INFLUENCES OF TRAINING

Assessment of training-related issues is difficult as they are influenced by the breed of horse, demeanor of the horse, age of horse, amount of training the horse has received, when the sample was taken in relation to exercise, intensity of exercise, and type of event in which the animal is engaged.[3,30,31] In spite of these variables, intense exercise is associated with transient RBC changes including increased Hgb (up to 23 g/dL), Hct (up to 65%) and RBC count.[3] These erythrocyte changes are attributed to epinephrine release, an increase in sympathetic tone, splenic contraction and fluid shifts out of the vascular compartment.[3,30] The degree of change and duration of elevations depend on the degree of training and intensity of exertion (values return to normal within 30 minutes after light exercise and up to 3 hours after hard exertion).[3] The effect of training on resting hematologic values has been variable and reports of no changes to decreases in erythrocyte parameters have been reported.[8,31] A relationship between hemograms, racing performance and fitness level has not been found.[30,31] Exertion-induced leukogram changes have been variable, and a leukocytosis characterized by a neutrophilia and lymphocytosis, or leukocytosis due to neutrophilia and lymphopenia have been reported and appear to depend on the type and intensity of exercise.[3,8] These leukogram changes have been attributed to epinephrine and cortisol release (also see Chapter 47).[3] Regular training has not produced any differences in baseline total leukocyte concentration or baseline differential leukocyte concentrations.[3,31]

BONE MARROW

Persistent anemia, leukopenia, thrombocytopenia, or hematopoietic neoplasms are the most frequent indications for examining bone marrow in the horse. Bone marrow can be collected from the sternum (preferred site), ilium and ribs in both adult and young horses as well as from the tuber coxae in young horses. Care must be taken when collecting samples from the sternum and ribs in order to avoid inadvertent penetration of the thoracic cavity. Detailed descriptions on collection techniques have been described (see Chapter 132).[21] Descriptions of the cellular composition of horse bone marrow have been published (Table 106.3;

Fig 106.1G–L).[21,34] Cellularity of horse bone marrow can be routinely assessed on bone marrow aspirates or bone marrow core biopsy specimens. Normocellular particles in the adult horse are typically composed of 50% fat and 50% cells but can vary based on the age of the horse.[21] Young horses can have up to 70% hematopoietic cells to compensate for normal cell turnover and in response to growth. Aged horses can have up to 70% fat. Thorough examination of the bone marrow involves evaluation of the megakaryocytes, including assessment of megakaryocyte numbers and maturity. Typically, one to several megakaryocytes are seen per 10× objective field of view in health; greater than 10–20 per 10× objective field of view are considered increased, and only finding a few after examination of multiple particles suggests decreased numbers.[21] Maturation of the erythroid series should be orderly, with approximately 5% of the erythroid series consisting of rubriblasts and prorubricytes and 95% of the series consisting of rubricytes and metarubricytes.[21] Maturation of the granulocytic series should be orderly, with approximately 85% of the granulocytes being metamyelocytes, bands or segmented cells and 15% being myeloblasts and progranulocytes.[21] The M:E ratio varies from 0.5 to 2.4. This large range limits the use of M:E as an indicator of accelerated erythropoiesis. Other cells present in health are small lymphocytes (2–9%), plasma cells (<2%), monocytes/macrophages (<1%), mitotic figures (<4%) and rarely osteoclasts or osteoblasts.[21] Stainable bone marrow iron should easily be found in health and the amount increases with age in horses.

Evaluating accelerated erythropoiesis in horses can be difficult to assess because polychromatophils are rarely present in peripheral blood films and reticulocytes are not detected by most hematology analyzers. Finding more than 5% reticulocytes in the bone marrow (demonstrated by methylene blue staining) supports a regenerative response. In intense regenerative responses, bone marrow reticulocyte percentages can go as high as 60%. Caution should be used because blood-contaminated bone marrow will have a falsely low marrow reticulocyte count.

Acronyms and Abbreviations

BLV, bovine leukemia virus; CBC, complete blood count; 2,3 DPG, 2,3 diphosphoglycerate; GPX, glutathione peroxidase; HgbA, adult hemoglobin; HgbE, embryonal hemoglobin; HgbF, fetal hemoglobin; Hgb, hemoglobin; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; MetHgb, methemoglobin; M:E ratio, myeloid to erythroid ratio; OxHgb, oxyhemoglobin; PC, phosphatidylcholine; RBC, red blood cell; RDW, red cell distribution width; MPV, mean platelet volume; SM, sphingomyelin; WBC, white blood cell.

ERYTHROCYTES

Erythrocyte Morphology

The mature red blood cell (RBC) of the adult bovine is biconcave in shape, has a width of 5–6 µm, has minimal central pallor and a relatively long lifespan of approximately 130 days.[37] Anisocytosis is mild to moderate in ruminants. Red blood cell shape is relatively uniform, but poikilocytosis is not unusual in blood smears from apparently healthy calves. This may reflect a unique hemoglobin molecule, its association with the RBC membrane, or inadequate iron stores.[33] Rouleaux formation of bovine RBCs is unusual unless inflammatory proteins are increased.

Polychromatophils are generally absent from the blood of normal adult cattle. However, when severe anemia occurs, reticulocytosis appears in peripheral blood in association with macrocytosis, polychromasia, and basophilic stippling of RBCs, indicating accelerated erythropoiesis. Basophilic stippling is not uncommon during accelerated erythropoiesis in ruminants and should be interpreted as evidence of a regenerative response.

Erythrocyte Membrane

The bovine RBC membrane (and that of other ruminants) is unique with respect to phospholipid composition in the external hemilayer. Instead of a predominance of phosphatidylcholine (PC), sphingomyelin (SM) is present in higher concentration.[10] This is thought to be due the presence of anti-PC antibodies, formed due to evolutionary pressure of coexisting rumenal ciliates whose membranes contain a similar analogue.[13] This variation may have an impact on the relatively low occurrence of rouleaux formation in this species.[35]

Hemoglobin

Ruminant hemoglobins are of particular interest because of the large amount of polymorphism that occurs between species, breeds, and even within the individual as it develops from embryo to adult.[21] This polymorphism is greatest in the β chain. As in many other species, ruminants have two hemoglobin types. The embryonal type (HgbE) maintains a dam to in utero O_2 gradient, and the adult type (HgbA) for the ex utero environment. Transition from HgbE to HgbA begins in

utero and may not be complete until months after birth. Like humans, domestic ruminants have a third type of hemoglobin, fetal hemoglobin (HgbF), which replaces HgbE in utero. As gestation progresses to the perinatal period, bovine HgbF is gradually replaced by HgbA. As prenatal RBCs live out their lifespan, HgbF-containing cells give way to HgbA-containing RBCs.

Bovine hemoglobin is a rich source of antimicrobial peptides.[30] A peptide isolated by Daoud et al. has antibacterial activity against several organisms including *Escherichia coli* and *Salmonella enteritidis*.[8] Another group isolated four distinct peptides with similar activity, three which corresponded to the bovine α chain and one to the β chain.[31] Bovine hemoglobin has also been used extensively as an oxygen-carrying substitute in humans and in small animals.[5,14]

Erythrocyte Metabolism

The metabolism of domestic animals' erythrocytes was reviewed recently by Harvey.[17] Glucose consumption by bovine RBCs is approximately 0.6 µmol/h/mL RBCs. Most cattle have moderate to high Na^+ and low K^+ RBCs. Some cattle with specific autosomal recessive phenotypes have high intra-erythrocytic K^+ associated with certain blood groups.[17]

The ferrous iron of oxyhemoglobin (OxHgb) is constantly being oxidized to the ferric iron of methemoglobin (MetHgb) by intracellular metabolic products.[9] Erythrocytes normally contain a low concentration of MetHgb that is cyclicly reduced back to OxHgb by the intra-erythrocytic antioxidant enzyme, NADH methemoglobin reductase. When the quantity of MetHgb reaches a certain point, polymerization occurs and the precipitated Heinz body becomes associated with the cell membrane. Accumulation of excessive Heinz bodies may cause both intravascular and extravascular hemolysis.

Erythrocytic 2,3 diphosphoglycerate (2,3 DPG) accumulation modifies the Hgb of some species, but not cattle. Ruminant feti and neonates have greater amounts of erythrocytic 2,3 DPG than adults. However, unlike many other species, 2,3 DPG is not bound as well to ruminant HgbF and HgbA.[15] Bovine HgbF has sufficient inherent oxygen affinity to maintain fetal Po_2.

The copper and zinc metalloenzyme superoxide dismutase was originally identified in cattle.[24] Although its value as an in vivo antioxidant is not entirely known, activity of this enzyme is increased in neonatal calves, presumably due to increased oxidative stress associated with parturition.[11]

Another erythrocyte metalloenzyme of clinical diagnostic significance is selenium-containing glutathione peroxidase (GPX). There is a direct correlation between selenium deficiency and enzyme activity.[18] Although erythrocytic GPX is directly related to white muscle disease, it is inconsistently accompanied by methemoglobinemia. Hemolytic anemia does not frequently occur with selenium deficiency in ruminants. Heinz bodies in selenium-deficient Florida cattle were resolved by selenium treatment.[17,23]

Differences in hemoglobin types and RBC metabolism of cattle do not appear to make the RBCs of this species any more susceptible to oxidation than those of other species. Cattle have intermediate amounts of the RBC pentose phosphate pathway's limiting enzyme activity, glucose phosphate dehydrogenase.[17] When plants containing large amounts of nitrates or fertilizer nitrates are eaten, microflora reduce the nitrate to nitrite, which when absorbed oxidizes OxHgb to MetHgb without Heinz body formation. Sulfoxide-containing kale and other *Brassica* sp. are converted by rumen microflora to an oxidant that, when absorbed, produces Heinz body hemolytic anemia. Methemoglobin with and without Heinz body formation and hemoglobinuria is associated with consumption of onions and rye grass as well as copper deficiency, toxicosis, and hypophosphatemia.[6,32]

Erythrocyte Development

During gestation and at birth, the hemoglobin types change and the erythron compartment increases. At birth about 60–90% of the neonatal calf's Hgb is HgbF and 9% of the RBCs are reticulocytes. Fetal calf RBCs are less fragile and larger than adult bovine RBCs. In early gestation, the bovine fetal RBCs have a mean corpuscular volume (MCV) of approximately 95 fL, but by birth it decreases to about 46 fL. From birth to about 8–12 weeks of age, the MCV continues to decrease to approximately 37 fL as HgbF-containing RBCs are replaced by RBCs containing HgbA. The MCV in cattle tends to decline until about 2 years of age.

Veal calves raised solely on a diet of milk or milk replacer have lower RBC values than conventionally raised calves as the result of milk's low iron content.[2] However, they do not have clinical signs of anemia.

LEUKOCYTES

Although the traditional leukogram is predominantly used to assess leukocytes, cell sorting by immune cell surface markers has improved specificity and sensitivity of cell counting.[29,34] Specific cell subset profiles, blood and organ distribution, and cytokines are the current subjects of clinical research and development, and may one day supplement or replace the conventional leukogram. Acute phase protein assessment is also frequently used as an additional indicator of inflammation.

Neutrophils

Cattle have a smaller granulocyte bone marrow reserve than many other species, as indicated by a myeloid to erythroid ratio of about 0.5–1.[3,19] This smaller granulocyte reserve is the reason for neutropenia during the early granulopoietic response to suppurative inflammatory disorders in cattle. Once granulopoiesis is accelerated, a regenerative left shift and neutrophilia develop.[19]

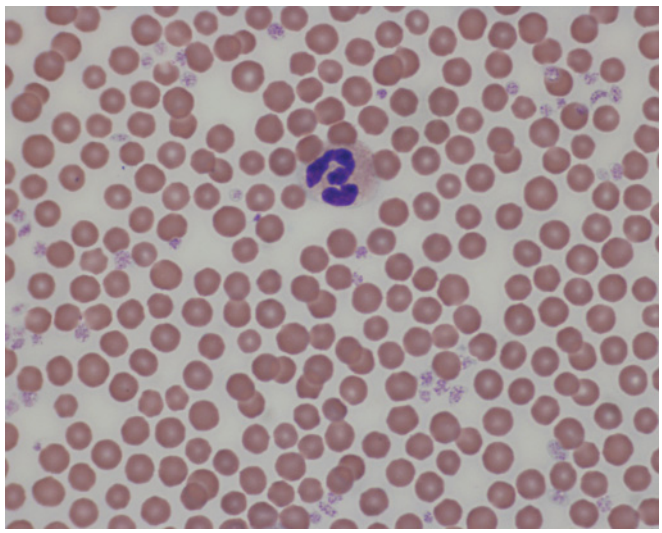

FIGURE 107.1 Segmented neutrophil. Wright's stain; magnification 1000×.

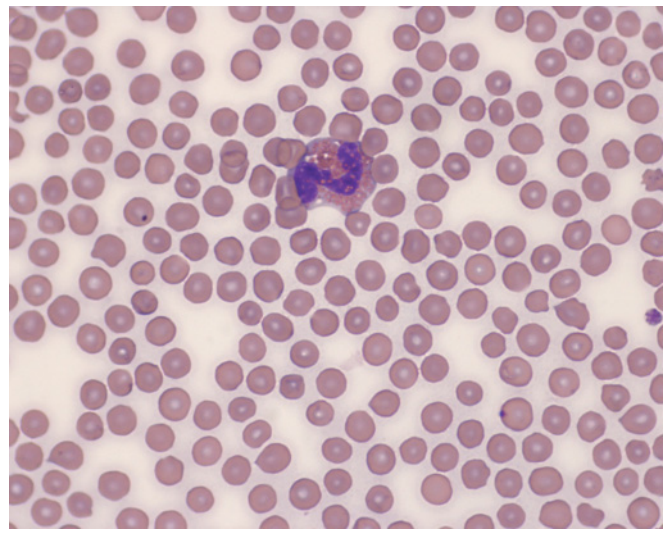

FIGURE 107.2 Bovine eosinophil. Wright's stain; magnification 1000×.

The neutrophils of cattle have three types of cytoplasmic granules. This third neutrophil granule is larger than the primary and secondary granules and occupies twice the cytoplasmic space as in sheep and other domestic species, giving the bovine neutrophil its eosinophilic cytoplasm (Fig. 107.1).[3] The bovine's large neutrophil granules have more antimicrobial activity than the cytoplasmic granules of nonruminant species.

Cytochemical and immunocytochemical staining reveals a range of enzymes and substrates in ruminant neutrophils.[1,17,19] Lysozyme, an enzyme common to many species, is not found in the neutrophils of cattle. Immunocytochemical cell membrane antigens serve to add to the specificity of neutrophil characterization[34] and proteomic studies assist in further characterizing the molecular profile of these cells.[22]

Eosinophils

The ruminant eosinophil has a band to bilobed nucleus which is surrounded by numerous, small, round, intensely stained, red cytoplasmic granules in basophilic cytoplasm (Fig. 107.2).

Parasite-free calves experience a doubling of eosinophil values from 6 months of age to adulthood. As in other animals, parasites and their larvae can produce eosinophilia. Seasonal parasite infestations can be reflected as seasonal eosinophilia. An example is the eosinophilia of subcutaneous migration of ox warble larvae in the spring that produces transient eosinophilia in cattle free of intestinal nematodes.

Basophils

The basophil of cattle is a rare cell about the same size as the eosinophil, with electron-dense, numerous, small, intensely blue-staining granules that sometimes can mask the nucleus (Fig. 107.3). Basophils occur at such low concentrations that they are not reliably quantified by the 100 differential cell method.

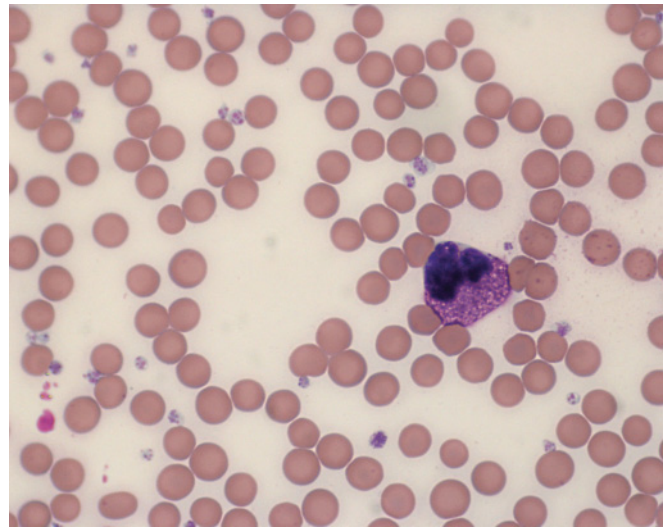

FIGURE 107.3 Bovine basophil. Wright's stain; magnification 1000×.

Lymphocytes

As in most species, the ruminant neonate has fewer lymphocytes than granulocytes. In a matter of weeks, the lymphocyte concentration doubles and by 3 months of age they compose 70–80% of the total WBC (Table 107.1). During adulthood, a slow progressive decline in lymphocyte concentration occurs. These age-related fluctuations in lymphocyte concentration exemplify the need for age-related reference intervals.

Bovine lymphocytes are 8–15 µm in diameter and are described in three sizes. Small lymphocytes have a round, centrally located nucleus with a densely staining

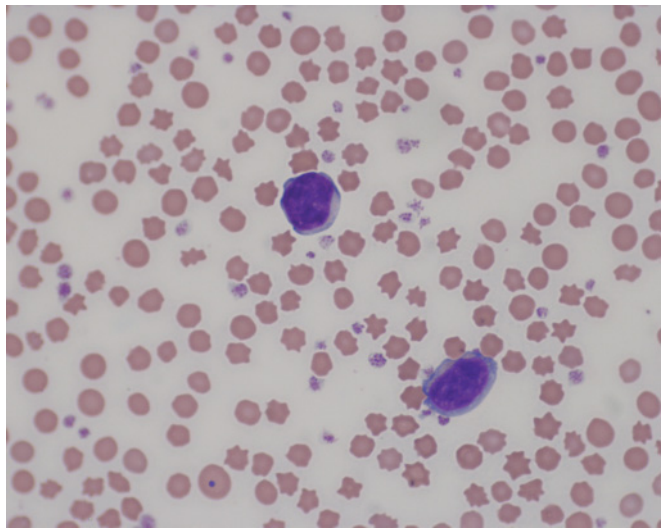

FIGURE 107.5 Small (top left) and medium (bottom right) lymphocytes. Wright's stain; magnification 1000×.

chromatin pattern in a small volume of clear to gray-blue cytoplasm (Fig. 107.4). The paucity of cytoplasm and density of the chromatin suggest that the small lymphocyte may be metabolically dormant or a less active cell than the other two forms of lymphocytes. In comparison to small lymphocytes, medium lymphocytes have larger, round to indented-shaped nuclei in which the same amount of chromatin is spread over a greater area, revealing lighter staining parachromatin adjoining areas of condensed chromatin (Fig. 107.5). The cytoplasmic volume of medium lymphocytes is also greater and encircles the central to eccentrically placed nucleus. Large lymphocytes have an even larger, lighter staining nucleus and more cytoplasm than the medium-sized lymphocyte. This large lymphocyte has a round or indented or deeply cleaved centrally placed nucleus. These lymphocytes are frequently confused with monocytes. Like monocytes, the cytoplasm of large lymphocytes stains blue to gray and sometimes contains small clear vacuoles. Variable shapes, sizes, and numbers of magenta cytoplasmic granules are frequently seen in a focal arrangement in the lymphocytes of cattle and may serve to identify the large bovine lymphocyte. Agranular large lymphocytes and monocytes are ultrastructurally inseparable, and cytochemical and immunocytochemical staining are needed to separate these two cell types. Chromatin centers, nucleolar rings, and nucleoli are seen with low frequency in Wright's-stained normal bovine lymphocytes, and caution must be taken in using these features as evidence of neoplasia for these species.

The subsets of ruminant leukocytes and their cytokines are active subjects of study. Cell sorting technology permits identification of subsets of lymphocytes beyond the T and B cells. Some subsets have a predilection for various anatomic sites, and disease states result in altered blood subset profiles.[3,7]

Monocytes

The bovine monocyte is a round to convoluted-shaped cell 13–19 µm in diameter. It has a large indented to bilobed to ameboid nucleus containing a diffuse chromatin pattern in a gray cytoplasm containing fine, small, indistinct, magenta to eosinophilic granules.

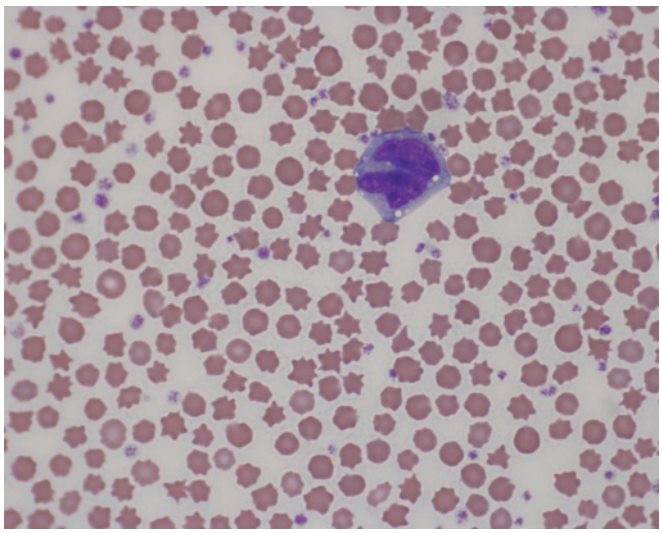

FIGURE 107.6 Bovine monocyte. Wright's stain; magnification 1000×.

Vacuoles are frequent and more irregular in shape than those seen in some large lymphocytes (Fig. 107.6).

PLATELETS

Bovine platelets in Wright's-stained peripheral blood are distributed singly or in aggregates, are generally round but can vary in size and shape, and often contain numerous prominent azurophilic granules. Cytoplasmic projections are rare. Normal circulating survival time is thought to be about 10 days. Enlarged platelet forms and pseudopodia are associated with accelerated production of platelets. The ultrastructure of the bovine platelets consists of extensive invaginations of surface membrane.[26]

GENERAL PHYSIOLOGIC AND ENVIRONMENTAL INFLUENCES

Physiological variables such as recent activity and stress have an impact on hematology values in cattle. Despite the range and sensitivity of technology used, cattle hematology reference intervals are uniformly broad (Table 107.2). Domesticated cattle may have little or no direct physical contact with humans; therefore, when sampling occurs, the animals must be physically restrained and become excited. Reports of reference intervals seldom include consideration of such variables as age, sex, physiologic state, history, form of restraint, ambient temperature, hydration status, BLV status or parasite burdens. It was recently reported that over the past few decades neutrophil counts have increased and lymphocyte counts have decreased compared with those provided in the 1965 edition of *Schalm's Veterinary Hematology*.[12]

Numerous reference values for domestic cattle have been reported and reveal few breed differences. Breed differences have been reported for beef cattle, which have higher RBC values compared to dairy cattle breeds.

TABLE 107.2 Hematology Reference Intervals for the Advia 120 from 99 Clinically Healthy Cows, 50% in First Lactation, All Milking 30–150 Days, from 10 Ontario Farms[a]

Parameter	Reference Interval	Units
Plasma protein	6.0–8.0	g/dL
Hemoglobin	8.4–12.0	g/dL

Basophils	0.0–0.2	$\times 10^3/\mu L$

[a]Reference intervals for the Animal Health Laboratory, Laboratory Services Division, University of Guelph, Guelph, Ontario, Canada and were derived from the central 95% of data using parametric or nonparametric statistics using Analyse-It Software. Differential leukocyte counts based on manual counting of 100 cells.

Care must be taken to use reference intervals that include similar environmental conditions and seasons as well as physiologic variables observed in the experimental population. Lactating cows have consistently lower white blood cell (WBC), RBC, and plasma protein values than do non-lactating cows.[19] Some reports fail to recognize lactation as a physiologic process and use as their point of reference the general bovine population, including bulls, steers, calves, and non-lactating cows. Bulls have appreciably greater RBC counts than cows.[28]

Seasonal and environmental changes may influence hematology values. In all species, differing oxygen tensions of altitudes alter the erythron. The greater the altitude, the lower the O_2 tension and the higher the erythron reference intervals. Some western American beef cattle experience two 5,000 ft (1524 m) elevation changes each year that result in a packed cell volume (PCV) change of 10–15%. In the spring they are moved from low winter pastures to high spring and summer pastures and then back down again in the autumn. Seasonal parasite burdens may also alter the complete blood count (CBC).

Aging results in WBC changes (Table 107.1). In the first few weeks of life, neutrophils are the predominant WBCs in calves. By about 2 weeks of age, the lymphocyte becomes the dominant WBC, with a neutrophil:lymphocyte ratio of 0.5 in calves.[4,27] As bovine adults age, the concentration of neutrophils and lymphocytes decreases but lymphocytes continue to be the predominant cell type.

Pregnancy causes minor changes in RBC and WBC concentrations. At birth, endogenous corticosteroids and the response of excitement and stress result in neutrophilia and lymphopenia.[19,29] The magnitude of steroid-induced neutrophilia is not as great in cattle as is reported in dogs, cats, and horses.[36]

BONE MARROW

Extensive studies of the bovine bone marrow in embryos, calves, and adults have been reported. The preferred sites for bone marrow collection in cattle are the sternum and the dorsal ends of the ribs (see Chapter 132). The single most remarkable feature of bovine bone marrow is the low myeloid:erythroid (M:E) ratio of 0.5–0.6 compared with other species. Harvey reports a ratio as low as 0.31.[16] A similar M:E ratio is reported in goats, but in sheep the ratio is about 1. The low bovine bone marrow M:E correlates with the low neutrophil concentration in peripheral blood and the rapid rate at which neutrophils are depleted during inflammation.

PLASMA PROTEINS

The color of bovine plasma ranges from colorless to dark yellow depending on the quantity of dietary plant chromogens being ingested. Summer green feed results in the deepest yellow, and winter dry fodder the lightest.

Precolostral neonatal ruminant plasma proteins are predominately albumin, hepatic origin alpha globulins, with very limited immunoglobulin. In the first day of life, dynamic changes occur in ruminant plasma proteins. Once colostrum is ingested immunoglobulins are quickly absorbed through the rapidly closing gut wall into plasma. Total body water increases, lowering the plasma albumin concentration, while colostral immunoglobulins, and enzymes (gamma glutamyl transferase and alkaline phosphatase) increase to a maximum by 48 hours. Total serum protein concentration in precolostral calves increases from about 4 g/dL to as much as 7 g/dL. There is an empirical direct relationship between the amount of total plasma protein in the postcolostral calf and frequency of neonatal diseases.[38] This relationship is so well established in the veal calf industry that veal calf buyers will frequently only accept calves with greater than 5 g/dL of plasma protein.

Plasma fibrinogen and haptoglobin are acute phase hepatic proteins. Fibrinogen has been used as an indicator of inflammatory disorders in cattle for some time, and haptoglobin has been used more recently. Both increase within the first day after onset of inflammation and remain elevated as long as the inflammation is present. As a rule, the greater the magnitude of increase, the greater the magnitude of inflammation. Some individuals regard hyperfibrinogenemia to be as good as or better than the neutrophil count as an indicator of inflammation.

Plasma fibrinogen is low (160 ± 130 mg/dL) to undetectable in neonatal calves. By 3–16 weeks of life it rises to adult values of 300–700 mg/dL.[19] Despite the low baseline value, inflammation can still result in hyperfibrinogenemia of the magnitude seen in adult cattle with inflammatory diseases. Dehydration increases plasma protein concentration, including fibrinogen. Compensation for dehydration in adult cattle can be determined by a ratio of plasma protein to fibrinogen. A ratio of less than 10:1, and more precisely 8:1, is indicative of an absolute increase in fibrinogen. A problem with using the ratio is that hypergammaglobulinemia from chronic inflammation may distort the ratio.

The efficacy of haptoglobin as an indicator of inflammation has been established,[20,25] but because of greater ease in measurement and reported clinical use, fibrinogen is a more established diagnostic procedure.

Acronyms and Abbreviations

2,3-DPG, 2,3-diphosphoglycerate; EDTA, ethylenediaminetetraacetic acid; EPO, erythropoietin; Hgb, hemoglobin; HgbA, hemoglobin A; HgbC, hemoglobin C; M:E ratio, myeloid:erythroid ratio; PCV, packed cell volume; RBC, red blood cell; seg, segmented neutrophil; WBC, white blood cell.

Domestic and wild sheep and goats are readily excited by the restraint needed for blood sampling. Consequently, in spite of the accuracy of laboratory methods used, the published reference intervals for sheep and goats vary widely (Tables 108.1, 108.2, 108.3 and 108.4).[2,3,7,15,21–23,34,35]

ERYTHROCYTES

Mammalian erythropoietin (EPO) is genetically well conserved. The efficacious parental use of commercial EPO and the ovine EPO assay has been established.[14,37,41]

Morphology

Ovine red blood cells (RBCs) are some of the smallest of mammalian RBCs and do not aggregate or deform as readily as RBCs of other species.[3,25,29,35,36,39] With the exception of the Angora breed, the RBCs of most sheep breeds are discoid in shape. Angora goats frequently have fusiform-shaped RBCs mixed in with discoid RBCs (Fig. 108.1).[16]

As in other species, accelerated erythropoiesis in sheep and goats is accompanied by reticulocytosis, macrocytosis, polychromasia, and basophilic stippling of reticulocytes.[17] Stippling is best demonstrated with freshly prepared, EDTA-preserved, rapidly air dried, Wright's or Giemsa stained RBCs.

Hemoglobins

In addition to increasing the circulating mass of the erythron, adult sheep and goats have a second means of increasing their effective oxygen delivery to tissues at high elevations and in anemias. In response to hypoxia, newly formed RBCs revert to synthesis of hemoglobin C (HgbC) which is normally only produced in immediate postnatal life.[4,18,40]

Metabolism

The metabolism of domestic animal RBCs has been reviewed by Harvey.[11] The ovine RBC glucose consumption rate is 0.7 µmol/h/mL of RBCs in contrast to the caprine RBC consumption rate of 1.9 µmol/h/mL of RBCs.

Plasma in most species contains an appreciably greater Na^+ concentration than K^+ concentration.[11] This is in contrast to RBCs where an energy-dependent, membrane pump maintains a high intracellular K^+ concentration and low Na^+ concentration gradient. There is an exception associated with a small proportion of

goats and sheep having specific autosomal recessive blood group phenotypes, in which the RBCs contain a relatively high Na^+ and low K^+ gradient.[11]

Ruminant fetuses and neonates have greater amounts of RBC 2,3-diphosphoglycerate (2,3-DPG) than do adults. However, unlike some other species, it does not bind to HgbF or HgbA, and an increase in RBC 2,3-DPG does not modify their Hgb oxygen affinity.[11]

LEUKOCYTES

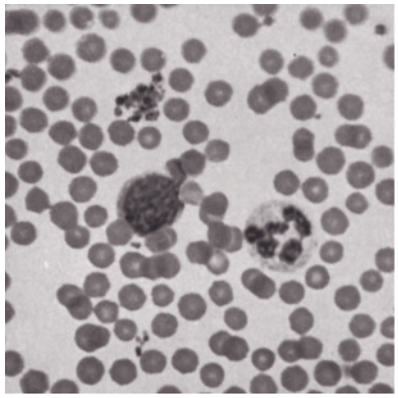
White blood cell (WBC) differential cell counts are useful for monitoring inflammatory states in sheep and goats and are also used in research performed with these species. The intermediate body size and disposition of sheep and goats permit relatively frequent and large blood sampling for research in hematopoiesis, oncology, and immunology.[6,9,26,30,31]

Ovine and caprine WBC differential cell counts change with age.[16,20,34] Neutrophils dominate the profile during the first 2 weeks of postnatal life. By 3 weeks of age, lymphocytes are dominant cells with a neutrophil : lymphocyte ratio of 0.5 in lambs and 0.6 in kids. In ewes and does, parturition is accompanied by minor changes in the RBC count and in WBC differential cell counts, such as neutrophilia and lymphopenia.

Neutrophils

When Wright's or Giemsa stains are used, the ovine neutrophil cytoplasm has an eosinophilic, granular texture. Neutrophils from sheep and goats contain primary, secondary, and tertiary granules. When compared to other species, tertiary granules are numerous, large and dense[1,5,12] (Figs. 108.2 and 108.3A; see Chapter 40).

Cytochemical and immunocytochemical staining reveal a range of enzymes and substrates in ruminant



Thrombocytes, lymphocyte, and neutrophil.

neutrophils (see Chapter 40). Lysozyme is an enzyme common to many species but absent from the cytoplasm of ovine and caprine neutrophils.[32]

Eosinophils

The nuclei of most ruminant eosinophils are band or bilobed and surrounded by numerous, intensely red-stained, small, round, refractile, cytoplasmic granules against the background of a sparse basophilic cytoplasm.[12] Within the ovine eosinophilic granules there are unique dense crystalline structures (Fig 108.2 and 108.3B).[1,12,16]

The ovine and caprine immunological response to seasonal parasitism is accompanied by eosinophilia.[8] This seasonal eosinophilia of parasitemia should not be

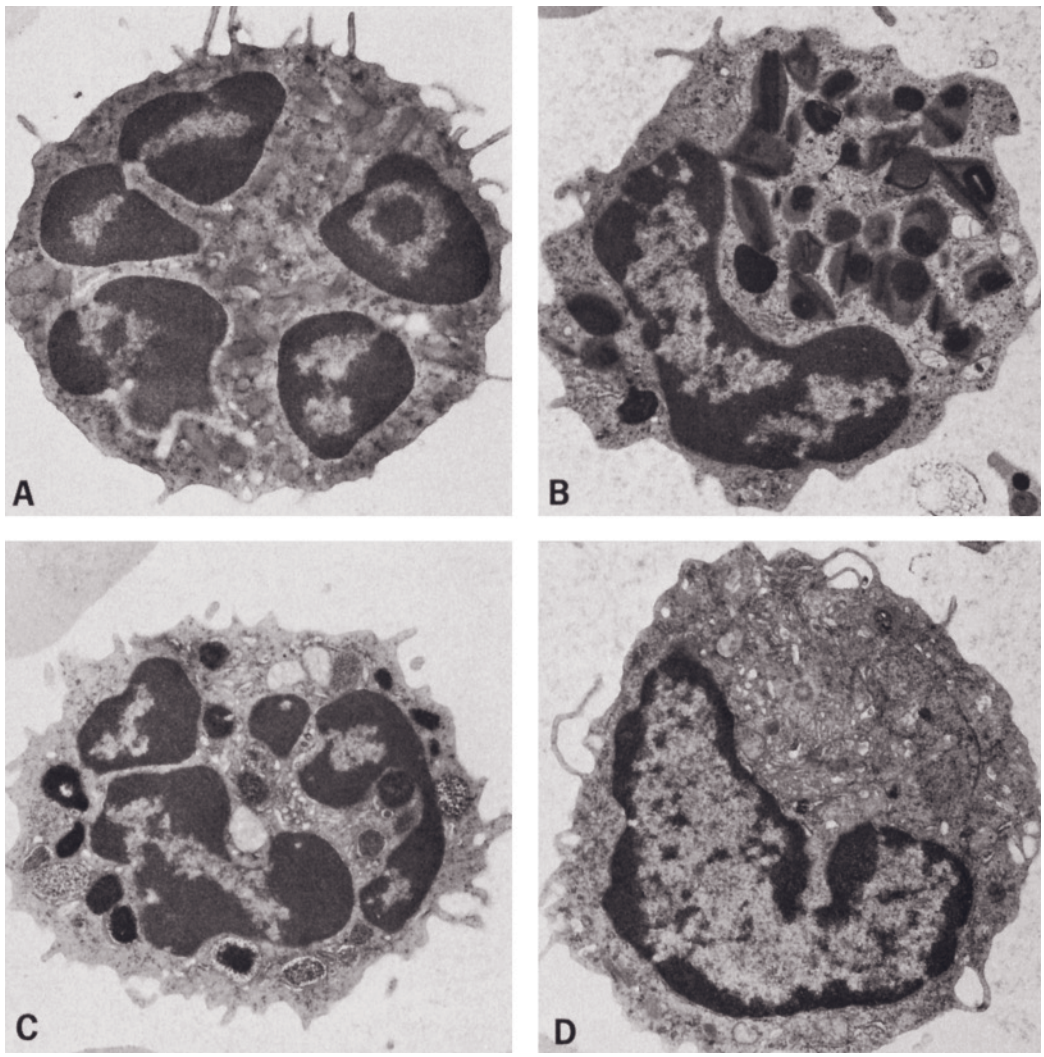

FIGURE 108.3 An ovine neutrophil (**A**), eosinophil (**B**), basophil (**C**), and monocyte (**D**). (**A**) The neutrophil has a multilobed nucleus and its cytoplasm is filled with large, electron-dense primary granules and smaller, less-dense specific granules. Few other organelles are seen. Magnification 14,000×. (**B**) The eosinophil is characterized by pleomorphic granules that contain crystalloid rods and membranous whorls. Cellular organelles are sparse. Magnification 12,000×. (**C**) The basophil contains a diverse population of cytoplasmic granules. Maturation of granules proceeds from lightly to densely stippled structures. Magnification 13,000×. (**D**) The cytoplasm of the monocyte has granules, vesicles, and abundant ribosomes. Rough endoplasmic reticulum, mitochrondria, and Golgi bodies are prominent Magnification 13,000×. (Courtesy of Dr. Kurt H. Albertine and Dr. Norman C. Staub.)

assumed to be "normal" resulting in inclusion in reference intervals. Investigators concerned with seasonal parasitism eosinophilia have observed it to be earlier and greater in some sheep in a flock. They hypothesize that the magnitude of the eosinophilia is a reflection of the familial immunological resistance to nematode infection.[30,31]

Basophils

Ovine and caprine basophils are infrequently seen in peripheral blood. When observed they contain numerous, small, electron-dense, intensely basophilic-staining cytoplasmic granules, that may completely mask the nucleus (Fig. 108.3C).[1,12] Basophils occur so infrequently in peripheral blood they are not reliably quantified. Marked basophilia is uncommon and may be associated with an eosinophilia.[16]

Lymphocytes

Ovine and caprine lymphocytes are small to medium in size and not readily confused with monocytes. They have a sparse blue to gray cytoplasm that frequently contains variably sized and shaped magenta granules of unknown significance (Fig. 108.2).[1,14,20,23,33]

Lambs and kids begin life with a greater proportion of granulocytes than lymphocytes. Within 3 months of age, lymphocytes represent 70–80% of the total WBC population. Within a few years, the lymphocytes begin

a slow relative decline in numbers.[13,16,20,23,27] These age-related changes exemplify the need for age-related reference intervals.

Monocytes

Ovine and caprine monocytes are round to convoluted-shaped WBCs with a diameter of 13–19 µm.[1,12,16] The nucleus is large, indented to bilobed, and contains a diffuse chromatin pattern. The cytoplasm is gray and contains small, indistinct, magenta to eosinophilic granules when stained with Wright's stain. Cytoplasmic vacuoles are common and more irregular in shape than those seen in some large lymphocytes (Figs. 108.2 and 108.3D).

PLATELETS

Wright's-stained blood platelets are distributed singly and in aggregates with azurophilic granules of variable size and shape (Fig. 108.2). Cytoplasmic projections are rare. Normal survival time in the blood is reported to be about 10 days. Giant platelet forms and pseudopodia are associated with recent proliferation from the parent megakaryocytes.[24]

BONE MARROW

Domestic goats and sheep occur in large commercial herds and flocks as well as in small groups and singles as personal companions. Bone marrow examinations are infrequent in commercial operations, where a clinical examination followed by a necropsy examination is typically more conclusive and cost effective. When concerned with individual animals or small numbers of clinical cases, such as a pet lamb or kid, bone marrow aspirates and biopsies may be desirable. Bone marrow aspirates and biopsies of wild and exotic sheep and goat populations may be informative but capture and restraint precipitate the risk of death.

Sites for obtaining caprine and ovine bone marrow aspirates and core biopsies are the iliac crest and ribs.[12,33] The single most remarkable difference between non-ruminant and ruminant marrow is the lower myeloid : erythroid (M : E) ratio of hematopoietic cells of the ruminant. Goats have an M : E of 0.5 : 1 to 0.6 : 1 and sheep have an M : E of 1 : 1 (Tables 108.1 and 108.2).[16,33] Cytologic evidence of accelerated erythropoiesis consists of a left shift of erythropoietic cells and macrophage activity (i.e. nucleophagocytosis, erythrophagocytosis, bilirubin, and iron pigments).[12,33]

Bone marrow of lambs and kids is predominantly hematopoietic tissue. As they mature, and if adequately fed, marrow fat becomes the dominant feature. As the seasonal availability of food decreases in winter, marrow fat is consumed. Should the poor nutritional state continue, marrow becomes gelatinous in appearance. At necropsy this gelatinous appearance is evidence of a starvation in both domestic and wild sheep and goats and can be confirmed by low plasma urea nitrogen values.

Acronyms and Abbreviations

EDTA, ethylenediaminetetraacetic acid; Hgb, hemoglobin; Hp, haptoglobin; MAP, major acute phase protein; RBC, red blood cell; WBC, white blood cell.

Routine hematologic tests are not frequently performed in pigs. The low intrinsic value of individual animals, difficulty in collecting blood, differing husbandry techniques, and wide range reported for many hematologic parameters reduce the utility of the complete blood count for swine. For more detailed information on porcine hematology and hematopoietic organs, reviews have been previously published.[22,33,55,60] An extensive collection of photographs of porcine blood and bone marrow cells has been published.[59] Ethylenediaminetetraacetic acid (EDTA) anticoagulant and a Romanowsky-type stain are preferred for optimal cytological evaluation. Because porcine red blood cells (RBCs) are relatively fragile, excess turbulence or improper handling of the sample frequently results in hemolysis. Routine hemogram values, except the differential cell count, are stable at 20°C or 4°C for up to 36 hours, whereas the white blood cell (WBC) differential cell count becomes less reliable within 12 hours after collection.[20] Automated counting of leukocyte subsets[75] and reticulocytes[24] has been reported.

Blood collection in pigs can be difficult due to poor accessibility of veins as well as variables associated with animal cooperation. Adequate blood volume can be obtained from the external jugular or anterior vena cava. Other sites include the ear (auricular) vein, tail vein, and subcutaneous abdominal vein, also known as the milk vein.[31] Intraosseous needle placement has also been reported.[28]

REFERENCE INTERVALS

Many reference intervals for porcine blood have been published.[8,18,23,59,60] Although most published intervals are comparable, the ranges for most elements of porcine blood are quite wide (Table 109.1). Variability may be due to sex, breed, growth rate, diet, age, stage of gestation or lactation, feeding method, management practices, or season.[8,14,78] Interpretation of porcine hematology data requires consideration of these factors.

ERYTHROCYTES

Porcine RBCs have an average diameter of 6.0 µm. Artifactual crenation is frequently encountered, and the cells tend to form rouleaux in health (Fig. 109.1). Central pallor is not visible in every cell. Anisocytosis is seen in adult pigs but is more prominent in younger pigs. Blood from young pigs contains many large polychromatic RBCs, nucleated RBCs and Howell-Jolly bodies.

The pig RBC is highly susceptible to hemolysis by hypotonic saline. Porcine RBCs have a bimodal pattern, with RBCs from adult and fetal pigs being more resistant to lysis than RBCs from weaned pigs. Osmotic resistance is temperature-, pH- and time-dependent,[49,50] but not influenced by sex or breed.[39] The sedimentation rate of pig RBCs is faster than that of other domestic animals[55,77] and is subject to daily fluctuations.[32]

TABLE 109.1 Reference intervals for the Domestic Pig[a]

Erythrocytic Series	Range	Average	Leukocytic Series	Range	Average
Erythrocytes ($\times 10^6/\mu L$)	5.0–8.0	6.5	Leukocytes ($/\mu L$)	11,000–22,000	16,000
Hemoglobin (g/dL)	10.0–16.0	13.0	Percentage distribution		
PCV (%)	32–50	42.0	Neutrophil (band)	0–4	1.0
MCV (fL)	50–68	60	Neutrophil (mature)	28–47	37.0
MCH (pg)	17.0–21	19.0	Lymphocyte	39–62	53.0
MCHC (%)	30.0–34.0	32.0	Monocyte	2–10	5.0
Reticulocytes (%)	0.0–1.0	0.4	Eosinophil	0.5–11	3.5
ESR (mm in 1 h)	Variable		Basophil	0–2	0.5
RBC diameter (μm)	4.0–8.0	6.0			
RBC lifespan (days)	86 ± 11.5		**Other Data**		
Resistance to hypotonic saline (%)			Thrombocytes ($\times 10^5/\mu L$)	5.2 ± 1.95	
Min.		0.70	Icterus index (units)	<5	
Max.		0.45	Plasma protein (g/dL)	6.0–8.0	
Myeloid:erythroid ratio	1.77 ± 0.52:1 (Lahey et al. 1952)		Fibrinogen (g/dL)	0.1–0.5

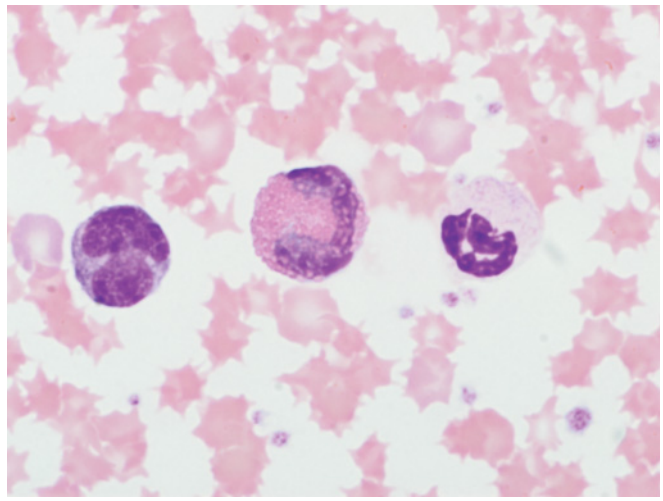

FIGURE 109.2 Monocyte (left), eosinophil (center), neutrophil (right) and platelets. (Courtesy of Dr. Charles Brockus.)

