems. Their systematic approach to studying the canine blood group systems was reviewed in 1961 and 1962.[94,95]

Nomenclature

The blood group antigens were first given letter designations A, B, C, D, E, F, and G in the order of their discovery. Two categories of A cells were recognized, a strongly reactive group (A), and a distinct series of less strongly reacting cells designated as A′ that could only be detected by the Coombs' antiglobulin test. This designation was later changed to A1 and A2.[95] Anti-E and anti-G typing sera were lost, so no future comparisons could be made.[12,26,93] International workshops met in 1972 and 1974 to standardize canine blood groups as defined by isoimmune sera and to standardize canine blood group system nomenclature.[101,102] The first workshop designated the terminology canine erythrocyte antigen (CEA) followed by a number to indicate the blood group antigen. The second workshop adopted the designation dog erythrocyte antigen (DEA) followed by a number from 1 onward for a locus, followed by a (.), followed by another number for each allele recognized at a locus. The new terminology was adopted to avoid confusion with the carcinoembryonic antigen (CEA) system.

A nomenclature system has been proposed that conforms with that used in other species.[26,80] This system would return to an alphabetical designation to name blood group systems (loci), and would also identify factors, alleles, genotypes, and phenotypes. Based on the last international cooperative effort at defining canine blood group antigens,[101] general usage among veterinary immunohematologists, and the availability of typing sera, the nomenclature system currently used in the United States is the DEA system which includes DEA 1.1, DEA 1.2, DEA 3, DEA 4, DEA 5, and DEA 7. There is not worldwide acceptance of the DEA nomenclature system, however, and some authors use the newer genetic nomenclature system in reporting new blood group specificities.[96,97] Until there is a standardized international nomenclature system, it is necessary to be familiar with both systems. The changes in nomenclature of the dog blood group systems are summarized in Table 92.1.

Typing sera are commercially available in the United States only for DEA 1.1, 1.2, 3, 4, 5, and 7 (see Chapter 139).[52] From a practical standpoint, therefore, these are the antigens with which the veterinary practitioner should be most familiar. However, many other blood group factors and systems have been described, and the lack of commercially available typing sera does not diminish the potential significance of these other systems in transfusion medicine.

Dog Erythrocyte Antigen System

DEA 1.1, 1.2, 1.3 (A system)

This system is a three factor, four phenotype system that contains the antigens DEA 1.1, 1.2, 1.3, (equivalent to Aa_1, Aa_2, Aa_3) and a null type.[96] Breeding studies suggest an autosomal dominant pattern of inheritance with the order of dominance being DEA 1.1, 1.2, 1.3, and null.[24,94,96] Individual dogs exhibit only one phenotype. The antigens are described as subtypes of a linear series.[88] A subtypic series has the characteristic that isoimmune antisera produced to one of the antigens can exhibit grades of cross-reactivity with other antigens in the series. Anti-A (anti-DEA 1.1, 1.2, 1.3) antiserum is produced by immunizing an A (DEA 1.1, 1.2, 1.3) negative dog with RBCs from a DEA 1.1 positive dog. Anti-A antiserum strongly agglutinates and hemolyzes (in the presence of fresh complement) RBCs having DEA 1.1 and causes variable agglutination (but not hemolysis) and sensitizes RBCs having DEA 1.2 and 1.3 in the antiglobulin test. Anti-A antiserum is, therefore, a mixture of anti-DEA 1.1, 1.2, and 1.3. Anti-DEA 1.1 antiserum is produced by immunizing a DEA 1.2 positive dog with RBCs from a DEA 1.1 positive dog.[52,94] Anti-DEA 1.1 antiserum reacts only with RBCs having DEA 1.1. When an A (DEA 1.1, 1.2, 1.3) negative dog is immunized with Aa_3 (DEA 1.3) positive cells, the initial antiserum contains antibodies that strongly agglutinate and hemolyze Aa_1 and Aa_2 (DEA 1.1 and DEA 1.2) cells and weakly agglutinate Aa_3 cells. Repeated exposure to Aa_3 cells results in antisera that are strongly reactive with all three cell types.[96] Attempts to produce specific anti-DEA 1.2 and anti-DEA 1.3 have been unsuccessful without performing RBC absorption procedures.[95,96]

Incidence The incidence of DEA 1.1 and DEA 1.2 in the United States is approximately 45% and 20%, respectively.[52,95] DEA 1.3 has been evaluated only in Australia.

Molecular Identity Immunoprecipitation experiments using polyclonal antisera to DEA 1.2 isolated a protein with a molecular mass of 85 kDa.[28] Western blotting experiments using monoclonal antibody specific for DEA 1.1 identified two membrane proteins with molecular mass 50 kDa and 200 kDa.[2]

Transfusion Reactions The A system is the most important blood group system from a practical stand-

point for transfusion in the dog. Anti-DEA 1.1 is a strong agglutinin and hemolysin in vitro and in vivo. Naturally occurring antibody to DEA 1.1 and 1.2 has not been documented, so first time acute hemolytic transfusion reactions do not occur. However, subsequent incompatible transfusions can result in severe hemolytic transfusion reactions with hemoglobinuria, hyperbilirubinemia and removal of the transfused RBCs in less than 12 hours (see Chapter 100).[42,111]

Transfusion of plasma containing anti-DEA 1.1 antibody in one study resulted in a hemolytic reaction in DEA 1.1 positive recipients.[111] DEA 1.1/1.2 negative dogs sensitized with DEA 1.1 positive RBCs will develop antisera that can on subsequent exposure remove transfused DEA 1.2 RBCs in 12–24 hours. DEA 1.2 positive dogs produce a strong anti-DEA 1.1 antibody when exposed to DEA 1.1 RBCs and experience an immediate hemolytic transfusion reaction when subsequently exposed to DEA 1.1 RBCs.[52] The third factor in this system, DEA 1.3 (or Aa_3) has been described, but transfusion experiments have not been performed.[96] However, the serological characteristics described above make the transfusion significance of this antigen obvious.

Neonatal Isoerythrolysis Hemolytic disease in neonatal pups proposed to be naturally occurring NI has been reported.[113] Experimental NI due to blood group A incompatibility has been produced in pups by immunization of an A-negative bitch by transfusion with A-positive RBCs, followed by mating to an A-positive sire.[22,109,110] Sensitization of a DEA 1.1 negative pregnant bitch by previous transfusion or pregnancy can result in NI in DEA 1.1 positive pups.[109]

DEA 3 (B system)

This is currently understood to be a one factor, two phenotype system with the antigen DEA 3 and a null phenotype, with DEA 3 being dominant. Naturally occurring anti-DEA 3 antibody has been reported in up to 20% of DEA 3 negative dogs.[52,113] In the United States, approximately 6% of the general dog population is DEA 3 positive.[95] However, 23% of greyhounds typed at

Michigan State University between 1990 and 1995 were DEA 3 positive.[52] Administration of DEA 3 positive RBCs to a sensitized dog results in loss of the transfused RBCs within 5 days and can result in severe acute transfusion reactions.[34,94]

In Japan, two reagents, a heteroimmune antiserum produced in rabbits, designated anti-D1, and an isoimmune antiserum, designated anti-E, were found in comparison tests with DEA reagents to be identical to anti-DEA 3.[31] Western blotting experiments using monoclonal antibody to DEA 3 identify five bands with molecular mass of 34, 53, 59, 64, and 71 kDa.[54]

DEA 4 (C system)

This is a one factor, two phenotype system with the antigen DEA 4 and a null phenotype, with DEA 4 being dominant. Naturally occurring antibody to DEA 4 has not been documented. Up to 98% of the general dog population in the United States expresses this antigen.[94] However, the incidence of DEA 4 may be significantly lower in some breeds and geographic locations.[52] DEA 4 negative dogs will produce antibody to this antigen when exposed by transfusion, but sensitized dogs did not show RBC loss or hemolysis when transfused with DEA 4 positive cells.[94] Attempts to induce NI with blood group C (DEA 4) incompatibility were unsuccessful.[112] However, a hemolytic transfusion reaction is described in a DEA 4 negative patient that received multiple transfusions of DEA 4 positive RBCs.[70] The transfusion significance of this antigen is considered incomplete.[52] Immunoprecipitation experiments using polyclonal antisera to DEA 4 isolated a protein of molecular mass 32–40 kDa.[28]

DEA 5 (D system)

This is a one factor, two phenotype system with the antigen DEA 5 and a null type, with DEA 5 being dominant. Naturally occurring antibody to this antigen has been reported in 10% of random non-transfused dogs in the United States.[94,113] The incidence of this antigen is generally low, but there is breed and geographic variation. Up to 30% of greyhounds in the United States are DEA 5 positive.[52] Transfusion of DEA 5 positive RBCs to sensitized dogs results in RBC sequestration and loss within 3 days.[94] Experimental attempts to induce NI with blood group D (DEA 5) incompatibility were unsuccessful.[112]

DEA 6 (F system)

This is a one factor, two phenotype system with the antigen DEA 6 and a null phenotype, with DEA 6 being dominant. Although reported in almost 100% of dogs in the United States,[95] this antigen also exhibits marked breed and geographic variation in expression.[33,53,102] Naturally occurring anti-DEA 6 has not been documented. Transfusion studies in one DEA 6-negative dog showed moderately rapid removal of transfused RBCs following sensitization.[95] Typing sera for DEA 6 no longer exists.

DEA 7 (Tr system)

The Tr antigen antibody system was defined by a naturally occurring isoantibody and by an identically reacting antiserum produced by isoimmunization.[16] Factor O is an allele in the Tr system, resulting in the Tr system being a two factor, three phenotype (Tr, O, and null) system with the order of dominance being Tr, O, and null.[27] The Tr antigen is not an integral RBC membrane antigen, but rather is believed to be produced elsewhere in the body, secreted into the plasma, and adsorbed onto the RBC surface.[20] The Tr antigen is expressed in approximately 40–54% of dogs.[16,26,102] Naturally occurring, weak, low titered, nonhemolytic anti-DEA 7 is present in 20–50% of DEA 7-negative dogs, and sensitized DEA 7-negative dogs, when transfused with DEA 7-positive RBCs show sequestration and loss of RBCs within 72 hours.[52] Immunoprecipitation experiments using polyclonal antisera to DEA 7 isolated three proteins of molecular mass 53, 58, and 66 kDa.[28]

DEA 8

This canine RBC antigen, originally designated as He, was discovered by antiserum raised by isoimmunization, and the antigen reported to exist in 40–45% of a random population of dogs.[19] Typing sera for DEA 8 no longer exists.

Other Specificities

N-Acetyl-neuraminic acid (NeuAc) and *N*-glycolyl-neuraminic acid (NeuGc) present on gangliosides (hematosides) of the RBC membrane define an unnamed blood group system described in Japan.[55,107] Sera from dogs with NeuAc hematoside contain an isoantibody that agglutinates RBCs of dogs with NeuGc hematoside, and the agglutination is inhibited by NeuGc hematoside. Comparison studies with standardized canine blood typing reagents have not been performed. Several Oriental breeds express NeuGc hematoside, especially native breeds of northern China, Korea, and southern Japan, including the Japanese mongrel, Kai, Kishu, Japanese spaniels, and Shiba dogs.

A blood group system referred to as the D system is described in Japan. The D system is composed of two antigens, D1 and D2, with three phenotypes, D1, D2, and D1D2. The phenotypes are based on agglutination testing with two rabbit heteroimmune antisera, anti-D1 and anti-D2. The D1 and D2 antigens are codominant factors and anti-D1 is identical to anti-DEA3.[31] The counterpart of D2 has not been described outside of Japan. The incidence of D1 and DEA 3 is high in purebred dogs indigenous to Japan such as the Akita, Shiba, Kishu, Shikoku, and native Japanese mongrel and mixed breeds, while most Western and European breeds are negative for these factors.[31,33,34] Repeated transfusion

of D2 type blood into a D1 type patient, or of D1 type blood into a D2 type patient results in severe acute transfusion reactions, indicating the importance of this system in transfusion medicine.[34]

The lectin extracted from seeds of *Clerodendron tricotomum* preferentially agglutinates RBCs of some dogs (designated type C) at titers up to 128, and is completely negative for other dogs (type c).[108] Genetic studies in Beagles (62 offspring from 18 matings) indicated that the characteristic is inherited as an autosomal dominant trait.[64] This system, designated as "C", was compared to the DEA system and found to be different.[3,31,62,64]

The *Dal* blood type is defined by specific IgG alloantibodies in a Dalmatian dog previously sensitized by blood transfusion.[15] Major crossmatching tests with 55 non-Dalmatian dogs were incompatible, suggesting the antibody recognized a common RBC antigen. Four of 25 unrelated Dalmatians were crossmatch compatible, suggesting that they lacked the antigen. Blood typing of the recipient and donors indicated that the alloantibodies were not associated with DEA 1.1, 1.2, 3, 4, 5, or 7.

Numerous other specificities have been reported and proposed to represent new blood group systems.[26,31,92,97,101]

RED BLOOD CELL ANTIGENS AND BLOOD GROUPS IN THE CAT

Historical Background

Ingelbringsten (cited by Ottenburg and Thalhimer)[75] first described naturally occurring isoagglutinins in cats, but did not find evidence of groups similar to the human ABO types. Holmes reported two groups of cats, one designated as group O that contained an isoagglutinin in the serum, and a group with the corresponding antigen on the RBCs named group EF.[58] Eyquem described two antigens, A and B, and stated that these antigens were identical to EF and O reported by Holmes.[35]

Auer and Bell used two naturally occurring antibodies, anti-A and anti-B, to characterize the cat blood group system which they designated as AB, and first reported the rare AB phenotype where both antigens were present on the RBC.[7] They were also the first to describe immediate experimental and naturally occurring transfusion reactions in previously unsensitized cats of known incompatible blood type.[9]

Cat AB Blood Group System

The AB blood group system characterized by Auer and Bell is the predominant blood group system in cats.[7] Three phenotypes occur: type A, type B, and type AB. A null phenotype does not occur.

The types are defined by naturally occurring isoantibody against the antigen they lack. Type A cats have low titered anti-B hemagglutinins of the IgM class and hemolysins consisting of equal amounts of IgG and IgM.[18] Approximately one-third of type A cats have macroscopic agglutinins and hemolysins. Microscopic examination or the antiglobulin test is required to detect the weak agglutination reactions in the remaining two-thirds of the cats. Type B cats have high titered anti-A hemagglutinins and hemolysins mainly of the IgM class with lesser amounts of IgG.[18,104] It is the presence of these naturally occurring isoantibodies that is responsible for transfusion reactions and NI in blood type incompatible cats. Type AB cats do not possess isoantibodies against either A or B antigens.

Genetics

The blood group antigens A and B are inherited as simple autosomal Mendelian traits with A being dominant to B.[12,41] All type-B cats are homozygous for the B allele (genotype B/B) and type-A cats can be either homozygous (genotype (A/A) or heterozygous (genotype A/B). Blood type AB is not the result of codominant inheritance of type A and B, nor is it the result of chimerism.[7] In spite of extensive breeding studies and pedigree analysis, the mode of inheritance of the AB phenotype remains unknown, although it appears to be recessive to type A and dominant to type B.[7,47]

Incidence of the Antigens

Type A is the most common blood type. Type B is less common, and type AB is very rare. The percentage distribution of types A and B in domestic shorthair (DSH) and domestic longhair cats (DLH) can vary markedly with geographic location within the United States and worldwide (Table 92.2). The breed incidence of type B in the United States ranges from 0% up to 60% among different purebred cats (Table 92.3).

In Turkey, 60% of Van cats and 46.4% of Angora cats are type B.[5] Type AB is exceedingly rare. In a survey of cats in the United States and Canada, 13 of 9,239 cats (0.14%) were type AB.[47] In Australia, 7 of 1895 cats (0.4%) were type AB.[7] Type AB occurs only in breeds in which type B is detected. Type AB has been found in DSH/DLH cats and in Abyssinian, Birman, British Shorthair, Norwegian Forest, Persian, Scottish Fold, Cornish Rex, Devon Rex, Maine Coon, Manx, Ragdoll, Sphynx, Bengal, Egyptian Mau, Siberian, European, and Somali purebred cats.[13,47]

Molecular Characterization of the Antigens

The form of neuraminic acid (sialic acid) on the RBC membrane glycolipids and glycoproteins determines the blood group antigens in the cat.[4,50] NeuGc is the determinant of the A antigen. Type-A RBCs have NeuGc-NeuGc-galactose-glucose-ceramide ($[NeuGc]_2G_{D3}$) as the major disialoganglioside, and it is the predominant blood type-determining ganglioside detected by feline anti-A antisera.[4] Type A RBCs also have NeuAc-NeuGc-G_{D3}, NeuGc-NeuAc-G_{D3}, and a very minor amount of $[NeuAc]_2G_{D3}$. Homozygous and

[a]Data compiled from refs. 41, 44, and 48.

heterozygous type A cats have some differences in their ganglioside profiles, and these differences can be used to determine the genotype of type A cats.[50]

NeuAc is the determinant of the B antigen. Type B RBCs have $[NeuAc]_2G_{D3}$ as the only form of the disialoganglioside. Type B RBCs do not contain any detectable NeuGc. Agglutination testing with the lectin of *Triticum vulgaris*, a lectin that binds sialoglycoproteins containing NeuAc, demonstrates selective agglutination of type B RBCs.[21] Type AB RBCs have features of both type A and type B. They are agglutinated by both anti-A and anti-B feline antisera, and by the lectin of *Triticum vulgaris* (see Chapter 139). Data from two studies using a panel of murine monoclonal anti-feline blood type A RBC antibodies in agglutination testing, ganglioside thin layer chromatography immunostaining, and flow cytometry suggest that there is more than one biochemical phenotype in the AB type.[45,46] This phenotypic difference is undetected by feline typing sera, which may explain the reason that investigators have been unable to provide a single genetic mechanism for the inheritance of the AB type.[4,47,50] Wild felids have the same AB blood group system, and thin layer chromatography of RBC membranes reveals similar ganglioside patterns in wild cats as reported in domestic cats.[49]

Molecular Genetics

Cytidine monophospho-*N*-acetylneuraminic acid hydroxylase (CMAH) is the enzyme that catalyzes the conversion of NeuAc to NeuGc.[71] DNA sequence analysis of the feline CMAH gene revealed several mutations, including two single nucleotide polymorphisms upstream of the start, an indel (insertion/deletion) site in the exon 1 5′-untranslated region, and three missense mutations in the coding region which are concordant with the type A and type B blood types of 18 breeds of cats from the USA and Europe.[13] These six mutations were homozygous in all type B cats and heterozygous in all heterozygous type A cats. No type A cats were homozygous for any of these six mutations. No concordance was found between the mutations and the blood type AB. This study suggests that the cat AB blood group system resulted from mutation(s) in CMAH that prevent the conversion of NeuAc (blood type B) to NeuGc (blood type A). The authors proposed renaming of the cat AB blood group system to contain three alleles, represented as $A>a^{ab}>b$. The allele A encodes the wild-type, fully active enzyme, a^{ab} the partially active enzyme, and b the inactive enzyme. Possible genotypes/phenotypes would be AA (type A); Aa^{ab} (type A); Ab (type A); $a^{ab}b$ (type AB); $a^{ab}a^{ab}$ (type AB), and bb (Type B).[13]

Transfusion Reactions

The presence of naturally occurring isoantibodies is responsible for transfusion reactions in previously unsensitized cats (see Chapter 100). Virtually all type B cats have highly titered anti-A agglutinins and hemolysins which can result in severe transfusion reaction and death when as little as 1 mL of type A blood is administered to a type B-cat.[8,9,39,105] Rapid intravascular destruction of the type A RBCs occurs within minutes to hours and is complement- and IgM-mediated. Type B RBCs administered to type A cats have a half-life of

about 2 days, and minor transfusion reactions can occur.[8] Removal of type B RBCs occurs mostly extravascularly, involving IgG and IgM without marked complement activity.[40]

Neonatal Isoerythrolysis

Neonatal isoerythrolysis occurs in type A or type AB kittens born to a type B queen.[47] The colostrum of type B queens contains high concentrations of anti-A antibodies, and colostral antibody is detectable in the serum of newborns as early as 4 hours after birth.[18] Clinical signs in affected kittens can be variable, ranging from unapparent, to severe hemolytic anemia with hemoglobinuria, icterus, and death. Neonatal isoerythrolysis is believed to be a major cause of the "fading kitten syndrome."[41]

Other Specificities

The *Mik* Red Blood Cell Antigen

This is a RBC antigen discovered by a crossmatch incompatibility between plasma from a feline renal transplant recipient and RBCs from a donor cat which were blood group AB compatible, but resulted in an acute hemolytic transfusion reaction. Plasma from three of 65 previously untransfused blood donor cats were also found to have naturally occurring alloantibody to this common antigen. Plasma from these three donor cats agglutinated RBCs from cats with type A, type B, and type AB blood, indicating the antigen is not part of the AB blood system. The name of the blood group system was designated *Mik* based upon identification of the alloantibody in the first blood donor investigated, a cat named Mike.[103] The mode of inheritance, frequency of the antigen, geographical distribution, and molecular characterization of the antigen remain to be determined.

RED BLOOD CELL ANTIGENS AND BLOOD GROUPS IN LIVESTOCK SPECIES

Historical Background

The identification of blood group antigens and analysis of their patterns of genetic inheritance in farm animal species were the subject of intense investigation for about 50 years. In contrast to humans and cats, naturally-occurring antibodies are seldom found in the sera of cattle, horse, sheep, goat, pig, llama and alpacas. Production of iso- and heteroimmune antisera by immunization and the use of RBC absorption procedures to isolate monospecific antibodies (blood typing reagents) were critical to uncover the genetic diversity of blood groups in these species. The molecular nature and function of the RBC antigens in farm animals remains largely unknown.

This section describes the blood group systems (or loci) of six livestock species: cow, horse, sheep, goat, pig and llama (and the related alpaca). Although blood group systems have historically been designated by a single letter, the loci are referred to here by the more recent nomenclature convention in which the two letters "EA" for *erythrocyte antigen* precede the traditional system designation. The literature in blood groups of livestock species is extensive and cannot be fully represented in this section. Excellent reviews of the subject are published that offer historical accounts and details of the complex serological intricacies of blood group loci in the major farm animal species. Readers are referred to the publications by Stormont,[87] Bell,[12] Di Stasio,[30] Hines,[56] Juneja & Vogeli,[66] and Sandberg & Cothran.[81] The greatest impact of blood group variation in farm animals was in the area of animal identification and parentage verification, because of the high level of individual discrimination that could be achieved and their classic Mendelian modes of inheritance. From a clinical perspective, knowledge of blood groups is significant only in horses because of the risk of NI posed by maternal-fetal incompatibility for certain factors.

Methods of Blood Group Detection

Hemolytic and agglutination techniques are used to assay blood group factors. The choice of procedure is largely determined by the characteristics of the RBCs of each species. Blood grouping assays for cattle, sheep, goat, llama and alpaca are hemolytic tests because the RBCs of these species are not prone to agglutination. Horse and pig blood groups factors are assayed by saline agglutination or by hemolytic tests. Some pig factors require an antiglobulin test (Coombs' test) or addition of dextran to facilitate agglutination and improve scoring of reactions.

Source of Blood Typing Reagents

Blood typing reagents (monospecific antisera) for livestock species are not commercially available. They have been traditionally prepared in laboratories that provided blood typing services. Comparison tests sponsored by the International Society of Animal Genetics for several decades provided a forum for standardization of blood factor specificities and nomenclature for each species. Blood typing comparison tests are no longer held and production of blood typing reagents has virtually ceased worldwide with the advent of DNA typing methods and technologies in the late 1990s.

Hemolytic Tests

Hemolytic tests are typically set up in round-bottom, 96-well microtiter plates. A standard procedure consists of combining, in order, 50 µL of blood typing reagent with 25 µL of a 2–2.5% saline suspension of washed, packed RBCs and 25 µL of undiluted rabbit complement. After addition of complement, the plate is shaken in a vibrating plate mixer. Reactions are read twice to record degree of hemolysis: once 30–45 minutes after

set-up and a second time 3 hours later. A concave mirror is used for visual determination of hemolysis which is graded as 0 (negative, no visible hemolysis), 1 (partial hemolysis), 2 (intermediate), 3 (strong, almost complete) and 4 (complete hemolysis). In negative reactions, RBCs remain intact and settle in a pellet at the bottom of the well, whereas with complete hemolysis intact RBCs are not visible and the reaction fluid is clear and reddish in color. A complement control consisting of 50 µL of saline, 25 µL of RBC suspension and 25 µL of complement is run in parallel with the test reactions.

Rabbit serum is the source of complement for hemolytic tests. Because rabbits lack the heterophile Forssman antigen, their sera can have Forssman antibodies in high titers. Cattle and camelids are Forssman-negative and thus hemolytic tests in these species are not affected by Forssman antibodies. For the Forssman-positive horse, sheep, goat and pig, rabbit serum needs to be absorbed with RBCs from these species prior to use as complement.[90] Two serial absorptions, carried out at 4 °C, for 15–20 minutes each and a 1:2 volume ratio of washed, packed RBCs to rabbit serum are usually sufficient to remove heterophile antibodies without affecting complement function.

Agglutination Tests

Saline agglutination tests are set up in the same way as hemolytic tests, except that complement is omitted. Reactions proceed at room temperature for 2–3 hours after which time the plates are then shaken briefly to loosen cells from the bottom of the wells. Degrees of agglutination are recorded 5–10 minutes after resuspension as 0 (no agglutination), 1 (partial clumping), 2 (intermediate clumping) and 3 (total clumping of red cells). A microscope can be used to help distinguish between negative and weak positive reactions.

Antiglobulin tests are used with incomplete antibodies that require the addition of rabbit antiglobulin serum to produce agglutination. This procedure is used to detect some blood group factors in pigs. Addition of dextran to a saline agglutination reaction at a final concentration of 1.5% has been used with some incomplete antibodies in pigs as an alternative to the antiglobulin test.

Blood Group Systems

Cattle

The blood groups of cattle were the first to be studied in detail and provided a model for investigation in other species. The early studies in the 1940s demonstrated the value of iso- and heteroimmunizations for development of antibodies for blood group factors and established the procedures for preparation of monospecific antibodies through absorption and for assaying blood groups with hemolytic tests.[36,37]

Cattle blood groups remain the primary example of extreme genetic variation of RBC antigens, as evidenced by more than 70 blood group factors internationally recognized and by the extensive allelic series known in the complex *EAB* and *EAC* systems. An alphabetical nomenclature designates blood group factors (e.g. A, L, S, Z) with numerical subscripts added to describe serologically related subtypes (e.g. A_1, A_2, Y_1, Y_2). The inclusion of the symbols ′ and ″ to a letter (e.g. A′, B′, A″, G″) indicates second and third rounds of use of alphabet letters, respectively. One of the most important contributions of the early cattle blood group research was the demonstration that multiple factors segregated together in specific combinations each of which defined an allelic variant.[89] The term "phenogroup" was coined to describe the combinations of factors.[86] As reviewed by Hines,[56] evidence from infrequent recombination events within *EAB* and *EAC* systems suggests that the molecular nature of these complex systems may involve a series of linked genes, each of which could result in products carrying multiple epitopes. With the completion of the bovine genome sequencing project in 2007, the tools are now at hand to investigate the molecular genetic basis of cattle blood group systems. It is of interest to note that the *EAJ* system is not an intrinsic component of the RBC membrane and anti-J is the only antibody that occurs naturally. The J factor is a tissue and serum antigen that attaches to RBCs as serum concentrations become sufficiently high. The attached J substance has been shown to be a glycolipid, while the serum form occurs as both glycolipid and glycoprotein.[98] The J factor is serologically related to human A, sheep R and pig A factors. Cattle blood group loci have been mapped to chromosomes by linkage analysis.[67] A summary of the 11 cattle blood group loci, factors and allelic variants is given in Table 92.4.

Horse

The first 16 blood group factors in the horse were identified through iso- and heteroimmunization followed by hemagglutination and hemolysis testing.[91] Research by laboratories worldwide led to the subsequent characterization of 34 factors distributed in seven systems. A summary of horse blood group systems, factors and alleles are presented in Table 92.5. By convention, factors within a system are assigned lower case letters and blood group alleles (phenogroups) are designated by the capital letter for the system, followed by lower case letters for the factor or factors detected.

The horse is the only livestock species for which blood group incompatibilities are clinically relevant. Blood group antibodies that cause transfusion reactions or NI can be found in the sera of horses either "naturally" or as a result of a blood group incompatible pregnancy. The majority of analyzed cases of NI are explained by incompatibilities of factors between stallion and mare at either *EAA* or *EAQ*. Naturally occurring anti-Aa (in any of its allelic combinations) and anti-Ac are occasionally found in the sera of horses lacking factor Aa, usually as agglutinins. Anti-Aa in mares may also be present as a hemolysin, particularly

if produced by a blood group incompatible pregnancy. Hemolytic screening for this antibody (and others) prior to foaling can provide an effective test to identify mares whose foals are at risk for NI. In *EAQ* sensitization, the mare is negative for factor Qa (for most breeds this means negative for Q^{abc}), while the stallion has this blood group. The detectable antibody response for Qa has only been reported as a lysin and would be missed by antibody screening based solely on agglutination testing. Occasionally the antibody presence can be detected only very late in pregnancy. Antibodies for blood group factors in *EAC*, *EAD*, *EAK*, *EAP* and *EAU* pose little risk as they do not occur naturally and have only rarely been implicated in NI cases, possibly as a result of blood incompatible pregnancies.

Five blood group loci have been mapped to chromosomes by linkage analysis.[76] A summary of the seven horse blood group loci, factors and allelic variants is given in Table 92.5.

Sheep and Goat

Eight blood group systems have been described in sheep: *EAA*, *EAB*, *EAC*, *EAD*, *EAM*, *EAR*, *EAF30* and *EAF41*.[74] The nomenclature of systems and factors follows the same rules as those used for the horse and pig. Although many antigen specificities have been identified, only 22 blood group factors are internationally recognized in sheep. Hemolytic tests are the method of choice for sheep blood group factors with exception of the D system whose antigens are detected by agglutination tests. The sheep *EAB*, *EAC* and *EAR* systems are homologous to cattle *EAB*, *EAC* and *EAJ*. Products of the *EAR* locus are not an intrinsic component of the RBC membrane. The antigens are soluble substances found in the serum and saliva which attach to the RBC membrane. The EAR^R allele is dominant to EAR^O and expression of both antigens is under the control of the suppressor gene *I*. Sheep with genotype *i/i* do not express R or O antigens in RBCs, serum or saliva. The *EAC* locus is closely linked to the *Amino Acid Transport* gene. This association is of interest because RBCs with defective transport are never Cb-negative. The *EAM* locus is associated with RBC potassium transport such that low-potassium cells are always Mb-positive and high-potassium cells are always Mb-negative. It has been postulated that Mb inhibits active potassium transport into cells.[100] Several sheep blood group

systems have been mapped by linkage analysis. A summary of sheep blood group loci, factors and allelic variants is given in Table 92.6.

Blood groups in goats are less developed than those of other farm animals. Six genetic systems have been identified and named *EAA*, *EAB*, *EAC*, *EAE*, *EAF* and *EAR*.[73] Several goat blood group factors cross-react with sheep blood typing reagents. The *EAA* system has a single specificity A1 that is homologous to sheep EAAa. In the *EAB* system, 14 specificities were identified, four of which are homologous to sheep factors Bb, Be, Bd and Bi. The *EAC* system has a single specificity related to sheep EACa. The *EAE* system contains two factors E6 and E18 and the EAF system is defined by a single specificity F19. The *EAR* system is defined by a single specificity R related to sheep R.

Pig

Development and expansion of pig blood groups is largely due to work carried out in Denmark, Germany, Poland and Russia. The source of blood typing reagents is primarily from isoimmune sera with most antibodies behaving as agglutinins and a few as hemolysins. Sixteen genetic systems are internationally recognized: *EAA*, *EAB*, *EAC*, *EAD*, *EAE*, *EAF*, *EAG*, *EAH*, *EAI*, *EAJ*, *EAK*, *EAL*, *EAM*, *EAN*, *EAO* and *EAP*.[66] Some of these, e.g. *EAE* and *EAM*, approach the *EAB* and *EAC* systems of cattle in complexity and diversity. The nomenclature of pig blood group factors follows that of the horse, except for the *EAA* system.

The *EAA* system is related to cattle *EAJ*, human A and sheep *EAR* systems. Pig A and O factors occur as soluble substances in the serum and saliva of A-positive and O-positive animals, respectively, and attach to the RBC membrane a few weeks after birth. The genetic inheritance of A and O factors is similar to sheep *EAR* system. EAA^A is dominant to EAA^O and their expression on RBCs is controlled by the suppressor gene, *EAS*. The EAA^A allele codes for uridine diphosphate *N*-acetylgalactosamine transferase that adds a terminal fucose residue to the H substance.[69] The recessive EAA^O allele contains a deletion within the gene and results in a non-functional enzyme product.[106] The *EAH* and *EAS* systems correspond to *fucosyl-transferase 1* (*FUT1*) and *fucosyl-transferase 2* (*FUT2*) that are involved in the production of the H substance and are related to human *H* (*FUT1*) and *Secretor* (*FUT2*) genes.[25,69] Antigens of the *EAN* system also occur as soluble substances in the serum and milk but are not secreted into the saliva.

Blood group loci have been mapped to pig chromosomes by linkage analysis.[78] A summary of pig blood group systems, factors and alleles is given in Table 92.7.

Llama and Alpaca

Little is known about blood group variation in the two domestic South American camelids, llama and alpaca. From iso- and heteroimmune sera developed for these animals, six blood group factors were identified and given alphabetical designations in order of discovery: A, B, C, D, E and F.[77] Factors A and B are inherited as co-dominant alleles and assigned to blood group system *EAA*. Factors C, D, E and F were assigned to four separate systems as they appeared to be transmitted independently from each other and from the *EAA* system. Blood groups in llamas and alpacas are detected by hemolytic tests.

Applications of Blood Groups

Animal Breeding

Accurate pedigree records are essential to many aspects of animal breeding, including selection of breeding stock, estimation of heritabilities, and breeding values based on progeny testing. Most breed registries throughout the world have mandatory parentage testing programs to validate pedigree records of registered animals. From the early 1950s through the mid 1990s, serological tests for blood groups, supplemented by electrophoretic assays that detected additional genetic variation in blood proteins, were the only methods available to verify parentage and to help breeders solve problems of questionable paternity or maternity. The high degree of variation of blood group antigens and protein variants resulted in probabilities of exclusion of incorrect parentage as high as 98% for most breeds.[17] The use of blood typing tests in animal breeding came to an end in the mid 1990s when more powerful and cost effective DNA typing technologies emerged and became established as the preferred genetic testing method for applied and research purposes.

Blood Transfusion

Clinically, knowledge of blood groups in cattle, sheep, goat, pig and llama/alpaca has not affected conventional practice in transfusion. Large animals are not commonly transfused, and matching of blood types for antigenic compatibility is not practical because of the high variability of blood groups between individuals

and limited availability of donors. Blood transfusions in large animals are indicated for certain acute, life threatening conditions and for plasma transfusion when failure of passive transfer occurs. Single, unmatched whole blood transfusions are generally safe and well tolerated. A gross crossmatch is recommended and sufficient when repeated transfusions are required. Matching is done with hemolytic and/or agglutination tests depending of the species and involves testing of the recipient's serum for antibodies against the RBCs of potential donors (major) and of the donors' sera for antibodies against the recipient's RBCs (minor) (see Chapter 139).

Pigs are often used as an animal model for organ or hematopoietic transplantation. Blood group compatibility is an important component of experimental protocols because of problems associated with immune-mediated tissue rejection or the need to provide transfusion support to patients.[85] In transplant experiments, mismatched transfusions for the *EAA* system result in adverse reactions that include disseminated intravascular coagulation, bleeding, and progressive hypotension[60,82] rather than typical hemolytic reactions seen in humans.

Horses merit special consideration because whenever a mare is given a whole blood transfusion, she is potentially being sensitized to blood group factors that may subsequently lead to NI problems for her foals. Selection of suitable donors that are negative for highly antigenic factors such as EAAa (and without circulating antibodies in the serum) is recommended although currently not practical because very few laboratories can perform the serological test for blood group specificities. Mares that received a blood transfusion should always be screened for potential risk of NI prior to foaling.

Plasma Transfusion

A blood transfusion may be used to restore fluid loss and replace necessary proteins, and the RBC component may not be essential. In this case, a plasma transfusion may fulfill the clinical requirements. Potential donors can be selected in a hematology laboratory by screening their sera against a RBC panel from 10 to 20 horses to identify those without antibodies with anti-blood group activity. Plasma can be collected and stored frozen to administer as needed.

Neonatal Isoerythrolysis in Horses

Neonatal isoerythrolysis is an acute hemolytic disease of newborn foals caused by immunologically-mediated RBC destruction resulting from maternal-fetal blood group incompatibility. Affected foals are healthy at birth but within 2–5 days develop signs of lethargy, elevated pulse and respiration rates, and clinical evidence of anemia. NI foals are usually from the second or later pregnancies of a mare but, on rare occasions, first foals can be affected. The antibodies that sensitize the RBCs of the foal are passively acquired from the dam's colostrum. Recovery may be spontaneous or the disease may progress to severe anemia and death.

The most common antibodies involved in NI are anti-Aa and anti-Qa, although others are infrequently found. Not all mares negative for EAAa or EAQa factors become sensitized, although they may have produced Aa-positive or Qa-positive foals. One source of sensiti-

zation is whole blood transfusion, but this accounts for only a small number of cases. Mares negative for both Aa and Ca factors may be protected from sensitization to Aa by naturally produced anti-Ca antibodies.[11] At present, no simple hypothesis explains why blood group sensitization occurs in only a few percent of mares at risk.

A serum sample taken about 3 weeks before a pregnant mare is due to foal can be screened for evidence of blood group incompatibility. If the test results are positive for hemolytic anti-blood group activity, it is strongly advised to withhold the foal from its dam's colostrum for 36–48 hours before putting it back to its dam's milk. An alternative colostrum and milk source must be provided to the foal during that period.

NI Disease in Mule Foals

Mule breeders are keenly aware that mares bred to jacks (male donkeys) can become sensitized to blood group factors of asses.[99] Monitoring of a pregnant mare's serum for antibodies against the RBCs of the jack to which she is bred is a prudent precaution to identify mule neonates at risk for NI.

Red Blood Cell Donors for Foals with NI

Appropriate management for a severely anemic NI foal may be a RBC transfusion to alleviate the anemia and prevent death. The best blood donor is one whose RBCs lack the factor to which the mare is making antibodies. The sire of the foal is the worst possible donor since he has the factor to which the mare's immune system has responded. The best immediate RBC donor is the mare. The mare's RBCs should be administered to the foal in a suitable transfusion solution, but first they must be separated from the plasma and washed in saline to remove the antibodies reacting with the foal's RBCs. The mare is unlikely to have a matching blood group type but it provides the foal with vital RBCs that will not be destroyed by the antibodies acquired from the colostrum. Hopefully, in a short time the blood group antibodies will be eliminated from circulation and the foal can make sufficient RBCs of its own to prevent a recurrence of the anemia crisis.

Acronyms and Abbreviations

EDTA, ethylenediaminetetraacetic acid; GP, glycoprotein; HLA, human leukocyte antigen; HNA, human neutrophil antigen; HPA, human platelet antigen; IMN, immune-mediated neutropenia; IMT, immune-mediated thrombocytopenia; LFA-1, leukocyte function antigen 1; PCR, polymerase chain reaction; PTP, post-transfusion purpura; TRALI, transfusion-related acute lung injury; VWF, von Willebrand factor.

Cell surface antigens on granulocytes and platelets play a role in recognition of self. Antigens vary in their ability to stimulate an immune response and, therefore, in their association with disease. Much of the published research has focused on the role of platelet and granulocyte antigens in immunologic disorders; however, antigen identification is also used as a marker of disease. In veterinary medicine expression of platelet or granulocyte antigens is determined to characterize myeloproliferative disorders. Expression of some antigens, such as P-selectin (CD62P) on platelets, is used to determine cellular activation.[29]

Immune responses targeting granulocyte or platelet antigens have been implicated in the pathogenesis of primary (autoimmune or idiopathic) and secondary immune-mediated neutropenia (IMN) or thrombocytopenia (IMT), neonatal alloimmune neutropenia or thrombocytopenia, and transfusion reactions.[9,10,40,41,50] Binding of antibodies to cell antigens may also cause dysfunction of the target cells.[8,25] Immunologic disorders resembling those listed above have been identified in veterinary species; however, the pathogenesis of these conditions is generally better characterized in humans because transfusion therapy and neonatal cytopenias are more common.[50] Most of the information provided in this chapter is based upon current understanding of the role of platelet and granulocytes antigens in immunologic disorders in humans. Whenever possible, comparisons between humans and veterinary species will be presented.

Platelet or granulocyte antigens can be specific to one cell type, shared by other blood cells, or widely distributed on systemic cells. Antigens are generally classified based upon their biochemical nature into glycolipids, glycoproteins (GPs), or proteins.[9,41] The roles of some, but not all, of these antigens in normal cellular function are known. The molecular structures of some of these antigens have been characterized, allowing the development of molecular techniques to detect alterations in the nucleic acid structure of the genes encoding the antigens.

Variations in the structure of an antigen that is present in some, but not all, individuals in a species are termed alloantigens. Alloantigens are the products of polymorphic genes. Most granulocyte and platelet alloantigens have been linked to single-point mutations.[27] The prevalence of the different alloantigens in humans varies significantly between ethnic groups.[8,41] It is likely that similar differences exist in the expression of alloantigens among different breeds and species of animals.[50]

Antibodies directed against alloantigens are termed alloantibodies. Alloantibodies may form when an individual receives a blood product that contains an alloantigen not present on self cells or when there is an incompatibility between fetal and maternal blood cells. Isoantibodies are antibodies that target a nonpolymorphic antigen found on the cells of the vast majority of normal individuals in a species. Generally, isoantibodies form when an individual who has an inherited defi-

ciency of an antigen is transfused with blood products from a normal individual.[50]

Antibodies that are produced against self-antigens are termed autoantibodies. The production of autoantibodies may be idiopathic or may be secondary to an underlying disorder.[10,55,65] Autoantibodies are sometimes produced following drug administration. In some cases the drug or its metabolite must be present for antibody binding to occur. In other cases the drug induces an antibody that persists after drug administration ceases.[3]

GRANULOCYTE ANTIGENS

The granulocytes consist of neutrophils, eosinophils and basophils. Neutrophils are present in highest concentrations in the blood and are most commonly implicated in immunologic disorders.[50] In humans immunologic disorders are associated with antigens in the human leukocyte antigen (HLA) or the human neutrophil antigen (HNA) systems.[56,57]

Human leukocyte antigens are widespread in distribution and found on many different cell types; HNA antigens are predominantly expressed on neutrophils (Table 93.1). It is currently unclear how many of the HNA antigens are expressed on other leukocytes.[8] The HNA systems are numbered according to the GP site where they are located. Antigens within each HNA system are listed alphabetically in order of their identification.[56] The HNA-1 antigens are found on FcγRIIIb (CD16b), a low affinity receptor for the Fc portion of immunoglobulins. They vary significantly in degree of glycosylation. The HNA-2 antigen is found on a 56–64 kDa GP (CD177) that is involved in adhesion to endothelial cells and subsequent transmigration into the extravascular space. The HNA-3 antigen is located on a 70–95 kDa protein whose function is not known. The HNA-4 antigen is located on the CD11b/CD18 complex (Mac-1, CR3), a β_2-integrin that plays a role in binding to endothelial cells and complement proteins. The HNA-5 antigen is found on the CD11a/CD18 complex (leukocyte function antigen 1 [LFA-1]), a β_2-integrin involved in adhesion to endothelial cells.[8,57]

Monoclonal antibodies are used in a variety of veterinary species to identify the GPs present on neutrophils. The relationship between the antigens recognized by these monoclonal antibodies and the antigens associated with immunologic disorders is not currently known.[50] Monoclonal antibodies to CD11a (LFA-1) and CD11b (Mac-1; CR3) bind to bovine neutrophils.[19,54] The monoclonal antibody to CD11a also binds to all other bovine leukocytes but not to erythroid cells or platelets. Monoclonal antibodies to CD11a also recognize antigens on neutrophils, lymphocytes and monocytes from dogs, horses, sheep, goats and rabbits.[6,28,31,49,59] The antibody to CD11b also binds to bovine monocytes and a subpopulation of B lymphocytes.[19,54] Antibodies to CD11b bind to neutrophils, monocytes and lymphocytes from sheep, goats, and pigs, as well as neutrophils and monocytes from cats and dogs.[6,49] Anti-CD16 antibodies bind to canine neutrophils.[31,59] Additional information on CD antigens is available in Chapter 4.

Laboratory Techniques to Identify Neutrophil Antigens and Antigen-Antibody Interactions

Identification of neutrophil antigens or anti-neutrophil antibodies has traditionally relied on agglutination or immunofluorescence assays.[56,57] In agglutination assays neutrophils clump if a patient's serum containing autoantibodies is added to neutrophils from a normal individual or if a patient's neutrophils have an alloantigen that is targeted by a specific alloantibody in test serum. In microscopic immunofluorescence assays a fluorescence-conjugated secondary antibody is used to detect binding of a specific alloantibody to its target alloantigen or autoantibodies to target antigens on neutrophils. Genotyping assays using polymerase chain reaction (PCR) techniques are replacing agglutination or immunofluorescence assays in humans to identify many of the major neutrophil antigens.[57] Similar assays are not available for veterinary species. Monoclonal-antibody capture assays have been developed to detect antibodies to specific HNAs.[56] Flow cytometry is used to phenotype neutrophils in humans and animals.[11,49,54,56,57] It is limited by the availability of mononclonal antibodies that specifically target the antigens of interest. Flow cytometry is also used to identify anti-neutrophil antibodies in animals, but specific target antigens have not been identified.[62] Further discussion of methods to detect anti-neutrophil antibodies is found in Chapter 140.

TABLE 93.1 Human Neutrophil Antigens and Associated Disorders

Antigen Location	CD Designation	Antigen System	Clinical Conditions in People Associated with Antibody-Antigen Interactions[a]
FcγRIIIb	CD16b	HNA-1	Neonatal alloimmune neutropenia, primary IMN, TRALI, drug-induced neutropenia
NB1 glycoprotein	CD177	HNA-2	Primary IMN, drug-dependent neutropenia, TRALI
70-,96-kDa protein		HNA-3	Neonatal alloimmune neutropenia, TRALI, febrile transfusion reaction
MAC-1; CR3	CD11b	HNA-4	Neonatal alloimmune neutropenia, primary IMN
LFA-1	CD11a	HNA-5	Unknown

[a]IMN, immune-mediated neutropenia; TRALI, transfusion-related acute lung injury.

CLINICAL DISORDERS ASSOCIATED WITH NEUTROPHIL ANTIGENS

In humans, clinical conditions associated with alloantibody interactions include neonatal immune neutropenia, transfusion-related acute lung injury (TRALI), alloimmune neutropenia after bone marrow transplantation, refractoriness to granulocyte transfusions, and febrile transfusion reactions.[8,10,57] Febrile transfusion reactions occur when the recipient has alloantibodies directed against antigens present on the donor leukocytes. Febrile transfusion reactions can be minimized by removing leukocytes from RBC and platelet components.[8] TRALI occurs when alloantibodies to HLA antigens or neutrophil specific antigens cause neutrophils to become entrapped in the pulmonary vasculature.[57] Binding of alloantibodies to neutrophil antigens also cause functional defects, such as impaired adhesion and altered respiratory burst.[8,48]

Disorders associated with alloantibody production are not commonly recognized in veterinary species. Neonatal neutropenia is rare but occurs in pigs and foals.[13,33] It occurs when the dam has been previously exposed to paternal antigens found on the fetal neutrophils and produces alloantibodies that are passed to the fetus in utero or to the neonate following ingestion of colostrum. Febrile reactions in dogs following transfusion of platelet concentrates have been associated with leukocyte contamination.[1] Additional discussion of transfusion reactions is found in Chapters 97 and 100.

In humans autoantibody production is implicated in the pathogenesis of primary IMN, secondary IMN, drug-dependent neutropenia, and autoimmune neutropenia after bone marrow transplantation.[8] The cause of the autoantibody production is unknown in primary IMN. Studies in humans have implicated antibodies targeting FcγRIIIb (anti-HNA-1a and anti-HNA-1g) in many patients.[10] Secondary IMN is associated with systemic immune-mediated disorders, infectious diseases, neoplasia, bone marrow or stem cell transplants, kidney transplants, and drug therapy.[10] The antigenic target in secondary IMN is often unknown. Antibodies bind to antigens on neutrophils and lead to premature neutrophil removal by macrophages. In some cases autoantibodies target antigens on hematopoietic precursor cells in the bone marrow leading to myeloid hypoplasia. Patients may also have defective neutrophil phagocytosis, as well as concurrent thrombocytopenia or hemolytic anemia. Diagnosis often depends on identification of anti-neutrophil antibodies using agglutination, monoclonal antibody capture assays, immunofluorescence or flow cytometric assays.[10,21,62]

Immune-mediated neutropenia is infrequently reported in veterinary species.[7,45] Antibodies generally target antigens on circulating neutrophils, but bone marrow directed immune response causing white cell aplasia has been reported.[63] IMN is suspected when an animal has unexplained neutropenia that is responsive to immunosuppressive drugs. Identification of anti-neutrophil antibodies is supportive, but the diagnostic assays required to detect these antibodies are often not performed due to limited availability.[45] Anti-neutrophil antibodies have been identified in dogs with IMN, but the specific target antigen has not been identified.[60,62] Drug associated neutropenia is rarely reported. Anti-neutrophil antibodies have been identified in neutropenic dogs receiving an antipsychotic drug or cephalosporin.[4,35]

Antibodies to neutrophil isoantigens have been identified in human neonates born to mothers who had neutrophils deficient in FcγRIIIb.[18] Although not reported, a similar disorder is possible in dogs or cattle with leukocyte adhesion deficiency syndrome, a deficiency of membrane CD11/CD18 complex.[50]

PLATELET ANTIGENS

In humans platelet antigens commonly implicated in immunologic disorders are those in the HLA system and the human platelet antigen (HPA) systems (Table 93.2). HLA antigens are widespread in distribution and found on many different cell types. HPA antigens are found predominantly on platelets, though some are expressed on other blood cells.[41] The HPA antigens are located on membrane GPs and include $GP\alpha_{IIb}\beta_3$ (IIbIIIa), GPIb/IX/V, $GP\alpha_2\beta_1$ (GPIa/IIa) and CD109.[14,16,40,41]

TABLE 93.2 Human Platelet Antigens and Associated Disorders

Antigen Location Site	CD Designation	Human Antigen Systems	Clinical Conditions Associated in People with Antibody-Antigen Interactions[a]
$GP\beta_3$	CD61	HPA-1, HPA-4, HPA-6, HPA-7, HPA-8, HPA-10, HPA-11, HPA-14, HPA-16w	Neonatal alloimmune thrombocytopenia; PTP; primary IMT
$GPIb_\alpha$	CD42b	HPA-2	Primary IMT
$GP\alpha_{IIb}$	CD41	HPA-3, HPA-9	Neonatal alloimmune thrombocytopenia; PTP; primary IMT
GPIa	CD49b	HPA-5, HPA-13	Neonatal alloimmune thrombocytopenia; PTP; primary IMT
$GPIb_\beta$	CD42c	HPA-12	Primary IMT
CD109	CD109	HPA-15	Neonatal alloimmune thrombocytopenia; PTP; refractoriness to transfusion

[a]IMT, immune-mediated thrombocytopenia; PTP, post-transfusion purpura.

$GP\alpha_{IIb}\beta_3$ (CD41/CD61) is an integrin that is critical for platelet aggregation. Following activation, $GP\alpha_{IIb}\beta_3$ undergoes a conformational change that allows binding to adhesive proteins such as fibrinogen and von Willebrand factor (VWF). Glanzmann's thrombasthenia, a functional or physical deficiency of $GP\alpha_{IIb}\beta_3$, is found in humans, dogs, and horses. Affected individuals have a bleeding disorder characterized by impaired platelet aggregation.[5,12] The $GP\alpha_2\beta_1$ complex is a collagen receptor. Alterations in this receptor cause impaired adhesion to collagen and impaired collagen induced aggregation.[40,42] The GPIb/IX/V complex binds to VWF and plays an important role in platelet adhesion to the vessel wall under high shear-stress conditions.[14] An inherited functional or physical deficiency of GPIb/IX, termed Bernard-Soulier syndrome, is found in humans and is associated with thrombocytopenia, giant platelets, and functional defects.[42] The role of CD109 is not clear. It is detected on activated platelets and may be involved in cell communication.[16]

The HPA alloantigens have been characterized at the molecular level. Most result from a single amino-acid substitution resulting from a single nucleotide change. The frequency of the different alloantigens varies in different ethnic populations.[40,41]

These major platelet GPs appear to be conserved between the species, though the number of different alloantigens and their role in immunologic disorders in veterinary species is unknown.[12,34,38] Monoclonal antibodies are used to identify platelet antigens in a number of species. The association between antigens recognized by the monoclonal antibodies and the antigens associated with disease is not known. Monoclonal antibodies against human or porcine CD41 ($GP\alpha_{IIb}$), CD42a (GPIX) and CD61 ($GP\beta_3$) bind to canine and equine platelets.[2,36,49] Monoclonal antibodies to porcine or ruminant CD41/CD61 ($GP\alpha_{IIb}\beta_3$) bind to bovine, porcine and equine platelets.[36,43,51] Monoclonal antibodies against human CD61a and CD62P (P-selectin) bind to bovine platelets.[54] Monoclonal antibodies against human GPIb react with feline platelets.[58] Canine GPIb α was cloned and is 82% identical with the human sequence in the carboxyl-terminus.[22] The nucleotide sequence of canine $GP\beta_3$ is 92% homologous with the human sequence.[34]

Laboratory Techniques to Identify Platelet Antigens and Antigen-Antibody Interactions

Platelets are commonly typed in people for purposes of platelet transfusion. Serologic phenotyping is generally limited to HPA-1a and HPA-5b because of limited availability of reliable alloantibodies to other alloantigens.[40] Agglutination tests similar to those used to phenotype neutrophils are not reliable for platelets, and platelet phenotyping more commonly utilizes immunoblotting or immunoprecipitation techniques.[16] Flow cytometry is used in human and veterinary medicine but is limited by the availability of reliable monoclonal antibodies.[40] Genotyping using PCR techniques to identify platelet antigens has become standard practice in human medicine.[20]

No single test has proven sufficient to detect anti-platelet antibodies in humans.[53] Available techniques include platelet immunofluorescence assays, flow cytometry, or monoclonal antibody-specific immobilization of platelet antigen assays. Immunofluorescence, flow cytometry and immunopreciptation have been used to measure anti-platelet antibodies in veterinary species.[23,25,30,50] Detection of anti-platelet antibodies is further discussed in Chapters 78 and 140.

Clinical Disorders Associated With Platelet Antigens

Clinical disorders associated with platelet alloantigens are most commonly associated with the ability of alloantigens to induce an immune response; however, polymorphisms in the platelet receptors that occur with the different alloantigens may also cause altered function.[40] Though conflicting results have been reported, studies suggest that some alloantigens in the HPA-1 system are associated with increased platelet reactivity and increased risk for coronary heart disease and stroke.[14]

The binding of autoantibodies and alloantibodies to platelet GPs often causes platelet destruction and thrombocytopenia. These antibodies may also cause platelet inhibition and increased risk for bleeding or platelet activation and increased risk for thrombotic disorders. Functional defects may be present independent of any associated thrombocytopenia.[15] One study suggested that platelets from dogs with IMT have impaired platelet function due to circulating antibodies.[26] Platelet aggregation was inhibited in mule foals with neonatal alloimmune thrombocytopenia, possibly due to alloantibody competition with collagen binding sites.[46]

In humans, disorders associated with alloantibody production include neonatal alloimmune thrombocytopenia, post-transfusion purpura (PTP), and refractoriness to platelet transfusions.[41,47] Neonatal alloimmune thrombocytopenia occurs when the mother produces alloantibodies against a paternal alloantigen expressed on fetal platelets. The majority of human cases are associated with an alloantibody against fetal $GP\beta_3$ (HPA-1a). Alloantibodies against fetal GPIa (HPA-5a), CD109 (HPA-15b), or $GP\alpha_{IIb}$ (HPA-3a) are less commonly implicated.[47] Neonatal alloimmune thrombocytopenia has been described in pigs, horses, and mules.[17,44,46] The specific target alloantigen was not identified in any of these reports.

Post-transfusion purpura is a rare condition that occurs 5–12 days after an individual receives a blood transfusion. It is most common in HPA-1a negative women who have been previously sensitized by prior transfusion or pregnancy. Other platelet specific antigens or HLA antigens have been less frequently implicated. The immune response causes the destruction of the individual's own platelets, as well as the transfused platelets.[41] PTP has been described in dogs and pigs; however, an association with a specific alloantigen has not been identified.[32,61]

Platelet refractoriness occurs in humans who receive multiple platelet transfusions. These individuals

produce alloantibodies that result in shortened survival of the transfused platelets. Anti-HLA antibodies are most commonly implicated; however, anti-HPA antibodies are found in a minority of individuals.[41] Platelet refractoriness has been experimentally reproduced in dogs.[52]

The pathogenesis of IMT is covered further in Chapter 78. Briefly, IMT occurs when antibodies bind to platelet antigens and cause premature destruction of platelets by the mononuclear phagocytic system or lysis in a complement-dependent manner.[24,65] Recent studies also implicate direct T cell mediated cytotoxicity and impaired megakaryopoiesis and thrombopoiesis in the pathogenesis of the thrombocytopenia.[55] In humans, the target antigens are most commonly located on $GP\alpha_{IIb}\beta_3$.[65] Other targets include specific regions on GPIb/IX, GPIV, and $GP\alpha_2\beta_1$.[24] Antibodies to multiple antigens are found in many patients.[55]

Cryptic epitopes, particularly involving $GP\alpha_{IIb}\beta_3$, have been implicated in both initiation and perpetuation of thrombocytopenia in humans with IMT.[65] These epitopes are normally hidden but may become exposed and initiate an immune reaction following an insult, such as an infection. Exposure of cryptic antigens is also involved in EDTA-dependent pseudothrombocytopenia in humans. EDTA binds calcium which causes a conformational change in $GP\alpha_{IIb}\beta_3$, exposing normally hidden epitopes which bind to circulating antibodies. EDTA-dependent psuedothrombocytopenia has been rarely reported in dogs, horses and pigs. The underlying mechanism in these veterinary species has yet to be determined.[64]

Immune-mediated thrombocytopenia is commonly diagnosed in dogs and sporadically identified in other species. In primary IMT the immune response is directed against autoantigens and an underlying disease is not identified. In secondary IMT the immune response is associated with an underlying disorder (e.g. systemic immune-mediated disease, infection, neoplasia). The antibodies can be directed against either autoantigens, foreign antigens absorbed to platelet membranes, or altered platelet antigens. Platelet surface associated antibodies have been demonstrated in dogs, cats, and horses with IMT.[23,25,30,39] In most veterinary cases the target antigens on the platelet membrane are not identified. $GP\alpha_{IIb}\beta_3$ and GPIb were identified as target antigens in some dogs with a clinical diagnosis of primary IMT.[30]

Isoantibodies have been detected in humans with an inherited deficiency of platelet membrane antigens. Humans with Glanzmann's thrombasthenia produce isoantibodies following transfusion of platelets from normal individuals.[37] The isoantibodies appear to target epitopes on β_3 or intact $\alpha_{IIb}\beta_3$, leading to inhibited function and rapid removal of the transfused platelets. Although not reported, similar responses could occur in animals with inherited membrane GP deficiencies.[50]

Acronyms and Abbreviations

ACD, acid citrate dextrose; APS, anticoagulant-preservative solution; AS, additive solution; CPD, citrate-phosphate-dextrose; CP2D, citrate-phosphate(2)-dextrose; CPDA-1, citrate-phosphate-dextrose-adenine-1; EBV, estimated blood volume; FFP, fresh-frozen plasma; FP, frozen plasma; FWB, fresh whole blood; Hgb, hemoglobin; MAP, mean arterial pressure; PCV, packed cell volume; pRBCs, packed red blood cells; PC, platelet concentrate; PRP, platelet-rich plasma; RBC, red blood cell; RT, room temperature; WB, whole blood.

BLOOD BANKING – INTRODUCTION

The advent of large-scale veterinary blood banks has made the practice of high-quality transfusion medicine possible by increasing availability of blood components. Strict adherence to blood collection, processing, and storage guidelines is essential to providing safe and effective transfusions. This chapter details the currently accepted blend of human protocol and veterinary modifications where necessary for the collection, processing, and storage of canine and feline blood components.

DONOR CONSIDERATIONS

Canine

Veterinary blood banks currently use resident dogs, client-owned dogs, or a combination of the two to meet supply demands. Because human blood packs are used to collect blood, a standard donation is one unit of blood (450 ± 45 mL). Based on an estimated blood volume (EBV) of 85 mL/kg body weight[15] and a recommended collection volume of 15–22% EBV,[11] the maximum donation volume is approximately 19 mL/kg. In a study evaluating changes in systolic blood pressure in 19 Greyhounds (27–41 kg) after donating 450 mL blood, the mean systolic pressure dropped from 145 to 134 mmHg, not a clinically relevant decrease.[11] Recommended minimal donor body weight varies among veterinary blood banks from 23 to 27 kg, with dogs of this size able to donate a unit as often as every 3–4 weeks without need for nutritional supplementation.[21] Donor blood-type issues are discussed in Chapters 92 and 100.

For the safety of both the blood donor and recipient, the health of a dog is evaluated prior to enrollment as a donor and then annually through a complete medical history, physical examination, and laboratory evaluation including a hemogram, serum biochemistry profile,

and infectious disease screening. In addition, a brief history, physical examination, and measurement of packed cell volume (PCV) or hemoglobin (Hgb) concentration is performed prior to each blood donation; donor PCV or Hgb concentration should be at least 40% or 13 g/dL, respectively. Donors should be current on vaccinations and maintained on heartworm prevention and flea and tick control. Most other drugs are unacceptable for use during the donation period because of unknown effects on blood quality and potential for adverse reactions in the recipient.

Minimal screening for infectious diseases based on the American College of Veterinary Internal Medicine Consensus Statement is recommended if there is risk for exposure.[30] These diseases include *Babesia canis* and *B. gibsoni*, *Leishmania* spp., *Ehrlichia canis* and other *Ehrlichia* spp., *Anaplasma* or *Neorickettsia* spp., and *Brucella canis*. Donors should be excluded based on a positive serologic test for a vector-borne disease. Serologic negative donors may be further screened by polymerase chain reaction assays. Screening for *Trypanosoma cruzi*, *Bartonella vinsonii* and hemotropic *Mycoplasma* spp. may also be considered. Exclusion from a blood donor program does not imply that the animal should be treated for the disease.

Prior transfusion is considered an exclusion criterion for dogs to become blood donors. Following a blood transfusion dogs may develop antibodies against foreign red blood cell (RBC) antigens, resulting in an increased risk of incompatibility reactions to their plasma. Previous pregnancy has long been considered an exclusion criterion in the event that a dog negative for a specific RBC antigen becomes sensitized by her pups positive for that antigen. This risk should be minimal considering the zonal placentation of dogs, and there is little evidence to support this exclusion criterion.[5]

Feline

Because cats typically require sedation for blood collection, most blood banks rely on resident cats. The estimated blood volume of a cat varies according to the reference, ranging from 40 to 60 mL/kg in the anesthetized cat[12] to as high as 67 mL/kg.[24] Donation volume should be calculated based on lean body weight; recommendations for *maximum* donation range from 11 to 15 mL/kg, and standard volumes collected (including anticoagulant) range from 50 to 70 mL.[1,13,14] In one study of 26 cats (5–8 kg), blood pressure was measured before and after donation of a 50 mL unit using sevoflurane anesthesia; mean arterial pressure (MAP) decreased from 87 mmHg (range 59–127 mmHg) to 71 mmHg (range 44–116 mmHg).[14] In another study with eight cats (4.0–6.5 kg) sedated with butorphanol, acepromazine, ketamine and diazepam, MAP dropped from 108 mmHg (range 80–140 mmHg) to 53 mmHg (range 20–100 mmHg) after collection of a 50 mL unit.[4] No cats in either study showed effects of hypotension upon recovery. However, in the second study, when the same volume was drawn in awake or mildly sedated cats through vascular access ports, two cats exhibited transient distress, including vocalization, vomiting, and defecation.[4] This is in contrast to another study of four awake cats using vascular access ports where no signs of hypotension were noted with donations of 10 mL/kg.[20] In the authors' experience cats donating less than 11 mL/kg are less likely to have hypotension-related problems. Most blood banks give donors supplemental iron. Assuming a similar mean concentration of 0.5 mg iron/mL blood in cats as in humans, a 60 mL donation represents a loss of 30 mg of iron. This may be replaced with 150 mg oral ferrous sulfate, typically divided into several doses in between donations and adjusted based on pre-donation PCV.

Initial and pre-donation health assessment and health maintenance are similar to canine donors. Donor PCV or Hgb concentration should be at least 30% or 10 g/dL, respectively. Feline donors should be kept indoors to minimize the risk of infectious disease transmission. Cats testing positive for feline leukemia virus and feline immunodeficiency virus by enzyme-linked immunosorbent assay and for hemotropic *Mycoplasma* spp. by cytology or polymerase chain reaction test should not be used as donors.[30] Screening for *Cytauxzoon felis* and rickettsial diseases may be considered based on exposure risk. As with dogs, exclusion from a blood donor program does not imply that the cat should be treated for the disease. In addition, one must consider the potential ramifications of false-positive results for feline viral infections, namely unwarranted euthanasia.

BLOOD COLLECTION PRINCIPLES

Blood is collected as whole blood (WB) and then separated into components by centrifugation. Alternatively, single components may be collected by apheresis. For optimal quality, WB is collected into commercially available, sterile, airtight systems that allow for subsequent processing and storage of components without exposure to the environment. These systems, known as closed systems, prevent exposure of blood components to air except when the component unit is entered with an administration set for transfusion. Conversely, an open system has one or more additional sites of entry and possible bacterial contamination, such as occurs when preparing for blood collection into syringes, acid-citrate-dextrose (ACD) bottles, or bags to which anticoagulant is added after manufacture. Components prepared from blood collected into an open system are not intended for storage. If an open collection system is used, the American Association of Blood Banks and Council of Europe advise that RBC products (stored at 1–6 °C) should be used within 24 hours and platelet products (stored at 20–24 °C) should be used within 4 hours.[6,10] The shelf-life of plasma from an open system is unaffected if it is frozen within 8 hours.[6,10] Throughout the following sections, processing and storage will refer to closed systems unless otherwise specified. Detailed illustrated methods of blood collection and processing

have been previously described and will be summarized here.[1,19,23]

BLOOD COLLECTION SUPPLIES

Canine

Commercial 450 mL collection bags manufactured for human blood banking are used for canine donations. These contain an anticoagulant-preservative solution (APS) and a sterile collection line with a 16-gauge thin-walled needle attached to the bag. The bags are available in a variety of configurations consisting of a primary collection bag with attached satellite bags (0 to 4). These satellite bags, some of which may contain RBC nutrient additive solutions (AS), are used for the separation of components as discussed later. After centrifugation and removal of plasma from the main collection bag, the nutrient AS is added to the packed red blood cells (pRBCs). Various AS are composed of saline, adenine, and dextrose ± mannitol ± citrate-citric acid, and are intended to extend the shelf-life of stored pRBCs. There are several APS and AS available that allow storage of canine pRBCs for approximately 1 month (Table 94.1).

Collection bags are available in a variety of sizes (150 mL, 250 mL, 350 mL, and 500 mL) and contain the appropriate amount of APS and AS. Another option for collection of <450 mL WB is to transfer the unwanted portion of the APS from the primary bag of a 450 mL pack into an empty satellite bag, which is later discarded. This allows collection of proportionately smaller units in a closed system without excessive concentration of anticoagulant; the desired ratio of APS to blood is 1.4:10.[6]

Feline

Closed collection systems designed specifically for feline blood donation are not currently commercially available. However, a feline closed collection system has been prepared by sterilely docking an 18-gauge apheresis needle (SysLoc Safety A.V. Fistula Needle Set, JMS, Singapore) to a 75 mL pediatric transfer pack (Pedi-Pack, Genesis BPS, Hackensack, NJ) containing APS using a commercial sterile tubing welder (Terumo, Elkton, MD).[25]

Current open collection systems for cats involve collecting blood by jugular venipuncture using a 19-gauge butterfly needle attached to a syringe or collection bag. The systems are open because APS must be transferred using a syringe and needle from a multi-use container to the collecting syringe or bag. The APS used most often is citrate-phosphate-dextrose-adenine-1 (CPDA-1) at an APS:blood ratio of 1:7 (e.g. 7.5 mL CPDA-1 + 52.5 mL collected blood for a final volume of 60 mL). Open systems include: (1) collection into syringes for prompt transfusion of WB; (2) commercial 100 mL bags and collection tubing with attached butterfly needle for gravity collection; (3) attached three-way stopcock, 60-mL syringe and butterfly needle for syringe collection and subsequent transfer to bag (Animal Blood Resources International, Stockbridge, MI); and (4) collection into syringes (preferably 35 or 60 mL) and then careful injection (to avoid hemolysis) into a transfer pack, either 75 mL (Pedi-Pak), or 150 mL (Fenwal). If an open system for cats is used, care must be taken to maintain sterility where possible, especially if the blood or blood components are to be stored. Periodic culture of stored bags is also recommended as a quality control procedure.

Apheresis

During apheresis WB is fractionated and unwanted components are returned to the donor, permitting collection of a greater quantity of the desired component. Apheresis may be performed as an extension of WB donation, with repetitive donations, separation, and return of unwanted components to the donor. However, the use of automated processors that perform continuous and discontinuous flow centrifugation apheresis is preferred due to greater efficiency and improved quality of the blood component. Apheresis has been used

mostly for the collection of platelets in dogs and is discussed in Chapter 97.

PREPARATION AND COLLECTION OF WHOLE BLOOD

Canine

A full unit contains 450 mL of WB, but 10% variation (405–495 mL) is acceptable considering the volume of anticoagulant in the collection bag. The volume of collected blood is estimated by weight. The specific gravity of whole blood at 37 °C is 1.053, so an ideal unit weighs 474 g and the acceptable range is 426–521 g.[6,28] The minimum acceptable under-draw for blood to be used to prepare pRBCs is 300 mL (316 g), in which case the plasma is discarded as it contains excessive anticoagulant. Weight during collection may be determined by placing the bag on a scale or by using a rocker which automatically clamps the collection tube at the desired weight (e.g. Sebra, Tucson, AZ; Docon, MacoPharma, France).

The jugular vein is the only recommended site for routine blood donation. The authors' choice of position for the donor is lateral recumbency on a table, but sternal recumbency or sitting on a table or floor may be better in some circumstances. The venipuncture site is clipped and surgically prepared.

Blood may be drawn into collection bags aided only by gravity and donor blood pressure, in which case the bag should be continuously and gently rocked by an assistant during collection, which typically takes 5–15 minutes. Alternatively, light suction may be used, shortening collection time to 3–10 minutes. The blood collection bag is hung from a hook inside a clear cylinder with a flat lid (Animal Blood Resources International) such that the blood will be forced to pass through the APS. The collection line with attached needle is brought through a notch between the cylinder and lid, and a tube clamp is placed on the line near the needle. A vacuum source is connected via tubing to an inlet in the chamber. The cylinder is placed on a scale, the scale is tared to zero, and the suction is adjusted to –127 to –178 mmHg (–5 to –7 inches Hg).[16] With one hand, the phlebotomist puts gentle pressure on the jugular vein below the prepared skin site, and the needle held in the other hand is inserted through the prepared site into the donor's jugular vein in either direction. When the tubing clamp is removed, blood flows into the collection line to the bag as the scale measures the grams of blood collected. When the desired amount has been obtained, pressure is released from the jugular below the venipuncture site, the line is clamped, and the needle is removed from the vein as pressure is applied over the site.

During blood collection, the well-being of the donor should be constantly monitored. Mucous membrane color, pulse rate and strength, respiratory rate, and donor attitude are easily evaluated by the phlebotomist and assistant. Any indication of donor compromise is cause for discontinuation of the collection.

Once the needle is removed from the donor, the blood in the tubing is stripped into the bag using a tube stripper, and the bag is gently rocked to ensuring adequate mixing. The bag is then manually compressed to refill the tubing, which is sealed (using hand sealer clips or a thermal sealer) at several points to provide small segments containing WB for quality and compatibility testing.

Feline

Sedation/anesthesia is usually achieved using ketamine and midazolam (ketamine 10 mg/kg + midazolam 0.2 mg/kg IM, or ketamine 2 mg/kg + midazolam 0.1 mg/kg IV) or sevoflurane by facemask.[27] Premedication may be given with butorphanol (0.4 mg/kg IM). The cat is positioned in lateral (preferred by authors due to steadiness) or sternal recumbency, and the jugular venipuncture site is prepared as for the dog. If a syringe or vacuum chamber is used, only gentle suction (–76 mmHg [–3 inches Hg]) is applied to avoid collapsing the vein or causing hemolysis. Blood collection is typically completed within 3–5 minutes. Careful monitoring of the cat is essential because hypotension may be encountered despite all precautions, and oscillometric monitoring should be considered. Some blood banks routinely give donors intravenous and/or subcutaneous saline at a total dose of 2–3 times the volume of blood drawn, while others only treat the donors if hypotension or signs of hypotension occur. However, collection of smaller volume units (≤50 mL) to reduce the risk of hypotension is safer for the donor and may obviate the need to supplement with fluids. Vascular access ports have been evaluated for donation to avoid anesthesia.[4,20]

SEPARATION OF WHOLE BLOOD INTO COMPONENTS

A flowchart for the separation of fresh whole blood (FWB, less than 8 hours old) by centrifugation is presented in Figure 94.1. Separation requires a large capacity, floor-model, swing-bucket, temperature-controlled centrifuge.

Canine Packed Red Blood Cells and Plasma

Standard separation of canine FWB into pRBCs and fresh plasma is begun by centrifugation of the blood bags at 5000 × *g* for 5 minutes at 4 °C. The centrifugation time includes acceleration time but not deceleration time. To transfer the plasma to a satellite bag, the primary bag is placed in a plasma extractor, and the seal in the tubing of the primary bag is broken. The plasma extractor is slowly engaged and allowed to gently squeeze the primary bag, which expresses the plasma into the satellite bag. Plasma may be transferred entirely to one satellite bag or divided between two or three bags. Expression of plasma is stopped by clamping the tube. If the pRBCs are to be stored in CPDA-1 without

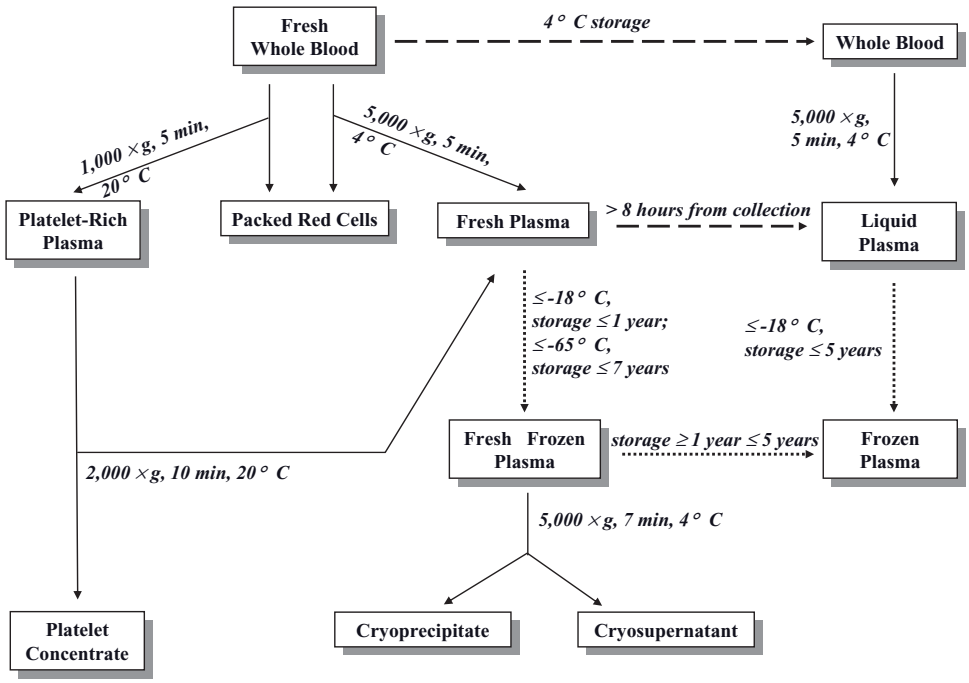

FIGURE 94.1 Flowchart for separation of canine fresh whole blood into components. (Adapted from Abrams-Ogg ACG. Practical blood transfusion. In: Day M, Mackin A, Littlewood J, eds. BSAVA Manual of Canine and Feline Haematology and Transfusion Medicine. Gloucester: British Small Animal Veterinary Association. 2000;263–303, Fig. 15.19, with permission.)

an AS, the pRBCs must have a PCV ≤ 80%. This requires leaving ≥50 mL of plasma with the pRBCs, which may be accomplished by stopping the expression of plasma when the buffy coat/plasma interface is about 2 cm from the top of the bag. If the pRBCs are to be stored in citrate-phosphate-dextrose (CPD) or CP2D (which contains twice as much dextrose as CPD) with an AS, all of the plasma may be removed from the pRBCs, as the AS will provide the pRBCs with the necessary fluid and nutrients. Once the plasma has been removed to one or more satellite bags, the AS is added to the pRBCs. The seal in the tubing to the AS bag is broken, and the solution is transferred into the primary bag by gravity and gently mixed. If desired, half of the pRBCs can then be transferred to an additional empty satellite bag if available to prepare half-units. The tubing attached to each component bag is then sealed.

Each bag of component is weighed and the weight of the component calculated by subtracting the weight of the bag. Volumes of plasma and pRBCs at room temperature (RT) are then estimated by dividing by 1.026 and 1.056, respectively.[28] (These values are for humans, and specific gravity varies with temperature, PCV, and protein concentration, but effects on volume estimates are clinically negligible.) Each component bag is labeled as to product, blood type, donor, volume, and dates of collection and expiration.

Fresh plasma contains albumin, globulins, and maximum possible quantities of all coagulation factors. If this plasma is stored below –18 °C within 8 hours of collection, it is labeled fresh-frozen plasma (FFP). If the plasma is not placed in a freezer within 8 hours of collection, it may still be frozen and labeled frozen plasma (FP). There are negligible differences between FFP and FP with respect to albumin, globulins and α-macroglobulins, vitamin-K dependent factors, and antithrombin.[6] Plasma products are discussed further in Chapter 96.

Canine Cryoprecipitate and Cryosupernatant

Once frozen, FFP may be further processed into cryoprecipitate and cryosupernatant, also referred to as cryopoor plasma and cryoprecipitate-reduced plasma. When separating plasma from FWB with the intention of further processing into cryoprecipitate, the plasma is transferred into a satellite bag and another empty satellite bag is left attached via tubing. The tubing connecting the two is temporarily obstructed by folding and securing with a rubber band. The two bags are frozen together in a cardboard plasma box. After freezing, the unit is slowly thawed in a refrigerator at 1–6 °C. When the unit reaches a slushy consistency, it is centrifuged at 5000 × *g* for 7 minutes and all but 10–15 mL of the supernatant plasma (cryosupernatant) is transferred to the empty bag, leaving the precipitate (cryoprecipitate) and small amount of plasma in the first bag. The bags are separated, sealed, labeled and immediately refrozen. Cryoprecipitate contains von Willebrand factor, factor VIII, fibrinogen, fibronectin, and factor XIII and is primarily indicated in the management of bleeding in dogs with von Willebrand disease and hemophilia A (see Chapter 96).

Canine Platelet-rich Plasma and Platelet Concentrate

Fresh whole blood can also be separated into platelet-rich plasma (PRP) and pRBCs. The FWB may be

allowed to rest for 1 hour after collection to minimize platelet activation, and the bag should be gently massaged before centrifugation to re-suspend platelets.[17] Centrifuge temperature should be set at 20 °C. Centrifugation to make PRP uses lighter gravitational forces than for standard separation of pRBCs and plasma, and isolates the platelets in the plasma above the buffy coat. When the PRP is expressed into the satellite bag, expression should be stopped when the RBC-plasma interface is 1 cm from the top of the bag to minimize leukocyte and RBC content of PRP while not sacrificing platelet yield.[7] One unit of FWB (450 ± 45 mL) yields 1 unit of PRP.

Percent platelet yield (platelets in PRP/platelets in FWB × 100) and PRP platelet count vary with the donor, donor platelet count, blood volume being centrifuged, technician, centrifuge, and centrifugation protocol. In a study comparing protocols to make PRP from small volumes of canine blood, protocols with shorter centrifugation times and higher gravitational forces had better yields than protocols with longer times and lower forces.[8] Most current blood bank protocols use about 1000 × *g* for 4–6 minutes or 2000 × *g* to 2500 × *g* for 2.5–3 minutes.[2] The brake on the centrifuge should be turned to a low setting or turned off. In the protocol used by the authors (1000 × *g* for 4 minutes), average yield is about 80% (range 35–97%), resulting in a mean of 6×10^{10} platelets/unit (range 3×10^{10} to 10×10^{10} platelets/unit).[2,3] A second centrifugation of the FWB can be used to increase yield, and is particularly useful with greyhounds which have low normal platelet counts (W.J. Dodds, personal communication).

Platelet concentrate (PC) may be prepared by centrifugation (2000 × *g* for 10 minutes) of PRP to pellet the platelets. The platelet-poor plasma (PPP) is expressed, leaving 35–70 mL of plasma and the platelet pellet behind in the satellite bag. The resulting PC is left undisturbed for 60–90 minutes to promote disaggregation. Gentle manual kneading and agitation are then used to disperse macroscopic leukocyte-platelet aggregates and re-suspend the platelets. The PPP may be used as fresh plasma or FFP. One unit of PRP yields 1 unit of PC. Units of PC can be pooled via transfer tubing. The pooled units are centrifuged at 570 × *g* for 15 minutes and PPP is expressed, leaving behind 8–10 mL per unit pooled. Once pooled, the concentrate needs to rest for at least 15 minutes at room temperature, prior to resuspension (K.J. Wardrop, personal communication).

Feline Blood Components

Feline FWB is placed in one bag, and the tubing between this bag and an empty satellite bag is obstructed by folding and securing with a rubber band or a hand sealer clamp. Due to the relatively small volume of blood being separated, the collection/satellite bags may be bound (via rubber band or tape) to a 500 mL bag of saline to prevent the bags from collapsing during centrifugation. The blood bags are centrifuged at 3000 × *g* for 10 minutes at 4 °C, and separation is continued as for dogs. The pRBCs may be stored without addition of AS (in which case 10 mL 0.9% sodium chloride is added just prior to administration to the patient), or 10 mL AS may be added to pRBCs prior to storage.

Feline PRP is rarely prepared due to a limited clinical need, as well as technical challenges; FWB is more likely to be administered to thrombocytopenic or thrombopathic cats with severe bleeding. However, preparation of feline PRP has been described, with the transfused platelets exhibiting in vivo efficacy.[8,9]

STORAGE

Red Blood Cell Products

Units of WB and pRBCs are stored at 1–6 °C. A refrigerator with an alarm to indicate unsafe temperatures is ideal. Alternatives include a regularly-checked thermometer placed in a container of fluid the volume of a small unit and HemoTemp II blood bag thermometer labels (Biosynergy, Elk Village, IL).

Red blood cell viability and function decrease during storage as a result of physical and metabolic changes collectively known as the *storage lesion* (see Chapter 95). Shelf-life is defined as the number of days after collection, assuming proper closed system collection and storage, at which 75% RBC viability is maintained.[6,10] Viability is measured as 24-hour post transfusion survival of radiolabeled or biotinylated RBCs.[29,31,32] Shelf-lives for canine pRBCs prepared in closed systems are summarized in Table 94.1.

Plasma Products

All plasma products should be stored at –18 °C or lower in a cardboard plasma box which protects the bag from breakage. A freezer with an alarm to indicate unsafe temperatures is ideal. The shelf-life of FFP is 1 year from collection if frozen at –18 °C (some countries specify –30 °C) and 7 years if frozen at or below –65 °C.[6] If a regular household freezer is used, exposure of the FFP to repeated freeze/thaw cycles will result in loss of the more labile plasma coagulation factors. Expired –18 °C stored FFP from dogs and cats may be relabeled as FP and stored for an additional 4 years.[19] Expired FFP is used primarily for treatment of hypoproteinemia and vitamin-K antagonist poisoning. The shelf-life of cryoprecipitate and cryosupernatant is 1 year from the date of collection, regardless of when during that year it was made from FFP.[6,19]

Platelet Products

Canine PRP and PC are most often produced on an as-needed basis. Current guidelines for human PC allow RT storage for 5–7 days, although there is increased risk for bacterial proliferation at RT storage.[26] The PCs are stored in plastic bags under continuous gentle agitation. The composition of the plastic bag, high surface area : volume ratio, and agitation facilitate gas exchange

and sustain aerobic metabolism, and thereby platelet viability. Canine PRP-derived PCs stored for 7 days at RT with to-and-fro agitation in polyolefin bags maintained platelet numbers, metabolic activity, and pH above 6.0, although there was progressive reduction in in vitro aggregation.[3]

QUALITY CONTROL

Units of pRBCs should be visually inspected during storage and prior to administration. The presence of murky, purple, brown, or red supernatant, RBC mass that appears purple in color, visible clots, or differences in color between the unit and the tubing segments gives reason to suspect bacterial contamination.[13,18]

Similarly, units of FFP should be inspected when issued for transfusion and discarded if cracks or leaks are noted.

Inadvertent thawing during storage may significantly reduce levels of factor VIII and von Willebrand factor, and allow for bacterial proliferation. In the absence of a freezer alarm or chart recorder, the following techniques may be used to detect inadvertent thawing and refreezing of a unit after its original freezing: (1) Store the plasma box initially laying flat in the freezer. After complete freezing, shift the box to sit on one end. Air bubbles present in the bag will move from the front edge to the upper edge of the bag if thawing occurs, and the unit will also be thicker on the lower edge. (2) Place a rubber band around the unit before freezing, so that it makes an indentation in the bag. After complete freezing, cut the rubber band. If thawing occurs, the indentation left by the rubber band will be less obvious or will vanish.

Acronyms and Abbreviations

BT, bleeding time; 2,3-DPG, 2,3-diphosphoglycerate; FFP, fresh frozen plasma; FWB, fresh whole blood; Hct, hematocrit; Hgb, hemoglobin; [Hgb], hemoglobin concentration; PCV, packed cell volume; pRBCs, packed red blood cells; RBC, red blood cell; SWB, stored whole blood; WB, whole blood; WBC, white blood cell.

The term red blood cell (RBC) transfusion includes administration of packed red blood cells (pRBCs), fresh whole blood (FWB), or stored whole blood (SWB). With a growing knowledge and expertise in veterinary transfusion medicine, as well as establishment of more commercial animal blood banks, the administration of pRBCs rather than whole blood (WB) has become more commonplace for treatment of anemia in dogs[4,11,24] and, more recently, cats.[5,12,17] Blood component therapy addresses a patient's specific transfusion needs while maximizing the use of a blood unit and decreasing potential adverse events associated with WB transfusion.

INDICATIONS

Red blood cell transfusions are indicated in the treatment of anemia caused by hemorrhage, hemolysis, or ineffective erythropoiesis. Because oxygen is poorly soluble in plasma, nearly all oxygen contained in blood is carried by hemoglobin (Hgb). Therefore, RBC transfusions increase the oxygen-carrying capacity of the anemic patient and thereby treat or prevent inadequate delivery of oxygen to tissues, with consequent tissue hypoxia. Hemorrhage (acute or chronic) was the major cause of anemia in 70% of dogs receiving RBC transfusions.[4,11] Blood loss anemia was also the most common indication (44–52%) for RBC transfusions in cats, followed by ineffective erythropoiesis (38%).[12,26]

Transfusion Threshold

The decision to administer a RBC transfusion is usually based on a measurement of the patient's packed cell volume (PCV), hematocrit (Hct), or Hgb concentration ([Hgb]) and, more importantly, on clinical evaluation of the patient. A "transfusion trigger" or threshold PCV below which a RBC transfusion is administered, has not been clearly defined in human or veterinary medicine. While for many years the standard transfusion threshold for a normovolemic anemic human patient was an Hct of 30% and [Hgb] of 10 g/dL, a more recent trend has been to lower this threshold.[13] In an analysis of 45 observational studies that assessed the independent effect of RBC transfusion on human patient outcomes, the risks of transfusion outweighed the benefits in 42 studies.[15] Acknowledging the inherent limitation in their analysis of cohort studies, the authors concluded that in adult, intensive care unit, trauma, and surgical patients, RBC transfusions are associated with increased morbidity and mortality and recommended an [Hgb] < 7 g/dL as a transfusion threshold for hemodynamically stable patients.[15] In a landmark multicenter, randomized, controlled clinical trial, the Transfusion Requirement in Critical Care (TRICC), "restrictive" and "liberal" RBC transfusion strategies in the management of 838 critically ill patients with [Hgb] < 9 g/dL were compared.[7] The "restrictive" group received blood when the [Hgb] fell below 7 g/dL to maintain the [Hgb] at 7–9 g/dL, whereas the "liberal" group received blood

to maintain the [Hgb] at 10–12 g/dL. Overall, the 30-day mortality was similar in both groups, but the mortality rate during hospitalization was significantly lower in the "restrictive" group, suggesting that a restrictive strategy of RBC transfusion is at least as effective as and possibly superior to a liberal transfusion strategy in critically ill patients.[7] In a recent review of RBC transfusion in human clinical practice, the following generalizations were made: (1) the physiology of oxygen delivery and clinical data indicate little need to transfuse patients with [Hgb] ≥ 10 g/dL; (2) at [Hgb] = 8–10 g/dL, the risk of hypoxic organ damage is low for most patients; and (3) patients with [Hgb] < 6 g/dL are usually at substantial risk, particularly if ongoing bleeding is a possibility.[13]

Currently, there are no clinical studies evaluating RBC transfusion threshold (or increased morbidity and mortality associated with RBC transfusion) in dogs and cats. However, it is well recognized that measurement of Hct, [Hgb], or PCV alone is an inadequate determinant of the threshold for RBC transfusion because many additional factors (e.g. cardiac output and oxygen consumption) are involved in adequacy of tissue oxygenation. Also, in patients with hypovolemic anemia, the PCV is falsely elevated: when the total blood volume normalizes because of an increase in the plasma volume, the PCV decreases. Animals with chronic anemia (e.g. anemia of chronic renal failure) typically better cope with a lower PCV than do animals with an acute onset of anemia (e.g. an acute blood loss or hemolytic crisis) because of cardiovascular and other compensatory mechanisms. Because many factors can influence the need for a RBC transfusion, it is imperative that clinical judgment, not PCV, be the ultimate factor in the decision to administer RBCs to a patient. Tachycardia, poor pulse quality, pallor, lethargy, weakness, and decreased appetite are important clinical signs and symptoms that may indicate that a patient may be in need of additional oxygen-carrying support.

Whole Blood Versus Packed RBCs

The majority of canine and feline blood collected at commercial blood banks and veterinary teaching hospitals is processed into pRBCs and fresh frozen plasma (FFP) (see Chapter 94).

Administration of pRBCs is appropriate in the medical management of anemia resulting from any cause, but whole blood (WB) transfusion may be considered in certain situations. By definition, FWB is blood that is less than 8 hours old from the time of collection and has not been refrigerated; therefore, FWB contains functional platelets, coagulation factors, and plasma proteins in addition to RBCs. Potential indications for FWB include anemia and a combined hemostatic disorder; anemia and thrombocytopenia or thrombopathia resulting in uncontrolled or life-threatening bleeding; and possibly massive transfusion. Stored whole blood is more than 8 hours old: the length of storage depends on the anticoagulant/preservative solution used and varies from 48 hours for 3.8% sodium citrate (no preservative) to 4 weeks for CPD-A1 (citrate, phosphate, dextrose, and adenine) (see Chapter 94). Stored whole blood contains plasma proteins and RBCs but not functional platelets or coagulation factors. A possible indication for SWB is anemia and hypoproteinemia (e.g. chronic gastrointestinal bleeding), although administration of pRBCs and, if there is a clinical need to increase the patient's oncotic pressure, a synthetic colloid or plasma would be appropriate. Given the loss of important blood components with storage, it is much more efficient to separate WB into pRBC and FFP than to store as WB. Also, in anemic patients with underlying cardiac disease, pRBCs would be clearly preferable to WB in an effort to avoid circulatory overload.

Fresh Versus Stored RBCs

Although storage of blood components allows for a readily available supply of RBCs for transfusion, it has been well-documented that during storage RBCs undergo a number of physical and chemical changes, collectively referred to as a "storage lesion," which reduce RBC function and viability after transfusion.[14] The effects of prolonged storage on RBCs include decreased deformability, which can impede microvascular flow; depletion of 2,3-diphosphoglycerate (2,3-DPG), which shifts the oxyhemoglobin dissociation curve to the left and reduces oxygen delivery; reduction in RBC ATP concentration, which may result in decreased phosphorylation of other proteins or lipid kinases important in maintaining RBC integrity; reduction in RBC-derived nitric oxide bioactivity, which may impair the vasodilatory response to hypoxia; and accumulation of proinflammatory bioactive substances.[1,14,16,21] Addition of various preservative solutions containing dextrose, adenine, and phosphate (substrates for RBC energy metabolism) improve RBC post-transfusion viability. A study of the effect of storage on canine pRBCs collected in citrate-phosphate-dextrose solution and resuspended in the additive solution Adsol (containing adenine, dextrose, saline, and mannitol) has documented a steady decrease in mean 2,3-DPG concentration from 15.2 µmol/g Hgb on day 1 to 3.7 µmol/g Hgb on day 44.[25] However, the decrease in 2,3-DPG concentration in stored human and presumably other animal RBCs is a reversible change, with complete restoration of 2,3-DPG levels post-transfusion taking up to 72 hours.[21] Decrease in RBC 2,3-DPG concentration with storage is not an issue when transfusing cats because feline RBCs contain very low levels of 2,3-DPG and feline Hgb does not require 2,3-DPG for release of oxygen.[3]

Experimental data in canine models have yielded conflicting results regarding oxygen delivery by fresh compared to stored RBCs. Although a diminished release of oxygen to tissue was demonstrated following administration of stored (21 days) RBCs compared with fresh RBCs in an isolated hind-limb model in the dog,[28] a study comparing the effects of administration of autologous stored (21 days) and fresh RBCs in restoring muscular tissue oxygenation after profound isovolemic

hemodilution in dogs did not reveal a difference in tissue oxygenation between the two groups at comparable [Hgb].[19] Currently, there are no clinical data in the dog to document increased morbidity or mortality associated with transfusion of stored rather than fresh RBCs.

There is considerable controversy in human medicine over recommendations for administration of "newer blood" (units stored for 14 days or less) in preference to "older blood" (units stored for more than 14 days). In a single-center, retrospective analysis of outcomes in 6,000 patients who had undergone coronary artery bypass grafting, valve surgery, or both, transfusion of "older blood" (median duration of storage 20 days) was associated with a significantly increased risk of postoperative complications, as well as reduced short-term and long-term survival.[14] On the other hand, a retrospective study evaluating age of transfused RBCs and early outcomes after similar cardiac surgeries in 901 patients found no correlation between duration of storage of RBCs and early adverse outcomes after cardiac surgery.[27] A review of nine clinical studies that evaluated the consequences of prolonged RBC storage suggested a possible detrimental clinical effect associated with transfusion of stored RBCs to critically ill patients.[21] However, one must consider that cardiac surgery and critically ill patients are not representative of all patients in need of RBC transfusions. In light of the consequences of shortening RBC storage time on the blood supply, both sides (for and against use of "older blood") agree that randomized clinical trials to evaluate the clinical consequences of transfusing older stored RBCs are required before changing blood banking standards for RBC storage time.

ADDITIONAL BENEFITS OF RBC TRANSFUSIONS

Enhanced hemostasis is an often overlooked benefit of RBC transfusions. A correlation between anemia and prolonged bleeding time (BT) has been reported in humans, and correction of the anemia results in shortening of the BT.[23] The effect of Hct on the volume of blood shed during a BT test can be dramatic: a reduction in Hct from 45% to 35% in normal, healthy humans resulted in a greater than two-fold increase in the volume of shed blood.[6] In a study evaluating the effect of Hct and platelet count on the BT measurement, healthy human volunteers underwent either a 2-unit RBC apheresis procedure followed by return of platelet-rich plasma from both units (resulting in a 15% reduction in the peripheral venous Hct and a 9% reduction in the platelet count) or a plateletpheresis procedure (resulting in a 32% decrease in platelet count and no change in peripheral venous Hct).[22] Interestingly, there was no change in BT following the plateletpheresis procedure, yet the RBC apheresis procedure resulted in a 60% increase in the BT, which was subsequently corrected by transfusion of RBCs.[22] Furthermore, the acute reduction in Hct following the RBC apheresis procedure was accompanied by a decrease in the shed blood thromboxane B_2 level at the template BT site, in agreement with results of in vitro studies showing that RBCs stimulate thromboxane production by platelets.[22] Other potential mechanisms for RBCs leading to an improvement in primary hemostasis include: dispersion of platelets from the center of the blood vessel toward the endothelial cells of the vessel wall, facilitating the platelet-vessel adhesion; shear stress-induced release of ADP, a platelet agonist, from RBCs; and scavenging of endothelial cell nitric oxide by oxidation and by nitric oxide binding to Hgb.[23] In light of the beneficial effects of RBCs on hemostasis, it has been recommended in human medicine that nonsurgical bleeding diatheses in anemic thrombocytopenic patients should be managed with RBC transfusions to increase the Hct to 35% prior to administering platelet transfusions.[23]

In addition to providing oxygen-carrying support and improving hemostasis, RBC transfusions are an excellent source of readily bioavailable iron, with 1 mL of pRBCs containing approximately 1 mg of iron. RBC transfusions, therefore, are of benefit in the initial treatment of patients with severe iron-deficiency anemia. However, repeated RBC transfusions to patients with anemia due to causes other than continuous blood loss may place them at risk for developing hemochromatosis, which manifests clinically as organ dysfunction secondary to iron-induced injury. There is a single case report of transfusional hemochromatosis in a dog with pure RBC aplasia that received RBC transfusions every 6–8 weeks for 3 years.[18]

ADMINISTRATION

Careful attention to administration is essential to prevent damage of the blood product and harm to the patient. Prior to a RBC transfusion, blood typing and/or crossmatching should be performed to assure RBC compatibility (see Chapter 139). Segments of tubing from the donor blood bag may be used for the blood crossmatch and for quality control and investigation of transfusion reactions (see Chapter 100).