LEUKOCYTES

The mature neutrophil is 12–15 μm in diameter. It has an irregular nuclear membrane and moderately coarse chromatin with well defined lobes (Figs. 109.1 and 109.2). The cytoplasm stains pale pink or blue and contains a few pink granules. Band neutrophils have a U-shaped nucleus but are otherwise similar to the mature form (Fig. 109.3). Band cells may be present in healthy pigs. Metamyelocytes have less mature chromatin patterns, and nuclear shape may vary from kidney-bean-shaped to ring forms with no lobation. The cytoplasm is pale blue. Eosinophil nuclei are poorly segmented and may appear immature. The cytoplasmic granules are round to oval, stain a pale orange color and tend to fill the cytoplasm (Fig. 109.2). The basophil nucleus stains lavender and has a smooth chromatin pattern (Fig. 109.1). The cytoplasmic granules of the basophil are coccoid to dumbbell-shaped and stain similarly to or more intensely than the nucleus.

Small lymphocytes are 7–10 μm in diameter (Fig. 109.4), have a round to oval nucleus with a condensed chromatin pattern, and a small rim of pale blue cytoplasm. Large lymphocytes are 11–15 μm in diameter

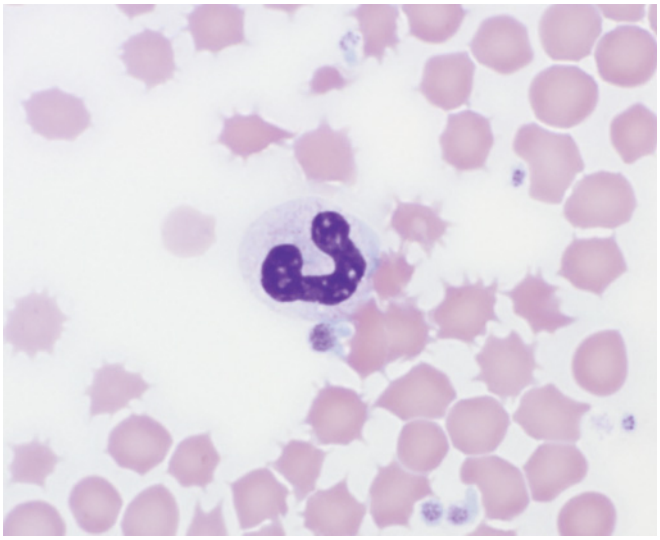

FIGURE 109.3 Band neutrophil. (Courtesy of Dr. Charles Brockus.)

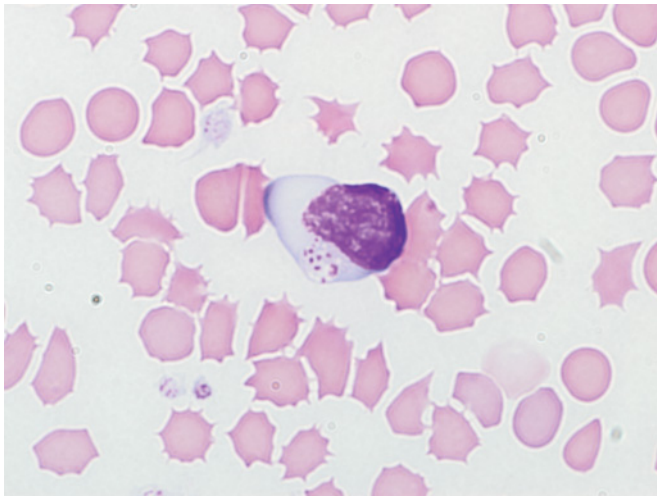

FIGURE 109.5 Granular lymphocyte. (Courtesy of Dr. Charles Brockus.)

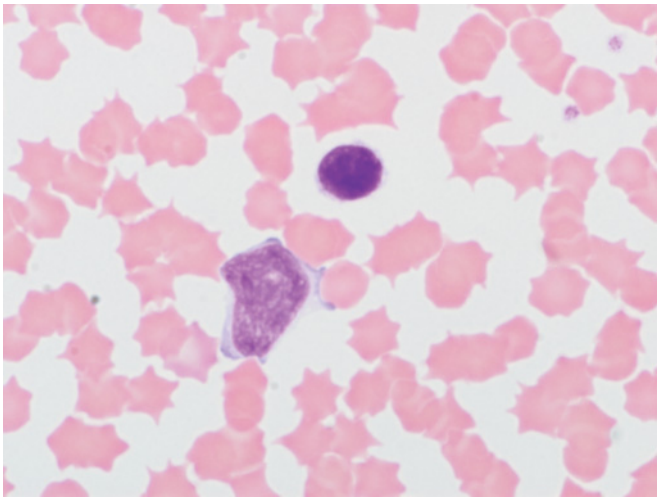

FIGURE 109.4 Large lymphocyte (bottom) and small lymphocyte (top). (Courtesy of Dr. Charles Brockus.)

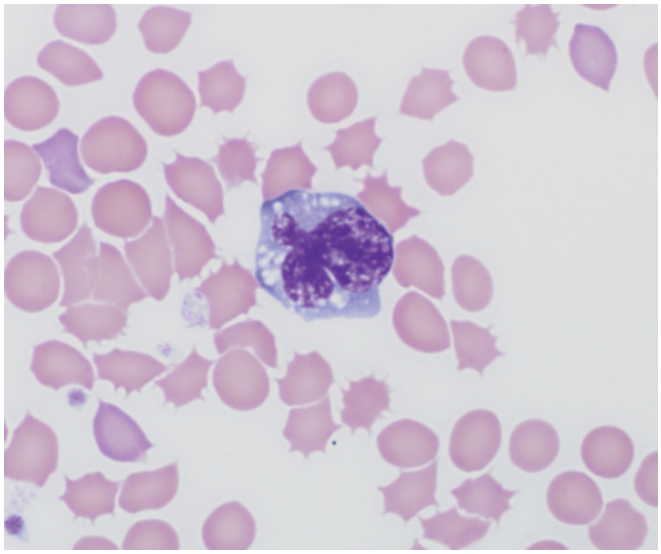

FIGURE 109.6 Monocyte. (Courtesy of Dr. Charles Brockus.)

(Figs. 109.1 and 109.4). The chromatin pattern is slightly coarse and does not stain as intensely as the small lymphocyte. The cytoplasm stains pale blue. Large lymphocytes may contain low numbers of round to oblong azurophilic granules usually located at the margin of the cell (Fig. 109.5). Many circulating lymphocytes are referred to as "null cells" based on lack of expression of cell surface antigens. Some T cells possess both CD4 and CD8 surface markers. The CD4:CD8 ratio is 0.6.[57]

Monocytes are 14–18 µm in diameter and have a convoluted nucleus with lacy chromatin and focal condensed areas (Fig. 109.6). The abundant blue-gray cytoplasm may contain granules or vacuoles. Some monocytes may be difficult to distinguish from a large lymphocyte or immature neutrophil.[32]

PLATELETS

Porcine platelets are morphologically similar to those of other domestic species (Figs. 109.1 and 109.2). They are variable in shape and are generally small (i.e. 1–3 µm in diameter) with a mean volume of 6.9–8.9 fL.[18] Platelets are anucleate and have deeply staining purple cytoplasmic granules. Platelets are frequently arranged in variably sized clumps.

BONE MARROW

Bone marrow samples are rarely evaluated in pigs. Myeloid to erythroid ratios of 1.77:1 to 2:1 have been reported.[33,59]

PLASMA PROTEINS

Plasma protein concentration in adult pigs is about 7.0–8.0 g/dL.[42] Fibrinogen concentration greater than 1.0 g/dL in adult pigs on an indication of inflammation.

The measurement of other serum acute phase proteins is increasingly being utilized for identification of acute inflammation as well as indicators of immunological stress and subclinical infection. Haptoglobin (Hp) and C-reactive protein have been identified as major acute phase proteins in the pig.[11,36] Major acute phase protein (MAP) has also been reported in pigs.[36] Measurement of serum Hp concentration aids in identifying subclinical infection with various respiratory agents[21,29,30] as well as providing a marker for production parameters such as growth rate[17], general hygiene[37] and injury.[53] Serum reference intervals for pigs from commercial farms have been reported for pig-MAP and Hp, and were found to vary with gender and age. Pig-MAP serum concentrations were lower in sows than in boars (mean values 0.81 vs. 1.23 mg/mL) while the opposite was found for Hp (1.47 vs. 0.94 mg/mL). Pig-MAP generally decreases with age while mean Hp concentration increases.[54]

COAGULATION

Coagulation of pig blood not collected into anticoagulant is rapid.[22] Coagulation parameters, tests for bleeding time and platelet function in pigs have been described but are seldom used.[1,4,32]

INFLUENCE OF AGE

Blood values for newborn and young piglets have been published.[13,33,48,59] Table 109.2 depicts the changes in the RBC and WBC parameters of piglets farrowed and kept on concrete for 10 days, then transferred outside to soil.

Many RBC changes take place after birth. Within a few days of age, RBC number and hemoglobin (Hgb) concentration drop 30–38% due to expansion of plasma volume.[43] Cell size increases soon after birth, decreases to its smallest size at 2–6 months of age, and then increases again to adult size. In suckling pigs, reticulocyte counts of 3–8% and nucleated RBC counts of 5% are common. These decrease as pigs mature. Polychromasia, Howell-Jolly bodies, crenation, rouleaux, and poikilocytes are frequently seen in the blood of young pigs. RBC counts and Hgb concentration increase to reach adult levels at about 5 months of age.

The WBC count is high at birth. Total WBC count decreases shortly after birth, then increases at about the fifth week of life. Actual cell numbers are quite variable. At birth, neutrophils represent about 65–70% of the leukocytes and lymphocytes account for about 20%. In the first week, neutrophils and lymphocytes are present in equal numbers; by 10 days of age, lymphocytes outnumber neutrophils. The ingestion of colostrum and age at weaning affect RBC and WBC numbers, and cell dynamics.[26,72] By 6 months, the neutrophil:lymphocyte ratio is about 1:2.

The proliferation of available monoclonal antibodies to pig T-cell and B-cells[2,58] has revealed the dynamics of pig peripheral blood lymphocytes throughout varying stages of growth. Proportions of T-cell and B-cell subsets have been monitored during the neonatal period[3] and in prefattening pigs.[68] Production performance as measured by average daily gain, carcass measurements, feed intake, feed conversion and the ability to predict growth, has been associated with the presence or absence of certain lymphoid phenotypes.[27]

Platelet numbers appear to be age dependent, but reported trends are inconsistent.[1,48] The concentration of plasma protein before and after the ingestion of colostrum is about 2.2 g/dL, and 5.5 g/dL respectively. Plasma proteins slowly increase during the first year of life to 7–8 g/dL.[42] In healthy pigs 2–3 months of age, plasma fibrinogen concentration ranges from 0.2 to 0.4 g/dL.

The rapid growth rate of young pigs places a large demand on iron requirements. Milk alone cannot meet this requirement. Unless a supplemental source of iron is provided, pigs develop a severe microcytic, normocytic to hypochromic anemia. Serum ferritin and total iron binding capacity become reduced.[63] Early contact with soil[35] or intramuscular injection of iron dextran is recommended.[22] Spontaneous recovery occurs about the fifth week of life when the pigs start to derive nutrients from other sources. The effect of low iron on WBC counts is variable;[25,66] however, iron deficient piglets have been shown to have decreased immunocompetence.[67]

INFLUENCE OF BREED AND SEX

There is no consistent significant influence of gender on hematologic parameters. Observed differences were not considered biologically important.[12,14,40,46] Breed differences in values have been reported.[12,19,34,78]

INFLUENCE OF PREGNANCY, PARTURITION, AND LACTATION

Hematologic changes occur with pregnancy, parturition, and lactation (Table 109.3). Approximately 2 weeks before parturition, RBC parameters in sows decrease and continue to do so until the end of lactation. Reticulocytes may be seen during this period. Total WBC number decreases during gestation, and anemia during pregnancy in sows has been documented.[9,44] Neutrophilia with a left shift and lymphopenia frequently occur at parturition. Within 24 hours of farrowing the neutrophil:lymphocyte ratio reverses.[45]

The influences of treatment with recombinant porcine somatotrophin,[64] growth hormone-releasing factor, and thyrotropin-releasing factor on sow blood during lactation have been reported.[9]

TABLE 109.2 Influence of Age and Husbandry on Hematologic Values of Young Duroc-Jersey Pigs. Values are Ranges and Means for a Single Litter of 5 Males and 4 Females. Pigs Were Kept on Concrete Until 10 Days of Age and Then Placed on Soil[a,b]

EFFECTS OF STRESS

In swine, sampling stress is the largest source of hematologic variation.[7] The stress response develops within 2 minutes, rapidly affecting the leukogram.[8] The total WBC and neutrophil count can increase by two- to three-fold, resulting in a stress leukogram with significant elevations also seen in Hgb concentration, hematocrit and RBC sedimentation rate.[15] Long- and short-term treatment with dexamethasone in weanling piglets causes a significant decrease in the percentage of peripheral blood CD8+ T cells.[38] The effect of sedation on hematological values is unpredictable; therefore, sedation is not recommended for blood collection.[18]

EFFECTS OF DISEASE

Hematologic changes associated with various inflammatory processes in swine have been examined.[46,62,73] Increased RBC sedimentation rates as well as decreased hematocrit and hemoglobin concentration have been reported.[18] Evaluation of a blood smear with a differen-

tial cell count may be a better indicator of an inflammatory process than total WBC counts.[22]

THE FETAL PIG

A number of studies have reported the hematologic characteristics of fetal pigs.[6,9,10,74] Nucleated RBCs are present in the fetal circulation at 30 days' gestation. Red blood cell number and Hgb concentration increase with age as nucleated RBCs decrease. Red blood cell size decreases during gestation.[9,74] Reticulocyte percent is maximal (6.5%) at mid gestation, but decreases to 1% by birth. Total WBC number increases throughout embryonic life consisting mostly of neutrophils. Serum protein concentration is 2–3 g/dL throughout gestation, with no sex or breed differences reported.

MINIATURE SWINE

Miniature pigs are an important animal model in biomedical research[51,71,76] and are also popular as pets.[5,61] Hematologic parameters of many breeds of miniature pigs have been characterized, with similar characteristics and cell morphology as larger domestic swine.[41,52,56,70] There was no effect on RBC or WBC parameters with

regard to sex,[47,52,56] but breed differences have been reported.[16] Age-related changes in miniature pigs are comparable to those in domestic swine.[16,47,52] Adult values are attained at about 9 months of age. Blood collection in these smaller pigs can be obtained easily and safely via the subcutaneous abdominal vein. Restraint is minimal and most of the pigs tolerate it well.[65]

Acronyms and Abbreviations

Hct, hematocrit; Hgb, hemoglobin; IL, interleukin; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; M:E, myeloid to erythroid; NHP, non-human primate; PCT, platelet crit; PCV, packed cell volume; PDW, platelet distribution width; RBC, red blood cell; RDW, red cell distribution width; WBC, white blood cell.

HEMATOLOGY OF LABORATORY RODENTS: MOUSE (*MUS MUSCULUS*) AND RAT (*RATTUS NORVEGICUS*)

ANNE PROVENCHER BOLLIGER and NANCY E. EVERDS

The use of the mouse and rats in biomedical research has contributed greatly to our understanding of mammalian hematology.[2,5,12,13,15] This chapter provides an overview of the applied biology and testing of red blood cells (RBCs), white blood cells (WBCs), platelets, and coagulation pathways in mice and rats, as well as an overview of the bone marrow composition.

Techniques

To ensure that correct values are obtained for hematology, appropriate quality control on sample collection

and handling is required. This is even more important for rodents, for which venipuncture of small vessels is more demanding. The blood volume collected from live rats can be sufficient for hematologic evaluation but in mice, it is typically collected as a terminal procedure. In the mouse, the range of mean circulating blood volume is 6.3–8.0 mL/100 g body weight, with a midpoint blood volume of 7.2 mL/100 g body weight.[11] The effect of daily blood collection of even small amounts of blood can be quite marked in the mouse. The blood volume in rats is between 5.0 and 7.1 mL/100 g of body weight.[25] In rats, approximately 5.5 mL/kg body weight of blood can be withdrawn safely during a single collection. Collection of up to 40% of blood volume over a period of 24 hours did not lead to increased mortality or morbidity and hematological values returned to control levels within 2 weeks. Younger rats have larger blood volume relative to their body weight than older rats. The choice of site of blood collection varies with experimental design and skill of the phlebotomist (Table 110.1). The sampling site and method must be kept consistent across experiments to avoid creating an unintended experimental variable. As with other species, RBC, WBC, and platelet counts in rodents are generally lower in central veins or in cardiac blood compared with more peripheral sites.[27] Sites of interim in vivo sampling in rats are the jugular vein, lateral tail vein, tail artery, and sublingual vein, and these procedures can be done with either manual restraint or with anesthesia. Retro-orbital sinus bleeds have also been utilized, but due to animal welfare concerns this technique is not used frequently for in-life sampling. Anesthesia is recommended if the retro-orbital sinus technique is used. In mice, limited amounts of blood can be obtained from the lateral tail vein or retro-orbital sinus.[6,34] A method of sublingual blood sampling in mice has been described.[16] Some facilities are able to obtain a larger volume from the jugular vein with manual restraint or anesthesia. Coating the needle and syringe with a solution of 7.5% EDTA before sampling may help to avoid clotting. Terminal samples are taken at the time of necropsy from the caudal vena cava, aorta, or via cardiac puncture[31] and due to the greater volume these samples are easier to use for hematological analysis.

Manual and automated methods can be used with murine or rat blood. Many laboratories conducting hematology tests in rodents use automated hematologic analyzers that have been successfully adapted for analysis of animal samples through the use of animal-specific software. The investigator should always ensure that the accuracy of the hematology instrument has been validated for counting of mouse and rat blood cells.

Preanalytical Considerations

As listed in Table 110.2, many preanalytical factors can affect experimental results and reference intervals in laboratory rodents (see Chapter 13). It is essential that all conditions be kept as similar as possible for control and treated groups of animals. For example, young mice and rats have more reticulocytes and lower RBC counts than slightly older animals. The stress of experimental or husbandry procedures (e.g. blood collection, transportation) may affect WBC counts. The following guidelines are suggested to minimize extraneous influences on hematology parameters and to ensure that experimental results can be interpreted accurately:[29] (1) determine that the laboratory's instrumentation is capable of counting rodent RBCs and platelets accurately; (2) minimize stressors such as dosing, transport, and noise prior to blood collection; (3) minimize blood volume collected when repeated collection is required so that previous blood collection will not complicate interpretation at later time-points; (4) collect blood the same way each at each sampling time (same feeding conditions, blood tubes, site of collection, anesthesia, etc); (5) collect blood using the proper blood/anticoagulant ratio; (6) collect and analyze blood either randomly or in replicate order (first animal in each treatment group, then second animal in each treatment group); (7) verify sample quality before analysis and do not use

results for animals with clotted samples, regardless of the size of the clot; (8) keep vials capped until analysis, because small samples evaporate rapidly; and (9) maintain consistent fasting/fed status across groups.[18]

Reference Intervals

Reference intervals are available in previous editions of this book[25,26] and are also provided in this chapter (Tables 110.3a–d). Extensive online reference intervals are also available.[40] Reference intervals should be used as a tool, but not as the sole guide to determine if values are normal or abnormal, or to determine whether or not hematologic changes are the result of an experimental procedure.

Erythrocytes

Erythrocyte Morphology

Mature mouse RBCs are round, anucleate, biconcave discs with central pallor, a mean diameter in adults of between 5 and 7 µm, and a cell thickness of 2.1–2.13 µm. Cell volumes vary from 40 to 50 fL. Rat RBCs

(Fig. 110.1) are also anucleated biconcave discs, with an average diameter of 6.2 µm (range 5.7–7 µm). Compared to non-rodent species, mice and rats have more polychromasia and anisocytosis due to higher concentrations of reticulocytes. Moderate anisocytosis of RBCs in rats is common and the diameter of some cells may be up to one-third of the average RBC size. Howell-Jolly bodies are sometimes observed in RBCs and occasionally nucleated RBCs are present in rats and mice.[13,25]

Erythrocyte Parameters

The RBC count, Hgb concentration, and Hct are generally lower in males than in females and vary with the strain of mouse and rat. Red blood cell counts of mice generally vary from $7 \times 10^6/\mu L$ to $11 \times 10^6/\mu L$. Hematocrits in mice generally vary from 35% to 52% and in rat from 37.6% to 51%.[19] Hemoglobin concentrations of mice generally vary from 10 to 17 g/dL and in rat from 11.6 to 16.1 g/dL.[19]

Hemoglobin (Hgb) concentrations and hematocrits (Hct) are lower and mean corpuscular volumes (MCV) are higher in rodent neonates. Red blood cells steadily increase from birth (3.7×10^6 RBCs/µL) to 2-3 months of age in mice (9.34×10^6 RBCs/µL) and in rats, RBC counts reach adult levels at approximately 4 months of age, with slightly lower counts in males than in females.[25] Hemoglobin declines during the early postnatal period (a phenomenon referred to as physiological anemia). Red blood cells of young mice and rats are morphologically variable and have more circulating reticulocytes than older animals. Reticulocyte counts in neonatal mice vary from 40% to 90%. In older rats, relative reticulocyte counts are generally 2–5%, while they can approximate 10–20% in young rats.[25] Hematocrits of aged rodents are generally lower than those of young adult animals. The lower Hcts are due to plasma volume expansion, rather than lower RBC mass.

The MCV of mice generally varies from 45 to 55 fL and in rat from 55.1 to 61.5 fL.[26] Mean corpuscular hemoglobin (MCH) is not a very useful parameter because it varies proportionally to MCV. Mean corpuscular hemoglobin concentration (MCHC), in conjunction with MCV and RBC distribution width (RDW), is very useful in evaluation of RBC changes in mice and rats. The MCHC in mice generally varies from 30 to 38 g/dL and in rat from 30 to 34 g/dL, depending on species, sex, and age.[25,26] The RDW indicates variation in RBC size (i.e. anisocytosis) and can only be determined with automated hematology analyzers. Values can be inconsistent among instruments, in part because instruments use different formulas for calculation of RDW.

Erythrocyte Lifespan and Reticulocytes

In mice, the estimated lifespan of RBCs is between 41 and 52 days,[12] while in rats it is between 56 and 69 days.[10] The reticulocyte response to increased demand for RBCs is rapid and robust in mice and rats. Reticulocytes can be counted on blood smears prepared with supravital stains or enumerated on newer automated hematology analyzers by flow cytometric methods (see Chapter 135). Absolute reticulocyte counts (automated methods) in non-anemic mice vary from 150,000 to 300,000/µL, while percentages of reticulocytes vary from 1% to 5%. In non-anemic adult Wistar rats, absolute reticulocyte counts vary between 154,000 and 271,000/µL while percentages vary from 1.88% to 3.27%.[21] Automated reticulocyte counts are a better indicator of erythropoiesis in rats than are reticulocyte percentages.[8] Some hematology analyzers are capable of subclassifying reticulocytes using size and staining characteristics to determine maturity (low, medium and high reticulocytes). Increases in the immature fraction are thought to have clinical relevance for indicating early erythropoiesis (A. Provencher Bollinger and N. Everds, unpublished observations).

Leukocytes

Evaluation of leukocytes in laboratory rodents includes quantification of total WBC count and of each type of WBC. Leukocyte concentrations in mice and rats demonstrate a diurnal variation. The most frequent WBC in the peripheral blood of the mouse and rat is the lymphocyte (approximately three-fourths of the cells) followed by the neutrophil. Generally, WBC counts of mice and rats vary from 2,000 to 10,000/µL. White blood cells vary with strain, sex, collection site, anesthesia, time of day, and procedures performed (Table 110.1). Consistent conditions for blood collection are important to minimize these variations. Reporting of WBC differential cell counts as percentages is of limited value[37–39] because they provide little information about the actual change that is occurring in the leukogram. Therefore, only absolute WBC counts should be interpreted and reported.

Neutrophils

In mice and rats, studies indicate that bone marrow may play an active role in removal of neutrophils from the circulation.[33] In rats, neutrophils preferentially home to bone marrow and macrophages are instrumental in regulating the neutrophil migration. Neutrophils account for between 20% and 30% (mice) and between 12% and 38% (rat) of the total WBC count, and neutrophil counts are higher in male mice than in female mice.

The normal rodent neutrophil has many indentations (many have 5–6 indentations making them look hypersegmented) and criteria used to classify hypersegmented neutrophils in other species should not be used in rats (Fig. 110.1).[3] Band forms are infrequently seen in rodents in health, but may be observed during inflammation. Occasional ring forms may be seen and these may increase during accelerated granulopoiesis. Unlike many other species, granulocytes of mice do not express alkaline phosphatase activity.[28] Mouse neutrophils have pale cytoplasm with faint pink granules. The nucleus is typically segmented and threads connect the nuclear segments. Nuclear chromatin consists of both pale and condensed DNA (N. Everds, unpublished observation). Rat neutrophils are approximately 11 µm in diameter and have pale cytoplasm with fine, diffuse granules. The nucleus is highly segmented, coiled, or ribbon-like, and has numerous indentations.

Eosinophils

Eosinophils represent 0% to 7% of blood WBCs in mice and 1% to 4% of WBCs in the rat. Mouse eosinophils have a band-shaped and occasionally ring-shaped nucleus that is partially obscured by the presence of ruddy orange to red granules. The granules are large, round, and fairly uniform in size, but have indistinct borders. Rat eosinophils have nuclei that are usually less segmented than neutrophils and contain small, round, reddish granules that fill the cytoplasm (Fig. 110.2). Occasional ring forms are present.

Basophils

Even though rodent basophils are quite distinctive, they are rarely observed on peripheral blood smears. In fact, an incorrect dogma has persisted in the literature and amongst biologists that mice or rats do not have basophils. In contrast to neutrophils or eosinophils, murine basophils lack tertiary granules, but have larger and less numerous mature granules. Basophils should be differentiated from mast cells that can occasionally be seen on blood smears, particularly when cardiac puncture is performed. Mouse and rat basophil nuclei are lobulated and the cytoplasm contains large round purple granules that may be few in number or so numerous that they obscure the nucleus (Fig. 110.3).

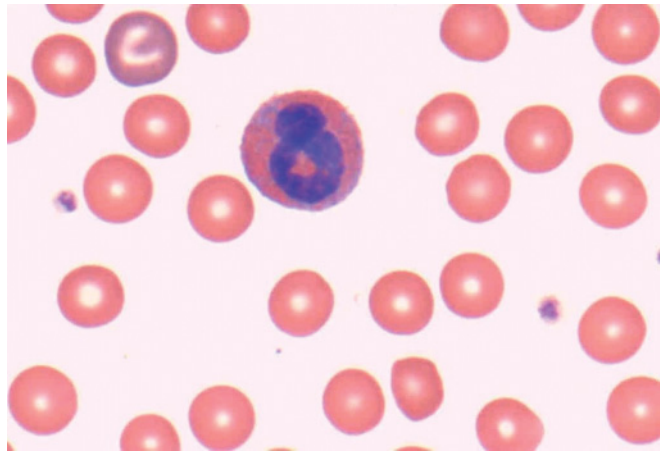

FIGURE 110.2 Blood smear from a healthy rat. Eosinophil. Modified Wright stain.

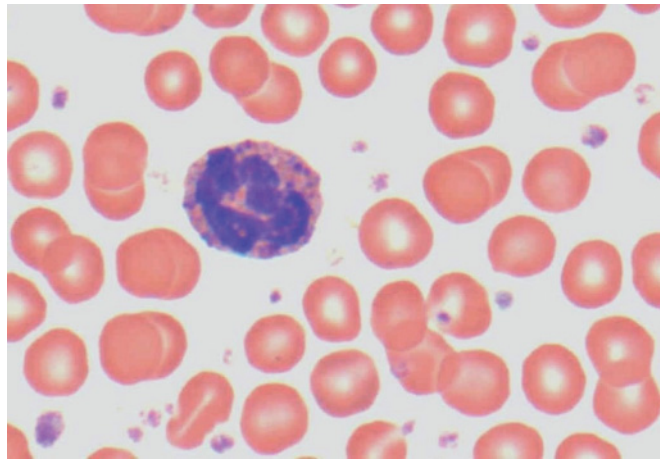

FIGURE 110.3 Blood smear from a healthy rat. Basophil. Modified Wright stain.

Monocytes

Monocytes comprise 0–2% (mice) and 1–6% (rat) of the total WBC count and are the largest leukocytes in both species. In mice, approximately 40% of blood monocytes are in the circulating pool and 60% are in the marginated pool. The blood half-life of murine monocytes is estimated to be between 24 hours[36] and 40–60 hours.[22]

Mouse and rat monocytes are similar to those of other species. Monocytes have pleomorphic nuclei that may be round, indented, or lobular (Fig. 110.4). The cytoplasm is extensive, stains pale gray blue, and often contains vacuoles. Occasionally acidophilic granules are present in the cytoplasm.[13]

Lymphocytes

Lymphocytes comprise 70–80% (mice) and 60–75% (rat) of the differential WBC count. They can represent more than 80% of the total leukocyte count in

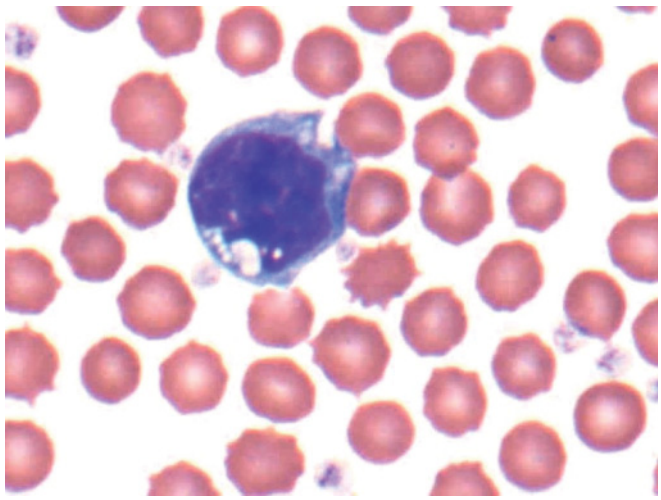

FIGURE 110.4 Blood smear from a healthy mouse. Monocyte. Modified Wright stain.

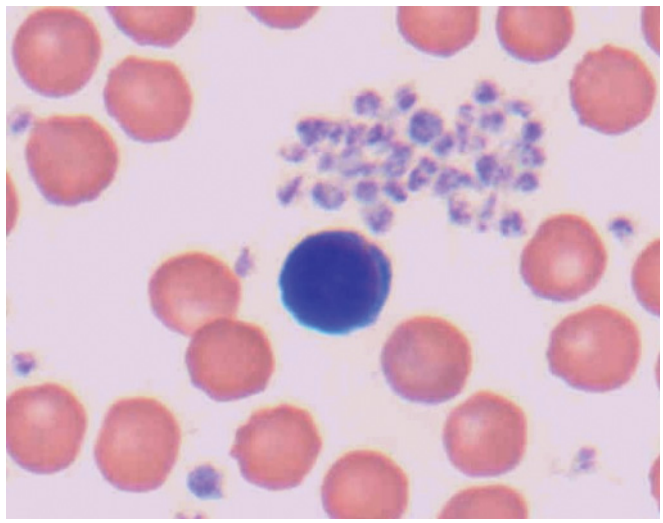

FIGURE 110.5 Blood smear from a healthy mouse. Lymphocyte and platelet aggregate. Modified Wright stain.

young mice. Age-dependent variation exists in the neutrophil:lymphocyte ratio, with the proportion of lymphocytes decreasing and proportion of neutrophils increasing as rodents age. In contrast to most other species, lymphocytes make up a significant portion of bone marrow cells in rodents.[3]

In mice, lymphocytes may be small or large. Small lymphocytes have scant cytoplasm and eccentric nuclei with smudgy chromatin (Figs. 110.1 and 110.5). Large lymphocytes have more extensive cytoplasm. Generally the chromatin is more stippled in large lymphocytes. Occasional clusters of bright pink to magenta granules are observed in lymphocyte cytoplasm. Rats also have small and large lymphocytes. Small lymphocytes have a diameter of about 6 µm with scant cytoplasm that can occasionally contain granules. Large lymphocytes have a diameter up to 15 µm with variable amount of cytoplasm, varying from deep to pale blue, sometimes containing large, dark staining, azurophilic granules.

Alterations in Leukocyte Numbers

Excitement and Stress In mice and rats, excitement increases both lymphocytes and neutrophils. Excitement is associated with release of endogenous catecholamines and results in leukocyte changes that occur within seconds or minutes, due to demargination of neutrophils increasing the circulating WBC count. Stress is a corticosteroid-mediated process, increasing circulating neutrophils, reducing circulating lymphocytes and reducing circulating eosinophils.[2,32]

Inflammation The inflammatory response in mice and rats, unlike that of other animals, is frequently associated with increased lymphocytes as well as increased neutrophils. In rodents, inflammation may be associated with a neutrophilia in the blood; however, unless the increase in neutrophils is substantial, circulating bands typically are not observed. With chronic inflammation, blood neutrophil counts increase due to increased production. The absolute increase in neutrophils in non-aged rodents is generally less than is seen in dogs or primates. In mice and rats, even small changes in neutrophil counts may be significant. In contrast, marked neutrophilia (up to 50,000/µL) may be observed in old mice with chronic inflammation.

Neoplasia Infrequently, hematopoietic neoplasms are associated with circulating neoplastic cells (i.e. leukemia). Peripheral blood smears of mice or rats with these neoplasms may have immature or abnormal leukocytes. In the case of lymphocytic leukemia, the neoplastic lymphocytes may be morphologically similar to normal peripheral blood lymphocytes, but the absolute lymphocyte count is variably increased. Hematopoietic and non-hematopoietic neoplasia may also result in decreased leukocyte counts, if the neoplastic population inhibits leukocyte production in bone marrow.

Stem Cell or Stromal Cell Damage Processes or substances that damage hematopoietic stem cells or bone marrow stromal cells may decrease leukocyte counts. Because neutrophils, eosinophils, and monocytes have the shortest half-lives, damage to stem cells or stromal cells is generally first recognized by decreases in these three leukocytes, followed by thrombocytopenia, and then anemia.

Decreased Egress from Blood (Leukocyte Adhesion Defects) Mutations or deficiencies that decrease the ability of leukocytes to egress from the vasculature result in greatly increased circulating WBC counts. Examples include deficiencies in P-selectin, E-selectin, interleukin (IL)-8 receptor, CD18, and/or ICAM-1.[4]

Platelets

Activation and aggregation of platelets are important steps in hemostasis (see Chapter 15). Mouse and rat platelets may be activated spontaneously or in response to stimuli (such as shear stress, adenosine diphosphate, thrombin, and collagen plus epinephrine). The platelet activation state may be strain-dependent. Platelets can be stained with nucleic acid dyes such as thiazole orange and counted using flow cytometry to determine the percentage of young platelets ("reticulated platelets") in blood (see Chapter 137). Conditions associated with a short platelet lifespan are usually associated with increased reticulated platelets (e.g. activation of platelets in circulation, immune-mediated destruction of platelets).

Mouse platelets have a diameter of 1–4 µm and have a lifespan of approximately 4–5 days (Figs. 110.1 and 110.5). On a blood smear, they are round to oval to elongated.[12] The margins of platelets are indistinct in Wright-Giemsa-stained smears. The cytoplasm stains faintly pink to gray and intensely blue angular granules are usually observed near the center of the cell. Red granules may also be present. Rat and mouse platelets have similar morphology. Round platelets as large as RBCs and platelet clumps are quite frequently observed.

Platelet counts in rodents are high compared with larger domestic species. Platelet counts in mice average $900 \times 10^3/\mu L$ to $1600 \times 10^3/\mu L$[12] and in rats, average between $430 \times 10^3/\mu L$ and $1450 \times 10^3/\mu L$.[25] Due to the small size of rodent platelets, some hematology analyzers are only capable of measuring larger rodent platelets and thus underestimate the platelet count. In addition, rodent platelets frequently become activated and clump in vitro, making platelet counts inaccurate.[20] Mean platelet volume varies between 4 and 6 fL; however, the variability in platelet size is greater than that of RBCs. Platelet size can also be subjectively assessed on the peripheral blood smear. The platelet crit (PCT), a measure of total platelet mass, is a parameter provided on some hematology analyzers. This parameter is analogous to the hematocrit, and is determined by multiplying the platelet count by the mean platelet volume. It has been proposed that PCT is more indicative of hemostatic capability than is the platelet count.[24] Platelet distribution width (PDW) is analogous to the RDW. Like RDW, PDW increases with variability in platelet size and is a measure of platelet anisocytosis.

Changes in platelet parameters

Increased platelet counts are generally due to increased platelet production. Accelerated platelet production is frequently associated with the presence of giant platelets in the blood. Platelet counts show modest increases during accelerated erythropoiesis, during some inflammatory diseases, and in iron deficiency. Decreased platelet numbers are a common hematologic finding in rodents. The most frequent cause is artifactual decreases secondary to blood collection difficulties. Mouse platelets readily aggregate and instrument-generated platelet counts will underestimate true platelet counts in the presence of platelet clumping. True thrombocytopenia is caused by decreased production and shortened half-life, usually due to activation and consumption.

Coagulation

Murine hemostatic factors have been reviewed.[4,17] The plasma protein factors involved in coagulation in mice and rats are similar to other species with some differences: prothrombin and factor IX activities of CAF1 mice are about half those of humans (see Chapter 15).[9]

Coagulation tests are commonly performed in rats, but less commonly conducted on mice, due to difficulty in sample collection (see Chapter 15). A few studies have determined reference values for coagulation times in mice. General reference intervals for bleeding time, prothrombin time, activated partial thromboplastin time, and fibrinogen are provided in Table 110.4. The anatomic site used for blood collection may influence results of coagulation tests. For example, in rats, prothrombin time and partial thromboplastin time are significantly increased and more variable in blood collected from the orbital venus plexus than in samples from the posterior vena cava. Other coagulation tests such as D-dimer, antithrombin, thrombin time, and specific factor assays may be useful when studying models of coagulopathy; however, published literature is limited.

Altered coagulation times in rodents and particularly in mice are most frequently caused by problems with sample collection, such as improper ratio of anticoagulant to blood, technical inexperience, or difficulty in collecting blood from animals with compromised health (see Chapter 15). When interpreting prolonged coagulation times, it is important to recognize that these tests are insensitive for detecting small changes

TABLE 110.4 General Hemostasis Parameters in Mice and Rats

Test	Mouse	Rat
In vivo		
Bleeding time (minutes)	<1[a]	2–5[b]
In vitro		
Prothrombin time (seconds)	7–19[a]	4–8[c,d]
		15–19[e]
Activated partial thromboplastin time (seconds)	16–110[a,f]	17–25[c,d]
		12–20[e]
Fibrinogen (mg/dL)	114–324[a]	150–230[c,d]

in coagulation factors. Therefore, small but consistent prolongations of coagulation times may indicate significant changes in coagulation factor concentrations and should be investigated for possible coagulation factor effects. Changes in coagulation times become significant when multiple animals in a treatment group are involved.

Bone Marrow Evaluation and Cytology

The overall examination of bone marrow smears in rats does not differ from bone marrow examination of other animal species. Evaluation should be made in light of available clinical information, physical signs, hematological data, and results of histological examination of hematopoietic organs. The accurate interpretation of bone marrow smears necessitates a systematic, stepwise approach. Indication for bone marrow collection in rodents, slide preparation and evaluation are described in Chapter 132.

Cytological evaluation of bone marrow has been described in rat and is similar in mice.[1,3,14,35] The ratio of myeloid to erythroid cells (M:E) in mouse bone marrow varies from 0.8:1 to 2.79:1 and averages 1.5:1.[14,23] These ratios are similar when determined by flow cytometry or by microscopy,[14] and are dependent on strain and age. Lymphocytes comprise one-fifth to one-third of bone marrow cells in mice and rats.[3,14,23] Megakaryocytes are about twice as numerous in murine bone marrow as in humans. In rodents, mature megakaryoctes are multinucleated and nuclei are frequently fused into a lobulated mass. A peculiarity in rats is the presence of megakaryocytes with mild pleomorphism, characterized by separated (i.e. non-fused) nuclei, with variable nuclear-to-cytoplasmic ratios.[3] Emperipolesis (passage of leukocytes through the cytoplasm of megakaryocytes) is occasionally observed in bone marrow from normal mice and rats. Megakaryocytes are not usually counted but assessed as present in sufficient or insufficient number, with adequate or inadequate maturation and normal or abnormal morphology. Maturation of the megakaryocytic series should be evaluated by assessing the number of mature versus immature forms and should be orderly, with lower numbers of immature forms than mature.

The erythroid cell line in rodents resembles those of other species (Fig. 110.6). The erythroid maturation sequence consists of rubriblasts, maturing into prorubricytes, then rubricytes that mature into basophilic rubricytes, polychromatophilic rubricytes and metarubricytes. After the metarubricyte stage, the nucleus is expelled and the cell matures into polychromatophilic RBCs (reticulocytes) then to mature RBCs. Reported percentages for erythroid precursors vary from 20% to almost 40% of all nucleated cells.[3] A low number of binucleated metarubricytes or metarubricytes with irregular nuclear shape may be observed in healthy rats.

Granulocyte precursors in rodents resemble those of other species but also have unique features, making identification sometimes challenging. Reported percentages of myeloid precursors vary from 33.6% to 52%.[3] The earliest stage that can be recognized by light microscopy is myeloblasts, progressing to promyelocytes, then myelocytes, metamyelocytes, band granulocytes, and mature cells. In rodents and non-rodent species, the nucleus of the myelocyte is usually round to slightly oval and, as maturation progresses, the indentation of the nucleus goes from round to horseshoe-shaped, to segmented. In mice and rats, precursors can take a "ring form" from the promyelocyte stage.[3] With cell maturation, the hole becomes larger and the nucleus thinner until a very thin rim of nuclear material is present in the band or non-segmented stage (Figs. 110.7 and 110.8). Ring forms can be seen in neutrophils and eosinophils, but not in basophil lines.

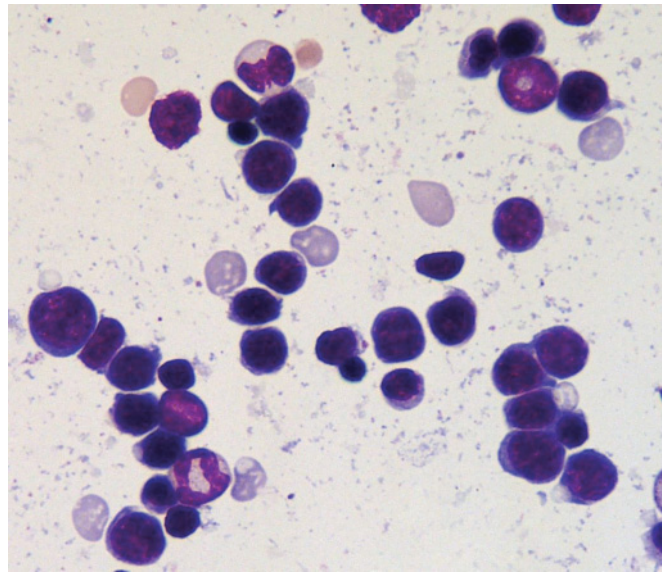

FIGURE 110.6 Erythroid precursors. (Bone marrow smear from healthy rat; May-Grünwald-Giemsa stain; 100× objective.)

Monocyte and macrophage precursors are present in low number in the bone marrow, unless there is a disease process making this cell line overrepresented. Monocyte precursors are difficult to differentiate from early granulocytic cells.

The percentage of lymphocytes in bone marrow of healthy mice and rats is quite variable, being reported to be between 7.34% and 21.1% of the total nucleated cell count.[3] Lymphocyte counts may vary with age, younger animals having more lymphocytes than adults.[30] Depending on the stain used, it can be challenging to clearly differentiate small mature lymphocytes from metarubricytes. Lymphoid precursors are present in low number and it can be difficult to differentiate precursors from other early myeloid precursors on Romanowsky-stained preparations. The use of flow cytometry in differentiating bone marrow cells can give a more accurate count of lymphoid cells than microscopic differential cell counting.[7,40] Plasma cells are present in low numbers, unless there is a proliferation due to a pathologic process.

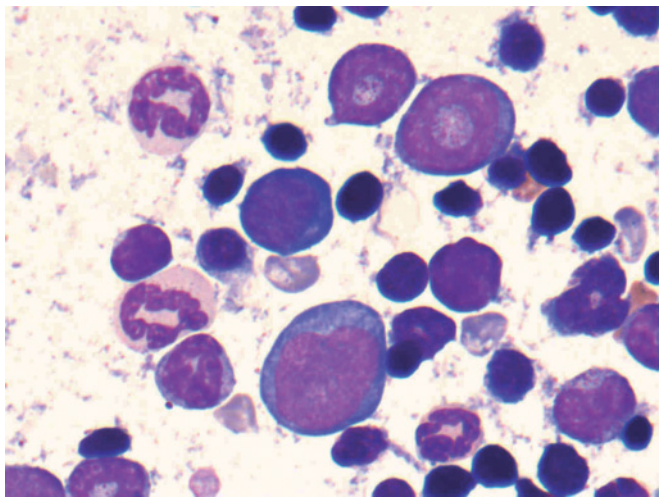

FIGURE 110.7 Granulocytic precursors; ring forms. Few small dark erythroid forms noted. (Bone marrow smear from healthy mouse; May-Grünwald-Giemsa stain; 100× objective.)

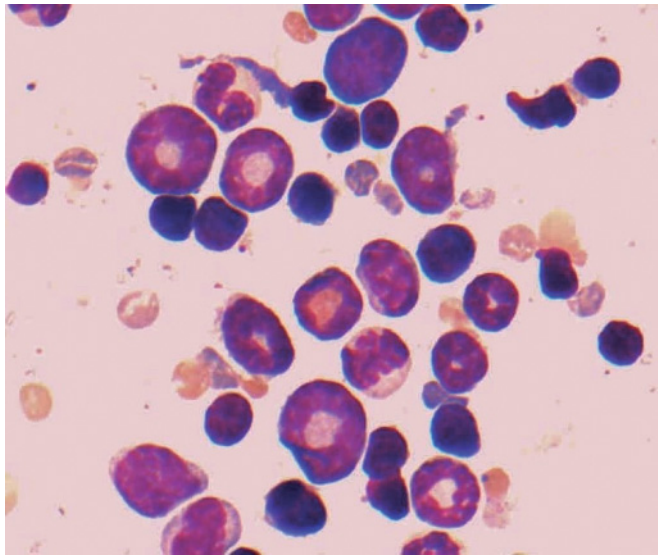

FIGURE 110.8 Granulocytic precursors; ring forms. Several small dark erythroid forms noted. (Bone marrow smear from healthy rat; May-Grünwald-Giemsa stain; 100× objective.)

Many other cells can be observed in bone marrow of rodents as in other species. These include mast cells, osteoblasts, osteoclasts, and endothelial cells. Mast cells can be present in very high number in rats, making cytological evaluation of smears difficult. Mast cells can degranulate and create a thick granular background. Mast cells are usually not counted in differential cell counts or M:E ratios. Osteoblasts and osteoclasts can be observed in low numbers and are not counted. These cells should not be confused with megakaryocytes. Endothelial cells can be seen when small capillaries are smeared on the preparation.

HEMATOLOGY OF LABORATORY RABBITS (*ORYCTOLAGUS CUNICULUS*)

KURT L. ZIMMERMAN, DAVID M. MOORE, and STEPHEN A. SMITH

Blood Collection

Blood is usually collected from the marginal ear vein of rabbits. The rabbit can be restrained in a commercial rabbit restrainer, a zippered cat bag (available at most veterinary clinics), or by securely wrapping the rabbit in a large towel.[24] The fur covering the marginal ear vein is plucked, which aids in visualization and dilation of the vessel. By warming the ear with a warm washcloth, warming it next to an incandescent light bulb, and/or stroking the central artery from the base to the tip of the ear, dilation of the vein will be enhanced. Pretreatment with the tranquilizer acetylpromazine (0.25 mL subcutaneously), will also result in dilation of peripheral veins including the marginal ear vein. A 23- to 25-gauge needle can be used when collecting blood. The vacuum from a Vacutainer tube frequently collapses the vessel, and attempting rapid withdrawal with a syringe may also collapse the vessel and prevent the free flow of blood. Alternatively, blood can be collected as it flows from the hub of a needle inserted in the marginal ear vein. A peristaltic pump or an Erlenmeyer flask to which a vacuum is applied using a vacuum pump, may facilitate blood collection from the marginal ear vein.[34] When using the flask, the fur over the vessel is plucked, the vessel is pricked with a sterile lancet, and the ear is inserted into the flask. A rubber stopper on the outlet port of the flask is inserted into an appropriately sized centrifugation tube for collection of nonsterile blood. Although the central artery of the ear can be used for blood collection by this technique, it should be used with caution, because formation of a hematoma is a potential sequela.

Other blood collection sites include the central artery of the ear, jugular vein, the lateral saphenous vein, and direct cardiac puncture (in an anesthetized animal).[6,24] An 18-gauge or larger hypodermic needle, between 1.5 and 2 inches (3.8–5.1 cm) in length, attached to tubing from a human blood collection set, can be inserted in the third left intercostal space, about 4 mm lateral to the sternum, until it penetrates the heart and blood is seen flowing into the tube. Cardiac blood collection is usually reserved for terminal exsanguination procedures, and should not be used for clinical patients because it can result in myocardial damage, hemothorax, pericardial tamponade, or death. The animal should be adequately anesthetized before cardiac blood collection is attempted. Generally, collection of blood from the jugular vein also requires sedation or light anesthesia (i.e. gas anesthesia administered with a nose cone).

The total blood volume in rabbits was estimated as 4.5–8.1% of total body weight, or approximately 53.8 ± 5.2 mL/kg.[24,27–29] However, Jain cautioned against introducing inaccuracies by expressing blood volume on the basis of actual body weight, and instead suggested that blood volume be correlated with lean body weight or body surface area.[13] The recommended maximum volume of blood that can be safely collected during one bleeding is 7.7 mL/kg of body weight.[29]

Morphology and Numbers of Blood Cells

Reported hematologic values for New Zealand white (NZW) rabbits (*Oryctolagus cuniculus*) are provided in Tables 110.5 and 110.6.[2,16,24,30] Hematologic values reported for some other breeds or species of rabbits are provided in Tables 110.7 and 110.8.[4,7,8,11,16,18,21,40] An excellent discussion of the sources of variation found in hematologic values was provided by McLaughlin and Fish and others.[24,25]

Erythrocytes

The rabbit RBC is a biconcave disc with an average diameter between 6.7 and 6.9 µm and an average thickness of 2.15–2.4 µm.[8,13,24,30] There is marked anisocytosis of the RBCs in rabbits, with microcytes of one-quarter the diameter of normal-sized RBCs sometimes seen. Schermer described the appearance of numerous thorn apple-shaped forms in blood smears as characteristic of rabbit blood, and observed that polychromasia was found in 1–2% of RBCs (Fig. 110.9).[33] Reticulocytes accounted for 1–7% of RBCs in adult animals and were determined to be 2 ± 0.5% in males and 3 ± 0.5% in females. One- to two-month-old New Zealand White rabbits were found to have reticulocyte counts of 7.4 ± 4.7%, with a 50% reduction in those counts occurring during the third month of life and a subsequent smaller decrease to 3.0 ± 1.3% in adult rabbits.[11] Reticulocyte counts were found to increase after

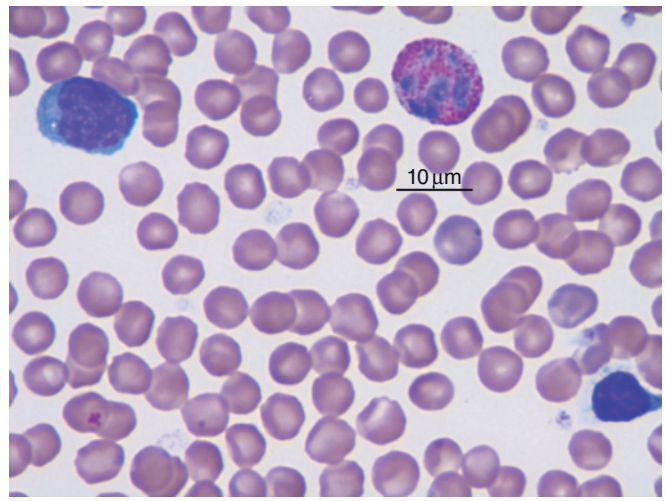

FIGURE 110.10 Erythrocytes with polychromasia, small and large lymphocyte, and heterophil from a New Zealand White rabbit. (Wright's stain; 100× objective.)

repeated blood collections, while gestation was associated with an initial increase then decline in reticulocyte count, Hct, and Hgb concentration.[38]

The lifespan of rabbit RBCs ranges between 45 and 70 days, with an average lifespan of 57 days with a predicted random destruction rate of 0.5% per day.[13,35] Red blood cell counts are low in newborn rabbits, returning to adult interval by 6 months of age, whereas the MCV and MCH values are higher than in adults.[2] Red blood cell count and Hgb concentration are slightly higher in male rabbits than in females (Table 110.5).

Platelets

Rabbit platelets appear as small clusters of azurophilic granules surrounded by pale blue cytoplasm.[24,30] Observed reference intervals of circulating platelets vary considerably. These vary from tight ranges such as 110,000–206,000/µL[16] to broad ranges like 200,000–1,000,000/µL.[7]

Leukocytes

The WBC count in rabbits may vary with diurnal fluctuations, nutritional variation, and differences in age, gender, and breed. Additionally, the differential WBC count in a healthy rabbit fluctuates considerably when evaluated over a single month.[29] Total WBC counts were lowest in newborn and juvenile rabbits, reaching adult levels after 6–12 months of age (Table 110.6). The neutrophil:lymphocyte ratio (expressed as percentage) at 2 months of age was found to be 33:60 and changed to 45:45 after 12 months of age.[13] However, in newborns the initial ratio was reversed at 58:31 and by 2 weeks had declined to approximately 31:59.

Rabbit neutrophils, referred to as heterophils, contain acidophilic granules. Some argue for the presence of both neutrophils and heterophils in rabbits.[23] The rabbit heterophil is approximately 10–15 µm in diameter. Its polymorphic nucleus stains light purple with a light blue nuclear membrane. The nucleus is surrounded by a diffusely pink cytoplasm, which contains small acidophilic specific granules and variable numbers of large red granules (Fig. 110.10). The nucleus of the rabbit lymphocyte is round, condensed, and surrounded by a narrow band of blue-staining cytoplasm, which may occasionally contain azurophilic granules (in larger lymphocytes).[30] Both small and large forms of lymphocytes may be observed. The rabbit monocyte is a large cell (15–18 µm in diameter) with an ameboid nuclear pattern (lobulated, horseshoe- or bean-shaped) and diffuse and lightly stained nuclear chromatin, with the nucleus surrounded by blue cytoplasm that may contain a few vacuoles (Fig. 110.11).[30] The rabbit eosinophil is larger than the heterophil (12–16 µm diameter) and has a nucleus that is bilobed or horseshoe-shaped. Its intensely acidophilic cytoplasmic granules are more numerous and are three to four times the size of heterophil granules. Basophils are found in rabbit blood in small to moderate numbers.[13] Basophil numbers are inversely proportional to the number of tissue mast cells.[13] The nucleus of the rabbit basophils stains light purple, and the cytoplasm is packed with purple to black metachromic granules (Fig. 110.1).[30]

Bone Marrow Evaluation and Cytology

Bone marrow samples may be obtained from an anesthetized rabbit from: (1) the wing of the ilium; (2) the proximal end of the femur; or (3) the proximal end of the humerus.[39] An 18-gauge Rosenthal pediatric biopsy needle can be used for bone marrow collection from the humerus and femur. The appearance of most cells and the maturation sequence in rabbit bone marrow is

similar to that in humans and other mammals.[25] Sanderson and Phillips have provided an excellent series of color photomicrographs of rabbit bone marrow.[32] The myeloid to erythroid (M:E) ratio of rabbit bone marrow is approximately 1:1.[3,32] The M:E ratio in rabbits from birth to 5 months of age was reported as follows: 0.72:1 at birth, 0.19:1 at 1 week, 1.09:1 at 4 weeks, 0.61:1 at 2 months, 0.81:1 at 3 months, 1.42:1 at 4 months, and 0.89:1 at 5 months.[3,31] Table 110.9 provides the differential cell counts of cells for bone marrow of healthy rabbits.

TABLE 110.10 Observed Coagulation Values in Rabbits

	(15.7–42.7)	26

Other Hematologic Values

Coagulation values for New Zealand White rabbits are provided in Table 110.10.[21,22,24,25,36] The RBC sedimentation rate for blood from rabbits was reported as follows: for male rabbits, 2.0 ± 0.5 mm/hr (range, 1–3 mm/hr); for female rabbits, 1.75 ± 0.4 mm/hr (range, 0.95–2.55 mm/hr) and 2–4 mm/hr.[28,31]

HEMATOLOGY OF LABORATORY PRIMATES

KIRSTIN BARNHART

Blood Collection

Blood from non-human primates (NHPs) may be collected from a number of venipuncture sites depending on the size of the animal, the method of restraint, and the sample volume required. The most common site for the collection of large volumes is the femoral vein. The cephalic, saphenous, coccygeal, and jugular veins also can be used. For small samples, a sterile lancet may be used to puncture the marginal ear vein, a finger, or a heel. The average circulating blood volume of rhesus macaques, cynomolgus macaques, and marmosets has been estimated at 56, 65, and 70 mL/kg, respectively. In general, 7.5–20% of the blood volume can be removed in a 24 hour period without causing significant disturbance to the animal's normal physiology. The approximate recovery period ranges from 1 to 3 weeks depending on the amount removed.[8]

Blood collection from NHPs frequently requires chemical restraint. The most commonly used anesthetic agent is ketamine hydrochloride,[30] but other agents such as Telazol®, isoflurane and sevoflurane are frequently used. A physiologic leukocytosis typically occurs when blood is collected from non-anesthetized and untrained macaques. This leukocytosis is generally characterized by a lymphocytosis, but a mature neutrophilia may also occur.

Ketamine anesthesia reportedly reduces lymphocytes and the MCV, but increases the RBC count, Hgb concentration and MCHC in macaques of both sexes.[30] Conversely, other studies concluded that ketamine reduced both WBC counts and RBC indices.[2] Sevoflurane may reduce WBC counts and RBC indices.[52] However, others reported no hematologic effects of anesthetic agents including ketamine, pentobarbital, isoflurane, propofol, or Telazol® (Table 110.11).[22]

The origin or strain of a particular NHP species can have significant effects on RBC and WBC indices. One of the most notable examples is the variation of hematologic parameters between cynomolgus monkeys that originate from Mauritius and those from South-East Asia. Specific differences include lower reticulocyte counts, higher RBC counts, decreased MCV, decreased MCH, and lower WBC counts in Mauritian monkeys.[9] These differences are probably due to the isolated geography and lower degree of genetic variability in monkeys of Mauritian origin. Platelet counts and coagulation parameters are similar in monkeys from both locations.

Reference Intervals

Reference intervals reported in the literature are provided in Tables 110.11–110.22 for species including rhesus macaque, cynomolgus macaque, marmoset, tamarin, baboon, owl monkey, squirrel monkey, African green monkey and chimpanzee. These values may provide general guidelines and information for interpreting NHP hematology; however, it must be emphasized that laboratory methodologies and animal care procedures have changed substantially over the past 20 years, and caution should be used in comparing results with those in the literature. In addition to analytical methodology, many pre-analytical variables exist that have the potential to affect the accuracy of reference intervals. These variables include number of animals, the subpopulation of NHP species utilized, age, apparent health status, seasonal variations, diurnal variations, diet, environment and type of restraint.[12] The statistical method selected to describe a reference interval can also significantly affect the results. A majority of studies report reference intervals as the mean ± one or two standard deviations. Depending on the number of animals utilized and the likelihood of Gaussian distribution, this may not be the most accurate method.

TABLE 110.11 Comparison of Erythrocyte and Leukocyte Parameters from Samples Obtained With and Without Anesthesia (Mean ± SD)

Reference	Year	Strain	Sex	Age	No.	Select Condition	RBC ($\times 10^6/\mu L$)

Erythrocytes

Red blood cells from NHPs are non-nucleated, biconcave discs with central pallor that are similar to those of other mammals. Some species, such as macaques, have a large area of central pallor that is reflected by lower MCHC values. A high degree of variability exists for RBC diameter and MCV due to the large number of species, many with marked phenotypic differences. Macaque RBC diameter ranges from 6.5 to 7.5 µm, and the range of RBC diameters across species varies between 3.5 and 8.5 µm.[47] Similar to humans, the circulating lifespan of macaque RBCs is approximately 100 days, and the normal reticulocyte counts are relatively low (0-80,000/µL). The Hgb concentration, RBC count, PCV, MCV and MCHC are high for neonatal baboons, similar to human infants. These values begin to decline after the first week of life.[3] Similarly, PCV, MCV and Hgb dropped significantly from 1–3 months after birth in healthy cynomologus infants.[55] These findings are transitional and considered normal physiologic responses. After sexual maturity, male cynomolgus monkeys, rhesus monkeys, baboons, chimpanzees and African green monkeys are frequently reported as having a higher MCV.[12,15,16,26,46,54] The MCV and MCH for rhesus monkeys are similar to those of humans, but cynomolgus monkeys have lower values.

Heinz bodies have been described frequently in blood smears from healthy marmosets and occasionally from healthy tamarins.[19,20] The clinical significance of these inclusions has been debated. The number of RBCs containing Heinz bodies ranged from 0% to 70%, and it is rare to find more than one inclusion per cell. Heinz bodies on marmoset RBCs do not adversely affect the properties of the membrane. Despite these findings, Heinz body hemolytic anemia has caused significant morbidity and mortality in marmoset colonies and has been linked to a frequently fatal disease termed Wasting Marmoset Syndrome.[19] To date, Wasting Marmoset Syndrome is considered a form of inflammatory bowel disease that may result from many causes.[53] Similar to felines, marmoset RBCs may be more susceptible to Heinz body formation during times of stress and disease. Vitamin E supplementation has been

reported to decrease the incidence of Heinz body anemia.

Low numbers of nucleated RBCs, typically 1–2 per 100 WBCs, are frequently seen in healthy New World monkeys (marmosets, tamarins, owl monkeys, squirrel monkeys) and probably reflect the relatively high RBC turnover rate of these species.[19,20,37] Slight to mild anisocytosis, polychromasia, and Howell-Jolly bodies are also commonly described for owl monkeys, squirrel monkeys, and tamarins.[7,19,20,37] Female tamarins typically have a lower PCV, Hgb, and RBC count and a higher reticulocyte count compared to males.[20,21] Poikilocytes and three types of reticulocytes are found frequently in healthy colony-born owl monkeys.[37] Low numbers of target cells (<10%) are commonly identified in blood smears from chimpanzees.

Stomatocytosis is a frequent finding in blood smears from normal squirrel and owl monkeys. The cause of the stomatocytosis is not known, and the number of stomatocytes in blood varies. A study performed on a colony of seven captive squirrel monkeys identified 9.4–89.2% stomatocytes (average 52%).[10] In addition, this study documented an association between increased numbers of stomatocytes and elevated Hcts that was probably caused by alterations in the normal packing characteristics of RBCs. Unlike many inherited and acquired forms of stomatocytosis in other species, squirrel monkey RBCs do not show increased osmotic fragility and shortened survival.

Old World monkeys and great apes have a true menstrual cycle, which can affect interpretation of RBC indices because a significant amount of blood may be lost during menstruation.[13] In addition, baboons and chimpanzees display marked turgescence and detumescence of the sex skin in association with the follicular and luteal phases of the menstrual cycle, respectively. During turgescence, plasma volume contracts, and as much as 2 liters of extracellular fluid can accumulate in the perineum. In early detumescence, this fluid is rapidly auto-infused into the plasma. These fluid shifts can affect RBC indices.[14,17] A study by Harewood et al. described a decrease in Hgb concentration, Hct, RBC count and WBC count, and an increased platelet count in the luteal phase as compared to the follicular phase.[17]

Although many prosimian NHPs are nocturnal, owl monkeys are the only nocturnal species of simian NHPs and the only nocturnal NHP species that is commonly used in research. Diurnal variation in both RBC and WBC parameters is due to circadian rhythms and alterations in hydration. These factors should be taken into consideration when sampling blood from owl monkeys.

Leukocytes

A recent report calculated the average diameter of WBCs from a group of macaques that consisted of four species (rhesus, cynomolgus, stump-tailed, and pig-tailed). Neutrophils and eosinophils measured 10.7–13.3 µm, lymphocytes measured 9.5–12.5 µm, monocytes measured 12.5–15.5 µm and basophils measured 10.5–13.0 µm.[45]

Neutrophils

Neutrophils generally exceed lymphocytes in the peripheral blood of normal adult chimpanzees, baboons, rhesus monkeys, and African green monkeys (Tables 110.16–110.20). The typical NHP neutrophil contains a condensed, twisted, or segmented nucleus that commonly presents 5–6 lobes but may possess as many as 10–12 (Fig. 110.12A, D, E, H). A small drumstick-shaped appendage (Barr body) is attached to the nucleus of neutrophils from females. The cytoplasm varies from pale to light pink, and granulation is a feature of most, if not all, neutrophils from NHPs. The color of eosinophil granules has been reported to vary from eosinophilic to azurophilic to basophilic in cotton-top tamarins, squirrel monkeys, and chimpanzees respectively.[6,7,19]

Lymphocytes

Lymphocytes exceed neutrophils in the peripheral blood of normal adult cynomolgus monkeys and in many New World monkeys including owl monkeys, squirrel monkeys, marmosets, and some species of tamarins (Tables 110.11–110.15, 110.19). Lymphocytes from most NHP species resemble human lymphocytes, although "atypical" or "reactive cells" may be seen (Fig 110.12A, B, D).

Monocytes

Monocytes in NHPs are larger than the lymphocytes and may appear in two forms. The first type of monocyte has a broader band of cytoplasm than is observed in the lymphocytes, with a mottled gray-blue color with a foamy appearance or with discrete vacuoles (Fig. 110.12A). The second type of monocyte, a transitional form, has a large oval nucleus devoid of depressions, and its cytoplasm appears darker adjacent to the nucleus and often has delicate pale reddish granulation. In general, monocyte counts are low in healthy NHPs, typically ranging from 0% to 4% of the total WBC count.

Eosinophils

As compared to other mammalian species, eosinophils and neutrophils are somewhat harder to distinguish due to their equivalent size and the presence of azurophilic or eosinophilic granules in both cell types. Eosinophils can be confidently identified using the following criteria: (1) eosinophil granules are almost twice as large and rounder than those of neutrophils; (2) eosinophil granules have a brighter yellow-red color; and may be superimposed on the nucleus; (3) the cytoplasm of eosinophils is slightly more gray-blue; and (4) the eosinophil nucleus is not as condensed or segmented (Fig. 110.12E, F, H).[47] Marmoset eosinophils contain irregular spherical granules which often have a bluish tinge and create a "muddy" gray-blue cytoplasm that can be confused with basophils.

Idiopathic eosinophilia has been described for specific owl monkey karyotypes. Early studies excluded parasitism and subclinical disease as a cause of the eosinophilia and suggested a genetic component. A more recent study analyzed eosinophils from two karyo-

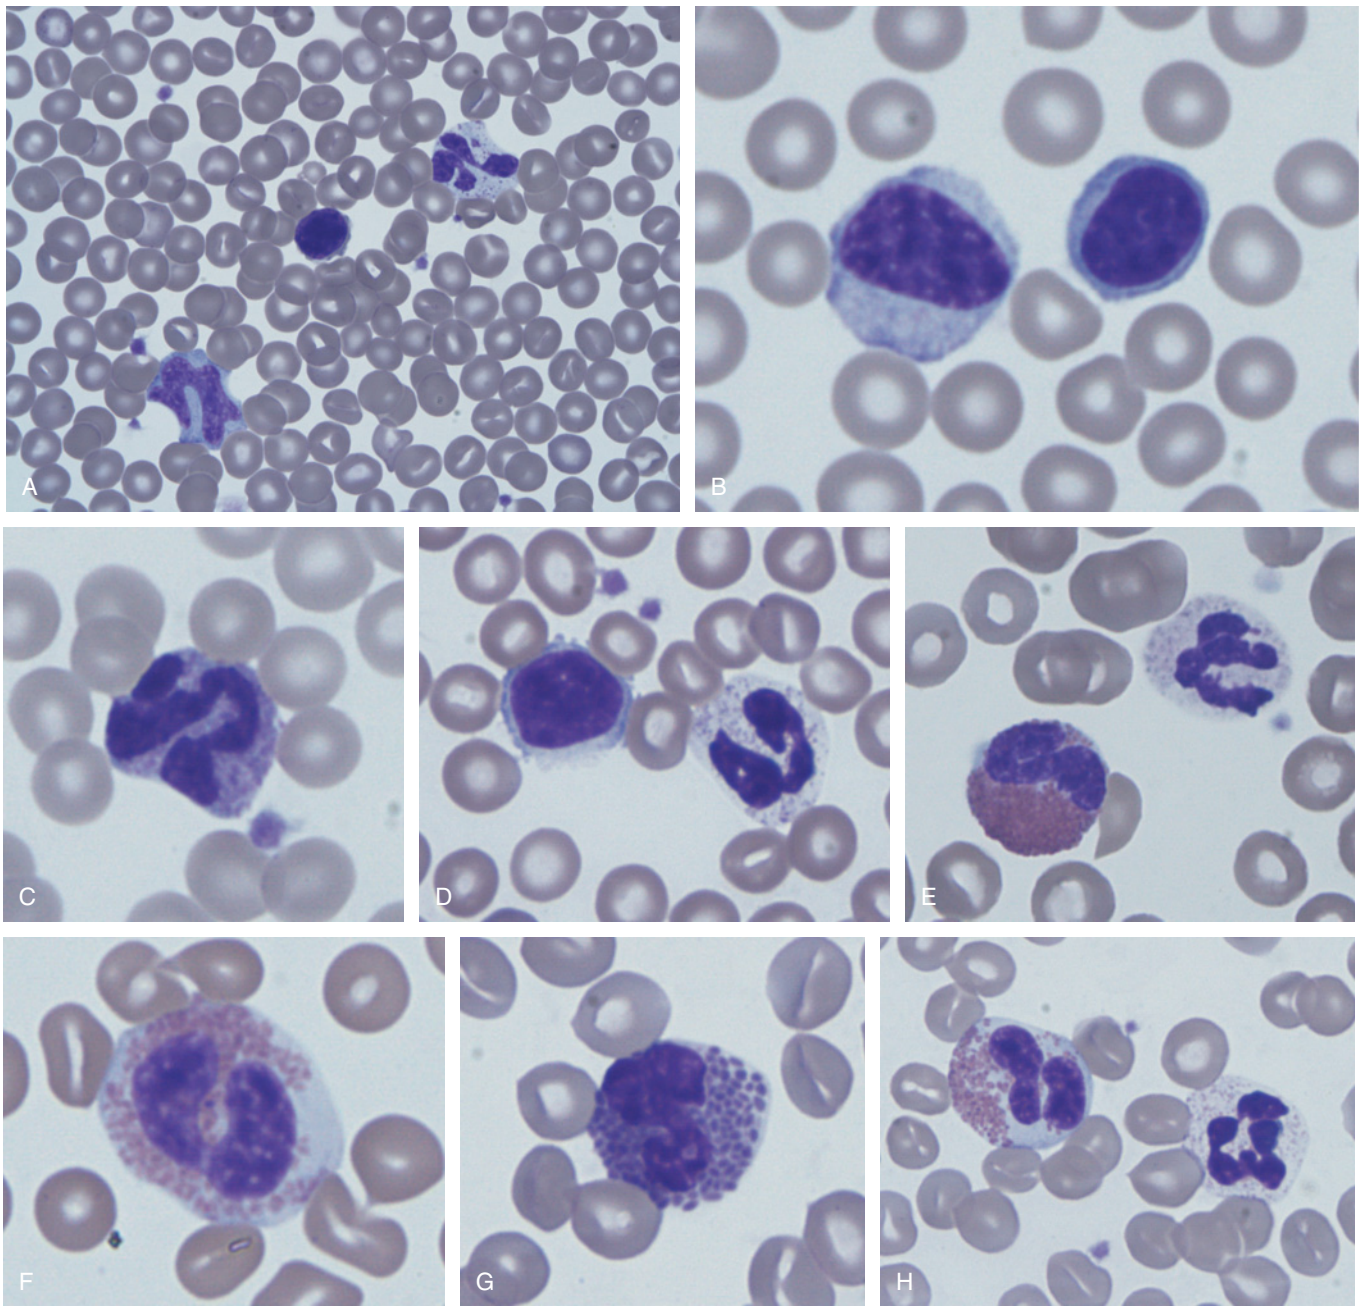

FIGURE 110.12 Peripheral blood cells: (**A**) Owl monkey (*Aotus nancymae*) – from left to right a monocyte, lymphocyte and neutrophil. (**B**) Bolivian squirrel monkey (*Saimiri boliviensis*) – two lymphocytes. (**C**) Bolivian squirrel monkey (*Saimiri boliviensis*) – basophil. (**D**) Bolivian squirrel monkey (*Saimiri boliviensis*) – lymphocyte and neutrophil. (**E**) Chimpanzee (*Pan troglodytes*) – eosinophil and neutrophil. (**F**) Guyanese squirrel monkey (*Saimiri sciureus sciureus*) – eosinophil. (**G**) Rhesus macaque (*Macaca mulatta*) – basophil. (**H**) Rhesus macaque (*Macaca mulatta*) – eosinophil and neutrophil. Modified Wright-Giemsa stain.

types, K-I (*Aotus nancymae*) and K-VI (*Aotus azarae boliviensis*) that are associated with low and high levels of eosinophils, respectively. The results indicated that the genetic basis of the eosinophilia in K-VI monkeys was likely a function of heightened eosinophilopoiesis and depressed recruitment kinetics from the peripheral circulatory pool in response to RANTES.[1]

Basophils

Basophils contain dull gray cytoplasm with dull gray rods and additional pale violet to dark purple, round or rod-like granules of varying sizes (Fig 110.12C, G). The granules typically do not obscure the nucleus, but the morphology and number of the granules may vary

significantly between species. As in many other mammalian species, basophils are present in low numbers in the blood and typically account for 0–2% of the total WBC count.

Platelets

The morphology of platelets from NHP species is similar to platelets from other species. They display an amorphous pale-blue ground substance and pronounced violet granulation. Transmission electron micrographs of chimpanzee and monkey platelets show that most of the internal structures are similar to those seen in many mammalian species with the exception of large clumps of glycogen and structures of unknown character circumscribed with fibrous strands.[32] Platelet numbers vary between species. Macaques frequently have higher platelet counts than humans, while chimpanzee platelet counts tend to be lower than humans and other primate species.[12] Although few reports on platelet activity in NHPs exist, differences between the activity of human platelets have been cited. Platelets from baboons and chimpanzees reportedly aggregate with collagen, ristocetin, and ADP. Biphasic aggregation (i.e. aggregation followed quickly by disaggregation) to ADP is common in both species; however, chimpanzee platelets are not responsive to arachidonic acid.[32] Platelets from rhesus monkeys aggregate in response to collagen, ADP and arachidonic acid in a manner similar to humans.[25,57] Marmoset platelets aggregate with ristocetin and collagen at higher concentrations than human platelets but fail to respond to epinephrine. In addition, they aggregate with arachidonate at concentrations similar to human platelets and have a monophasic response to ADP.[36]

Coagulation

Reported coagulation values from healthy animals of multiple NHP species are provided in Table 110.21. In general, coagulation values for most species are similar to those reported for humans. Comparisons between the clotting system of rhesus macaques, cynomolgus macaques, and humans concluded that both NHP species are suitable for studying coagulation defects that occur in humans. Specific differences included higher levels of factors II, VII, VIII, and XII in rhesus macaques and lower levels of factor IX activity in both rhesus and cynomolgus macaques as compared to humans.[4,50] Activation of fibrinolysis, intrinsic coagulation, prothrombin consumption, and functional levels of most coagulation factors in cynomolgus macaques were very similar to humans.[4] Clotting times for baboons, chimpanzees, and macaques are typically short, with clots being retracted partially or completely by 4 hours.[32] A recent comparison of 18 analytes that assessed excessive thrombin activation, clotting inhibition, endothelial damage, and fibrinolysis between normal baboons and humans showed a high level of concordance. Exceptions included elevated thrombin/antithrombin complex and fibrinopeptide A and lower plasminogen activity in NHPs.[11]

Aging

Studies designed to determine the effects of aging on hematologic indices have generated conflicting results. Studies by Smucny et al.[51] and Nakamura et al.[39] concluded that WBC counts are unchanged in aged rhesus monkeys up to 30 years old, while a third study by Kessler et al.[29] identified decreased WBC counts in aged male and female rhesus monkeys (15–28 years). In addition, Smucny et al.[51] and Nakamura et al.[39] noted general increases in Hct and Hgb for monkeys over 20 years old, while Kessler et al.[29] documented lower Hcts and MCH for aged female rhesus monkeys (15–28 years). All studies concurred that MCV generally declined with age.

Bone Marrow Evaluation and Cytology

In larger NHPs, bone marrow can be collected from a number of sites including the iliac crest, the ischial tuberosity, the trochanteric fossa of the femur, the tibial crest or the proximal humerus.[13] The trochanteric fossa and the proximal humerus are useful for collection from smaller animals. The site of bone marrow aspiration and the technique used may affect the percentage of hematopoietic cells. In cynomolgus monkeys, samples collected by conventional aspiration from the ilium contained greater than 20% total T cells, while perfusion aspirates from the long bones (humerus and femur) contained less than 4% T cells.[31] This difference is probably due to blood contamination.

Bone marrow constituents are reportedly similar when sampled from three separate sites: sternum, ribs, and femur.[47] With the exception of rhesus macaques, the literature contains few reports on the normal cellular composition of NHP bone marrow. Table 110.22 details the published results for quantification of bone marrow populations in the rhesus macaque, cynomolgus macaque, and baboon. For these species the M:E ratio was notably lower than humans, in which the reference interval is approximately 2.0–4.0. Some reported values for rhesus macaques were variable. The M:E ratio ranged from 0.8 to 1.97.[41,44] Most authors reported a lymphocyte count between 4% and 9% while one author reported 24.6% lymphocytes.[41] This discrepancy may have resulted from blood contamination.

The morphology of the hematopoietic cell populations has been described for cynomolgus monkeys.[43] Several morphologic descriptions of hematopoietic cells from rhesus monkeys indicate strong similarity between the two species.[56] Examples of different hematopoietic cell types from the rhesus monkey are provided in Fig. 110.13. A unique feature of bone marrow from rhesus and cynomolgus macaques is the presence of "giant" band neutrophils and metamyelocytes.[43,56] Marrow from both species contains stainable iron, rare monocytes, monocyte precursors, and less than 1% nonhematopoietic elements. Lymphocyte, plasma cell,

CHAPTER III

Hematology of the Ferret

KURT L. ZIMMERMAN, DAVID M. MOORE, and STEPHEN A. SMITH

Blood Collection
Morphology and Numbers of Peripheral Blood Cells
  Erythrocytes
  Platelets
  Leukocytes
Bone Marrow Cytology
Other Hematologic Values

Acronyms and Abbreviations

Hgb, hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean cell volume; M:E, myeloid to erythroid ratio; PCV, packed cell volume; RBCs, red blood cells; WBC, white blood cell count.

BLOOD COLLECTION

Several reviews have described a number of methods for collection of blood from ferrets, including toenail clipping (yielding less than 0.5 mL of blood), retroorbital sinus blood collection (safely yielding 1–3 mL of blood in ferrets weighing 100–300 g and 5–10 mL of blood from adults), cardiac puncture, caudal arterial puncture in the tail, and jugular venipuncture.[2–4,6,9,11,18,19,27,29,30,34] Chronic jugular catheterization for repeated blood sampling has also been described.[10,26]

The total blood volume of the ferret is estimated to be between 5 and 7% of body mass, resulting in a total blood volume in adult males of approximately 60 mL and approximately 40 mL in adult females.[13,15,24] Terminal blood collection (exsanguination) from the abdominal aorta in anesthetized ferrets will yield approximately 3% of body mass in blood.[35]

MORPHOLOGY AND NUMBERS OF PERIPHERAL BLOOD CELLS

Reported hematologic reference intervals for the ferret (*Mustela putorius furo*) are provided in Tables 111.1 and 111.2. Additional reported values for ferrets can be found in the literature.[7,8,12,17,21,28,37] As a cautionary note, the hematocrit, white blood cell (WBC) numbers, and platelet findings from anesthetized ferrets can be significantly less than reported reference intervals.[23,25]

Erythrocytes

The mean diameters reported for red blood cells (RBCs) of ferrets were found to be 5.94 µm in males (range, 4.6–7.7 µm) and 6.32 µm in females (range, 4.6–7.7 µm).[14,24,34,35] Hematocrit and RBC count values for ferrets were found to be higher than indices for dogs and cats.[13] Thornton et al. observed the range of reticulocytes in albino ferrets to be 1–12% (mean, 4%) in males and 2–14% (mean, 5.3%) in females.[35] Howell-Jolly bodies were seen in about 5% of male and female ferrets but were not observed in large numbers in those animals[34,35] (Fig 111.1).

Platelets

The mean diameters reported for platelets of ferrets were found to be 1.7 µm (range, 1.5–2.3 µm) in males and females (Fig. 111.1).[14,35] Kawasaki provided reference intervals of circulating platelets from ferrets seen in his practice, 297–730 $\times 10^3/\mu L$ (mean, 453 $\times 10^3/\mu L$), and a range suggested by his colleagues, 350–550 $\times 10^3/\mu L$ (mean, 400 $\times 10^3/\mu L$).[20] Thornton et al. observed the following platelet numbers in adult albino ferrets: 297–730 $\times 10^3/\mu L$ (mean, 453 $\times 10^3/\mu L$) in males, and 310–910 $\times 10^3/\mu L$ (mean, 545 $\times 10^3/\mu L$) in females.[35] Besch-Williford presented a reference interval of platelets as 245–910 $\times 10^3/\mu L$, with a mean of 650 $\times 10^3/\mu L$ in Fitch (wild coat color) ferrets and a range of 453–545 $\times 10^3/\mu L$ in albino ferrets.[1] Female ferrets develop

thrombocytopenia during estrus.[33] In females with severe anemia associated with hyperestrogenism, platelet counts may be less than $20 \times 10^3/\mu L$.[20] Blood group antigens have not been identified in the ferret and repeated transfusions do not seem to pose the same risk as in other mammals.[15,16,31,34]

Leukocytes

Neutrophils are the predominant leukocyte observed when performing differential counts. The mean diameter of neutrophils was reported as 11.2 µm in males (range, 10–13.1 µm) and 9.6 µm in females (range, 9.2–10.0 µm).[5,35] The cytoplasm of ferret neutrophils contains polychromatic granules (Fig. 111.2). The mean diameter of small lymphocytes was reported as 7.7 µm in males (range, 6.2–9.2 µm) and 8.7 µm in females (range, 7.7–10.0 µm); the mean diameter of large lymphocytes was reported as 11.1 µm in males (range, 9.2–13.1 µm) and 11.9 µm in females (Fig. 111.2).[35] Eosinophils (mean diameter 12.7 µm in males, 12.6 µm in females) have either a one or two lobed nucleus and have more numerous and rounder granules compared to neutrophils (Fig. 111.3).[34,35] The nucleus of basophils is segmented, and their mean diameter was reported as 13.5 µm in males and 13.8 µm in females.[35] Monocyte diameters were in the range 12–18 µm, and almost all cells were vacuolated (Fig. 111.4).[35]

BONE MARROW CYTOLOGY

In normal ferrets, the myeloid to erythroid (M:E) ratio was found to be 3.4 ± 1.1:1.0.[33] Hypoplasia of the bone

TABLE 111.3 Ferret Coagulation Data

Parameter	Mean ± SD	Reference
Clotting time (seconds)	120 ± 0.5	22
Prothrombin time (seconds)	15.7 ± 0.4	35
	10.3 ± 0.1	22
Activated partial thromboplastin time (seconds)	18.4 ± 1.4	22

marrow in ferrets frequently occurs secondary to prolonged exposure to estrogens associated with protracted estrus.[32,33] Severely affected jills had depletion of both erythroid and granulocytic precursors and almost a total absence of megakaryocytes.[33]

OTHER HEMATOLOGIC VALUES

The RBC sedimentation rate in ferrets was reported as 1–3 mm/hour.[36] Because of the almost negligible RBC sedimentation rate in ferrets, blood for packed cell volume (PCV) determinations must be spun for 20% longer than samples from other species.[35] Observed coagulation values for ferrets are presented in Table 111.3.[22]

Acronyms and Abbreviations

Hgb, hemoglobin; KC, Foa-Kurloff cells; MCHC, mean corpuscular hemoglobin concentration; MCV, mean cell volume; M:E, myeloid to erythroid; PCV, packed cell volume; RBC, red blood cell; WBC, white blood cell.

BLOOD COLLECTION

Blood collection from guinea pigs is a balancing act determining the volume of blood needed for analysis, and selecting a vessel or method that will supply the required quantity without threatening the animal's well-being. Up to 50 µL of blood can be obtained by filling a single microhematocrit tube from the metatarsal veins, ear veins, saphenous veins, or toenails of non-anesthetized guinea pigs. Blood is collected after the vessels are pricked with either a sterile lancet or a sterile hypodermic needle (23–27 gauge), or the toenails cut to the "quick" with nail clippers.[20] Somewhat larger samples can be obtained from the saphenous veins, by first anesthetizing the guinea pig, inserting a sterile hypodermic needle into the vessel, and then collecting the blood as it drips from the hub of the needle. For research purposes, blood collection methods that yield significantly larger volumes of blood include cardiac or vena cava punctures (both generally used as a terminal procedure in anesthetized cavies), venipuncture of the jugular or saphenous veins, or collection from the retro-orbital plexus in anesthetized animals (as described for rats in Chapter 110).[4,11,20,26]

The blood volume of the adult guinea pig is approximately 69–75 mL/kg of body weight, and about 7–10% of the blood volume (0.5–0.7 mL/100 g of body weight) can be safely drawn in a single collection from a healthy guinea pig.[9,12,20,24]

MORPHOLOGY AND NUMBERS OF PERIPHERAL BLOOD CELLS

Erythrocytes

Guinea pig red blood cells (RBCs) have moderate anisocytosis with a diameter ranging between 6.6 and 7.9 µm, although microcytes, when present, may be 3.5 µm in diameter (Fig. 112.1).[28] The guinea pig RBC is the largest in comparison with the other common laboratory animal species.[14] Polychromatic RBCs total approximately 25% of circulating RBCs in neonates, 4.5% in juveniles, and 1.5% in adult cavies.[1,28] The RBC indices in guinea pigs (i.e. RBC count, hemoglobin [Hgb], and packed cell volume [PCV]) given in Table 112.1 are relatively low when compared with the values observed in other laboratory rodent species.[18,20,30]

Platelets

Guinea pig platelets have an irregular oval shape (2–3 µm in length), and the periphery of the cytoplasm is pale in comparison to a more intensely stained central zone (Fig. 112.1).[28] Reference intervals for circulating platelets have been reported in several publications: 120–132 × 10^3/µL;[28] 161–368 × 10^3/µL;[22,23] 530 ± 149 × 10^3/µL;[27] 250–850 × 10^3/µL;[9] 250–850 × 10^3/µL;[15] 260–740 × 10^3/µL.[12]

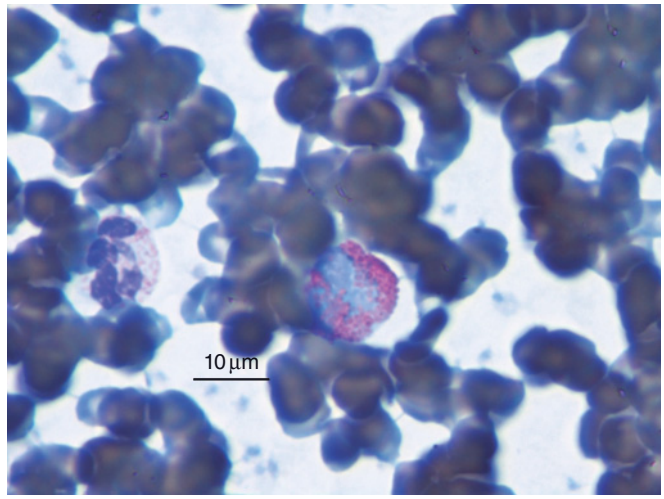

FIGURE 112.3 Guinea pig blood. Eosinophil with numerous bright eosinophilic granules filling the cytoplasm and adjacent heterophil; Wright's stain; 100× objective.

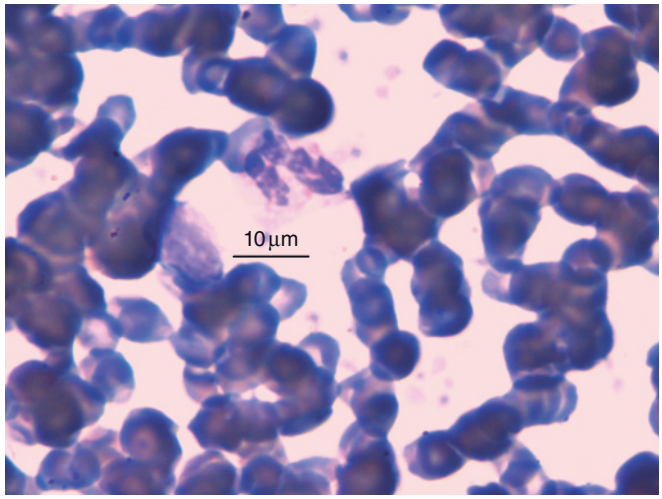

FIGURE 112.2 Guinea pig blood. Heterophil with a few small eosinophilic cytoplasmic granules and a small lymphocyte; Wright's stain; 100× objective.

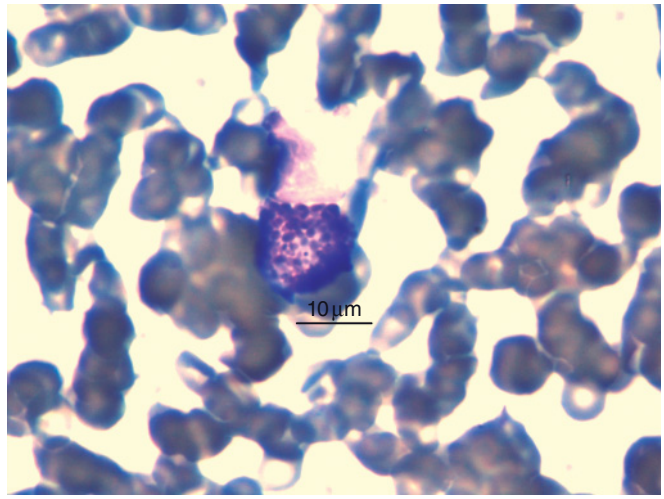

FIGURE 112.4 Guinea pig blood. Basophil with numerous oval dull basophilic-lavender granules filling the cytoplasm; Wright's stain; 100× objective.

Leukocytes

Guinea pig heterophils are the counterpart of the neutrophil in other species.[25] Heterophils are approximately 10–12 µm in diameter, have a condensed, segmented nucleus (with up to five or more segments), and eosinophilic granules in the cytoplasm, causing some to refer to it as a pseudoeosinophil (Fig. 112.2). A "drumstick" sex chromatin lobe may be present on the nuclei of heterophils in female guinea pigs. Cavy eosinophils are larger than heterophils (about 10–15 µm in diameter), have a less segmented nucleus with a lesser degree of pyknosis, and thick, round bright red granules that almost completely fill the cytoplasm (Fig. 112.3).[28] Basophils are rarely found, are about the same size as heterophils or somewhat larger, have a lobulated homogeneously purple-stained nucleus, and their cytoplasm is closely packed with round violet granules of varying size (Fig. 112.4).[28] Lymphocytes are the predominant leukocyte (Table 112.2), and small lymphocytes, which are present in greater numbers than large lymphocytes, are not much larger than RBCs. The small lymphocytes of cavies have a round, condensed nucleus surrounded by a narrow band of cytoplasm. Large lymphocytes are almost twice as large as small lymphocytes, with a less condensed, more oval-shaped nucleus and a brighter, broader zone of cytoplasm that may contain variably-sized azurophilic granules.[28] Guinea pig monocytes are

usually larger than the large lymphocytes, have an oval nucleus with a dispersed chromatin structure, and have a gray-blue cytoplasm that is darker than the cytoplasm of large lymphocytes (Fig. 112.1).