Canine pRBCs stored in a RBC preservative solution such as Adsol can be administered directly, whereas other pRBC products should be diluted by adding 100 mL of saline to the blood bag (or 10 mL of saline to feline pRBCs), thus decreasing the viscosity of the donor blood. Concurrent administration of any drugs or fluids other than physiologic saline through the same catheter should be avoided to prevent blood coagulation and lysis of RBCs induced by contact with calcium-containing solutions and hypotonic solutions, respectively.

Warming of Blood

In the routine administration of RBC products to normovolemic anemic patients, refrigerated blood components do not require warming prior to transfusion; in fact, warming may accelerate the deterioration of stored RBCs and may permit rapid growth of contaminating microorganisms.[9] However, in patients that are hypo-

thermic or receiving large volumes of blood, refrigerated RBC products should be prewarmed to temperatures between 22 °C and 37 °C immediately before transfusion to prevent exacerbation or development of hypothermia, the consequences of which may include cardiac arrhythmias and coagulopathies.[9] Several types of blood warmers are available: thermostatically controlled waterbaths, dry heat devices with electric warming plates, and high-volume countercurrent heat exchange with water jackets.[2] Such devices are not typically available in veterinary practices. Alternatively, blood units can be warmed by keeping the unit at room temperature for 30 minutes or by running the tubing of the blood administration set through warm water (37 °C) during the transfusion. While it is unnecessary (and not recommended) to warm blood for RBC transfusions at conventional rates, in situations requiring blood warming it is necessary to carefully monitor the temperature of the warming system to prevent RBC vesiculation and fragmentation, as well as hemolysis.

Blood Filters and Infusion Devices

Red blood cell transfusions must be administered through a filter designed to remove clots and particles potentially harmful to the patient. Standard blood infusion sets have in-line filters with a pore size ranging from 170 µm to 260 µm that trap large cells, cellular debris, and coagulated proteins. According to human blood banking standards, a filter may be used to administer 2–4 units of blood to a patient or for a maximum time limit of 4 hours; the combination of a high protein concentration at the filter surface and room temperature conditions promote proliferation of any contaminating microorganisms, and accumulated material slows the rate of flow.[2] Other blood filters with a pore size of 20–40 µm remove microaggregates composed of degenerating platelets, white blood cells (WBCs), and fibrin strands that form in blood after 5 days or more of refrigerated storage. Microaggregate filters are designed primarily for transfusions of RBCs. A pediatric microaggregate blood filter (18 µm pore size, priming space <1 mL) (Hemo-Nate Filter, Gesco International, San Antonio, TX) is particularly helpful in administering small volumes of blood (<50 mL WB or <25 mL pRBCs) to cats and small dogs: administering larger volumes of blood could result in hemolysis due to a progressive decrease in pore size as more blood is filtered.

Leukocyte reduction filters have received much attention in human blood banking because of the potential complications in transfusion recipients associated with residual WBCs in cellular blood components, namely febrile nonhemolytic transfusion reactions, human lymphocyte antigen alloimmunization, and cytomegalovirus transmission.[2] The American Association of Blood Bank Standards defines a leukocyte-reduced RBC product as containing $<5 \times 10^6$ residual donor WBCs.[2] The frequency of adverse effects attributed to WBCs in blood products has not yet been documented in veterinary patients. It is unlikely that leukoreduction will be cost effective and play an important role in general RBC transfusions in dogs and cats.

In most instances the blood flow rate through an administration set by gravity alone is adequate to meet a patient's needs. Electromechanical infusion devices that deliver crystalloid or colloid solutions at a controlled rate have been evaluated for administration of blood. Depending on the pump design, some of the infusion devices may induce hemolysis, and some require special plastic disposables or tubing supplied by the manufacturer for use with blood.[2] In addition to pump design, the degree of hemolysis induced by mechanical pumps depends on the age of the blood (storage time), flow rates, and viscosity of the blood.[2,20] If considering the use of an infusion pump designed for crystalloid or colloid solutions to administer RBCs, the manufacturer should be consulted first. In the event that a blood flow rate greater than gravity can provide being needed, a specially designed pressure bag that completely encases the blood unit and applies pressure evenly to the bag surface can be utilized: pressures greater than 300 mm Hg may cause the seams of the blood bag to rupture or leak, necessitating close monitoring.[2] If blood is administered under pressure, large-bore catheters/needles are recommended for venous access to decrease hemolysis.

Route, Volume, and Rate of Transfusion

The intravenous route of administration is recommended for all RBC transfusions; however, intraosseous administration is an excellent alternative if venous access cannot be obtained. Central veins allow for the use of large-bore catheters and thereby more rapid transfusion in the case of hemorrhagic shock. However, peripheral veins may be preferred in animals with an increased bleeding tendency.

The volume of blood to be administered depends on the degree of anemia, the patient's clinical status, and the size of the animal. Similar to the transfusion threshold, a "target PCV," or the desired PCV post-transfusion, has not been clearly defined and is likely to vary depending on the patient's overall condition. It is typically not necessary to transfuse RBCs with the aim of restoring a normal PCV. Dogs and cats with chronic anemia may be cardiovascularly stable with a PCV of 20%, whereas those with an acute onset of anemia and ongoing blood loss or hemolysis may require transfusion to a higher PCV for stabilization. As a general guideline, administration of 2 mL/kg of WB or 1 mL/kg of pRBCs will increase the patient's PCV by 1%, assuming that there is not ongoing hemorrhage or hemolysis. As an alternative to calculating the volume of donor blood required to reach a target PCV, one may administer an average volume of 10 mL/kg of pRBCs or 20 mL/kg of WB to a normovolemic dog and, if deemed necessary based on clinical evaluation of the patient post-transfusion, follow with additional blood. For practical purposes, most anemic cats will initially receive 1 unit of WB (typically 50 mL) or 1 unit of pRBCs (typically 25 mL).

The rate of blood administration depends on the patient's overall condition. In normovolemic anemic patients, the maximum rate of transfusion is 10–20 mL/kg/h to avoid circulatory overload; hypovolemic anemic patients may tolerate replacement of their blood volume as quickly as the blood can be infused. In animals with advanced cardiac disease, the infusion rate should not exceed 2–4 mL/kg/h; pRBCs are preferable to WB in such cases where the transfusion volume tolerated by the patient may be a limiting factor in providing sufficient oxygen-carrying support. In all cases, including those in which the donor and recipient have been blood typed and/or crossmatched, the initial rate of transfusion should be slow while observing for any immediate adverse reactions. In general, a blood transfusion should be complete within 4 hours to ensure administration of functional blood components and to prevent growth of bacteria in the event of contamination.[2]

Massive Transfusion

Massive transfusion represents a special situation with regard to volume and rate of blood transfusion, as well as blood components administered. Massive transfusion has been defined as transfusion of a volume of whole blood or blood components that is greater than the patient's estimated blood volume within a 24-hour period or replacement of half the patient's estimated blood volume in 3 hours.[10] In a retrospective study of dogs receiving massive transfusion, the mean volumes of pRBCs and FFP administered were 66.5 mL/kg and 22.2 mL/kg, respectively, resulting in a mean plasma:RBC ratio of 1:3.[10] Clinicopathologic changes noted post-transfusion included ionized hypocalcemia and hypomagnesemia and progressive thrombocytopenia and prolongation of prothrombin and activated partial thromboplastin times.[10] There is limited information on massive transfusion in cats.[17]Guidelines for massive transfusion in dogs and cats have not been established. In a retrospective study of massively transfused human trauma patients, 30-day survival was increased in patients with high plasma:RBC ratio (≥1:2) relative to those with low plasma:RBC ratio (<1:2), resulting in the recommendation that massive transfusion practice guidelines should aim for a 1:1 ratio of plasma:RBCs.[8]

PATIENT MONITORING

Early recognition of transfusion reactions requires careful evaluation of patient's attitude, vital signs, and perfusion (i.e. capillary refill time and pulse quality) before, during, and after a RBC transfusion. Measurement of PCV and total solids pre- and post-transfusion (at a minimum, immediately and at 24 hours) and evaluation of the plasma and urine for the presence of Hgb are recommended. Any unexpected change in attitude, vital signs, or laboratory parameters may be indicative of an adverse reaction, in which case the RBC transfusion should be stopped immediately, the intravenous line left open with physiologic saline, and other supportive care provided as necessary (see Chapter 100 for a complete discussion of transfusion reactions).

Dogs and cats receiving RBC transfusions frequently have serious underlying diseases, reflected by a high mortality rate, with approximately 60% surviving to hospital discharge.[4,12,26] However, the benefit of RBC transfusions in providing additional oxygen-carrying support to severely anemic dogs and cats is readily apparent. RBC transfusions can be lifesaving, provided that blood typing and crossmatching are performed to assure RBC compatibility and that donor blood is collected, stored, and administered according to blood banking guidelines.

Acronyms and Abbreviations

CPD, citrate-phosphate-dextrose; DIC, disseminated intravascular coagulation; FFP, fresh frozen plasma; FP, frozen plasma; IMHA, immune-mediated hemolytic anemia; IMT, immune-mediated thrombocytopenia; IVIG, intravenous immunoglobulin; RBC, red blood cell; rhFVIIa, recombinant human factor VIIa; TRALI, transfusion-related acute lung injury; TRIM, transfusion-related immunomodulation; VWD, von Willebrand disease; VWF, von Willebrand factor.

PLASMA CONSTITUENTS

Plasma contains a myriad of proteins that maintain homeostasis within the body and respond to environmental challenges. The major therapeutic constituents of plasma include hemostatic proteins, albumin, and immunoglobulins. The term "plasma component" is reserved for products prepared by differential centrifugation using blood banking techniques, while "plasma derivative" refers to products prepared by fractionation in manufacturing facilities.[1,4] The advent of commercial, referral, and academic veterinary blood banks facilitates routine transfusion of animal components in clinical veterinary practice. Although immunoglobulin concentrates are not available at this time, commercial canine and feline albumin derivatives have recently been developed (Animal Blood Resources International, Stockbridge, MI) not available at this time.

Hemostatic Proteins

In addition to all the coagulation factors required for fibrin clot formation, plasma contains platelet adhesive proteins, potent anticoagulants, and fibrinolysins. The transformation of soluble plasma fibrinogen to insoluble, polymerized fibrin occurs through the action of serine protease coagulation factors (factors II, VII, IX, X, XI, and XII), cofactors (factors V and VIII), and a transglutaminase (factor XIII). Platelet adhesion under conditions of high shear requires the large multimeric glycoprotein, von Willebrand factor (VWF). The major anticoagulant proteins in plasma are antithrombin, protein C, and protein S. Plasma also contains the fibrinolytic enzyme plasminogen and its primary regulatory proteins, antiplasmin and plasminogen activator inhibitor-1. Fibrinogen is the highest concentration hemostatic protein, circulating in plasma at approximately 300 mg/dL.

Albumin and Immunoglobulins

Albumin is the major oncotic protein in plasma and a carrier protein for lipophilic compounds. The immunoglobulin fraction of plasma consists of IgG (up to 85%), IgA, and IgM. The plasma albumin concentration of most species ranges from approximately 2 g/dL to

4 g/dL, with immunoglobulins generally present at equivalent or slightly lower concentration. Derivative concentrates, rather than plasma components, are used in human medicine to supply therapeutic levels of albumin and globulins.

PLASMA COMPONENTS

Centrifugation of whole blood sediments the heavier cellular elements from the supernatant plasma. All protein activity and concentration are retained in the plasma if separation occurs within 8 hours of blood collection.[1] This supernatant plasma can be transfused immediately as fresh plasma, but it is usually frozen and stored as fresh frozen plasma (FFP) for subsequent transfusion, or further processed to yield cryoprecipitate and cryosupernatant (Fig. 96.1). The general procedures for preparation of animal components in the United States follow human blood banking guidelines, e.g. collection of whole blood in citrate-phosphate-dextrose (CPD) anticoagulants, initial quick-freeze of separated plasma, and storage temperatures at or below –18 °C.[1,8]

Fresh Frozen Plasma

Fresh frozen plasma refers to plasma separated from whole blood within 8 hours of collection and quick-frozen within 1 hour of separation. It contains essentially all the hemostatic proteins, albumin, and globulin as the plasma from which it was prepared. The term FP24 is used in human blood-banking for plasma separated and frozen within 24 hours from collection. Compared to FFP, this product has diminished activity of labile factors, but is approved as a source of coagulation factors for patients with moderate, combined factor deficiencies.[2,12] Veterinary studies have confirmed the retention of functional hemostatic proteins in FFP units for up to 1 year of storage.[15,17]

Frozen Plasma

Frozen plasma (FP) refers to FFP units stored longer than 1 year or thawed FFP units stored under refrigeration for more than 24 hours before transfusion. Hemostatic proteins retain variable activity in FP, and the product does not supply replacement levels of the most labile coagulation factors, factors V and VIII. FP is a source of albumin and globulins.

Cryoprecipitate

Cryoprecipitate is prepared by slowly thawing FFP at temperatures between 1 to 6 °C, followed by centrifugation to sediment the large, cold-insoluble proteins.[1,12] The resultant cryoprecipitate fraction is then refrozen for storage within 1 hour of separation. "Units" of cryoprecipitate may be defined based on the volume of starting FFP, or fibrinogen or factor content. Cryoprecipitate contains fibrinogen, the VWF-factor

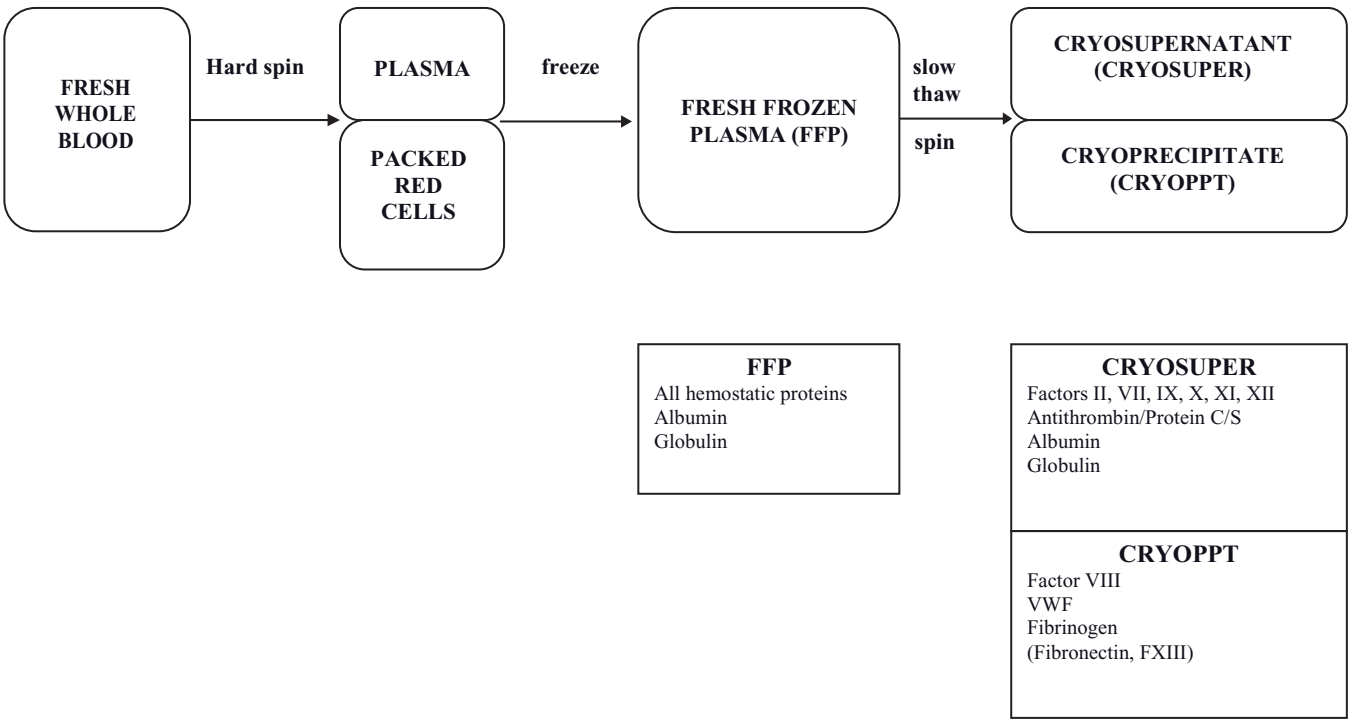

FIGURE 96.1 Flow chart of plasma component processing and composition.

VIII complex, factor XIII, and fibronectin. The process of cryoprecipitation yields approximately 50% factor activity, in one-tenth volume, of the starting FFP. Volume reduction is the major advantage of cryoprecipitate transfusion; therapeutic levels of factors are attained within minutes over the course of a single bolus infusion. Cryoprecipitates are stable for up to 1 year of storage and are often used for animals as sources of VWF and factor VIII.

Cryosupernatant

Cryosupernatant is the plasma component remaining from production of cryoprecipitate.[1,12] This product is deficient in fibrinogen, VWF-factor VIII, and other cold-insoluble proteins, but retains proteins such as albumin and most hemostatic proteins and immunoglobulins. Cryosupernatants are often used as a source of the vitamin K-dependent coagulation factors (factors II, VII, IX, and X) and are stable for this purpose for at least 1 year of storage.

PLASMA DERIVATIVES AND RECOMBINANT PROTEINS

Human apheresis plasma provides most of the source material for commercial manufacture of pharmaceutical protein derivatives.[6] Human albumin, immunoglobulin, and factor concentrates (factor VIII and VWF) are among the most commonly used derivatives in medical practice. The first production methods developed in the 1940s and 1950s (Cohn's fractionation) separated constituent proteins based on differential solubility under conditions of varying temperature, pH, and ethanol concentration. Subsequent advances include the use of chromatography and immunopurification processing techniques. The final protein concentrates are supplied as solutions or lyophilized powders with long (2–3 year) shelf-lives at room temperature. To ensure product safety, the manufacturing process of human protein concentrates incorporates donor and plasma screening and highly effective pathogen inactivation procedures.

In addition to high purity factor VIII and IX concentrates, recombinant human factor VIII and IX products are approved to prevent and control hemorrhage in hemophilic patients. Although recombinant factors carry no risk of blood-borne disease transmission, they do not prevent development of inhibitory alloantibodies, a severe complication of replacement therapy. Recombinant human factor VIIa (rhFVIIa) was developed as a bypassing agent to treat hemophiliacs and other patients with acquired coagulation inhibitors.[9] At supra-physiologic levels, rhFVIIa generates thrombin independent of factors VIII and IX by directly activating factor X on the surface of procoagulant platelets.

INDICATIONS FOR PLASMA THERAPY

Plasma components are the mainstay for treatment of hemorrhagic disorders caused by hemostatic protein deficiencies. Plasma components are also transfused to animals as a source of albumin and immunoglobulins because of the lack of allogeneic derivative protein concentrates.[10] The therapeutic goal for each transfusion should be clearly established in order to select the most specific replacement product (Table 96.1). This approach maximizes the use of scarce plasma resources and helps minimize recipient exposure to foreign antigens.

Hemorrhagic Disorders

Hereditary Bleeding Disorders

Plasma components are indicated to control active hemorrhage and for preoperative prophylaxis for animals with hereditary coagulation factor deficiencies and von Willebrand disease (VWD) (see Chapters 81, 86, and 90). In many cases, appropriate component therapy will eliminate the need for red blood cell (RBC) transfusion with its inherent risks of sensitization and adverse reaction to RBC antigens.

Von Willebrand disease, among the most common hereditary bleeding disorders of dogs, horses, and people, is often managed with plasma component therapy. The most clinically severe forms of VWD (types

TABLE 96.1 Plasma Components and Plasma Derivatives

Product	Dosage Guidelines	Indications
Fresh Frozen Plasma	6–12 mL/kg q8–12 h	Inherited and acquired coagulation factor deficiencies, von Willebrand disease, hypoproteinemia, hypoglobulinemia
Cryoprecipitate[a]	1 unit/10 kg q4–12 h	Hemophilia A, von Willebrand disease, hypofibrinogenemia
Cryosupernatant	6–12 mL/kg q8–12 h	Hemophilia B, hereditary deficiencies of Factors II, VII, X, XI, vitamin K deficiency, hypoproteinemia, hypoglobulinemia
Frozen plasma	12–20 mL/kg q12–24 h	Hypoproteinemia, hypoglobulinemia
Human albumin solution[b]	0.5–1.0 g/kg	Hypoproteinemia
Human intravenous immunoglobulin[b]	0.5–1.0 g/kg	Refractory immune-mediated disorders
Recombinant human FVIIa[b]	35–120 μg/kg	Factor bypassing agent, surgical hemostasis

[a]1 unit cryoprecipitate prepared from 200 mL fresh frozen plasma.
[b]Administration of human protein products may induce severe adverse reactions in animals.

2 and 3 VWD) are characterized by dysfunctional or absent VWF protein, respectively. Type 1 VWD is clinically variable, associated with a quantitative VWF deficiency. Patients with severe forms of VWD invariably require replacement therapy if they undergo invasive procedures and are subject to spontaneous mucosal bleeds that may persist without transfusion. Transfusion requirements are generally lower for type 1 VWD; however, each patient's risk of hemorrhage should be assessed based on severity of VWF deficiency, prior history of abnormal bleeding, presence of concurrent disorders, and the nature and site of surgery or trauma. The highest potency VWF plasma component is cryoprecipitate; however, FFP can be transfused as a source of VWF if cryoprecipitate is unavailable.

Hemophilia occurs in many different breeds and species. There are two clinically indistinguishable forms: hemophilia A (factor VIII deficiency) is much more common than hemophilia B (factor IX deficiency). Both are X-linked recessive traits, and, therefore, signs of a bleeding disorder are seen predominantly in males. Heritable coagulopathies caused by deficiencies of fibrinogen and factors II, VII, IX, X, and XI have also been identified in animals. These autosomal traits are generally restricted to a single breed or line; however, de novo and low frequency mutations can be propagated widely if asymptomatic carriers are bred. Transfusion requirements vary among hereditary factor deficiencies. Clinical expression of a bleeding tendency depends on the physiologic role of the deficient factor and the severity of factor deficiency. For example, hemophilia A and B often manifest as clinically severe coagulopathies, whereas most patients with factor VII deficiency have no signs of a bleeding tendency (see Chapter 86). Hemophilia A and fibrinogen deficiency or dysfunction (dysfibrinogenemia) respond to cryoprecipitate or FFP, if cryoprecipitate is unavailable. All other hereditary factor deficiencies can be treated with FFP or cryosupernatant.

Acquired Factor Deficiencies

Acquired coagulopathies are caused by simultaneous deficiencies of many factors rather than specific deficiency of a single factor. Acquired coagulopathies are more common than hereditary disorders and often develop in patients with vitamin K deficiency, liver disease, disseminated intravascular coagulation (DIC), and massive blood loss treated with large-volume fluid replacement (see Chapter 85).

Transfusion is required for vitamin K-dependent coagulopathies if fulminant hemorrhage develops in critical sites, e.g. respiratory tract or central nervous system, since vitamin K replacement therapy corrects coagulopathy only after a period of 12–24 hours. Cryosupernatant is the most cost-effective plasma component to supply the vitamin K-dependent factors (factors II, VII, IX, X), but FFP is an acceptable alternative (Table 96.1).

In addition to coagulation factors and fibrinogen, the liver is the sole site of synthesis of plasminogen, anticoagulant proteins, protease inhibitors, and albumin. While FFP contains all these proteins, volume overload can limit the efficacy of FFP replacement therapy.[2,10,12] FFP transfusion is useful, however, for short-term replacement of hemostatic levels of coagulation factors in patients with liver failure. FFP transfusion, given at a ratio of 1:1 with packed RBCs is also recommended to manage dilutional coagulopathy in humans with massive blood loss. Controlled studies of DIC in humans have not shown consistent benefit of FFP or factor concentrates in improving clinical outcomes.[2,3] Therefore, use of FFP is generally restricted to DIC patients with signs of hemorrhage caused by severe fibrinogen and factor depletion.

Non-hemorrhagic Disorders

Hypoproteinemia

Hypoproteinemia develops in numerous disease conditions including vasculitis, protein losing disorders, hepatic failure, and peritonitis. In medical practice, albumin concentrates are used to restore the oncotic properties and carrier functions of albumin.[5] Antigenic differences among species, however, render human albumin immunogenic, resulting in life-threatening reactions in healthy dogs receiving pharmaceutical human albumin solutions.[7,14] In light of these findings, off-label use of human albumin solutions for veterinary patients should be carefully considered and proceed only after obtaining owners' informed consent. The plasma components FFP and cryosupernatant contain albumin and are potential sources for veterinary replacement therapy. However, high volume transfusions (20–25 mL/kg) of these components are predicted to obtain calculated increments of 0.5 g/dL plasma albumin in recipients. Clinical trials are needed to determine whether plasma component transfusions can improve clinical outcomes in hypoproteinemic veterinary patients.

Immune Disorders

Human intravenous immunoglobulin (IVIG) concentrates were initially developed for treating immunodeficiencies; however, these products are now used to modulate the immune response for diverse human disease syndromes including immune cytopenias, myasthenia, rheumatic disease, and immune-mediated dermatopathies.[4] The clinical use of human IVIG in animals includes management of refractory immune-mediated disorders, including immune-mediated hemolytic anemia (IMHA), immune-mediated thrombocytopenia (IMT), pemphigus foliaceous, and cutaneous drug eruptions.[13] The immunoglobulin content of plasma components does not supply supraphysiologic levels of immunoglobulins for immunosuppression; however, FFP (and cryosupernatants) can serve as sources of immunoglobulin replacement therapy for neonates with failure of passive transfer, and to augment response to infectious agents.

GUIDELINES FOR PLASMA ADMINISTRATION

Sources of Plasma Products

The number of commercial veterinary blood banks has more than doubled over the past 5 years to meet rising demands for animal blood products (Table 96.2), in addition to the advent of local and university blood banks. The species and selection of plasma components supplied by different commercial blood banks varies.

Guidelines for screening canine and feline donors have been published recently;[16] however, nationwide standards do not exist for unit definition, potency, or processing techniques to prepare plasma components. Information on quality assurance, quality control, and specific dosage and handling recommendations must be obtained from each supplier.

Plasma Product Administration

Plasma Components

Plasma components are prepared in sterile plastic bags and then stored and shipped frozen in individual boxes.[1,11] Plasma bags are brittle and must be handled carefully to prevent breakage. All products should be stored at –20 °C or lower and then warmed to 37 °C in a water bath or incubator just before transfusion. Unopened bags can be refrozen without significant loss of factor activity when kept at 37 °C for up to 1 hour, but any product remaining in opened bags should be discarded if not transfused within 3–4 hours.

Intravenous transfusion of plasma components is the preferred route of administration; however, intraosseous transfusion may be indicated in emergency situations when attempts at vascular access have failed. Catheter sites for transfusion should be aseptically prepared and the catheters reserved for plasma component administration (or flushed with sterile saline before and after plasma transfusion). Plasma components should be infused through blood filters and should not be mixed with other fluids, drugs, or additives to prevent contamination, precipitation, or clot formation.

In the author's experience, routine pretreatment with corticosteroids or antihistamines is not required before plasma component transfusion. Plasma products should be infused at a slow initial rate of 1–2 mL/minute and the recipient closely monitored for signs of transfusion reaction. Maintenance of this rate is advisable for patients at risk for volume overload (e.g. puppies, kittens, cardiac patients). Transfusion rates of 3–6 mL/minute (to total transfusion time of 1.5–2 hours) are generally well tolerated for more rapid factor replacement. Low volume cryoprecipitate can be transfused as a slow intravenous bolus over a period of 10–20 minutes.

The dose and frequency of transfusion vary for different products and different disease conditions (Table 96.1). In general, FFP, FP and cryosupernatant are transfused at 10–12 mL/kg, with an interval of 6–8 hours between doses to prevent volume overload. Cryoprecipitates are supplied in arbitrary "units" defined by each blood bank and should be transfused, therefore, according to the suppliers' recommended dosages. The best strategy for rapidly restoring hemostasis in patients with severe factor deficiencies is to initiate high dose and short interval component transfusion. The high end of dosage range is also appropriate for preoperative prophylaxis. The dose can be decreased and transfusion interval increased after hemostasis is restored. While coagulation assays and point-of-care monitors aid in assessing patient response (Fig. 96.2), clinical assessment and confirmation of rising or stable hematocrit are important parameters to guide subsequent transfusion.[3] Patients with severe factor deficiencies usually require more than a single preoperative transfusion to undergo surgery or to control hemorrhage severe enough to cause blood loss anemia. A second (postoperative) transfusion should be given routinely, with access to additional components as needed. Transfusion over a maximum period of 3 days is usually sufficient to support hemostasis and postoperative wound healing in patients with even the most severe factor deficiencies.

Plasma Derivatives and Recombinant Proteins

Administration of human albumin, immunoglobulin, and rhFVIIa has been reported in dogs; however, treatment trials adequately powered to judge clinical effi-

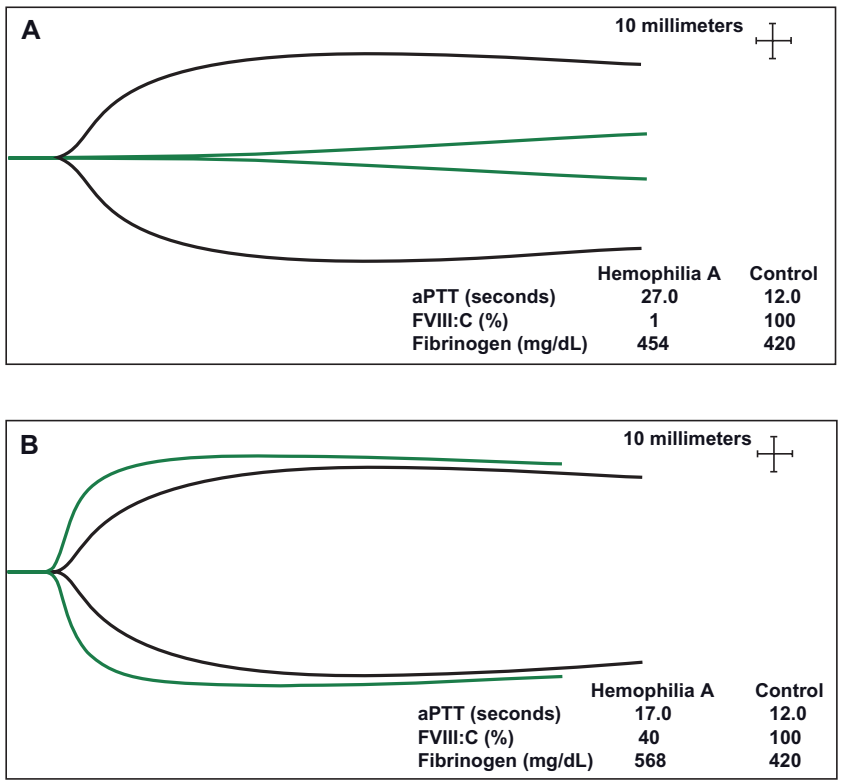

FIGURE 96.2 Response to cryoprecipitate in a dog with severe hemophilia A. Cryoprecipitate was transfused to a hemophiliac dog preoperatively and postoperatively for cutaneous mass excision. Citrate-anticoagulated blood samples were collected before transfusion and 45 minutes after postoperative transfusion to monitor activated partial thromboplastin time (aPTT), factor VIII coagulant activity (FVIII:C), fibrinogen, and thromboelastography (TEG). TEG was performed without activating agents. In each panel, the hemophiliac dog's TEG tracing (green line) is superimposed over a normal dog tracing (black line). Inset tables display aPTT, FVIII:C, and fibrinogen values. (**A**) Pre-treatment TEG depicts minimal fibrin formation in the absence of factor VIII. (**B**) Post-treatment TEG depicts a marked increase in the rate and tensile strength of the fibrin clot formed in the presence of hemostatic levels of factor VIII.

cacy have not yet been performed. In a recent case review,[14] a pharmaceutical 25% human albumin solution was infused (after dilution in sterile saline to a concentration of 10% albumin) to critically ill dogs over a 12 hour interval to deliver a total albumin dosage of 0.5–1.25 g/kg. This dosage regimen produced a median increase in serum albumin of 1.1 g/dL; however, approximately one-quarter of the recipients developed complications, including 4% (3 of 73) with severe delayed immune reactions. Human IVIG has been used in the dosage range of approximately 0.5–1.5 g/kg for refractory IMHA and IMT in dogs.[13] Cytopenias generally resolved in more than two-thirds of the dogs treated with a single IVIG dose. The hemostatic effects of rhFVIIa have been demonstrated in research dogs with hereditary factor deficiencies (hemophilia A, hemophilia B and factor VII deficiency), at dosages ranging from 5 to 30 µg/kg.[9] Pending additional veterinary studies, any potential benefit of human plasma-derived or recombinant concentrates must be weighed against their high cost and cross-species immunogenicity.

ADVERSE REACTIONS TO PLASMA PRODUCTS

All plasma recipients should be observed during transfusion, with minimum monitoring of temperature, pulse, and respiration before and after transfusion. Based on the indication for plasma therapy, the appropriate samples to monitor coagulation status, hematocrit, or protein concentration should be collected before and after transfusion to gauge recipient response. Plasma product administration should be stopped immediately and the product saved for analysis if the recipient displays any signs of discomfort or change in clinical status (see Chapter 100).

Immune-mediated Reactions

Plasma components and concentrates are acellular but contain potentially immunogenic proteins and other compounds (e.g. anticoagulants) capable of eliciting immune reactions. Acute allergic reactions characterized by urticaria, erythema, and facial edema are among the most common reactions and may occur during a first transfusion, or in patients previously transfused many times. Signs typically manifest within the first 30–60 minutes of infusion. The antigens or factors responsible for these reactions have not been defined, but most patients respond quickly if the transfusion is discontinued and they are given antihistamines and/or short-acting steroids. Cats have clinically significant alloantibodies to foreign RBC antigens. Therefore, cats should be transfused only with type-matched plasma products. A minor cross-match (recipient RBCs plus donor plasma component) can be performed in any species to detect hemolysins and agglutinins before transfusion. The off-label use of pharmaceutical agents containing human proteins or any cross-species plasma transfusion carries an inherent risk of potentially fatal acute and/or delayed immune reactions.

The acronyms TRALI (transfusion-related acute lung injury) and TRIM (transfusion-related immunomodulation) refer to deleterious antibody and/or cytokine-mediated plasma component reactions.[8] TRALI is attributed to alloantibodies in donor plasma activating recipient granulocytes which results in severe pulmonary edema. TRIM is an immunosuppressive syndrome caused by donor leukocytes or leukocyte-derived intermediaries inducing an increased susceptibility to cancer recurrence or bacterial infection in recipients.

Non-Immune Reactions

Non-immune reactions to plasma products are caused by improper collection, storage, or administration procedures or by disease transmission from infected donors.[2,11] Volume overload is a common non-immune reaction caused by too rapid rate or too high volume transfusion. Clinical signs of this reaction include emesis, vocalization, and dyspnea. Signs of respiratory distress may also develop secondary to transfusion of unfiltered plasma products containing fibrin clot fragments or precipitates formed by plasma contact with calcium or glucose-containing solutions. Although RBC and platelet products are more frequently implicated in disease transmission, appropriate donor screening and careful attention to aseptic procedures for catheter placement are important to minimize risk of infection. Blood banking recommendations to minimize plasma component contamination include avoidance of transfusion times longer than 4 hours and prohibiting introduction of any drugs or solutions into the plasma product.

The demand for animal plasma components and derivatives is likely to intensify as veterinarians provide increasingly complex medical and surgical services. The challenge remains for clinicians and researchers to develop mechanisms for evaluating the risks and benefits of plasma transfusion and protocols for optimizing plasma usage and clinical outcomes.

Acronyms and Abbreviations

AABB, American Association of Blood Banks; CoE, Council of Europe; DMSO, dimethyl sulfoxide; FWB, fresh whole blood; G-CSF, granulocyte colony-stimulating factor; GC, granulocyte concentrate; IMT, immune-mediated thrombocytopenia; PC, platelet concentrate; PPR, percent platelet recovery; PRP, platelet-rich plasma; RBC, red blood cell; RT, room temperature; VWF, von Willebrand factor.

PLATELET TRANSFUSION

Platelet transfusion is indicated for the control of bleeding due to severe thrombocytopenia or thrombopathia. Platelet transfusion has not been as widely used in veterinary medicine as red blood cell (RBC) and plasma transfusion, and most reports concern platelet transfusion associated with experimental hematopoietic stem cell transplantation in dogs. However, with the use of more aggressive anticancer therapy and the increased willingness to treat complex hematologic disorders, there is an increasing need for platelet-rich blood products. These products include fresh whole blood (FWB), platelet-rich plasma (PRP) and platelet concentrate (PC). The latter may be prepared by centrifugation of FWB or by plateletpheresis, the selective removal of platelets from the donor's blood via an automated cell separator with return of RBCs and plasma to the donor.

ASSESSMENT OF PLATELETS FOR TRANSFUSION

Methods for the collection and storage of human platelets are being continuously evaluated; results are compared on the basis of in vitro and in vivo tests of platelet quantity and quality in PRP and PC.

Platelet *quantity* is typically determined using standard methods of platelet counting for hemograms, but automated hematology analyzers are not specifically calibrated for this purpose and results will vary with the method used (see Chapter 135). Platelet *yield* from centrifugation is calculated by dividing the number of platelets in the final product by the number of platelets in the initial product. Platelet *survival during storage* is calculated by dividing the number of platelets remaining at the end of the storage period by the number present at the beginning. American Association of Blood Banks (AABB) standards specify that human PC production by centrifugation should result in $\geq 5.5 \times 10^{10}$ platelets in ≥90% of units,[10] while Council of Europe (CoE) standards specify $\geq 6.0 \times 10^{10}$ platelets in ≥75% of units.[15] Plateletpheresis should result in $\geq 3.0 \times 10^{11}$ (AABB) or $\geq 2.0 \times 10^{11}$ (CoE) platelets in ≥90% of units.[10,15]

During platelet collection and storage, deleterious physical and metabolic changes referred to as the *storage lesion* occur, which are greater than what is expected with senescence alone. They correlate to some extent with decline in pH, and, while there is not a direct correlation between pH and platelet health, pH remains an important parameter. The AABB standards specify a

pH > 6.2 in 90% of units at the end of the allowable storage period; CoE standards specify a pH of 6.4–7.4 in all units.[10,15]

Many of the tests discussed in Chapter 142 to evaluate platelet function in vitro have been used in a largely unsuccessful effort to predict post-transfusion behavior.[32] The poor predictive value occurs at least in part because the metabolic stress in stored platelets may be reversible after transfusion.[40] The most useful tests are response to hypotonic stress and evaluation of platelet morphology, including "shape change" in response to agonists, morphology scoring using light or electron microscopy, and evaluation of swirling in the blood bag with the unaided eye. Of these, only the latter is practical as a routine test in the clinic; the others are used primarily in a research capacity. Given the paucity of evidence-based data on clinical platelet transfusion in dogs and cats, the following tests are recommended for routine use: (1) measurement of platelet count in the product prior to transfusion; (2) assessment of swirling in PRP and PC; and (3) measurement of pH in PRP and PC after storage.

Platelet *in vivo viability* refers to platelet survival following transfusion. This is determined by radiolabeling or biotinylating platelets and measuring a decrease in labeled platelets over time (see Chapter 134).[28,47] In the clinical setting, platelet viability is determined by measuring the incremental increase in platelet counts following transfusion. One-hour and 24-hour platelet increments are standard measurements; 10 minute increments have also been used.[36]

The final proof of platelet quality is control of hemorrhage in experimental or naturally-occurring thrombocytopenia or thrombopathia.[27] Improved hemostasis may be documented by subjective observation of the bleeding patient and comparison of pre- and post-transfusion bleeding time, Platelet Function Analyzer-100 (Siemens Healthcare Diagnostics, Deerfield, IL) closure time, and whole blood (WB) clotting assays using thromboelastography, resonance thrombography, or a Sonoclot analyzer (Sienco, Arvada, CO) (see Chapters 138 and 142). In addition to the quality of the PRP or PC, improved hemostasis is dependent on the number of transfused platelets and recipient factors affecting platelet function and viability.

WHOLE BLOOD-DERIVED AND APHERESIS PLATELETS

Preparation of PRP and PC from FWB is described in Chapter 94. Platelet-rich plasma and PC should be labeled with donor blood type as these products invariably have some RBC contamination. As indicated above, the main benefit of apheresis PC over whole blood-derived PC or PRP is a greater total platelet yield ($\geq 3.0 \times 10^{11}$ vs. $\geq 5.5 \times 10^{10}$ platelets per unit).

Plateletpheresis has been performed successfully in dogs (10–28 kg body weight) using both automated continuous[4,11] (Fresenius AS 104, Fresenius AG, Bad Homburg, Germany; and COBE Spectra, Caridian BCT, Lakewood, CO) and discontinuous[24,49] (Haemonetics MCS Plus and Haemonetics 30, Haemonetics Corporation, Braintree, MA) flow centrifugation. Blood is typically collected through a 14–16 gauge jugular venous catheter, and platelet-poor blood is returned via a peripheral venous catheter. Platelet concentrate volume and platelet yield from plateletpheresis has ranged from 120 to 322 mL and 1.26×10^{11} to 4.5×10^{11} platelets/PC, respectively.[4,11,24,49] Collection time is approximately 1–2 hours, depending on desired platelet yield.[4,11] In vivo platelet recovery, defined as the percentage of transfused platelets (^{51}Cr-radiolabeled or biotinylated) that survived in the recipient, has been described as approximately 80% at 1–2 hours post-transfusion.[6,49] The transfused apheresis platelets have a mean half-life of 3.5–3.8 days and a lifespan of 7–9 days.[6,49]

The main adverse effects of plateletpheresis on the canine donor are thrombocytopenia and hypocalcemia. Thrombocytopenia is usually mild, with most counts remaining above 100,000/μL and returning to baseline by 4–6 days. Ionized calcium levels drop during plateletpheresis because of citrate toxicosis during reinfusion of PPP and RBCs to the donor. Clinical signs of hypocalcemia were only noted in 3 of 14 dogs in one study and were generally mild, but occurred despite intravenous calcium supplementation.[11] There were no long-term side effects noted in any study.

STORAGE OF PLATELET PRODUCTS

Veterinary hospitals with blood component-producing capabilities usually prepare PRP and PC on an as-needed basis, but PRP and PC may be stored for 5–7 days at room temperature (RT, 20–24 °C) with continuous or intermittent agitation; FWB may be stored for up to 8 hours at RT (see Chapter 94). Due to the increased risk for bacterial proliferation at RT storage, there has been much interest in evaluating chilled (4 °C) storage of platelets. In addition, cryopreservation and lyophilization of platelets have been evaluated as long-term storage options for platelets. Commercial availability of cryopreserved and lyophilized canine PCs (Animal Blood Resources International, Stockbridge, MI) provides an immediate source of platelets for transfusion in clinical practice.

Chilled Platelets

Prior to 1969 human platelets were refrigerated at 4 °C, similarly to RBCs.[35] However, evidence of reduced in vivo viability after 8–24 hours of chilling prompted the current standard of preparation and storage at RT.[10,20,35,44] During the first 24 hours of refrigeration platelets actually had normal-to-increased in vitro aggregation responses and demonstrated immediate in vivo hemostatic efficacy in humans with thrombocytopenia and aspirin-induced thrombocytopathia.[8,20,48] However, after 24 hours of refrigeration in vitro aggregation, in vivo viability, and hemostatic efficacy rapidly dimin-

ished.[8,20,44] The mechanism of reduced in vivo viability has been recently elucidated: chilling platelets clusters their von Willebrand factor (VWF) receptors, eliciting recognition of platelets by hepatic macrophage complement type 3 receptors, with subsequent phagocytosis.[30] The clustering does not impair functional binding of VWF.[30] Galactosylation of 2-hour chilled murine platelets blocked complement type 3 receptor-mediated phagocytosis and restored platelet in vivo viability, but unfortunately did not prevent rapid clearance of either murine or human platelets chilled for 48 hours.[51] There are no published reports on in vivo viability of chilled canine platelets. However, in light of the effect of chilling on survival of both murine and human platelets, refrigerated storage of canine platelet-rich products (FWB, PC, PRP) cannot be recommended at this time without studies documenting adequate post-transfusion survival.

Cryopreserved Platelets

Another approach to prolong shelf-life and minimize bacterial growth is cryopreservation, which is approved for human PC and has been used to store canine PC for up to 2 years. Platelets are cryopreserved using a cryoprotectant solution in approved plastic bags at a freezing rate of 1–3 °C per min. In general, cryopreserved human platelets have reduced function and viability compared to platelets stored at RT.[10] In unrelated studies, canine platelets cryopreserved in 6% dimethyl sulfoxide (DMSO) have been shown to have impaired in vitro function based on marked reduction of aggregation, although cryopreserved platelets can be activated in vitro as demonstrated by thrombin-stimulated P-selectin expression.[5,6,22] Furthermore, cryopreserved canine platelets have reduced in vivo recovery (~50%) and survival (half-life ~ 2 days) compared to fresh canine platelets,[6,49] but were reported to have hemostatic efficacy in lethally irradiated dogs.[49] These results may reflect the poor predictive value of in vitro tests and/or the clinical benefit of transient platelet support. Canine platelets cryopreserved in polyethylene glycol-DMSO were also anecdotally effective in controlling bleeding in Basset hounds and Otterhounds with thrombopathia (W.J. Dodds, personal communication).[39] An augmented cryoprotectant containing 2% DMSO and Thrombosol (a mixture of amiloride, adenosine, and sodium nitroprusside, second-messenger effectors that inhibit platelet activation) improved human, but not canine, platelet viability in comparison to 6% DMSO.[6]

Lyophilized Platelets and Platelet Substitutes

Lyophilization has also been reported for long-term storage of canine platelets and for preparing infusible platelet membranes, a platelet transfusion substitute, using a proprietary freeze-thaw process.[9,13] Other potential platelet transfusion substitutes include liposome-encapsulated platelet membrane fractions and polymerized albumin particles carrying fibrinogen gamma-chain dodecapeptide.[37,42]

TRANSFUSION OF PLATELET PRODUCT

Platelet transfusion is most useful in the management of bleeding in patients with severe thrombocytopenia due to decreased platelet production, where transfused platelet lifespan is normal. It is clinically most rewarding when prompt marrow recovery is anticipated, e.g. following anticancer chemotherapy. Platelet transfusion is less beneficial in disseminated intravascular coagulation (increased platelet consumption), but may be given if the patient is bleeding. Platelet transfusion is least beneficial in immune-mediated thrombocytopenia (IMT) because transfused platelets may be rapidly destroyed; however, platelet transfusion has been useful in some cases and should be considered when there is critical hemorrhage.[1,12] Platelet transfusion is beneficial in most cases of bleeding due to thrombopathia.

Platelet transfusion triggers and doses have been reviewed.[1] A platelet transfusion may be *therapeutic*, given with intent to stop bleeding, or *prophylactic*, given with intent to prevent bleeding. Although controversial, prophylactic transfusion is the most common practice in human medicine, with transfusion triggers of 10,000/μL in the absence of other risk factors for bleeding, 20,000/μL with other risk factors, and 50,000–100,000/μL prior to invasive procedures. Prophylactic transfusions increase the use of platelet products. Most transfusions given to dogs and cats are therapeutic. The latter approach requires close patient monitoring and a readily available platelet product.

Platelet dose is also controversial.[1] A strategy of higher-dose, less frequent transfusions may be used, versus one of lower-dose, more frequent transfusions. Platelet survival is increased at higher platelet counts, supporting the first strategy, which is particularly applicable if transfusions are given on an outpatient basis. However, this may increase the total number of units used. Economics and resources often dictate a minimal transfusion dose in animals (especially large dogs), which are usually hospitalized and transfused therapeutically, promoting the latter strategy. It is often not necessary to raise the platelet count by large increments – critical spontaneous hemorrhage can usually be prevented by transfusions to keep the platelet count above 10,000–15,000/μL.

As with RBC and plasma components (see Chapters 95 and 96), platelet transfusions should be given using standard blood administration sets with 170 μm filters. Transfusion sets should be free of latex, which can bind platelets. Most infusion pumps may be used without damaging platelets, but the manufacturer should be consulted.

The success of a platelet transfusion is judged by control of hemorrhage and by comparing the expected and measured 1-hour platelet increment. If the transfusion was beneficial, active hemorrhage will be reduced.

If bleeding is well-controlled, existing petechiae and ecchymoses will fade over 12 hours. The expected 1-hour post-transfusion platelet count may be calculated as follows: expected 1-hour platelet count = platelet count pre-transfusion + expected 1-hour platelet increment, where expected 1-hour platelet increment = unit platelet count × unit volume × percent platelet recovery (PPR)/estimated blood volume. The PPR corrects for a fixed loss of transfused platelets due to splenic sequestration and other factors.[17,46] If the measured platelet count is much below the expected count, there is accelerated destruction, consumption, increased sequestration, or the quality of the transfused product was suboptimal. If there is minimal platelet production, but no accelerated platelet loss or sequestration, the recipient's platelet count should drop by approximately 33% each day following transfusion.[3] When interpreting the success of a platelet transfusion, it should be noted that platelet counts at low values are imprecise.

Fresh Whole Blood

Component therapy is advocated, but FWB is the only platelet-rich product available to many veterinary clinics. It also has maximum hemostatic properties. In a human randomized clinical trial, 1 unit FWB was equivalent to 10 FWB-derived PCs after open heart surgery,[34] at least partially because the most functional platelets remain in the RBC fraction after centrifugation.[33] However, consistent with the observation that marked hemorrhage is required to lower platelet counts, so large-volume transfusions are required to substantially raise them. As a rule-of-thumb, a FWB transfusion of 10 mL/kg will raise the recipient's platelet count by a maximum of 10,000/μL and will stop critical hemorrhage if there is no ongoing platelet loss.[2] The transfusion is given over 1 hour unless a slower rate is indicated.

Platelet-rich Plasma and Platelet Concentrate

The recommended initial dose for FWB-derived PRP or PC is 1 unit/10 kg, although resources may dictate a smaller dose. If the units contain on average 6×10^{10} platelets, the 1-hour platelet increment should be ~35,000/μL based on 51% PPR.[45] Assuming ~50% fixed platelet loss is perhaps extreme given that other studies suggest ~20% loss.[6,49] However, in the author's experience platelet increments are even lower than that predicted with ~50% loss, perhaps reflecting decreased platelet survival in the presence of thrombocytopenia.[25,29] Assuming canine apheresis PC contains on average 2.4×10^{11} in 200 mL (about four times the number of FWB-derived platelets), a minimum initial dose would be 1 apheresis PC/40 kg. Apheresis PCs are clearly superior for high-dose platelet support and platelet transfusion to large dogs. Cryopreserved apheresis PCs (Animal Blood Resources International) are available as half-units of 1.0×10^{11} platelets in 100 mL, with a recommended dose of 1 PC/10 kg and an expected 1–2 hour increment of 20,000/μL, about 50% of that expected with FWB-derived PC.[22,23] Fresh or cryopreserved PCs are transfused over 1 hour and PRP at 10 mL/kg/hour, unless a slower rate is indicated.

A vial of lyophilized apheresis PC (Animal Blood Resources International) contains approximately 5×10^{10} platelets, which are rehydrated in 60 mL of 0.9% sodium chloride just prior to administration; a recommended dose is 1 vial/15 kg administered over 15–20 minutes (A.S. Hale, personal communication).

Platelet-Poor Blood Components

If a platelet-rich product is not available, fresh-frozen plasma (10 mL/kg) or cryoprecipitate (1 unit/10 kg) could be considered as an alternative in the situation of severe hemorrhage due to thrombocytopenia. These products contain hemostatically functional platelet microparticles, and have been beneficial in treating thrombocytopenic bleeding.[21] Hemostatic benefit may also be via augmentation of other aspects of hemostasis. Stored whole blood or packed RBCs may also reduce thrombocytopenic bleeding in anemic patients, as bleeding time is longer at lower hematocrits[50] (see Chapter 95): this is likely a benefit in dogs with IMT.

PLATELET TRANSFUSION REACTIONS

Transfusion reactions are discussed in Chapter 100. Febrile reactions are the most common reaction to PC; frequency is reduced by pre-storage leukoreduction.[38] Alloimmunization to platelet antigens (see Chapter 93) occurs readily in immunocompetent dogs receiving multiple transfusions, resulting in platelet transfusion refractoriness, a failure to achieve an expected increment in platelet count in response to a platelet transfusion.[45] Two currently accepted methods for preventing the development of platelet alloimmunization include leukocyte reduction and ultraviolet B irradiation.[43] The combination of centrifuge- and filter-leukoreduction was shown to be superior to either leukoreduction procedure alone for prevention of platelet alloimmunization in dogs.[43]

Transfusion-associated sepsis is a particular concern with transfusion of PRP or PC due to the increased risk for bacterial proliferation at RT storage. The rate of contamination in human PC is 1 in 2000–5000 units.[31] Visual inspection of a contaminated unit may reveal gaseous distention of the bag and loss of swirling, but contaminated units may have a normal appearance. Veterinary blood banks should closely monitor RT-stored platelet products microbiologically.

GRANULOCYTE TRANSFUSION

Granulocyte concentrate (GC) transfusion produces a transient increase in neutrophil numbers to a critical level that may permit survival in otherwise fatal sepsis. While promoted in the 1970s and early 1980s in human

medicine, usage of GC then declined because of expense, febrile reactions, controversial benefit, and newer antibiotics. The availability of granulocyte colony-stimulating factor (G-CSF) paradoxically led to a resurgence of GC transfusion.[16] Granulocyte concentrate is usually prepared by continuous-flow centrifugation leukapheresis, with pre-administration of G-CSF (with or without corticosteroids) to the donor to increase neutrophil yield. Donors should be blood-type compatible, and irradiation of GC (25–50 Gy) is recommended to minimize transfusion-associated graft-versus-host disease.[10]

Therapeutic GC transfusions in small animals have been used primarily in experimental models of myelosuppression and neonatal sepsis.[14,19] They have been rarely used in clinical veterinary medicine. In addition to leukapheresis, centrifugation of FWB, with or without colloid-facilitated sedimentation, may be used to isolate canine and feline buffy coats;[7,41] sedimentation alone may also be used in the cat. Granulocytes are stored at RT without agitation for 24 hours.[10] The initial dose is 1×10^9 granulocytes/kg in a volume of 15 mL/kg once to twice daily.

Granulocytes may also be used diagnostically. Infusion of radiolabeled autologous granulocytes and scintigraphy have been used to detect sites of inflammation in animals with nonspecific clinical signs.[18,26]

Acronyms and Abbreviations

CPDA-1, citrate-phosphate-dextrose with adenine; FFP, fresh frozen plasma; FPT, failure of transfer of passive immunity; NI, neonatal isoerythrolysis; PCV, packed cell volume; pRBC, packed red blood cell; RBC, red blood cell; TP, total protein; USDA, United States Department of Agriculture; WB, whole blood.

Blood product transfusion is an integral part of equine practice, both in referral institutions and in ambulatory practice. Blood products may be administered for conditions ranging from life-threatening acute hemorrhage to failure of transfer of passive immunity (FPT). The available equine blood products and indications for transfusion will be discussed in this chapter. Practical considerations for donor selection and collection and administration of blood will also be provided. A brief discussion of whole blood (WB) and blood product transfusion in ruminants and camelids is presented at the end of the chapter.

INDICATIONS FOR BLOOD PRODUCT TRANSFUSIONS

Whole blood

Whole blood transfusions are most often indicated for horses that have suffered acute blood loss from trauma, surgery, or other conditions such as splenic rupture or uterine artery hemorrhage. In cases of blood loss, the transfusion serves to restore blood volume as well as oxygen-carrying capacity. While there are no set variables that serve as "transfusion triggers," a combination of physical examination and clinicopathologic parameters can be used to guide the decision to transfuse. It is important to remember that the packed cell volume (PCV) may remain normal for up to 12 hours in cases of acute hemorrhage due to the time required for fluid redistribution and the effects of splenic contraction. Serial monitoring of PCV and total protein (TP) as the horse is rehydrated with intravenous fluids will give an indication of the extent of blood loss. Suspicion of large volume blood loss, combined with tachycardia, tachypnea, pale mucous membranes, lethargy, and decreasing TP, may lead to the decision to transfuse.[16] Blood transfusion is likely needed during an acute bleeding episode when the PCV drops below 20%, although in acute severe cases, transfusion may be needed before there is a significant drop in PCV.

Estimation of blood loss at surgery can be used to guide the decision to transfuse, with greater than 30% blood loss generally requiring transfusion.[12] Anesthetized horses may have very stable heart rate and PCV despite massive blood loss; pale mucous membranes with prolonged capillary refill time, decreasing TP, hypotension, and hypoxemia are better indicators of blood loss.[45]

Oxygenation status can help to determine the need for blood transfusion in cases of both acute hemorrhage and chronic anemia. A rise in blood lactate concentration despite volume replacement with crystalloid or

colloid fluids may indicate continued tissue hypoxia and a need for blood transfusion.[14,21] The oxygen extraction ratio is also a useful measure:

$$ER_{O_2} \approx \frac{S_{aO_2} - S_{vO_2}}{S_{aO_2}} \qquad \text{(eqn 98.1)}$$

where ERo_2 is the oxygen extraction ratio, S_ao_2 the arterial oxygen saturation, and S_vo_2 the mixed venous oxygen saturation. A ratio greater than 40–50% in the context of blood loss may indicate a need for blood transfusion.[22]

Due to the short half-life of transfused red blood cells (RBCs), transfusion should be considered a temporary measure to restore oxygen-carrying capacity, relying on the horse's erythropoeitic response or resolution of underlying disease to provide long-term resolution.[19,36]

Packed Red Blood Cells

Packed RBCs (pRBCs) are indicated for normovolemic anemia, such as neonatal isoerythrolysis, erythropoietic failure, and chronic blood loss. In cases of chronic or hemolytic anemia, markers of tissue oxygenation, such as lactate and oxygen extraction are still useful. PCV is a better "transfusion trigger" for chronic anemia compared to acute hemorrhage, with transfusions suggested for horses with evidence of tissue hypoxia and a PCV less than 10–12%. Transfusions may be given at a higher PCV for horses with concurrent conditions (e.g. respiratory disease, anesthesia, sepsis) or risk of further blood loss. When pRBCs are not available, WB may be used for the same indications, although attention should be paid to the total volume given so that volume overload is avoided.

Plasma

Plasma transfusion is indicated for the treatment of clotting factor deficiency, hypoalbuminemia, decreased colloid oncotic pressure, and FPT. Fresh and fresh frozen plasma (FFP) contain immunoglobulins, coagulation factors (fibrinogen and factors II, VII, IX, X, XI, and XII), and cofactors (factors V and VIII), as well as the anticoagulant proteins antithrombin, protein C, and protein S. Plasma has also been used for treatment of disseminated intravascular coagulation in horses.[43]

Colloid support is generally recommended in patients with a total protein less than 4.0 g/dL or serum albumin concentration less than 2.0 g/dL. Other indications for colloid support are colloid oncotic pressure less than 14 mmHg, clinical signs such as ventral edema, and conditions which increase microvascular permeability, such as sepsis. When plasma is not necessary for clotting factor replacement, a synthetic colloid such as hydroxyethyl starch (hetastarch) is preferred for volume expansion and more effective oncotic support.

EquiPlas (Templeton, CA)	www.plasvaccusa.com

Failure of transfer of passive immunity in neonatal foals more than 12 hours of age is best treated by plasma transfusion, as colostrum absorption is greatly diminished after 12 hours.[18] An IgG concentration less than 200 mg/dL is considered complete FPT, and IgG between 400 and 800 mg/dL is considered partial FPT. Although plasma transfusion is not always needed for foals with partial FPT, it is recommended for foals that have pre-existing infection or exposure to pathogens. Commercially available fresh frozen hyperimmune plasma is most commonly used for treatment of neonatal foals (Table 98.1). Equine FFP is a USDA-licensed product, and most products have a minimum guarantee for IgG concentration and a 2–3 year shelf-life when frozen. Although commercially available hyperimmune plasma has very high IgG concentrations (1500–2500 mg/dL), plasma from local donor horses may provide better protection against specific local pathogens.

There are multiple hyperimmune plasma products with bacterial- or viral-specific antibodies. There is some evidence for the efficacy of *E. coli* (J5) and *Salmonella typhimurium* hyperimmune plasma for the treatment of equine endotoxemia; however, there are also reports which dispute the efficacy of such products.[9,31,37,38] The use of *Rhodococcus equi* hyperimmune plasma for the prevention of *R. equi* has also been controversial.[5,13,17,20,32] Other plasma products available for specific disease treatment include botulism antitoxin, West Nile virus antibody, and *Streptococcus equi* antibody.

Oxyglobin

Oxyglobin® (Biopure Corp., Boston, MA), a hemoglobin-based oxygen-carrying solution, has been used experimentally in ponies with normovolemic anemia.[3] Oxyglobin improved hemodynamic and oxygen transport parameters; however, one pony did have an anaphylactic reaction. The use of Oxyglobin was also reported for treatment of a pony mare with chronic hemorrhage and a history of acute transfusion reactions.[25] Although Oxyglobin is currently commercially available, the cost and volume (125 mL) per bag limit its utility for equine treatment.

BLOOD DONOR SELECTION

The ideal equine blood donor is a healthy, young gelding weighing at least 500 kg. Donor horses should be up-to-date on vaccinations, including rhinopneumo-

nitis, tetanus, eastern and western encephalitis, rabies, and West Nile virus. Donors should be tested annually for equine infectious anemia. Because RBC antigens Aa and Qa are the most immunogenic, the ideal donor should lack the Aa and Qa alloantigens. There are breed-specific blood factor frequencies, so a donor of the same breed as the recipient may be preferable, especially when blood typing is not available. Horses that have received blood or plasma transfusions and mares that have had foals are not suitable as donors as they have a higher risk of carrying RBC alloantibodies. Donkeys have a RBC antigen known as "donkey factor," which is not present in horses; therefore, donkeys or mules should not be used as donors for horses, as the transfused horses can develop anti-donkey factor antibodies.[26]

When a surgical procedure is planned in advance and there is a high risk of blood loss, preoperative autologous donation should be considered, as the horse would be its own ideal blood donor.[28] The lifespan of allogeneic transfused RBCs is approximately 2–5 days, whereas autologous transfused RBCs have been shown to have a half-life of approximately 12 days.[19,36] Intraoperative or post-hemorrhage cell salvage is also an option for autotransfusion, and its use has been reported in a horse with postcastration hemorrhage.[39] Red blood cell recovery can be performed with specialized cell salvage equipment which washes and filters collected blood, but cell salvage can also be performed with simple anticoagulation and filtration.[41] The technique of cell salvage is limited to cases in which the salvaged blood is not in an area of infection or malignancy.

BLOOD TYPING AND CROSSMATCHING

In an emergency situation, an immediate blood transfusion may be given for the first time with a very minor risk of serious transfusion reaction. Horses can develop alloantibodies within 1 week of transfusion, so blood typing and crossmatching are recommended before a second transfusion is performed.[46] However, a second blood transfusion may be performed safely within 2–3 days of the first transfusion without a blood crossmatch.

Blood typing and alloantibody screening can be used to help find the most appropriate donor horse for the patient requiring transfusion (see Chapters 92 and 139). Unfortunately, since blood typing is time-consuming and laboratories performing blood typing are very limited, this is not often a practical method of donor selection (Table 98.2). Blood typing and antibody screening prior to initial transfusion are more important for horses for which subsequent blood transfusions are anticipated and for broodmares which may produce foals with neonatal isoerythrolysis (NI) if sensitized to other blood group factors.[46] A rapid agglutination method for detection of equine RBC antigens Ca and Aa has been developed which may be more practical for pretransfusion testing.[30]

A blood crossmatch is recommended prior to a transfusion, especially for any horse which may have previously been exposed to RBC antigens (see Chapters 92 and 139). Hemagglutination crossmatching is widely available and rapidly performed; however, it will not predict all transfusion reactions, namely the hemolytic reactions. Rabbit complement can be added to the reaction mixture to detect hemolytic reactions.[2]

COLLECTION TECHNIQUES

Blood is collected from the jugular vein of the donor horse, either via direct needle cannulation or catheterization. When a large volume of blood is needed, a 10 or 12 gauge catheter is recommended, although a 14 gauge catheter is also sufficient. Blood flow may be improved by placing the catheter opposite the venous blood flow (catheter directed toward the head). A healthy horse can donate approximately 20% of its total blood volume every 30 days.[24] When 15% or greater blood volume is collected, volume replacement with intravenous crystalloid fluids is recommended. The donor horse's heart rate, respiratory rate, and attitude should be monitored during the blood collection. Vital parameters should normalize within 1 hour of collection.

Plastic bags and vacuum-collection glass bottles are available for blood collection in sizes ranging from 450 mL to 2 L (Baxter Fenwal, Deerfield, IL; MWI Veterinary Supply, Meridian, ID). The glass bottles are preferred by many due to the speed of collection; however, the glass inactivates platelets and causes some damage to RBCs.[27,33]

When blood is collected for immediate transfusion, anticoagulation with 3.2% sodium citrate is adequate.

However, when blood is stored for later transfusion, optimal pH and support of RBC metabolism are necessary to sustain RBC viability (see Chapter 94). Although post-transfusion viability studies have not yet been performed on stored equine blood, biochemical and hematologic parameters suggest that WB may be stored in CPDA-1 bags for at least 3 weeks.[27] Red blood cell concentrates stored in saline-adenine-glucose-mannitol solution may be suitable for transfusion for up to 35 days after collection.[29] Storage conditions for equine blood are similar to those for canine and human blood (see Chapter 94).

Equine blood can be processed to provide plasma and pRBC components, as with other species. Due to the rapid sedimentation of equine RBCs, the RBC component can be administered without specialized processing; however, the pRBCs will still contain plasma components unless centrifugation and repeated washing are performed. Washing of RBCs is the preferred technique when a transfusion is given to an NI foal using the mare as a donor. When RBC washing or other processing is planned, blood should be collected into bags rather than bottles due to ease of centrifugation and sterile transfer.

Plasma processing can be performed by gravity sedimentation, centrifugation using a double-bag system, or plasmapheresis. Plasmapheresis is the preferred technique as it is more rapid than WB collection and processing, and results in plasma with minimal RBCs and leukocytes.[10] Plasmapheresis of between 4 and 11 L can be performed every 30 days on donor horses.[23] Immunoglobulins are well-maintained for at least 1 year in FFP; however, coagulation factor activity may decrease after 2–4 months of storage.[15]

The process of plateletpheresis has not been described for the collection of equine platelets in the clinical setting. Platelet-rich plasma has been prepared from fresh WB in horses, especially for orthopedic applications such as injection of injured tendons.[40]

ADMINISTRATION AND ADVERSE REACTIONS

The volume of blood to be transfused depends on estimated blood loss, estimated total blood volume, and donor PCV:

$$\begin{aligned}&\text{Blood transfusion volume (mL)}\\&\quad=\text{Body weight (kg)}\\&\qquad\times\text{Blood volume (mL/kg)}\\&\qquad\times\left[\frac{(\text{Desired PCV}-\text{Actual PCV})}{\text{Donor PCV}}\right]\end{aligned}\qquad\text{(eqn 98.2)}$$

In cases of acute blood loss, PCV is often not useful for estimates of volume to be transfused since it does not accurately reflect blood loss. Instead, estimates of blood loss and evaluation of clinical parameters are used to determine the volume of blood needed. Between 25% and 50% of the total blood lost should be replaced by transfusion since much of the circulating volume will be replaced by fluid shifts. It is important to remember that up to 75% of RBCs lost into a body cavity (e.g. hemoperitoneum) are autotransfused back into circulation within 24–72 hours.[34] Therefore, lower percentages of blood volume replacement may be needed in cases of intracavitary hemorrhage. Blood and plasma products should be delivered with an in-line filter to remove small clots and fibrin.

Volumes of plasma for treatment of hypoproteinemia can be estimated by TP or albumin concentrations, although the use of plasma to normalize severe hypoproteinemia can be prohibitively expensive in the adult horse.

$$\begin{aligned}&\text{Plasma transfusion volume (mL)}\\&\quad=\text{Body weight (kg)}\times 45\text{(mL/kg)}\\&\qquad\times\left[\frac{(\text{Desired TP}-\text{Actual TP})}{\text{Donor TP}}\right]\end{aligned}\qquad\text{(eqn 98.3)}$$

Volumes of plasma given for treatment of hypoprotenemia or coagulopathy are often determined by clinical and clinicopathological response. The volume of plasma needed in a foal with FPT can be determined if the IgG concentrations of the foal and the plasma are known. A dose of 20 mL/kg of plasma (IgG approximately 1200 mg/dL) will generally raise the foal's IgG concentration by 200–300 mg/dL. A larger volume of plasma may be needed to achieve a similar rise in IgG in clinically ill foals.[44]

In order to monitor for transfusion reactions, blood should be delivered at a rate of approximately 0.3 mL/kg over the first 10–20 minutes, while monitoring heart rate, body temperature, and respiratory rate. Horses should also be monitored for signs of muscle fasciculation, piloerection, and urticaria. Adverse reactions reported in horses receiving blood transfusions include urticaria, hemolysis, and acute anaphylactic reactions. The rate of adverse reaction to WB transfusion has been reported as 16%, with 1 of 44 horses (2%) having a fatal anaphylactic reaction.[16] If no signs of reaction are seen, the rate of administration can be increased to 5 mL/kg/h for normovolemic horses and up to 20–40 mL/kg/h for hypovolemic horses. If signs of anaphylaxis are present, epinephrine (0.01–0.02 mL/kg IV of 1:1000 solution) should be administered immediately. More mild transfusion reactions, such as urticaria, fever, and tachypnea, may be treated with an anti-inflammatory (e.g. flunixin meglumine 1.1 mg/kg IV) or an antihistamine (e.g. tripelennamine 1.1 mg/kg IM).

Similar to the risks in other veterinary species, bacterial contamination of blood, transmission of blood-borne disease from donor to recipient, and hypocalcemia associated with citrate toxicity are all potential concerns related to transfusion in the equine patient (see Chapter 100). An additional concern in horses is the possible sensitization of a broodmare to blood group antigens, leading to the risk of NI in subsequent foals.[46] Although plasma transfusions are not commonly associated with serious adverse reactions, serum hepatitis has been

reported in association with transfusions of commercial plasma.[1]

RUMINANTS AND CAMELIDS

Indications for Transfusion

The indications for WB and plasma transfusion in ruminants and camelids are similar to those for horses. Chronic anemia may be a more common problem in ruminants, as gastrointestinal parasites, especially *Haemonchus contortus*, and ectoparasites (e.g. *Haematopinus* spp. and *Linognathus* spp.) are causes of chronic blood loss anemia, and iron-deficiency anemia can affect neonatal calves.[35] The blood parasites *Anaplasma* and *Babesia* are both associated with the development of chronic anemia although by different mechanisms. Infections in llamas and alpacas due to *Mycoplasma haemollama* result in a chronic anemia due to extravascular hemolysis, frequently resulting in a PCV of less than 10%. In the case of acute hemorrhage or ongoing blood loss (e.g. abomasal ulcers), transfusion should be considered when the PCV falls below 20%. Ruminants with chronic blood loss may not require blood transfusion until the PCV is below 12%.

Failure of transfer of passive immunity is a common indication for plasma transfusion in neonatal calves and crias. While a TP less than 5.0 g/dL is suggestive of FPT in neonates, radial immunodiffusion can be performed to quantitatively determine IgG concentration.[4,42] Commercial FFP is available for both ruminant and camelid transfusion (Animal Blood Resources International, Stockbridge, MI), although fresh plasma or even WB can be very effective for treatment of FPT. Hyperimmune serum products are available for subcutaneous and intramuscular dosing in ruminants, including products with antibodies against *E. coli*, *Pasturella*, *Aercanobacter pyogenes*, *Salmonella typhimurium* and *Clostridium* (Poly Serum, Novartis Animal Health, Greensboro, NC). The use of Oxyglobin has been reported in a sheep with anemia due to gastrointestinal parasites and in two alpacas with hemolytic anemia; however, Oxyglobin is not commonly used in larger animals due to cost and more ready availability of WB from donors.[7,11]

Donor Selection

The initial blood transfusion should generally be safe, regardless of the donor; however, a J-negative donor (cattle) is ideal (see Chapter 92).[8] Routine crossmatching is not useful in ruminants since agglutination reactions do not occur. Testing for hemolytic reactions should be performed using complement, although this testing is not available in all laboratories. Initial transfusions are generally safe to administer without a blood crossmatch. However, if more than 48–72 hours have elapsed since the initial blood transfusion, crossmatching is recommended. Blood donors should be free of disease, including bovine leukosis virus, anaplasmosis, and bovine viral diarrhea virus. If a donor animal is selected from the herd, it is especially important to check PCV and TP prior to blood collection, since the donor animal may also be affected by the same endo- or ecto-parasites.

Collection Technique

Up to 20–25% of total blood volume can be removed from the donor animal, usually via needle cannulation or jugular catheterization, with total blood volume estimated at 80 mL/kg in cattle. As with equine transfusions, blood can be collected into bottles or bags with citrate anticoagulant. Blood stored in CPDA-1 may retain adequate viability for 2–3 weeks.[6] Since bovine blood does not readily separate, a centrifuge is needed to process WB into plasma and pRBC components.

Administration and Adverse Reactions

Blood should initially be delivered slowly in order to monitor for transfusion reactions. Complement-mediated hemolysis is the primary transfusion reaction which occurs with ruminant blood type incompatibility. Volume overload should be avoided, and total volumes delivered should especially be considered in neonates and small ruminants.

ACKNOWLEDGMENT

The author would like to acknowledge Dr. Mike Rings for his review of the ruminant and camelid section of this chapter.

Guidelines for Other Species

Acronyms and Abbreviations

ACD, acid-citrate-dextrose; CPD, citrate-phosphate-dextrose; CPDA-1, citrate-phosphate-dextrose-adenine; CRI, constant rate infusion; Hgb, hemoglobin; HBOC, hemoglobin-based oxygen carrier; IMHA, immune-mediated hemolytic anemia; IO, intraosseous; PCV, packed cell volume; RBC, red blood cell; WB, whole blood.

Transfusion medicine in exotic species is both exciting and frustrating to the clinician. Often, information from more traditional companion species is extrapolated to guide the treatment of exotic species. There is still much anecdotal information on the subject of transfusion medicine; however, experimental data will be provided when possible.

AVIAN

Anemia in Birds

Anemia in birds is caused by the same mechanisms as in mammals: blood loss, hemolysis, or ineffective erythropoiesis. Blood loss anemias are most commonly seen in birds secondary to injuries, although more chronic forms, such as gastrointestinal bleeding, can occur. Healthy birds are remarkably adept at dealing with acute blood loss. Clinical signs of anemia and hypovolemia do not usually occur until 50–60% of the blood volume is lost.[15] Hemolytic anemias are less common in birds but can be caused by toxicities, hemoparasites, and septicemia. Immune-mediated hemolytic anemia (IMHA) has recently been reported in a pet bird.[14] Ineffective erythropoiesis is often seen as an anemia of chronic disease associated with underlying infectious, metabolic, and neoplastic disorders. Birds develop this type of anemia more quickly than mammals because of the shorter lifespan of the avian red blood cell (RBC).

Indications for Transfusion

The decision to administer a blood transfusion is based on several factors: packed cell volume (PCV), clinical condition of the patient, chronicity of the anemia, cause and severity of the anemia, possibility of further blood loss (by either hemorrhage or diagnostic sampling), and the ability of the patient to tolerate the stress associated with administering a transfusion. A study of acute blood loss in pigeons demonstrated that birds receiving intravenous crystalloid fluids alone had the best response to hemorrhage, as judged by the PCV at 24 and 48 hours, when compared to birds receiving heterologous (different species) and homologous (same species) transfusions.[4] However, another study in pigeons in which 60% of the blood volume was removed

showed that the homologous transfusion of 30% of the blood volume ameliorated the effects of the anemia, but both birds with and without a transfusion returned to a normal PCV by day 6.[10] These findings suggest that the best course of action in acute blood loss in birds would be intravenous administration of balanced crystalloids for mild to moderate hemorrhage (loss of up to 25% of the blood volume) and a blood transfusion for moderate to severe hemorrhage (greater than 25% loss of blood volume).

There is evidence that birds may be better able to deal with chronic anemias because the nucleated RBC can produce more hemoglobin (Hgb) in response to anemia.[27] Anemias of a chronic nature, therefore, may not require transfusions if the patient is stable and no further blood loss is expected. Clinical evidence, however, suggests that birds may benefit from transfusions even with chronic anemia because of increased oxygenation of tissues and improved healing and appetite.

Blood Groups

Blood group antigens have been studied in chickens and other species in an attempt to identify gene markers associated with desirable traits and for pedigree purposes.[11] Twenty-eight blood group antigens have been found in the chicken, many of which have more than 10 alleles for a single antigen.[9] To date, there is no available information regarding blood groups in pet birds.[13] Serologic incompatibility has been demonstrated in a number of parrot species. All blood crossmatches between African grey parrots to cockatiels were incompatible, as were most crossmatches between umbrella cockatoos to cockatiels and pigeons to cockatiels. Crossmatch reactions were found in one study between various species of conures, yet administration of these apparently incompatible transfusions resulted in an increase in the PCV and no untoward effect on the recipient.[7]

Compatibility and Donor Selection

Because of the lack of identified blood groups in pet birds, compatibility for transfusion is based on blood crossmatching (see Chapter 139). Several studies have shown homologous transfusions to have a longer RBC survival time when compared to heterologous transfusions.[4,6,24] Heterologous transfusions between members of the same genus may have similar survival times as homologous transfusions.[2,12] Therefore, the recommended donor is a bird of the same species or, if not possible, the same genus.

Unlike mammals, a single transfusion from different species may be safe and efficacious.[2,12] The half-life of heterologous transfusions, however, ranges between 12 hours and 3 days, much shorter than that of a homologous transfusion which lasts for 6–11 days.[6,24] With the number of avian species seen in practice, keeping a large variety of blood donors is impractical. A feasible option is to have a list of client-owned, healthy birds of a variety of species to use as donors when necessary. Donor birds should be screened as in Table 99.1.

An alternative to whole blood (WB) transfusions is the use of an Hgb-based oxygen carrier (HBOC), such as Oxyglobin® (Biopure Corp., Cambridge, MA), an ultrapurified polymerized bovine Hgb solution. HBOCs eliminate the need for crossmatching and can be used as both a colloid and RBC substitute in any species of bird. Following Oxyglobin administration to chickens, mild renal tubular damage was evident in some birds

TABLE 99.1 Donor selection criteria for exotic species

Species	Ideal Donor	Donor Screening
Avian (psittacine)	The same species or genus Housed singly or closed aviary One time heterologous transfusion possible	Yearly physical examination, CBC and biochemical profiles Screened for polyoma, psittacine beak and feather disease, and chlamydophilosis Major and minor crossmatch
Ferret	Male, less than 3 years of age	Yearly examination, CBC, heartworm testing (antibody and antigen) and biochemical profiles Placed on heartworm preventatives in endemic areas Vaccinated yearly for canine distemper and rabies
Rabbit	Female, less than 3 years of age Related animals may reduce disease transmission	Yearly examination, CBC, and biochemical profile Negative testing for *Encephalitozoon cuniculi* Screened for viral hemorrhagic disease and myxomatosis (in endemic countries) Major crossmatch
Rodents	Male guinea pigs less than 3 years of age Female chinchillas less than 5 years of age Male rats less than 1 year of age	Yearly examination, CBC and biochemical profile in larger species Major crossmatch
Reptiles	Young, healthy animal of same species Same genus Singly housed or closed herpetarium Do not use blood filter	Yearly examination, CBC and biochemical profile PCV, blood glucose and total solids in smaller species Screen for hemoparasites

at 24–48 hours, but these changes were subclinical and not detected at day 7.[1]

Blood Collection and Storage

In general, it is safe to withdraw 10–20% of the blood volume of a healthy bird (with a standard blood volume of 100 mL/kg this would be approximately 1–2 mL/100 g body weight). For psittacines, ratites and soft bills, the right jugular is usually the most reliable and readily accessible site for blood collection. In waterfowl and gallinaceous birds, the medial metatarsal vein is easily identified on the dorsomedial surface of the lower leg and can be used, in addition to the jugular vein, for blood collection. The basilica or wing vein can be visualized as it crosses the proximal ulna and can be used in most species, especially pigeons and doves, but may be smaller and more fragile than other veins.

Blood may be collected into syringes containing an anticoagulant, preferably 3.2% sodium citrate. Heparin, acid-citrate-dextrose (ACD), citrate-phosphate-dextrose (CPD), or CPD with adenine (CPDA-1) can also be used. Sodium citrate is added to the syringe before collection of the blood at 0.1 mL of citrate per 0.9 mL of blood. A similar volume of CPD, CPDA-1, and ACD can be used. Care should be taken when transfusing smaller species or hypocalcemic patients since citrate binds calcium in the blood. Alternatively, heparin can be used for avian transfusions at 0.25 mL per 10 mL of blood collected.

Blood is collected into a syringe using a butterfly catheter or injection needle. A small amount of anticoagulant should be flushed through the needle to prevent clotting in the needle. The sample may then be administered from the collection syringe. The author has used WB stored in ACD for 24 hours without apparent deleterious effect; however, the long term storage of avian blood in this medium is not possible because of differences in avian RBC metabolism.[19]

Blood Administration

The amount of WB administered will depend on several factors, including the degree of anemia, size of the donor, and the stability of the patient. As a general guideline, 10–20% of the blood volume of the recipient (1–2 mL/100 g) is administered in most circumstances. If more is needed, several donors may be used. Transfusions can be given IV or IO (intraosseous), as a bolus or by constant rate infusion (CRI). Constant rate infusion is preferred because it is less likely to cause circulatory overload but does require the placement of an indwelling IV or IO catheter. Indwelling IV catheters can be placed in the median metatarsal vein in larger psittacines and all fowl; IO catheters are placed in the distal ulna or proximal tibiotarsus. The transfusion should be given over 2–4 hours, depending on how quickly the blood was lost. A blood filter should be used to remove clots or cellular aggregates from the transfusion.

The bolus method of transfusion delivery has the advantage of requiring only temporary venous access but can cause circulatory overload and may require longer handling time. In some patients, it can be useful to use a butterfly catheter to obtain blood for analysis and then deliver a transfusion and other IV treatments using the same catheter. A bolus transfusion is typically given over 1–5 minutes, quickly enough to avoid overstressing the patient but slowly enough to prevent circulatory overload.

Transfusion Reactions

Acute hemolytic reactions have not been reported in birds receiving a single blood transfusion. Incompatible blood crossmatches, however, have been reported.[6–8,24] In one study 66% of heterologous crossmatches in raptors, pigeons, parrots, and gallinaceous birds showed agglutination and hemolysis.[26] In another study of psittacine crossmatches, all major crossmatches between African gray parrots (*Psittacus erithacus*) and cockatiels (*Nymphicus hollandicus*) were found to be incompatible, and 80% of the cockatoo (*Cacatua alba*) to cockatiel crossmatches were incompatible.[8] In addition, all blue-fronted Amazon parrots (*Amazona aestiva*) were found to be compatible on the first transfusion, but four of five pairs were incompatible before the second transfusion.[8] Interestingly, no visible signs of transfusion reactions were seen in any of the recipient birds, and all birds appeared healthy while monitored for 6 months after three separate transfusions.

Transfusion reactions have been reported in two other studies in birds given multiple heterologous transfusions.[2,12] These birds were given three transfusions at 2-week intervals, resulting in the deaths of five of six birds. Histopathology revealed hemoglobin casts in the renal tubules, consistent with hemolytic transfusion reactions. Antibodies against heterologous RBCs lasted approximately 3 weeks in one group of birds studied.

FERRETS

The most unique aspect of transfusion medicine in ferrets is the lack of detectable blood groups.[17] No naturally occurring anti-RBC antibodies were identified when serum and RBCs of 26 ferrets were randomly paired and tested for agglutination and hemolysis. Clinically, ferrets have received multiple blood transfusions without developing transfusion reactions.[18] In light of this information, blood crossmatching ferrets before transfusion is not standard protocol.

Anemia in Ferrets

Blood loss may be caused by trauma, severe flea infestation, and gastrointestinal bleeding secondary to foreign bodies, gastric ulcers, helicobacterosis, and gastroenteritis. These conditions can result in severe hemorrhage that warrants a transfusion as part of the supportive care regimen. IMHA has not yet been reported in this species.

Ineffective erythropoiesis in ferrets has been reported with a variety of conditions, including lymphoma and other neoplasias, hyperestrogenism, Aleutian disease, adrenal disease, and anemia of chronic inflammation.[3,20,23,25] In addition, the author has diagnosed anemia due to presumptive immune-mediated erythroid hypoplasia in a ferret that responded to immunosuppressive doses of prednisolone.

Indications for Transfusion

As in other species, the decision to administer a transfusion should be based on the PCV and the clinical status of the ferret. Transfusions in ferrets are generally recommended if the PCV falls below 25%, more than 30% of the blood volume is lost (blood volume is approximately 8% of the body weight), blood loss is associated with collapse, or ongoing hemorrhage is present.[22,25] Ferrets may tolerate PCVs lower than 25% if the anemia is of gradual onset. The blood volume required for transfusion can be estimated using the same formulas for other mammals. In general, the administration of 20 mL/kg of WB will increase the PCV by approximately 10%.

Donor Selection and Blood Collection

Healthy male ferrets are suggested for blood donors because of their larger size and blood volume. The donors should be screened as in Table 99.1.

An alternative to WB transfusion in ferrets is the use of a HBOC. Oxyglobin has been used with success in ferrets, both as a RBC substitute and a colloid. A suggested dose is 6–15 mL/kg IV administered over 4 hours.[21]

Blood for transfusion is typically collected from the donor using inhalant anesthesia or other sedation. Isoflurane anesthesia has been shown to decrease PCV, Hgb concentration, and RBC count in ferrets as soon as 15 minutes after induction.[18] Blood should be collected as quickly as possible if using isoflurane. Sevoflurane has not been tested but is thought to cause similar splenic sequestration of RBCs in ferrets. Tractable ferrets may be sedated sufficiently using butorphanol at 0.3–0.5 mg/kg IM. Propofol (2–5 mg/kg) may be given via an IV catheter or butterfly catheter in the jugular vein or cranial vena cava and will cause rapid anesthesia and recovery in the donor ferret.

Blood for transfusion is best collected from the cranial vena cava or jugular vein using 23–25 gauge butterfly catheters. Jugular venipuncture is similar to other species. The cranial vena cava or base of the jugular vein is accessed at the thoracic inlet. The needle is inserted at the angle between the manubrium and base of the first rib and directed caudally toward the opposite hind leg. The blood is collected into an appropriately sized syringe containing 3.2% sodium citrate, ACD or CPDA-1. For citrate and ACD, the ratio of anticoagulant to blood is 1:7, whereas for CPDA-1 the ratio is 1:9. Long-term storage of ferret WB is possible using ACD or CPDA-1, but is not currently practised.

Blood Administration

The blood should be administered by syringe pump via CRI over a 4 hour period. The blood can be administered into a peripheral or jugular venous catheter. Intravenous catheters (24–26 gauge) can be placed in the cephalic or lateral saphenous veins. A cut-down procedure may be required to place a jugular catheter. Intraosseous catheters can be placed in the proximal femur or tibial crest in small patients or in patients with vascular compromise. A blood filter should be used to prevent the transfusion of clots or larger cellular aggregates.

Transfusion Reactions

Transfusion reactions have not been reported in ferrets, ostensibly because of the lack of detectable blood groups due to an absence of genetic diversity, as in cheetahs. Ferrets have received up to 13 separate transfusions from many different ferrets without apparent development of anti-RBC antibodies.[23]

RABBITS AND RODENTS

There is limited experimental work on transfusions in rabbits and rodents, but the author has administered many transfusions to rabbits, guinea pigs, chinchillas, and rats with success.

Anemia in rabbits and rodents is caused by similar mechanisms as in other species. Blood loss can occur from traumatic injuries, as well as reproductive problems such as uterine aneurysms, adenocarcinomas, endometrosis, and dystocia. Hemolytic anemias are uncommon in these species but can occur with toxin ingestion. Anemia of chronic disease is a common finding in sick rabbits and rodents. A PCV of 30% (reference interval, 35–48%) is a common finding in animals with chronic illness.

Indications for Transfusion

A transfusion is indicated in rabbits and rodents with a PCV less than 20% or in animals experiencing hypovolemic shock from acute blood loss. Some authors recommend transfusions at lower PCVs in rabbits, such as 10–15%.[5] The duration of anemia and clinical signs will also help to determine at which point a transfusion is given. Acute blood loss of 20–25% can result in shock in this species and warrants a transfusion using WB or an HBOC as part of the treatment protocol.

Donor Selection and Blood Collection

Blood donor criteria are presented in Table 99.1. In rabbits blood can be collected from the jugular vein, central artery of the ear, or lateral saphenous vein. Severe damage to the ear artery can result in loss of the pinna, so owner consent to this approach is mandatory. Most rabbits will have to be lightly sedated for collec-

tion of blood for a transfusion. The use of topical anesthetic cream (2.5% lidocaine and 2.5% prilocaine, EMLA, AstraZeneca, Wilmington, DE) is helpful. The author routinely uses midazolam (1 mg/kg IM) and butorphanol (0.5 mg/kg IM) for this procedure. Inhalant anesthesia can also be used. A volume of 1% of the body weight can be safely collected from the donor. Blood should be collected using 21–25 gauge butterfly catheters and the standard anticoagulant/preservative solutions as mentioned above. Whole blood may be stored at 4–6 °C in CPD-A for 28–35 days.[5]

In guinea pigs and chinchillas the blood is usually collected from the jugular vein or cranial vena cava. Donors are sedated using inhalant anesthetics or the midazolam/butorphanol combination described above. Total blood volume of the donor is approximately 70 mL/kg, and it is considered safe to remove 10% of this volume. Blood is collected via 25 gauge butterfly catheters using the standard anticoagulant/preservative solutions. There is no information on storage of rodent blood.

Blood Administration

Information on blood types in rabbits and rodents is not readily accessible. Therefore, at a minimum, a major crossmatch is warranted in these species. Transfusions should ideally be given over 4 hours; however, faster delivery is warranted in acute blood loss. A syringe pump can be used with a low flow extension set and blood filter. Intravenous catheters can be placed in the lateral saphenous and cephalic veins of rabbits, guinea pigs, and chinchillas, and in the lateral tail vein of rats. In some cases it is difficult to place an indwelling catheter, so transfusions can be given into the vena cava in rodents or lateral ear vein or lateral saphenous in rabbits using a butterfly catheter. Bolus transfusions should be given over 5 minutes, if restraint for that length of time is possible, in an effort to avoid circulatory overload of the recipient.

Transfusion Reactions

Acute hemolytic transfusion reactions have not been documented in rabbits or rodents. However, it has been suggested to give the transfusion slowly (0.25 mL/kg/h) for the first 15 minutes to detect any potential adverse reactions, such as urticaria, anaphylaxis, erythema, or fever.[5]

GUIDELINES FOR OTHER SPECIES

There are several guidelines to follow when considering a transfusion in other species. In general, a transfusion is warranted in acute blood loss of greater than 30% of an animal's blood volume or a 50% decrease in the low normal PCV. In reptiles, transfusions should be considered when the PCV is 15% or less. The clinical assessment of the animal is crucial. If the patient is tolerating an anemia, the risks and benefits of a transfusion should be considered. The clinical condition of most animals improves dramatically with a transfusion of even 10% of the blood volume from a healthy donor. The donor should be a large, healthy specimen of the same species, although the author has used the same genus in reptiles with success. At a minimum, a major blood crossmatch should be performed to help determine the potential for transfusion reactions. A new donor should be found if an incompatibility is noted on the blood crossmatch. If this is not possible, the clinician may consider administration of an HBOC. The blood transfusion should be given over 2–4 hours, and the animal monitored for signs of a transfusion reaction, as above. If an adverse reaction is noted, the transfusion should be discontinued immediately and the recipient monitored for signs of an acute hemolytic transfusion reaction (e.g. hemoglobinemia, hemoglobinuria, lack of rise in PCV). A blood filter is useful in most species but it has been recommended that a blood filter not be used in reptiles because of the large RBC size causing damage to or limiting the passage of cells.[16]

Acronyms and Abbreviations

AHTR, acute hemolytic transfusion reaction; DHTR, delayed hemolytic transfusion reaction; FFP, fresh frozen plasma; FNHTR, febrile non-hemolytic transfusion reaction; HTR, hemolytic transfusion reaction; PCV, packed cell volume; pRBCs, packed red blood cells; PTP, post-transfusion purpura; RBC, red blood cell; TA-GVHD, transfusion-associated graft-versus-host-disease; TRALI, transfusion-related acute lung injury; WB, whole blood.

Blood is a complex biologic product which, like any tissue transplant, can result in as much harm as benefit to the recipient. The term transfusion reaction denotes any adverse event associated with transfusion of blood or a blood component. The reaction may occur during or within hours to weeks after administration of a blood product. Understanding how to prevent a transfusion reaction and recognizing the potential clinical and clinicopathologic signs of an adverse reaction should one occur are key to good transfusion medicine practice.

Transfusion reactions have been classified using various terminologies in both the human and veterinary literature but are most often characterized by immunologic and non-immunologic mechanisms. There have been several reviews in the veterinary literature on blood transfusions in cats, dogs, and horses, with the incidence and type of transfusion reactions varying between institutions and species but ranging from 3–13%.[10,11,19,20,23–26] Reports of adverse reactions underscore the need for further education on their prevention and identification.

IMMUNE COMPLICATIONS

Hemolytic Transfusion Reactions

Hemolytic transfusion reactions (HTR) jeopardize the health of an already compromised patient. A HTR is the result of naturally-occurring or induced antibodies present in the recipient plasma which can destroy donor red blood cells (RBCs) immediately upon transfusion or within hours to weeks. These reactions are classified as a type 2 hypersensitivity and are mediated by antibodies directed against antigens present on the surface of RBCs.[1] After reacting with the RBC surface antigen, IgG or IgM antibodies activate the complement system, culminating in the formation of a membrane attack complex which disrupts the lipid bilayer of the RBC membrane, causing intravascular hemolysis.[1] Also, antibody or complement fragments, primarily C3b or C4b, can adhere to the RBC surface (opsonization), enhancing RBC susceptibility to phagocytosis by leukocytes expressing receptors for these proteins.[1] Either intravascular or extravascular hemolysis can result, depending

on whether the leukocytes recognize the opsonized RBCs while in circulation or within the reticuloendothelial system. The severity of a HTR is influenced by the concentration of recipient alloantibody, the immunoglobulin type, whether the antibody is warm or cold-reacting, the amount of blood transfused, and the condition of the recipient.[46]

Acute Hemolytic Transfusion Reactions

Acute hemolytic transfusion reactions (AHTRs) present within 24 hours of a RBC transfusion.[12,36] Preformed antibodies in the recipient react with transfused donor RBCs. The recipient has previously formed an alloantibody against an antigen present on the donor's RBCs which is not present on the recipient's RBCs. Cats are similar to humans, as both have naturally-occurring alloantibodies which can result in a potentially fatal AHTR. Anti-A alloantibodies in type B cats are strong hemagglutinins and hemolysins and are present in a high concentration[8,28] (see Chapter 92). Transfusion of type A blood to a type B cat can be fatal if not immediately recognized, with subsequent discontinuation of the transfusion and institution of supportive care.[11,15,16] Within seconds to a few minutes of receiving as little as 1 mL of type A blood, a type B cat may exhibit restlessness, vocalization, vomition, urination, salivation, and recumbency.[15,16] Bradycardia, cardiac arrhythmias, decreased pulse strength, pale mucous membranes, and prolonged capillary refill time are also expected in the initial phase.[16] If the reaction is recognized and the transfusion stopped, hemoglobinemia and hemoglobinuria will follow, as these reactions are IgM and complement-mediated with obvious intravascular hemolysis.[15,16] Acute renal failure, which is seen in humans with blood type ABO transfusion reactions, has not been documented in type B cats receiving type A blood under experimental conditions.

As type B blood is not commonly stored and type B cats comprise a small percentage of cats (outside of a few breeds), inadvertent transfusion of type B blood to a type A cat is unlikely. Inaccurate blood typing results, however, could result in a type A or AB cat being mislabeled as type B with subsequent transfusion of type B blood.[33] Although type A cats generally have lower concentration of weak anti-B antibodies which are of both IgM and IgG classes, transfusion of type B blood can still cause both clinical and clinicopathologic features of a transfusion reaction including discomfort, listlessness, tachycardia and tachypnea, as well as mild hemoglobinemia, hemoglobinuria, and bilirubinuria.[8,16,28] Direct antiglobulin tests (Coombs' test) are variably positive in both type A and type B cats receiving mismatched blood.[16]

A blood type AB cat could receive either type A or B pRBCs, but plasma or whole blood (WB) from a blood type A or B cat could increase the risk of a HTR reaction due to the presence of anti-B and anti-A alloantibodies, respectively. Given the generally weaker nature of anti-B alloantibodies, plasma or WB from a type A cat would be preferred: type AB WB or plasma would be ideal, but unrealistic in most settings given the low frequency at which type AB cats are found.

Hemolytic transfusion reactions in cats can be avoided by blood typing both the donor and recipient. Crossmatching is also important, especially if the intended recipient's transfusion history is unknown or if the recipient has been previously transfused. A crossmatch test (see Chapter 139) can identify preformed alloantibodies against a blood group antigen, thus preventing an AHTR. Until recently, blood types and naturally-occurring alloantibodies outside of the AB blood group system were not recognized, but incompatible crossmatches between AB blood type compatible cats have been described, suggesting the existence of other blood groups (see Chapter 92).[20,44] *Mik*, a newly described blood group in cats, can also result in HTRs.[45] A cat negative for the *Mik*-RBC antigen can experience an AHTR, similar to those described in type A cats receiving type B blood, after transfusion with *Mik*-positive RBCs.[45] Given that this antibody was demonstrated to be naturally-occurring, crossmatching cats prior to even a first blood transfusion may be warranted. An incompatible crossmatch test, in the face of blood-type compatibility, suggests alloantibody formation and should not be ignored.