Occasional Foa-Kurloff cells (KC), which are unique to the guinea pig, may be observed in the circulation, accounting for up to 3–4% of the differential leukocyte count.[14,18] There is no significant difference in numbers of KC observed in males and females after 2–3 months of age.[14] The KC cell is a specialized mononuclear leukocyte that contains an intracytoplasmic, finely granular to fibrillar 1–8 µm inclusion body consisting of a mucopolysaccharide (Fig. 112.5).[20,25] The inclusion is within a cytoplasmic vacuole and displaces the nucleus.[25] Whereas these cells may be found in blood vessels and in thymus, their highest density shifts from lungs and red pulp of the spleen to thymus and placenta under the stimulation of estrogen and pregnancy.[13] The exact origin and function of these cells is unknown, although it has been speculated that they may function as killer cells in the general circulation or as protectors of fetal antigen in the placenta.[5,8,19]

BONE MARROW CYTOLOGY

Bone marrow is perhaps best obtained from the proximal end of the femur in guinea pigs. The myeloid to erythroid (M:E) ratio was estimated to be between 1.2:1.0 and 1.6:1.0.[6,7,10,20,24]

OTHER HEMATOLOGIC VALUES

The sedimentation rate for blood from guinea pigs was reported as follows: 2.3–8.1 mm/hr;[22,23] 1–14 mm/hr;[3] 2–4 mm/hr;[29] and 1.1–14 mm/hr.[12] Observed coagulation values for guinea pigs[17] are presented in Table 112.3.

TABLE 112.3 Observed Coagulation Values in Guinea Pigs

CHAPTER 113

Hematology of the Mongolian Gerbil

KURT L. ZIMMERMAN, DAVID M. MOORE, and STEPHEN A. SMITH

Blood Collection
Morphology and Numbers of Peripheral Blood Cells
  Erythrocytes
  Platelets
  Leukocytes
Bone Marrow Cytology
Other Hematologic Values

Acronyms and Abbreviations

Hct, hematocrit; Hgb, hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; M:E, myeloid to erythroid ratio; PCV, packed cell volume; RBC, red blood cell; WBC, white blood cell.

BLOOD COLLECTION

The blood volume of the Mongolian gerbil (*Meriones unguiculatus*) is approximately 7.7 mL/100 g of body mass, and thus approximately 0.8 mL of blood can be safely collected at one time without adversely affecting the animal's well-being.[8] In research laboratories, blood is usually collected from anesthetized gerbils from the retro-orbital venous plexus or by cardiac puncture (described for the rat in Chapter 110). Less invasive procedures, that yield significantly smaller volumes of blood, involve filling a single microhematocrit tube with blood obtained from a cut toenail or the saphenous vein after puncture with a sterile lancet or hypodermic needle. Analysis of blood samples obtained from the tail vein or heart demonstrated almost identical results for packed cell volume (PCV), hemoglobin (Hgb), and red blood cell (RBC) numbers, whereas samples obtained from the tail vein had higher white blood cell (WBC) counts associated with a greater concentration of lymphocytes.[17] Lipemic plasma, prevalent in both sexes and at all ages, with a more pronounced lipemia in males 13 months of age or older, was attributed to addition of sunflower seeds to the diet.[17]

MORPHOLOGY AND NUMBERS OF PERIPHERAL BLOOD CELLS

Reported hematologic values for the gerbil are provided in Tables 113.1 and 113.2. A significant sexual dimorphism exists with respect to RBC indices (i.e. mean corpuscular volume [MCV], Hgb, hematocrit [Hct], and mean corpuscular hemoglobin concentration [MCHC]), with higher values for the erythrocyte indices reported in adult male gerbils.[2,4,5,9,11,13,20]

Erythrocytes

When compared to adult reference values, neonates have RBC macrocytosis, panleukocytosis, and lower RBC counts. These values reach adult values by about 8 weeks of age.[19,20] Polychromasia/reticulocytosis and basophilic stippling are notable features of gerbil blood, particularly of newborns.[15] Basophilic stippling and polychromasia of RBCs were observed in 40% of cells of fetal and newborn gerbils, but declined to adult levels of 5.4 ± 2.4% by 20 weeks of age.[15,18] A range of 5–40 basophilic particles, approximately 0.3 µm in diameter, may be present in the stippled RBCs.[17] Red blood cells with diffuse basophilic staining usually are larger than the mature RBCs (Fig. 113.1). Red blood cells with basophilic stippling are thought to be relatively immature erythrocytes that still possess remnants of cytoplasmic ribonucleoprotein.[6,18] Normochromic stippled RBCs may be slightly larger than mature erythrocytes, but are smaller than the diffusely stained basophilic RBCs. The presence of stippled RBCs should not be confused with the intracellular organism *Mycoplasma (Haemobartonella)* sp. In another study, polychromatophilic RBCs were found with almost equal frequency in male and female gerbils (about 1.7%).[2] The presence of stippled RBCs and reticulocytes at levels higher than observed in most other domestic

13	3	M	609.17	432–710
13	3	F	590.67	540–632

rodent species may be a result of the relatively short RBC lifespan in gerbils, noted as 9–10 days, which necessitates continuous replacement of circulating RBCs.[1,8,15,17]

Platelets

Platelet counts for gerbils are similar to those found in rats.[17] Observed ranges of numbers of circulating platelets have been reported in several references: $638 \times 10^3/\mu L$;[3] $400 \times 10^3/\mu L$ to $600 \times 10^3/\mu L$;[20] and $400 \times 10^3/\mu L$ to $600 \times 10^3/\mu L$.[10] A comparison of platelet counts by age and gender is provided in Table 113.3.

Leukocytes

The ratio of lymphocytes to neutrophils averages 6.1:1 in male gerbils and 3.2:1 in females (Fig. 113.1).[12] The total leukocyte count in gerbils is closer to that of the mouse than the hamster.[7] Basophils are rare but have been seen in association with nematodiasis (Fig. 113.2).[14] Examples of eosinophils and monocytes are shown in Figures 113.3 and 113.4. Reported leukocyte reference

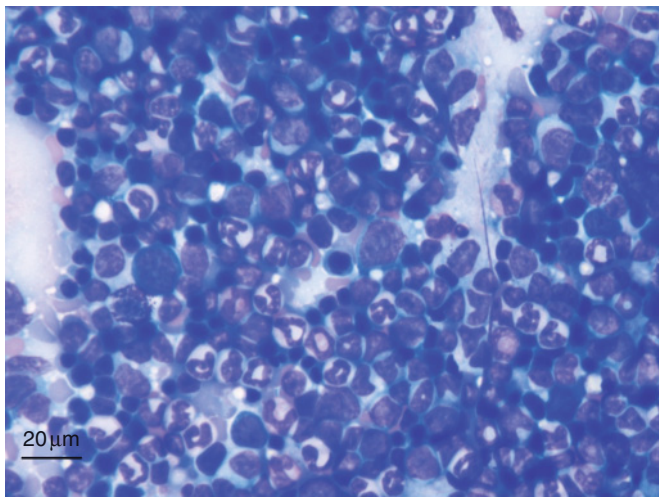

FIGURE 113.5 Bone marrow from a Mongolian gerbil (*Meriones unguiculatus*). Wright's stain; 100× objective.

intervals for Mongolian gerbils are provided in Table 113.2.

BONE MARROW CYTOLOGY

The myeloid to erythroid (M:E) ratio in the bone marrow of gerbils was reported to be 1.6 ± 0.75:1, with an observed range of 0.6:1 to 3.6:1.[22] One study reported mean percentages of selected bone marrow cells as follows: neutrophil, 38.5%; erythroid cells, 26.8%; plasma cells, 2.0%; eosinophils, 1.9%; and basophils, 0.2%.[16] Basophilic stippling was seen in 26.1 ± 7.6% of RBCs in bone marrow (Fig. 113.5).[18] In another study, lymphocytes in bone marrow samples accounted for about 8.4 ± 4.2% of cells observed, with a range between 1.4% and 20.1%.[22] In this study there was a significant difference between males and females in the total number of neutrophils (42% and 35%, respectively).[22] Ring neutrophils are seen in gerbil marrow, similar to those observed in rats and mice.[22] The bone marrow of adult gerbils contains a higher proportion of stippled red cells than is observed in the blood.[18]

OTHER HEMATOLOGIC VALUES

The sedimentation rate for normal gerbil blood was reported as 0–2 mm/hr.[21]

CHAPTER 114

Hematology of the Syrian (Golden) Hamster

STEPHEN A. SMITH, KURT L. ZIMMERMAN, and DAVID M. MOORE

Blood Collection
Morphology and Numbers of Peripheral Blood Cells
  Erythrocytes
  Platelets
  Leukocytes
Bone Marrow Cytology
Other Blood Findings
Other Hematologic Values

Acronyms and Abbreviations

Hgb, hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean cell volume; M:E ratio, myeloid to erythroid ratio; PCV, packed cell volume; RBC, red blood cell; WBC, white blood cell.

BLOOD COLLECTION

Blood is collected from laboratory hamsters either from the retro-orbital venous plexus or by cardiac puncture while the animal is anesthetized (these procedures are described for the rat in Chapter 110). Alternative blood collection methods for hamsters include use of a micro-hematocrit tube to obtain blood from a clipped toenail or from the saphenous vein after puncture with a sterile lancet or hypodermic needle. The blood volume in a hamster is between 65 and 80 mL/kg of body mass, of which approximately 1–1.5 mL can be withdrawn safely during a single collection.[8,9]

MORPHOLOGY AND NUMBERS OF PERIPHERAL BLOOD CELLS

Reported hematologic values for the Syrian hamster (*Mesocricetus auratus*) are listed in Tables 114.1 and 114.2. Additional published hematologic reference values for other species of hamsters can be found in the literature (Table 114.3).[1,14,17,22]

Erythrocytes

Hamster red blood cells (RBCs) are biconcave, have an average diameter of 6 µm (range, 5–7 µm), with moderate polychromasia and anisocytosis (Fig. 114.1).[18] The proportion of nucleated RBCs may be as high as 10–30% in newborn hamsters, whereas in adults there are usually 2% or fewer of these cells.[5,8] The relatively high reported reticulocyte percentages (2.0–12.5% and 0.4–2.8%) are probably due to the relatively short RBC lifespan of 50–70 days.[18,20,21] The hematocrit and hemoglobin (Hgb) levels in neonates increase until about 8–9 weeks of age.[5] Elevated Hgb levels are observed in 2- to 3-week-old hamsters and in animals that are anorexic or have been starved.[9] The number of circulating RBCs decreases by 25–30% after castration of male hamsters,[21] and testosterone administration restores RBCs to pre-castration levels.[10] Red blood cell counts and Hgb concentrations are higher in hibernating animals, with the mean number of RBCs increasing from 7.7–10^6/µL to approximately 8.2×10^6/µL, and Hgb increasing from a mean of 13.5 g/dL to approximately 16.7 g/dL.[20] Red blood cell senescence is delayed and RBC destruction is virtually absent during hibernation, with an observed increase in RBC lifespan of up to 160 days, as compared with the normal erythrocyte lifespan of 50–70 days in non hibernating hamsters.[2,19] However, no change in mean cell volume (MCV) was observed in cold acclimated hamsters as has been reported in rats.[6]

Platelets

Platelets appear to be amorphous veils of a gray-blue ground substance with violet granulation (Fig. 114.1).[20] Platelet numbers have been reported in several references: 336×10^3/µL to 587×10^3/µL;[20] 247×10^3/µL to 372×10^3/µL;[5] 300×10^3/µL to 573×10^3/µL;[16] 200×10^3/µL to 590×10^3/µL;[25] 200×10^3/µL to 500×10^3/µL;[8] 200×10^3/µL to 500×10^3/µL;[11] and 297×10^3/µL to 439×10^3/µL.[13] Platelet counts were found to be reduced during hibernation and cold acclimation.[6,19]

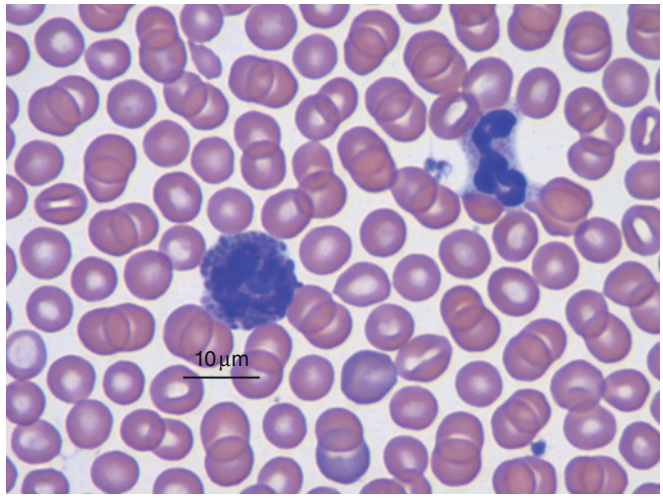

FIGURE 114.2 Neutrophil with a basophil from a Syrian hamster; Wright's stain; 100× objective.

Leukocytes

Neutrophils, also referred to as heterophils, have annular lobulated condensed nuclei and contain round- or rod-shaped acidophilic cytoplasmic granules. (Figs. 114.1 and 114.2).[18] Neutrophils are either segmented or unsegmented and generally have a diameter between 10 and 12 µm. Two classes of lymphocytes, small and large (with the small form in greater prevalence), comprise between 60% and 80% of all circulating white blood cells (WBCs; Figs. 114.3 and 114.4).[18] The nucleus of the hamster lymphocyte is round, condensed to the point that it almost seems granulated, and is infrequently indented.[20] A narrow band of blue-staining cytoplasm surrounds the lymphocyte nucleus and may contain azure granules. Occasionally, the band of cytoplasm of some lymphocytes may be reduced to the

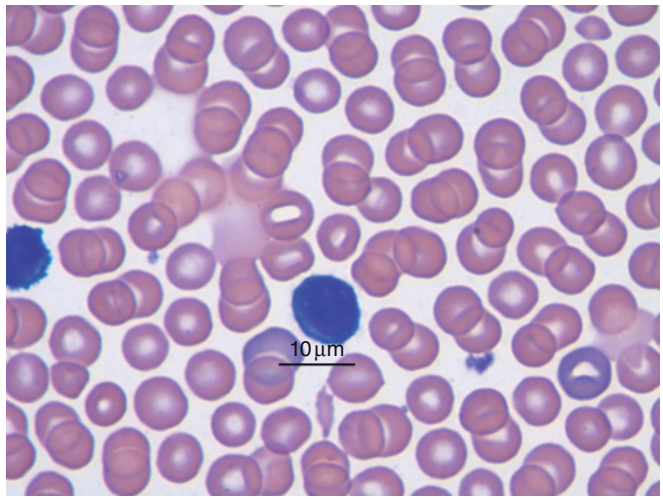

FIGURE 114.3 Small lymphocytes from a Syrian hamster; Wright's stain; 100× objective.

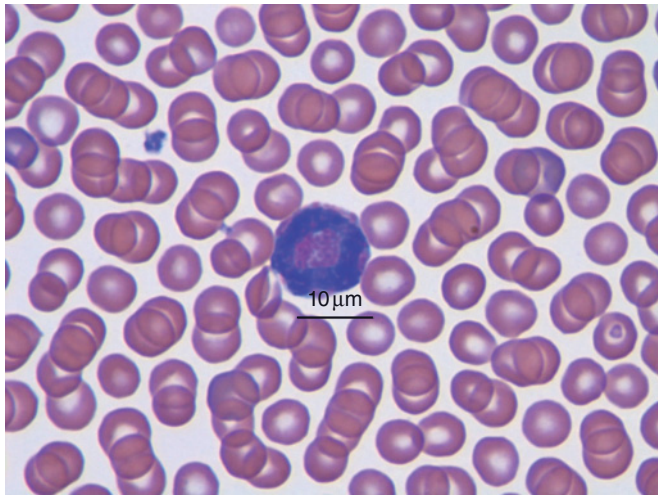

FIGURE 114.5 Eosinophil from a Syrian hamster; Wright's stain; 100× objective.

extent that the cells may be mistaken as basophils, although basophils are rarely observed (Fig. 114.2). The morphology of eosinophils, basophils, and monocytes is similar to that of other rodents. Eosinophils are relatively rare and may not be observed in some animals. Eosinophils have an annular nucleus, sometimes slightly twisted, that fills the periphery of the cell as a wide condensed band, surrounded by a narrow zone of cytoplasm (Fig. 114.5).[20] The closely packed cytoplasmic granules in the eosinophils of hamsters are shaped like short rods, in contrast to the more rounded granules observed in rats and mice. Monocytes are the largest cells observed in hamster blood and are characterized as having a large, swollen, indented, or trilobulate nucleus and a delicately reticulated gray-blue cytoplasm (Fig. 114.6).[20]

A diurnal variation in the numbers and types of leukocytes can be observed in the hamster. Leukocyte levels increase to a range of $8 \times 10^3/\mu L$ to $10 \times 10^3/\mu L$ of blood at night when the nocturnal animal is most active, peaking in the early morning around 12×10^3 leukocytes/µL, with an increase of neutrophils rather than lymphocytes.[20] Because most clinical and research manipulations of hamsters occur during daylight hours when the animals would typically be asleep, the implications of diurnal variation on hematologic indices should be considered when interpreting results.

White blood cell counts decline during hibernation to approximately 2,500 cells/µL in Syrian hamsters and to approximately 1,000 cells/µL in European hamsters, with an observed neutrophil to lymphocyte ratio of 1.[16,19] After awakening from hibernation, a pronounced leukocytosis occurs (i.e. range of 10,000–20,000 leukocytes/µL, mean of 13,600 cells/µL) with a predominant neutrophilia, totaling 70–90% of the cells counted.[20]

BONE MARROW CYTOLOGY

The cellular constituents of the bone marrow of hamsters are quite similar to those observed in rats and mice. Reports differ widely as to the myeloid to erythroid (M:E) ratio in normal bone marrow, with Desai reporting the M:E ratio as 8–10:1, and Trincao reporting a much lower ratio of 1.7:1.[5,24] The results of the latter study are presented in Table 114.4.

Myeloblasts are frequently observed in the bone marrow of hamsters and have a large swollen nucleus that may contain one or two nucleoli, and are surrounded by a narrow basophilic band of cytoplasm. Myelocytes, each with a large swollen nucleus, have a brighter appearing cytoplasm that may occasionally

contain a few violet granules. Giant cells may be numerous, plasma cells are occasionally observed, and distinct lymphocytes or monocytes are rarely seen.[12,20]

OTHER BLOOD FINDINGS

Nucleated cell types other than WBCs are occasionally observed in hamsters. Intravascular fetal trophoblasts may be seen in blood of pregnant and post-partum hamsters and are considered incidental findings.[3] Megakaryocytes have been reported in blood in association with extramedullary hematopoiesis.[23]

OTHER HEMATOLOGIC VALUES

Reported coagulation values for Syrian hamsters are listed in Table 114.5. The sedimentation rate (mm/hr) for normal hamster blood was reported by a number of authors: 0.5 mm at 60 minutes, and 0.7 mm at 120 minutes;[20] 0.3–0.96 mm/hr;[16] and 0.32–0.96 mm/hr (mean, 0.64 ± 0.16 mm/hr) for males, and 0.30–0.70 mm/hr (mean, 0.50 ± 0.10 mm/hr) for females.[16] However, seasonal temperature variations may influence these results as hamsters exposed to lower temperatures may have reduced coagulability.[6]

EDTA, ethylenediaminetetraacetic acid; Hgb, hemoglobin; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume, M:E ratio, myeloid to erythroid ratio; PCV, packed cell volume; RBC, red blood cell; WBC, white blood cell.

The biological family Camelidae includes two Old World species, the Bactrian and dromedary camels and four New World species, the domestic llama and alpaca and the wild guanaco and vicuna. They are in the order Artiodactyla that also includes pigs, hippopotami, and ruminants including cattle, goats, and antelopes, among others. Fossil records indicate that Camelidae originated in North America with subsequent migration to Asia and Africa by the Old World camelids and to South America by the New World camelids.[14,33] In these environments, the camels adapted to severe dry deserts and the South American camelids adapted to the high altitude altiplano.

Genetic relationships between the four South American camelid species are complex. Genetic analyses provide conflicting evidence that alpacas and llamas are descended from the guanaco and that alpacas are descended from vicunas, but have undergone extensive hybridization.[14,31] In veterinary medicine, llamas and alpacas are often considered to be the same with respect to laboratory reference intervals and interpretation, but there are metabolic differences between these species and separate reference intervals should be used.[3]

Unique features of the Camelidae include their feet that are two-toed with footpads rather than hooves and their red blood cells (RBCs) that are elliptical in shape, unlike those of any other mammals.[2,5,7,13]

ERYTHROCYTES

Erythrocyte Parameters

Healthy camelids have packed cell volumes (PCVs) that are usually slightly lower than those of other herbivores (Tables 115.1 and 115.2). They have higher RBC numbers but smaller RBC size. Red blood cell numbers in camelids are usually reported in the range $12 \times 10^6/\mu L$ to $14 \times 10^6/\mu L$ for South American camelids and some Asian camels[2,7,12,13,37,40], with lower numbers reported in some camel samples.[22,23] The average RBC size in all camelid species is smaller than most other domestic species with mean corpuscular volumes (MCVs) reported in the range 21–28 fL (Tables 115.1 and 115.2).[6]

Hemoglobin (Hgb) concentrations in South American camelid RBCs are similar to those in horses, but higher than cattle.[6] The Old World camelids have somewhat lower mean Hgb concentrations than the South American camelids (Tables 115.1 and 115.2). The mean corpuscular hemoglobin concentration (MCHC) of camelids is generally higher than that of horses, cows, and sheep. However, the mean corpuscular hemoglobin (MCH), which is an index of the average amount of Hgb per RBC, is usually lower than reported in species that have larger erythrocytes.[6]

Erythrocyte Shape and Physical Properties

The elliptical erythrocytes of camelids are flat and thin with no central pallor. Because of their shape, they are sometimes folded on blood smears.[37] Hemoglobin crystals that appear as darkly eosinophilic, dense, rhomboid-shaped structures, are frequently seen on blood smears from clinically-healthy, non-anemic camelids. The cause and significance of these structures is not known (Fig. 115.1).[37] Cabot rings are also occasionally seen in erythrocytes from clinically-healthy camelids. These are narrow, thread-like structures in the form of rings or figure eights within RBCs. They are thought to be denatured membrane proteins, and have no known clinical significance.[13]

There are several structural and physiologic features of camelid RBCs that contribute to their high resistance to osmotic lysis, decreased deformability, and high affinity for oxygen. These attributes are adaptive for life in areas of low water availability or lowered oxygen availability. Membranes of camelid RBCs contain higher concentrations of the integral membrane protein, band 3, compared to other species.[16] In addition, increased cross-linking of band 3 with other membrane proteins in camelid erythrocytes probably contributes to their decreased deformability and resistance to hypotonic lysis.[20,27] Although decreased deformability of RBCs could be disadvantageous for animals facing a variety of environmental pressures, the disadvantage is minimized by the shape and small size of camelid RBCs that allows them to easily pass through capillaries without having to deform.

Oxygen Diffusion and Oxygen-Hemoglobin Dissociation Curve

The size and shape of camelid RBCs facilitates the diffusion of oxygen by providing a higher effective surface area for gas exchange.[39] Goat RBCs that are of similar size, but with a smaller surface area, have a much lower oxygen capacity as well as a lesser oxygen affinity for blood.[39]

Another adaptation to life at high altitude and low oxygen tension is an oxygen-hemoglobin dissociation curve that is shifted to the left, especially at lower partial pressures of Po_2, facilitating uptake of oxygen by the lung.[30] In addition, the percentage of alkali-resistant (fetal) Hgb with increased oxygen affinity is higher in adult alpacas than in adults of other species.[30]

Response to Anemia

Anisocytosis, polychromasia, reticulocytes, and nucleated RBCs may be seen in response to anemia, but the response is not as predictable as it is in other species. In normal, non-anemic llamas, reticulocyte numbers are reported in the range 12,000–79,000/μL of blood, (i.e. 0.2–0.6% or 0–0.4%).[2,7,37] Mean reticulocyte percentages for normal alpacas and vicunas are reported to be 1.4% and 1.2%, respectively.[29] As many as 2–3 nucleated RBCs per 100 white blood cells (WBCs) may be seen in non-anemic llamas.[2,7] In alpacas made acutely and severely anemic by phlebotomy, reticulocyte percentages increased, but only to a maximum of 1.5%, with the peak reticulocyte response occurring at a mean of 10.4 days after induction of anemia.[36]

Other morphologic features of camelid RBCs that are occasionally observed in anemia include dacryocytes, or tear-drop-shaped cells, spindle-shaped erythrocytes, and uneven distribution of Hgb in the cells (Fig. 115.2).[24,25,31] Although these have been reported in association with iron deficiency anemia, they are seen in moderate to marked anemias of other etiologies (S.J. Tornquist, unpublished observations). Heinz bodies have been reported in two alpacas that had ingested red maple leaves.[4] '*Candidatus* Mycoplasma haemolamae', a hemotropic mycoplasma, may be observed as small, round or ring-shaped basophilic organisms on the

margin of the erythrocytes, or in the background, if blood smears are not made promptly after blood collection.[19,28,35]

LEUKOCYTES

Leukocytes of camelids do not have the unique features of their RBCs. In general, the white blood cell (WBC) count for camelids is somewhat higher than for many similar species. Reference intervals are in the range 8,000–22,000/μL (Tables 115.3 and 115.4). In contrast, typical reference intervals for total leukocyte numbers of cattle and sheep are 4,000–12,000/μL and for horses 5,500–12,500/μL.[6]

The neutrophil to lymphocyte ratio in adult llamas and camels is about 1.5 which is more similar to humans, dogs, cats, and horses than it is to ruminants (Tables 115.3 and 115.4).[7,9,37] The neutrophil to lymphocyte ratio was reported to be lower (0.5–2.9) in a group of 29 alpacas, but these were 10–18 months old so the difference may be more age- than species-based.[12] Band neutrophils are seen in blood in response to inflammation and their morphology is like that of other species.[10]

Eosinophil numbers tend to be higher in healthy adult llamas than in other species.[7,13] Eosinophils are usually hyposegmented with band-shaped to bilobed nuclei (Fig. 115.3).[37]

Camelid lymphocytes vary in size as they do in ruminants. The percentage of granular lymphocytes in circulation in healthy llamas has been reported to be higher than that seen in cattle and horses. In three different studies, the percentage of granular lymphocytes was 7–29%, 1–19%, and 10–30% of blood lymphocytes.[2,9,37] Granules vary in size (Fig. 115.4).[2]

PLATELETS

Platelets from camelids are generally small in volume, similar to those from cows and horses, round to irregular, and contain azurophilic granules (Table 115.3).[2,8,17,34] Gader et al. recently showed that camel platelets, like those from cattle and horses, lack the open canalicular system that is present in platelets from other species.[8]

REFERENCE INTERVALS

There are challenges in comparing published reference intervals between camelids of different ages, sexes, species, and physiologic conditions, because so many of the reference intervals are based on relatively small numbers of animals and because sampling conditions can vary greatly.

Age

Some of the more frequently reported age-related differences in camelids include lower PCV and Hgb, and higher absolute lymphocyte and platelet numbers in juvenile llamas and guanacoes compared to adults.[7,13,21] Juvenile llamas have a lower neutrophil to lymphocyte ratio and juvenile alpacas have fewer absolute eosinophil numbers compared to adults.[7]

Gender

There are few reported significant gender differences in camelid reference intervals. Packed cell volume is reported to be higher in adult male llamas than in adult female llamas.[21] In studies of adult Bactrian and dromedary camels, no significant differences in hematologic parameters were reported between males and females.[22,40] Eosinophil numbers were reported to be significantly higher in females than males in a group of 29 10–18 month old alpacas.[12]

Environment

In studies of captive (n = 17) versus free-ranging guanacoes (n = 20), the captive population had a lower PCV range (28–42%) than did the free-ranging population (30–48%). In addition, the range of the total leukocyte count was much higher and wider (14.3×10^6/μL to 53.4×10^3/μL) in the free-ranging population than in the captive guanacos (1.5×10^6/μL to 9.2×10^3/μL). Animals in both populations were reported to be clinically healthy, but these differences may reflect response to handling and stress.[13,15]

The effects of altitude on hematologic parameters in camelids are not clear. For example, Ellis reported a PCV range of 33–42% for 40 alpacas at the La Raya, Peru, experimental station located at an altitude of 4,200 meters, but Reynafarje et al reported a range of 34–37% for 12 alpacas at the same station.[5,29] Fowler reported a range of PCVs for 116 alpacas at 3,900 meters as 24–45%.[6] The PCV range for 37 healthy Oregon alpacas living at an altitude of approximately 68 meters was 25–37% and for 29 alpacas in Australia (altitude not reported) was 30–42%.[12]

Stress

The effects of stress and excitement on hematologic parameters in camelids is also somewhat unclear. Miller and Banchero showed that llamas given injections of epinephrine to simulate stress or excitement had increases in PCV of approximately 10% at 3 and 6 minutes post-injection. The PCV typically dropped to resting level in 20 minutes.[21] These finding suggests a large splenic reserve with splenic contraction releasing RBCs into the circulation in response to excitement or stress in the llama. In contrast, the change in PCV in racing camels is small in response to the stress of racing, suggesting that there is not a large splenic reservoir of RBCs released.[32]

Physiologic neutrophilia, a shift of marginated neutrophils to the circulating pool in response to catecholamine release during handling and blood sampling,

may account for at least some of the discrepancies reported in neutrophil: lymphocyte ratios in camelid species. While the neutrophil: lymphocyte ratio is most frequently reported as being greater than unity and thus more similar to horses than to sheep and cattle, at least one author has reported a lower ratio and suggests that catecholamine-mediated neutrophilia affects the ratio in many studies.[5,6]

BONE MARROW

Sites

Bone marrow is most frequently obtained from the sternum or ribs of camelids. Andreasen, et al. aspirated bone marrow from the sternum of llamas after sedation with intravenous xylazine. The llamas were sampled either while standing or in left lateral recumbency.[1] McKenzie et al. obtained sternal bone marrow samples from alpacas also sedated with intravenous xylazine. These alpacas were placed in lateral recumbency and bone marrow was obtained from the midline of the sternum at the level of the caudal aspect of the elbow when positioned naturally.[18] Bone marrow aspiration from non-sedated dromedary camels has been described by Nazifi et al. who took samples from the 5th-8th ribs.[26] In all cases, the site was aseptically prepared and an 11–16 gauge bone marrow biopsy needle used to obtain samples. Bone marrow samples are most frequently aspirated into EDTA but may be collected with no anticoagulant if bone marrow smears are prepared immediately. Slides are air-dried and stained with appropriate stains including Wright's or Wright-Giemsa for general evaluation or with Perl's iron stain to assess iron stores.

Morphology

Cellularity of normal camelid bone marrow is reported to be similar to or somewhat increased in comparison with other mammals. In studies of seven llamas and 20 dromedary camels cellularity of 50–85% was noted.[1,26] The morphology and maturation of erythroid cells in bone marrow was similar to that seen in other species in both llamas and camels. Eythroid cells started to change from round to elliptical as they became less polychromatophilic.[1] No dacryocytes, spindle-shaped erythrocytes or uneven Hgb distribution were reported in bone marrow samples. No unique features of leukocyte morphology or maturation have been reported in camelid bone marrow samples. Percentages of bone marrow eosinophils are increased in comparison to other species, which parallels the higher percentages seen in blood.[1] Megakaryocyte numbers and morphology appear to be similar to those seen in other species. Stainable iron was present in moderate amounts in macrophages in the bone marrow of both llamas and dromedary camels.[1,26]

Cell Distribution

The average M:E ratio in bone marrow of healthy camelids is similar to that of other species. It is reported to average 1.21 in dromedary camels,[26] 0.9–2.9 in llamas,[1,6] and 0.47–1.01 in alpacas.[18] Myeloid:erythroid ratios in bone marrows from small numbers of alpacas, llamas, and vicunas living at 4,200 meters (13,800 feet) were reported to be much lower, with an average of approximately 0.5.[29]

CHAPTER 116

Hematology of Cervids

KATIE M. BOES

Properties of Blood Cells
- Erythrocytes
- Leukocytes
- Platelets

Reference Intervals
- Influence of Age
- Influence of Gender
- Influence of Reproductive Status
- Influence of Stress and Handling
- Response to Disease

Acronyms and Abbreviations

CBC, complete blood count; Hct, hematocrit; Hgb, hemoglobin; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean copuscular volume; PCV, packed cell volume; PLT, platelet; RBC, red blood cell; TPP, total plasma protein; WBC, white blood cell.

The Cervidae family is composed of various species of deer, wapiti, elk, moose, and reindeer, also known as caribou, that have adapted to a variety of climactic and geographic areas throughout the world.[9,11] Consequently, it is difficult to define the "normal" hematology for such a wide range of species and subspecies. The hematologic profile of cervids is influenced by a variety of factors: age, gender, reproductive status, seasonality, stress, method of capture, and disease all have an effect. Therefore it is useful to establish "normal" reference intervals for each animal population in accordance with its respective life stage and method of capture. Furthermore, the most useful data for an individual animal are to reference previous data that were taken from the same individual under the same conditions. With this said, this chapter will characterize the "normal" hematology of a variety of cervids. However, due to their differences in red blood cell (RBC) morphology, reindeer will be discussed in Chapter 119.

PROPERTIES OF BLOOD CELLS

Erythrocytes

Members of the family Cervidae have erythrocytes with unique characteristics. The erythrocytes circulate in the vasculature as round cells, which are slightly smaller than bovine red cells. However, shortly after phlebotomy, deer red cells tend to assume a sickle shape (Fig. 116.1A, B). The cells are not sickled when first removed from the body, but the shape change occurs if the blood is alkalinized, oxygenated, or left to stand at room temperature or at 4 °C.[18,19] This sickling phenomenon was first reported in 1840 by Gulliver,[10] and has since been observed in a variety of cervids, including barasingha (*Rucervus duvaucelii*), barking deer (*Muntiacus muntjak*), chital deer (*Axis axis*), fallow deer (*Dama dama*), hog deer (*Axis porcinus*), mule deer (*Odocoileus hemionus*), Père David's deer (*Elaphurus davidianus*), red deer (*Cervus elaphus*), Reeve's muntjac (*Muntiacus reevesi*), Rocky Mountain wapiti (*Cervus elaphus nelsoni*), rusa deer (*Rusa timorensis russa*), sambar deer (*Rusa unicolor*), sika deer (*Cervus nippon nippon*), and white-tailed deer (*Odocoileus virginianus*).[2,7,9–12,23,33] The sickling effect can be prevented by acidifying the blood. At pH 7.0, few red cells are sickled; at pH 7.4, most of the red cells have a sickle shape.[33] Furthermore, sickling may be enhanced by oxygenation of the red cells.[18] Subsequent addition of carbon dioxide will reverse the sickling, and round the cells.[18] In vivo, transient alkalosis and increased oxygenation may have similar effects on red cell morphology.[20] There are at least two exceptions within the Cervidae family: the erythrocytes of reindeer (*Rangifer tarandus*) and Eurasian elk (*Alces alces*) do not assume the sickle shape when exposed to oxygen. Fig. 116.1C, D show parasitized non-sickled red cells in wapiti blood.[33]

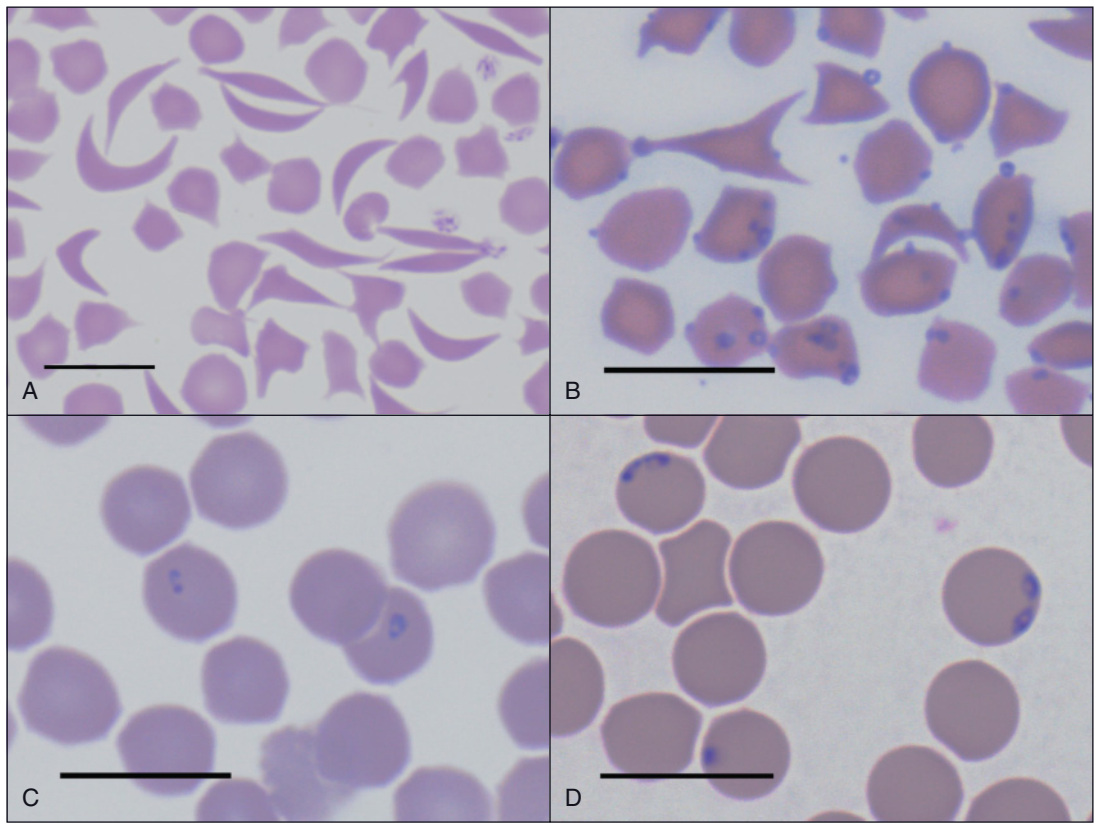

FIGURE 116.1 Normal and parasitized cervid erythrocytes. Modified Wright stain; bar = 10 µm. (**A**) Deer, erythrocytes with normal sickled appearance. Platelets are small and moderately granulated. (**B**) Deer, erythrocytes with *Mycoplasma ovis*-like organisms. (**C**) Wapiti (elk), round, non-sickled erythrocytes containing centrally located small, unpaired *Theileria cervi* organisms. (**D**) Wapiti (elk), erythrocytes with peripherally located paired *Babesia odocoilei* organisms.

The sickling effect is due to the formation of insoluble tactoids of variant forms of hemoglobin (Hgb) in the oxygenated state.[19] Deer erythrocytes contain several morphologic forms of Hgb, each of which has different electrophoretic properties and is associated with a distinct morphologic red cell shape.[19] These various morphologic forms are composed of 21 structurally different hemoglobins.[20] Consequently, an individual deer may have 1–3 different morphologic and 1–6 different structural forms of Hgb.[20] Morphologic types I and III Hgb are present in approximately half the deer population.[19] Hemoglobin type II alone or in combination with Hgb types I, III, or IVb is often associated with the development of a matchstick shape, which forms subsequent to the development of sickling. Red cells that contain Hgb type IVa may assume a burr shape. Other red cell shapes include the traditional crescent or holly leaf. The sickle effect does not occur if Hgb type V or VII is present.[19] The sickling phenomenon is an interesting laboratory observation but does not appear to have a deleterious effect on the deer.[19] One in vivo study of cervid erythrocytes demonstrated a RBC lifespan comparable with those of other domestic species.[23] The erythrocytes of five white-tailed deer, one sika deer, and one Rocky Mountain wapiti survived in circulation for 125, 159, and 149 days, respectively.[23]

As seen in other mammals, there is a relationship between body size, RBC size, and RBC count in cervids. Observations on several species of deer have revealed a direct relationship between RBC size and body size in members of the Cervidae. Furthermore, there is an indirect relationship between RBC size and RBC number.[13] In white-tailed deer, discoid erythrocytes measure 3.5–4.5 µm in diameter.[19]

Leukocytes

The most extensive characterization of cervid leukocyte morphology, cytochemical staining, and ultrastructural properties has been conducted on reindeer white blood cells (see Chapter 119). Deer and wapiti leukocytes show similar morphology using Romanowsky stains (Figs. 116.2–116.4). Of the cervid leukocytes, lymphocytes and neutrophils are the most numerous. Neutrophil to lymphocyte ratios are typically less than, or equal to unity, but some studies have shown that neutrophils predominate (Tables 116.1 and 116.2).

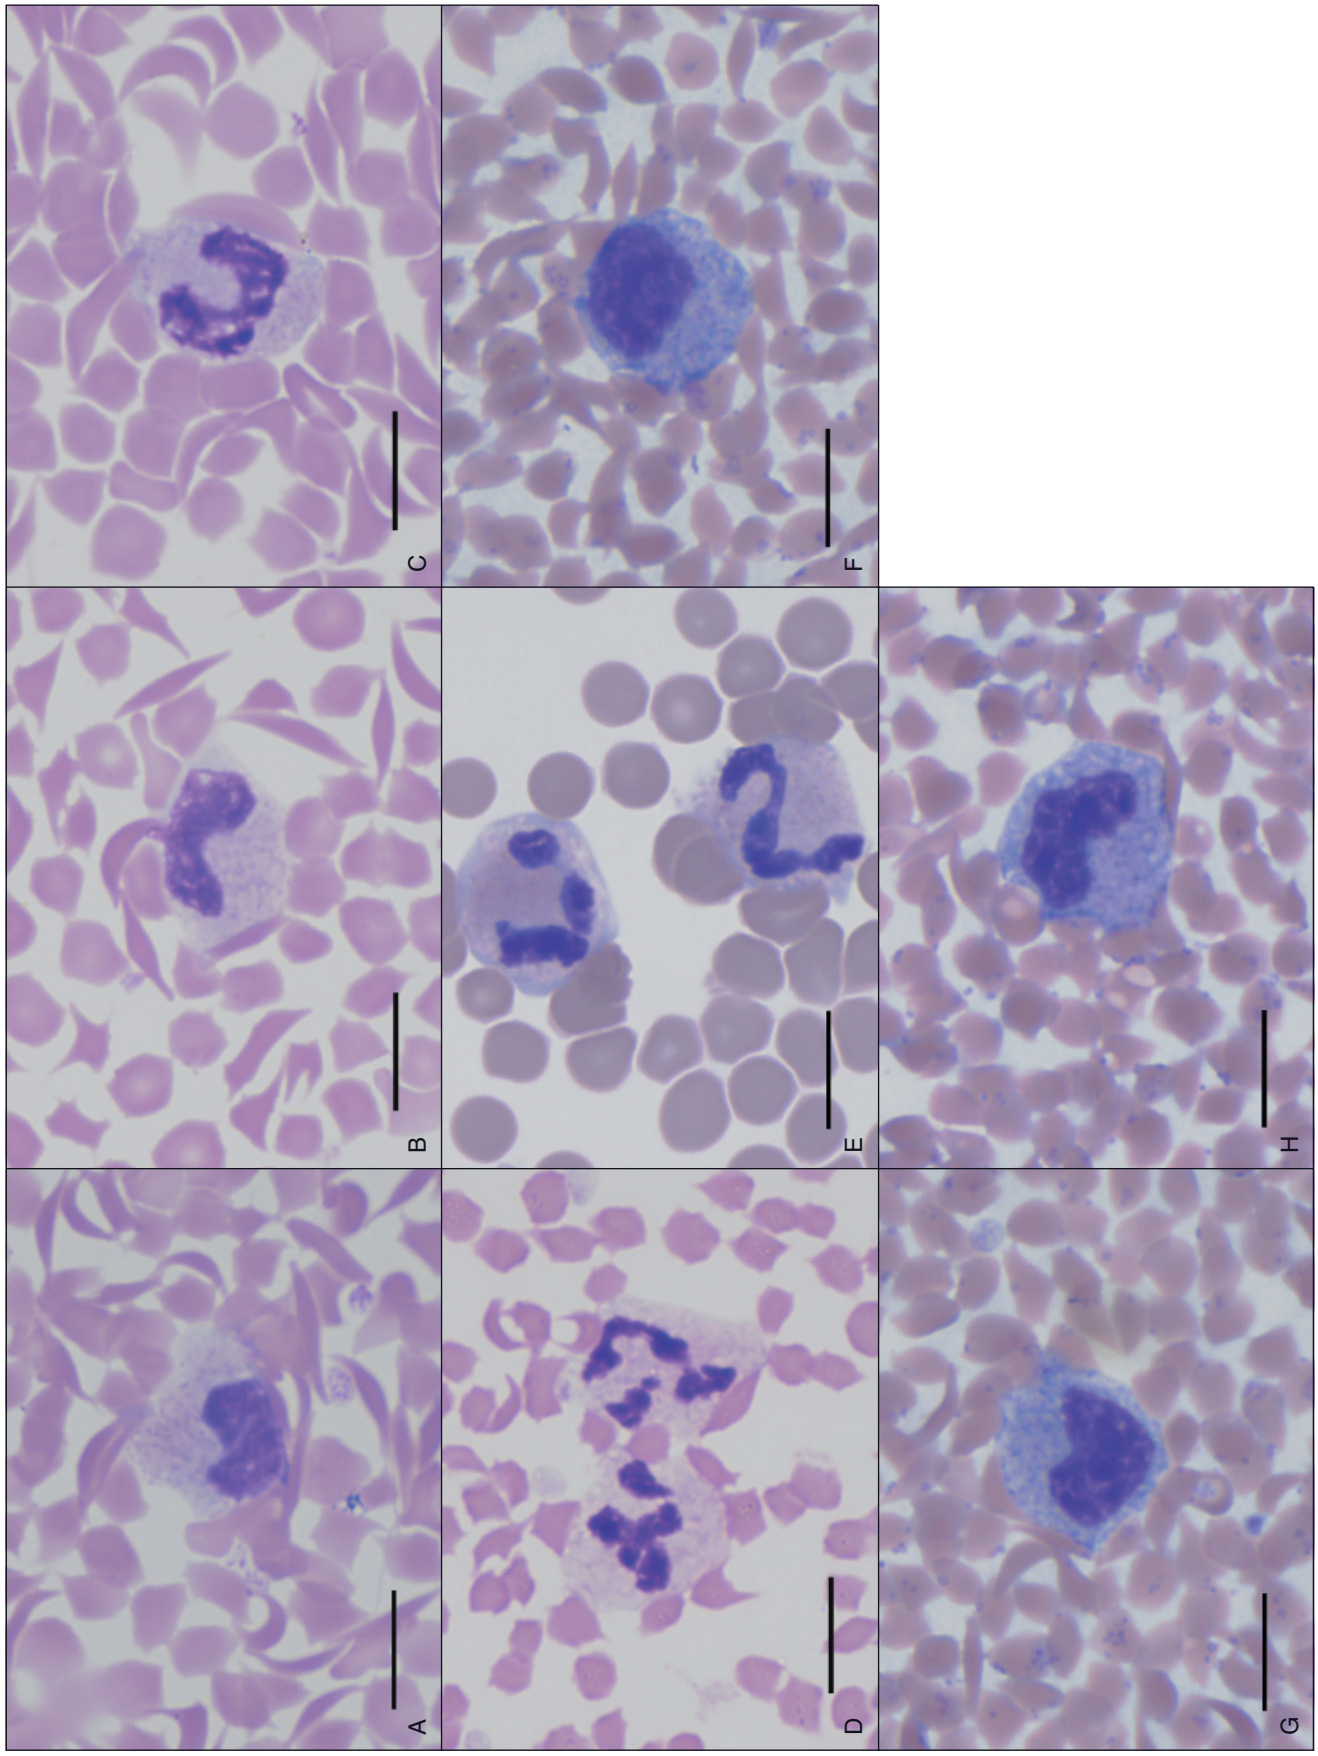

FIGURE 116.2 Normal and toxic cervid neutrophils. Modified Wright stain; bar = 10μm. (**A**) Deer, metamyelocyte neutrophil. (**B**) Deer, early band neutrophil. (**C**) Deer, late band neutrophil. (**D**) Deer, segmented neutrophils. (**E**) Wapiti (elk), segmented neutrophils. (**F**) Deer, toxic myelocyte neutrophil and *Mycoplasma* infection. (**G**) Deer, toxic metamyelocyte neutrophil and *Mycoplasma* infection. (**H**) Deer, toxic band neutrophil and *Mycoplasma* infection.