Some dogs may have naturally-occurring RBC alloantibodies, though there is controversy regarding their clinical significance. Generally, HTRs require prior sensitization through a previous blood transfusion or, to a much lesser extent, pregnancy.[5] A DEA 1.1 negative dog who has been sensitized by transfusion of DEA 1.1 positive blood will develop anti-DEA 1.1 antibodies. A second transfusion with DEA 1.1 positive blood will cause an AHTR. Such a reaction has been documented clinically: a DEA 1.1 negative recipient had been sensitized to the DEA 1.1 antigen through a previous transfusion, and upon inadvertently receiving DEA 1.1 positive blood 3 years later exhibited a 2 °C rise in temperature within one hour of transfusion and developed hemoglobinemia and hemoglobinuria.[17] Following an AHTR plasma will be red-tinged due to hemoglobinemia (Fig. 100.1); this is most often identified when a post-transfusion PCV is measured. An AHTR is not exclusive to the DEA 1.1 antigen; alloantibody production and HTRs have been documented for other RBC antigens in dogs, including known DEA, as well as RBC antigens without DEA designation.[4,9,31] When a compatible donor is not easily identified on a blood crossmatch, testing both siblings of the patient or potentially dogs of the same breed has been shown to be successful in identifying a compatible donor.[4,9]

Delayed Hemolytic Transfusion Reactions

Delayed hemolytic transfusion reactions (DHTRs) are defined as those occurring more than 24 hours following a transfusion, but the time of onset can vary to 48 hours post-transfusion depending on the reference.[12] DHTRs are often the result of an anamnestic response to a RBC antigen that the recipient lacks, with the previously produced reactive alloantibody weak or present

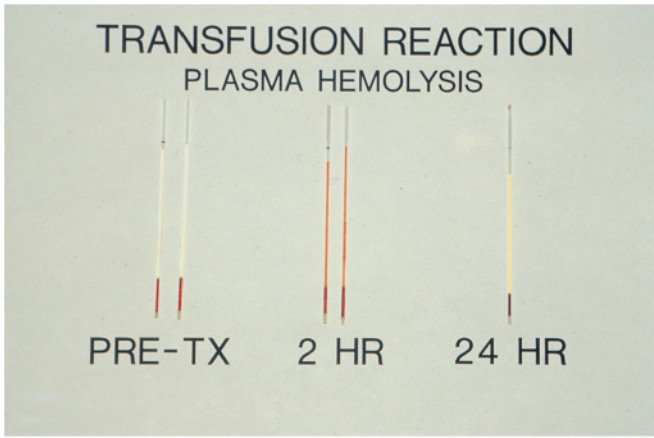

FIGURE 100.1 Serial packed cell volumes (PCVs) from a dog experiencing an acute hemolytic transfusion reaction. Note the transfusion of plasma from clear to hemolyzed to icteric over 24 hours. As a consequence of the transfusion reaction, the PCV fell following the transfusion. (Courtesy of Dr. Ann Hohenhaus.)

in very low concentrations. Pre-transfusion crossmatch testing may not identify the potential incompatibility if the test is insufficiently sensitive. Alternatively, DHTRs may be a result of primary alloimmunization to a RBC antigen, with hemolysis occurring weeks later after sufficient time for alloantibody production.[12]

A DHTR should be suspected if there is a more rapid decline than expected in PCV in the weeks following a blood transfusion, based on the patient's underlying disease. Additional clinicopathologic signs to support a diagnosis of DHTR include hyperbilirubinemia, bilirubinuria, or hemoglobinuria: fever can develop but often goes unnoticed. Diagnosis of a DHTR requires documentation of development of antibodies by the recipient against the donor(s) RBCs.

Preventing HTRs requires knowledge of blood groups present within a species, presence of naturally-occurring antibodies, prior transfusion history, and blood crossmatch testing. Regardless of the designation of acute versus delayed, the majority of HTRs can be prevented through proper blood typing and crossmatch testing.

Non-hemolytic Transfusion Reactions

Febrile and Allergic Reactions

Febrile and allergic reactions are two of the most common types of transfusion reactions reported in veterinary medicine, comprising 60–90% of reported reactions.[20,24,25] Febrile, non-hemolytic transfusion reactions (FNHTRs) are defined in human medicine as a rise in temperature of either 2 °F or 1 °C during or within 4 hours post-transfusion without an obvious other cause for the rise in temperature.[46] Additional clinical signs can include vomiting and tremors: the vomiting will often resolve without treatment, but a decreased transfusion rate may help to alleviate this symptom.[10,36]

Febrile, non-hemolytic transfusion reactions are frequently attributed to recipient alloantibodies which react with histocompatibility leukocyte antigens or other antigens present on donor lymphocytes, granulocytes, or platelets.[6,36] Cytokines released from leukocytes and platelets within stored blood are also implicated as causes for FNHTRs and some allergic-type reactions.[27,46] Pre-storage leukoreduction has been shown to decrease, but not eliminate, FNHTRs. Interestingly, leukoreduction of human platelet products did not significantly decrease the rate of allergic reactions, which were attributed to platelet-derived chemokines.[6,27] Leukoreduction of canine WB does not decrease RBC viability but, for maximum reduction of leukocytes, needs to be performed on cooled blood following collection.[7] Extrapolating from human data, leukoreduction at the time of administration would be less effective in veterinary medicine for decreasing FNHTRs; ideally, leukoreduction should be performed within a few hours of collection to minimize cytokine production and thereby prevent febrile reactions. However, routine leukoreduction of veterinary blood products is difficult to justify given the cost of the special leukoreduction filters and limited potential benefit to the majority of recipients. Platelet antigens would remain a potential source of reactivity even in leukoreduced WB or pRBCs. Recommendations for management of FNHTRs include stopping the transfusion but maintaining the intravenous line open with saline while excluding an AHTR or transfusion-related sepsis due to bacterial contamination of the unit (Fig. 100.2).

Allergic reactions are more often associated with transfusion of plasma products and are triggered by exposure to a substance, likely a protein, present in donor plasma to which the recipient has been sensitized.[36] Signs of an allergic reaction typically start within the first 15 minutes of a plasma transfusion but can occur during or within a few hours of administration. Clinical signs include mild to sometimes dramatic urticaria, pruritis, and erythema (Fig. 100.3). Additional signs can include vomiting, nausea, diarrhea, and/or abdominal pain.[12] Treatment of an allergic reaction to a plasma product includes stopping or, at least, decreasing the rate of transfusion, as well as administering an antihistamine such as diphenhydramine (1–2 mg/kg IM). Although pretreatment to prevent these types of immune reactions has been previously advised, administration of diphenhydramine to humans prior to leukoreduced platelet transfusions did not decrease the frequency of allergic-type urticarial reactions.[41]

Uncommon Immune Reactions

Post-transfusion purpura (PTP) is a relatively uncommon transfusion reaction in humans and has been described once in veterinary medicine.[36,43] Thrombocytopenia develops 1–2 weeks post-transfusion due to recipient-produced anti-platelet antibodies. These antibodies are most often directed against a platelet specific antigen (e.g. in humans, HPA-1a) which the recipient lacks: platelets targeted for destruction are

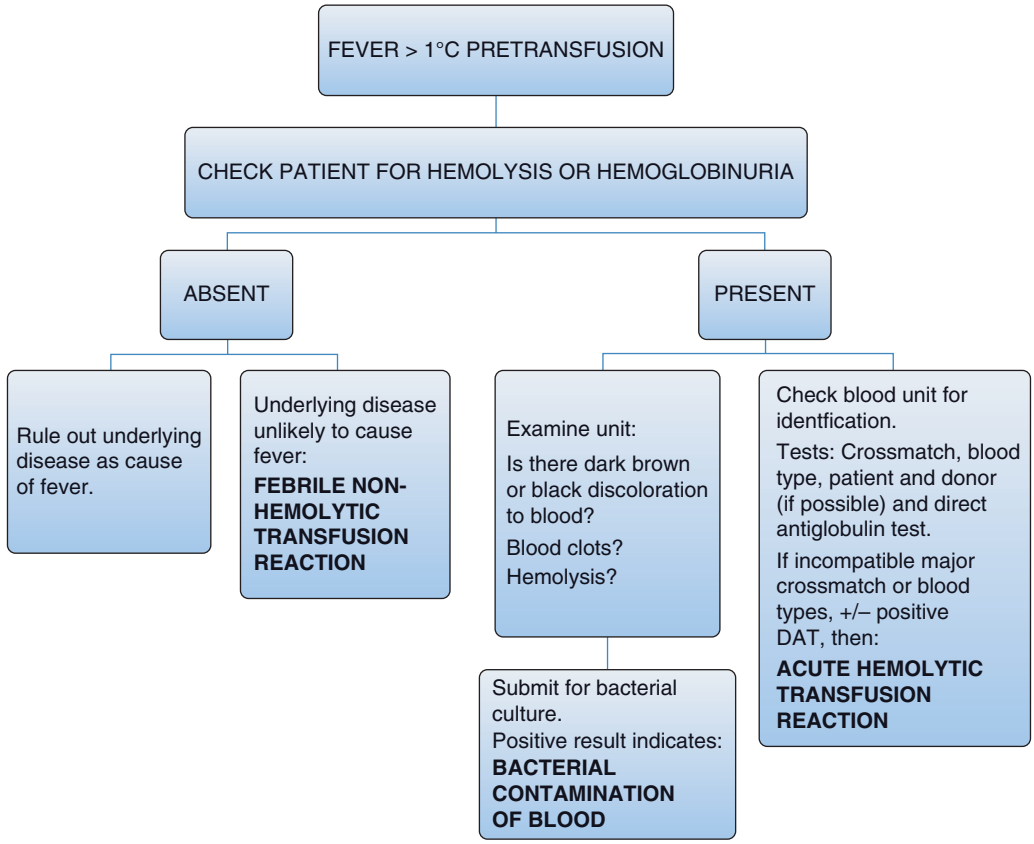

FIGURE 100.2 Algorithm for evaluation of a patient with a febrile transfusion reaction.

FIGURE 100.3 An urticarial reaction in a dog receiving plasma to treat rodenticide intoxication. Treatment with antihistamines and steroids induced resolution in 24 hours. (Courtesy of Dr. Ann Hohenhaus.)

typically those of the donor but targeting of recipient/patient platelets has also been documented.[36] PTP must be differentiated from worsening underlying disease or development of a concurrent disorder.

Anaphylaxis secondary to IgA deficiency has been reported in a single dog.[2] Anaphylaxis results from patient anti-IgA antibodies reacting to IgA antibodies in the donor plasma.[2] Clinical signs vary from facial swelling, urticaria, and erythematous skin to respiratory distress, vomiting, diarrhea, and shock.[1] An IgA-deficient patient who previously demonstrated a severe anaphylactic reaction would require future transfusions that are free of IgA.

Transfusion-related acute lung injury (TRALI) is characterized by dyspnea, hypoxia, pulmonary edema, and fluffy, bilateral infiltrates on thoracic radiographs which develop during or within 6 hours of a transfusion. To date, TRALI has been described only in humans.[35,39] Transfusion-related acute lung injury clinically mimics acute respiratory distress syndrome, circulatory overload, or cardiac failure, so it could be easily misdiagnosed. Fever may or may not be present.[39] Transfusion-related acute lung injury may result from several mechanisms, including both antibody-mediated pathways and non-immune causes, with neutrophil activation and subsequent leakage from capillaries (pulmonary microvasculature leakage) being the common final pathway.[35,39] Treatment typically involves oxygen therapy and ventilation, when needed.[36]

Transfusion-associated graft-versus-host-disease (TA-GVHD) also has yet to be reported in veterinary medicine. It results from the proliferation of viable donor T lymphocytes, which go unrecognized as foreign by the recipient's immune system; these donor T lymphocytes recognize and subsequently attack the recipient (or host).[12] In humans, certain cellular immunodeficiencies predispose the transfusion recipient to

this reaction; also, recipients of blood transfusions from close relatives place the recipient at greater risk for TA-GVHD.[12] Since leukoreduction is insufficient in preventing TA-GVHD, component irradiation is recommended in patient populations at increased risk of developing TA-GVHD (e.g. hematopoietic progenitor cell transplant recipients).[12] Clinical signs of TA-GVHD in man reportedly manifest within 2–50 days of transfusion and include a rash, diarrhea, liver dysfunction and pancytopenia. Mortality is greater than 90%.[12]

NON-IMMUNE COMPLICATIONS

Infectious Disease Transmission

Transmission of infectious agents to a blood transfusion recipient, though a relatively infrequent complication in both human and veterinary transfusion medicine, is not a true transfusion reaction but is obviously an avoidable and potentially devastating complication of transfusion. Infectious diseases documented to have been transmitted via transfusion in veterinary medicine include babesiosis, leishmaniasis, bartonellosis, and diseases caused by *Mycoplasma* sp.[3,13,14,29,30,34,37,40] Although WB and pRBCs carry a greater risk of infectious disease transmission, plasma is not without risk; recently, herpesvirus was inadvertently transmitted to horses receiving commercially prepared plasma.[3] A recent consensus statement from the American College of Veterinary Internal Medicine includes guidelines for recommended testing for both canine and feline blood donors based on the literature and known blood-borne agents (see Chapter 94).[42] Documentation of a transfusion-acquired infection requires testing of pre-transfusion recipient blood, in addition to testing the donor; unfortunately, pre-transfusion recipient samples are not always available. Proper transfusion records will allow for easy identification of the suspected infected donor, removal of any remaining blood units from that donor, and appropriate treatment of the donor.

Transfusion-associated Sepsis

Bacterial contamination of a blood unit can result in transfusion-associated sepsis. Clinical signs associated with transfusion of a contaminated blood unit include fever, vomiting, diarrhea, hypotension, and hemolysis.[12] Contamination can occur at the time of collection from inadequate preparation of the venipuncture site or contamination of materials used in collection. Once contamination of a unit occurs, bacterial numbers tend to increase with storage time, even when the unit is refrigerated. Storage at room temperature, which is necessary to preserve the post-transfusion survival of platelets in fresh WB and platelet-rich preparations, can also lead to bacterial proliferation in contaminated units. It has been documented that units of human pRBCs stored for longer than 21 days are more likely to contain proliferating bacteria.[18] The severity of a reaction will ultimately depend on the bacterial species, the number of bacteria present, and the clinical condition of the recipient/patient.[21]

Reports of bacterial contamination of blood products and transfusion-associated sepsis are infrequent in veterinary medicine.[2,22] Contamination of feline blood units with *Serratia marcescens* was attributed to contaminated supplies used in donor collection. Vomiting was the most common clinical sign seen in cats receiving contaminated units, and four recipients died.[22] This report illustrates the importance of bacterial culture of materials other than the unit and demonstrates the steps necessary to identify the source of contamination. Contaminated WB or pRBC units are typically discolored (dark brown, purple, or black), and clots and air bubbles may also be present.[22,36] The discoloration associated with bacterial contamination indicates deoxygenation, hemolysis, and the formation of methemoglobin. Blood units with such an abnormal appearance should not be used, and an investigation to confirm bacterial contamination and identify the source of contamination should be pursued. Lastly, administration of a blood component unit should ideally take no longer than 4 hours to reduce the potential for bacterial proliferation. Once a unit is opened, even if refrigerated, it should be used within 24 hours. If bacterial contamination is suspected after the transfusion has been started, the transfusion should be stopped immediately and the unit submitted for a Gram stain and bacterial culture. Blood culture of the recipient may also be warranted.

Uncommon Non-immune Complications

Citrate Toxicity

Citrate is the anticoagulant used in most standard blood collection systems. Plasma and WB have the greatest concentrations of citrate when compared to pRBCs. Patients most at risk for citrate toxicity include those receiving large volumes of blood products, such as in cases of massive transfusion (see Chapter 95) and, potentially, patients with severe liver disease since citrate is metabolized by the liver. Ionized hypocalcemia and hypomagnesemia result from chelation of these cations by citrate, and associated clinical signs include muscle tremors, vomiting, cardiac arrhythmias, ear twitching, hypotension and/or tetanic seizures.[2,24] Intravenous calcium can be administered to treat clinically significant transfusion-related hypocalcemia.

Circulatory Overload

Patients with chronic anemia and a compensatory expanded plasma volume or patients with compromised pulmonary and/or cardiac function may be at risk for circulatory overload.[36] Expected clinical signs include respiratory distress and, in some cases, congestive heart failure; signs may be seen during or soon after transfusion. Management of fluid overload with diuretics is advised. Slowing the transfusion rate and using pRBCs rather than WB in anemic patients can help to decrease the risk of circulatory overload.

Non-immune Hemolysis Unrelated to Bacterial Contamination

Hemolysis unrelated to a blood group incompatibility or bacterial contamination may occur in vitro due to improper storage or handling of blood units, including use of a hot waterbath, inadvertent freezing, use of pumps not approved for administration of blood products, and concurrent administration of incompatible fluids, such as 5% dextrose or hypertonic saline through a shared intravenous line.[32,36,38] Warmed blood has been demonstrated to have decreased survival in the patient which could mimic a delayed transfusion reaction.[32]

PREVENTION AND RECOGNITION OF TRANSFUSION REACTIONS

Prior to blood product administration, baseline values of temperature, heart rate, and respiratory rate should be determined and pre-transfusion PCV should be recorded (see Chapters 95–99). Pre-transfusion WB and serum samples should be collected from the recipient, if not already submitted for other routine testing. These samples can be invaluable in cases of HTRs and in documentation of infectious disease transmission. Transfusion of any blood product is ideally started at a slower rate for the first 15 minutes while monitoring for signs of any adverse reactions. Clearly, in cases of severe, ongoing blood loss, rapid administration from the start may be necessary. Transfusion monitoring should be performed every 15 minutes for the first hour, with serial measurement of temperature, heart and respiratory rates. If there is any concern about an AHTR, evaluation of plasma and/or urine for the presence of hemoglobin is indicated. Lack of an expected increase in PCV post-transfusion may also be suggestive of an AHTR.

EVALUATION OF A PATIENT WITH A SUSPECTED TRANSFUSION REACTION

Investigation of hemolytic and febrile reactions should include inspection of the patient's plasma for evidence of hemolysis or icterus; evaluation of the blood product unit administered including unit labels, the administration set, Gram stain and blood culture of the transfused product; comparison of patient bilirubin both pre- and post-transfusion; retesting of patient and donor blood type, especially for reactions involving RBC-containing units; and post-transfusion crossmatch testing of recipient-donor compatibility. If a crossmatch test was performed pre-transfusion, it should be repeated in the case of a HTR; if one was not performed, a crossmatch test should be done using both pre- and post-transfusion plasma/serum, if available. In general, if a transfusion reaction is suspected, the transfusion should be stopped but the intravenous line kept open with saline until the patient and blood product can be further evaluated.

Adequately screening potential blood donors, transfusing patients only when clinically indicated, selecting the most appropriate blood component, properly administering blood products, and carefully monitoring transfusion recipients will greatly diminish the risk of a transfusion reaction.

Species Variations

Acronyms and Abbreviations

CYP21, 21-hydroxylase; DSCP, double-strand conformation polymorphism; HSP 70, heat shock protein 70; LA, lymphocyte antigen; MHC, major histocompatibility complex; PCR, polymerase chain reaction; RFLP, restriction fragment length polymorphism; SSCP, single-strand conformation polymorphism; SSOP, sequence specific oligonucleotide probes; TNF, tumor necrosis factor.

The major histocompatibility complex (MHC), a large region of associated genes, is the backbone of the immune system for most animals, birds, reptiles, and amphibians.[11] Genes in this region are responsible for encoding proteins that control all aspects of antigen presentation and processing leading to disease resistance or immune tolerance. This region seems extremely polymorphic and highly conserved as a unit in most species evaluated to date.[67] Classical MHC is made up of three classes: I, II, and III. Class I MHC genes encode for surface glycoproteins or histocompatibility antigens found on all somatic cell surfaces. Responsible for presentation of endogenously derived peptides to the T-lymphocyte cell receptor, class I molecules mediate the destruction of virus and tumor through activation of CD8-positive, CD4-negative cytotoxic T cells and natural killer cells. Class II MHC genes encode for surface glycoproteins found on antigen-processing cells like B lymphocytes, dendritic cells, macrophages, and epithelial cells. Class II molecules present exogenously derived peptides and mediate the activation of CD4-positive, CD8-negative T-helper cells, resulting in the secretion of specific cytokines leading to cell mediated and humoral immune responses. Within the class II region of most MHC complexes lie genes that encode proteins responsible for endogenous antigen processing. For example, genes encoding subunits for the 20S proteasome (LMP2 and LMP7) are here. Proteasomes are responsible for intracellular peptide degradation.[45] These genes are inducible. Peptide transporter molecules (TAP1 and TAP2) move peptides derived by the 20S proteasome across the membrane of the endoplasmic reticulum for loading into class I molecules for presentation. TAP genes are also within the class II region. It is interesting that genes encoding antigen-processing and genes presenting antigen to the immune system are linked in most species. The class III region of the MHC encodes for several complement factors (Bf, C2, C4), 21-hydroxylase (CYP21), tumor necrosis factor alpha and beta (TNF-α and -β), and heat shock protein 70 (HSP 70). Nomenclature for the MHC has included different names for different species with the lymphocyte antigen (LA) designation. Attempts at standardization have led to the suggestion of a system reliant on the first letters of the genus and species. For example, dog LA (DLA) would be replaced with *MHCCafa*.[34] Several species would retain their old designation: H-2/mouse, HLA/human, and RT-1/rat. This system is frequently seen in the literature but has not been accepted by the entire scientific community; therefore, both nomenclatures are in use.

TYPING PARADIGMS

Serologic Typing

Typing paradigms to recognize and define the highly polymorphic MHC genes and gene products (antigen expressed on the cell surface) have undergone evolutions. Complement-mediated cell lysis with absorbed complement and sera derived from multiparous or immunized animals or man was one of the early, serologic methods used.[7,39] This assay is often referred to as

the microlymphocytotoxicity assay. It was run in Terasaki microtiter plates and used microliter quantities of reagents. The sera used were often validated through international workshops under the auspices of the International Society of Animal Genetics. Examples of sera validation are cited under species-specific information later in this chapter.[8,12–14,32,35] Serologic typing can be used for both class I and class II antigen characterization.[7,39]

Cellular Typing

Cellular typing was first used to recognize class I antigen and is still useful for determining functionality for the plethora of class II antigens seen in most species.[15] Cellular assays include the use of the mixed lymphocyte culture or reaction.[43] In brief, lymphocytes of two test subjects are mixed together in culture. The lymphocytes of one subject are treated with either chemicals or radiant energy to render them incapable of response and serve as stimulator for the other population of cells. If stimulated, the untreated cells undergo lymphoblastogenesis. The intensity of the response is proportional to the increase in the number of cells. A second form of cellular typing is termed primed lymphocyte testing.[44] The format of this testing is very similar to a mixed lymphocyte culture, with treated and untreated cells used, except it often employs well-characterized cell lines that are used as a reference base.

Molecular Typing

Molecular methods now dominate the MHC typing modalities.[9] Initially, these methods offered very crude estimates of alleles present by the performance of restriction fragment length polymorphism (RFLP) testing, often using xenogeneic probes. For many species this method represents the only testing data available. Further refinement in testing modalities has brought forward methods based on amplification of a portion of a MHC gene (usually exon 2 for class II and exon 3 for class I). The polymerase chain reaction (PCR) is most often used for this amplification.[54] Amplified fragments may be bound to a membrane and probed with sequence specific olgionucleotide probes (SSOP) that recognize the polymorphic position within the gene; this method is termed PCR-SSOP typing.[9,66] Fragments may also be digested with endonuclease and the resulting RFLP patterns used to recognize polymorphic variation within the region tested; this is termed PCR RFLP.[9,27] Secondary structure differences introduced by the sequence variation can be seen when the molecules migrate within a gel. Such structures can be single stranded or double stranded. Amplified fragments can also display secondary structure, and this characteristic is used to recognize variation seen in different MHC alleles. This type of testing, based on secondary structure, is termed single-strand conformation polymorphism (SSCP) typing or double-strand conformation polymorphism (DSCP) typing. When amplified products are used, the terms PCR SSCP or PCR DSCP are used.[6,9]

Specific alleles can also be amplified with PCR in a testing protocol that allows for high-resolution typing.[9] Briefly, primer pairs are anchored in the polymorphic regions of specific alleles. This methodology may share one of the primers with other alleles but each allele has a unique set. This type of testing is often referred to a PCR SSP.[49]

The most definitive type of MHC typing is sequenced-based typing.[9] This form of analysis allows for discrete allele assignments even in the presence of heterozygous alleles. One note of caution: although the detection of alleles can be accomplished at the molecular level, there is no assurance that these molecules may be expressed.[52] This can lead to errors in expected outcomes of research protocols and transplantation results.

As a result of the numerous genomic mapping projects completed in many species, the identification of microsatellite markers within the MHC complex provides unique tools for haplotype studies within a family or related population.[18] Microsatellite markers are short tandem repeats present in the genome. Primers flanking the tandem repeat are designed so that, when amplified, the product length variation depends on the number of repeats present. Because of the high degree of linkage disequilibrium or lack of recombination, the haplotype (full complement of MHC of one parental chromosome) can be followed throughout a family for pedigree, transplant, or disease association. Microsatellites may be used to track MHC alleles within a family but not outside the family or related species.[16]

Recent advances in molecular typing described above have allowed definition of the MHC in nonhuman species without the need for access to large serum antibody databases. Knowledge of MHC "type" allows several clinical applications: paternity testing, disease resistance prediction, and transplantation pairing. Paternity testing has been used in man and animals for the purpose of defining shared alleles. Because of the high degree of polymorphism within the MHC, unique inheritance patterns can be used to predict the likelihood of unknown paternity. Studies of the MHC in man and mouse have led to the association of MHC type with disease resistance, disease inheritance, and potential autoimmune disease. As a point of example, ankylosing spondylitis occurs in 96% of Caucasians demonstrating a class I haplotype, HLA-B27. This association of ankylosing spondylitis is also seen in rats, mice and primates carrying a B27-like haplotype.[71] Frequent association of MHC haplotype and virally mediated leukemia has been made in several species, including the mouse, rat and bovine.[67]

Transplantation in humans relied on MHC typing for selection of donor-recipient pairs for over 30 years.[36] Strong clinical evidence supports the theory that concise allelic matching minimizes the graft versus host disease seen in solid organ and bone marrow transplantation. With the advent of molecular typing techniques, nonhuman species may be evaluated for MHC type before transplantation in an attempt to maximize post graft survival. The algorithm provided (Fig. 101.1) is designed to offer a general means of selecting donor-recipient

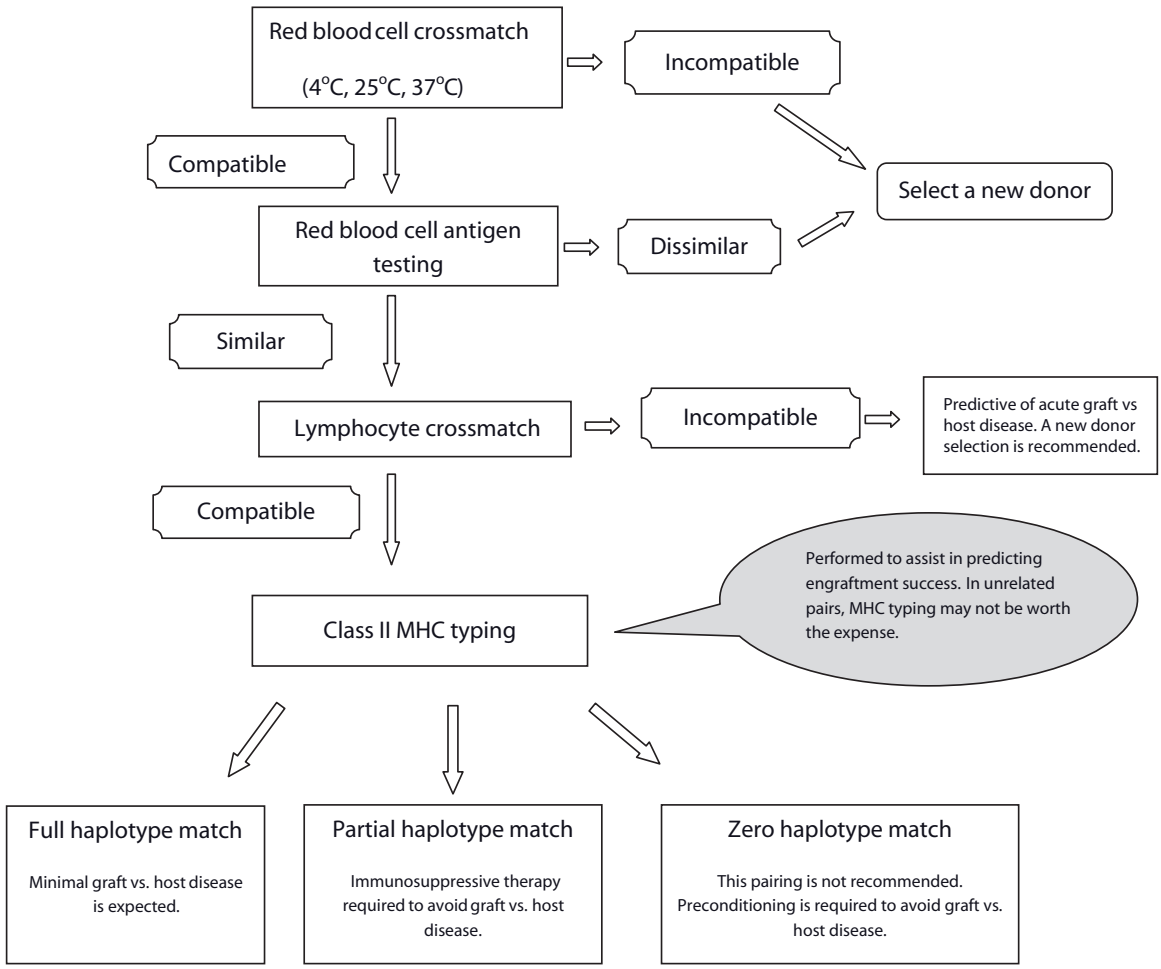

FIGURE 101.1 Donor-recipient pair selection for solid organ and bone marrow transplantation.

pairs for transplant in which MHC haplotype is used.[25] Recently, in nonhuman species, the use of protective conditioning through hematopoietic cell transplant and chimeric development has been explored to minimize immunosuppressive therapy post engraftment and expand the potential donor pool in highly polymorphic populations with limited donor organs.[65] Using this technique, the recipient is prepared through immunosuppression to receive peripheral blood stem cells from the donor. After engraftment is confirmed, the recipient receives the solid organ transplant. Early studies by Storb and others suggest that protective conditioning may offer a reasonable long-term outcome in the dog.[21,22,65]

SPECIES VARIATIONS

The human MHC, often referred to as the HLA complex, is perhaps one of the most well-defined systems (Table 101.1). This characterization was initially performed by serologic and cellular techniques, and over the past 20 years by molecular methods.[9] Allelic specific typing paradigms for all three classes of HLA genes have been developed with the progression of molecular science. HLA-A, HLA-B and HLA-C are traditional class I genes present on most nucleated cells of man; non-traditional genes, HLA-E,-F,-G,-H,-J,-K and -L are also present.[67] The class II regions have HLA-DR, HLA-DQ, and HLA-DP genes. The numbers of DRB genes present can vary, depending on which DRB gene is present. Within the class II region are the antigen-processing and transporter molecules, TAP and LMP. The class III region contains genes for HSPs and the CYP21 responsible for steroid metabolism. TNF genes are also present in the HLA class III region; from an evolutionary perspective, genes in this region are thought to be precursors to class I and class II genes. There are numerous microsatellites in the HLA region suitable for haplotype assignment and disease association studies.[18]

Primate MHC is very similar to that of man.[71] Class I products are defined as -A and -B. Higher monkeys such as the chimpanzee also have a -C locus. The class II molecules vary by Old World or New World species.

TABLE 101.1 Characterization of Animal MHC Systems

Species	Nomenclature	Class I	Class II	Class III	Unique Feature
Human	HLA	A, B, C	DR, DQ, DP	C2, C4, TNF, HSP, CYP21	
Rhesus	RhLA (Mamu)	A, B			
Chimpanzee	ChLA (Patr)	A, B, C	DR, DQ, DP	C2, C4, TNF, HSP, CYP21	
Mouse	H-2	K, D, L	A, E	Bf, C2, C4, M, TNF, HSP70	
Rat	RT1	A	DR, DP	Bf, C2, C4, TNF, HSP70	
Guinea Pig	GPLA (Capo)	B	DR	Bf, C2, C4, TNF, HSP70	No DP
Rabbit	RLA (Orcu)	A	DR, DQ, DP	Not linked	
Canine	DLA (Cafa)	88, 12, 64, 79	DR, DQ, DP	C2, C4, TNF, HSP, CYP21	
Feline	FLA (Feca)	H, K, E	DR, DQ	C2, C4, TNF, HSP70	
Bovine	BoLA (Bota)	A, B	DR, DQ, DY	Bf, CR, CYP21, HSP70, M	No DP
Ovine	OLA (Ovar)	N	DR	C4, CYP21, TNF	
Caprine	CLA (Cahi)	N	DR, DQ	C2, C4, TNF, HSP, CYP21	
Equine	ELA (Eqca)	A	DR, DQ	C4	
Swine	SLA (Sudo)	1, 2, 3, 6	DR, DQ	Bf, C2, C4, TNF, HSP70	Class II on resting T cells
Chicken	B complex	F	L	Not linked	Expression on RBC
Reptilian	Species specific	U	D	Data not available	
Amphibian	Species specific	A	DR	Data not available	
Fish	Species specific	U, Z/Ze	D	Data not available	

Old World monkeys demonstrate -DR, -DQ, and -DQ class II genes;[53] New World monkeys have dropped some of these class II alleles.[62] Class III genes include Bf, C2, C4, CYP21 and HSP70.[1] Microsatellites for many primate species exist, like the microsatellite facilitating rapid DRB haplotyping in Rhesus macaques.[16,62]

The mouse MHC, H-2, has been extensively characterized by serologic, cellular, and molecular techniques.[33] Situated on chromosome 17, the H-2 is organized in a similar fashion to the human MHC. Mouse class I equivalents include H2-K, -D and -L. Class II is made up of H2-A and -E. Class III is found exactly patterning the human MHC.[67] Many microsatellite markers have been characterized within the H-2. Strains of mice have been developed demonstrating H-2 disease associations; examples include leukemia and Gross virus infection.

The rat MHC, R-1, is homologous with the human MHC to a large degree. However, the genomic sequence of the rat MHC has recently been published indicating a significant difference in class I molecules when compared to the human MHC. Class II and III molecules maintain homology with the human MHC.[26] A model of multiple sclerosis, myelin oligodendrocyte glycoprotein-induced experimental autoimmune encephalitis, can be characterized as acute versus remitting/relapsing based on RT1-A, a class I molecule. This association reinforces the strong role that MHC plays in disease resistance and susceptibility.

The guinea pig (*Cavia porcellus*) MHC has class I, II, and III gene products.[72] Class I products have been identified by serology and molecular methods; GPLA-B is the only class I molecule currently defined. Class II molecules include a -DR homologue, the -I region.[59,64] Class III gene products include Bf, C2, C4, TNF and HSP70.[19]

The rabbit MHC, or rabbit LA (RLA), has been largely characterized through molecular techniques. RLA-A is a class I molecule; RLA-DR, RLA-DQ, and RLA-DP are class II gene products. Class III is not linked physically to the class I and class II genes as in most other species.[73]

The canine MHC (DLA) complex was initially characterized by both serologic and cellular assays.[55,56] Both class I and II antigens are present.[8,14,32] Class I genes include DLA-88, DLA-12, DLA-64 and DLA-79. DLA-88 is highly polymorphic.[31,68–70] With the advent of molecular typing, the class II genes have been well defined.[32] The DLA-D region of the dog has -DR, -DQ, and -DP homologues as seen in man, as well as -DO and -DN homologues and an LMP-2 gene. The class III region in the dog has C2, C4, CYP21, and TNF genes present.[57] Numerous microsatellites have been described for haplotype description in purebred and mixed breed dogs.[10,32,68] Despite frequent use of the dog as a transplant model for human preclinical studies, easily accessible molecular typing of DLA is not available.[21]

The feline MHC (FLA) could not be characterized until the advent of molecular typing. Cats do not readily form the anti-FLA antibody necessary for routine serologic identification. Until molecular characterizations were performed, the cat was considered uniquely monomorphic.[74,75] Class I, class II and class III equivalents have been identified on chromosomes B2 and 3. Three class I genes (FLA-H, FLA-K, and FLA-E) are described.[74] Class II genes have also been described (FLA-DR, FLA-DQ). The importance of FLA-DR in skin allograft suggests that MHC typing and matching prior to transplant may extend graft longevity.

The bovine MHC, bovine LA (BoLA), has been well characterized by both serological and molecular methods.[12,13] Cattle have BoLA-A and -B class I homologues. BoLA-DR and -DQ are class II molecules. Cattle

do not have a -DP homologue but do have a third class II gene expressed, BoLA-DY. The BoLA system has been associated with the susceptibility and resistance to several pathogens.[67] Cattle have the following class III genes linked to the BoLA complex: Bf, C4, CYP21, HSP70, and the blood group M.[37] Recent evaluations of BoLA-DQA indicate susceptibility to mastitis based on haplotype.

The ovine MHC, ovine LA (OLA) complex, has been primarily defined by molecular methods.[42] There are OLA-A and OLA-B class I genes. Class II genes include OLA-DR, -DQ, -DN, -DM and -DY.[73] Class III genes are described, together with multiple microsatellite markers.[60]

The MHC complex of goats, caprine LA (CLA), is less well defined than those of other ruminants.[47] Molecular sequencing has allowed the definition of the class I molecule, as well as a -DR region representing a class II molecule.[1,2,76] Class III molecules are homologous with the human MHC.

Equine LA (ELA) has been characterized by serologic, cellular and molecular methods.[35,38] The loci defined are ELA-A, ELA-B, and ELA-C for class I, and ELA-DR and -DQ for class II molecules. Class III molecules are present but have not been fully defined.[23,24]

The swine MHC, swine LA (SLA), has been characterized by serologic, cellular and molecular techniques.[58] This gene cluster has been found to be the smallest MHC in mammals tested to date. Class I, class II and class III molecules are present. SLA-1, -2, and -3 are class I molecules.[3] Class II molecules include SLA-DR and SLA-DRB. Several microsatellite markers on chromosome 7 within the SLA gene complex are available.[4,63] Recent interest in the use of the miniature swine as a research model for xenotransplant has spurred the completion of MHC mapping the pig.

The chicken MHC, B complex, is unique in that it has class I, II, III, and IV gene products present. Class I genes are defined as F, whereas class II genes are L. Unlike other MHC complexes reviewed, chicken class III products are not physically linked to the class I or II genetic regions. Class IV gene products (-B,-G), unique to the chicken and reptile, are expressed on red blood cells.[29]

Reptilian MHC is now predominantly defined by molecular methods. Class I and class II molecules with homology to the human MHC have been described.[17,40,41] Definition of non-avian reptilian MHC is ongoing through sequence analysis, but limited by sample availability.

The amphibian MHC has received much attention in the past 3 years as scientists search for reasons for species variation and decline.[5,61] Molecular methods have allowed an economically feasible means of determining the presence and defining the sequence of major histocompatibility molecules.[30] Class I and class II molecules, as well as a loosely linked class III molecular region, have been identified in several species of amphibians.[28] Unique to amphibians, the class I molecule is extremely stable with only one class I gene found in species separated for up to 100 million years. A great deal of work has been performed on *Xenopus*, a species of clawed frog.[46]

Evaluation of the MHC in fish has largely been connected with the advance of aquaculture.[51] Similarly to the poultry industry, aquaculturists have found the MHC to be useful in predicting disease resistance and parasite vunerability.[50] Molecular methods have allowed a detailed body of work to develop defining class I (-U, -Z/ZE) and class II (-D) molecules in fish.[20,48]

Classical MHC genes have been defined more completely by molecular methods in the past decade. The importance of this gene region to adaptive immune response, disease resistance, and population genetics has been enhanced as our testing methods have advanced. Through evaluation of this gene complex, clues to the evolutionary history and future of all species can be found.

In 2003, the Immuno Polymorphism Database[73] was developed. Established by the HLA Informatics Group of the Anthony Nolan Research Institute, this free database offers a section solely dedicated to sequencing data relating to the MHC (IPD-MHC) and provides a concise way for scientists to gather, share, and evaluate the MHC of vertebrate species.

The concept of a pluripotent stem cell capable of recapitulating all the cell lines of the hematolymphoid system was born from experiments with lethally irradiated mice in the early 1960s. However, it was not until 1988 that hematopoietic stem cells (HSCs) were prospectively isolated from mice.[61] The prevailing model of hematopoiesis is hierarchical and holds that mature, differentiated cells arise from primitive HSCs (see Chapter 3). Recently, a new model of HSC regulation has been put forth that represents a transformational view of hematopoiesis.[32,48] This view is of a continuous rather than hierarchical model of HSC regulation, and postulates that HSCs vary in phenotype according to cell cycle stage.[46] Cell cycle-dependent traits include in vivo engraftment, progenitor numbers, expression of adhesion proteins and cytokine receptors, and differentiation into megakaryocytes and granulocytes.[48] Clearly, if shown to be accurate, a continuum model of HSC regulation will impact upon current transplantation strategies, as well as the concept of a rigid HSC phenotype.

Bone marrow provided the source of HSCs in the original transplantations in the late 1950s. The first bone marrow transplantations (BMTs) in humans were performed with little to no knowledge of transplant antigens or engraftment mechanisms, and results were less than promising. It was the use of animals in research, especially dogs, which helped realize the clinical potential of BMT in humans. The discovery of specific HSC markers opened the door to non-marrow sources of HSCs and expanded our knowledge of HSC biology. Stem cell biology both derives from and contributes to transplantation science. We continue to rely upon animals to further our knowledge of stem cell biology and translate therapeutic strategies into clinical practice.

TYPES OF TRANSPLANTATIONS

Donor Types

Hematopoietic stem cell transplantations (HSCTs) can be syngeneic, allogeneic, or xenogeneic. These donor types relate to the genetic and, therefore, antigenic relation between donor and recipient. Syngeneic transplants are derived from monozygotic twins, animals of the same genotype (i.e. mice of the same strain), or autologous HSCTs. In allogeneic transplants, HSCs are intraspecific and the genotype differs from the recipient, whereas xenogeneic transplants are between species. Table 102.1 provides a comparison between the three types of transplantation donors.

Allogeneic Transplantation

Allogeneic transplantations are further subcategorized according to both histocompatibility and to their relation to the recipient. Immunosuppressive therapy is required for allogeneic HSCT in order to suppress both host and donor responses; the former is necessary for engraftment, whereas the latter prevents graft versus host disease (GVHD). GVHD is one of the most significant impediments to allogeneic HSCT and results from immune targeting of host cells by the donor T cells. For many years the GVHD associated with allogeneic HSCT precluded its clinical application, but advances in immune modulation, donor and HSC selection, and supportive therapy have greatly decreased many of the adverse effects. However, GVHD can be exploited to eliminate host leukemic cells; allogeneic HSCT is more effective than autologous HSCT in tumor killing. This phenomenon is referred to as "graft versus leukemia" (GVL). The GVH effect may also eliminate host autoreactive T cells; thus HSCT is now being explored for the treatment of autoimmune diseases.[65] For diseases in which the recipient's HSCs are inherently defective (e.g. severe combined immunodeficiency, Fanconi anemia), allogeneic transplantation is currently the best option.

Syngeneic/Autologous Transplantation

With autologous or syngeneic transplantation, there is no genetic incompatibility, which obviates the need for post-transplantation immune suppression, the risk of GVHD, and engraftment failure. On the other hand, autologous HSCT does not provide the benefits of GVL. Autologous HSCT is principally used as a rescue therapy following myeloablative therapy for hematologic malignancies. Interestingly, autologous HSCT does appear to have some success in the treatment of some autoimmune disorders. The positive effect is correlated with early disease stages and very intensive conditioning regimens.[65] The mechanism by which this occurs is thought to be a "re-setting" of the immune system following ablation of the existing hematolymphoid system; HSCT recapitulates ontogeny with concomitant re-self-tolerization of T cells.[68]

As gene therapy advances, applications for autologous HSCT will expand when the patient's own HSCs can be corrected ex vivo and returned, permitting autologous HSCT therapy for genetic conditions. Select animal models of genetic disease have been successfully treated by ex vivo gene therapy and HSCT.[4]

Xenogeneic Transplantation

One of the biggest obstacles to the use of xenogeneic HSCs is graft rejection. While graft rejection remains a significant hurdle to overcome, a benefit of xenogeneic HSCT is the near absence of GVHD.[18] To date, xenogeneic HSCTs are used mainly for research rather than therapy; in a notable exception for an AIDS patient, the HSCT proved unsuccessful.[40] Several rationales are presented for therapeutic xenogeneic transplantation. The

TABLE 102.1 HSCT Donor Types: Indications and Consequences

	Allogeneic[a]	Autologous	Xenogeneic
Indications	Leukemias Lymphoma Genetic diseases Autoimmune diseases Myelodysplasia	Marrow rescue Gene therapy for genetic disease Autoimmune diseases	Tolerance induction for organ xenografts Genetic diseases Infectious diseases (e.g. AIDS)
Advantages	GVL Gene correction	No immune suppression Donor availability No GVHD No transmission of infectious agents	Donor availability Gene correction No GVHD
Disadvantages	GVHD Immune suppression Donor availability Graft rejection Donor transmission of infectious agent	No GVL	Xeno- or zoonoses Immune suppression Graft rejection Ethics (animal rights)

[a]GVL, graft versus leukemia; GVHD, graft versus host disease.

first is that xenogeneic transplants offer a readily available supply of donors. Secondly, for infectious diseases such as AIDS, HSCT from a resistant species would reconstitute the hematolymphoid system with resistant cells; the flipside of this argument is the potential for zoonotic infection or, worse, introduction of a new pathogen to humans (xenozoonosis). Finally, xenogeneic HSCT can induce tolerance for solid organ xenografts.[25]

Bone Marrow

Whole Marrow

Historically, marrow was used to reconstitute marrow. In addition to HSCs, marrow also contains other cells that have been shown to affect engraftment, GVHD, and tumor immunity; i.e. T cells, mesenchymal stromal cells (MSCs), and myeloid progenitor cells (MPCs). Marrow grafts can now be modified by decreasing proportions of the deleterious components responsible for GVHD while enriching for MSCs, MPCs, and CD34+ cells that can enhance engraftment and reconstitution.[8] T cell modulation for HSCT is an ongoing challenge. Whereas T cell depleted marrow will produce little to no GVHD, graft rejection is very high due to the role donor T cells play in promoting engraftment.[44] There is also significant loss of GVL effects with T cell depleted marrow.

Purified Hematopoietic Stem Cells

The rationale for the use of purified or enriched populations of HSCs rests in improving engraftment and preventing GVHD. The poor engraftment following depletion of donor T cells to prevent GVHD can be reversed by increasing the dosage of CD34+ cells.[49] Recent studies have shown that HSCTs enriched for CD34+ cells can overcome even haploidentical (genetically related but MHC-mismatched) transplantation barriers by inducing tolerance in residual host T cells. The mechanism of tolerance involves tumor necrosis factor-α mediated deletion of host T cells by a CD34+ cell subset.[50]

However, the use of pure CD34+ cell populations for HSCT has two big disadvantages: delayed immune reconstitution (as a result of the lack of donor T cells and conditioning-induced host T cell depletion) and high leukemia relapse rates (due to the lack of GVL). Delayed immune reconstitution puts the host at increased risk for serious infections. In veterinary medicine, the ability to purify HSCs is limited to those species for which anti-CD34 antibody is available, obviating the use of purified HSCs for all other species. The expense and technical expertise necessary for CD34+ cell isolation and culture further limit its practical use for most veterinary patients.

Mesenchymal Stromal Cells (MSCs)

Bone marrow contains at least two types of stem cells: HSCs and MSCs. The prevalence of MSCs in marrow is 10–100 times less than that of HSCs. MSCs have been described in rats, mice, humans, and dogs, and can be isolated from marrow and peripheral blood.[29,31,45] MSCs are plastic-adherent when maintained in standard culture conditions; CD105+, CD73+ and CD90+; CD45– and CD34–; and able to differentiate in vitro into osteoblasts, adipocytes, and chondroblasts.[17] In HSCT clinical trials, MSCs were non-immunogenic and exerted immunomodulatory effects that promoted engraftment, accelerated hematopoietic recovery, and diminished GVHD.[35] Use of MSCs in HSCT may have a strong impact for the treatment of GVHD and for tissue repair.