(**G**) Deer, reactive lymphocyte with basophilic cytoplasm. (**H**) Wapiti (elk), reactive lymphocyte.

Platelets

The platelets (PLT) of cervids are relatively small (Fig. 116.1A), and the reference interval is variable between different studies.[13,22,29] PLT values in physically restrained and sedated wild red deer are $344 \pm 138 \times 10^3$ and $311 \pm 117 \times 10^3$ PLT/μL, respectively.[22] Wild, physically restrained tule wapiti have PLT counts of $310 \pm 76.8 \times 10^3$ PLT/μL, with a range of $43–581 \times 10^3$ PLT/μL.[29]

REFERENCE INTERVALS

Complete blood count data from various species of deer and wapiti are depicted in Tables 116.1 and 116.2, which summarize data acquired through impedance cytometry. Data from older methodologies that utilize the hemocytometer can be found in the previous editions of this book.

Within the Cervidae, interspecies variations of "normal" hematology exist. White-tailed deer have RBC, Hgb, and packed cell volume (PCV) values that are considerably higher than those found in mule deer, black-tailed deer, or chital deer.[31] Inversely, the leukocyte count of white-tailed deer tends to be slightly lower than that reported for other species of deer.[31]

Influence of Age

Neonate and juvenile deer erythrocytes have less of a tendency to sickle. This is due to the presence of fetal hemoglobin, which precludes sickling.[17] At birth, 95% of the total hemoglobin is fetal hemoglobin. By 8–12 weeks of age, the fetal hemoglobin is completely replaced by adult hemoglobin.[17] At this age, sickling may be readily observed if the appropriate hemoglobin forms are present.

There is a distinct and direct relationship between the RBC count, Hgb, and PCV and age, regardless of sex or species.[4,21] Newborn animals have lower RBC values and higher reticulocyte counts than juveniles and adults, and juveniles tend to have lower RBC values than adults.[4,5] Increases in RBC count and hematocrit (Hct) by 40–60% from birth to 10 months of age were noted in chital deer.[4] Similar findings have been reported for captive reindeer, fallow deer, and white-tailed deer.[3,4,27,36]

There is an unclear relationship between age and white blood cell (WBC) parameters in deer. While some studies have reported wide WBC reference intervals for neonates, or failed to demonstrate a relationship between age and WBC counts, other studies have shown a correlation.[16,25,27,32] Chapple determined that the total WBC count in neonatal chital deer was significantly greater than that of juveniles or adults, largely due to increased numbers of neutrophils and a neutrophil : lymphocyte ratio of 2 : 1.[4] In adult chital deer, lymphocytes predominate.[4]

Influence of Gender

Gender-related changes in hematologic patterns are not apparent in neonates or juveniles but may be evident in adults. Chital stags have higher RBC values than females after 140 days of age. Red cell parameters were 15–22% higher in chital stags than in chital hinds, but the erythrocyte indices were lower in the stags than in the hinds. The total WBC count was significantly higher in stags.[4] Similar patterns have been noted in male and female rusa deer and farmed fallow deer.[2,36] However, this observation does not appear to be absolute, since several studies did not observe these patterns.[1,22]

Influence of Reproductive Status

Complete blood count changes due to reproductive status are seen in both male and female cervids. During the annual rutting period, chital deer stags have altered differential leukocyte counts, and red deer stags have their lowest mean RBC count.[4,5,36] Pregnancy results in significant increases in Hgb, RBC count, Hct, and mean corpuscular volume (MCV) with a decrease in mean corpuscular hemoglobin concentration (MCHC).[29,36] The WBC count also increases due to increased numbers of lymphocytes. Lactating does may have lower red cell numbers.[36]

Influence of Stress and Handling

Deer are easily excitable as a species, which is often reflected in the hematologic parameters. Red and white cell values are significantly higher in excited deer than in resting or chemically restrained deer. This is likely due to a combination of drug-specific effects in the anesthetized deer and a greater stress response, and subsequent splenic contraction, in the physically restrained deer.[21,22,30] Erythrocyte and leukocyte parameters may differ between the sexes in response to handling and restraint. This effect is most appreciable in chital does, resulting in significantly greater increases in PCV and red and white cell numbers than seen in chital bucks.[4] However, little or no difference in WBC count may be seen between excited and resting males, or between farmed male and wild female deer.[21]

Periodic handling of cervids may reduce handling stress, and subsequently impact hematologic parameters. One study observed that regularly handled hinds had reductions in their Hgb, RBC count, and Hct from 10% to 20% over time.[4] Stags did not show these distinct and sequential erythron changes with handling.[4,21] However, they did have an altered differential leukocyte count during initial sampling periods. The annual male reproductive cycle may have confounded hematologic alterations associated with adaptation to handling stress.[4]

Response to Disease

The hematologic response in deer has been evaluated in response to experimental infection with numerous

infectious agents such as epizootic hemorrhagic disease virus, bluetongue virus, and *Yersinia pseudotuberculosis*.[6,15,26] Lymphopenia was a common response. One wapiti infected with *Babesia odocoilei* presented with a normocytic normochromic non-regenerative anemia and an inflammatory leukogram, characterized by a leukopenia and neutropenia.[8]

CHAPTER 117

Hematology of Water Buffalo (*Bubalia bubalis*)

TAMARA B. WILLS

Blood
- Erythrocytes
- Leukocytes
  - Neutrophils
  - Lymphocytes
  - Monocytes
  - Eosinophils
  - Basophils
- Platelets
- Plasma Fibrinogen

Reference Intervals
- Age Related, Physiologic, Environmental, and Miscellaneous Influences Affecting the Hemogram

Acronyms and Abbreviations

ESR, erythrocyte sedimentation rate; MCV, mean corpuscular volume; PCV, packed cell volume; RBC, red blood cell; WBC, white blood cell.

BLOOD

Features of a normal water buffalo hemogram are comparable to cattle with minor variations. The morphology of the red blood cells (RBCs), white blood cells (WBCs), and platelets is similar to cattle. Differences include a faster erythrocyte sedimentation rate (ESR), lower icteric index, and greater rouleaux formation in water buffalo compared to cattle.[3,6] Tables 117.1 and 117.2 summarize reported hematology values in the literature of water buffalo, including comparisons with respect to age, sex, pregnancy, and lactation.

Erythrocytes

Buffalo RBCs are similar to those of cattle with a mean cell size of 5.5 ± 0.7 µm. Red blood cells in normal water buffalo exhibit mild anisocytosis and no significant polychromasia. Only rare Howell-Jolly bodies are found and prominent central pallor is not observed. Reticulocytes are not typically present in normal water buffalo.[2,3] Unlike cattle, slight to marked rouleaux formation is a frequent finding.[3,6]

Leukocytes

Neutrophils

Neutrophils have a mean size of 13.2 ± 0.7 µm and are multilobed or occasionally monolobed. Multilobed neutrophils have an irregular nuclear outline with 2–4 lobes and a dense chromatin pattern.[3] Monolobed nuclei have 1–2 constrictions, with decreased amounts of condensed chromatin compared to multilobed neutrophils. The cytoplasm is pale with fine indistinct, sometimes brown granules.[2,3] Band neutrophils are rarely found in normal water buffalo, but have a smooth nuclear outline with no nuclear constrictions.[3]

Lymphocytes

Similar to cattle, small, medium, and large lymphocytes are present in varying numbers, although one size frequently predominates in a single animal. The average size is 11.1 ± 1.8 µm.[2] The nuclei range from round to oval and sometimes contain a slight indentation. The nuclear pattern is frequently coarsely granular, although it appears slightly more homogeneous in larger lymphocytes. Occasional lymphocytes also contain nucleolar rings. The cytoplasm ranges from pale to basophilic and sometimes contains eosinophilic granules or clear vacuoles.[3] Larger lymphocytes can sometimes be difficult to differentiate from monocytes.[2] Similar to sheep, goats, and cattle, lymphocyte numbers frequently exceed neutrophils at approximately 1.5:1.[3]

Monocytes

Monocytes are typically larger than lymphocytes, approximately 15.4 ± 1.5 µm in size, with an amoeboid

nucleus and a lacy to granular chromatin pattern.[2] The cytoplasm is basophilic, frequently containing vacuoles, although sometimes it appears granular. Azurophilic granules are occasionally noted in the cytoplasm.[3]

Eosinophils

Eosinophils are approximately 13.9 ± 0.9 µm in size and are less lobulated, with a smoother nuclear outline than neutrophils.[2] The cytoplasm contains uniform, round, bright pink granules which fill the pale cytoplasm.[3]

Basophils

Basophils are approximately 13.4 ± 1.0 µm in size and contain numerous purple round to rod shaped granules that frequently obscure the nucleus.[2]

Platelets

Platelets are abundant and present individually as well as in clumps. Platelets range from round to elongate in shape and frequently contain distinct, variably sized purple granules. Platelet size ranges from 2.4 to 3.0 µm but can be larger.[2,3]

Plasma Fibrinogen

Fibrinogen levels are lower in water buffalo calves compared to 6 month old and adult water buffaloes. One study reported that 2 week old water buffalo calves had a mean plasma fibrinogen level of 530 mg/dL compared to 6 month old buffaloes with a mean plasma fibrinogen concentration of 820 mg/dL.[8] Other reported fibrinogen levels are 513 ± 62 mg/dL, 615 ± 90 mg/dL, and 544 ± 74 mg/dL for buffalo calves, lactating buffaloes, and non-lactating buffaloes, respectively.[5]

REFERENCE INTERVALS

The impact of age, environment, corticosteroid administration, response to endotoxin, and some miscellaneous environmental conditions on the hemogram have been reported.

Age Related, Physiologic, Environmental, and Miscellaneous Influences Affecting the Hemogram

Hematologic differences with respect to age include differences in the packed cell volume (PCV), mean corpuscular volume (MCV), ESR, and the neutrophil to lymphocyte ratio. For example, the PCV of water buffalo decreases between 1 and 3 months of age and increases gradually to 6 months, stabilizing at approximately 24 months of age (Table 117.1). Total leukocyte counts are also slightly lower in newborns compared to adults (Table 117.2).[7,10] The MCV increased in one study at 1 month of age with a concurrent decrease in PCV and then decreased to adult values.[7] A separate study reported a similar change in MCV in young calves 0–3 months of age compared to adults.[10] The variations in MCV reported in the literature may be affected by the environment, parasite control, and differences in nutrition and husbandry. The neutrophil to lymphocyte ratio decreases gradually from birth to adulthood due to a decrease in neutrophil numbers and a gradual increase in lymphocytes.[7,10] The ESR increases gradually and is highest in adults and is associated with a concurrent increase in whole blood viscosity.[8]

Leukocyte responses due to corticosteroid injection have been evaluated in buffalo calves. A single injection of corticosteroid, either prednisolone or dexamethasone, resulted in a leukocytosis with a neutrophilia and no left shift, lasting from 2 to 24 hours. Prednisolone administration also caused an initial monocytosis 2–8 hours post-administration and an eosinopenia and basopenia by 6 hours post-administration. Interestingly, a lymphopenia was not evident after prednisolone administration. Inconsistent changes were noted in lymphocyte, monocyte, eosinophil, and basophil numbers after dexamethasone administration. The lack of a lymphopenia with steroid administration is dissimilar to many other species.[4]

Very little research has been performed to evaluate the impact of the environment on the water buffalo hemogram. Spray cooled and wallowing buffalo had lower RBC numbers, hemoglobin concentration, and PCV compared to those in normal environmental temperature.[1]

Other miscellaneous influences on the water buffalo hemogram include gender, diurnal variations, and response to endotoxin. Differences between males and females have been reported, the most significant being that males frequently have increased hemoglobin content and sometimes PCV compared to females (Table 117.1).[10] Diurnal variations in leukocyte numbers have also been suggested in water buffalo calves.[4]

Hematologic changes are observed in response to endotoxin injection and are dose dependent. Low dose endotoxin injection (10 µg) resulted in mild leukopenia and mild lymphopenia and a moderate neutrophilia 6 hours post-administration. A trend toward a more significant leukopenia, neutropenia, and lymphopenia was noted with higher doses of endotoxin. A rebound neutrophilia was not observed after endotoxin administration, although numbers of neutrophils returned to normal by 6 hours for endotoxin doses of 50 µg or less and within 24 hours for doses of 100 µg endotoxin.[4]

CHAPTER 118

Hematology of the American Bison (*Bison bison*)

KURT L. ZIMMERMAN, DAVID M. MOORE, and STEPHEN A. SMITH

Blood Collection
Morphology and Numbers of Peripheral Blood Cells
Erythrocytes
Leukocytes
Reference Interval Influences

Acronyms and Abbreviations

CBC, complete blood count; Hgb, hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; PCV, packed cell volume; RBC, red blood cell; WBC, white blood cell.

BLOOD COLLECTION

Venipuncture sites for blood collection in the American Bison (*Bison bison*) include the jugular vein and coccygeal (tail) vein, using the same techniques that would be used in domestic cattle. Blood collection can be accomplished in an unanesthetized animal when restrained within a squeeze chute.

MORPHOLOGY AND NUMBERS OF PERIPHERAL BLOOD CELLS

Reported hematologic values for American Bison are provided in Tables 118.1 and 118.2.[1,2,4,7,13,14,17,19,21,22] The morphology of erythrocytes, leukocytes, and platelets (Figs. 118.1, 118.2, 118.3, 118.4) in bison is comparable to that observed in domestic cattle (*Bos taurus*).[1,2,11,13–15,17,19,21,22] These hematologic morphological similarities with domestic cattle extend to the presence of similar red-cell antigens (A, B, C and F of various systems).[3,16] However, unique red cell antigens and hemoglobin types are also recognized.[3,10,20]

Erythrocytes

The average packed cell volume (PCV) in bison is approximately 47% (range, 24–61%). Compared with reported values for domestic cattle, sheep, and goats, the following parameters are higher in bison: red blood cell (RBC) counts, PCV, and the hemoglobin (Hgb) concentration. The average Hgb in bison is about 16.8 g/dL (range, 8.2–23.0 g/dL).[1,2,11,13,14,19,21,22]

Leukocytes

The following leukocyte parameters are comparable with reported values in domestic cattle, sheep, and goats: white blood cell count (WBC), neutrophil count, lymphocyte count, eosinophil count, and monocyte count.[18] Lymphocytes outnumber neutrophils in both bison and domestic cattle. This is in contrast to earlier reports that indicated that the neutrophil:lymphocyte ratio in bison was opposite to that observed in cattle.[14,19] The average total leukocyte count for all ages and sexes of bison is $8.0 \times 10^6/\mu L$ (range, $1.0 \times 10^6/\mu L$ to $18.4 \times 10^6/\mu L$).[1,2,11,13,14,19,21,22]

Reference Interval Influences

Bison calves have significantly higher RBC counts than do adult bison, which is also the case with calves of domestic cattle.[18] Average oxygen-carrying capacity was 17.0 mL/100 mL from calf blood and 22.2 mL/100 mL blood from adult blood; Hgb concentration averaged

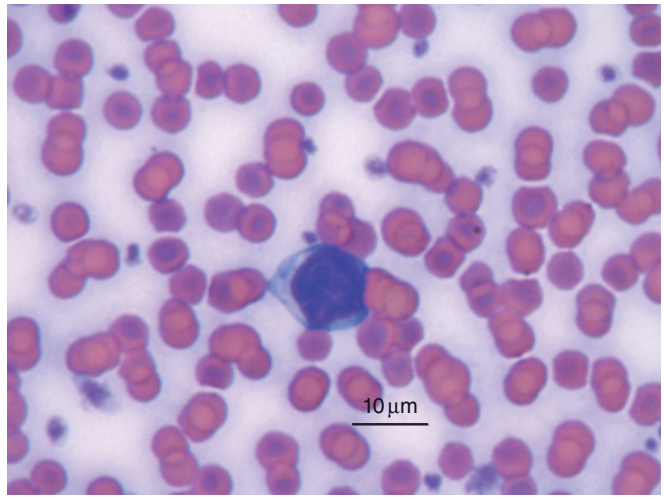

FIGURE 118.4 Lymphocyte of the American Bison (*Bison bison*). 100× objective; Wright's stain.

13.6 g/dL in calves and 17.1 g/dL in adults.[6] Other age related variations in bison complete blood count (CBC) results include: RBC, monocyte, hematocrit, and neutrophil numbers which are negatively correlated, while lymphocyte numbers are positively correlated with increasing age.[1]

Bison raised and/or maintained under ranch conditions comparable to those used in beef cattle operations have similar hematologic values as free-ranging bison living on range lands or in national parks.[19] However, an increase in the PCV is seen in free-ranging wild bison impounded for 24 hours before blood collection.[7] Seasonal variation in the PCV, mean corpuscular hemoglobin concentration (MCHC), mean cell volume (MCV), and Hgb values are observed and may be a factor in establishing reference intervals.[4]

Variation of hematologic values from those summarized above have been specifically reported in bison in association with infection with *Trypanosoma theileria* and *T. evansi*, *Theileria annulata*, *Mycobacterium bovis*, and Degnala disease.[5,8,9,12,15]

Acronyms and Abbreviations

CBC, complete blood count; Hgb, hemoglobin; LGL, large granular lymphocyte; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; PCV, packed cell volume; RBC, red blood cell; WBC, white blood cell.

Routine hematology is not often performed in reindeer (*Rangifer tarandus*; order Artiodactyla, family Cervidae), but reindeer hematology has received more attention than usual in recent years. A new hemomycoplasma organism that may cause anemia in reindeer was recently identified.[7] An unrelated reindeer was diagnosed with a potentially new *Theileria* sp. most similar to *Theileria cervi* type F (B.C. Garner, in preparation). With the introduction of these previously unidentified infectious agents it becomes increasingly important to know what is normal for a healthy reindeer. Several factors can affect the hematologic parameters of normal reindeer. Such variables include the animal's age, gender, and reproductive status, as well as the stress of blood collection. These effects on the normal components of the reindeer complete blood count (CBC) are discussed in this chapter.

PROPERTIES OF BLOOD CELLS

Erythrocytes

The erythrocytes of reindeer are discoid with an average diameter of 5.5 µm.[3] A standard peripheral blood smear from a healthy animal shows mild anisocytosis, but polychromasia is rare. Central pallor, although present, is often indistinct. Reindeer erythrocytes do not sickle *in vitro* when exposed to oxygen like erythrocytes from others within the Cervidae family (discussed in Chapter 116), and rouleaux formation is uncommon.[3]

Leukocytes

The morphology, cytochemistry, and ultrastructure of reindeer leukocytes have been extensively studied (Figs. 119.1–119.6).[2,3] On a stained peripheral blood smear, the granulocytes and mononuclear cells of reindeer can be readily identified.

Neutrophils

Neutrophils comprise nearly half of all leukocytes (Table 119.1).[1,3] They are typically 18–25 µm in diameter with pale eosinophilic cytoplasm. Reindeer neutrophils may occasionally exhibit a low number of basophilic cytoplasmic granules. The nuclei resemble those of other species, but they may be more segmented with up to seven lobes.[2]

Lymphocytes

Lymphocytes are typically the second most abundant leukocyte in healthy reindeer. Their diameters range

from 15 to 35 µm, and they may be round, oval, or angular in shape, with variable nuclear to cytoplasmic ratios. The cytoplasm, which is usually lightly basophilic, may contain a few fine azurophilic granules. This cellular morphology is consistent with that of large granular lymphocytes (LGLs).

Eosinophils

Eosinophils are slightly larger than neutrophils at 25–30 µm in diameter. The red-orange cytoplasmic granules are typically small and round, with an electron-dense appearance via electron microscopy.[2] The granules frequently exhibit polar or bipolar clustering as they form aggregates on one or both sides of the nucleus.[2]

Monocytes

Monocytes have reniform to oval-shaped nuclei with pale, blue-gray cytoplasm on peripheral blood smears. Occasionally, there are clear cytoplasmic vacuoles and a small quantity of red-to-pink cytoplasmic granulation.[2]

Basophils

The reindeer is somewhat unique in that it has two distinct basophil populations (Fig. 119.7). The first has the typical appearance noted within most other mammals. These are characterized by numerous, pale to dark basophilic granules throughout the entire

cytoplasm. The second population is cytologically similar to "gray" basophils seen in limited other species. These cells have variable numbers of clear cytoplasmic granules (or vacuoles) that are less than 1.0 µm in diameter interspersed with variable numbers of intensely basophilic, perinuclear granules of similar size. The perinuclear granules may obscure a portion of the nucleus and make it appear tattered or deformed. Both basophil populations can be identified within the same blood smear, and the relative proportions of each can vary between individuals.[2]

Platelets

The platelets of reindeer are relatively small (Fig. 119.7), and the reference interval for platelet quantity is wide (Tables 119.1, 119.2).

TABLE 119.2 Hematological Reference Values for Healthy Reindeer of Different Ages

	Newborn (0–14 days) *n* = 11		Juveniles (1–18 months) *n* = 22		Adults *n* = 30

REFERENCE INTERVALS

Effects of Age

Age has several effects on hematologic values (Table 119.2). Compared to juveniles and adults, newborns have lower hemoglobin (Hgb) levels, red blood cell (RBC) counts, and packed cell volume (PCV).[1,8] Mean corpuscular hemoglobin concentration (MCHC), white blood cell (WBC) count, and eosinophil counts are also often lower in newborns compared to juveniles. In contrast reticulocyte and platelet counts are higher in newborns. Marked red cell anisocytosis and poikilocytosis can be found in blood smears from healthy newborn reindeer, but only mild anisocytosis is expected in normal adults. Basophilic stippling and a small number of nucleated RBCs may also be identified in the neonates.[1]

Juveniles (up to 18 months old) have the highest Hgb and PCV values. Lymphocyte and RBC counts are also higher in juveniles than adults. Reindeer hematologic values stabilize at approximately 5 months of age; therefore, adult reference intervals may be useful when interpreting data from animals 5 months or older if juvenile reference intervals are not available.[3,8]

Effects of Gender

Adult females living in zoological parks have higher Hgb, PCV, mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and WBC counts than adult males (Table 119.1).[8] These values are higher (and may peak) in females during the autumn months.[8] Published CBC data from two adult female and two adult male reindeer living on a Michigan farm fell within these previously established reference intervals, but the disparities between the males and females were less drastic.[2] Significant differences between newborn and juvenile males and females are not reported as gender-related variations in hematologic parameters typically become more significant with sexual maturity and adulthood.[1]

Effects of Reproductive Status and Seasonal Changes

The Hgb concentration of pregnant females decreases by approximately 3 g/dL during winter and decreases further following parturition.[8] Hemoglobin increases sharply during the summer toward its peak in autumn. Plasma total protein concentrations decline during winter and are at their lowest in May and their highest in October.[5] Similar fluctuations due to changing seasons and reproductive status are reported in other hematologic parameters.[8]

Effects of Blood Sampling

A stress response to various handling conditions has been repeatedly demonstrated in reindeer.[4,6] As reported in other species, reindeer stressed during venipuncture may demonstrate lymphopenia and eosinopenia, as well as moderate increases in PCV, Hgb and RBC count.[4] Another study showed five- to six-fold increases in plasma cortisol and significant increases in plasma noradrenaline during manual blood sampling of eight mature reindeer.[6]

ANAE, alpha naphthyl acetate esterase; ANBE, alpha naphthyl butyrate esterase; CAE, chloroacetate esterase; CO, carbon monoxide; DCF, dichlorofluorescein; DCFH, dichlorofluorescein; ESR, erythrocyte sedimentation rate; Hgb, hemoglobin; LAP, leukocyte alkaline phosphatase; Mgb, myoglobin; MCV, mean corpuscular volume; PAF, platelet activating factor; PCV, packed cell volume; RBC, red blood cell; TEM, transmission electron microscopy.

Hematology values are available for two main species of elephants. The Asian elephant, *Elephas maximus*, has lived in human society since the time of ancient India, while the African elephant, *Loxodonta africana*, has not been as closely associated with human culture and is more difficult to manage in captivity.

Accurate interpretation of CBC results for elephants depends on the ability to correctly identify leukocyte morphology and cell types.

BLOOD AND BONE MARROW COLLECTION

A blood volume of over 100 L was measured in an Asian elephant weighing 3216 kg.[29] This represents a blood volume of approximately 3.5% body weight. Blood can be collected from several of the subcutaneous auricular veins located on the medial (caudal) surface of the ear. Many elephants are trained to allow access to the ear for routine venipuncture while standing and are not physically restrained or sedated. Alternatively, the elephant can be trained to lie down on the ground. For access, the ear must be pulled forward and away from the skin of the neck by the handler or assistant. The collector stands caudal to the ear where the caudal surface can be examined and palpated. The skin of the ear should be wiped clean of loose debris; the selected site should be cleaned and prepared for standard aseptic venipuncture. Care must be taken to distinguish the soft fluctuant veins from the firm, pulsatile arteries of the ear. Collection from one of the auricular arteries produces subcutaneous hematomas that can occasionally leave disfiguring fibrous scars in the ear. In general, the ear veins are subject to large fluctuations in size due to temperature and blood pressure dependent factors. The veins of the ear can be very difficult to visualize or palpate if attempting to collect blood when the air temperature is below 21 °C (70 °F). Placing mild heat to the medial surface of the ear for several minutes with a warmed moist towel or forced heated air can help dilate the veins; however, care must be taken not to cause thermal injury to the skin of the ear. Alternatively, auricular vasodilatation can be induced by vigorously exercising the elephant prior to blood collection or by allowing the animals to stand outside in the sun.

Due to the thickness of the skin, there are few other venipuncture sites available for blood collection. The lateral (anterior) surface of the ear may have visible veins. The medial saphenous veins located on the inner surfaces of the hind legs are accessible for venipuncture. These large vessels are usually visible and not as subject to variations in size due to ambient temperatures. To provide safe access to this site, the animal must be

trained to allow manipulation of the vein without moving or kicking. Blood can also be obtained from the ventral tail vein as described in bovine species. Any collected blood should be placed in EDTA anticoagulant tubes and refrigerated until processed.

Although elephant bone marrow has not been well described to date, a technique for its collection has been described but is rarely performed.[4] Bone marrow is absent from the ribs and long bones of elephants, but is present in the dorsal spinous processes of the first lumbar vertebra.[22]

ERYTHROCYTES

Elephants have the largest erythrocytes of terrestrial mammals, measuring an average of 125 fL. Early reports in the 1950s report mean cell volumes of up to 168 fL.[7] The packed cell volume (PCV) averages around 35% and ranges from 25% to 45%, similar to domestic livestock.[23,30,31] The red blood cell (RBC) count is lower at an average of $2.9 \times 10^6/\mu L$ and ranges from $1.7 \times 10^6/\mu L$ to $5.0 \times 10^6/\mu L$ in nonpregnant adults.[23,31] Pregnant females have been reported to have a lower average RBC count of $1.8 \times 10^6/\mu L$ and a PCV of 30% with increased erythrocyte sedimentation, likely due to volume expansion and hormonal effects during fetal development.[23] These numbers are remarkably similar to one of the elephant's closest evolutionary cousins, the manatee.[13]

The degree of anisocytosis is similar to that observed in the manatee and in cattle.[13] Low numbers of Howell-Jolly bodies may be found if blood films are scanned at low power. Elephant RBCs have a high resistance to osmotic lysis, which may be related to the large surface/volume ratio of the biconcave disc.[32] The lifespan of the elephant RBC has not been reported at this time.

Reticulocytes are typically absent from the blood of apparently healthy African and Asian elephants.[1,14,15] Nucleated erythrocytes are very rarely recognized in healthy animals and should be considered an abnormal finding. Reticulocytes may be observed in the blood of anemic elephants.

The erythrocyte sedimentation rate (ESR) has revealed dramatically different results in different authors' hands: 29 mm/hr, [39] 21–62 mm/hr (African) and 36–64 mm/hr (Asian),[5] and a mean of 120 mm/hr with a range of 64–148 mm/hr.[31] This is quite rapid in elephants, either due to erythrocyte size, the ability of elephant RBC to form rouleaux, interaction with the protein matrix, or most likely, a combination thereof. Though this analysis is now rarely performed clinically, this may be important when considering sample handling in the laboratory, or post-mortem collection. Cells will settle very rapidly and accurate quantification requires continuous rocking.

It has been reported that an increased PCV due to splenic contraction and stress is unlikely as the splenic capsule has been reported to be fibrous similar to a cow.[22] To date, increased PCV due to stress and splenic contraction has not been documented in the elephant.

Elephant hemoglobin (Hgb)[19,28] and myoglobin (Mgb)[18] studies reveal some structural changes at the protein level. Elephant Hgb has been sequenced and found to have alpha-chains that differ by 24 exchanges and beta-chains by 27 exchanges from the human sequence. There are only five phosphate binding sites, similar to that of the llama. The elephant has a low $Po_2 50$ and reduced interaction with 2,3-bisphosphoglycerate in comparison to humans.[19] Elephant Mgb has glutamine in the distal, heme-binding position instead of histidine. Elephant Mgb has a carbon monoxide (CO) affinity approximately six times higher than that of human or sperm whale Mgb,[18] and reacts with nitric oxide 500–1000 times faster than does human Mgb.[28] It is postulated that new interactions resulting from the conformational change accompanying ligand binding may be responsible for the increased CO binding.[18]

LEUKOCYTES

A combination of Wright-Giemsa, cytochemical stains, and transmission electron microscopy (TEM) demonstrates that all elephant leukocyte types other than monocytes are similar to other mammalian leukocytes, as shown in Figure 120.1. Monocytes with round to pleomorphic to distinctly bilobed nuclei are found in elephants.

Asian and African elephants have heterophils rather than neutrophils. Using light microscopy under 400× power, Wright-Giemsa stained elephant heterophils measure 12–16 µm in diameter. Heterophil nuclei contain dark, coarsely clumped chromatin and are moderately lobulated with an average of four to five segments, similar to equine species. The large quantity of clear to light blue cytoplasm generally contains more than 30 fine, variably sized, round, oval or rod shaped pink granules. The fine granules in some heterophils stain weakly to moderately positive with peroxidase while other heterophils are negative for peroxidase stain. Individual variability between elephants is noted. Heterophils also stain slightly to moderately positively for leukocyte alkaline phosphatase (LAP) and chloroacetate esterase (CAE). Heterophils are negative for both alpha naphthyl acetate esterase (ANAE) and alpha naphthyl butyrate esterase (ANBE). Heterophil granules are round and are 400–700 nm in diameter or can be elongated, oblong structures up to 670 nm × 600 nm, as seen using transmission electron microscopy (TEM). There are two types of distinct granules present, with primary granules being larger and electrolucent. The secondary granules contain a distinct band of electrolucency. Heterophils contain few mitochondria and varying numbers of tubulovesicular structures as well as numerous vacuoles. Vacuolation is observed to increase with toxic change in the heterophil line.

Oxidative metabolic burst activity of Asian elephant heterophils and Holstein cattle neutrophils has been compared indirectly using the oxidation of non-fluorescent intracellular dichlorofluorescein (DCFH) to fluorescent dichlorofluorescein (DCF).[33] Phorbol myristate

acetate was used to activate the cells. Elephant heterophils and bovine neutrophils oxidized intracellular DCFH to DCF in a similar manner. A wide range of mean channel fluorescence intensity (1803–7393) was observed among individual elephants which was similar to that observed in the bovine neutrophils.

Elephant lymphocytes evaluated with Wright-Giemsa stain on light microscopy are variable in size, ranging from small to large. Medium sized lymphocytes predominate in most animals. In some apparently healthy animals there is a predominance of large lymphocytes. Nuclei are round to oval and occasionally

cleaved. Chromatin is diffuse in larger cells but in smaller cells is denser with 1–3 chromocenters. There is a scant rim of pale basophilic cytoplasm which rarely contains large purple granules approximately 2 µm in diameter. Lymphocytes do not stain with peroxidase, CAE, or alkaline phosphatase stains and only occasionally show focal staining with ANBE stain (Fig. 120.1). Ultrastructurally, lymphocytes are agranular or contain a few round to oval granules ranging from 100 to 200 nm in diameter with homogeneous or granular matrices of varying electron density, and occasional myelin figures. Lymphocytes contain many mitochondria and varying numbers of tubulovesicular structures.

Discrepancy in the literature regarding a unique bilobed leukocyte and differentiation of lymphocytes and monocytes[1,11,22,30,31] has resulted in highly variable and imprecise results, likely due to misidentification of this cell type. The bilobed cells are identical in cytochemical staining to the traditional monocyte. Monocytes are typically positive for peroxidase while lymphocytes are typically negative for peroxidase. The presence of small granules and phagocytic vacuoles with rare mitochondria on electron microscopy supports identification of both the bilobed cell and round nuclear cell types as monocytes (see below).

Monocytes of three distinct morphologies are present in elephant blood. The monocyte typical of most domestic mammals, with a rounded, polymorphic nucleus with clumped chromatin and moderate quantities of vacuolated basophilic cytoplasm when stained with Wright-Giemsa, is also present in elephants in low numbers. The overall cell size is >20 µm. The second type of monocyte is bilobed, with an overall cell size approximately 16–18 µm diameter. The nuclei are horseshoe-shaped to bilobed, and the cytoplasm is lightly basophilic using a Wright-Giemsa stain. The cytoplasm has an irregular border with cytoplasmic vacuoles occasionally present. It is also important to note that there are monocytes that, when spread on a glass slide, appear to have a round to oval to slightly indented nucleus similar to the lymphocyte population. The chromatin pattern, however, is coarse to clumped and vacuoles are typically present in the relatively small amount of cytoplasm. When stained with peroxidase these cells, especially the vacuoles, are moderately peroxidase positive which clearly differentiates them from nearby lymphocytes (Fig. 120.1).

All monocytes have 1–2 positive granules when stained with peroxidase, indicating a phagocytic function. This weak staining was also found in a study of the bilobed leukocyte in African elephants.[1,38] When stained with peroxidase, monocytes demonstrate weak peroxidase activity in rats,[37] humans, and other species.[3,16,17,24] The peroxidase activity in the bilobed leukocyte provides further evidence that these are not likely to be lymphocytes, which lack myeloperoxidase granules.

The monocytes are usually negative for CAE; however, weak positive areas that may be vacuoles, are present in a few monocytes. Chloroacetate esterase typically stains positively in neutrophils and mast cells. Monocytes of other species have been noted to be weakly reactive with this stain.[16] In contrast, lymphocytes, plasma cells, eosinophils and blast stages of erythrocytes will all stain completely negative.

All of these monocytes are negative for LAP, ANAE, and ANBE. Alkaline phosphatase may be found in mature neutrophils/heterophils in some species, thus supporting evidence that this unique cell type is not of the neutrophil line.

Ultrastructurally, round monocytes contain small numbers of round granules, 200–300 nm in diameter, with granular matrices of variable electron density. Mitochondria are numerous, and tubulovesicular structures are present in varying numbers. There are rare, diffuse granules present along with vacuoles surrounded by an indistinct membrane. Ultrastructurally, bilobed monocytes are also similar to the round monocyte type. They contain small numbers of round granules, varying from 100 to 300 nm in diameter, with granular matrices of variable electron density surrounded by an indistinct membrane. Mitochondria and tubulovesicular structures are present in varying numbers. The bilobed cell type has a larger nucleus relative to cytoplasm volume than the traditional monocytes encountered. Additionally, the bilobed monocyte has a slightly smaller cell size than the more typical monocyte.

Eosinophil cell size varies from 14 µm to 18 µm in diameter. Nuclei are trilobed, bilobed, or band-shaped, and have coarsely clumped chromatin that is less condensed than neutrophil chromatin. Nuclei are 6–7 µm × 11–12 µm in size. Eosinophils have pale basophilic cytoplasm, with a staining intensity intermediate between neutrophils and mononuclear cells. The eosinophil granules are red-orange, round, less than 1 µm in diameter, and distinctly separate. On peroxidase, numerous, strongly positive, ovoid granules are present. When stained for CAE using a purple chromagen, eosinophils have a diffuse, pale, orange background with refractile granules suggesting a negative reaction. Eosinophils are negative for alkaline phosphatase; however, both ANBE and ANAE produce a strong reaction. Ultrastructurally, eosinophil granules are round to oval and vary from 300 to 600 nm in size. The granular matrix is moderately electron dense and homogeneous, with a tendency towards greater electron density near the periphery. Few mitochondria and varying numbers of tubulovesicular structures are present.

Basophils measure 14–18 µm in diameter. The cytoplasm is clear to basophilic and contains lavender to magenta staining punctate granules. Nuclei are bilobed to band shaped with clumped chromatin that is not as coarse as heterophils. Because there are generally low numbers in patient samples, these cells are only confirmed in peroxidase stain. Basophils are negative when stained with peroxidase, which is consistent with findings in rats and humans.[2] Further study is required. One study of 23 elephants found basophils in only two of the individual animals.[39] Reported reference intervals indicate a mean value of less than 40 basophils/µL in African elephants and 160/µL in Asian elephants.[5] A

TABLE 120.1 Summary of Results of Cytochemical Staining for Elephant Leukocytes and Platelets

summary of cytochemical reactions for leukocytes and platelets is shown in Table 120.1.

PLATELETS AND COAGULATION

In observations by chapter authors, using a CellDyn 3500, platelets were found to range from $342 \times 10^3/\mu L$ to $719 \times 10^3/\mu L$ in Asian elephants, with a relatively small mean platelet volume. This is similar to the literature which reports $540 \times 10^3/\mu L$ to $637 \times 10^3/\mu L$ in Asian elephants and $294 \times 10^3/\mu L$ to $455 \times 10^3/\mu L$ in African elephants.[5] It should be noted that the reported reference intervals from the literature are based on post-mortem samples and are likely lower than would be found in well-handled samples from live animals.

A detailed study of blood platelets and their function in four captive Indian elephants found relatively high platelet counts, with a mean of $637 \times 10^3/\mu L$.[20] Aggregation with ADP and collagen was less marked than in human platelet-rich plasma.[20] Asian elephant platelets were highly responsive to stimulation with platelet activating factor (PAF) and collagen, less responsive to ADP and non-responsive to arachidonic acid, serotonin, and epinephrine.[9] The cyclooxygenase inhibitor, acetylsalicylic acid, produced no inhibition of either collagen or PAF induced aggregation.[9] On ultrastructural examination, the unactivated elephant platelets contain large randomly distributed granules but lack the internal cristae that usually comprise the open canalicular system in many types of mammalian platelets.[6] After PAF administration, large platelet aggregates form, but some platelets lack pseudopod formation or fusion of membranes while other behave as would be expected. The lack of platelet membrane fusion within the aggregates may permit the reversal of aggregation that is characteristic of the elephant platelet response to PAF.[6]

General coagulation studies have revealed that clotting factor concentrations are considerably higher in elephant whole blood than in human whole blood.[14,20] The average factor VIII:C value in one study was 1.95 units/mL, approximately twice that of the human value.[10] Human recombinant tissue factor was effective in activating the tissue factor-factor VII pathway, as measured by the prothrombin time assay. Elephant factor XII was not readily activated by the commercial activated partial thromboplastin time (APTT) reagent formulated with a soluble activator. The average APTT results were twice as long as that of the human reference plasma.[10] In contrast, and likely due to a difference in activating reagents, Indian elephant blood has been reported to clot rapidly, with APTT results less than in humans though similar to other mammals. Coagulation was reported to be less rapid in the African elephant.[14] Relatively high fibrinogen concentrations, $4.6 \pm 0.5\,g/L$, have also been reported in elephants[10] which are consistent with the findings presented in Table 120.2.

REFERENCE INTERVALS

Hematologic reference intervals are useful in health assessment and diagnosis of disease in exotic species, which frequently suppress their clinical signs. For many species, however, such reference intervals are lacking, as they are based on few samples, are produced from an inadequately described population of animals, and/or do not report laboratory methodologies. Though elephant blood has been studied for many years, the original reference intervals of elephant hematology were often generated from post-mortem samples with extensive transport times in the heat.[5,8,36] Caution must be used when examining older reports or citations thereof and hemolysis must be considered when values seem abnormal.

In the twentieth century, reference intervals for elephants have varied significantly because of inaccurate differential cell counts where the different forms of monocytes were counted as lymphocytes. One study counted the bilobed and round cell type as lymphocytes in African elephant blood, which resulted in 60–80% relative lymphocyte counts.[8] In another study, a review of Asian elephant blood revealed that nearly 30% of cell counts listed as lymphocytes were monocytes.[28] An additional study counted the bilobed cells as lymphocytes with relative counts of 73% lymphocytes and 3% monocytes.[20] Silva and Kuruwita counted the bilobed cells as monocytes, but counted all cells with round nuclei as lymphocytes;[30,31] this resulted in

TABLE 120.2 Hematological Reference Intervals for Asian elephants (Elephas maximus)[a]

	No.	Mean	S.D.	Reference Range
RBC ($\times 10^6/\mu L$)	20	2.9	0.4	2.1–3.6
Hgb (g/dL)	20	12.3	1.26	9.6–15.3
PCV (%)	20	35.7	3.79	27–44
MCV (fL)	20	125	7.42	111–138
MCHC (g/dL)	20	34.7	0.58	33.4–35.7
RDW	18	16.8	1.08	14.9–18.7
Fibrinogen (mg/dL)	20	400	137.17	100–600
Platelets ($\times 10^3/\mu L$)	18	513	98.43	342–719
WBC ($\times 10^3/\mu L$)	20	13.6	2.7	8.6–18.2
Bands/μL	20	0	0	0.00–0.00
Segmented neutrophils/μL	20	3180	820.59	1800–4300
Lymphocytes/μL	20	2650	1456.64	990–5000
Monocytes/μL	20	7140	2751.96	1600–12600
Eosinophils/μL	20	220	172.94	0–580
Basophils/μL	20	50	60.88	0–150
Plasma protein (g/dL)	20	8	0.66	6.7–9.3

[a]Complete blood cell counts were performed using Cell Dyn 3500 (Abbott Diagnostics, Inc, Abbott Park, IL) with manual differentials using modified Wright-Giemsa staining. The reference intervals are based on $n = 25$ adult, predominantly female Asian elephants assessed as normal by physical exam and behavior over a 1 year time period. Animals were determined to be negative for tuberculosis.

relative lymphocyte counts of 38% and monocyte counts of 29%. Because monocytes with round nuclei are common in blood, this is likely still an overrepresentation of the lymphocyte population. Though these publications are older, inaccurate differential cell counts still regularly occur in practice today. When evaluating the published literature for reference intervals, one must pay particular attention to the standard deviation of the lymphocyte and monocyte counts. If the standard deviations are large, it is likely that inconsistent cell identification has been included in the reference interval. ISIS reference intervals, often cited as normal values for elephants, have lymphocyte and monocyte counts with large standard deviations and may be an example of inconsistent cell identification (see International Species Information System, http://www.isis.org/CMSHOME/).

The importance of accurate hematology reference intervals cannot be underestimated. Monocytosis can be an indicator of chronic inflammation in most species. Although monocytes generally have less potent bactericidal activity than neutrophils, they are important components of response to bacterial, viral, and fungal infections. Considering their predominance, it is likely that these cells play a crucial role in fighting infection in elephants. Highly variable, inaccurate reference intervals prevent the clinician from accurately assessing this important cell type. The authors have presented reference intervals (Table 120.2) for a small population of elephants that have been confirmed to be healthy with behavioral, physical, and laboratory examinations for over a 1 year time period. These reference intervals have cell counts that were performed based upon the cytochemical stains presented in this chapter.

The effects of age and gender differences on reference intervals have been examined. There have been several studies that have looked for age and gender difference in hematologic reports.[1,8] Except for the previously mentioned changes in pregnant females, none have been found. Studies of elephant calves (0–5 years) have consistently revealed increased WBC counts.[14,23,36]

There have been anecdotal reports of clinical situations where accurate reference intervals may provide important information. For example, in case reports of endothelioptropic herpesvirus infection in an elephant, monocytosis was noted as part of this often fatal disease process.[27] Also monocytopenia has been reported in a case of *Streptococcus zooepidemicus* infection that led to pyelonephritis.[26]

HEMATOLOGIC DISEASE

Tuberculosis

Tuberculosis is caused by bacteria within the *Mycobacterium tuberculosis* complex and can infect numerous mammalian species. Elephants are unique as one of the few species other than man that is primarily infected by *M. tuberculosis*, although infection with *M. bovis* has also occurred. *M. tuberculosis* is known to cause pulmonary and generalized disease in elephants and currently infects between 3% and 5% of elephants housed in captivity in North America.[21]

Hematology values that have been found to be significantly lower in tuberculosis infected animals include the mean corpuscular hemoglobin concentration. Hematologic values that were significantly higher in positive animals included band heterophils, eosinophils, and platelets.[12] Though clinicians frequently look for monocytosis as an indication of tuberculosis,

no significant difference in monocyte counts was found between culture positive and negative elephant samples.[12]

Elephant Endotheliotropic Herpesvirus

Both African and Asian elephants are the primary hosts for multiple species of elephant endotheliotropic herpesvirus (Betaherpesvirinae) and several newly described Gammaherpesvirinae.[35] Within the primary host, nonlethal vaginal, oral, cutaneous, and pulmonary lesions can be present. Of more clinical importance, individual elephants, most commonly juvenile Asian elephants, can present with a rapidly fatal hemorrhagic disease that is characterized by severe endothelial lesions. Deaths from elephant endotheliotropic herpesvirus are one of the leading causes of elephant calf mortality and have been documented in over 40 cases throughout the world.[35] Hematologic findings included mild leukopenia and anemia with more moderate to severe thrombocytopenia and lymphopenia in Asian elephants with fatal disease.[25] An elephant that was treated successfully in Missouri had a leukocytosis (up to $20 \times 10^3/\mu L$) with heterophilia and monocytosis but still had a lymphopenia.[27] Consensus polymerase chain reaction (PCR) may be used to screen whole blood as well as tissues at necropsy.

Blood Parasites

Trypanosomiasis, African sleeping sickness or surra, is caused by the protozoan *Trypanosoma* sp. in tropical regions. *T. evansi* has been reported in Asian elephants and *T. congolense* and *T. brucei* have been reported in African elephants.[22,34] Hematologic abnormalities may be consistent with hemolytic anemia. Blood parasites are abundant, few, or absent in blood smears as in other species.

Filariasis, the presence of microfilaria in the blood, occurs in both species of elephants. In African elephants, thrombophlebitis and parenchymal liver lesions suggest that *Dipetalonema* sp. can cause hepatic disease.

SUMMARY

Due to the presence of a novel cell type (monocyte) in elephants, technologists require special education so that blood cells are identified and counted correctly. Definitive cell identification will allow for more accurate differential cell counts and thus more accurate reference intervals to be established, improving disease diagnosis and leading to better veterinary care of an endangered species.

CHAPTER 121

Hematology of Marine Mammals

THOMAS H. REIDARSON

Sample Collection
What is Normal?
Response to Infectious Disease
Response to Noninfectious Disease
Species Variation

Acronyms and Abbreviations

ACT, activated clotting time; AID, anemia of inflammatory disease; aPTT, activated partial thromboplastin time; CBC, complete blood count; EDTA, ethylenediaminetetraacetic acid; ESR, erythrocyte sedimentation rate; Hgb, hemoglobin; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean cell volume; PCV, packed cell volume; WBC, white blood cell.

As we learn more about hematologic changes associated with various infectious and noninfectious diseases in marine mammals, we arm ourselves with tools to make crucial decisions about a patient's clinical condition. This would be impossible if not for years of routine clinical testing on marine mammals providing reference values for many of the marine mammals including beluga whales (*Delphinapterus leucas*), killer whales (*Orcinus orca*), captive and free-ranging bottlenose dolphins (*Tursiops truncatus*), hooded seals (*Cystophora cristata*), northern elephant seals (*Mirounga angustirostris*), Hawaiian monk seals (*Monachus schauinslandi*), Pacific walrus (*Odobenus rosmarus*), harp seals (*Phoca Groenlandica*), harbor seals (*Phoca vitulina*), Baikal seals (*Pusa sibrica*), California sea lions (*Zalophus californianus*), and Florida manatees (*Trichechus manatus latirostris*).[1–5,7–9,11,16,23–25,28,30–32,35–36,38–40]

SAMPLE COLLECTION

For cetaceans, blood samples can be collected from the ventral fluke vasculature, ventral peduncle where the fluke veins converge, central vein of the dorsal fin, or interdigital flipper veins. Blood from pinnipeds can be drawn from the caudal gluteal vasculature or jugular in otariids (true sea lions), the extradural sinus for phocids (seals), and either extradural sinus or interdigital hind flipper veins in odobenids (walruses). Manatee blood can be collected from the inter-radial-ulnar vasculature.[36] Blood can be collected from either the jugular or sublingual veins in polar bears. Blood can be collected from northern and southern sea otters from either the femoral or popliteal veins.[38]

Blood is ideally drawn into collection tubes containing EDTA or heparin (for complete blood cell and white blood cell (WBC) differential counts), citrate (for blood clotting tests and fibrinogen), and thrombin clot activator tubes (for serum chemistry and iron tests). Because most cetaceans are factor XII (Hageman factor) deficient, the intrinsic pathway is not functional; therefore activated coagulation time (ACT) and activated partial thromboplastin time (aPTT) tests are inaccurate.[26] If serum is desired, blood from cetaceans should be collected into thrombin-containing blood tubes to stimulate clotting. When cetacean blood is collected into tubes without thrombin, clotting occurs very slowly and organizes poorly.

With blood volumes as small as 1.25–1.5 mL, complete hematologic and most serum chemistry tests can be analyzed using only whole blood from a citrate tube. After completing the complete blood count (CBC), the sample is centrifuged to harvest plasma for fibrinogen and serum chemistry tests. To compensate for dilution from the citrate solution, test values should be multiplied by a factor of 1.11 or 1.07 for 1.25 mL and 1.5 mL samples, respectively. Multipliers are not necessary for volumes greater than 1.5 mL (T.H. Reidarson,

unpublished observations). Unreliable values are obtained for calcium, sodium, and total carbon dioxide using this method, and erythrocyte sedimentation rate (ESR) tests cannot be run due to the small volume of blood. Although unconventional, the capacity to run this entire group of tests with small volumes of blood is valuable, especially when larger samples are difficult or impossible to obtain.

WHAT IS NORMAL?

When using published reference intervals or ranges, the clinician must make several assumptions about the health of the individuals in the dataset. Most authors define "clinically normal" individuals as appearing normal with respect to body mass, condition, and behavior, non-pregnant, and off medication for at least two weeks. Even with this rather strict definition some results fall outside statistical ranges, especially with small data sets. Using standard statistical methods most of these outliers are removed; however, certain ranges still appear broader than expected. This is especially true with wild populations and small datasets. It is therefore the responsibility of the clinician to determine the relevance of a value when it falls either in the high or low end of a range.

Having many years of cumulative data from individuals in a large collection, it is possible to evaluate where an individual fits in the overall species range and is conceivable for certain individuals to have statistically different values from the normal cohort. Individual differences can occur with white blood cell (WBC) counts, differential cell counts, mean corpuscular volume (MCV), ESR, iron, and fibrinogen. Explanations for these differences include age, sex, and health status. Therefore, it may be necessary to establish reference intervals for individuals from which to track health changes from normal status. When dealing with free-ranging animals or animals in a rehabilitation setting this approach is not practical, so reference means and intervals offer the best measure of the distribution of "normal" in each of these species. Tables 121.1A, B, 121.2A, B and 121.3 provide normal hematology values from a variety of marine mammal species.

RESPONSE TO INFECTIOUS DISEASE

The majority of diseases of marine mammals are from infectious agents and as such produce several inflammatory changes in the hemogram and leukogram. These indicators of inflammation include the WBC count and differential cell count, reticulocyte count, platelet count, hemoglobin (Hgb) (or packed cell volume [PCV]), fibrinogen, ESR, and iron.[14,15,20]

In an effort to more closely detect the early stages of inflammation, we have altered the criteria for identification of band neutrophils. Rather than the more conventional definition (i.e. cells with pinched filaments greater than 50% of the filament diameter) we count any neutrophil with chromatin spanning the lobules as a "band" (Fig. 121.1). The use of this definition permits the identification of marine mammals in early stages of band production before a left shift is present. Using this definition, 2–5% of WBCs are identified as "band" neutrophils in clinically normal marine mammals.

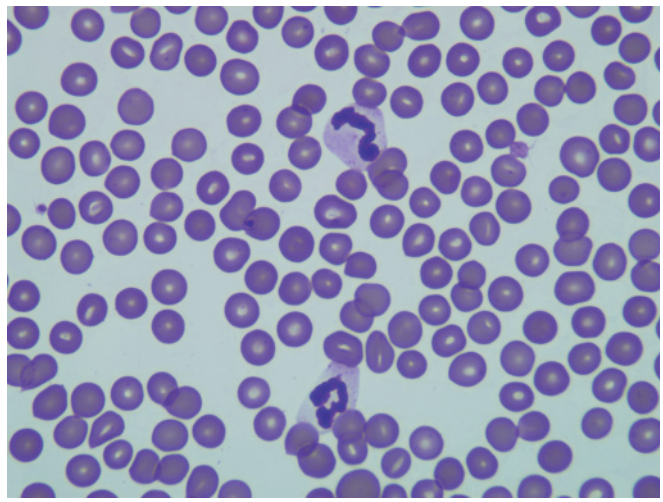

FIGURE 121.1 Blood smear from a killer whale (*Orcinus orca*) showing two "band" neutrophils. Any neutrophil with chromatin spanning the lobules is counted as a "band" even if the lobule is pinched greater than 50% of the diameter. Note that the neutrophil in the bottom would have been labeled a segmented neutrophil using the more traditional definition of a band. Wright's stain; 100× objective.

The vast majority of marine mammals with acute inflammation have decreased Hgb and PCV averaging 9–10%. These changes can be due to fluid shifts occurring in response to the release of inflammatory mediators. Once the inflammatory nidus is controlled, these parameters should return to normal, generally without evidence of reticulocytosis. If, on the other hand, Hgb and PCV slowly drop to subnormal levels, anemia of inflammatory disease (AID) may be the cause.

Anemia of inflammatory disease can be differentiated from blood loss anemia by a reticulocyte count. In AID, the reticulocyte count is low and in blood loss the reticulocyte count is increased even though the Hgb and PCV continue to drop. Reticulocyte counts vary between laboratories, as with other manually read tests (such as the differential cell count), so it is important to determine reference values for individuals under each veterinarian's care.[15]

A recent study also demonstrated an increase in absolute platelet numbers in California sea lions as part of the leukocytic response, so as WBC and absolute neutrophil counts rise, an increase in platelet count should be expected. If platelet numbers are not increased during inflammation it should be considered clinically significant.[14]

During the acute phase of a bacterial infection, serum iron can drop rapidly and dramatically. Iron is sequestered by iron-binding proteins and temporarily stored in the liver, making it less available to the pathogenic bacteria. Acute phase proteins (e.g. interleukin-1, interleukin-6, C-reactive protein, prostaglandins, tumor necrosis factor, and interferon) help mediate this iron sequestration.[5] The opposite is true of hepatocellular bacterial infections and even some noninfectious diseases, such as hemochromatosis, lipidosis, and azole hepatopathies, where iron is liberated from the liver and into the serum.[19] Trends in serum iron levels are important when evaluating clinical condition and prognosis; however, the change in magnitudes do not appear to correlate directly with severity.

In our experience, a quantitative test for plasma fibrinogen is the most reliable indicator of inflammation. Qualitative heat precipitation methods are not as accurate. Some clinicians believe fibrinogen correlates directly with ESR; however, in our practice, we have seen variable effects. Although we frequently observe an increased ESR when the fibrinogen is increased, the converse is frequently not true. In dehydrated patients, increased viscosity slows the sedimentation of RBCs, but has little or no effect on the concentration of fibrinogen.

RESPONSE TO NONINFECTIOUS DISEASE

There are a number of noninfectious conditions that produce the hallmark features of inflammation, thus making them nearly indistinguishable from infectious diseases. These include certain types of neoplasia, trauma, and reproductive abnormalities. Neoplasia such as urogenitial carcinoma of California sea lions and extensive sublingual squamous cell carcinoma of bottlenose dolphins is capable of inciting a systemic inflammatory response and, even though a gamma herpes virus has been linked to the urogenital cancer, its contribution to inflammation is minor compared to the necrosis associated with tumor growth and invasion of internal organs (J. St. Leger, personal communication).

Trauma, especially involving muscles or gastrointestinal tract, and reproductive abnormalities, such as fetal distress, premature birth, or abortion, lead to an inflammatory reaction from tissue damage. Release of tissue thromboplastins, RBC fragments, peroxidases, and other muscle cell membrane fragments can initiate an inflammatory response.[34] Ensuing shock can compromise the gastrointestinal mucosa leading to translocation of bacteria and toxins across the mucosa.[11,13,33] Any of these processes can also stimulate production of local and systemic cytokines and other inflammatory mediators.

Inflammatory changes are frequently seen in CBCs of females in the last 2–3 weeks of gestation.[27,29] In our experience, these include all of the parameters mentioned except reticulocyte count. If these changes are seen earlier in pregnancy, they signify fetal distress, premature birth, or abortion. In all cases it is difficult to determine whether inflammation is the result of an infectious agent or the cascade of events involved in pregnancy termination. Implantation, endometrial development, abortion, and parturition are mediated by hormones, interleukins, and cytokines. The main initiators of inflammation appear to be interleukin- 6 and C-reactive protein that stimulate cervical ripening and softening.

SPECIES VARIATIONS

In cetaceans, beluga whale MCV values are significantly greater than those of other species, and pilot whales and false killer whales have elevated ESR compared to cetacean species. To our knowledge, the only cetacean species with a zero ESR at 60 minutes are killer whales, common dolphins (*Delphinus delphis*), Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), and Commerson's dolphins (*Cephalorhynchus commersoni*). Statistically significant differences between free-ranging and captive bottlenose dolphins include greater MCV, platelet count, lymphocyte and eosinophil numbers, ESR, and globulins in the former.[5,21] The only statistically significant sex difference was lymphocyte numbers in captive bottlenose dolphins where females had greater numbers.

Of the 10 species of pinnipeds examined, the only remarkable differences include increased MCV, mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC), and lower RBC numbers for northern elephant seals (*Mirounga angustirostris*) (Fig. 121.2).[21] Known for being the deepest divers (over 1,500 meters) these differences are presumed to be adaptations for breath holding.[22] Fewer, larger RBCs with higher MCHC, and hence elevated oxygen storage, accompanied by reduced blood viscosity and reduced flow resistance near stasis suggest that this feature of phocid seal blood is an adaptation to circulatory redistribution during long dives. Furthermore, these changes occur early in life as juveniles reach weanling age, with the development of cardiorespiratory changes related to diving.[6,10,12,37]

Marked pressure changes are known to activate human platelets.[17] However, killer whale platelets are not altered during or after diving to great depths, nor do they experience abnormal bleeding associated with platelet dysfunction.[18] Thromboxane, a known platelet aggregating agent in mammals, is produced in normal amounts in killer whales; however, killer whale platelets are less responsive to thromboxane.[40] This phenomenon may serve a protective role in these mammals, and perhaps other deep divers such as northern elephant seals, by preventing thrombosis during diving and resurfacing.

The predominant segmented nucleated cell type of the Florida manatee contains small, pleomorphic, rod to round, eosinophilic cytoplasmic granules. As such, this cell is termed a heterophil or heterophilic granulocyte. However, recent evidence has shown this cell to be biochemically related to the neutrophil (Fig. 121.3).[36]

Other unique features of marine mammal hematology include the presence of codocytes in 25–50%

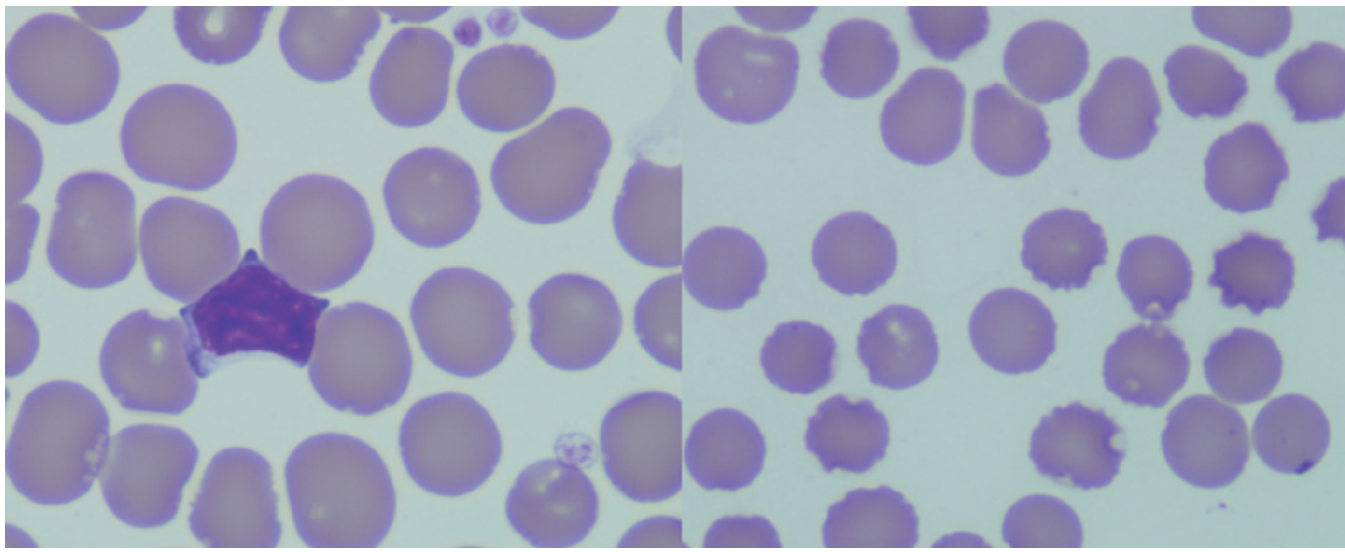

FIGURE 121.2 Blood smears comparing RBCs of (**A**) a northern elephant seal (*Mirounga angustirostris*) with (**B**) a California sea lion (*Zalophus californianus*). Northern elephant seals have the largest MCV of any mammal at greater than twice the size of the California sea lion. Wright's stain.

of normal walrus RBCs, hypersegmented neutrophils in greater than 50% of normal harbor seal blood smears, and Howell-Jolly bodies in 1–5% of all species of normal cetacean RBCs (T.H. Reidarson, unpublished data).

ACKNOWLEGMENTS

Many thanks to the Medical Technologists from Veterinary Services Laboratory of SeaWorld of California including Bea Stark, Pam Thomas, Melinda Tucker, Patty Alley, Megan Mangina, Teresa Avila, and Cathy Yamada. The author is grateful to Drs. Jim McBain and Judy St. Leger for their valuable insights, and to Drs. G. Bossart, M. Cattet, N. Caulkett, L. Dunn, F. Gulland, and T. Williams for contributing tables on normal hematology from various species.

Acronyms and Abbreviations

ATP, adenosine triphosphate; CO_2, carbon dioxide; EDTA, ethylenediaminetetraacetic acid; FMLP, formyl-methionyl-leucyphenylalanine; H:L, heterophil:lymphocyte ratio; IL, interleukin; iNOS, inducible nitric oxide; IP5, inositol pentaphosphate; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; MHC, major histocompatibility complex; N:C, nuclear:cytoplasmic ratio; NMB, new methylene blue; NO, nitric oxide; PAS, periodic acid-Schiff; PCV, packed cell volume.

Although the chicken has been used as the research animal model for establishing normal parameters for other avian species, little information has been published on hematology of chickens and turkeys in a clinical setting. The chicken and turkey have recently become more popular as backyard "pets" and visits to the veterinary hospital are increasing. Most of the current information about routine hematologic parameters is extricated from clinical values established for psittacines. Although serology is the predominant method of disease monitoring in commercial poultry, examination of blood smears, bone marrow and clinical chemistry values is rarely done. The genetics, body size and production purpose of chickens and turkeys is highly divergent and influence disease resistance as well as production parameters.[57] Commercial broiler chickens have increased normal Pco_2 when compared to laying chickens (P.S. Wakenell, personal observation) and macrophage inducible nitric oxide (iNOS) is influenced by genetic lineage.[38,44,45,55] The following information has been obtained primarily from the White Leghorn research chicken, and the influence of genetics, reproduction, geographic location, breed and season are just now being explored.[37]

BLOOD COLLECTION

The most common location for venipuncture in both the chicken and the turkey is the wing (brachial) vein. Size of the bird and bird type (show, game or fighting chicken) may dictate use of the jugular vein or the medial metatarsal vein. Cardiac puncture can be used by highly skilled personnel or in cases where the bird is euthanized immediately after blood collection.

The wing vein is superficial and easily visualized in adult birds and chicks and poults older than 1.5–2 weeks of age. Either wing can be used and collection can be performed with or without assistance. To prevent flapping and kicking, control of the unused wing and feet is essential. This is usually achieved by holding the bird in one arm with the bird's feet facing behind the upper arm toward the rear, pinning the unused wing between the bird's body and the collector's trunk and outstretching the target wing with the holding arm. The bird's head generally hangs down which has a calming effect. This method leaves the collector one hand free to collect the blood but also can be used when assisting others. Most chickens and turkeys need a short time to relax after holding but then will remain calm throughout the procedure. For heavy birds, the venipuncturist

may need to kneel during the procedure with the bulk of the bird's weight resting on the handler's leg, or have assistance. The underside of the wing is generally free of most feathers over the vein and the remainder can be plucked without distress. The vein can be accessed by either directing the bevel of the needle toward the bird's body or toward the wing tip. The vein does not need to be held off either before or after the procedure as high levels of tissue thromboplastin induce rapid clotting, which can be problematic for producing good samples. However, if blood on the wings and body are upsetting to the owner or may result in cannibalism, pressure should be applied to the site after collection. It is best to enter the skin first and then access the vein. The vein is superficial so needle placement is best at halfway between joints and almost horizontal with respect to the wing. Hematomas result even with clean procedures.

For highly aggressive breeds (fighting chickens), heavy birds (tom turkeys) and newly hatched birds, the right jugular vein is used. Highly aggressive breeds often cannibalize their wing if there is blood spotting and/or hematomas. The right jugular vein is more superficial than the left jugular vein and the hematoma formation is less than with wing vein puncture. Small birds can be held in one hand with the head held between the fingers and the neck outstretched. No feather plucking is necessary as the adjacent feather tracts can be parted to visualize the vein.

Cardiac puncture is used in situations where the bird will be euthanized immediately after the procedure and is commonly used for assessing maternal antibody levels in newly hatched chicks. Due to the risk of damaging the lungs and expectoration of blood, this technique must only be used by trained personnel if birds are not euthanized. The bird is held upside down by the feet in one hand with the bird's back supported by the holder's arm. With heavy weight birds (broilers and turkeys), the bird is laid on a table in a dorsal recumbent position with the feet held by one hand. The thoracic inlet is palpated and the needle is placed through the inlet without angling to either side and horizontal to the bird's backbone. The length of the needle placement and needle depends on the size of the bird.

An alternate location to those described above is the medial metatarsal vein which is located on the medial side of the tarsometatarsal bone. This site is used in half grown and older chickens and turkeys weighing approximately 300 grams or more. Since hematomas usually do not occur in this area, this site is ideal for situations where multiple blood samples need to be collected over a short time period.

As with psittacines (Chapter 123), the maximum volume of blood collected is 1% of the bird's body weight. This is generally not a limiting factor for turkeys and chickens as with small psittacines and passerines. Birds are more tolerant to blood loss than mammals, probably due to volume replacement from tissue fluids and, in some species, baroreceptor reflexes.[3] Vacuum tubes exert too much pressure on the vein causing collapse and are not recommended.

CELL COUNTS AND STAINING

Although anticoagulants, particularly heparin, can cause artifacts in blood smears, it is generally impractical to do a blood smear immediately after blood collection.[5] Blood can be collected in a syringe coated with anticoagulant, traditionally ethylenediaminetetraacetic acid (EDTA) for avian samples, or in an uncoated syringe with blood transferred to a coated collection tube. Although EDTA has historically been preferred for avian samples, a recent study showed that the differences between differentials done on heparinized samples versus EDTA samples were minimal.[18] Transferring to a coated tube allows more control of the ratio of the blood volume to anticoagulant, particularly in cases where small quantities are drawn. The standard two slide pushing technique can often result in a high number of smudge cells as some avian cells tend to be more susceptible to rupture than mammalian cells.[41] When using this technique, sufficient numbers of smears need to be produced to accommodate loss of imperfect smears. Two alternate methods can be used: (1) Place a drop of blood onto a slide and place a coverslip over the drop. Horizontally remove the coverslip as the blood drop spreads.[41] This method sometimes results in overly thick viewing areas and granule shape can be difficult to ascertain. (2) Put a small drop of blood on a coverslip and use a Cytospin centrifuge to distribute the drop evenly around the coverslip. Smears using all three methods need to be scanned to determine the percentage of smudge cells in relationship to 100 counted cells. The traditional stains used for mammalian smears can also be used for avian blood smears. Recently a new staining method specifically designed for avian cells has been described.[24] Using this staining method, white blood cell color differences help cellular identification in addition to size and shape.

Leukocyte counts using the eosinophil Unopette 5877 (Becton-Dickinson, Rutherford, NJ) or Natt-Herrick's solution are considered the gold standard for counting avian samples.[41] Automated systems, while useful in some situations such as determining the heterophil/lymphocyte ratio (H:L),[43] are not accurate for differentiating all cell types.[30] Flow cytometry has been successfully used and has been shown to accurately separate lymphocytes from thrombocytes, but may not be practical in a clinical setting.[2,33] Manually counting cells from a blood smear is often inaccurate and is only recommended for situations where other methods are not available. Since some cell types can be preferentially lysed when using the two slide pushing technique, it is important to use only good quality smears. Counting the number of leukocytes observed in 2–4 high power fields each on at least five smears helps increase accuracy. If limited to one smear, count the number of leukocytes per high power field on at least 10 fields, average, and multiply by 2000.

Erythrocytes can be counted using an erythrocyte Unopette (Becton-Dickinson) method or by using an automated cell counter. Both leukocytes and erythrocytes will be counted using the automated counters but

the leukocyte numbers are small in comparison with the erythrocytes and do not skew erythrocyte counts. Packed cell volume (PCV) is determined by using the microhematocrit method. Hemoglobin can be determined using the same method used for mammalian species but the sample needs to be centrifuged before obtaining the optical density to remove nuclei after cell lysis. Mean corpuscular hemoglobin (MCH), MCH concentration (MCHC), and mean corpuscular volume (MCV) can be calculated. Reticulocytes can be estimated after staining with new methylene blue (NMB). Residual cytoplasmic RNA stains basophilic with NMB. A reticulocyte count of approximately 3% can be seen in normal healthy chickens.

Often attempts are made to remove thrombocytes from blood samples, using flow cytometry in order to reduce interference with lymphocyte counting.[2] Using the same method, thrombocytes can be preferentially sorted after labeling with monoclonal antibodies.[1,54] Thrombocyte numbers can also be estimated on blood smears and each oil immersion field should have 1–3 thrombocytes. Since thrombocytes tend to clump and be dragged farther out on the feathered edge, visual estimation is difficult and numbers are usually reported as decreased, increased or normal.

HEMATOPOIESIS

Most research on ontogeny of the hematologic and lymphoid systems has been done in the chicken and quail, frequently by using chicken quail chimeras.[34,42] Lymphoid, erythroid and probably thrombocyte precursor cells start in intraembryonic mesenchyme in the para-aortic region around 2–3 days of embryonation.[4,6,46] Primitive lymphoid stem cells travel to the yolk sac between days 2 and 7 of embryonation and are first found in the yolk sac on day 7. The earliest the prebursal and prethymic stem cells are detected is day 5, but it is speculated that they are present starting day 2.[11,46] This is the same site identified as the origin of mammalian B cells.

The thymus is populated in three waves (chicken and quail) by extrinsic stem cells from the yolk sac (probably also the spleen, and by embryonation day 4, the thoracic aorta as well may directly contribute).[11] The avian liver is not an important transient site for prethymic stem cells as in mammals. The liver is mainly for extramedullary hematopoiesis and prebursal stem cell "transients."

The bursa is first observed as an outgrowth of the urodeal membrane (base of the posterior cloaca) at 3–4 days of embryonation.[46] Epithelial cells in the bursa attract bursal stem cells to the bursa. Entrance to the bursa is regulated at the level of the endothelial cells of the bursa microvasculature. Epithelial cells retain the ability to attract lymphocytes even after involution. Bursal stem cells from the yolk sac or other sites of hematopoiesis such as the spleen, liver, bone marrow, and blood seed the bursa starting around 7–10 through 15 days of embryonation. Those that remain outside of the bursa (most of the population) undergo apoptosis. B lymphocytes from the bursa seed secondary lymphoid organs just prior to and post hatch. The bursa is required for generation of antibody diversity and functional maturation of the B cell and the thymus is required for T cell maturation. Major histocompatibility complex (MHC) "dosage" appears to modulate the cellularity of both the bursa and the thymus.[9] Chickens have been produced that have three and four copies of the MHC microchromosome. These chickens have decreased bursal, thymus and body weight. Both the bursa and the thymus involute at sexual maturity and it is unknown where the post-bursal and thymic "stem" cells that presumably maintain the B and T cell pool after involution are located. There are three populations of B lymphocytes in the periphery. A cell surface antigen, LT2, which is on all precursor cells, is used to help sort these populations.

1. Short lifespan (3 days): the peripheral blood lymphocyte concentration is 60%, comprise 90–95% of bursal emigrants, do not divide in periphery, come from the cortex, have high levels of LT2 which decrease with age, disappear after involution.
2. Longer-lived (2 weeks): 35% of peripheral blood lymphocytes, do not divide in periphery, 5–10% of bursal emigrants.
3. Indefinite lifespan (unable to document through surgical bursectomy): divide rapidly, lifespan of individual cells is probably short but cells are always being replaced, population in blood increases with time, "post bursal stem cells."[46]

The role of the bone marrow in avian lymphopoiesis is unclear. It is probably not a primary organ as in mammals but may contain a small population of post-bursal and thymus "stem" cells that provide a source of self renewal. B cells migrate into thymus after hatching and the thymus behaves as a secondary organ which is not found in mammals.

Spleen germinal centers are B cell dependent but T cells are required for formation. Spleen germinal center formation is age dependent and reaches the maximum number at 4–5 weeks of age. Intestinal germinal centers are not age dependent and continually increase.

Erythroid and thrombocyte stem cells (no megakaryocytes) also colonize the yolk sac and hematopoietic activity peaks around 10–15 days of embryonation. Hematopoietic activity persists in the yolk stalk of hatched chicks. Erythrocytes and thrombocytes are formed in the vascular sinuses and granulocytes are formed extravascularly.[3] Erythrocytes and thrombocytes and their precursors are predominant in the circulating blood of the embryo, with leukocyte precursors being less common. After hatch, hematopoiesis occurs in many visceral and nonvisceral organs but is primarily located in the marrow of the vertebrae and long bones. Limited hematopoietic activity can be observed in the heart and serosa of the small intestine shortly after hatch. More extramedullary hematopoiesis is observed in avian species other than the chicken, and the liver is the most common location. Granulopoiesis

is the most predominant hematopoietic activity in the spleen before hatch, with lymphopoiesis predominating after hatch.[3] Bone marrow occurs in conjunction with medullary bone. The extravascular space in the marrow also contains fat and lymphoid aggregates. The avian bone marrow is predominantly dedicated to producing erythroid cells: the number of reserve mature granulocytes is very low compared to mammals.

The ultrastructural anatomy of the embryonic and adult bone marrow in chickens is different from that of mammals.[3,5] Capillary branches from marrow arterioles empty into medullary sinuses. Unlike capillaries, these sinuses are lined by endothelium without a basement membrane. The endothelium is continuous with numerous intercellular junctions between immature erythrocytes and endothelial cells. This adherence to the endothelium is thought to play a role in preventing immature erythrocytes from entering the circulation and in regulating erythropoiesis. Thrombocyte precursors have not been definitively identified in avian bone marrow, presumably due to their fragility and subsequent loss during processing, but they are also believed to occur in the intravascular sinuses. Early thrombocyte precursors may be indistinguishable from erythrocyte precursors. Stem cells observed migrating through endothelium between intravascular and extravascular sinuses likely represent migration of the pluripotent stem cell to the extravascular sinus. Maturing granulocytes also migrate through the endothelium and may undergo final maturation extravascularly. Monocytogenesis is not apparent in avian marrow, and early monocyte prescursors are likely indistinguishable from early granulocyte prescursors. Macrophages are not prominent in avian bone marrow.

The spleen also plays an important role in hematopoiesis, particularly with lymphopoiesis and granulopoiesis, as mentioned previously. The spleen is located at the junction of the proventriculus-gizzard and the shape is variable within avian species. It is oval in the chicken and turkey and brick red in color.[23] Accessory spleens can sometimes occur in various locations in the abdominal and, to a lesser extent, thoracic cavities and are considered normal. The red and white pulp have less distinct separation than in mammals and there is indistinct connective tissue trabeculae. The circulation is open with no direct connections between arteries and veins. The spleen has sheathed capillaries (Schweigger-Seidal sheaths) which appear as pale areas on microscopic examination.[17,36] These sheaths differ in prominence depending on species, with owls having the largest. Capillaries are surrounded by macrophages with phagocytic capabilities. White pulp is diffuse with occasional germinal centers and is concentrated primarily around arteries and sheaths.

HEMATOPOIETIC GROWTH FACTORS

The identification and description of avian cytokines and lymphokines has expanded exponentially in recent years.[15,25] Due to the general lack of homology between avian and mammalian cytokines, use of mammalian monoclonal antibodies for identification of avian cytokines resulted in limited information. Most of the research has been done with chickens, ducks and turkeys. To date, the following cytokines have been either fully or partially characterized in avian species: erythropoietin,[19] interleukin-1 (IL-1),[35] IL-2,[29] IL-6,[49] IL-8,[56] IL-10,[47] IL-12,[8] IL-15,[29] IL-16,[32] IL-17,[20] IL-18,[16] granulocyte colony stimulating factor,[48] thrombocyte inhibitory factor,[3] and tumor necrosis factor.[39]

ERYTHROCYTES

Avian erythrocytes are oval, nucleated cells with round immature form. Maturation of erythrocytes is outlined in Table 122.1. Mature chicken and turkey erythrocytes found in the peripheral blood are large elliptical cells measuring approximately 12 × 6 μm. They have homogeneous eosinophilic cytoplasm and a central round to oval nucleus with a condensed chromatin pattern. Because erythropoiesis is intravascular or intrasinusoidal, occasional rubricytes can be found in the peripheral blood of healthy birds (Fig. 122.1). The percentage of reticulocytes seen in the peripheral blood of normal chickens and turkeys is somewhat higher than in most mammals. Polychromasia is more prominent in younger birds, but typically does not exceed 5%. Common artifactual abnormalities in erythrocyte morphology include cytoplasmic refractile vacuoles, smudge cells, and various morphologies induced by stretching cells while preparing the smear such as spindling, bilobed nuclei, bare nuclei and erythroplastids (anucleate fragments of erythrocyte cytoplasm).

TABLE 122.1 The Erythrocyte Maturation Sequence[3]

Cell Maturation Stage	Description
Rubriblast	Large cell, central round nuclei, granular chromatin, prominent nucleoli, very basophilic cytoplasm with mitochondrial spaces
Prorubricyte	Nucleoli and mitochondrial spaces inapparent
Basophilic rubricyte	Clumped chromatin pattern, very basophilic cytoplasm
Early polychromatic rubricyte	Cytoplasm becoming grayish, indicating hemoglobin production, chromatin more clumped, smaller nucleus
Late polychromatic rubricyte	More grayish to eosinophilic cytoplasm, clumped chromatin, small round nucleus
Polychromatic erythrocyte	Similar to mature erythrocytes but slightly larger with a more basophilic cytoplasm; should be 1–5% of circulating erythrocytes
Mature erythrocyte	Homogeneous eosinophilic cytoplasm, oval cell with central oval nucleus and condensed chromatin pattern

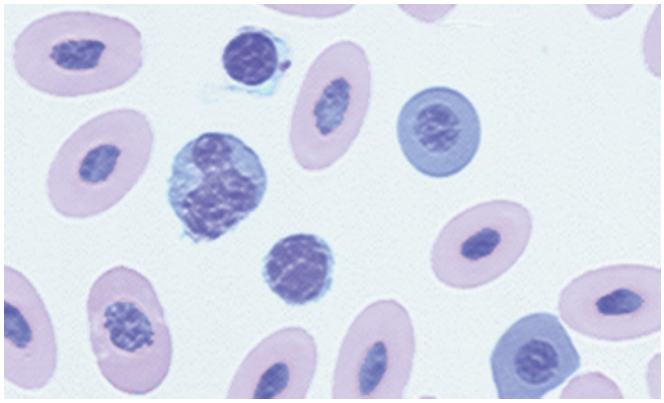

FIGURE 122.1 Thrombocyte with cytoplasmic azurophilic granule at one pole, two rubricytes, small lymphocyte, monocyte. Cells are identified in a clockwise manner. Wright-Giemsa stain; magnification 100×.

Avian erythrocytes function similarly to mammalian erythrocytes with some biochemical differences.[10] Like fish erythrocytes, avian erythrocytes can participate in the immune response by producing cytokine-like factors.[40] The structure of avian hemoglobin, however, is similar to mammals. 2,3-Bisphosphoglycerate is present only in chicken embryonal erythrocytes and disappears shortly after hatch.[3] Myoinositol is readily taken up by erythrocyte precursors and converted to inositol pentaphosphate (IP5). IP5 and adenosine triphosphate (ATP) concentrations increase rapidly after hatch, with corresponding decreases in blood oxygen affinity due to IP5 binding to hemoglobin. The highest concentration of IP5 is in the mature erythrocyte, and this concentration does not change for the life of the cell regardless of requirements for oxygen. Various degrees of IP5 binding result in a wide range of hemoglobin oxygen affinity among species. However, pH is a much more important regulator of oxygen affinity. Decreasing pH results in decreasing oxygen affinity (Bohr affect), presumably due to IP5 binding[3]. Carbon dioxide (CO_2) has a minimal effect on oxygen affinity because the efficient respiratory system of avian species is thought to maintain a very constant blood CO_2 level. Formation of bicarbonate from CO_2 and hydrogen ion release indirectly may regulate oxygen affinity.

GRANULOCYTES

As in other avian species, the peripheral blood of chickens and turkeys contains heterophils, eosinophils, and basophils. The above cells arise from a common precursor in the bone marrow. Maturation of granulocytes is described in Table 122.2.

Heterophils

The heterophil is the most common avian granulocyte. Granules are eosinophilic and rod shaped in chickens and turkeys. However, granules tend to round up in tissue samples due to degeneration. Species variation in granule shape and depth of coloration can occur. The cytoplasm is colorless and the granules commonly cover the nucleus at least partially. The mature heterophil is round and measures approximately 13 µm in diameter (Figs. 122.2 and 122.3) The nucleus has 2–3 lobes and a coarse chromatin pattern.

Heterophil function is similar to mammalian neutrophil function. However, there are differences in granule contents and response to some stimuli.[12,13,52,55] It has been speculated that avian heterophils either do not contain or contain minimal quantities of specific lysozyme. Heterophils lack myeloperoxidase and alkaline phosphatase. Chicken and turkey heterophils, unlike neutrophils, do not respond to stimulation by formyl-methionyl-leucylphenylalanine (FMLP) and their production of oxygen radicals is lower than that of mammalian neutrophils.[3] However, there is a significant difference in heterophil function when comparing

TABLE 122.2 The Granulocyte Series Maturation Sequence[3]

Cell Maturation Stage	Description
Myeloblast	Large, round cell with rim of lightly basophilic cytoplasm around a large nucleus with a delicate chromatin pattern and nucleoli
Promyelocyte	Light blue cytoplasm, eccentric nucleus with delicate chromatin pattern, primary granules in cytoplasm are orange spheres, heterophil and basophil promyelocytes also have magenta granules and rings (smaller in basophil promyelocyte)
Myelocyte	Smaller, more condensed nucleus, contain less than half the definitive number of specific or secondary granules and still retain magenta granules and rings (except eosinophil myelocytes)
Metamyelocyte	Smaller, slightly indented nucleus, more than half the number of definitive granules
Band	Similar to mature cell without nuclear lobes; nucleus is elongate to U-shaped, rare to see bands in circulation in avian blood, usually see mature granulocytes only
Mature heterophil	Round cell with no cytoplasmic coloration, eosinophilic rod-shaped cytoplasmic granules with a distinct refractile central body, 2–3 lobed nucleus with coarse chromatin often partially obscured by granules
Mature eosinophil	Round, similar to heterophil but granules more brightly eosinophilic (more arginine) and without central refractile body; cytoplasm usually pale blue
Mature basophil	Round cell with a round central nucleus; deeply basophilic cytoplasmic granules that may partially obscure the nucleus and dissolve or coalesce in alcohol solubilized stains like Wright's

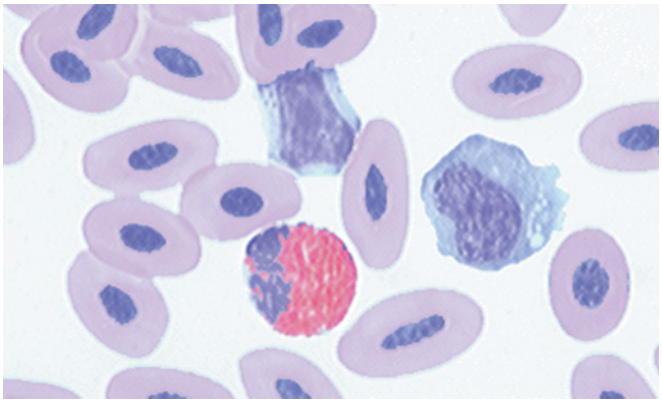

FIGURE 122.2 Medium lymphocyte with intracytoplasmic granules to left of nucleus, monocyte, and heterophil from a wild turkey. Cells are identified in a clockwise manner. Wright-Giemsa stain; magnification 100×.

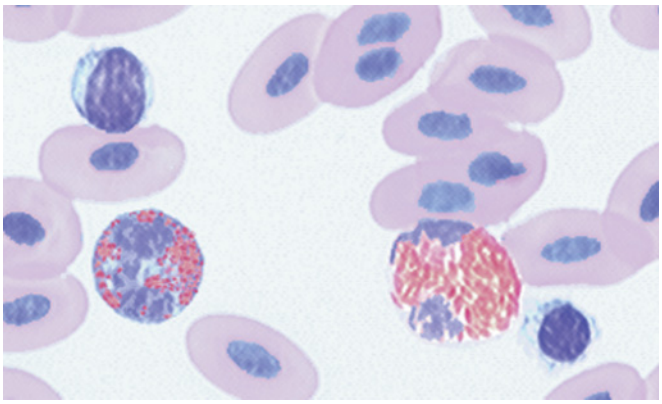

FIGURE 122.3 Lymphocyte, heterophil, thrombocyte, and eosinophil of a domestic chicken. Cells are identified in a clockwise manner. Wright-Giemsa stain; magnification 100×.

different lines or strains of chickens and turkeys.[14,51] Avian heterophils have been shown to participate in antibody dependent cellular cytotoxicity, possess Toll-like receptors, and use extracellular traps to kill antigens.[7,26] Interleukin-2 (IL-2) is a strong stimulator of neutrophil activation in mammals but is not as strong in chickens. IL-2 stimulation appears to be age dependent with effects noted at 7 and 14 days of age but not at hatch or at 21 days of age. In chickens, IL-2 can modulate certain functions such as priming heterophils for a significantly strengthened respiratory burst subsequent to stimulation with phorbol myristate acetate and increased phagocytosis of opsonized bacteria.[27] IL-2 has no effect on degranulation of heterophils post stimulation.

The pineal gland exerts some control of heterophils via the hormone melatonin.[53] Heterophils appear to be the first line of defense against bacterial pneumonia, although the ability to generate oxidative metabolites is

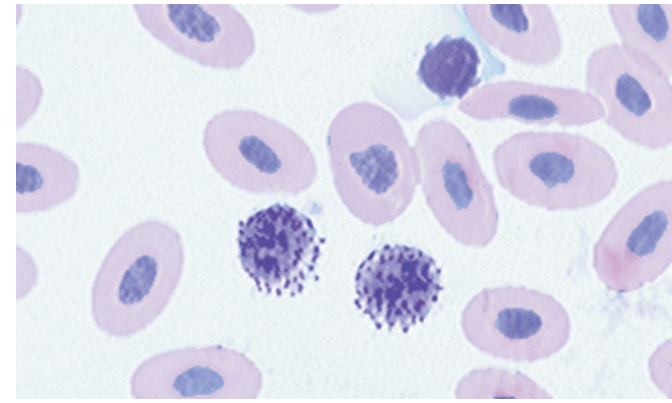

FIGURE 122.4 Thrombocyte and two basophils from a domestic chicken. Cells are identified in a clockwise manner. Wright-Giemsa stain; magnification 100×.

lower in heterophils derived from the respiratory tract than in heterophils from the peripheral blood. Defensins are antimicrobial proteins stored in the lysosome-like granules of heterophils, macrophages and epithelial cells. Originally termed "lysosomal cationic proteins" in the neutrophils of rabbits, there are two types, alpha and beta in man, and a third type, theta, found only in Rhesus monkeys. Only the betas have been found so far in birds. Gallinacin-3 has been identified in chickens and gallopavin-1 in turkeys.[58] The largest (primary) granules contain lysozyme and defensins which are first detectable in the promyelocytic stage adjacent to the Golgi.

Eosinophils

These cells are round to irregularly shaped and are approximately 12 µm in diameter. They have a lobed nucleus and light blue cytoplasm with eosinophilic round to oval granules that stain brighter than those of heterophils and lack the central body (Fig. 122.3). Immature heterophils have round granules and could be confused with eosinophils. Cytochemical stains can distinguish between the two types of cells. Eosinophils are positive for peroxidase and acid phospatase activity and Sudan black B, while heterophils are negative.[3]

Basophils

The basophil is a round cell with deeply basophilic granules in the cytoplasm and a round, light blue, central nonindented nucleus. It resembles the mammalian mast cell. Birds appear to have more mast cells and basophils than mammals. The basophil measures approximately 12 µm in diameter and the granules often partially obscure the nucleus (Fig. 122.4). These granules may dissolve or coalesce in Wright's stains. Basophils are one of the first leukocytes to enter tissue as part of the early inflammatory response in birds and the cutaneous basophil response can be measured to help assess immunocomptence.[3,28]

MONOCYTES

Chicken and turkey monocytes are usually the largest leukocytes (approximately 14 µm in diameter) and need to be differentiated from large lymphocytes (Figs. 122.1 and 122.2). Monocytes are round cells, usually have indented nuclei and abundant pale, vacuolated blue-gray cytoplasm. The cytoplasm contains fine azurophilic granules. The monocyte is a pleomorphic cell and can be difficult to identify. It is important to be consistent with lymphocyte classification to aid in differentiation from monocytes. Lymphocytes are round and generally have less cytoplasm than monocytes. Size is dependent upon activation state in chickens and blood monocytes can not be differentiated from lymphocytes solely on the basis of size.