A subset of MSCs that is pluripotent has been isolated by in vitro culture.[30] These cells, termed multipotent adult progenitor cells (MAPCs), have been shown to be transferred in unfractionated marrow grafts.[51] A recent study demonstrated lymphohematopoietic reconstitution from MAPCs, a finding that would permit what was previously impossible: in vitro HSC expansion.[57] The use of MSCs for cellular and HSC therapy is expanding rapidly and has been recently reviewed.[36,45]

HEMATOPOIETIC STEM CELL PURIFICATION

Stem Cell Markers

The HSC phenotype has been defined as lineage marker negative (Lin–), Sca-1+, CD34+, c-kit+, Hoechst low, and rhodamine low in mice and baboons.[5,61,75] Canine CD34+/rhodamine low cells are c-kit+.[64] CD34 expression was considered the hallmark of the "true" HSC for transplantation until it was demonstrated that CD34– HSCs were capable of successful long-term engraftment.[26,43] Data suggest CD34 expression reflects activation state and is reversibly expressed by HSCs; thus, HSCs may be variably CD34+ or CD34–.[55] In dogs, humans, baboons, pigs, cattle, and mice, CD34+Lin– HSCs are capable of long-term multi-lineage hematopoiesis.[5,12,34,53,61] Anti-canine and anti-bovine CD34 monoclonal antibodies are available for HSC enrichment.[39,53] The feline CD34 molecule has recently been cloned, but the long-term repopulating ability of feline CD34+Lin– cells has not yet been characterized.[77]

Sources

Bone Marrow

Bone marrow is the classical source of stem cells; HSCs represent approximately 1% of nucleated marrow cells. Studies have shown that marrow-derived HSCs have superior proliferative and reconstitutive ability compared with peripheral blood CD34+ cells, although these differences do not appear to have clinical significance.[69] Using marrow as a source of HSCs is less demanding technically than the use of peripheral blood, which requires leukapheresis.[38]

Peripheral Blood

Although "steady-state" (unmobilized) peripheral blood has been shown to be capable of marrow reconstitution, it is ineffective, requiring nearly ten times as many peripheral blood mononuclear cells (PBMCs) as marrow cells. A steady-state PBMC graft comprises only 0.06% HSCs and contains 10 times as many T cells as a marrow graft.[33] However, extravascular HSCs can be mobilized into the blood with the use of hematopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) and granulocyte macrophage colony-stimulating factor (GM-CSF). Mobilization with G-CSF/GM-CSF in humans, mice, and dogs produces a log increase in HSCs so that numbers equal or exceed those in marrow.[16,33] A recent alternative to G-CSF/GM-CSF is AMD3100, a reversible CCXR4-antagonist that mobilizes HSCs by disrupting binding to stromal-cell-derived factor 1-α. AMD3100 was used successfully in dogs for mobilized PBMC transplants.[13]

There are advantages to the use of mobilized PBMCs over marrow for HSCT. Peripheral blood is more readily accessible and much larger volumes are available; hence many more CD34+ HSCs can be collected than from marrow. The increased proportion of HSCs results in significantly quicker hematologic recovery times with mobilized PBMC transplants compared with BMTs.[69] A leukapheresis protocol for mobilized canine blood has been described.[38]

Umbilical Cord Blood

In humans, umbilical cord blood (UCB) contains hematopoietic precursor cells capable of long-term reconstitution. The number of HSCs in UCB is 1–2 logs fewer than in a comparable unit of marrow, but studies have demonstrated UCB to be superior to marrow in reconstituting the marrow progenitor cell population.[21] Umbilical cord blood grafts show slower hematopoietic recovery, but less GVHD. Greater MHC disparity between donor and host is tolerated for UCB than for PBMCs or marrow.[11]

In animals, there is little published information on UCB as a source of HSCs.[67] However, the ontogeny-related functional differences in UCB progenitors are also noted in murine and canine neonatal HSCs. Neonatal HSCs may serve the same purposes in animal models as human UCB transplantation.[56,64]

TRANSPLANTATION METHODOLOGY

Donor Selection

The risk of graft rejection is correlated to the degree of major histocompatibility complex (MHC) disparity between donors and recipients. Ideal donors for HSCT are matched for both class I and II genes encoded by the MHC gene family. The MHC gene subset that encodes cell surface antigen presenting proteins is known as the leukocyte antigen (LA; see Chapter 101). Leukocyte antigen has been best characterized in humans and mice. Dog leukocyte antigen (DLA) is fairly well defined, and characterization of feline LA is progressing rapidly.[79]

In allogeneic HSCT, a related LA-matched donor is ideal. A haploidentical donor is a genetically related donor with 1–3 histocompatibility loci mismatches. While GVL is stronger with a haploidentical donor, GVHD and chances for engraftment failure are also greater. In order of suitability, the choices for HSCT donors are: a related LA-matched donor, a haploidentical donor, and an unrelated LA-matched donor. Unrelated LA-matched donors often have other MHC mismatches that are not tested for in routine tissue typing.[25]

Recipient Conditioning

The two principal aims of recipient conditioning comprise facilitation of HSC engraftment and prevention of GVHD. Requisites for successful engraftment are thought to be the creation of available "space" for donor HSCs within stem cell niches and suppression of the host T cell response to prevent a host versus graft (HVG) response. Currently there is a difference of opinion regarding whether engraftment requires supplanting endogenous HSCs within niches.[3,7–9,59,63] Historically, the "space" requirement prevailed and pre-transplantation recipient conditioning for both autologous and allogeneic HSCTs predicated myeloablation, usually with total body irradiation (TBI) and/or chemotherapy. Because of the high toxicity associated with myeloablative conditioning, HSCT was only a viable option for young, relatively healthy patients. Hematopoietic stem cell transplantation became more feasible for older patients after dog studies proved that stable chimeras could be achieved with non-myeloablative TBI (2 Gy) followed by immunosuppression to control both GVHD and HVG reactions.[62]

The "space" theory was challenged by dog studies in which successful marrow engraftment was accomplished when irradiation was targeted to lymph nodes, suggesting that TBI functioned to enable engraftment via immune suppression, not by making "space" in marrow niches.[63] These findings were refuted in mouse experiments where, in the absence of conditioning, the occupancy of niches did limit donor HSC engraftment.[7] In support of this, one dog study showed significantly enhanced long-term autologous HSC engraftment with some form of pre-transplantation conditioning.[3] However, the debate remains open as to how much and what type of conditioning are necessary, as other groups have achieved successful chimerism with autologous HSCT in dogs and cats without any conditioning.[9,20,59]

Focused conditioning strategies may avoid toxicities associated with myeloablation. In support of the "space" requirement theory, pre-transplantation conditioning with an anti-HSC (anti-c-kit) antibody in immunodeficient mice permitted robust donor HSC engraftment in the absence of myeloablation.[15] Other strategies to reduce the toxicity of conditioning regimens target the host T cell response. An example is anti-T cell

receptor αβ conditioning, which resulted in successful engraftment of DLA-matched HSCs in the absence of irradiation.[6]

Post-transplantation, additional immune suppression is required for allogeneic but not autologous HSCT, to prevent HVG and GVH reactions. However, autologous HSCs that are "corrected" via gene therapy may require sustained immune suppression if a novel immmunogenic protein is expressed. The incidence of GVHD has been decreased by augmenting a purine inhibitor (e.g. mycophenolate mofetil) with a T cell activation inhibitor (e.g. cyclosporine) or by graft T cell depletion.[78]

Transplantation

The transplantation procedure for HSCs, regardless of source, is similar. Because HSCs home to marrow, there is no need for homotopic transplantation. Grafts are typically administered intravenously at a dose ranging from 10^7–10^9 nucleated cells/kg body mass in canine and feline BMTs. Grafts enriched for CD34+ HSCs have been administered in dogs at doses of 10^6–10^7 CD34+ cells/kg, similar to the "megadose" HSCTs in humans.[28]

Outcomes

The HSC graft may either be accepted or rejected by the host. Engraftment is determined by the degree of host chimerism and hematopoietic recovery, and may be either short-term or long-term. The importance of sustained engraftment is defined by the graft's indication. For marrow reconstitution following intensive chemotherapy for malignancy, short-term engraftment is acceptable if it enables autologous recovery. Conversely, for correction of congenital hematologic disease, long-term engraftment is essential. Because successful engraftment is often associated with GVHD, the overall aim of HSCT is to balance the host and donor immune responses, enabling engraftment but avoiding GVHD.

COMPLICATIONS OF CONDITIONING AND TRANSPLANTATION

The complications of HSCT are consequences of immune suppression, myeloablation, and GVHD. Susceptible patients acquire infections from infected donor grafts, from the environment, or from reactivation of a latent viral or parasitic infection. Myeloablation complications, apart from immune suppression, primarily concern the propensity for hemorrhage. Today, allogeneic donors are antigenically matched as closely as possible to the recipient, but nearly a third of histocompatible human HSCTs will still develop GVHD. In haploidentical canine HSCTs, median onset for acute and chronic GVHD is 13 and 124 days, respectively.[2] The clinical signs associated with canine GVHD correlate with the principal organs typically affected, namely gastrointestinal tract, skin, and liver.

The use of TBI for conditioning may result in damage to tissue such as thyroid and pancreas, and may interfere with normal growth in young recipients. In one study, insulin-dependent diabetes mellitus was noted in a feline HSCT patient post-TBI.[19] In dogs, intussusception is a reported potential complication in up to 4.9% of BMT recipients.[80] The mechanism is not understood, but may be related to post-transplantation immunosuppressive therapy.

CURRENT AND FUTURE APPLICATIONS

Current Treatment Applications

Published uses and outcomes of HSCT in dogs and cats are listed in Table 102.2. This table represents a large sampling of the literature but is not a comprehensive

TABLE 102.2 Therapeutic Applications of HSCT in Dogs and Cats

Application	Species	Outcome	References
Leukemia	Feline	Positive effect	24
Lymphoma	Canine	Positive effect	1, 22, 37, 73
Genetic diseases			
MPS I	Canine, Feline	Positive effect	10, 19, 58

review. Hematologic malignancies, including lymphoma, are one of the most common indications for human HSCT, but few published reports for this use appear for dogs and cats.[1,22,24,37,73] Therapeutic transplantation for genetic disease is one of the most published uses of veterinary HSCT because of the invaluable role of animal genetic disease models. The clinical use of autologous "corrected" HSCs for transplantation therapy for genetic disease is in its infancy and many issues remain to be resolved before it can be widely used.[27] In humans, HSCT is used to treat aplastic anemia and myelodysplasia, and recently has shown promise for autoimmune disease therapy.[65,68] Currently there are no published reports for dogs and cats on the use of HSCT for these disorders.

Future Potential: "Transdifferentiation?"

Over the past decade, multiple groups have reported that bone marrow and/or HSCs have the ability to produce non-hematopoietic cells including neurons, liver, and muscle. Some of this "transdifferentiation" was explained by the phenomenon of donor hematopoietic cell fusion with host cells.[72] However, rare instances of true non-hematopoietic differentiation from donor HSCs have been documented. Some scientists suggest that it may be the MAPC subpopulation in HSC grafts that is responsible for this plasticity.[57] The field of HSC/MSC plasticity, though contentious, is actively being investigated and is producing interesting results.[47,52,70]

One of the main impediments to the clinical use of HSCT is the lack of compatible donors. Many veterinary patients are obtained from shelters or pet stores; thus related donors are not available. The overall expense, complications of immune suppression, lack of widely available donor typing, and intensive supportive care measures are all prohibitive factors to its use outside of the academic arena. Finally, the ethics of HSCT in veterinary patients cannot be dismissed. In a patient incapable of informed consent, the consequences of HSCT must be carefully weighed against those of the disease process and alternative therapeutic strategies.

Acronyms and Abbreviations

BMT, bone marrow transplantation; CRF, chronic renal failure; EPO, erythropoietin; FDA, Food and Drug Administration; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; Hct, hematocrit; HGF, hematopoietic growth factor; IL, interleukin; M-CSF, macrophage colony-stimulating factor; PBPC, peripheral blood progenitor cell; RBC, red blood cell; rcEPO, recombinant canine erythropoietin; rfEPO, recombinant feline erythropoietin; rhEPO, recombinant human erythropoietin; SCF, stem cell factor; TBI, total body irradiation; TPO, thrombopoietin.

The hematopoietic system is an exquisitively controlled hierarchical tissue, with multipotent stem cells residing mainly in the bone marrow eventually becoming nonreplicative mature hematopoietic cells that circulate in the peripheral blood. The endogenous elaboration of hematopoietic growth factors (HGFs), stimulatory glycoproteins that affect the growth and differentiation of bone marrow-derived cells from these stem cells, drives this process. Some of these HGFs exert their effects on multiple cell lineages, while others are cell lineage specific. The availability of these HGFs has become invaluable in human medicine, with marked clinical advancements in bone marrow transplantation (BMT) and chemotherapy-induced myelosuppression, as well as in a variety of other disorders.

Several canine and feline HGFs have been cloned, although none are commercially available for clinical applications. The use of recombinant human HGFs is relatively commonplace in veterinary medicine but still considered strictly an extra label application. The following brief review will discuss the most clinically relevant HGFs used in veterinary medicine.

ERYTHROPOIETIN

Background

Erythropoietin (EPO), a red blood cell (RBC) lineage-specific hormone, is produced mainly by juxtatubular interstitial cells of the renal cortex, with a small amount being produced by the liver. Erythropoietin cooperates with various other HGFs (interleukin-3 [IL-3], stem cell factor [SCF], thrombopoietin [TPO]) in the development of colony-forming unit-erythroid cells in the bone marrow from a common myeloid precursor. Erythropoietin promotes erythroid progenitor cell survival through apoptosis evasion via up-regulation of the antiapoptotic protein $BCLX_L$[16] and by reducing the level of cell-cycle inhibitors. The end result is increased production of proerythroblasts and release of more RBCs into the circulation. It is now recognized that hypoxia, the most potent stimulus of EPO production, increases the activity of the primary EPO transcription factor, hypoxia-inducible factor 1α.[40]

In 1989 EPO became the first HGF to become commercially available for clinical use in the United States.

Recombinant human EPO (rhEPO, epoetin alpha) (Epogen, Amgen, Thousand Oaks, CA; Procrit, Ortho Biotech, Bridgewater, NJ), is approved by the US Food and Drug Administration (FDA) for the treatment of anemia associated with chronic renal failure (CRF), zidovudine (Retrovir) therapy in patients infected with human immunodeficiency virus, and chemotherapy for nonmyeloid malignancies, as well as anemia in patients scheduled for elective, noncardiac, nonvascular surgery. In 2001 darbepoetin alpha (Aranesp, Amgen), a hyperglycosylated molecule based on the protein backbone structure of human EPO, was approved by the FDA to allow a new option for treatment of anemia of CRF. The increased level of glycosylation allows a longer duration (up to three times longer than EPO) of the drug in the circulation.[11] Subsequently, darbepoetin alpha was approved for the treatment of chemotherapy-induced anemia in patients with nonmyeloid malignancies.

Use in Veterinary Medicine

Similar to the human experience, EPO most likely plays an important role in the pathogenesis of anemia in companion animals. The suppressed rate of RBC formation caused by lack of renal production of EPO is a major problem in the treatment of patients with CRF.[36]

Fortuitously, the structure of EPO is well conserved across species lines. When given to dogs and cats with CRF, rhEPO causes a dose-dependent increase in the hematocrit (Hct) and corrects anemia.[6] A transient, moderate reticulocytosis is initially seen and the bone marrow myeloid:erythroid ratio decreases, illustrating the increased erythropoietic response. Depending on the dose given and the initial Hct, correction of the Hct to low normal takes from 2 to 8 weeks. When RBC production is noted, it usually results in a 1% increase per day in the dog's or cat's Hct.[6]

Dosing schedules for EPO have not been standardized for veterinary patients. Both intravenous and subcutaneous routes of administration of rhEPO appear effective, although plasma concentrations persist longer after subcutaneous administration, which allows lower total doses to be given. Starting doses of 50–150 U/kg given subcutaneously three times per week are currently recommended for dogs (100 U/kg in cats) with weekly monitoring continued until a target Hct is achieved (30–35% in dogs and 25–30% in cats).[3,15,26,50] Thereafter, the dosing interval should be decreased to twice weekly. To maintain RBC count and Hct in the target range, most animals require 50–100 U/kg one to two times weekly, although the dosage required varies significantly among treated individuals. Therefore, periodic monitoring of the Hct is required for proper adjustment of the dose or dosing interval or both. Pharmacological activity in dogs has also been demonstrated using a mucoadhesive tablet containing 100 U/kg rhEPO.[51] Supplementation with oral ferrous sulfate (100–300 mg/day for dogs and 50–100 mg/day for cats) is recommended for all patients treated with rhEPO due to the high demand for iron associated with stimulated erythropoiesis, even if the pretreatment transferrin saturation is normal.[21]

Reported adverse reactions to EPO include transient cutaneous or mucocutaneous reactions with or without fever (rare and self-limiting upon cessation of rhEPO), hypertension, seizures, polycythemia, vomiting, discomfort at the site of injection, and, most significant clinically, the development of neutralizing antibodies and RBC aplasia. Approximately 20–30% of rhEPO treated animals develop neutralizing antibodies against the foreign protein, leading to RBC aplasia.[6,15] Although anti-rhEPO antibody titers may decline after discontinuation of treatment and pretreatment levels of erythropoiesis can be attained, the severe anemia seen before treatment remains since these levels are not sufficient to maintain adequate RBC numbers. Due to the possible long-term prevalence of anti-rhEPO antibodies in treated dogs and cats, administration of rhEPO is generally not recommended until the anemia of CRF is negatively impacting the animal's quality of life.

More recently, the clinical safety and efficacy of recombinant canine EPO (rcEPO) was investigated in dogs with CRF and rhEPO-induced RBC aplasia.[37,39] Recombinant canine EPO stimulated RBC production in dogs with nonregenerative anemia secondary to CRF without causing the profound RBC aplasia that can occur in rhEPO-treated dogs, although rcEPO was not as effective in restoring RBC production in dogs that had previously developed rhEPO-induced RBC aplasia.

Recombinant feline EPO (rfEPO) has also been produced in Chinese hamster ovary cells.[1,38] The biological activity of rfEPO was broadly equivalent to rhEPO, with the median Hct and absolute reticulocyte count in cats with CRF treated with rfEPO increasing significantly during the first 3 weeks of treatment. Unfortunately, development of RBC aplasia during treatment with rfEPO was also seen, most likely due to the development of antibodies against a Chinese hamster ovary antigen that cross-reacts with feline EPO.

Darbepoetin alfa has also been anecdotally used at several veterinary institutions to correct canine and feline CRF-induced anemia, although published data documenting its efficacy are lacking.

GRANULOCYTE-COLONY STIMULATING FACTOR

Background

Granulocyte-colony stimulating factor (G-CSF) is an 18.8 kDa glycoprotein produced by bone marrow stromal cells, monocytes/macrophages, and endothelial cells. Granulocyte-colony stimulating factor binds primarily to granulocyte progenitor cells in the bone marrow, stimulating the proliferation and maturation of neutrophil precursors. At higher doses, G-CSF can act in a multilineage fashion, stimulating the differentiation of several other hematopoietic progenitors. Granulocyte-colony stimulating factor also promotes

neutrophil migration across the vascular endothelium and primes neutrophils for cell killing. FDA approved, commercially available human G-CSF includes: lenograstim (Granocyte, Chugai Pharma, USA), filgrastim (Neupogen, Amgen), and pegylated filgrastim (Neulasta, Amgen).

Human G-CSF was cloned in 1986 and approved by the FDA in 1991 to protect cancer chemotherapy patients. In humans, G-CSF administration causes a dose-dependent rise in neutrophils, as well as a moderate increase in monocytes. Granulocyte-colony stimulating factor is now routinely given to human patients undergoing chemotherapy to help prevent episodes of severe neutropenia; G-CSF may also be beneficial in the treatment of established afebrile or febrile neutropenia by reducing the length, and thus expense, of hospitalization stays.[5]

Granulocyte-colony stimulating factor has also been used in humans for the treatment of cyclic neutropenia, an inherited disease characterized by recurrent episodes of neutropenia occurring every 20–24 days. Following rhG-CSF administration the mean neutrophil counts increase, and the severity of neutropenia associated with the cycles decreases. Granulocyte-colony stimulating factor does not completely eliminate the neutrophil cycling or the clinical signs associated with disease, suggesting a defect in receptor signaling, rather than a paucity of G-CSF production.

Another important setting in human medicine where G-CSF is routinely used is in association with BMT. The administration of G-CSF after high-dose chemotherapy and autologous BMT improves the rate of peripheral blood neutrophil recovery, reducing the morbidity and mortality associated with febrile neutropenic episodes. Granulocyte-colony stimulating factor also mobilizes hematopoietic CD34+ progenitors for collection prior to myeloblative therapy. After treatment with G-CSF for 5 days, high concentrations of CD34+ progenitor cells are found in the peripheral blood which can be collected by leukapheresis and administered to a patient after high-dose chemotherapy or total body irradiation (TBI) in place of marrow. "G-priming" of donors is now standard practice in human transplant protocols. Other uses of G-CSF include treating patients with myelodysplasia and acquired immunodeficiency syndrome-associated bone marrow aplasia.

Use in Veterinary Medicine

Canine G-CSF has been cloned (rcG-CSF, Amgen) and produced synthetically for research purposes but is not commercially available. rcG-CSF transiently increases neutrophil and macrophage numbers in dogs and cats. At a dose of 5 μg/kg/day, mean neutrophil counts in healthy dogs increased to 26,330/μL within 24 hours of the first injection of rcG-CSF and reached a maximum of 72,125/μL by day 19.[33] A similar effect on neutrophil counts was noted in cats following administration of rcG-CSF at a dose of 5 μg/kg/day.[34]

Mirroring the human experience, rcG-CSF is able to reduce the duration and severity of chemotherapy-induced myelosuppression.[35] Five of 10 dogs administered mitoxantrone (5 μg/m^{2}IV) were also given rcG-CSF (5 μg/kg/day SC beginning 1 day after chemotherapy and continued for 20 days), resulting in median neutrophil counts dropping below 3,000/μL for only 2 days in comparison to 5 days for those dogs not receiving rcG-CSF. Additionally, four of the five dogs that did not receive rcG-CSF developed severe neutropenia (<1,500/μL) while none of the rcG-CSF treated dogs did.

Cyclic hematopoiesis has also been identified in gray collie dogs.[52] Dogs with this disease respond similarly to humans given rhG-CSF, although the development of neutralizing antibodies and subsequent prolonged neutropenia with chronic rhG-CSF usage occurs.[22] This problem was negated by giving rcG-CSF at a dose of 1–2.5 μg/kg SC every 12 hours.[29]

The use of G-CSF in the setting of TBI and BMT has also been reported in the veterinary literature. Granulocyte-colony stimulating factor leads to complete bone marrow reconstitution within 21 days after lethal TBI[44] and can also mobilize bone marrow CD34+ progenitor cells for peripheral blood stem cell transplantation.[9] Granulocyte-colony stimulating factor can also "prime" dogs before marrow harvesting in the setting of malignant lymphoma. rcG-CSF increased donor peripheral blood mononuclear cell numbers (containing CD34+ progenitor cells) for harvesting via leukapheresis with subsequent allogeneic BMT to an unrelated dog with stage V(b) T-cell multicentric lymphoma who received 8 Gy TBI.[25] The transplanted dog maintained a complete remission for at least 58 weeks after BMT. rcG-CSF has also been used to successfully "prime" dogs before bone marrow harvesting via bone marrow aspiration.[13] The reader is referred to a comprehensive review of the use of hematopoietic cytokines, including G-CSF, in the BMT setting,[24] as well as an original study describing the use of leukapheresis, both with and without rcG-CSF "priming", to harvest peripheral blood progenitor cells (PBPCs) from dogs.[23]

GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR

Background

Granulocyte-macrophage colony-stimulating factor (GM-CSF) is a variably glycosylated (10–30 kDa) protein produced by fibroblasts, endothelial cells, monocytes, and T lymphocytes that has a variety of biological activities. These include prolonging the survival of hematopoietic progenitors and mature neutrophils, eosinophils, and macrophages, stimulating the proliferation of progenitor cells, and enhancing the functional capacity of the mature cells.

The FDA approved formulations of rhGM-CSF (sargramostim) are Leukine (Bayer HealthCare Pharmaceuticals, USA) and Prokine (Amgen). Both are approved for use in human patients more than 55 years

of age with acute myelogenous leukemia following induction chemotherapy. Leukine is also approved for use in a number of hematopoietic stem cell transplant settings, including BMT failure or engraftment delay, myeloid reconstitution after autologous and allogeneic BMT, and mobilization and following transplantation of autologous PBPCs. The reported side effects of rhGM-CSF in human patients include bone pain, fever, and flu-like symptoms.

Use in Veterinary Medicine

Recombinant canine GM-CSF (rcGM-CSF) has been cloned,[30] although it is not commercially available for clinical use. rcGM-CSF given to normal dogs caused a significant increase in circulating neutrophils and monocytes, whereas the effect on circulating eosinophils was more variable.[31] rhGM-CSF is active in dogs,[28] inducing neutrophilia and eosinophila, although it produced variable results in dogs with chemotherapy-induced myelosuppression.[45] This is most likely because rcGM-CSF is only 70% homologous with the human protein, and, therefore, higher doses of rhGM-CSF may be necessary to achieve the same effect as rcGM-CSF. rhGM-CSF also prevents recurrent neutropenia in gray collie dogs with cyclic hematopoiesis, although most dogs developed antibodies to the protein within 2–3 weeks of treatment and hematopoietic cycling persisted.[17]

Importantly, GM-CSF also has the ability to activate monocytes and macrophages, increasing their ability to recognize and destroy malignant cells.[14] DNA plasmid vectors containing the coding sequence for GM-CSF can deliver GM-CSF directly to tumors, which theoretically allows the local recruitment and activation of macrophages. rhGM-CSF cDNA was cloned into a xenogeneic expression vector and injected intramuscularly biweekly for a total of four vaccinations into three dogs diagnosed with oral malignant melanoma. In this same study, nine dogs were injected with both rhGM-CSF and huTyrosinase.[2] The authors reported a median survival time of 148 days for dogs receiving rhGM-CSF alone and >402 days for dogs receiving both rhGM-CSF and huTyrosinase. Another anti-malignancy strategy is to remove the primary tumor or metastatic lesion, culture the tumor cells in vitro, and transfect them with a eukaryotic vector encoding GM-CSF or use GM-CSF transfected cell lines established from primary tumors.[12,18] There are currently a wide variety of human clinical trials examining the safety and efficacy of both viral and non-viral vectors encoding GM-CSF for the treatment of many types of solid and hematopoietic malignancies.

THROMBOPOIETIN

Background

Thrombopoietin, a 35 kDa glycoprotein produced primarily in the liver, is an important regulator of thrombopoiesis via its role as a late-acting megakaryocyte maturation factor. It also stimulates hematopoietic progenitor cells (CD34+) to undergo proliferation and differentiation into megakaryocytic colonies and synergizes with SCF and IL-3 to stimulate hematopoietic progenitor cell division and differentiation. The receptor for TPO is encoded by the proto-oncogene c-*mpl*. Neumega (oprelvekin, Wyeth, USA) is a synthetic 19 kDa version of human IL-11 with FDA approval for use to prevent severe thrombocytopenia and reduce the need for platelet transfusions following myelosuppressive chemotherapy. Nplate (romiplostim, a thrombopoietin analog, Amgen) is a commercially available peptibody protein with FDA approval for the treatment of thrombocytopenia in adults with chronic immune thrombocytopenic purpura.

In the setting of BMT, TPO can stimulate enhanced platelet recovery and improve the recovery of other hematopoietic lineages after BMT, and act synergistically with G-CSF to accelerate neutrophil recovery in mice after radiation or chemotherapy. The reader is referred to two recent review articles for a more thorough discussion of TPO and the development of TPO mimetics.[20,49]

Use in Veterinary Medicine

Theoretically, mirroring the human experience, TPO or any TPO mimetics could be useful in veterinary medicine for any disease process causing thrombocytopenia. Additionally, TPO may be useful in the setting of chemotherapy-induced thrombocytopenia and for hematopoietic recovery after BMT. Feline, but not canine, TPO has been cloned.[27] However, there are no reports in the literature describing use of rfTPO, Nplate, or Neumega in either research or clinical settings in companion animals.

INTERLEUKIN-3

Background

Interleukin-3 is a 25 kDa glycoprotein produced primarily by T cells that acts mainly on CD34+ hematopoeitic progenitor cells. Interleukin-3 promotes the survival and expansion of these cells and also, to a lesser extent, produces the same effects on committed progenitors of the granulocyte-macrophage, erythroid, eosinophil, basophil, megakaryocyte, and mast cell lineages. Interleukin-3 also enhances myeloid cell functions. Clinically, IL-3 leads to multilineage expansion of myeloid cells, including platelets, neutrophils, and monocytes, when used alone or in combination with rhGM-CSF. Therefore, IL-3 may be useful to treat chemotherapy-induced myelosuppression, although signs of toxicity, including fever, fatigue, and headaches are common. The reader is referred to a recent review article describing the role of Il-3 in hematopoietic cell development.[8]

Use in Veterinary Medicine

Canine IL-3, which was cloned in 2001,[19] has approximately 37% amino acid homology to the human protein. This may explain the lack of efficacy of the human protein (rhIL-3) in increasing neutrophil or macrophage numbers when administered to dogs. rhIL-3 failed to correct recurrent neutropenia in gray collie dogs with cyclic hematopoiesis, although it did stimulate eosinophilia.[17]

STEM CELL FACTOR

Background

Stem cell factor is a 30 kDa glycoprotein produced by bone marrow stromal cells, fibroblasts, and endothelial cells. The SCF receptor is encoded by the proto-oncogene c-*kit* that is expressed on hematopoietic progenitor cells, mast cells, and melanocytes.

Stem cell factor acts synergistically with many other HGFs to promote the production of lymphoid, myeloid, and erythroid lineages from hematopoietic progenitor cells.[48] Therefore, SCF has potential benefit in a number of clinical settings involving either hematopoietic precursor damage or defects and in the setting of BMT. Administration of rhSCF to humans results in significantly increased hematopoietic progenitor cells in the bone marrow and blood. Stem cell factor can enhance the proliferation of bone marrow cells derived from patients with aplastic anemia when used with other HGFs. Other uses include the administration of SCF after BMT or chemotherapy to enhance hematopoietic recovery.

Use in Veterinary Medicine

Canine SCF was cloned in 1992 and shares approximately 85% amino acid homology to the human protein.[42] Feline SCF, which has a high degree of homology at both the nucleic acid and protein level to other species, has also been cloned.[10] The vast majority of veterinary literature describes the use of rcSCF in veterinary patients in the settings of hematopoietic recovery after BMT and canine mast cell disease.[46,47] rcSCF supports the survival of hematopoietic progenitors in long-term marrow culture[32] and acts synergistically with rcG-CSF to decrease the time to hematopoietic recovery in dogs after TBI.[41] rcSCF, either alone or in combination with rcG-CSF, also significantly increases the level of PBPCs and stem cells.[9,43] rcSCF logically enhances IgE-mediated histamine and TNF-α release in canine mast cells since mature mast cells express c-*kit*.[4] rcCSF, alone or in combination with rcG-CSF, has also been used to treat gray collies with cyclic neutropenia.[7]

CONCLUSIONS

Hematopoietic growth factors have significant potential in the treatment of veterinary patients in a wide variety of settings. The greatest benefit associated with the use of HGFs is for those patients with profound blood cell dyscrasias secondary to chemotherapy administration or BMT. Mirroring the human experience, the use of HGFs in conjunction with the administration of chemotherapies that are toxic to the bone marrow may provide an arena to allow the safe exploration of increased anticancer dose intensity which could result in increased survival times while improving quality of life. In addition, as more reports of canine BMT are published, HGFs will most likely become an important part of these protocols in an effort to increase our ability to harvest hematopoietic progenitor CD34+ cells and aid in post-BMT hematologic recovery. Unfortunately, until recombinant canine and/or feline HGFs become affordable commercially available products, a veterinarian's only option is to use recombinant human proteins which are, quite often, expensive, ineffective, and have the potential to lead to the development of debilitating neutralizing antibodies with chronic use.

Acronyms and Abbreviations

Hct, hematocrit; Hgb, hemoglobin; MCH, mean cell hemoglobin; MCHC, mean cell hemoglobin concentration; MCV, mean cell volume; N:C ratio, nuclear:cytoplasmic ratio; nRBC, nucleated red blood cell; RBC, red blood cell; RDW, red cell distribution width; WBC, white blood cell.

ERYTHROCYTES

Morphology

The canine erythrocyte is a biconcave disc, approximately 7 µm in diameter. The biconcave shape is more pronounced in the dog than in other domestic animals, giving their red cells a clearly visible central pallor when viewed in the monolayer of well made blood films (Fig. 104.1). This prominent central pallor, which normally encompasses approximately the central one-third to one-half of the diameter of the cell, makes recognition of spherocytes possible in this species. Central pallor may be lost at the edges of a smear or in very thin smears, where sheer forces distort normal morphology (Fig. 104.2).

Canine erythrocytes normally display only mild anisocytosis and poikilocytosis. Echinocyte formation may be an artifact related to smear preparation (i.e. crenation), but has also been reported in certain disease states.[44] Clear, refractile areas (artifacts) within red cells may be seen if the blood smear is not adequately dried before staining. Stain precipitate may sometimes adhere to erythrocytes and must not be confused with parasites (Fig. 104.3).

When blood smears are stained with Romanowsky stains, such as Wright's stain, polychromatophilic (blue staining) cells may be seen occasionally, but in health these comprise less than 1% of the cells (Fig. 104.4). These represent erythrocytes recently released from the bone marrow and are recognized as reticulocytes when blood is stained with certain supravital stains, such as new methylene blue. Canine reticulocytes are mostly of the aggregate type, containing one or more large, distinct clumps of blue staining material (Fig. 104.5). In dogs, polychromasia noted on Romanowsky stained smears correlates well with reticulocytosis, although accurate, reproducible evaluation of polychromasia requires more microscopy experience.[19]

Rare nucleated red blood cells (nRBCs) and Howell-Jolly bodies can be seen in blood smears from normal dogs. Nucleated RBCs may be more numerous in newborn pups, but numbers decrease rapidly within the first week of life and reach adult levels by approximately 1–2 months of age.[11,39] Hemoglobin (Hgb) crystals are square to rectangular structures which stain similarly to or slightly darker than Hgb and often deform the RBC that contains them. Low numbers (1–10 per slide) of Hgb crystals have been reported in blood smears of clinically normal dogs and dogs less than 3

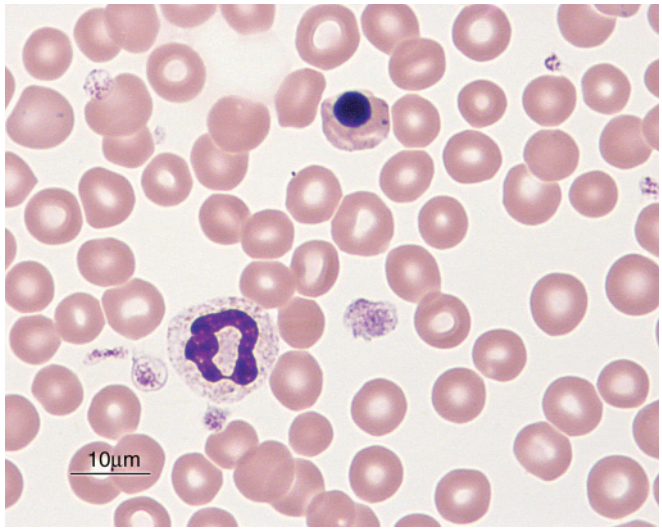

FIGURE 104.1 Canine erythrocytes showing normal central pallor. A single mature neutrophil is present. The granules in this neutrophil stain a faint pink. A single metabrubricyte is present at the top. Wright-Giemsa stain.

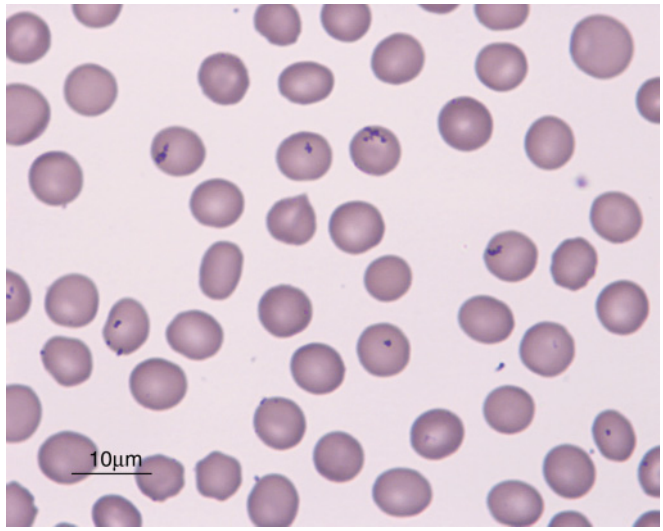

FIGURE 104.3 Stain precipitate adhered to erythrocytes. Wright-Giemsa stain.

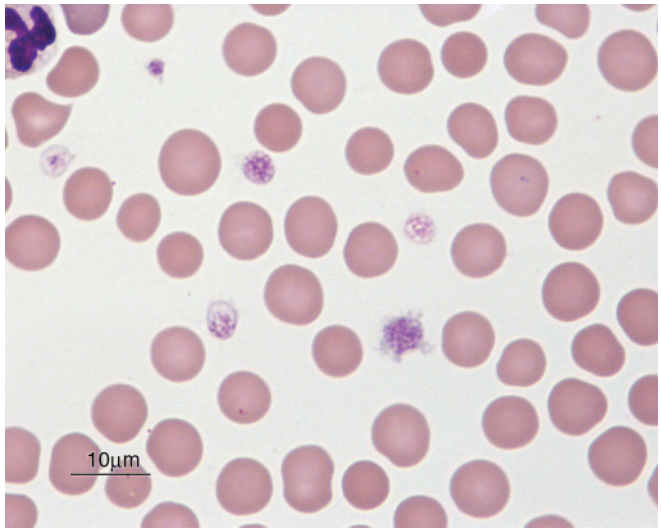

FIGURE 104.2 Different field from the same blood film. The erythrocytes have lost their pallor due to sheer artifact. Wright-Giemsa stain.

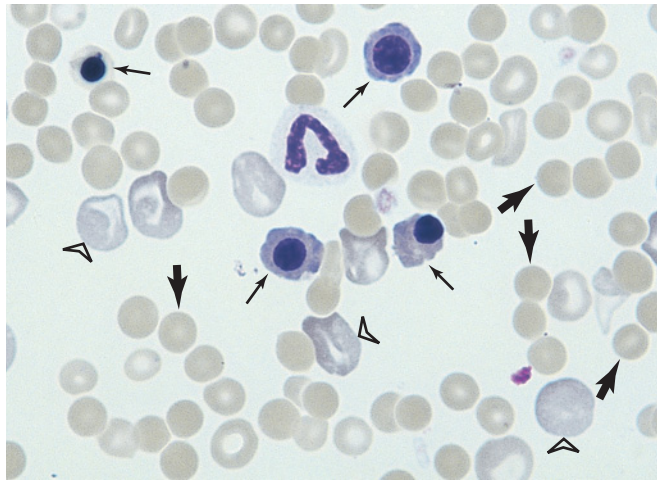

FIGURE 104.4 Blood smear from a dog with an immune-mediated hemolytic anemia. Many large, polychromatophilic erythrocytes are present (arrowheads). Four nucleated read cells (rubricytes and metarubricytes) are also present (thin arrows). Many of the mature erythrocytes are spherocytes (thick arrows). Wright-Giemsa stain; 100× objective. (Courtesy of Oklahoma State University Clinical Pathology Teaching Files.)

months of age.[23] Their formation may be an in-vitro artifact associated with delayed sample processing.[2] They have not been associated with abnormal Hgb molecules.

Quantitative Parameters

Table 104.1 provides historically published reference intervals for erythrocyte parameters of adult dogs. Reference intervals are designed to include values found in the majority of "normal" animals and will vary according to analyzer, population used to collect the data and the definition of "normal." Many published reference intervals for canine hematologic values are derived from research animals and represent a single breed raised under confinement conditions. Such intervals may be narrower than would be applicable to a general patient population in which breed, age and environmental variables are present. Alternatively, reference intervals that are derived from shelter dogs or

"clinically healthy" animals brought to a veterinary clinic may be inappropriately wide because of subclinical disease, nutritional status, and physiologic or environmental influences (e.g. fear associated with being in a strange environment and phlebotomy). Common, clinically significant sources of variability are discussed below.

Hemoglobin, Hematocrit, and Red Blood Cell Count

All three of these measurements of red cell mass are interrelated and, in the absence of marked alterations of RBC size and Hgb concentration, tend to parallel each other. Hematocrit (Hct), the percentage of blood volume comprising erythrocytes, can be determined either as a spun Hct by centrifugation ("packed cell volume;" PCV) or a calculated Hct based on the mean corpuscular volume (MCV) and RBC count. Most current automated hematology analyzers utilize calculated Hct, although spun Hct is still commonly determined in practice and when artifactual calculated Hct values are suspected.

The RBC mass of neonatal animals varies significantly from that of adults (Table 104.2). At birth, Hgb, Hct and the RBC count are near adult values but decline rapidly over about the first 2 months of life. The magnitude of the drop is clinically significant, with Hct values reaching a nadir in the high 20s to low 30s.[39] After this, values start to increase, generally reaching adult levels by approximately 6 months to 1 year of age.[1,4,11,15]

Some authors have found a gender affect on RBC mass. One study of Beagles showed that males had a slightly higher Hgb concentration than females (16 g/dL vs. 15.6 g/dL).[27] The magnitude of this change is not likely to be clinically significant as all values are well within the standard reference intervals for adult dogs. Pregnant females have significant changes during gestation. In one study, the Hct of pregnant dogs fell from a baseline of 53% to 32% at term.[4] Numerous studies have shown that Greyhound dogs generally have higher values related to RBC mass than other dogs, with Hcts up to about 65% commonly reported in clinically healthy animals.[9,11,20,34,38] This effect is age related, with values for parameters of RBC mass being higher than non breed-specific reference intervals by approximately 9–10 months of age.[38]

Mean Corpuscular Volume, Mean Corpuscular Hemoglobin and Mean Corpuscular Hemoglobin Concentration

These RBC indices characterize the size and hemoglobinization of the red cell population. In the dog, fetal red cells are larger than those of adults. The MCV of umbilical cord blood is 100–110 fL and in newborn pups is 95–100 fL, but rapid replacement of fetal erythrocytes following birth brings this value to adult levels by 2–3 months.[24,39] Breed variations of erythrocyte size have been reported. Some lines of toy and miniature poodles have an inherited macrocytosis with abnormal erythropoiesis.[5,37] These animals have RBC counts that are below standard reference intervals, but due to the large size of the RBCs and increased Hgb content, their Hct and Hgb are normal. The reported MCV of affected animals ranges from 84.5 to 106.7 fL (compared to 60–77 fL in unaffected animals). Japanese Akita and Shiba breeds have microcytic RBCs with MCV ranging from 55 to 65 fL.[7,13]

Red Cell Distribution Width

The red cell distribution width (RDW) represents the size variability of individual erythrocytes analyzed.

TABLE 104.2 Blood Values in Normal Beagles to 2 Months of Age[a]

	Age				
	0–3 days	14–17 days	28–31 days	40–45 days	56–59 days
Number of dogs	46	46	48	44	42
RBCs ($\times 10^6/\mu L$)	4.8 ± 0.8	3.5 ± 0.3	3.9 ± 0.4	4.1 ± 0.4	4.7 ± 0.4

[a]Data from Shifrine M, Munn SL, Rosenblatt LS, et al. Hematologic changes to 60 days of age in clinically normal beagles. Lab Anim Sci 1973;23:894–898.
[b]Data from Earl FL, Melveger BE, Wilson RL. The hemogram and bone marrow profile of normal neonatal and weanling Beagle dogs. Lab Anim Sci 1973;23:690–695. Values were approximated for various age groups shown here; 5 males and 5 females were studied in each group.

Numerically it represents the coefficient of variation of RBC volumes and can be graphically represented on a histogram. Increases in RDW indicate increased anisocytosis of the erythrocyte population and may be more sensitive than the MCV in detecting early changes in erythrocyte size.[31]

Reticulocytes

Reticulocytes are released from the canine marrow in a cyclic manner with a periodicity of approximately 14 days.[30] Reference intervals will vary between laboratories based on methodology employed and reference population used; however, adult dogs generally have less than 1.0% reticulocytes in peripheral blood or an absolute reticulocyte count of less than 70,000/μL. Neonatal animals have significantly higher reticulocyte counts, a manifestation of increased erythropoiesis needed to keep up with a rapidly expanding vascular volume. Reticulocyte counts of up to approximately 10% can be seen in dogs during the first 2 months of life.[10,11] This number decreases to adult levels by approximately 5–6 months of age.

LEUKOCYTES

Normal Morphology

Neutrophils are the most abundant leukocyte in the peripheral blood of normal dogs (Fig. 104.6). The mature neutrophil has an elongated nucleus which contains several distinct lobes separated by constricted areas.

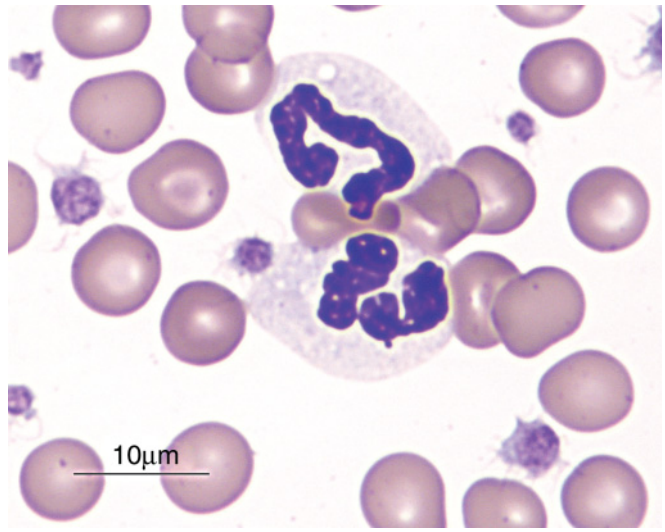

FIGURE 104.6 Two mature neutrophils showing mature chromatin and segmented nuclei. Wright-Giemsa stain.

These constricted areas are usually simply narrowing of the nuclear material, but may form thin filamentous structures. The nucleus stains dark purple and has a clumped chromatin pattern consisting of many areas of densely staining heterochromatin. Cytoplasm is typically clear to slightly eosinophilic. Neutrophil granules in the dog are typically indiscernible, but may be faintly eosinophilic. Immature, or band shaped, neutrophils may be present in low numbers in normal animals.

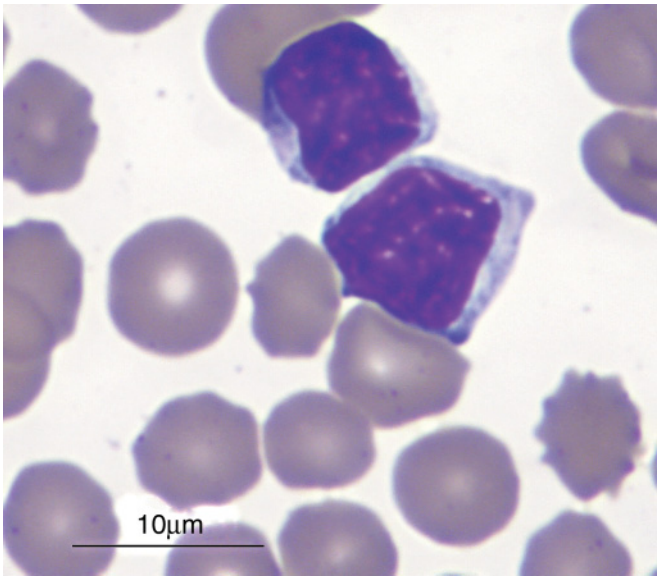

FIGURE 104.7 Two small lymphocytes with dark chromatin and scant cytoplasm. Wright-Giemsa stain.

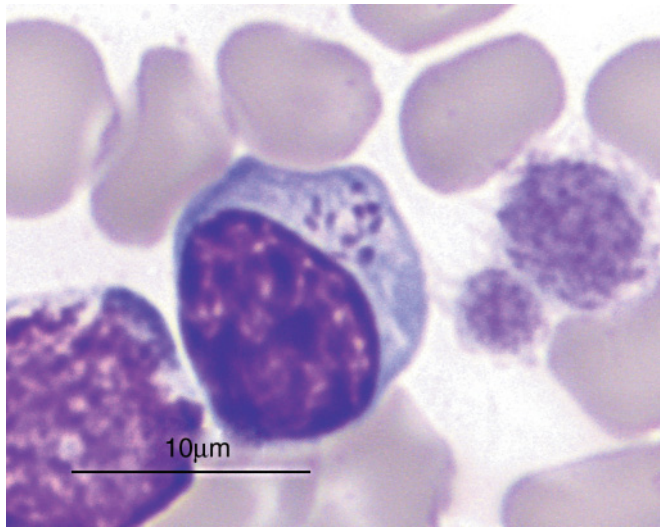

FIGURE 104.8 A large granular lymphocytes with pink-purple granules clustered to one side of the nucleus. Wright-Giemsa stain.

These cells contain elongated nuclei that lack the distinct lobation that characterizes mature cells. The nucleus should have generally parallel sides, lacking any discrete nuclear constrictions. The nuclear chromatin of a band cell is generally less condensed and lighter staining than that of a mature cell. Cytoplasm is similar to that of mature neutrophils.

Lymphocytes in the peripheral blood vary in size, with small lymphocytes being most abundant (Fig. 104.7). Small lymphocytes have densely staining nuclei which range from generally round with a flattened side to oval to slightly indented. Nuclear chromatin is densely clumped. Small lymphocytes have only scant amounts of cytoplasm which is pale blue. The cytoplasm is often only a thin rim or crescent which cannot be seen completely encircling the nucleus.

Medium sized lymphocytes occur in blood smears from normal dogs and have more abundant cytoplasm which may completely encircle the nucleus. Medium sized lymphocytes in peripheral blood may approach the size of neutrophils. Occasionally, these lymphocytes will contain several small pink-purple cytoplasmic granules and are referred to as large granular lymphocytes (Fig. 104.8). These granules may be confined to a small cluster near one side of the nucleus. Reactive lymphocytes can be seen in blood smears from dogs responding to an antigenic stimulation. Reactive lymphocytes may be larger and have increased amounts of intensely basophilic cytoplasm (Fig. 104.9). Rarely, they may take on morphology similar to mature plasma cells, with an eccentric nucleus and a perinuclear clear area.

Monocytes are larger than neutrophils (Fig. 104.10). Monocyte nuclei are extremely variable and may be round, multilobated, band-shaped, or S-shaped (Figs. 104.11, 104.12). Those that are band shaped are generally wider and may have rounded, knob-shaped ends that differentiate them from band neutrophils (Fig. 104.13). The nuclear chromatin is less condensed than that of the mature neutrophil. Their cytoplasm is moderate to abundant and gray-blue to deeply basophilic. Canine monocytes may have variable numbers of clear, distinct-walled cytoplasmic vacuoles. Occasionally, faint, dust-like azurophilic granules can be seen evenly spread throughout the blue cytoplasm.