Chicken and turkey monocytes are similar to the mammalian cells. Monocytes from turkeys and chickens are capable of oxidative activity as well as phagocytosis and killing. Heterophils from chickens and turkeys have greater phagocytic activity and killing ability than macrophages.[3] More is known about macrophage phagocytosis and killing in the chicken and turkey than about that of monocytes. There are few resident "peritoneal" macrophages harvestable in chickens.[44,45,55] All macrophages must be elicited, usually using Sephadex™ or other agents. Sephadex™ elicits and activates macrophages via the alternate complement pathway. Macrophages respond to inflammation by induction of adhesion molecules, chemotaxis to the site of greatest concentration of the chemoattractant and, once there, by initiation of a respiratory burst. FMLP is a chemoattractant for chicken macrophages but not for turkey macrophages. Chicken macrophages need higher concentrations of FMLP than human macrophages, possibly due to binding of receptors to different polypeptide structures than their mammalian counterparts. Other chemoattractants to avian macrophages are endotoxin-activated chicken serum and E. cloacae culture supernatant. The respiratory burst consumes oxygen for the production of superoxide anion, hydrogen peroxide and eventually hydroxyl radical and singlet oxygen.[44,45] Early inflammatory macrophages from young chickens are better than blood monocytes or late inflammatory macrophages for generation of superoxide anion after stimulation with phorbol myristic acid. Macrophages kill tumor cells by four different processes: (1) via tumor necrosis factor, (2) via antibody dependent cellular cytotoxity, (3) via an arginine dependent process and (4) via direct contact.[55] Since birds are uricotelic, there is no de novo synthesis of l-arginine as in the mammalian urea cycle, and this amino acid is required in birds for the production of these intermediates.[3] The arginine dependent process probably uses the enzyme arginine deiminase (in some papers referred to as arginase) to convert arginine to citrulline and nitric oxide (NO) which have been associated with the ability of macrophages to deplete tumor cells of iron-sulfur prosthetic groups required for mitochondrial respiration. Another pathway to produce NO is via the enzyme inducible NO synthase in place of arginine deiminase. The activation state and the phenotype of the pathogen are important factors in the macrophage's ability to kill a pathogen. The monocyte maturation series is described in Table 122.3.

TABLE 122.3 The Monocyte Maturation Sequence[3]

Cell Maturation Stage	Description
Monoblast	A poorly defined cell, probably indistinguishable from the myeloblast
Early promonocyte	Large cells with abundant, clear blue cytoplasm, round nucleus, reticular chromatin
Late promonocyte	Round, eccentric nucleus with granular basophilic cytoplasm, sparse eosinophilic granules
Mature monocyte	Large and irregular with a round to bilobed nucleus, fine chromatin pattern, abundant blue-gray granular cytoplasm, and occasional cytoplasmic vacuoles and/or fine dust-like eosinophilic granules

LYMPHOCYTES

Lymphocytes are the predominant leukocyte in the peripheral blood of chickens and turkeys. Both small and medium lymphocytes normally occur. The small lymphocytes are round with a round nucleus, clumped chromatin, high nuclear:cytoplasmic (N:C) ratio, and a rim or small amount of basophilic cytoplasm (Figs. 122.1 and 122.3). Occasionally the cytoplasm of small lymphocytes may only be seen as cytoplasmic projections, and they may be confused with thrombocytes. Thrombocytes can be distinguished by their clear cytoplasm. Medium lymphocytes have more abundant and sometimes more pale basophilic cytoplasm. They often "mold" around adjacent cells. Lymphocytes may have nuclear indentation, and sometimes larger lymphocytes may have more angular nuclei or nuclei with a flattened side. Medium to large lymphocytes must be distinguished from monocytes as mentioned previously.

Reactive lymphocytes can be seen in peripheral blood. Cell size is increased and the cytoplasm is deeply basophilic, sometimes with a clear perinuclear area (Golgi). Plasma cells may only rarely be found in peripheral blood. Reactive lymphocytes may resemble rubricytes. However, rubricytes have a lower N:C ratio and are typically seen in peripheral blood with polychromatophilic erythrocytes in regenerative responses.[3] The presence of eosinophilic (azurophilic) granules in peripheral blood lymphocytes is rare, and its significance is unknown (Fig. 122.2). These cells are readily distinguished from monocytes, because the lymphocyte azurophilic granules are larger and more intensely staining than the dust-like granules of monocytes.

TABLE 122.4 The Thrombocyte Maturation Sequence[3]

Cell Maturation Stage	Description
Thromboblast	Large, ameboid cells with a rim of very basophilic cytoplasm around a large nucleus with punctate chromatin (chromatin is not coarse as in the rubriblast), nucleolus not always apparent, some clear vacuoles within cytoplasm
Early immature thrombocyte	Slightly lower N:C than thromboblast, more cytoplasmic vacuoles evident; chromatin becomes clumped

THROMBOCYTES

Chicken and turkey thrombocytes are round to slightly oval cells with a round nucleus in the center of a clear cytoplasm. Thrombocytes can be confused with small lymphocytes in tissue samples and blood smears as mentioned previously. Monoclonal antibodies against chicken thrombocytes have been developed and can aid in identification.[21] Avian thrombocytes contain azurophilic cytoplasmic granules, stain periodic acid-Schiff (PAS) and Grimelius positive, clump readily and produce little thromboplastin. It is likely that they are capable of phagocytosis, although definitive proof has not been obtained.[31] Thrombocytes respond to lipopolysaccharide through Toll-like receptor 4.[50] Frequently, one or more distinct small granules are present at the poles of the thrombocyte (Fig. 122.1). A C3b-like receptor and analogs to mammalian platelet glycoproteins IIb and IIIa have been identified in chicken thrombocytes.[3] Nuclear retention in avian thrombocytes results in the continued ability of the mature cell to synthesize proteins. Similar to mammalian platelets, avian thrombocytes have fibrinogen receptors that localize when thrombocytes are activated, facilitating thrombocyte aggregation.[3] The thrombocyte maturation series is described in Table 122.4.

NORMAL REFERENCE INTERVALS FOR CHICKENS AND TURKEYS

Total erythrocyte numbers are approximately $3 \times 10^6/\mu L$, or a PCV of 25–42%. Chicks typically have a lower PCV (as low as 24%) that increases with age. The MCV has been reported in the range 90–140 fL^3. Chicks tend to have fewer, larger erythrocytes. Hemoglobin concentrations of chicken and turkeys have been reported from 8.6 to 15.2 gm/dL.[3] Variation in erythrocyte parameters may reflect different lines of chickens and turkeys and different methods of determination. Erythrocyte lifespan is 28–35 days in chickens.[3]

Early data showed PCV to be lower in heavy type (30.1–30.9%) than in White Leghorn type (31.9–33.9%) chickens.[3] More recent hematology data of chickens are shown in Tables 122.5, 122.6, and 122.7. Mean hematocrits from specific pathogen-free White Leghorn chicks of 5–42 days of age ranged from 32.7% to 36.7%, respectively.[3]

Limited hematologic data are available for domestic turkeys (Table 122.8). Reference intervals for 4 month old wild turkeys are detailed in Table 122.9. As in chickens, studies have shown that differences exist in hematologic parameters of closed genetic lines and different

TABLE 122.5 Hematologic Values for the Chicken (*Gallus gallus domesticus*)[3]

ERYTHROCYTE MORPHOLOGY

The normal mature psittacine red blood cell (RBC) is a large (compared to mammalian RBC), flattened elliptical cell with an elliptical, centrally positioned nucleus and smooth nuclear margins (Fig. 123.1). The nuclear chromatin is uniformly clumped and becomes increasingly condensed with cellular age. In Wright-stained blood films, the nucleus stains purple while the cytoplasm appears orange-pink with a uniform texture.

The shape of RBCs in blood films from normal psittacine birds is relatively uniform with slight variability; therefore, a minor degree of poikilocytosis is considered to be normal. Variations in RBC color include polychromasia and hypochromasia. Polychromatophilic RBCs occur in low numbers (usually less than 5% of the total RBC count) in the blood of most normal birds. Polychromatophilic RBCs are similar in size to mature RBCs and appear as reticulocytes when stained with vital stains, such as new methylene blue. The cytoplasm appears weakly basophilic, and the nucleus is less condensed than the nucleus of mature RBCs.

Determination of reticulocyte count can be made by staining RBCs with a vital stain, such as new methylene blue. Reticulocytes have a distinct ring of aggregated reticular material that encircles the nucleus. As the cells mature the amount of aggregated reticular material decreases and becomes more dispersed throughout the cytoplasm. With further maturation the reticular material becomes nonaggregated, and the cells begin to resemble the "punctate" reticulocytes of felids; therefore, most mature avian RBCs contain a varying amount of aggregate or punctate reticulum. Reticulocytes that reflect the current RBC regenerative response are those that have a distinct ring of aggregated reticulum that encircles the RBC nucleus.[1,9]

Hematologic methods used to evaluate avian erythrocytes include determination of a packed cell volume (PCV) or microhematocrit, hemoglobin (Hgb) concentration, RBC count, and evaluation of the RBC morphology on a stained blood film. The PCV is determined using the same method used in mammalian hematology. The hemoglobin concentration is determined using the cyanmethemoglobin method with centrifugation of the free nuclei from lysed erythrocytes before obtaining the optical density value to avoid overestimation of the true Hgb concentration. A RBC count can be determined by using automated methods (electronic particle counter) or manual methods. Two manual methods commonly used are the erythrocyte Unopette (Unopette,

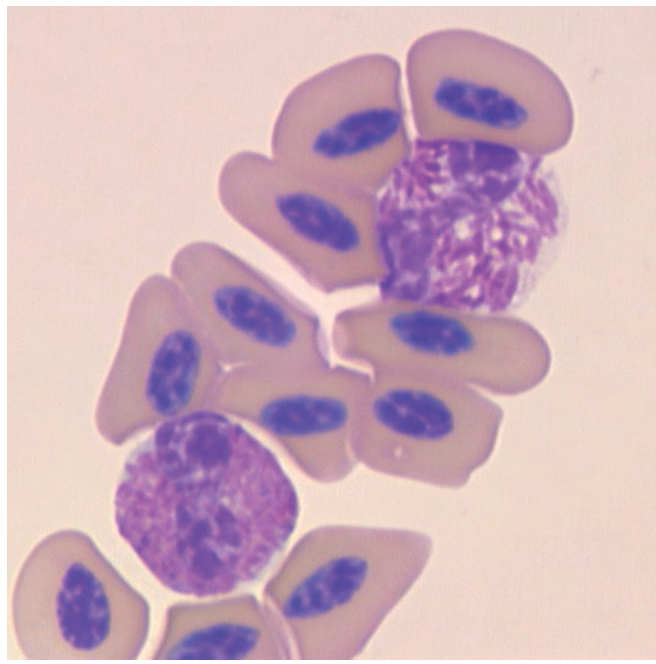

FIGURE 123.2 Blood film of a parrot. A heterophil (top) and an eosinophil (bottom). Wright stain.

Becton-Dickinson, Rutherford, NJ) method as used in mammalian hematology and the Natt and Herrick method.[1] Both methods are labor intensive and require accurate dilutions (made easier using the Unopette system) and counting cells in a hemacytometer. Once the PCV, Hgb concentration, and total RBC count have been determined, the secondary hematologic indices, including the mean corpuscular volume (MCV), mean corpuscular hemoglobin concentration (MCHC), and mean corpuscular hemoglobin (MCH) can be determined.

LEUKOCYTE MORPHOLOGY

Leukocytes in the blood of a psittacine bird include lymphocytes, monocytes, and granulocytes. The granulocytes are further classified as heterophils, eosinophils, and basophils. In general, psittacine heterophils tend to be round (although their shape may be distorted) and uniform in size. The nucleus of the mature heterophil, which is frequently partially hidden by the cytoplasmic granules, is lobed (two to three lobes), with coarse, clumped, purple-staining chromatin (Figs. 123.1, 123.2, and 123.3). The cytoplasm of normal mature heterophils appears colorless and contains granules that stain an eosinophilic color (dark orange to brown red) with Romanowsky-type stains, although the granules can be affected by the staining process and may appear atypical (i.e. poorly stained, partially dissolved, or fused). Typically the cytoplasmic granules of psittacine heterophils appear elongated (rod or spicular shaped) and frequently contain a central refractile body.

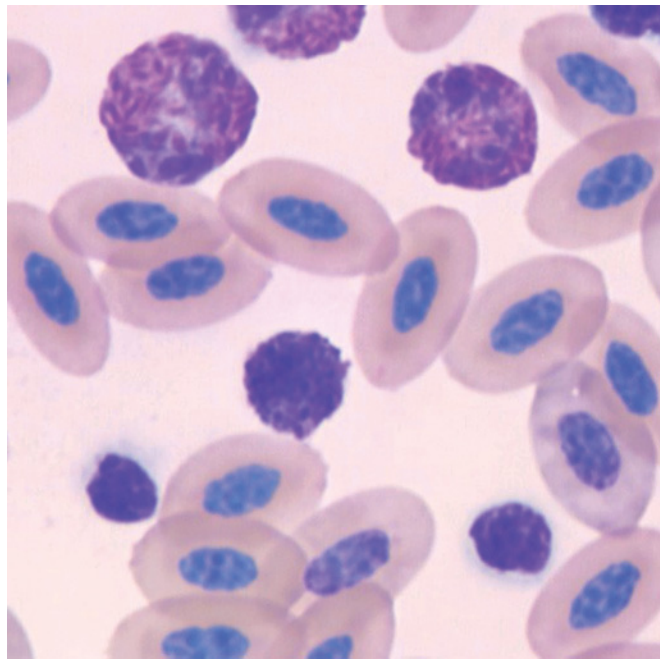

FIGURE 123.3 Blood film of a parrot. Two heterophils (top), a basophil (middle), and two thrombocytes (bottom). Wright stain.

In general, most eosinophils of psittacine birds are similar in size to the heterophils in the same blood film. The nucleus of the eosinophil is lobed and usually stains darker than a heterophil nucleus and the cytoplasm stains clear blue in contrast to the colorless cyto-

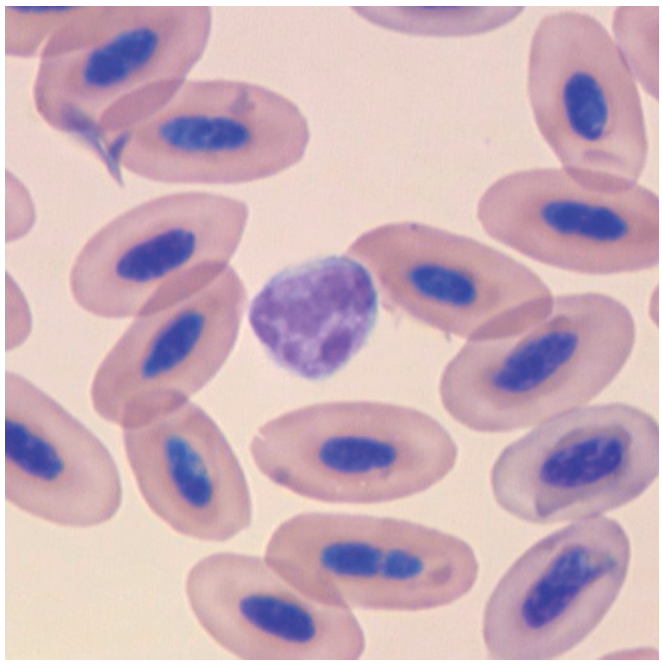

FIGURE 123.4 Blood film of a parrot. A small mature lymphocyte. Wright stain.

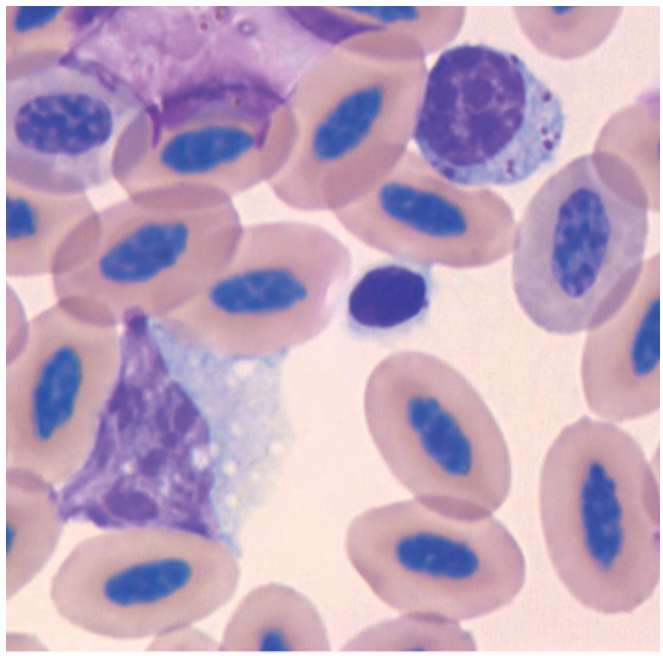

FIGURE 123.5 Blood film of a parrot. A monocyte (bottom) and a large lymphocyte with azurophilic granules (top right). Wright stain.

plasm of normal mature heterophils (Fig. 123.2). The cytoplasmic granules of these cells are strongly eosinophilic and are typically round in shape and tend to stain more intensely compared to granules of heterophils in the same Romanowsky-stained blood film. Occasionally, granules of eosinophils of psittacine birds may be affected by the staining process and appear colorless, pale blue, or swollen.

Psittacine basophils contain deeply metachromic granules that frequently obscure the cell nucleus (Fig. 123.3). The nucleus is usually nonlobed, causing them to resemble mammalian mast cells. The cytoplasmic granules of basophils are frequently affected by alcohol-solubilized stains and may partially dissolve or coalesce; therefore, they may appear abnormal in blood films stained with Romanowsky-type stains. Unlike mammals, basophils are frequently found in the peripheral blood of psittacine birds.

Avian lymphocytes resemble mammalian lymphocytes (Fig. 123.4). They are mononuclear cells identified as round cells that frequently show cytoplasmic irregularity as they mold around adjacent RBCs in the blood film. Lymphocytes have a round, occasionally slightly indented, centrally or slightly eccentrically positioned nucleus. The nuclear chromatin is heavily clumped or reticulated in mature lymphocytes. The cytoplasm of small mature lymphocytes is typically scant resulting in a high nuclear to cytoplasm ratio (N:C), and typically appears homogeneous, weakly basophilic (pale blue), and lacks vacuoles or granules. Although small mature lymphocytes are the most frequent form of lymphocyte in blood films; medium and large lymphocytes with more abundant and lighter staining cytoplasm may occur as well. Occasionally, lymphocytes in the blood film of normal psittacine birds may contain distinct azurophilic granules or irregular cytoplasmic projections (Fig. 123.5).

Monocytes in the blood films from normal psittacine birds are usually the largest leukocytes and resemble their mammalian counterpart. These cells vary in shape from round to ameboid (Fig. 123.5). The nucleus of monocytes also varies in shape and can appear round to lobed with relatively pale, less dense chromatin as compared to lymphocyte nuclei. The cytoplasm of the psittacine monocyte is abundant, blue-gray in color and may appear slightly opaque. Vacuoles or fine dust-like eosinophilic granules may also be present.

An avian total white blood cell (WBC) count is obtained by most laboratories using a manual method. The two commonly used manual methods are the direct and the semidirect methods. The semidirect method involves the staining of avian heterophils and eosinophils with a phloxine B solution that is also used as a diluent. This method uses a hemacytometer to count cells (heterophils and eosinophils) that stain red to obtain an absolute heterophil and eosinophil count. Because other leukocytes are not counted, they must be factored into the total leukocyte count after obtaining a leukocyte differential from a stained blood film. An absolute heterophil and eosinophil count is obtained with the appropriate formula using the dilution factor and number of squares counted as one would use for counting cells in a hemacytometer. Once this has been determined, the total WBC count is determined by multiplying the absolute heterophil and eosinophil count (heterophils and eosinophils/mm^3) by 100 and dividing

that number by the percent heterophils and eosinophils from the leukocyte differential.

The commonly used direct manual method for obtaining a total leukocyte count involves making a 1:200 dilution of the blood with Natt and Herrick solution to charge the hemacytometer. The total leukocyte count is obtained by counting the dark blue cells (presumed to be leukocytes) in the hemacytometer. The advantage of this method is that an absolute leukocyte, erythrocyte, and thrombocyte count can be obtained from the same charged hemacytometer. The disadvantage is that it is often difficult to differentiate small lymphocytes from thrombocytes.

THROMBOCYTE MORPHOLOGY

Like all avian thrombocytes, those in the blood films of psittacine birds are nucleated cells and are the second most numerous cell (after RBCs) found in the blood. Thrombocytes are typically small round to oval cells (smaller than RBCs) with a round to oval nucleus that contains densely clumped chromatin (Fig. 123.3). The nucleus is more round than an RBC nucleus and thrombocytes tend to have a higher N:C ratio. The cytoplasm of normal mature thrombocytes is colorless to pale gray and may have a reticulated appearance. This feature is useful in differentiating thrombocytes from small mature lymphocytes. Thrombocytes also frequently contain one or more distinct eosinophilic (specific) granules (actually aggregates of many small granules) grouped in one area of the cytoplasm.

Absolute thrombocyte counts are rarely determined in avian blood samples because they tend to clump, making meaningful counts difficult. The direct manual method for obtaining a total thrombocyte count involves making a 1:200 dilution of the blood with Natt and Herrick's solution to charge the hemacytometer. The total thrombocyte count is obtained by counting the small oval cells that fail to stain blue in the hemacytometer. Alternatively, determination of the number of thrombocytes in relation to the number of erythrocytes on the blood film provides a reasonable assessment of the thrombocyte numbers. In general, 10–15 thrombocytes per 1000 erythrocytes are considered to be an adequate number for normal birds. Numbers less than that suggest thrombocytopenia and those greater suggest thrombocytosis.

REFERENCE INTERVALS

Age Influences

Little has been reported in the literature concerning the influence of aging on the hemogram of psittacine birds. In one study, the PCV and MCV tended to increase with age in budgerigars (*Melopsittacus undulates*), whereas the MCHC decreased.[8] Because the Hgb was unaffected by aging, it was presumed that the decline in MCHC was a function of an increase in MCV. No age-related changes in the leukogram were detected in this study.

A transition from a differential WBC count that is primarily heterophilic to one that is primarily lymphocytic has been observed in several species of psittacine birds as they mature; however, the opposite has been reported in other species.[6] It is speculated that this change is species-specific.

In another budgerigar study, male birds had higher RBC counts, PCV values, and Hgb concentrations compared to females.[10] The reason for this may be related to the negative influence of estrogen on erythropoiesis in females and the positive influence of testosterone in males. In other studies no differences in the hemogram were noted between males and females; however, it should be noted that frequently the gender of a psittacine bird is unknown.

Species Influences

Normal reference intervals (Table 123.1) reveal that with a few exceptions, psittacine birds have similar RBC parameters: PCV of 35–55%; RBC count of 2.4–5.0; hemoglobin concentration of 11–16 mg/dL; MCV of 90–200 fL; and MCHC of 22–33%.[1] Likewise, the normal total WBC count of most psittacine birds tends to fall within a range 5,000–15,000/μL.

Differences in the normal heterophil: lymphocyte (H:L) ratios of various psittacine birds have been reported. For example, evaluation of the data of three species of macaws in one study revealed an H:L ratio of 2.1–2.2, whereas another study reported the range between 0.7 and 0.9.[11,16] In general, most psittacine birds appear to exhibit a predominance of heterophils with an (H:L) ratio ranging between 1.1 and 2.4 (average 1.7) when examining reported reference intervals.[3,4]

Physiological and Environmental Influences

Reference intervals for hematologic parameters of psittacine birds have a broad range owing to the influence of various intrinsic and extrinsic factors. In general, avian hematological values are subject to extensive variability resulting from different environment and management practices that can affect physiological responses.[7] For example, heterophil numbers are altered by seasonal changes, diurnal rhythm, gender, age, and diet.[5,6,14,15,17] Normal hematologic values vary between the species as well. The different avian species from which blood samples are submitted to veterinary laboratories creates a significant logistical challenge to the development of clinically relevant normal values. Thus, published reference intervals should only be used as guidelines.

Blood Sampling Conditions

Blood collection for hematologic evaluation in psittacine birds begins with proper restraint and many birds

[a]Adapted from Polo FJ, Peinado VI, Viscor G, et al. Hematologic and plasma chemistry values in captive psittacine birds. Avian Dis 1998;42:523–535.

can be physically restrained without anesthesia. The beak of these birds can inflict injury to the handler; therefore, proper restraint of the head is required. Cloth towels can be used to safely restrain psittacine birds during the blood collection procedure as long as excessive restraint around the keel is avoided to prevent asphyxiation. Excessive stress that occurs during capture and restraint of birds, especially those not accustomed to being handled or that are ill, can further compromise the health of the patient and alter the hematologic indices.

The blood volume of the galah (*Eolophus roseicapillus*), using the indocyanine green method was determined to be 10.6 ± 2.9% of body weight; therefore, the blood volume of psittacine birds is generally considered to be 10% of the body weight.[12] A maximum blood sample representing one percent of the bird's body weight (or 10% of the blood volume) is generally considered to be a safe amount of blood that can be obtained from a psittacine bird. For routine hematological evaluations in birds, a sample size of 0.2 mL is usually adequate.

A variety of venipuncture sites for blood collection in psittacine birds are available and include the jugular, basilic vein (cutaneous ulnar, wing or brachial), and the medial metatarsal (caudal tibial) vein. Blood can be collected using a needle and syringe when performing venipuncture on the jugular vein or other large veins. Collection of blood with vacuum tubes is not recommended because the excessive aspiration pressure that occurs causes the thin walled veins to collapse during the procedure. A needle and syringe without the use of an anticoagulant is commonly used with rapid collection and transfer of the sample into a collection tube containing the appropriate anticoagulant, such as ethylenediaminetetraacetic acid (EDTA). This method allows for the blood sample to be divided into various collection tubes depending on the intended use of the sample. Blood samples may also be obtained using an anticoagulant in the syringe at the time of collection. A disadvantage of this technique is that the amount of blood collected is not always predictable and frequently results in an inappropriate ratio of anticoagulant to blood.

In general, a short (1 inch [2.54 cm] or less), 25–22 gauge needle attached to a 3 mL syringe is typically used for jugular venipuncture. Venipuncture of the right jugular vein can be performed in most psittacine birds and is the blood collection method of choice for small birds that lack other veins large enough for venipuncture. Because this vein is highly movable and surrounded by a large subcutaneous space predisposing this method of blood collection to hematoma formation, the jugular vein must be stabilized before attempting venipuncture.

The basilic vein crosses the ventral surface of the humeral-radioulnar joint (elbow) directly beneath the skin and is easily visualized by wetting the area lightly with alcohol once the bird is restrained and in dorsal recumbency with the wing stretched away from the body. Venipuncture of this vein can be used to collect blood from medium to large psittacine birds; however, unless anesthetized, most will struggle and move during this type of restraint making blood collection without laceration of the vein difficult.

Venipuncture of the medial metatarsal vein is a common blood collection method in psittacine birds. Blood can be collected either by aspiration into a syringe or by using the drip technique that allows the blood to flow from a needle into a collection tube. The medial metatarsal vein is located on the caudomedial aspect of the tibiotarsus just above the tibiotarsus-tarsometatarsal joint. The vein frequently courses along the caudal aspect of the tibiotarsus and often hides beneath the calcaneal tendon. Because the leg is easy to restrain and the vein is protected by the surrounding muscles of the leg, hematoma formation is minimal compared to venipuncture of a basilic or jugular veins.

BONE MARROW SAMPLING

Collection Sites

Bone marrow samples for cytological evaluation can be successfully obtained in psittacine birds by aspiration of the proximal tibiotarsus.[1] Marrow may also be collected from most of the long bones, except the pneumatic bones. A general or local anesthetic can be used. The type of biopsy needle used for aspiration depends upon the size of the bird, location of the biopsy site, and preference of the cytologist. Bone marrow biopsy needles frequently used for marrow collection in domestic mammals and humans (Jamshidi bone marrow biopsy-aspiration needles and disposable Jamshidi Illinois-Sternal/Iliac aspiration needles, Kormed Corp, Minneapolis, MN) can be used for marrow collection in birds. The pediatric sizes are preferred because of the relatively small bone size of most birds compared to mammals. Spinal needles containing a stylet can be used for marrow collection in very small birds.

The procedure for collecting bone marrow from the proximal tibiotarsus begins with application of a skin disinfectant as for any surgical procedure. The medial or cranial aspect of the proximal tibiotarsus just below the femoral-tibiotarsal joint is a suitable location for aspiration. A small skin incision is made using a scalpel blade to facilitate passage of the needle through the skin. The biopsy needle with stylet is placed against the bone and using gentle pressure and rotary movements, the needle is advanced into the marrow cavity. A perpendicular approach to the bone should be used. The hand not used for manipulating the needle is used to stabilize the tibiotarsus. Once the needle is positioned into the marrow cavity, the stylet is removed and a 3–6 mL syringe is attached. The marrow sample is aspirated only into the lumen of the needle by applying negative pressure to the syringe. Excessive or prolonged negative pressure should be avoided to minimize blood contamination of the marrow sample.

When aspiration is completed, the needle and syringe are removed from the tibiotarsus, making sure negative

pressure is not being applied to the syringe. The needle is removed from the syringe, the syringe is filled with air, and the marrow is forced from the needle lumen onto a glass microscope slide. A second glass microscope slide is placed on top of the marrow sample and the marrow is allowed to spread between the two slides as they are pulled apart. Marrow core biopsies for histologic evaluation can be obtained from birds using a technique similar to marrow aspiration. Once the bone marrow biopsy needle is introduced into the marrow space, the stylet is removed and the needle is advanced deeper into the marrow cavity toward the opposite cortex. Once the opposite cortex has been reached, the needle is twisted and redirected slightly to detach the marrow plug within the lumen of the needle. Gentle vacuum may be applied to the syringe to aid in holding the marrow plug in the needle as the needle is withdrawn from the marrow cavity. The marrow core sample is removed by reinsertion of the stylet (usually beginning at the tip of the needle) to push the sample out of the needle. Imprint films can be made from the core sample for cytological evaluation before the sample is placed in neutral buffered 10% formalin. A sample holder is frequently required to maintain the marrow core while it is being fixed in the formalin solution.

Bone marrow slides are stained with the same Romanowsky stains used for staining blood films. Interpretation of the avian bone marrow begins with scanning the marrow film, using the 10× microscope objective to evaluate the number and distribution of cells. Because an actual cell count of a bone marrow sample cannot be obtained, the cellularity is estimated by evaluation of the ratio of fat and cells in marrow particles and compared with the cellularity of normal bone marrow. Normal bone marrow films should provide enough hematopoietic cells to easily perform a 500-cell differential. The degree of cellularity is estimated as poor, normal, or high.

The distribution of cells can also be estimated. Myeloid, erythroid, and thrombocytic elements may appear normal, decreased, or increased. While a more objective approach is to perform an actual differential count based on 1000 cells or more, this is time consuming, and may not provide more information.

Besides estimating the degree of cellularity and evaluating the distribution of the types of cells in the marrow sample, the cytologist should also estimate the myeloid:erythroid ratio (M:E). Any changes involving the maturation sequence of each cell line should be noted. The cell lines include erythroid cells, granulocytes (heterophils, eosinophils, and basophils), monocytes, and thrombocytes. Other cells occasionally found include lymphocytes, plasma cells, osteoblasts, and osteoclasts. The presence of abnormal cells should also be noted.

An accurate interpretation of the bone marrow response can be made only in conjunction with knowledge of the current cellular changes in the blood. Therefore, an evaluation of a hemogram should be made from a blood sample collected at the same time the bone marrow sample is obtained.

Cell Morphology

Erythropoiesis

The stages of maturation in normal avian erythropoiesis appear to be similar to those of mammals. The terminology used for the different stages of erythrocyte maturation varies in the literature.[1,9,13] In general, there are six recognizable stages involved in RBC development based upon Romanowsky stains. These include rubriblasts, prorubricytes, basophilic rubricytes, early polychromatic rubricytes, late polychromatic rubricytes, polychromatic RBCs, and mature RBCs. As erythroid cells mature, the nuclear size decreases, the chromatin becomes increasingly condensed, the nuclear shape changes from round to ellipsoid, the amount of cytoplasm increases, the Hgb concentration increases (resulting in increasing eosinophilia), and the cell shape changes from round to ellipsoid. Unlike mammalian RBCs, avian RBCs retain their nucleus.

Avian erythropoietin, a glycoprotein that differs structurally from mammalian erythropoietin, is necessary for the multiplication and differentiation of precursor stem cells committed to the erythroid series.[18,19] Erythropoietin can be obtained from the blood of anemic birds and the site of its production is considered to be the kidney.

The rubriblast is a large, round, deeply basophilic cell with a large, round central nucleus resulting in a high nuclear to cytoplasmic (N:C) ratio. The nucleus has coarsely granular chromatin and large prominent nucleoli or nucleolar rings. The cytoplasm is deeply basophilic and frequently contains clear spaces that most likely represent mitochondria.

The prorubricyte resembles the rubriblast but lacks prominent nucleoli. It also has a high N:C ratio with the large nucleus being surrounded by a narrow rim of blue cytoplasm. The cytoplasm is predominantly basophilic, but may contain spots of reddish material suggestive of the beginning of hemoglobin development. The cytoplasm lacks the mitochondrial spaces of the rubriblast.

Rubricytes are round cells that are smaller than rubriblasts and prorubricytes. They can be divided into three stages based primarily upon the appearance of the cytoplasm. The basophilic rubricyte is the earliest rubricyte stage, and is characterized by a homogeneous basophilic cytoplasm and a round nucleus with clumped chromatin. The early polychromatophilic rubricyte is smaller than the basophilic rubricyte, and has a gray (basophilic to slightly eosinophilic) cytoplasm because of increased Hgb production. The nucleus of this cell contains clumped chromatin and is small in relation to the amount of cytoplasm. The final rubricyte stage, the late polychromatophilic rubricyte, is ellipsoid with more eosinophilic (eosinophilic gray to weakly eosinophilic) cytoplasm than earlier stages and the nucleus varies from round to slightly ellipsoid with irregularly clumped chromatin.

Cells in the final stages of erythropoiesis are the polychromatophilic RBCs and mature RBCs. These cells are

found in the blood of normal birds and have been previously described.

Granulopoiesis

Avian granulocytes appear to develop in a manner similar to those of mammals; therefore, they show a progressive decrease in size and cytoplasmic basophilia as they mature. Specific cytoplasmic granules appear in later stages of development and progressively increase in number until a full complement is reached in the cytoplasm of the mature granulocyte. The nuclei of granulocytes are initially round and progress toward segmentation, except basophils which do not segment. The nuclear chromatin becomes increasingly condensed with maturity. The developmental stages of avian granulocytes include myeloblasts, progranulocytes, myelocytes, metamyelocytes, band cells, and mature granulocytes, in order of maturation.

The myeloblast is a large round blast cell with a high N:C ratio and its cytoplasm stains a lighter blue than that of rubriblasts. The nucleus is typically round with a delicate reticular (fine) chromatin and prominent nucleoli. Myeloblasts do not contain specific cytoplasmic granules and possibly represent a stage common to all granulocytes. Myeloblasts are frequently found in association with other developing granulocytes, especially in imprints of bone marrow core biopsies.

The progranulocyte is a large cell with a light blue cytoplasm and slightly eccentric nucleus. The N:C ratio of this cell is smaller than that of myeloblasts because of the increase in cytoplasm volume. The nucleus has a delicate reticular chromatin, absence of nucleoli, and indistinct margins. Progranulocytes contain primary granules that vary in appearance among the types of granulocytes. For example, the heterophil progranulocyte contains primary granules that vary in color and shape that often appear as orange or deeply basophilic spheres and rings. In contrast, eosinophil progranulocytes contain only brightly staining orange primary granules and appear to lack the dark magenta granules and rings found in heterophilic progranulocytes. Basophil progranulocytes contain basophilic granules that appear smaller than the specific basophilic granules and the immature granules of the heterophil series. Fewer ring forms are seen in basophil progranulocytes.

The myelocyte is smaller than myeloblasts and progranulocytes. This cell type contains the secondary or specific granules of the mature granulocytes, making identification of this cell somewhat simple. The round to oval nuclei of the myelocyte appears more condensed than the nuclei of myeloblasts and progranulocytes. Heterophil myelocytes are typically round cells with a light blue cytoplasm that contains a mixture of rod-shaped specific granules and primary granules and rings. The eosinophilic, rod-shaped specific granules occupy less than one-half the cytoplasmic volume. Eosinophil myelocytes lack the deeply basophilic granules and rings occasionally found in early heterophil myelocytes. Basophil myelocytes contain basophilic specific granules that occupy less than one-half the cytoplasmic volume. The specific basophil granules have a slightly eosinophilic tinge compared to the deep violet of the smaller primary granules that may also be present.

The metamyelocyte is slightly smaller than the myelocyte, has a slightly indented nucleus, and possesses specific cytoplasmic granules that occupy greater than one-half the cytoplasmic volume.

Band cells resemble mature granulocytes except that the nucleus appears as a curved or coiled band rather than segmented. It is often difficult to identify band cells because the exact shape of the nucleus is obscured by specific cytoplasmic granules in blood films stained with Romanowsky stains. Because mature basophils lack a segmented nucleus, the band stage of the basophil is not apparent. Mature granulocytes are generally the most abundant cell of each granulocytic cell line in the bone marrow of normal birds and have been described previously.

Thrombopoiesis

Unlike mammalian platelets that are cytoplasmic fragments of large multinucleated megakaryocytes, avian thrombocytes are derived from a distinct line of mononuclear cells found in the bone marrow. The thrombocyte series consists of thromboblasts, immature thrombocytes, and mature thrombocytes. Thromboblasts resemble rubriblasts but tend to be smaller with round nuclei, fine to punctate nuclear chromatin, and one or more nucleoli. The scant cytoplasm stains deeply basophilic and may contain clear spaces. These cells tend to be round to oval with cytoplasmic blebs.

Immature thrombocytes are divided into three groups: early-, mid-, and late-immature thrombocytes, based upon their degree of maturity. Early-immature thrombocytes are intermediate in size between thromboblasts and more mature stages. They tend to be round to oval with more abundant cytoplasm than thromboblasts. The cytoplasm is basophilic and may contain vacuoles. The nuclear chromatin is aggregated into irregular clumps. Mid-immature thrombocytes are slightly elongate or irregular with pale blue cytoplasm. Cytoplasmic specific granules and vacuoles are occasionally seen at this stage of development. The nucleus contains heavy chromatin clumping. Late-immature thrombocytes are oval and slightly smaller than the mid-immature stage. The cytoplasm stains pale blue with vaguely defined clear areas. Specific granules are frequently seen at one pole of the cell. The nucleus is oval with densely packed chromatin. The mature thrombocyte is the definitive cell in the thrombocyte series and has been previously described.

Other Cells Present In Avian Bone Marrow

Monocytes and macrophages are frequently found in avian bone marrow samples. Monocytopoiesis is poorly defined in birds. Monocytes originating in hematopoietic tissue become the monocytes and macrophages

found in blood and body tissues, respectively. Because they are involved with iron metabolism during hemoglobin synthesis and catabolism, macrophages in bone marrow frequently contain gray to black (or sometimes golden crystalline) iron pigment in their cytoplasm.

Aggregates of lymphocytes are found in bone marrow of birds, although major sites of lymphopoiesis in adult birds are located in the spleen, liver, intestines, and cecal tonsils.[2] Immature avian lymphocytes are larger than mature lymphocytes and are classified as lymphoblasts or prolymphocytes, based on morphology. Lymphoblasts have large nuclei with fine chromatin and contain one or more prominent nucleoli. The cytoplasm is relatively abundant and deeply basophilic. Prolymphocytes resemble lymphoblasts but the nuclear chromatin is coarser and nucleoli are absent. Mature lymphocytes have been previously described.

Avian osteoblasts are large cells found in bone marrow and resemble those of mammals. They have abundant, foamy, basophilic cytoplasm with a distinct clear Golgi apparatus. The nucleus is round to oval, eccentrically located in the cell, contains reticular to coarsely granular chromatin, and possesses one or more distinct nucleoli. Osteoblasts are polygonal to fusiform and may have indistinct cytoplasmic margins.

Osteoclasts are large multinucleated giant cells with an ameboid shape. The cytoplasm is weakly basophilic and vacuolated. Red cytoplasmic granules may be present. Nuclei are round to oval and frequently contain prominent nucleoli.

Cell Distribution

The normal M:E ratio of psittacine birds is presumed to be 1.0:1.0. Studies investigating the normal bone marrow cytology of other species of birds indicate the M:E ratio to be 1.2, with a mean erythroid percentage of 39.9%, a mean myeloid percentage of 49.4%, a mean thrombocyte percentage of 6.0% and a mean percentage of all other cells percentage of 4.8%.[20] Increased erythropoiesis is indicated by an increase in polychromasia (reticulocytes) in the blood and bone marrow films. A decrease in the M:E ratio with a normal heterophil concentration in the peripheral blood is an indication of accelerated erythropoiesis. Alternatively, an anemic psittacine bird with a normal peripheral blood heterophil concentration, little or no polychromasia, and an increased M:E ratio is consistent with a decrease in erythropoiesis. Erythroid dysplasia in the peripheral blood film and a marked decrease in the M:E ratio in the bone marrow indicate a myelodysplastic disorder with erythroid predominance. Increased granulopoiesis is usually indicated by a peripheral heterophilia and an increased bone marrow M:E ratio. A decrease in peripheral blood heterophil concentration and decrease in bone marrow M:E ratio indicate a decreased granulopoiesis. Myeloid leukemias exhibit increased numbers of myeloid blast cells in the peripheral blood and bone marrow.

Starvation can result in a decrease in myeloid, erythroid, and thrombocyte elements, but the bone marrow M:E ratio may be normal. A profound leukopenia, heteropenia, and anemia associated with severe bone marrow suppression and hypoplasia can be associated with toxicities, such as fenbendazole or albendazole toxicity, in birds.[21]

EDTA, ethylenediaminetetraacetic acid; Hgb, hemoglobin; H:L, heterophil:lymphocyte ratio; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; N:C, nuclear:cytoplasmic ratio; PCV, packed cell volume; RBC, red blood cell; WBC, white blood cell.

WATERFOWL

Erythrocyte Morphology

Mature erythrocytes of waterfowl, like those of other birds, are elliptical cells with an elliptical, centrally positioned purple nucleus that contains uniformly clumped chromatin and a uniform orange-pink cytoplasm in Wright's stained blood films.[21] In general, mature erythrocytes appear uniform in size in the blood film of birds; however, erythrocyte subpopulations where larger erythrocytes (mean corpuscular volume [MCV] = 308 fL) most likely represent those most recently released from the hematopoietic tissue and smaller cells (MCV = 128 fL) likely representing older aging cells have been reported in ducks.[13]

Polychromatophilic erythrocytes represent cells recently released into the peripheral blood. As these cells mature, the nuclear chromatin becomes more condensed and the cytoplasm less blue. Polychromatic erythrocytes are more prevalent in the peripheral blood of waterfowl compared to mammals because the erythrocyte lifespan of birds is generally shorter in comparison to that of mammalian erythrocytes. For example, the erythrocyte lifespan of ducks is 42 days.[35]

Erythrocytes that vary in size from the majority of erythrocytes are occasionally observed in peripheral blood films of normal waterfowl; however, a greater degree of anisocytosis as well as polychromasia is observed in birds with a regenerative response to anemia.

Likewise, a minor deviation from the normal shape of erythrocytes is considered normal in the peripheral blood of birds; however, marked poikilocytosis is an indication of erythrocytic dysgenesis.

Hypochromatic erythrocytes are occasionally found in the peripheral blood film of normal waterfowl; however, when they occur in high numbers, it is considered abnormal and a significant hypochromasia will be reflected as a decrease in the mean corpuscular hemoglobin concentration (MCHC).

Hypochromasia can be seen with iron deficiency, chronic inflammatory diseases and lead toxicosis.[11,20] Hypochromatic erythrocytes frequently appear in blood films from waterfowl with chronic inflammatory diseases, presumably related to iron sequestration as part of the bird's defense against infectious agents. In such cases, hypochromatic cells are often observed in blood films before the red cell indices, such as MCHC, suggest hypochromasia.

The presence of immature erythrocytes (i.e. rubricytes) in peripheral blood films of waterfowl, in addition to increased polychromasia, indicates a marked erythrocytic regenerative response as seen with hemolytic or blood loss anemias.[40]

A nonregenerative normocytic normochromic anemia is indicative of decreased erythropoiesis (depression anemia) which can develop rapidly in birds with inflammatory diseases, especially those involving infectious agents, owing to their short erythrocyte half-life. Thus, the degree of polychromasia or reticulocytosis is poor to absent in birds with depression anemias.

Leukocyte Morphology

Leukocytes in blood films of waterfowl, like those of other birds, include lymphocytes, monocytes, and granulocytes. The granulocytes are classified as heterophils, eosinophils, and basophils. In general, the morphology of these cells is the same as that of other birds (Chapter 123).[21]

In the species of Anseriformes (ducks and geese) whose normal leukograms have been studied, lymphocytes have been shown to be the most abundant leukocyte.[7,40] For example, the heterophil:lymphocyte ratio (H:L) for the American black duck, wood duck, mallard, and snow goose ranges between 0.4:1 and 0.7:1.[7,22,23,39]

Lymphocytes of waterfowl, like those of other birds, can be small or large. Reactive lymphocytes are occasionally found in the blood films of normal birds. These lymphocytes have a deep staining blue cytoplasm, often with an irregularly shaped nucleus and pink-purple cytoplasmic granules, compared to nonreactive lymphocytes. Reactive lymphocytes without the cytoplasmic granules are considered to be B cells, whereas those with granules are thought to be natural killer or T cells.

Thrombocyte Morphology

Like those of all birds, the blood films of waterfowl contain thrombocytes. The morphology of these cells is consistent among the various species of birds. Because thrombocytes participate in the coagulation process, they tend to clump in the blood film.

Reference Intervals

These are given in Table 124.1.

Age Influences

Age can be a cause of variation in the normal hemogram of healthy waterfowl. For example, 4- to 10-week-old ducklings exhibit a lower packed cell volume (PCV) and slightly higher protein concentration compared to adult ducks.[18] This difference is likely associated with the high metabolic rate of young rapidly growing ducks that are consuming diets higher in protein and carbohydrates.