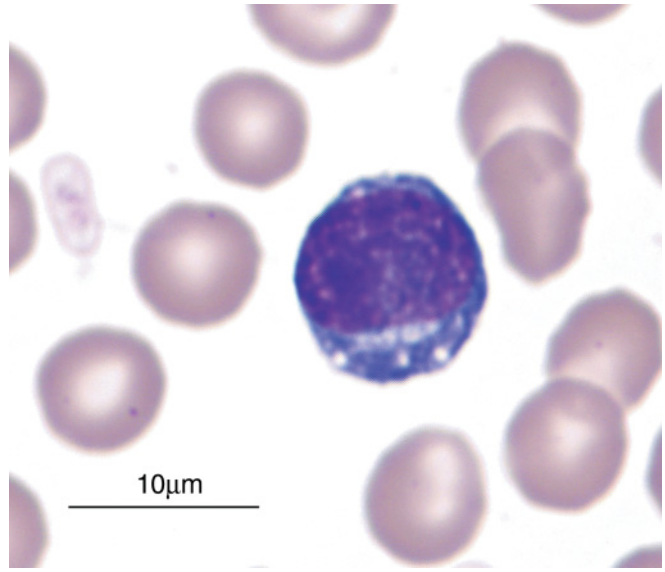

FIGURE 104.9 A reactive lymphocyte with increased volume of intensely basophilic cytoplasm. Wright-Giemsa stain.

Eosinophils can usually be found in low numbers on blood smears from healthy dogs. Eosinophils are slightly larger than neutrophils. Their most characteristic feature is the presence of prominent eosinophilic

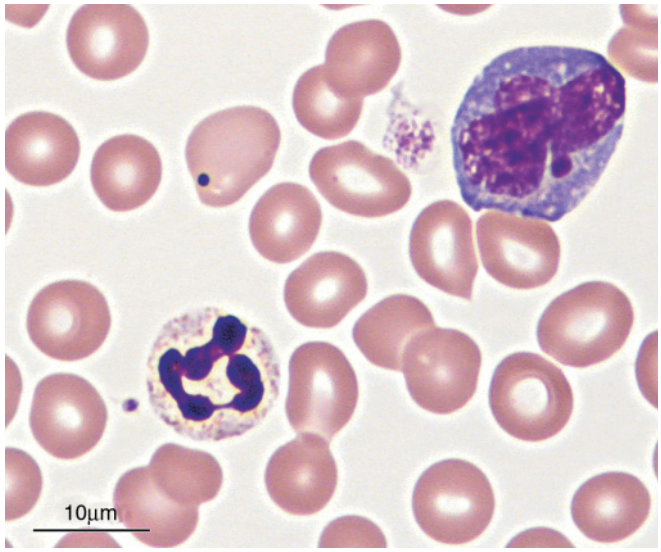

FIGURE 104.10 A neutrophil (lower left) and monocyte (upper right). The monocyte is large and has basophilic cytoplasm. This monocyte does not have cytoplasmic vacuoles, a feature that is variable. Wright-Giemsa stain.

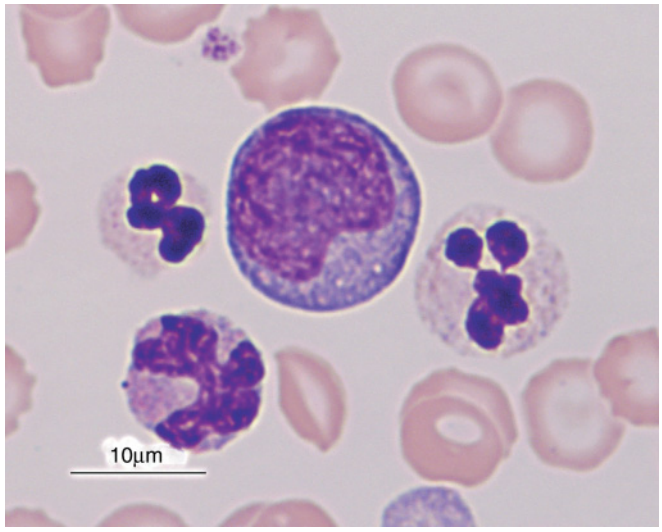

FIGURE 104.11 Monocyte (center) with a rounded, indented nuclear shape. Wright-Giemsa stain.

FIGURE 104.12 Monocyte (bottom) with "S" shaped nucleus and three neutrophils. Wright-Giemsa stain.

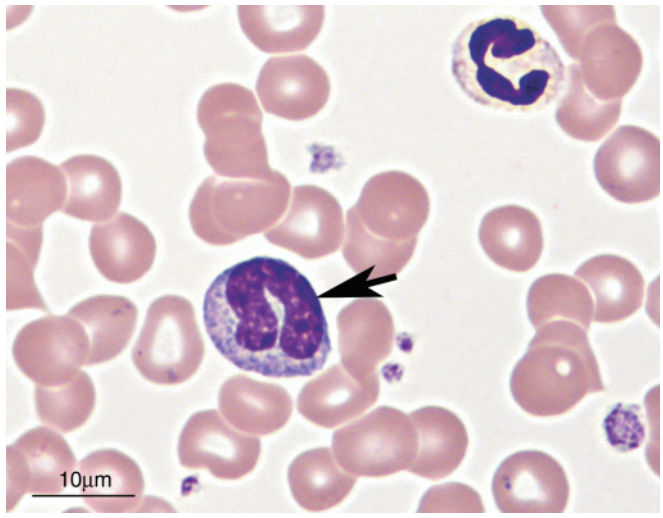

FIGURE 104.13 Monocyte (arrow) with band shaped nucleus. Nucleus is thicker than that of neutrophil (upper right). Wright-Giemsa stain.

granules. In dogs, the number and size of these granules is greatly variable (Figs. 104.14 and 104.15). Size of the granules within a single cell may also be variable. Occasionally, an eosinophil may contain only one or two extremely large granules which could be mistaken for an inclusion body or parasite. Cytoplasm between the granules is lightly basophilic and may contain a few clear vacuoles.

Eosinophil nuclei are less lobated than those of neutrophils, usually having only two or three lobes. Eosinophils of adult Greyhounds are unique in that they contain numerous clear vacuoles and often lack distinct granules (Fig. 104.16).[18] Interestingly, eosinophils of Greyhound pups contain granules, although these are a dull slate color rather than orange as in other species.

Basophils are rare in blood smears from normal dogs. Basophils are larger than neutrophils and have a more elongated, convoluted nucleus (Fig. 104.17). Compared to other species, canine basophils contain only scattered, small, purple to pink-purple cytoplasmic granules (Fig. 104.18). Cytoplasm is blue-gray to slightly purple.

Quantitative Parameters

Reference intervals for leukocyte parameters of adult dogs are given in Table 104.1. As noted before, reference

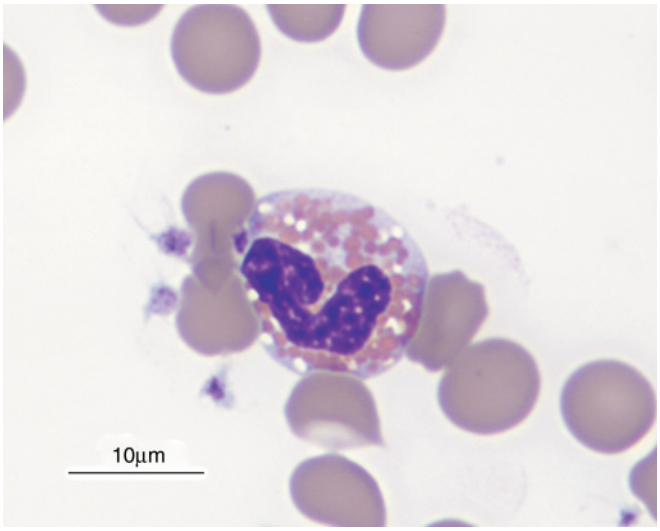

FIGURE 104.14 Canine eosinophil with numerous small granules. Wright-Giemsa stain.

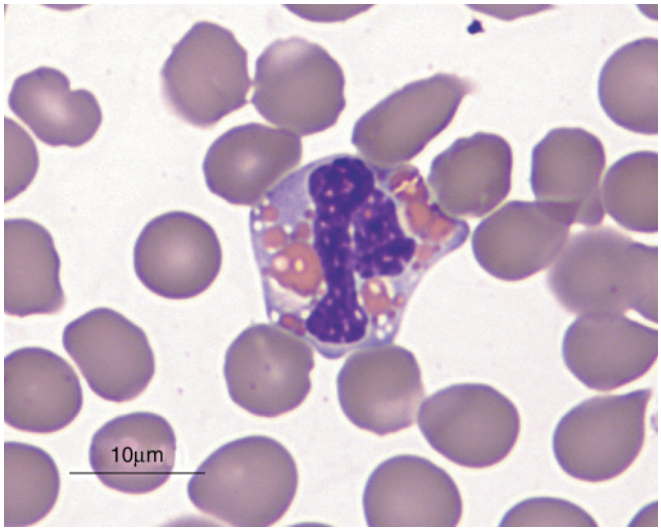

FIGURE 104.15 Canine eosinophil with variably sized granules. Wright-Giemsa stain.

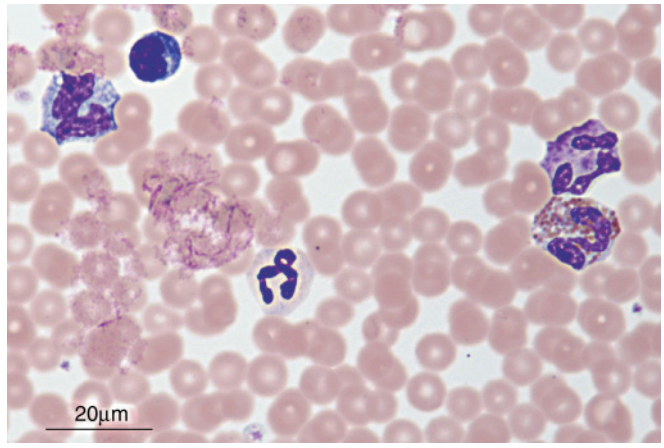

FIGURE 104.17 Monocyte, lymphocyte, neutrophil, basophil (top right) and eosinophil (bottom right). Having all the major leukocyte types in one field allows comparison of size and nuclear shapes. Note the elongated, thin nucleus of the basophil. Wright-Giemsa stain.

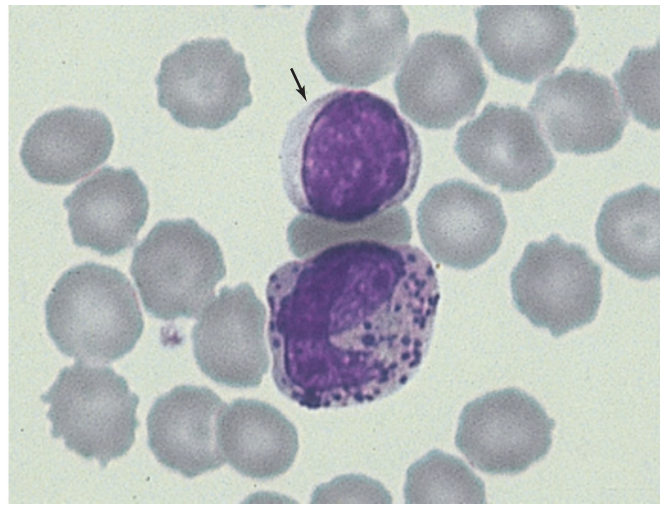

FIGURE 104.18 Canine basophil and medium lymphocyte. Canine basophils have a segmented nucleus and sparse granules. The lymphocyte (arrow) is slightly larger than a small lymphocyte and contains more abundant cytoplasm. Wright-Giemsa stain; 100× objective. (Courtesy of Oklahoma State University Clinical Pathology Teaching Files.)

intervals will be affected by the methodology used and population from which they are derived. This could potentially have a greater effect on leukocyte parameters than on those of other cell lines, since animals not in controlled environments have greater exposure to a variety of antigens. Diurnal and seasonal variations have been reported in leukocyte counts, although the fluctuations are relatively minor and do not exceed the limits of standard reference intervals.[21,41] In some geographic areas, animals may have higher eosinophil counts in certain seasons due to environmental allergens and parasite load. In addition, short term alterations in leukocyte numbers may occur as part of an epinephrine- or corticosteroid-induced response in

animals that are not conditioned to blood collection (Chapter 48).

Physiologic leukopenia has been reported in healthy adult North American Belgian Tervuren dogs.[14] No difference in leukocyte parameters was found between Belgian Tervuren dogs and other dogs in a more recent study.[12] Study differences in North American Belgian Tervuren and Belgian Tervuren dogs were thought to reflect genetic or environmental factors.[12]

Fluctuations in total white blood cell (WBC) and neutrophil counts have been noted in Beagles during the first 2 months of life; however, with a few exceptions, values generally remained within the reference intervals listed in Table 104.2.[39] In one study, newborn animals (0–3 days) had band neutrophil counts that were slightly outside the adult reference interval, indicating a left shift. Occasionally, metamyelocytes were seen during this period without any other evidence of disease. Band neutrophils decreased to within reference limits by 7–10 days of life.[39] Lymphocyte counts are significantly higher in young dogs. Dogs less than 6 months of age typically have lymphocyte counts of at least 2,000/μL, with some as high as 10,000/μL.[39]

After maturity, there is little change in hematologic parameters. Studies have found no significant trends in WBC counts of dogs from 1.5 to 14 years of age.[8,22] During pregnancy, total WBC counts may increase to levels that are slightly above reference intervals (~19,000/μL) near parturition. White blood cell counts decrease into the reference interval during lactation, but may not return to baseline values until the pups are weaned.[1]

PLATELETS

Morphology

Canine platelets appear as small, oval to round structures on blood smears. Canine platelets are generally one-fourth to one-half the size of erythrocytes, but some platelets are larger than a RBC (Fig. 104.2). They have clear to light gray cytoplasm and numerous small pink to purple granules. The granules may be dispersed throughout the platelet or aggregated into a central cluster. Occasionally, platelets become partially activated and have a spider-like appearance with small cytoplasmic pseudopodia (Fig. 104.19). Alternatively, activated platelets may form small clumps or a large agglutinated mass. Such large masses of platelets generally get pulled out to the feathered edge of a smear.

Quantitative Parameters

Normal parameters for platelets in adult dogs are listed in Table 104.1. Platelet counts between 200,000 and 500,000/μL are generally considered normal. Low platelet counts have been noted in seemingly healthy racing Greyhounds.[36,40] The mean platelet count from 60 Greyhounds in one study was 190×10^3/μL (90×10^3–290×10^3/μL: mean ± 2 SD). No dog had increased platelet surface associated immunoglobulin.[36]

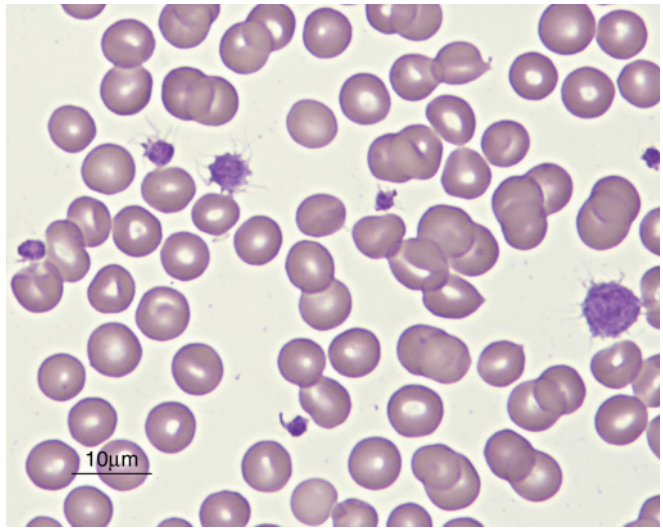

FIGURE 104.19 Canine platelets with long, filamentous cytoplasmic projections. Wright-Giemsa stain.

Asymptomatic thrombocytopenia with enlarged platelets (macrothrombocytopenia) is common in Cavalier King Charles spaniels.[3,32] The condition is associated with a mutation in the β1-tubulin gene.[6] The median platelet count from 105 Cavalier King Charles spaniels in one study was 92×10^3/μL ($25–394 \times 10^3$/μL) with 56% of the dogs having platelet counts less than 100×10^3/μL.[32]. Analyzers that assess "plateletcrit" rather than impedance-based or optical-based particle counting have shown the total platelet mass in affected animals to be normal.[42]

Mean platelet volumes (MPV) from colony raised Beagles has been reported to be 8.5 (± 0.53) fL.[43] Reference intervals vary significantly between analyzers (see Table 104.1).

BONE MARROW

Morphology

Marrow samples in the dog are commonly collected from the trochanteric fossa of the femur, proximal humerus and the iliac crest. The morphology of canine hematopoietic cells found in bone marrow aspirates has been reviewed.[16] Morphologic assessment consists of an evaluation of the major hematopoietic cells lines (i.e. erythroid, granulocytic and megakaryocytic) as well as other cells normally found in the marrow (i.e. lymphocytes, plasma cells and macrophages).

Erythroid Series

Stages of nucleated erythroid precursors recognizable in marrow aspirates are rubriblasts, prorubricytes, rubricytes, and metarubricytes. With progressive maturation, the nucleated cells become smaller, undergo nuclear condensation, and cytoplasm color changes from deeply basophilic to red-orange (Figs. 104.20 and 104.21).

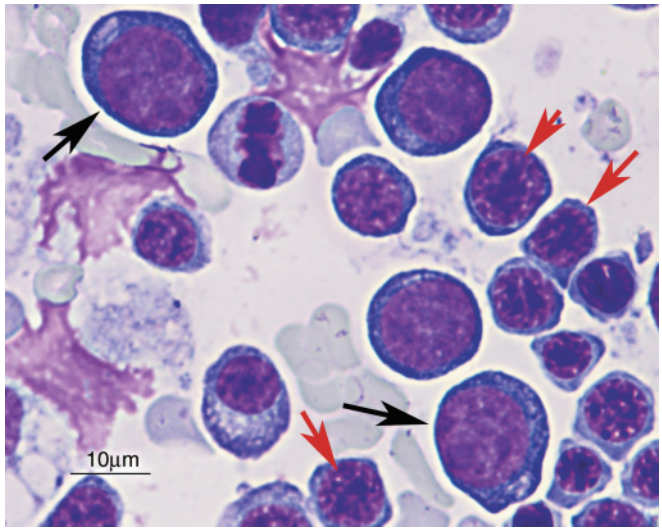

FIGURE 104.20 Canine bone marrow showing developing erythroid cells. Rubriblasts (black arrows) have nucleoli, round nuclei and deeply basophilic cytoplasm. Developing rubricytes (red arrows) are small with coarse chromatin. Diff-Quick stain.

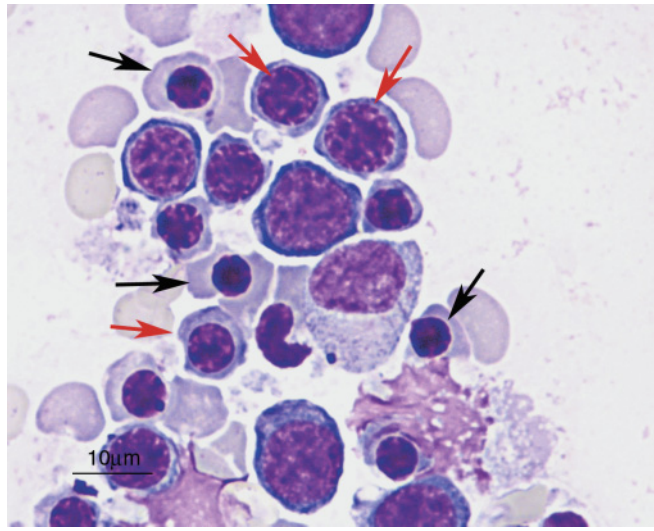

FIGURE 104.21 Canine bone marrow. Developing rubricytes (red arrows) have coarse chromatin. Metarubricytes (black arrows) have condensed pyknotic nuclei. Diff-Quick stain.

Rubriblasts are present in relatively low numbers. They are a large cell with a high N:C ratio. The nucleus is nearly perfectly round with fine chromatin and one or more visible nucleoli (Fig. 104.20). The cell has moderate amounts of deeply basophilic cytoplasm. Prorubricytes are slightly smaller, lack visible nucleoli and have somewhat coarser chromatin. The N:C ratio is slightly lower and cytoplasm remains intensely basophilic.

The next stage in maturation is the rubricyte. Rubricytes are decidedly smaller with a lower N:C ratio. The nucleus is smaller, has extremely coarse chromatin and nucleoli are not visible (Figs. 104.20 and 104.21). The cytoplasm undergoes a progressive color change from deeply basophilic to polychromatophilic (blue-orange) to red-orange representing progressive production of Hgb. Rubricytes are sometimes separated into three types (basophilic, polychromatophilic and orthochromic) based predominantly on change in cytoplasm color. Metarubricytes are the smallest of the nucleated erythroid precursors and are characterized by a pyknotic nucleus that lacks a discernible chromatin pattern (Fig. 104.21). Progressive maturation results in polychromatophilic erythrocytes, non-nucleated cells similar to those seen in low numbers in the peripheral blood.

Granulocytic Series

The granulocytic series goes through a similar progression of relatively low numbers of early precursors to more numerous maturing cells (Fig. 104.22). The recognizable stages of granulocytic maturation in the marrow are myeloblasts, promyelocytes (also called "progranulocytes"), myelocytes, metamyelocytes, bands and mature granulocytes.

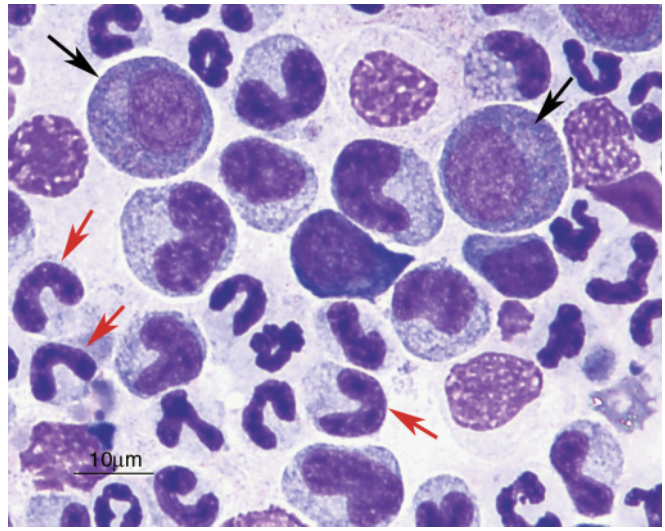

FIGURE 104.22 Canine bone marrow. Developing myeloid cells are shown. Promyelocytes (black arrows) are recognized by the presence of pink-purple primary granules. Bands (red arrows) are more numerous. A few large metamyelocytes with indented, but not band shaped, nuclei are also present. Diff-Quick stain.

Myeloblasts are large cells with a high N:C ratio, fine chromatin and one or more visible nucleoli. Compared to rubriblasts, the myeloblast has a more irregularly shaped nucleus and lighter staining cytoplasm. The next stage in granulocytic development is the promyelocyte. Often, these cells are slightly larger than myeloblasts but have a lower N:C ratio due to cytoplasmic enlargement. Nuclear chromatin is somewhat coarser. Nucleoli may or may not be present. The main feature identifying the promyelocyte is the presence of numerous fine, azurophilic, granules termed primary granules, in the cytoplasm (Fig. 104.22). These granules help

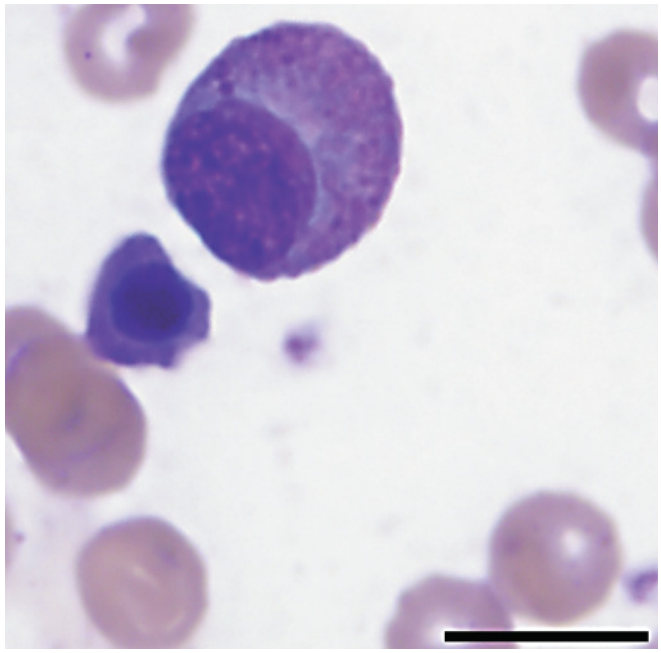

FIGURE 104.23 Canine bone marrow. An eosinophilic myelocyte (upper right) is identifiable due to the presence of developing secondary, eosinophilic granules. Wright-Giemsa stain.

identify the cell as one of granulocytic origin. Myelocytes, smaller than promyelocytes, are characterized by loss of visible primary granules, round to oval nuclei with dense chromatin and no visible nucleoli. Cytoplasm becomes progressively lighter to clear and secondary granules may be present identifying the cells as eosinophils or basophils (Fig. 104.23). Secondary granules in neutrophilic cells are generally indistinct.

Metamyelocytes are the next stage in maturation and are characterized by the beginnings of indentation of the nucleus. The nucleus often has a kidney bean shape. If the indentation is >25% of the thickness of the nucleus, then the cell is considered a metamyelocyte while those with less of an indentation are considered myelocytes. Cytoplasm is clear, with the presence of prominent secondary granules in the eosinophilic and basophilic precursors. Progressive indentation of the nucleus gives rise to the "band" cell which has a rod shaped or curved band shaped nucleus with parallel sides and no indentations/constrictions. The final stage is the mature granulocyte characterized by nuclear constrictions giving rise to the classic polylobated appearance. If the nucleus of the cell has any constrictions that are less than half the diameter of the remainder of the nucleus, the cell is characterized as a mature granulocyte. Cytoplasm remains clear in neutrophilic precursors and has well formed granules in the eosinophilic and basophilic cells.

Megakaryocytic Series

Cells of the megakaryocytic series are classified as megakaryoblasts, promegakaryocytes and megakaryocytes. These cells are typically identified on low magnification

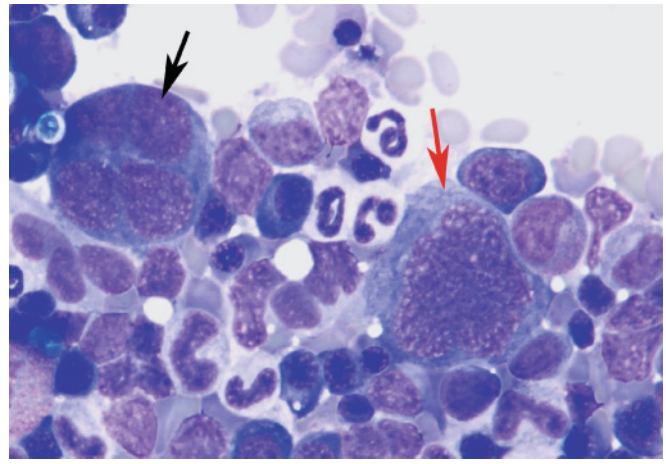

FIGURE 104.24 Canine bone marrow. A promegakaryocyte (black arrow) is recognizable as a large cell with four visible nuclei. An early megakaryocyte (red arrow) has a large, convoluted nuclear mass from multiple nuclear reduplications but retains deeply basophilic cytoplasm. Diff-Quick stain.

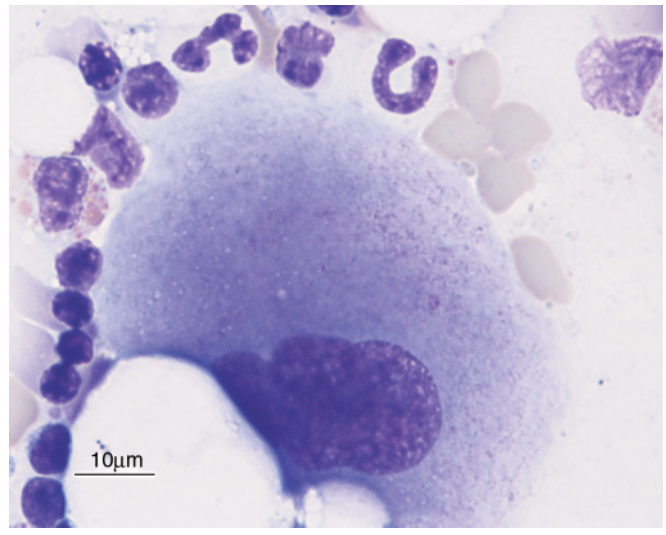

FIGURE 104.25 Canine bone marrow. A mature megakaryocyte is shown with abundant cytoplasm that has pink-purple granules similar to those seen in peripheral blood platelets. (Diff-Quick stain)

as most are substantially larger than the other hematopoietic precursors. Megakaryoblasts are present in low numbers. They have a high N:C ratio, single nucleus and deeply basophilic cytoplasm. It is difficult to reliably differentiate them from blasts of other cell lines. Promegakaryocytes are more easily identified. Endomitotic reduplication of the nucleus results in a large cell with 2–4 nuclei (Fig. 104.24). These may appear to be separate or may be seen to be connected by strands of nuclear material. They have more abundant, deeply basophilic cytoplasm than the megakaryoblast. Further maturation with progressive reduplication of the nucleus gives rise to variably sized megakaryocytes that have an enlarging polylobated nuclear mass (Figs. 104.24 and

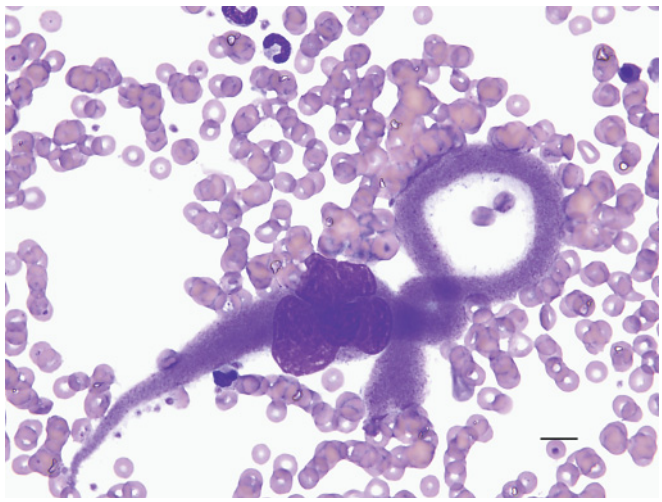

FIGURE 104.26 Canine bone marrow. A mature megakaryocyte is seen with elongated strands of mature, granular cytoplasm. These cytoplasmic extensions would have shed platelets into circulation by fragmentation. Wright-Giemsa stain.

104.25). As megakaryocytes mature, the cytoplasm becomes more abundant and changes from deeply basophilic to eosinophilic and granular, having an appearance similar to platelets (Figs. 104.24, 104.25 and 104.26).

Cells of the monocytic series comprise only a small percentage of the cells in normal marrow. Mature monocytes resemble those in peripheral blood. Cells of the earlier stages, monoblasts and promonocytes, are difficult to clearly separate from granulocytic precursors. Their nuclear shape is more irregular and they lack the primary granules seen in promyelocytes.

Mature lymphocytes may be present in moderate numbers, and low numbers of plasma cells and mature macrophages can be seen admixed amongst the hematopoietic precursors.

Quantitative Parameters

The relative proportion of hematopoietic cells found in samples of bone marrow from normal dogs is given in Table 104.3.[25,28] The M:E ratio of canine marrow is generally reported as being between 1.0:1 and 2.0:1. In one study, normal males had a significantly higher M:E ratio than females, some ranging as high as 2.9:1.[33] Comparison of marrow samples collected from various anatomical sites has shown that the percentages of various cellular elements are fairly uniform.[33,35] Also, repeated sampling of bone marrow from the same anatomic location seems to have little effect on differential cell counts.[17,29] Neonatal dogs have a significantly increased percentage of lymphocytes in bone marrow samples compared to adults.[10] In one study, mean lymphocyte percentages peaked at 54.7% by 21 days of age decreasing to 17.6% by 56 days. Bone marrow samples from normal adult dogs generally have less than 10% lymphocytes.

TABLE 104.3 Differential Cell Counts from Bone Marrow Samples of Normal Dogs

Cell Type	Mean ± SD[a] (%)	Mean ± SD[b] (%)
Myeloid series		
Myeloblasts	0.9 ± 0.2	0.11 ± 0.14
Progranulocytes	2.1 ± 0.4	2.27 ± 0.99
Neutrophilic myelocytes	6.3 ± 1.0	2.76 ± 0.98
Neutrophilic metamyelocytes	7.9 ± 2.1	5.80 ± 1.71
Neutrophilic bands	11.3 ± 2.2	26.1 ± 5.82
Neutrophils	23.5 ± 1.3	3.32 ± 1.85
Eosinophilic myelocytes	0.6 ± 0.2	0.57 ± 0.47
Eosinophilic metamyelocytes	0.7 ± 0.3	0.85 ± 0.62
Eosinophilic bands	1.2 ± 0.4	1.30 ± 0.97
Eosinophils	0.8 ± 0.5	0.20 ± 0.22
Basophils	0.02 ± 0.04	0.00 ± 0.01
Total myeloid series	55.32	43.7 ± 8.68
Erythroid series		
Rubriblasts, prorubricytes	6.5 ± 0.5	4.4 3 ± 1.23
Rubricytes, metarubricytes	27.6 ± 4.4	40.59
Total erythroid series	34.1	45.0 ± 9.81
Myeloid:erythroid ratio	1.7 ± 0.4	1.8 ± 0.61
Lymphocytes	8.2 ± 2.7	6.39 ± 3.75
Plasma cells	0.7 ± 0.3	2.98 ± 1.65
Mitotic figures	1.4 ± 0.3	1.14 ± 0.53
Macrophages	0.4 ± 0.2	0.22 ± 0.24
Megakaryopoietic cells	—	0.23 ± 0.20

Acronyms and Abbreviations

Hct, hematocrit; Hgb, hemoglobin; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; M:E ratio, myeloid:erythroid ratio; MPV, mean platelet volume; N:C ratio, nuclear:cytoplasmic ratio; RBC, red blood cell; RNA, ribonucleic acid; WBC, white blood cell.

ERYTHROCYTES

Morphology

The feline erythrocyte is a biconcave disc, 5.5–6.3 µm in diameter.[13] They typically lack discernible pale centers on blood smears and exhibit mild anisocytosis (Fig. 105.1). When stained with Romanowsky stains, such as Wright's stain, rare polychromatophilic (gray-blue staining) cells may be seen, but these comprise less than 0.4% of erythrocytes (Fig. 105.2).[4] These polychromatophilic cells are erythrocytes recently released from the bone marrow and when stained with a supravital stain, such as new methylene blue, are aggregate reticulocytes.[1] Feline reticulocytes are classified as aggregates and punctates (Fig. 105.3). Aggregates are larger than mature erythrocytes with varying amounts of residual ribonucleic acid (RNA) and organelles (polyribosomes and mitochondria). Aggregate reticulocytes are the youngest anucleate erythrocytes. Punctate reticulocytes may be similar in size to mature erythrocytes and contain less RNA. Feline reticulocytes appear to have prolonged maturation times and punctate reticulocytes can be identified in new methylene blue stained preparations 2–3 weeks after blood loss.[1,4] Supravital stains, such as cresyl blue or new methylene blue, penetrate the cell membrane and cause the variable amounts of RNA to clump (aggregate reticulocytes) or diffusely precipitate (punctate reticulocytes) depending on their age.

Moderate rouleaux can be observed on blood smears from normal cats, and 0–1% of red blood cells (RBCs) can contain Howell-Jolly bodies (Fig. 105.1). Low numbers of Heinz bodies (less than 5% of RBCs) can be found on blood smears of some healthy, nonanemic cats[11] (Fig. 105.4).

Two blood groups have been reported in cats and are designated the AB system and the recently recognized Mik red cell antigen reported in 2007 in four cats.[23] In one study of geographic variation of blood groups, the prevalence of type A (98.2%) was much higher in domestic shorthair/domestic longhair (DSH/DLH) populations than type B (1.7%) and only rarely type AB (0.1%) was encountered.[6] In the same study, the prevalence of blood type B increased in purebred populations. The frequency of blood type B blood in Abyssinian was 13.5%, Persian 9.6%, and Devon Rex cats 49.7%.[6] Sera of either type A or type B cats can contain naturally occurring isoagglutinins to the opposite blood type.[8] Blood type AB cats do not contain anti-A or -B isoagglutinins. The anti-A isoantibodies in type B cats are highly agglutinating and hemolytic to both blood type A and blood type AB.[8]

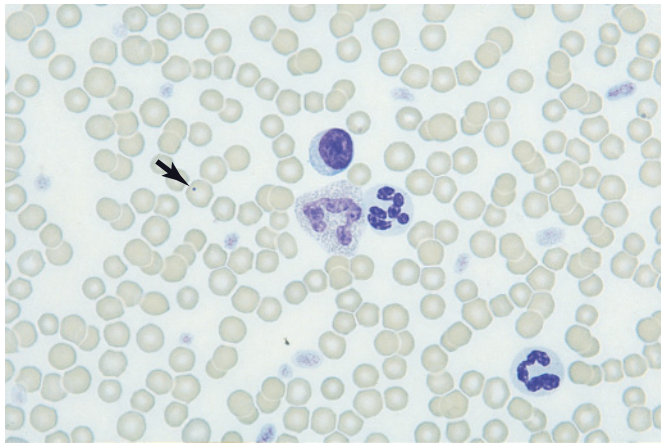

FIGURE 105.1 Feline RBCs exhibit moderate anisocytosis. Pale centers are frequently not readily apparent. A Howell-Jolly body (arrow), two segmented neutrophils, a lymphocyte, an eosinophil, and both round and elongated platelets are present. Wright-Giemsa stain; 100× objective.

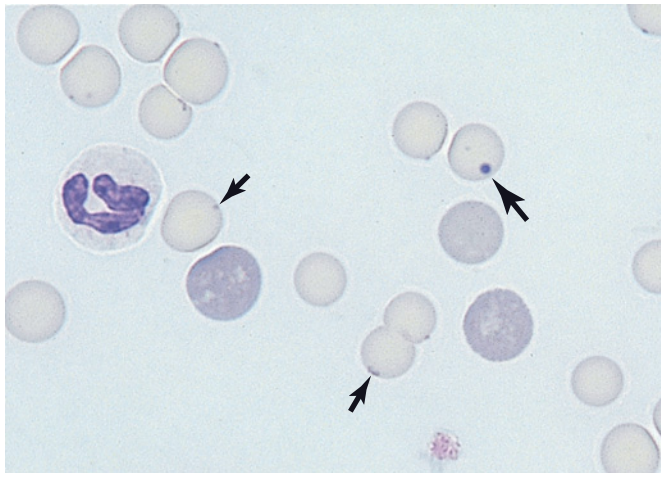

FIGURE 105.2 Macrocytic gray-blue polychromatophilic RBCs and normal feline RBCs are present. A single Howell-Jolly body (large arrow) is seen in contrast to many rod-shaped, peripherally located *Mycoplasma haemofelis* organisms (small arrows). A few platelets and a segmented neutrophil are also seen. Wright-Giemsa stain; 100× objective.

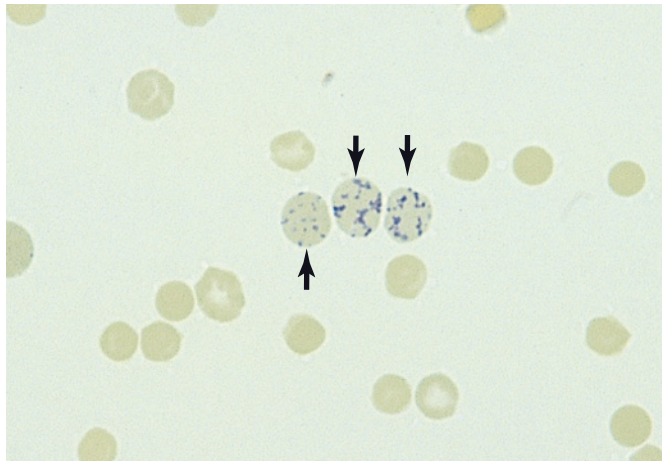

FIGURE 105.3 Two feline aggregate reticulocytes with markedly aggregated reticulation (top arrows) and one punctate reticulocyte with slight focal reticulation (bottom arrow) are present. New methylene blue stain; 100× objective.

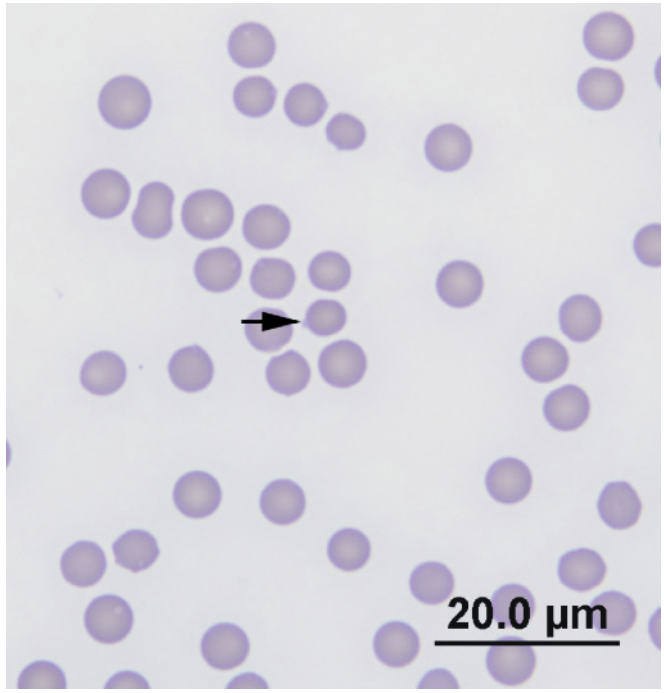

FIGURE 105.4 Feline RBCs with Heinz body (arrow). Low numbers of Heinz bodies may be seen on a blood film from normal cats. Aqueous Romanowsky stain.

Quantitative Parameters

Hemoglobin, Hematocrit, and Red Blood Cell Count

The hemoglobin (Hgb), hematocrit (Hct) and RBC count are all interrelated measurements of erythrocyte mass; in the absence of significant alterations in erythrocyte size and Hgb concentration, changes in these parameters tend to parallel each other. Hematocrit is the most frequently used parameter by practitioners to evaluate RBC mass.

Several sets of reference normal values are available for kittens. The normal hematologic values for kittens are presented in Table 105.1. The agreement among reference values for adult cats is better, particularly for the means. The ranges for WBC and absolute neutrophil counts vary the most; this is likely caused by varying degrees of physiologic leukocytosis present in various sampling groups of normal cats. The normal

hematologic values for adult cats are presented in Table 105.2.

Hematologic reference intervals are available from both research colonies and randomly sampled healthy cats.[2,5,7,12] These reference intervals show satisfactory agreement for the means of most values with the widest variation occurring in the white blood cell (WBC) count. Age, sex, nutritional status, and husbandry as well as pregnancy, anesthesia, or pharmacologic treatment can affect the measured hematologic values. The effects of most of these factors on hematologic values are not peculiar to the cat, but are common for all domestic species. Queens can exhibit a mild normocytic, normochromic anemia during the last third of pregnancy; this resolves by 1 week post-parturition.[3]

Mean Corpuscular Volume, Mean Corpuscular Hemoglobin, and Mean Corpuscular Hemoglobin Concentration

The indices mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH) and mean corpuscular hemoglobin concentration (MCHC) characterize the size and degree of hemoglobinization of the erythrocyte populations.

At birth, feline fetal erythrocytes are larger than those of adults. The MCV is approximately 67 fL at birth and decreases as the cat matures. The nadirs of means for RBC and Hct can be as low as $4.8 \times 10^6/\mu L$ and 26%, respectively.[2] Fetal RBCs are replaced by 1–4 months of age, resulting in the values for RBC, Hgb, Hct, and MCV reaching those for the adult during this time.

LEUKOCYTES

Normal Morphology

The WBC and differential counts in cats are more variable than those for dogs. This may be caused in part by a higher percentage of leukocytes in the marginated pool, estimated to be 70%, than in other domestic species.[18] Increased blood flow caused by anxiety shifts leukocytes from the marginated pool to the circulating pool, resulting in higher and more variable WBC and differential counts (physiologic leukocytosis). At birth, the WBC and differential counts are typically within the adult reference interval. For kittens between 3 and 4

months of age, the WBC count may increase to $23 \times 10^3/\mu L$ and be composed of 50% segmented neutrophils and 50% lymphocytes.[2,5] The WBC count declines to adult normal range for cats at 5–6 months of age.

The morphology of feline neutrophils is similar to that of other domestic species with segmented nuclei with condensed chromatin and clear to slightly eosinophilic staining cytoplasm (Fig. 105.5). Bar bodies or "drumstick" protrusions of the nucleus can be present in 4–11% of neutrophils of female cats (Fig. 105.6).[15]

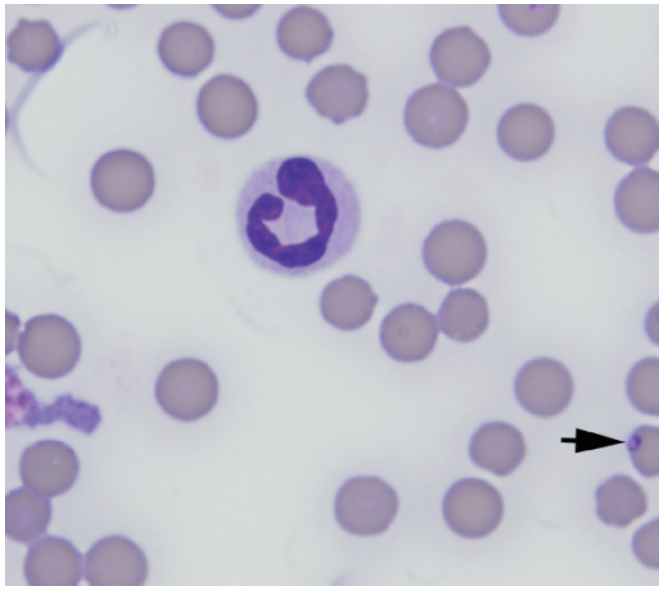

FIGURE 105.5 Feline neutrophil with segmented nuclei with condensed chromatin and an intraerythrocytic *Cytauxzoonan felis* organism (arrow). Aqueous Romanowsky stain.

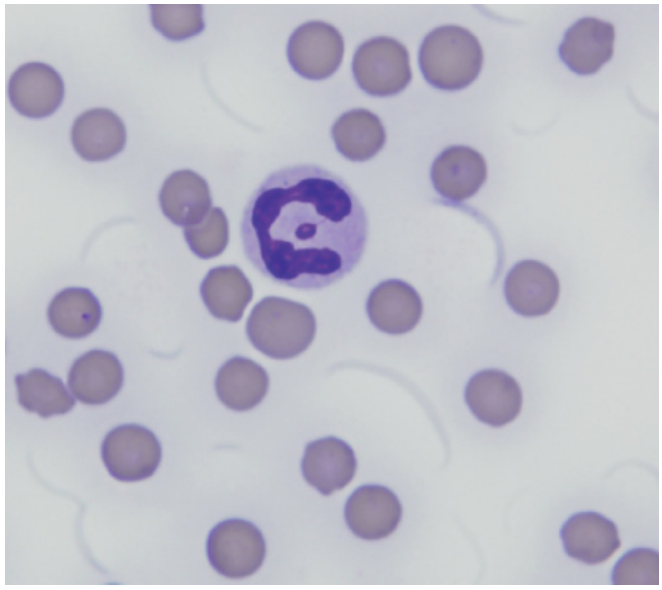

FIGURE 105.6 Feline neutrophil with bar body or "drumstick" protrusion attached to the nucleus with a thin filamentous strand. Aqueous Romanowsky stain.

A hereditary anomaly of granulation in neutrophils of Birman cats has been described.[10] The neutrophils have fine eosinophilic granules in the cytoplasm and do not have any functional abnormalities. Pelger-Huët anomaly has been reported in cats.[14]

Eosinophils typically are slightly larger than neutrophils and have segmented nuclei, which are often bilobated with condensed chromatin, and the cytoplasm has abundant, small, uniform-sized, rod-shaped, pale orange staining granules (Fig. 105.7).

Basophils are similar in size to eosinophils and have segmented nuclei with condensed chromatin and abundant, small, uniform-sized, round-shaped, pale lavender to pink staining cytoplasmic granules (Fig. 105.8).

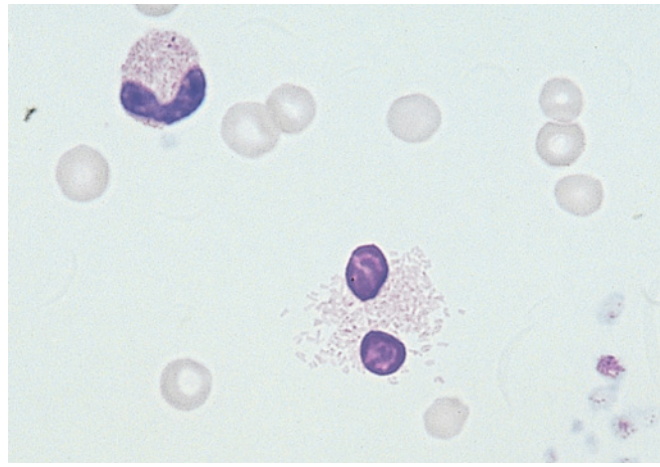

FIGURE 105.7 A ruptured eosinophil demonstrates the rod-shaped pale orange cytoplasmic granules of feline eosinophils. An intact eosinophil is also present. Wright-Giemsa stain.

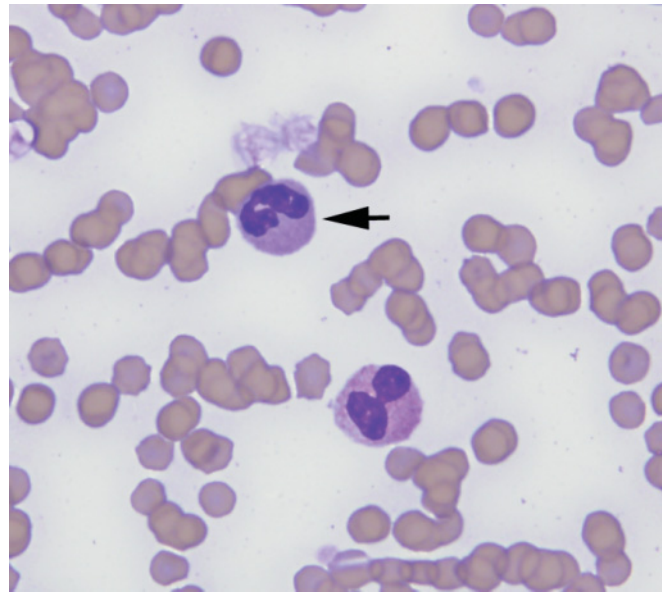

FIGURE 105.8 A feline basophil (arrow) with lavender, round, intracytoplasmic granules and a feline eosinophil. Platelets and rouleaux are also present. Aqueous Romanowsky stain.

A few less-mature dark purple granules may be observed occasionally in feline basophils.

Lymphocytes are smaller than neutrophils, have round to cleaved nuclei, condensed chromatin that appears smudged and lacks discernible nucleoli, and scant basophilic cytoplasm that often appears to extend only one-third of the way around the nucleus (Fig. 105.9). Some lymphocytes can have a few small azurophilic cytoplasmic granules (Fig. 105.10).

Monocytes are larger than neutrophils; have rounded, strap-, bi-, or trilobated or amoeboid-shaped nuclei with reticulated chromatin pattern; and abundant lightly basophilic to gray cytoplasm with a few to several clear variable-sized cytoplasmic vacuoles (Fig. 105.11).

PLATELETS

Feline platelets have morphology similar to other domestic animals except platelets are often macrocytic and occasional elongated forms may be encountered on blood smears (Fig. 105.12). Feline platelet size often overlaps with the size of erythrocytes and they are also prone to clumping after blood collection. The combination of macrocytic platelets and the propensity of feline

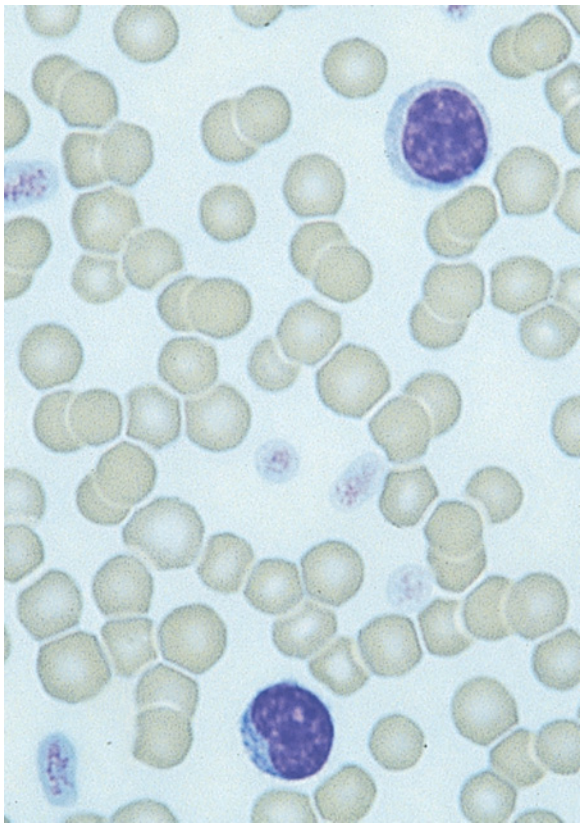

FIGURE 105.9 Two lymphocytes and round and elongated platelets are present. Wright-Giemsa stain; 100× objective. (Courtesy of Oklahoma State University, College of Veterinary Medicine Teaching Files.)

FIGURE 105.10 A lymphocyte containing small azurophilic intracytoplasmic granules (arrow). Wright-Giemsa stain; 100× objective. (Courtesy of Oklahoma State University, College of Veterinary Medicine Teaching Files.)

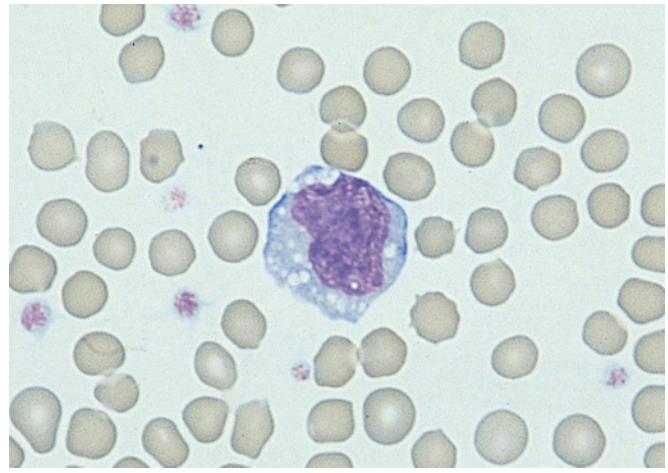

FIGURE 105.11 A monocyte with numerous cytoplasmic vacuoles. Wright-Giemsa stain; 100× objective. (Courtesy of Oklahoma State University, College of Veterinary Medicine Teaching Files.)

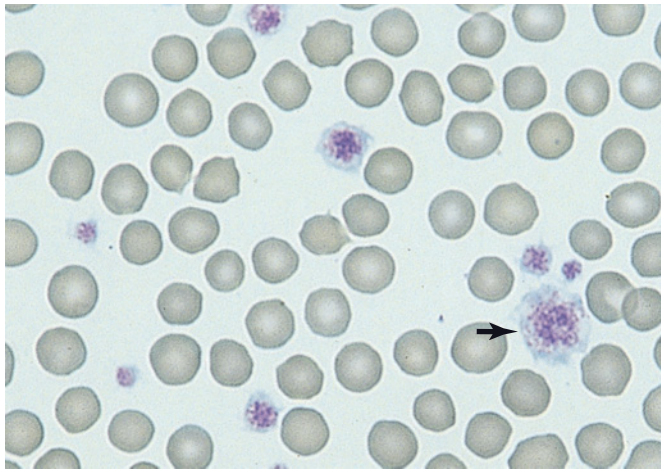

FIGURE 105.12 A large platelet (arrow) and normal-sized platelets. Wright-Giemsa stain; 100× objective. (Courtesy of Oklahoma State University, College of Veterinary Medicine Teaching Files.)

platelets to clump often cause falsely decreased automated platelet counts. The examination of a peripheral blood film can reliably estimate platelet counts in cats. The average number of platelets per 100× field is multiplied by 20,000.[22] Published reference intervals for mean platelet volume (MPV) is reported as 14.2–14.7 fL.[24,25]

BONE MARROW

Morphology

Marrow samples in the cat are commonly collected from the trochanteric fossa of the femur and the proximal humerus as they are the most accessible sites; however, samples can also be obtained from the iliac crest and sternebra. The morphology of feline hematopoietic cells found in bone marrow aspirates has been reviewed.[7,9,19,20,21] Morphologic assessment consists of an evaluation of the major hematopoietic cell lines (i.e. erythroid, granulocytic and megakaryocytic) as well as other cells normally found in the marrow (i.e. lymphocytes, plasma cells and macrophages).

Erythroid Series

Stages of nucleated erythroid precursors recognizable in marrow aspirates are rubriblasts, prorubricytes, rubricytes, and metarubricytes. With progressive maturation, the nucleated cells become smaller, undergo nuclear condensation and cytoplasm color changes from deeply basophilic to red-orange. Rubriblasts are present in relatively low numbers. They are a large cell with a high N:C ratio. The nucleus is nearly perfectly round with fine chromatin and one or more visible nucleoli (Fig. 105.13). The cell has moderate amounts of deeply basophilic cytoplasm. Prorubricytes are slightly smaller, lack visible nucleoli and have somewhat coarser chromatin. The N:C ratio is slightly lower and cytoplasm remains intensely basophilic (Fig. 105.14).

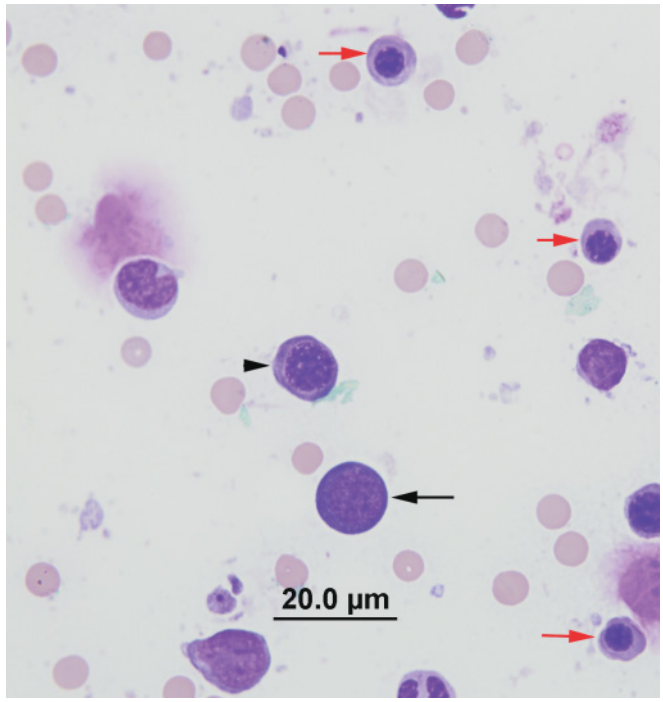

FIGURE 105.13 Feline bone marrow showing developing erythroid cells. A rubriblast (black arrow) with a round nucleus, visible nucleoli and deeply basophilic cytoplasm. A basophilic rubricyte (arrowhead) and three metarubricytes (red arrows). Wright-Giemsa stain.

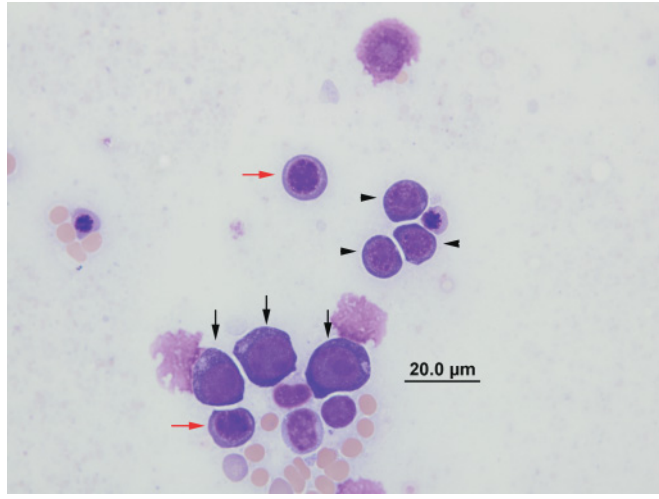

FIGURE 105.14 Feline bone marrow showing early developing erythroid cells. Three rubriblasts (black arrows), three prorubricytes (arrowheads), and two rubricytes (red arrows). Note the chromatin becoming more coarse and condensed as the cell matures. Wright-Giemsa stain.

The next stage in maturation is the rubricyte. Rubricytes are decidedly smaller with a lower N:C ratio. The nucleus is smaller and has extremely coarse chromatin; nucleoli are not visible. The cytoplasm undergoes a progressive color change from deeply basophilic to polychromatophilic (blue-orange) to red-orange representing progressive production of hemoglobin. Rubricytes are sometimes separated into three types (basophilic, polychromatophilic, and orthochromic) based predominantly on change in cytoplasm color. Metarubricytes are the smallest of the nucleated erythroid precursors and are characterized by a pyknotic nucleus that lacks a discernible chromatin pattern (Figs. 105.15 and 105.16). Progressive maturation results in polychromatophilic erythrocytes, non-nucleated cells similar to those seen in low numbers in the peripheral blood.

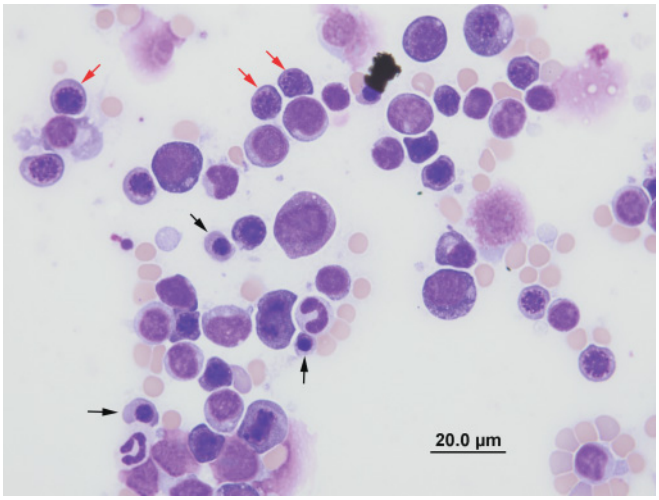

FIGURE 105.15 Feline bone marrow. Developing rubricytes (red arrows) have coarse chromatin. Metarubricytes (black arrows) have condensed pyknotic nuclei. Wright-Giemsa stain.

Granulocytic Series

The granulocytic series goes through a similar progression of relatively low number of early precursors to more numerous maturing cells. The recognizable stages of granulocytic maturation in the marrow are myeloblasts, promyelocytes (also called "progranulocytes"), myelocytes, metamyelocytes, bands and mature granulocytes.

Myeloblasts are large cells with a high N:C ratio, fine chromatin and one or more visible nucleoli. Compared to rubriblasts, the myeloblast has a more irregularly shaped nucleus and lighter staining cytoplasm. (Fig. 105.16) The next stage in granulocytic development is the promyelocyte stage. Often, these cells are slightly larger than myeloblasts but have a lower N:C ratio due to cytoplasmic enlargement. Nuclear chromatin is somewhat coarser. Nucleoli may or may not be present. The main feature identifying the promyelocytes is the presence of numerous fine, azurophilic, granules termed primary granules in the cytoplasm (Fig. 105.17). These granules help identify the cell as one of granulocytic origin. Myelocytes, smaller than promyelocytes, are characterized by loss of visible primary granules, round to oval nuclei with dense chromatin and no visible nucleoli. Cytoplasm becomes progressively lighter to

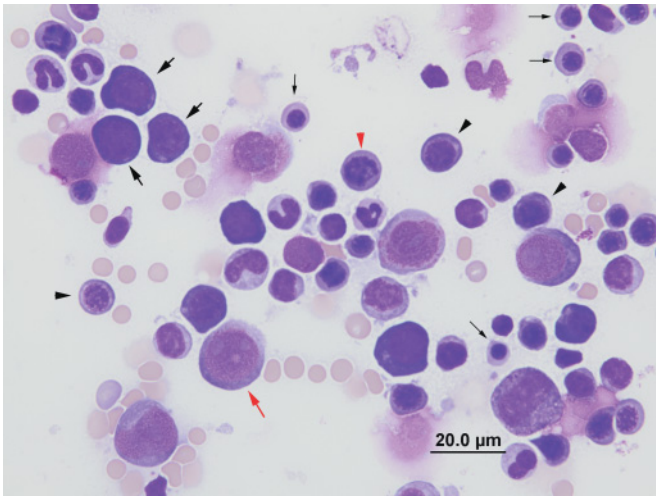

FIGURE 105.16 Feline bone marrow. Developing erythroid cells. Three rubriblasts (large black arrows), rubricytes (black arrowheads), metarubricytes (small black arrows). A few developing myeloid cells-myeloblast (red arrows). A single mitotic figure (red arrowhead). Wright-Giemsa stain.

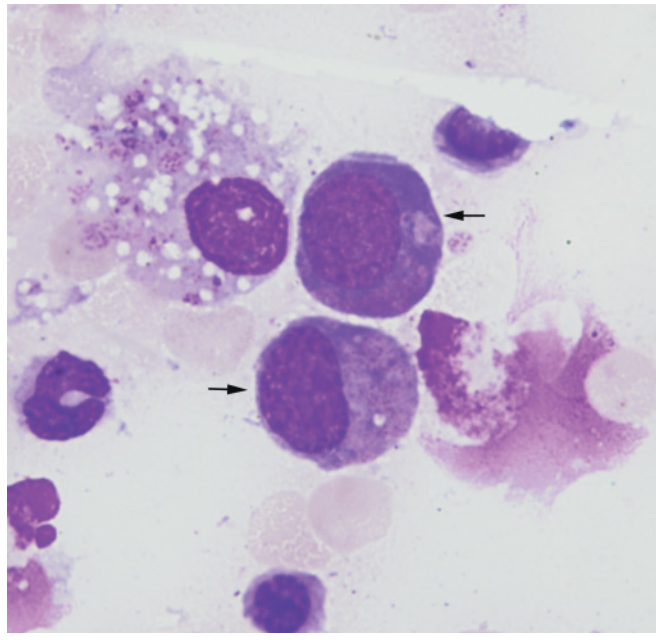

FIGURE 105.17 Feline bone marrow. Two promyelocytes (arrows). Promyelocytes are recognized by the presence of pink-purple primary granules. Wright-Giemsa stain.

clear and secondary granules may be present identifying the cells as eosinophils or basophils (Fig. 105.18). Secondary granules in neutrophilic cells are generally indistinct.

Metamyelocytes are the next stage in maturation and characterized by the beginnings of indentation of the nucleus. The nucleus often has a kidney bean shape. (Fig. 105.19) If the indentation is >25% of the thickness of the nucleus, then the cell is considered a metamyelocyte, while those with less of an indentation are considered myelocytes. Cytoplasm is clear, with the presence of prominent secondary granules in the eosinophilic and basophilic precursors. Progressive indentation of the nucleus gives rise to the "band" cell which has a rod shaped or curved band shaped nucleus with parallel sides and no indentations/constrictions (Fig. 105.19). The final stage is the mature granulocyte characterized by nuclear constrictions giving rise to the classic polylobated appearance. If the nucleus of the cell has any constrictions that are less than half the diameter of the remainder of the nucleus, the cell is characterized as a mature granulocyte. Cytoplasm remains clear in neutrophilic precursors and has well formed granules in the eosinophilic and basophilic cells.

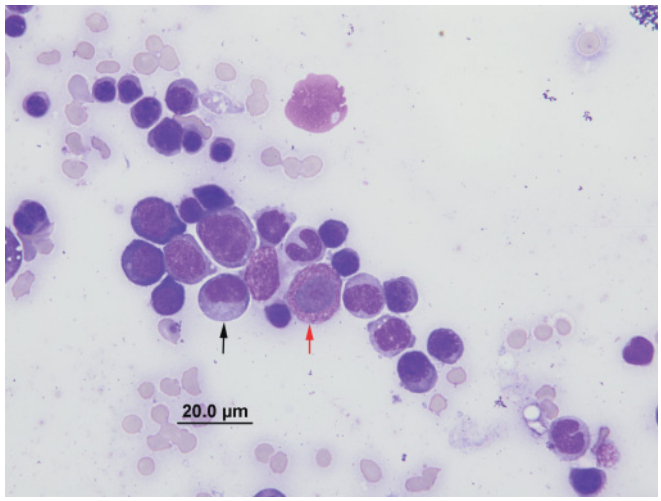

FIGURE 105.18 Feline bone marrow. Developing erythroid and myeloid cells. Neutrophil myelocyte (black arrow) eosinophil myelocyte (red arrow). Wright-Giemsa stain.

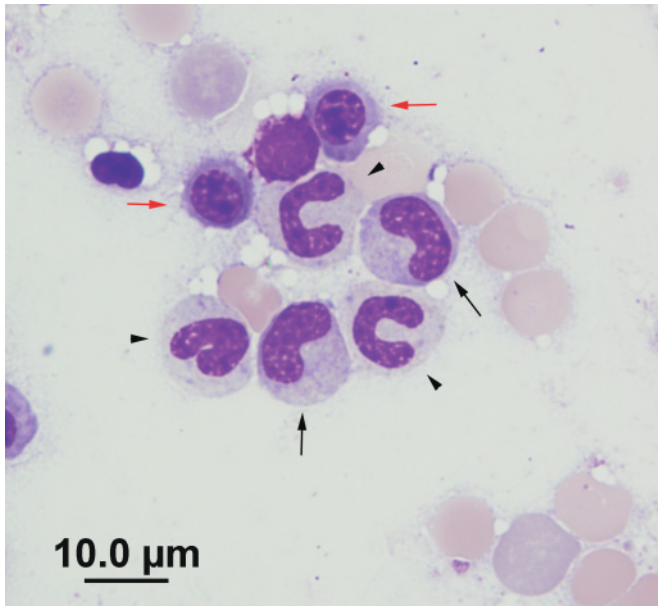

FIGURE 105.19 Feline bone marrow. Developing myeloid cells. Two metamyelocytes (black arrows) and three band neutrophils (black arrowheads). Two rubricytes (red arrows) are also present. Wright-Giemsa stain.

Megakaryocytic Series

Cells of the megakaryocytic series are classified as megakaryoblasts, promegakaryocytes and megakaryocytes. These cells are typically identified on low magnification as most are substantially larger than the other hematopoietic precursors. Megakaryoblasts are present in low numbers. They have a high N:C ratio, single nucleus and deeply basophilic cytoplasm. It is difficult to reliably differentiate them from blasts of other cell lines. Promegakaryocytes are more easily identified. Endomitotic reduplication of the nucleus results in a large cell with 2–4 nuclei (Fig. 105.20). These may appear to be separate or may be seen to be connected by strands of nuclear material. They have more abundant, deeply basophilic cytoplasm than the megakaryoblast. Further maturation with progressive reduplication of the nucleus gives rise to variably sized megakaryocytes that have an enlarging polylobated nuclear mass. As megakaryocytes mature, the cytoplasm becomes more abundant and changes from deeply basophilic to eosinophilic and granular, having an appearance similar to platelets (Figs. 105.21 and 105.22).

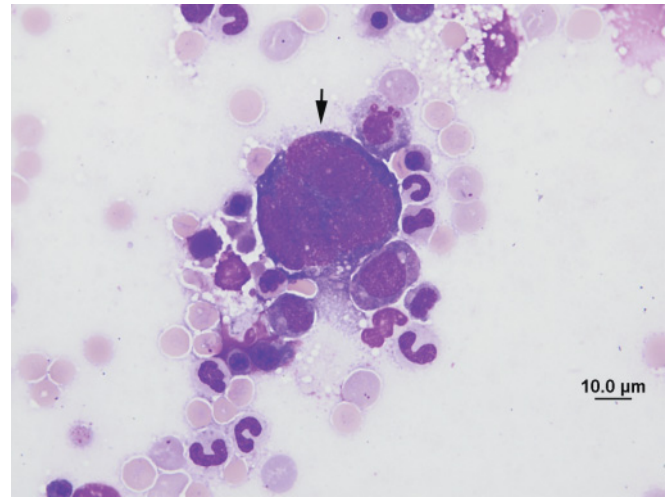

FIGURE 105.20 Feline bone marrow. A promegakaryocyte (black arrow) is recognizable as a large cell with four visible nuclei. Wright-Giemsa stain.

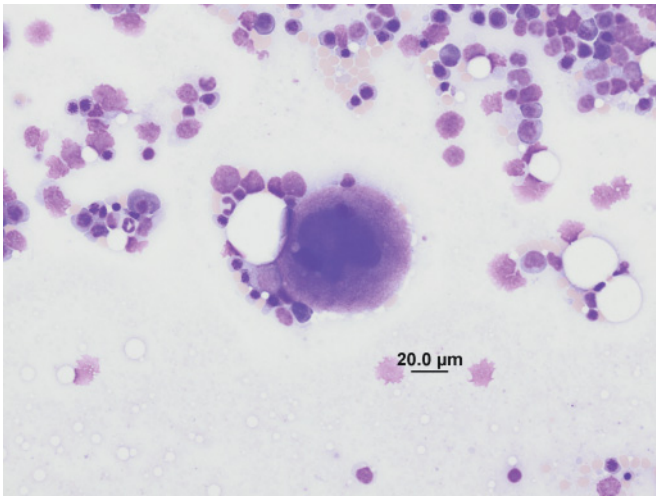

FIGURE 105.21 Feline bone marrow. An early megakaryocyte has a large, convoluted nuclear mass from multiple nuclear reduplications but retains deeply basophilic cytoplasm. Wright-Giemsa stain.

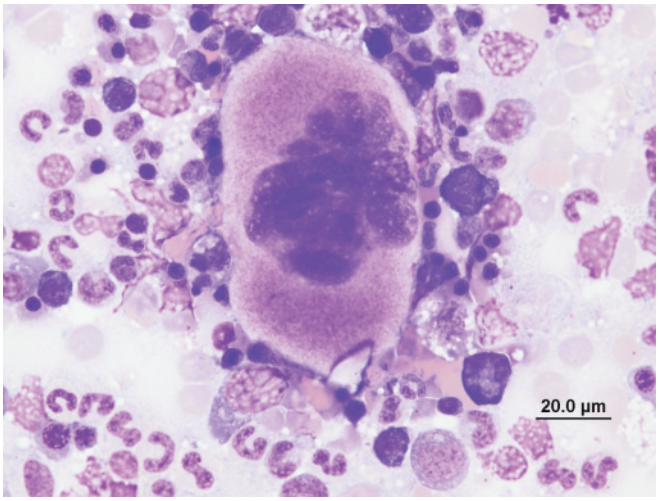

FIGURE 105.22 Feline bone marrow. A mature megakaryocyte is shown with abundant cytoplasm that has pink-purple granules similar to those seen in peripheral blood platelets. Wright-Giemsa stain.

Monocytic and Lymphocytic Cells

Cells of the monocytic series comprise only a small percentage of the cells in normal marrow. Mature monocytes resemble those in peripheral blood. The earlier stage cells, monoblasts and promonocytes, are difficult to clearly separate form granulocytic precursors. Their nuclear shape is more irregular and they lack the primary granules seen in promyelocytes.

Mature lymphocytes may be present in moderate numbers, and low numbers of plasma cells and mature macrophages can be seen admixed amongst the hematopoietic precursors.

TABLE 105.3 Differential Cell Counts from Bone Marrow Samples of Normal Cats

	Gilmore et al. 1964[a]	Jain 1993[b]
	Mean (%)	Mean ± SD (%)
Number of cats	15	7
Myeloblasts	1.1	0.08 ± 0.16

Quantitative Parameters

The relative proportion of hematopoietic cells found in samples of bone marrow from normal cats is given in Table 105.3. The M:E ratio of feline marrow is generally reported as being between 1.2:1 and 2.0:1.[13] Bone marrow samples from normal adult cats average less than 10% lymphocytes[9], but may be as high as 21%.[13]

Acronyms and Abbreviations

CBC, complete blood count; Hct, hematocrit; Hgb, hemoglobin; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; M:E ratio, myeloid:erythroid ratio; MPC, mean platelet component; MPV, mean platelet volume; N:L ratio, neutrophil:lymphocyte ratio; nRBC, nucleated red blood cell; PCDW, platelet component distribution width; RBC, red blood cell; RDW, red cell distribution width; WBC, white blood cell.

The common domestic equine species (horses, donkeys, and their hybrid the mule) have various hematological differences as a result of age, breed, sex, reproductive status, emotional status and physical activity. Other differences are minor and observations from ponies and horses are frequently used interchangeably. Complete blood cell count (CBC) reference intervals for horses, neonates and donkeys have been assembled (Tables 106.1 and 106.2); however, it is important to note that these reference intervals have been established for particular methodologies and instruments and as a result they are not applicable to all laboratory methods.

ERYTHROCYTES

The equine red blood cell (RBC) is a biconcave discoid cell that has mild to no central pallor (Fig 106.1A). The cells measure 5–6 µm in diameter and a have lifespan of 140–155 days. Polychromatophilic RBCs are rarely detected in the peripheral blood of horses because equine reticulocytes mature in the bone marrow even when erythropoiesis is increased. Low reticulocyte concentrations have been detected in anemic horses using an automated hematology analyzer (Advia 120, Bayer Corp., Tarrytown, NY, USA).[10]

Rouleaux

Equine RBCs have prominent rouleaux that appear as a stack of coins on a blood film. Rouleaux formation is common in horses because horses have decreased RBC membrane charge (zeta potential) compared to other species.[5] Increased rouleaux formation can be seen with hyperglobulinemia and hyperfibrinogenemia because these can further mask erythrocyte negative surface charge.[5] Rouleaux are responsible for the rapid RBC sedimentation rate of equine blood.[19] Thorough mixing of blood specimens is required to prevent erroneous laboratory measurements that result from a rapid sedimentation rate.

Agglutination

Autoagglutination can be seen in some horses without hemolysis as a result of cold antibodies that have maximal activity at 4–20 °C or as a result of unfractioned heparin treatment.[23,24] Macroscopically, agglutination has a granular appearance and microscopically appears

TABLE 106.1 Reference Intervals for Horses and Donkeys

	Hot–Blooded Breeds[a]	Cold–Blooded Breeds[b]	Miniature Horses[c]	Donkeys[d]	Mixed Breeds[e]

as grape-like clusters of RBCs. Rouleaux and agglutinated erythrocytes can be difficult to differentiate in a blood film. Agglutination can be differentiated from rouleaux by performing a saline dilution test. Typically a 1:2 dilution will disperse rouleaux but not the autoagglutinated erythrocytes. Infrequently, a higher dilution (up to 1:10) may be needed to disperse rouleaux. Agglutination can cause erroneous MCV values and erythrocyte concentrations determined by impedance because the aggregates may interfere with the electronic or optical evaluation of the erythrocytes. Pre-treating cell suspensions from agglutinated heparin treated horses with trypsin can reverse the agglutination and improve the accuracy of cell counts and indices.[24]

Howell-Jolly Bodies

Howell-Jolly bodies are nuclear remnants that occasionally can be seen in equine peripheral blood films in health (Fig. 106.1A). They are small, round, purple inclusions found in discocytes. Increased numbers of Howell-Jolly bodies can be seen with increased eryth-

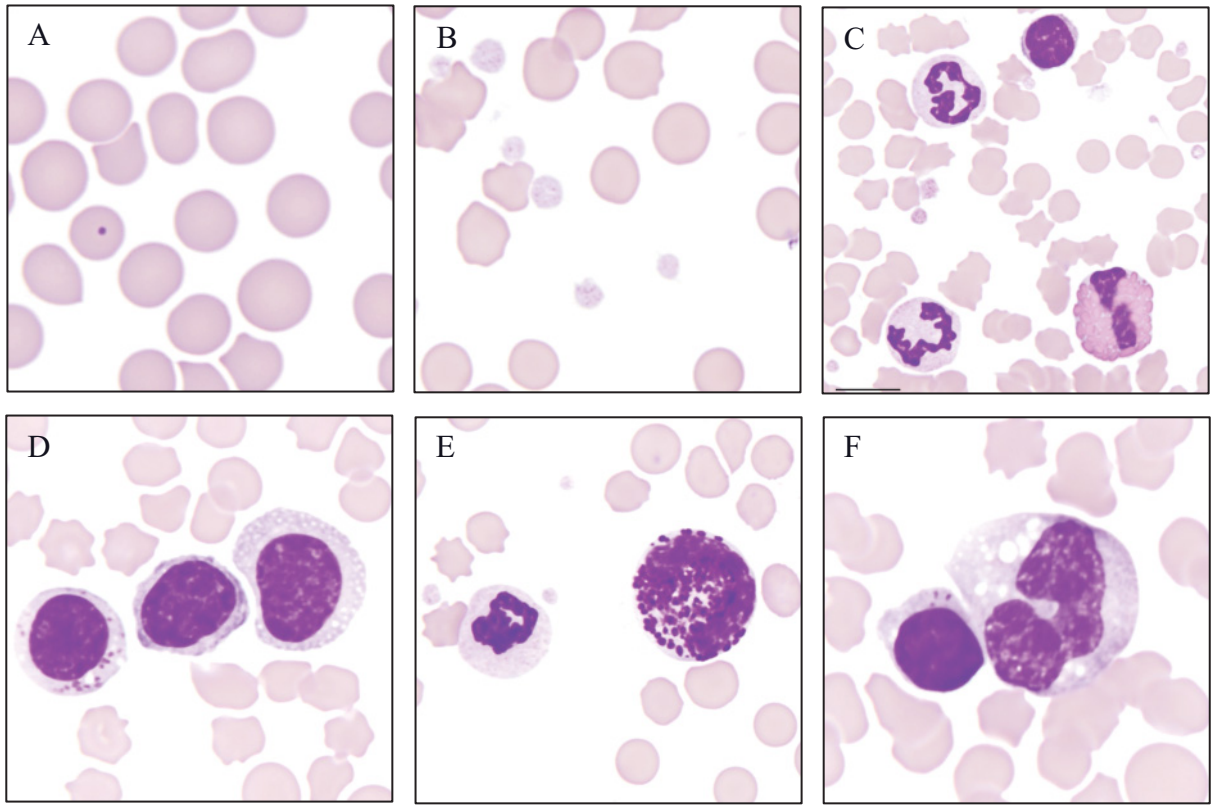

FIGURE 106.1 (**A**–**F**) Peripheral blood film from a horse. Modified Wright's stain: (**A**) Discocytes that lack a central pallor and an erythrocyte that contains a Howell-Jolly body. (**B**) Six light-staining platelets. (**C**) Two segmented neutrophils, one small lymphocyte, one eosinophil, erythrocytes and platelets. ropoiesis and with decreased or compromised splenic function.

Hemoglobin Crystals and Artifacts

Hemoglobin crystals are rarely seen in peripheral blood films in health and their significance has not been determined to date. Refractile artifacts can be seen and develop as a result of the drying or staining process.

LEUKOCYTES

Automated determination of differential leukocyte counts has been attempted on several hematology instruments using species-specific programs, but to date no methods have been found to be completely reliable.[2,13,26,29] Therefore, it is still recommended that leukocyte differential cell counts be verified by examination of a peripheral blood film.

Neutrophils

The nuclei of equine neutrophils are lobulated with scalloped to jagged nuclear membranes and have heavily plaqued chromatin (Fig 106.1C). Nuclear filaments that separate lobes are rarely seen.[19] Barr bodies (sex chromatin lobe/drumstick) can be recognized in females and resemble a small purple body attached to the nucleus by a thin chromatin strand. The neutrophil cytoplasm is colorless with granules that may or may not stain depending on the type of stain and stain conditions used. Equine band neutrophils are less frequently seen because horses do not exhibit marked left shifts in inflammatory states compared to other species (i.e. dog and cat). Because of this, hyperfibrinogenemia is frequently used as an additional indicator of inflammation.

Hypersegmented neutrophils are rarely seen in health and historically are recognized by having five or more lobes separated by filaments. Prolonged storage of blood may lead to the artifactual development of hypersegmented leukocytes. Idiopathic hypersegmentation has been found in Quarter Horses that lacked evidence of clinical disease.[27]

Hyposegmented neutrophils have been reported in apparently healthy Arabian horses that were diagnosed with Pelger-Huët anomaly.[14]

Eosinophils

Eosinophils contain large, reddish-orange, specific granules that tightly pack the cytoplasm, often obscuring the nuclei and giving a raspberry-like appearance

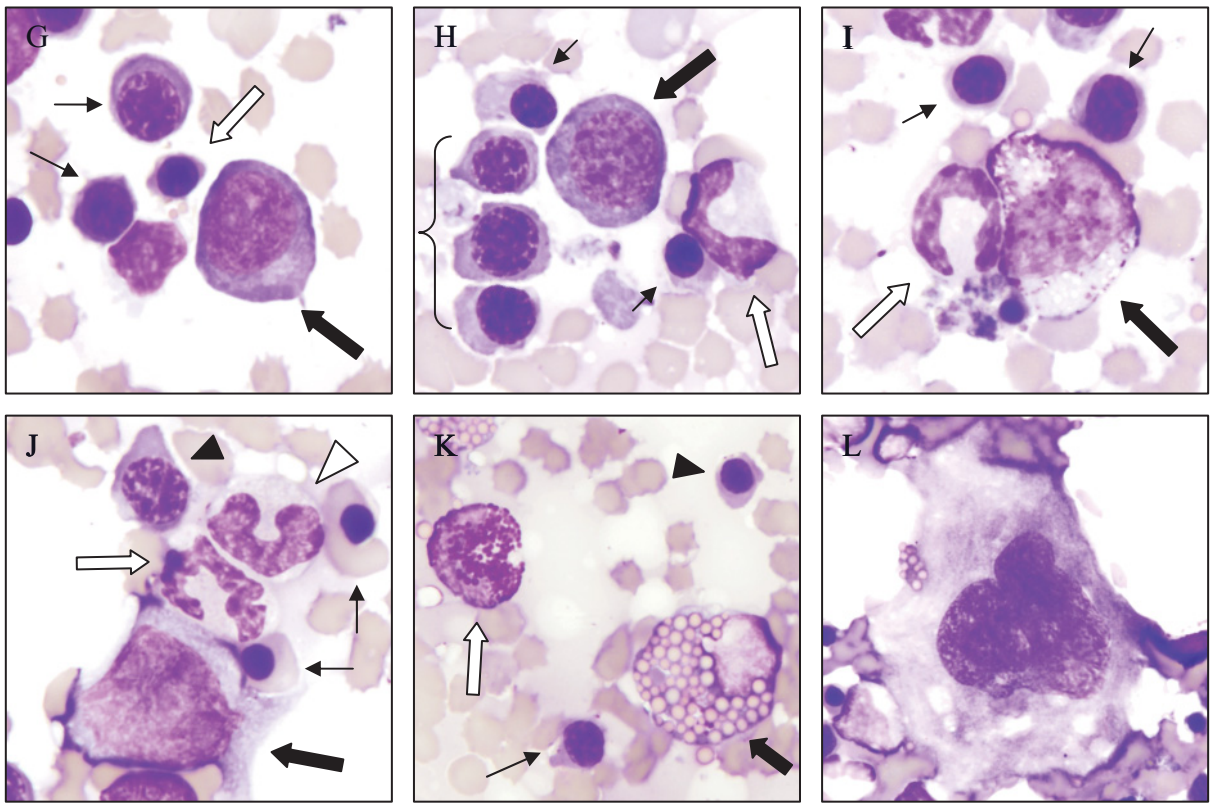

FIGURE 106.1 *continued* (**G–L**) Bone marrow preparation from a horse. (Fig. 106.1C). Their cytoplasm is pale blue. The lobulated nucleus seldom shows fine filamentation. Degranulated eosinophils are vacuolated and are rarely seen in health.

Basophils

Equine basophils contain few to many purple granules that vary in size and shape (Fig 106.1E).[19] When granules are abundant, they mask the nucleus. The nuclei of basophils are less segmented compared to the nuclei of mature neutrophils.[19] Cytoplasms vary from clear to light blue.

Lymphocytes

Lymphocytes are made up of 38–66% T cells, 17–38% B cells with the remainder being null cells.[22,33] Lymphocytes are smaller than granulocytes with a dark-staining nuclei, coarse chromatin patterns and scant amounts of blue cytoplasms (Fig. 106.1D). On Wright-stained blood films, about 5% of the lymphocytes contain small, magenta, irregularly-shaped, cytoplasmic granules (Fig. 106.1D). Occasionally, larger lymphocytes are present that have smooth chromatin patterns and large amounts of pale blue cytoplasm.[19] Reactive lymphocytes (immunocytes) are rarely seen in health. They are slightly larger than small lymphocytes, have scalloped nuclear margins, moderately aggregated chromatin, occasionally have discernible nucleolar rings, scant to moderate amounts of intensely basophilic cytoplasm, and occasionally have a pale-staining Golgi zone.

Monocytes

The nucleus of the equine monocyte is large, broad, variable in shape (i.e. oval, bilobed, horseshoe-shaped, trilobed or irregular) with lacy chromatin (Fig. 106.1F). Cytoplasm is gray-blue, has small azurophilic granules and may have a few clear vacuoles. Prolonged storage of blood has resulted in an artifactual increases in the proportion of mononuclear cells detected by the Advia 120 hematology analyzer (Bayer Corp., Tarrytown, NY, USA).[9]

PLATELETS

Equine platelet concentrations are some of the lowest reported for mammals (Table 106.1).[4] Reported reference intervals for different horse breeds have been

summarized elsewhere.[19] Finding 6–10 platelets/oil-immersion field (100× objective) in a peripheral blood film indicates an adequate platelet concentration. Equine mean platelet volume (MPV) (4.3–5.6 fL) and mean platelet mass (0.47–0.96 × 10^6/fL) have been determined.[4] Additionally, mean platelet component (MPC) concentration (26.2 ± 3.5 g/dL) and platelet component distribution width (PCDW) (7.9 ± 1.2 g/dL) have been summarized.[32] MPC was found to decrease with disease processes that caused activation of platelets. Equine platelets stain very lightly with Wright-Giemsa stain and sometimes can be difficult to discern on blood films. However, platelets stain well with Diff-Quick® stain. Platelets are round, oval, or elongate, measure 2.5–3.5 µm in diameter, and have light blue cytoplasm that contains fine azurophilic granules (Fig. 106.1B). Pseudopodia may be noted with activated platelets. Giant platelets (greater than the diameter of an RBC) are associated with increased thrombopoiesis. Platelet clumping indicates platelet activation and aggregation during blood collection, and can lead to erroneously low platelet concentrations. Prolonged sample storage can result in pseudothrombocytosis due to misclassification of ghost RBCs as platelets with the Advia 120 (Bayer Corp., Tarrytown, NY, USA).[9] EDTA-dependent pseudothrombocytopenia has been reported in a Thoroughbred gelding.[18]

BREED-RELATED DIFFERENCES

Horses of Arabian ancestry (light-horse breeds) are called "hot-blooded" and include Arabian and Thoroughbred breeds. "Cold-blooded" horses are the draft horse and pony. Most horse breeds fall into the "warm-blood" category which are crosses between hot-bloods and cold-bloods (Standardbreds and Quarter Horses). Hot-blooded horses have been found to have higher RBC counts, hemoglobin (Hgb) concentration, hematocrit (Hct), and blood volume compared to cold-blooded horses.[19] Hcts as low as 24% have been found in healthy draft horses and pony breeds. Thoroughbreds have a smaller RBC mean corpuscular volume (MCV) than draft horses.[19] Specific breeds have minor differences in Hgb, mean corpuscular hemoglobin (MCH) and mean corpuscular hemoglobin concentration (MCHC); however, these differences are insignificant.[19] American miniature horses have lower Hct, Hgb, and RBC counts, but higher MCV, MCH and MCHC.[17] Reference intervals for different breeds of donkeys have been established and compared.[7,11,12,25,35] Donkeys have similar RBC counts, Hgb and Hct compared to ponies; however, donkeys were found to have much higher MCV.[20]

Minor differences have been found among various breeds in relation to WBC count, with hot-blooded horses having slightly higher WBC counts compared to cold-blooded horses.[19] Thoroughbreds and Arabians have a mean neutrophil:lymphocyte (N:L) ratio of 1.0 whereas cold-blooded horses have a mean N:L ratio of 1.7.[19] Miniature horses have a N:L ratio of 0.67.[17]

AGE-RELATED CHANGES

Red blood cell parameters (i.e. Hct, RBC count and Hgb) are increased at birth, decline sharply within 12–24 hours, then decline gradually over the subsequent 2 weeks where they remain in the lower portion of the normal adult reference interval during the first year of life (Table 106.2).[15,19] The initial hematologic changes in foals at birth are thought to be due to the transfusion of placental blood to the foal. The sharp decline of RBC values in the first 12–24 hours of life have been attributed to catecholamine secretion and adjustment of fluid balances as a result of the osmotic effect of absorption of colostral immunoglobulins. Further decline in these values has been attributed to decreased RBC survival time, decreased iron delivery to bone marrow, decreased stimulus for erythropoietin production as a result of higher Hgb saturation, increased blood oxygen content, and enhanced delivery of oxygen to the tissues due to lower 2,3-diphosphoglycerate concentrations.[15] Normal adult hematologic values are attained at 1–2 years of age. A similar trend of declining erythroid parameters during the first year has also been noted in donkeys.[6]

Mean cell volume values are high at birth and then decrease, reaching their lowest values at 3–5 months of age (see Table 106.2).[15,19] They do not increase to adult values until approximately 1 year of age.[15] Microcytosis has been attributed to a decrease in serum iron as a result of increased growth demand.[16] These RBCs may be too small to be recognized as erythrocytes by some impedance counters, hence generating false MCV, RBC, and Hct values. Mild anisocytosis is a typical finding in young foals.[15] The MCHC remains constant after birth and is similar to adult values.[15] Donkey foals between 6 and 12 months of age have higher MCV (44–52 fL) values compared to horse foals.[20]

Neutrophil numbers are low in the fetus (<1,500/µL, before 300 days of gestation), increase after birth in response to cortisol (8,000/µL), and then decrease to mean adult values (4,000/µL) at about 4–6 months of age.[1,15,19] Band neutrophils do not exceed 150/µL in healthy foals.[15] Foals born at term have higher neutrophil concentrations than foals born prematurely. In donkeys, neutrophil numbers decreased from birth to 10 months of age and then increased to adult reference intervals by 18 months of age.[6] Lymphocyte numbers in foals are low at birth (average 1,400/µL), increase to 5,000/µL at 3 months of age, and reach adult values at 1 year of age.[15,19] Consequently, N:L ratios have been found to decrease from 2.8 at birth to 1.0 at 1 year of age; a similar trend is seen in donkeys.[6,19] Lymphocyte numbers further decline during adulthood while neutrophil numbers remain the same, resulting in a higher N:L ratio in aged horses compared to foals.[19] Eosinophils are not routinely detected in the fetus and foals at birth, and reach a mean of 400/µL by 4 months of age.[15] In donkeys, eosinophil numbers were found to increase at a relatively constant rate up to 2 years of age.[6] Monocyte numbers remain constant and do not change with age.[15]

TABLE 106.2 Reference Intervals for Thoroughbred and Quarter Horse Foals of Both Sexes (mean ± 1 S.D.)[a]

	1st Day	2–7 Days (Average 5)	8–14 Days (Average 9)	21–30 Days (Average 28)	1–3 months (Average 51 days)

[a]Adapted from Jain NC. Schalm's Veterinary Hematology. 4th ed. Philadelphia: Lea & Febiger, 1986. Numbers in parentheses indicate number of foals when less then total for series. Methods used for determination of these reference intervals are unknown.

Platelet numbers in foals appear to be constant over the first year of life and do not appear to be influenced by age.[15] Equine MPV (range 4.8–6.1 fL) and mean platelet mass (range 0.62–1.29 $\times$ $10^3/\mu L$) have been determined in foals at 24–48 hours of age.[4] Additionally, MPC concentration (28.1 ± 1.7 g/dL) and PCDW (6.6 ± 0.8 g/dL) have been determined for foals less than 21 days of age.[32] MPCs were found to be higher in neonates compared with adult horses.[32] In donkeys, platelet concentration increases in the first month of life and then remains within adult reference intervals.[6]

Total plasma protein concentration increases from 5 to 6 g/dL after birth due to immunoglobulins absorbed from colostrum.[15] Fibrinogen concentration is low at birth (about 200 mg/dL) and increases to 500 mg/dL by 3 months of age.[15]

Hematologic values have been evaluated in equine fetuses (202 and 238 days of gestation) and consist of lower RBC count, Hgb, Hct, plasma protein, fibrinogen and white blood cell (WBC) count; higher MCV, MCH, increased numbers of nucleated RBC, Heinz bodies, and Howell-Jolly bodies, marked polychromasia; mean N:L ratio of 0.2; and no difference in platelet concentration and MCHC when compared with previously published reference intervals for foals.[1]

Hematologic data were compared among young horses (<5 years of age) and geriatric horses (>20 years of age).[28] Geriatric horses were found to have consistently larger RBCs; however, the MCV still remained within the reference interval for the normal horse population. Hct and Hgb did not differ significantly. When comparing donkeys of various age groups (<1 year of age to >6 years of age); RBC, lymphocyte, platelet, and fibrinogen concentrations were lower in older donkeys, while eosinophil concentrations, MCV values, MCH values, and plasma protein concentrations were greater in older donkeys.[35]

GENDER-RELATED DIFFERENCES

Minor differences between adult females and adult males have been reported. Males had slightly higher RBC counts, Hgb and Hct, while females had higher MCH, MCHC, and WBC values.[19]

Mares in late pregnancy and during the first few weeks postpartum have lower Hct, RBC count, and Hgb, which has been attributed to a hemodilution effect resulting from increased plasma volume. Lactating mares also tend to have lower mean values for Hct, RBC count, and Hgb.[19] Female donkeys were found to have higher MCH, and leukocyte and neutrophil counts compared to males in one study;[35] while others found no differences between genders.[11,12]