Age may also affect the normal leukogram. For example, ducklings and goslings younger than 60 days of age have lower relative lymphocyte and higher relative heterophil counts compared to adult ducks and geese.[7]

Age also influences the thrombocyte count. Young ducklings and goslings tend to have lower thrombocyte concentrations compared to adult birds of the same species. The number of thrombocytes in the peripheral blood begins to increase at 5 days of age and reaches adult concentrations by 18 days of age.[7]

Species Influences

Significant differences occur between species of waterfowl in regard to the red blood cell (RBC) parameters. For example, mallard ducks (*Anas platyrhynchos*), a dabbling duck, have higher average PCV and RBC counts in the winter and pre-nesting period compared to diving ducks (*Aythya* spp. and *Oxyura jamaicensis*).[31] The same study demonstrated that diving ducks, on the other hand, have higher MCV values during the winter and pre-nesting period compared to mallards. In general, ducks tend to have higher RBC counts than geese, but geese have higher MCV and hemoglobin (Hgb) than ducks during the winter.[31] Total RBC counts tend to be slightly higher for snow geese (*Chen caerulescens*) compared to Canada geese (*Branta canadesis interior*); however, these differences are clinically insignificant.[39]

Birds with a normal H:L ratio less than 1.0, such as many species of waterfowl, exhibit an initial leukogram response to stress and inflammation with leukopenia associated with a lymphopenia followed up to 12 hours later by a leukocytosis, heterophilia, and lymphopenia.[5,10] Birds with a higher proportion of heterophils than lymphocytes in their normal leukograms tend to exhibit a less dramatic response in the stress leukogram.

Immature heterophils are rarely found in the blood film of normal waterfowl. Immature heterophils have increased cytoplasmic basophilia, nonsegmented nuclei, and immature cytoplasmic granules when compared to normal mature heterophils (see Chapter 123). When present, they represent a left shift indicating an increased demand for heterophils owing to an inflammatory stimulus and can be associated with either a heterophilia or heteropenia. Leukemia would be a rare cause for the presence of immature heterophils in the blood film of waterfowl.

In response to severe systemic inflammation, avian heterophils exhibit toxic changes similar to those seen in mammalian neutrophils.[3] Also, as in mammalian hematology, toxic changes in avian heterophils are subjectively quantified as to the number of toxic cells and severity of toxicity.[38] When present, toxic heterophils represent a severe inflammatory response regardless of the leukocyte count.

Physiological and Environmental Influences

Like those of other avian species, the normal values for the hematologic parameters of waterfowl have a broad

TABLE 124.1 Selected Hematology Data for Normal Ducks and Geese

	American Black Duck[a]	Wood Duck[b]	Canada Goose[c]		Snow Goose[d]	Mallard Duck[e]	
			January	June		January	June
RBC ($\times 10^6/\mu L$)	2.78 ± 0.22	2.79 ± 0.22	2.67 ± 0.3	2.18 ± 0.3	2.25	3.35 ± 0.3	2.01 ± 0.4
PCV (%)	40.24 ± 4.21	45.54 ± 3.41	51 ± 3.1	46 ± 3.5	46	49 ± 2.5	39 ± 5.1
Hb (g/dL)	12.96 ± 1.36	14.95 ± 1.22	16.2 ± 1.0	14.0 ± 1.2	14.0	15.6 ± 0.8	11.4 ± 1.6
MCV (fL)	144.68 ± 9.96	164.24 ± 14.43	193.3 ± 16.6	210.1 ± 19.4	204	148.4 ± 13.7	199.6 ± 27.7
MCHC (g/dL)	32.23 ± 1.16	32.99 ± 3.7	31.6 ± 0.1	30.7 ± 1.4	30.4	31.6 ± 0.2	29.2 ± 2.0
WBC ($\times 10^3/\mu L$)	19.7 ± 6.60	25.58 ± 5.72	20.4–21.8		20.1 ± 4.71	23.4–24.8	
Heterophils ($\times 10^3/\mu L$)	4.86 ± 1.37	8.45 ± 2.59	39%		7.0	38% ± 1.5	29% ± 1.4
Lymphocytes ($\times 10^3/\mu L$)	13.03 ± 1.53	13.28 ± 1.77	46%		12.3	54% ± 1.6	66% ± 1.4
Monocytes ($\times 10^3/\mu L$)	1.46 ± 0.99	1.05 ± 0.68	6.0%		0.2	3.6% ± 0.3	2.5% ± 0.3
Eosinophils ($\times 10^3/\mu L$)	0.22 ± 0.16	0.51 ± 0.06	2.0%		0.5	0.4% ± 0.1	0.2% ± 0.17
Basophils ($\times 10^3/\mu L$)	0.16 ± 0.15	0.41 ± 0.23	7.0%		0.1	3.6% ± 0.3	2.2% ± 0.3

range owing to the physiological and environmental influences on the blood cells (Chapter 123). Seasonal variations, age, and species affect the erythrocyte parameters, such as the PCV, RBC count, Hgb concentration, MCHC, and MCV of normal waterfowl. In general, variations in these parameters in adult ducks and geese most likely reflect seasonal effects associated with hormonal and nutritional changes caused by alterations in the photoperiod and migration. For example, variations in erythrocyte parameters associated with gender in ducks and geese are generally not statistically significant; however, differences between males and females have been reported and reflect a seasonal variation, where females tend to have higher PCV, Hgb, RBC counts, and MCHC values compared to males in the pre-nesting period.[22,23,38] Other studies have shown that averages for these parameters tend to be higher in the winter and pre-nesting period in adult ducks and geese regardless of gender compared to the post-nesting period and fall.[31,39] During migration, ducks tend to have slightly lower RBC counts compared to wintering ducks and post-nesting MCV averages for these birds tend to be higher in the winter or pre-nesting periods.[18,31] These changes also occur in captive ducks that are not able to migrate.

In general, the leukogram (white blood cell [WBC] count and H:L ratio) is not affected significantly by the reproductive state (pre-egg laying, egg-laying, incubation, molting, and post-egg laying) of ducks and geese, and there is no significant difference between genders.[7,39] However, the percentage of heterophils in the peripheral blood of ducks has been shown to decrease during and immediately following the molting of the flight feathers (remige molt).[6]

Thrombocyte concentrations are also influenced by seasonal changes. For example, a decrease in thrombocyte concentration has been demonstrated in female ducks during the incubation, molting, and post-reproductive periods compared to other periods.[7]

Blood Sampling Conditions

Blood collection for hematologic evaluation in waterfowl requires proper restraint. In general, these birds are relatively harmless to humans, with large geese and swans being an exception. Most can be physically restrained safely in a cloth towel without anesthesia before venipuncture as long as excessive restraint around the keel is avoided to prevent asphyxiation. Excessive stress that occurs with the capture and restraint of birds, especially those not accustomed to being handled or birds that are ill, can further compromise the health of the patient and the hematologic indices.

A maximum blood sample representing 1% of the bird's body mass (or 10% of the blood volume) is generally considered to be a safe amount of blood that can be obtained from birds. For routine hematological evaluations in birds, a sample size of 0.2 mL is usually adequate.[4]

A variety of venipuncture sites for blood collection in waterfowl are available and include the jugular,

basilic vein (cutaneous ulnar, wing or brachial), and the medial metatarsal (caudal tibial) vein. Blood can be collected using the same procedure described for other avian species (Chapter 123).

Bone Marrow Sampling

Collection Sites

Marrow samples for cytological evaluation can be successfully obtained in waterfowl by bone marrow aspiration of the proximal tibiotarsus or other non-pneumatic long bones using the same technique as for other birds (Chapter 123).

Cell Morphology

The study of avian hematopoiesis lags behind research in mammalian hematopoiesis because the maturation stages of avian granulocytes have been described based only upon their morphologic appearance, primarily in chicken bone marrow.

Erythropoiesis The stages of maturation in normal avian erythropoiesis appear to be similar to those of mammals. The terminology used for the different stages of erythrocyte maturation varies in the literature.[3,8,11] In general, there are six recognizable stages involved in red blood cell development based upon Romanowsky stains. These include rubriblasts, prorubricytes, basophilic rubricytes, early polychromatic rubricytes, late polychromatic rubricytes, polychromatic erythrocytes, and mature erythrocytes (Figs.124.1–124.3). As erythroid cells mature, the nuclear size decreases, the chromatin becomes increasingly condensed, the nuclear shape changes from round to ellipsoid, the amount of cytoplasm increases, the Hgb concentration increases (resulting in increasing eosinophilia), and the cell shape changes from round to ellipsoid. Unlike mammalian erythrocytes, avian erythrocytes normally retain their nucleus.

Avian erythropoietin, a glycoprotein that differs structurally from mammalian erythropoietin, is necessary for the multiplication and differentiation of precursor stem cells committed to the erythroid series.[35] Erythropoietin can be obtained from the blood of anemic birds and the site of its production is considered to be the kidney.

Granulopoiesis The developmental stages of avian granulocytes include myeloblasts (granuloblasts), progranulocytes (promyelocytes), myelocytes, metamyelocytes, band cells, and mature granulocytes, in order of maturation. (Fig. 124.4) In general, avian granulocytes show a progressive decrease in size and cytoplasmic basophilia as they mature, similar to granulocytes of mammals. Specific cytoplasmic granules appear during the later stages of development and progressively increase in number until a full complement is reached in the cytoplasm of the mature granulocyte. The nuclei of avian granulocytes are initially rounded, and progress toward segmentation and the nuclear chromatin becomes increasingly condensed with maturity. Basophils are the exception because the nucleus of the avian basophil does not segment with maturation.

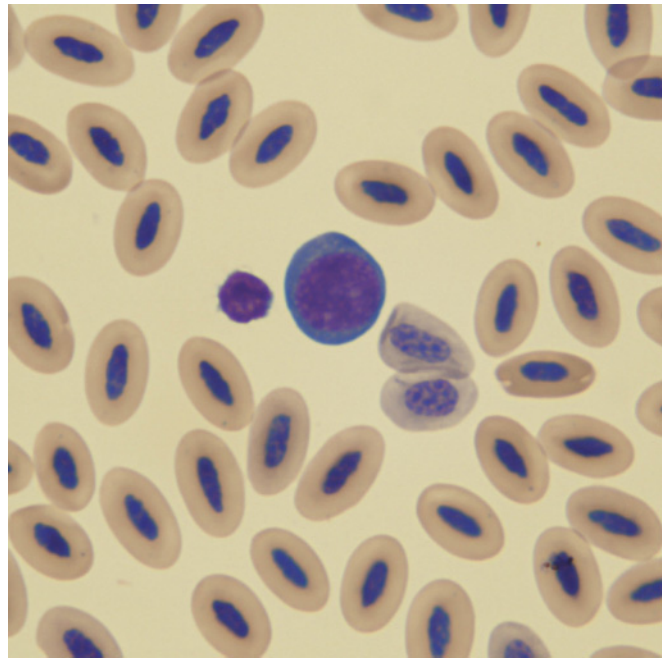

FIGURE 124.1 A prorubricyte in the bone marrow sample of a duck. Wright stain.

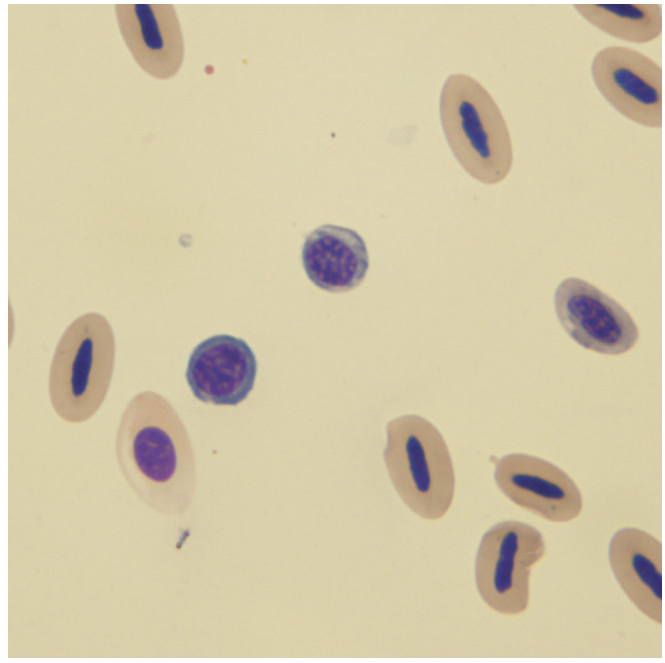

FIGURE 124.2 A basophilic (bottom round cell) and an early polychromatic rubricyte (top round cell) in the bone marrow sample of a duck. Wright stain.

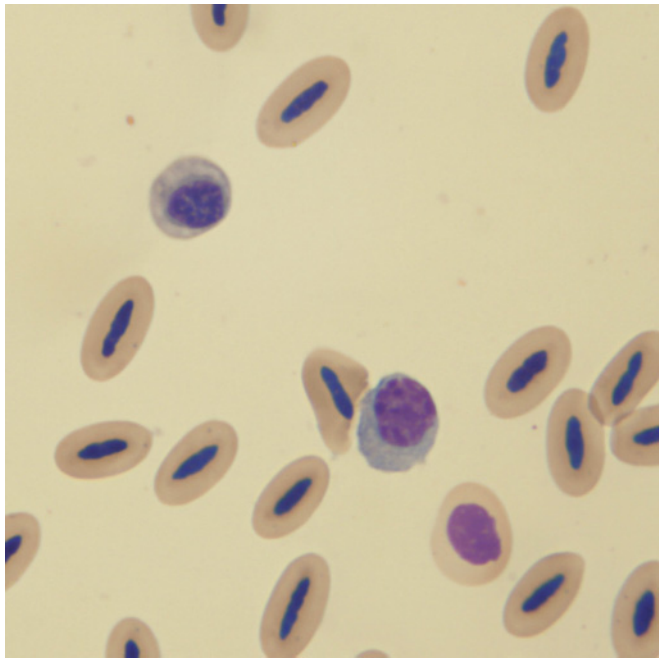

FIGURE 124.3 A late polychromatic rubricyte (top round cell) in the bone marrow sample of a duck. Wright stain.

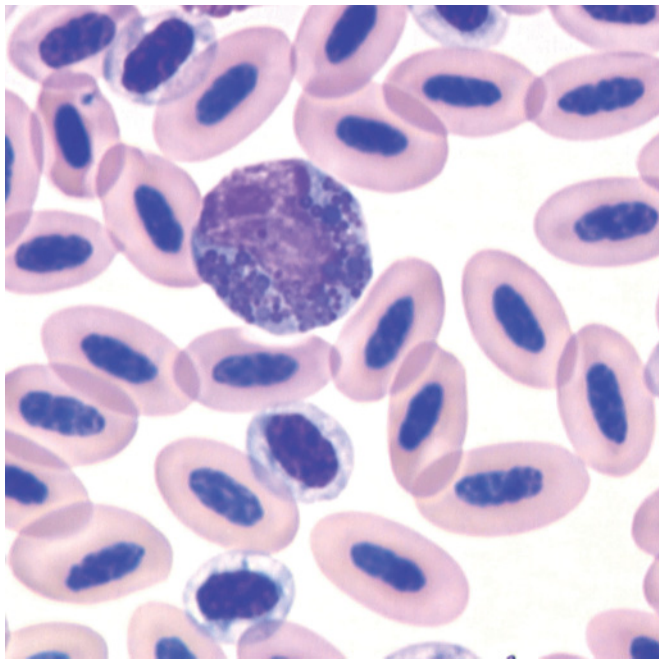

FIGURE 124.4 A progranulocyte in the bone marrow sample of a duck. Wright stain.

Thrombopoiesis Avian thrombocytes appear to be derived from a distinct line of mononuclear cells found in the bone marrow, unlike mammalian platelets which are cytoplasmic fragments of large, multinucleated megakaryocytes. The avian thrombocyte series consists of thromboblasts, immature thrombocytes, and mature thrombocytes (Fig. 124.5). Thromboblasts appear as small, round to oval cells that resemble rubriblasts, and contain round nuclei with fine to punctate nuclear chromatin, and one or more nucleoli. Cytoplasmic blebs may be present on the cell margins.

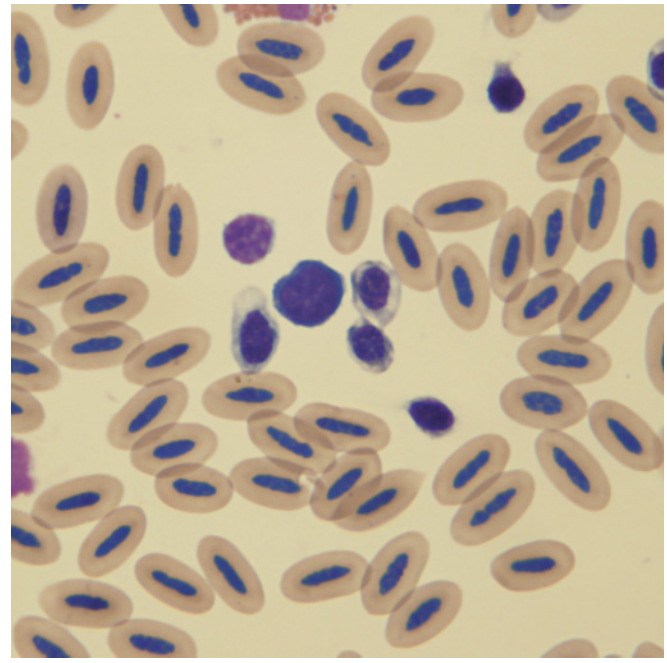

FIGURE 124.5 A thromboblast (dark cell in the center) flanked by mature thrombocytes in the bone marrow sample of a duck. Wright stain.

Immature thrombocytes may be divided into three groups: early-, mid-, and late-immature thrombocytes based upon their degree of maturity. Avian thrombocytes show a progressive decrease in cell size, nuclear size, and cytoplasmic basophilia as they mature. There is also a progression toward the ovoid shape of the mature cell and the nucleus becomes more pyknotic with age. Cytoplasmic specific granules and vacuoles appear at the mid-immature thrombocyte stage of development.

RAPTOR HEMATOLOGY

Raptor, or birds of prey, is an informal grouping of several families including: Accipitridae (hawks, eagles, buzzards, harriers, kites, Old World vultures), Pandionidae (osprey), Sageittaridae (secretary bird), Falconidae (falcons, caracaras), Cathartidae (New World vultures, condors), Strigidae (typical owls), and Tytonidae (barn and bay owls).[2] Literature regarding hematological data from raptorial birds is limited. Additionally, most studies do not provide enough information for the establishment of proper reference intervals, usually due to a small sample size and lack of medically pertinent information, such as age, sex, health, season, and breeding status. Therefore, some clinicians suggest that only significantly abnormal blood values which correspond with clinical findings in support of a disorder be considered valid.[12] However,

the lack of established hematology reference intervals on birds of prey should not deter the clinician from using hematology as a diagnostic tool.

As with other avian species, the blood of raptors contains nucleated erythrocytes, nucleated thrombocytes, and various types of leukocytes. The normal avian hemogram usually includes PCV, RBC and WBC counts, and the determination of the Hgb concentration. Factors that may influence the hematologic results include individual variation between species, wild versus captive status, age, sex, nutrition, environmental conditions and health status.[12]

Blood Sampling Condition

Common sites of collecting blood from raptors include the cutaneous ulnar (wing) vein, jugular vein, or medial metatarsal vein. Even with large birds of prey such as eagles, hawks and owls, only short 25–22 gauge needles should be used to obtain blood samples as the vessel walls of birds are relatively thin and easily damaged.[4] Larger volumes of blood can be collected via cardiac puncture or occipital venous sinus but with risk of serious complications. Adequate restraint of the bird is essential to prevent the inadvertent formation of hematomas from lacerated vessels. Blood should be immediately used to make fresh smears or drawn into tubes containing EDTA anticoagulant, as heparin often causes clumping of leukocytes and changes in the affinity of cells to Romanowsky (Wright's or Wright-Giemsa) stains.[16] Ethylenediaminetetraacetic acid (ETDA) has been associated with mild hemolysis in some species, in which cases heparinized tubes can be used with the added advantage that the plasma can be used for blood chemistry analysis.[4]

Laboratory Evaluation

The PCV can be determined by use of a microhematocrit capillary tube and centrifugation as with mammalian blood. Total RBC counts can be determined manually by using a hemocytometer and erythrocyte Unopette (Becton-Dickinson, Rutherford, NJ) method. Directions for use of other special diluents (Natt-Herrick's) for counting avian blood cells can be found in Chapters 50 and 123 of this book. Properly calibrated, automated cell counters can also be used with a higher degree of precision for rapidly determining RBC counts in avian species.[16] The WBC count can be performed manually using either Natt-Herrick's solution or the eosinophil Unopette 5877 (Becton-Dickinson) method. The free nuclei from lysed RBCs interfere with the cyanomethemoglobin spectrophotometric measurement of Hgb in avian blood samples. Therefore, as with other avian species, the blood sample must be centrifuged following cell lysis to remove the free nuclei before evaluating Hgb concentration. Following determination of total RBC number, PCV, and Hgb concentration, the MCV, MCH, and MCHC are calculated as for other species.[4]

Erythrocyte Morphology

The raptorial RBC, like those of other avian species, is an elliptical, biconvex cell that contains an elongated oval nucleus. The centrally located nucleus has clumped chromatin which becomes more condensed as the cell ages.[16] Immature polychromatophilic erythrocytes have a clear light blue cytoplasm and may constitute up to 5% of the cell count in mature birds with normal RBC mass with higher percentages seen in association with increased erythrogenesis in responsive anemia (Fig.124.6). With vital stain (new methylene blue) polychromatophilic red cells will stain as reticulocytes with prominent dark aggregates of reticulin material surrounding the nucleus. Reticulocytes mature rapidly to normochromic erythrocytes which have a relatively short lifespan of 20–45 days.[15]

The PCV of raptors ranges from 30% to 50%, with an average being around 40% (Table 124.2). Redig reported hematocrits of wild raptors as being between 42% and 45%, with values of 50% common in the larger falcons.[28] The MCV in raptors and most avian species is considerably higher than in mammals, ranging from 105–220 fL.[16,34] Smith and Bush found that the RBCs for hawks and falcons were slightly smaller and more numerous than those of eagles and owls.[32] Generally, the RBC counts in raptors (species range $1.5–5.4 \times 10^6/\mu L$) are also lower than seen in mammalian blood, while Hgb concentration is similar.[4,14,16] Variation in MCHC and mean corpuscular hemoglobin (MCH) from mammalian values is secondary to differences in raptor RBC counts and MCV.

Unlike pigeons and doves, no apparent difference existed in the PVC and RBC values between the sexes of the same species of raptor.[33] This same study also demonstrated no significant differences in these values for kestrels maintained under different lighting regimens or of differing breeding experience (i.e. juvenile versus breeding).

Leukocyte Morphology

The leukocytes consist of granulocytes (heterophils, eosinophils, basophils), lymphocytes, and monocytes (Figs. 124.7, 124.8). Heterophils are round cells 10–12 µm in diameter with a lobulated nucleus. The cytoplasm is usually colorless to pale pink and contains numerous rod-shaped to oval eosinophilic granules which may be partially refractile. Lymphocytes vary in size and shape but are generally approximately the size of erthrocytes or slightly smaller, and have a large, dark-staining nucleus with scant basophilic cytoplasm that lacks vacuoles and granules. The eosinophil is an irregularly rounded cell similar in size to the heterophil with a clear to light blue cytoplasm and a bilobed nucleus. These cells contain intensely eosinophilic spherical inclusions that are generally more numerous than those of the heterophil. Basophils are similar to heterophils in size and shape but contain strongly basophilic granules. Monocytes are slightly larger than lymphocytes with a large, less darkly staining, variably shaped nucleus and

more voluminous gray-blue cytoplasm that occasionally contains vague small eosinophilic granules and vacuoles. These cells are often mistakenly identified as lymphocytes.

Smith and Bush found the WBC values of normal birds of prey were relatively close, with eagles having the highest values (Table 124.3).[32] In most raptorial species, the heterophil is the most common leukocyte, but the lymphocyte appears to be the most common cell type in owls.[17] Increases in heterophils may be seen during episodes of stress, infections, and exposure to cold.[14] Increases in basophil and eosinophil counts may reflect intestinal parasitism or hemoparasites.[15,17]

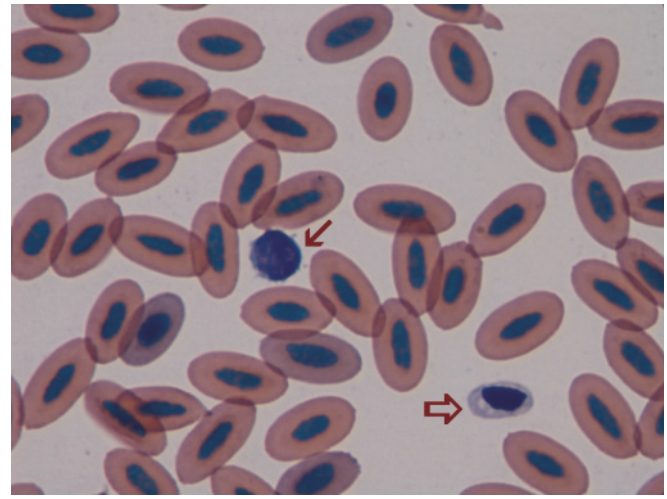

FIGURE 124.8 Barn owl (*Tyto alba*): lymphocyte, solid-arrow; thrombocyte, open-arrow. Wright stain; 100× objective.

Thrombocyte Morphology

The thrombocytes are small, rounded cells that contain a clear reticulated cytoplasm which may contain small red granules or vague vacuolation. Their nuclear:cytoplasmic ratio (N:C) is high and nuclear chromatic staining is dense. Features helpful in distinguishing thrombocytes from lymphocytes are the presence of clear cytoplasm, vacuoles, and granules in the former (Fig. 124.8).[4] Thrombocytes can also be selectively stained with a periodic acid-Schiff stain to aid in differentiation.[30]

Evaluation of the ratite hemogram is important in the veterinary care of diseased birds. The usefulness of ratite hematology is limited by technical difficulties similar to other avian species having nucleated erythrocytes and thrombocytes; however, their large blood volume means that ample blood can be obtained easily for evaluation. The value of the hemogram in confirming health and evaluating disease is well established in most domestic species. Unfortunately, wide laboratory-to-laboratory differences in reference intervals and sparse clinical information concerning hematologic changes expected with specific ratite diseases frustrate the interpretation of ratite hematology.

The focus of ratite medicine varies from the care of an individual bird to that of flock management. Although a full hemogram is quite useful in the diagnosis of or therapy for an individual sick ratite, partial automated hemograms can also provide useful clinical information in screening for the presence of disease in a flock. To this end, the development of automated laser-based hematologic analyzers provides an inexpensive way to perform hematologic screening of ratite flocks. The authors' experience with the Abbott CELL-DYN 3500 Hematology Analyzer (Santa Clara, CA) is that it accurately determines the hematocrit (based on mean corpuscular volume [MCV] and red blood cell [RBC] count) and the absolute heterophil count. The instrument has difficulty separating the similar-sized ratite small lymphocytes from thrombocytes. However, once a specific disease problem is identified in a flock, knowing the status of heterophils and hematocrit in individual birds can be quite useful in the treatment and evaluation of the disease in the flock. As their accuracy improves, the automated hematologic analyzers of the future may prove increasingly useful in efficient, economic evaluation of flock problems.

SAMPLE COLLECTION

In larger ratites, blood is commonly collected from the cutaneous ulnar vein located on the ventral surface of the wing. In smaller ratites and ostrich chicks, the jugular vein is the preferred site for venipuncture. Blood collection is facilitated in large ratites by using a 21-gauge butterfly needle attached to a 12 inch (30.5 cm) flexible plastic infusion set. This allows some movement of the minimally restrained patient after venipuncture without dislodging the needle and causing hematoma formation. After sufficient blood has been aspirated into the syringe, any bubbles in the infusion line are cleared and the needle is inserted into appropriate Vacutainer tubes. Blood is allowed to flow into the Vacutainer tube without pressure on the syringe. Covering the eyes of ratites, particularly ostriches, by the use of a head hood facilitates their restraint. This technique may initially cause some degree of

excitement or struggling, which compromises interpretation of the hemogram values.

The preferred anticoagulant in ratite blood is citrate (blue top Vacutainer tube). When comparing citrate values to other values, the effect of 1:9 citrate dilution must be considered.[7] Heparin interferes with staining and causes marked heterophil clumping.[2] There is increased scatter of the ostrich heterophil population collected in heparin compared with the rather homogeneous heterophil population when collected in citrate (Fig. 125.1). Ethylenediaminetetraacetic acid (EDTA) adversely affects blood from some ratites, causing severe hemolysis or poor cell preservation. It is recommended that blood smears be made immediately after collection for optimal morphology of ratite blood cells. Some laboratories have found that smears made by the coverslip method have fewer smudge cells.[4]

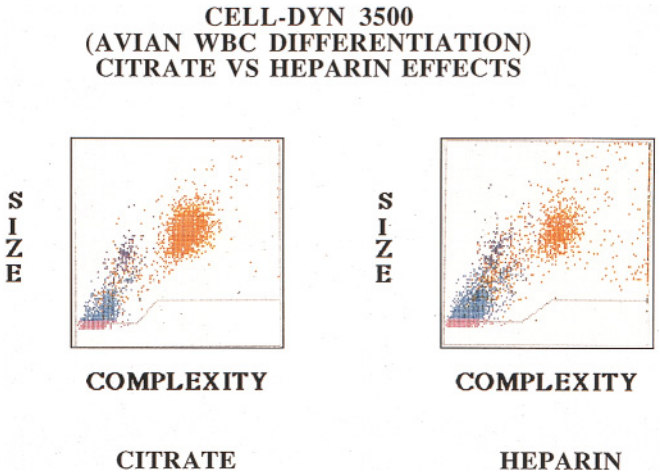

FIGURE 125.1 CELL-DYN 3500 outputs of ostrich blood collected in either sodium citrate or heparin anticoagulants. Note the uniformity of the (orange-colored) heterophil population in citrate compared with the scattered, more diffuse heterophil population when collected in heparin.

The same laboratory hemogram techniques are used with ratite blood as with other avian species and will not be repeated here.[3] If automated hematology analyzers can accurately determine the absolute heterophil count in ratites, then that count along with the manual differential could be used to establish the white blood cell (WBC) count. This would replace the inaccurate and labor-intensive absolute granulocyte count using the eosinophil Unopette (Becton-Dickinson, Rutherford, NJ) and the hemocytometer. The variable spectrophotometric effects of avian erythrocyte nuclei can invalidate automated hemoglobin measurement.

REFERENCE INTERVALS

Reference intervals for ratites are sparse and vary considerably from laboratory to laboratory (Tables 125.1 and 125.2). In part, this reflects the high laboratory error inherent in manual granulocyte count and the common 100-cell count differential, which are used to estimate the total WBC count. Automated hematology analyzers have greatly improved the accuracy of counting and sizing ratite RBCs.

Because ratite hematocrits are similar to other species, there is an inverse relationship between their large RBC size (MCV greater than 175 fL) and their low RBC counts (less than 2–3 10^6/μL). There are age-related differences in reference interval values, particularly with respect to erythrocyte parameters. Ostrich chicks (1–3 months of age) have hematocrits of about 30%, whereas adult ostriches have hematocrits of about 40%.[8] Despite the lower MCV of juvenile ostriches, their higher RBC count makes their hematocrit approach that of adult ostriches. In contrast to reports suggesting that the presence of a nucleus in the avian erythrocyte causes lowered mean corpuscular hemoglobin concentration (MCHC), most ratite reference interval MCHC determinations appear quite similar to those of mammals (Tables 125.1 and 125.2).[11] In ratite patients, the presence of lipemia or incomplete removal of erythrocyte nuclei causes spuriously increased hemoglobin values (which

also increase MCH or MCHC). It is noted that the WBC count of juvenile ostriches is higher than that of adults, so heterophilic leukocytosis must be interpreted with caution in young ratites.[4,8] Some reference ranges show higher lymphocyte and basophil counts in young ostriches than in adults.

COMMENTS ON SPECIFIC BLOOD CELL MORPHOLOGY

Erythrocyte Morphology

The ratite erythrocyte is an oval nucleated cell that is much larger (MCV > 200 fL) than most other avian species (MCV = 125–179 fL) or common domestic animals (MCV = 40–70 fL). It has a centrally placed compressed oval nucleus with uniformly clumped chromatin which becomes progressively more condensed as cells age. The nucleus of the ostrich erythrocyte varies in shape from an elongated oval to teardrop-shape. The erythrocyte cytoplasm has a uniform orange-pink color when stained with most Wright stains.

Young polychromatophilic ratite erythrocytes normally comprise approximately 1–2% of the total erythrocyte population and reflect the status of marrow erythrocyte production. Immature ratite erythrocytes have a more round shape than mature erythrocytes, and their cytoplasmic color ranges from blue to gray-purple (Fig. 125.2). Their nucleus is also more round and much less condensed than the mature erythrocyte nucleus. Reticulocyte counts are uncommonly performed on ratite blood but can be used in quantifying regenerative responses similar to other avian species. Using Wright stain, reticulocytes tend to be slightly larger and bluer (polychromatophilic macrocytes) than mature erythrocytes. The new methylene blue stain reveals variable numbers of dark blue staining RNA aggregates that surround the reticulocyte nucleus. Both punctate and aggregate reticulocytes are present in ratites, but only the aggregate forms are counted in performing a reticulocyte count (similar to the evaluation of feline reticulocytes).[3]

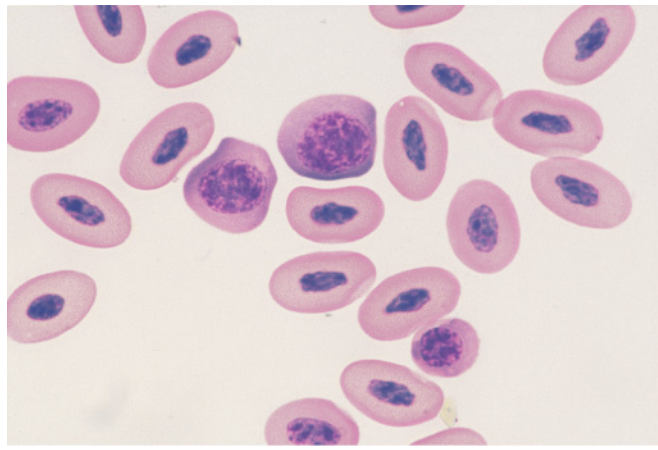

FIGURE 125.2 Diff-Quik stain of emu blood showing immature erythrocytes. Note the two larger rubricytes and the smaller metarubricyte having blue-gray (polychromatophilic) cytoplasm with nuclei that are more round and have less condensed nuclear chromatin than the mature erythrocytes.

Thrombocyte Morphology

The ratite thrombocyte is a nucleated cell that is about half the size of their erythrocytes. It has a round to oval shape, with a dense pyknotic round nucleus and a moderate amount of clear, somewhat reticulated cytoplasm. The cytoplasm often has several reddish granules and may have several clear spaces or vacuoles (which are more commonly noted in partially activated thrombocytes) (Figs. 125.3A and 125.4). Thrombocytes often

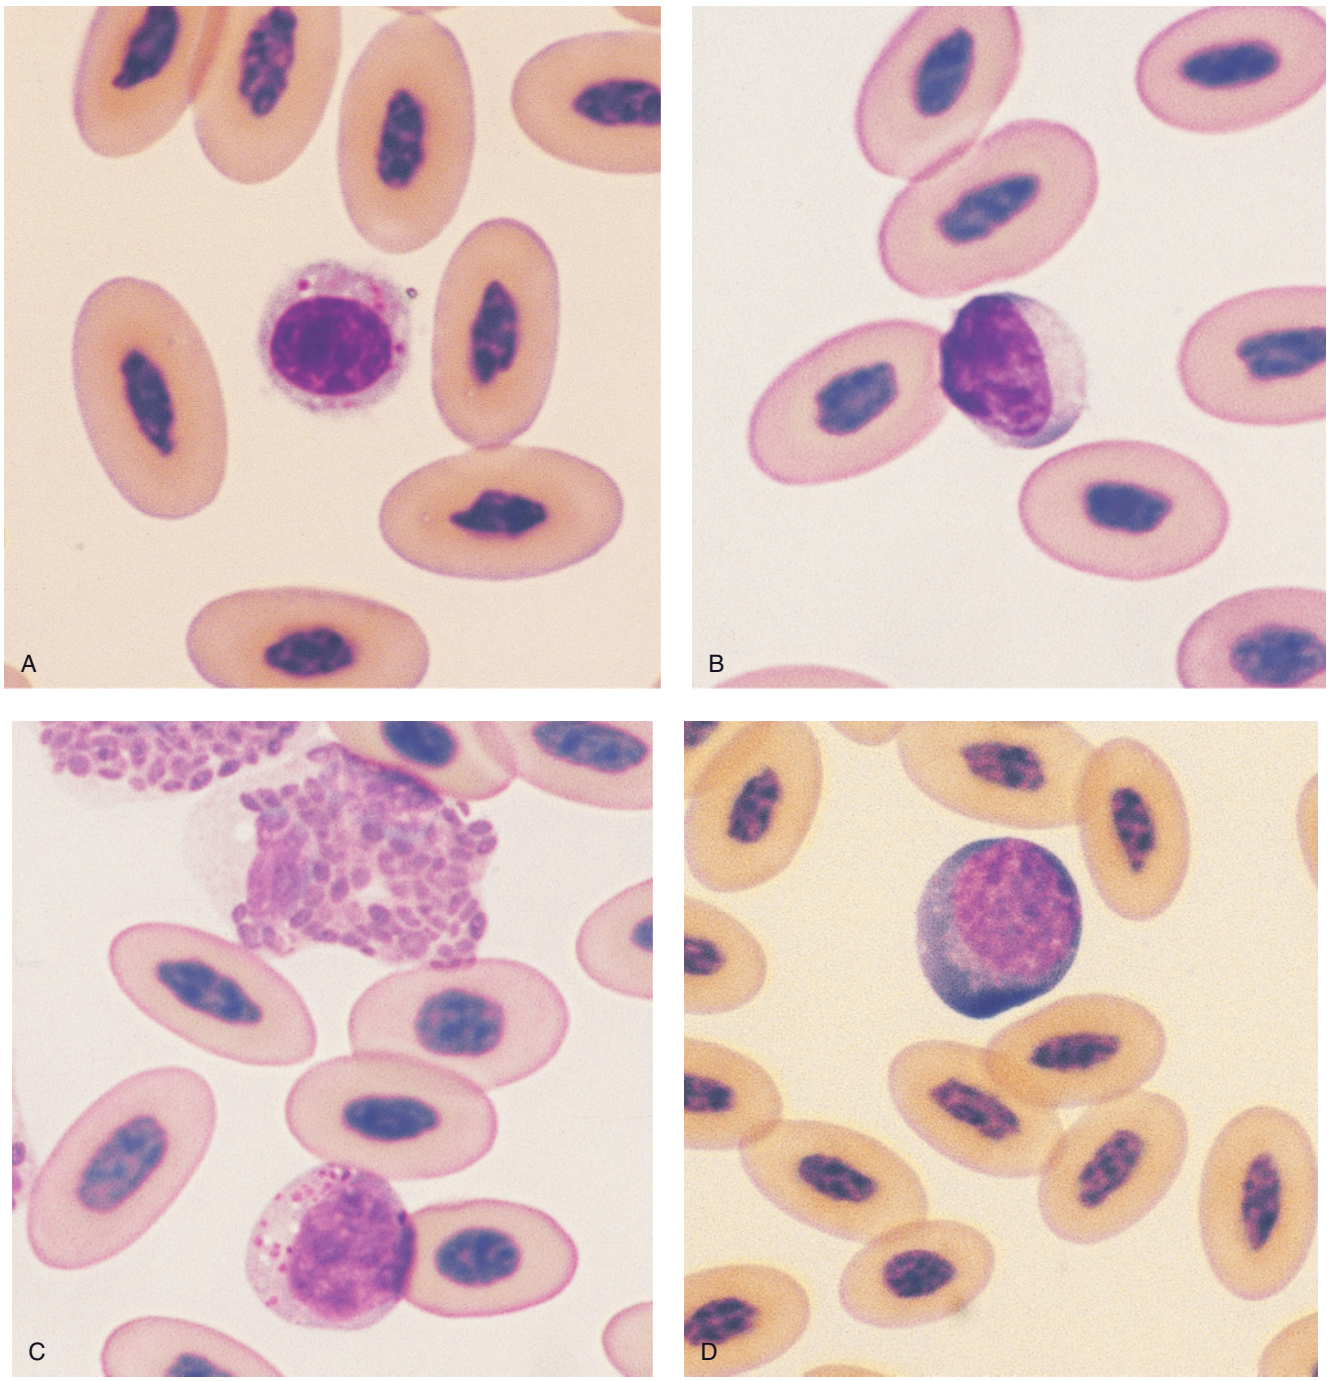

FIGURE 125.3 (**A**) Typical ostrich thrombocyte showing a few red granules in its cytoplasm with a centrally located, highly condensed oval nucleus. (**B**) Small ostrich lymphocyte showing a less condensed, indented eccentric nucleus with light blue cytoplasm. (**C**) A heavily granulated heterophil (top) with an immature thrombocyte (bottom) having granules similar in appearance to the mature thrombocyte and a slightly enlarged, moderately condensed oval nucleus. Alternatively, this cell may be a granulated lymphocyte, although its granule and nuclear characteristics seem more consistent with a thrombocyte classification. (**D**) A plasma cell (or reactive lymphocyte) characterized by a round eccentric nucleus with dark blue cytoplasm and a prominent Golgi zone adjacent to the nucleus.

tend to aggregate in clusters of reactive thrombocytes on blood smears, which makes estimating the thrombocyte count difficult. Although not well established in ratites, normal thrombocyte counts range from 20,000 to 30,000/μL or 10–15 per 100 erythrocytes on blood smears. A qualitative thrombocyte count is often determined during blood smear evaluation and is usually reported as decreased, adequate, or increased. Adequate thrombocyte numbers are usually associated with finding 5–10 thrombocytes per five oil immersion fields on a blood smear. Immature thrombocytes are occasionally noted on smears, indicating enhanced thrombocyte

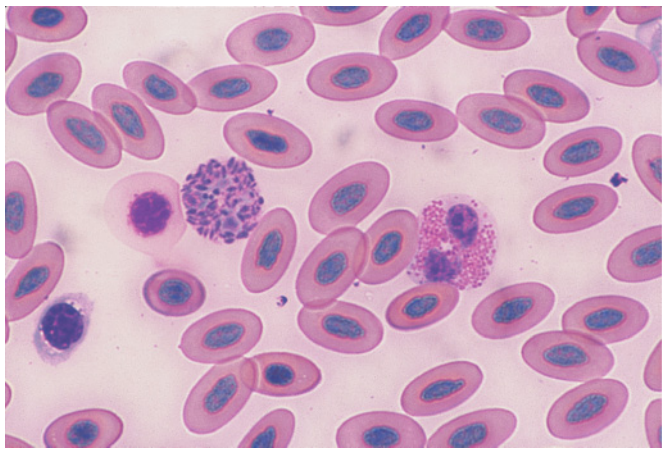

FIGURE 125.4 Comparison of the Diff-Quik stain appearance of the ostrich eosinophil (right) having a bilobed nucleus and numerous small round red granules with that of a heavily granulated heterophil (center). A thrombocyte (lower left) with a centrally located oval nucleus and several perinuclear clear zones is also present.

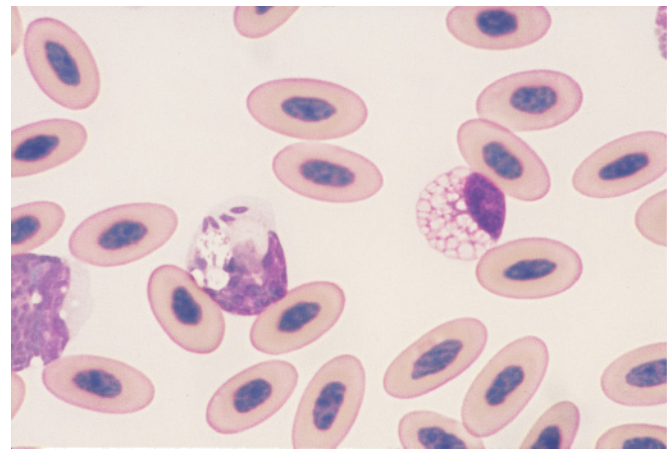

FIGURE 125.5 Diff-Quik stain of ostrich blood showing a basophil (right) with an eccentric nucleus and a vacuolated appearance due to lysis of its granules. Compare this cell with the toxic heterophil (left of center) characterized by cytoplasmic hypogranularity and vacuolization.

production. Their size is somewhat larger than mature thrombocytes (approaching the size of a large lymphocyte). Their nuclear shape is round, with a condensed clumped chromatin pattern; their cytoplasm is lightly basophilic with increased numbers of small, round, red granules, similar to those found in mature thrombocytes (Fig. 125.3C).

Recent studies using aspirin to inhibit normal thrombocyte aggregation in whole blood from ostriches suggested that prostaglandin-dependent mechanisms play a role in thrombocyte activation, similar to mammalian platelets.[10] Agonists causing irreversible whole blood thrombocyte aggregation included platelet-activating factor and collagen, but not adenosine diphosphate (ADP). Hemorrhagic diseases of ratites caused by abnormal thrombocyte function are uncommon; however, thrombocyte dysfunction may be responsible for a high incidence of hemorrhage noted in emus with hereditary gangliosidosis.[1]

Granulocyte Morphology

Heterophils are the most numerous WBCs in ratite blood and have similar functions to those of neutrophils in mammalian blood. The mature heterophil is a round cell with a segmented nucleus that is often partially occluded by numerous round to fusiform granules that have a red-orange color (Figs. 125.3C and 125.4). The background cytoplasm is clear in the mature heterophil. Immature heterophils are uncommon in normal ratite blood, and their stage of maturation is based on nuclear shapes, similar to other species. The cytoplasm of immature heterophils is slightly more basophilic than that of mature heterophils.

The granulation of immature heterophils ranges from early cells with moderate numbers of basophilic round (primary) granules, to intermediate cells having mostly round eosinophilic granules, to mature cells having mostly orange fusiform granules. Increased immature heterophils in blood (called a left shift) imply increased demand for heterophils, often associated with inflammatory diseases of ratites. In diseases associated with toxicity, it is common to see abnormal heterophil granulation characterized by cells that are poorly granulated or retain the round primary granules of early precursors (Fig. 125.5). In severe toxicity, heterophils may partially degranulate, nuclear swelling occurs, and their cytoplasm becomes more basophilic.[3] An Abbott CELL-DYN output from an ostrich with septicemia shows the effect of increased immature heterophils by causing the heterophil population pattern to be extended upward compared with the control (Fig. 125.6). Inflammatory diseases of ratites associated with heterophilic left shifts and toxic changes are usually associated with a poor prognosis.

Eosinophils are found in low numbers in blood from normal ratites, and their function is uncertain. The emu reference interval suggests slightly higher levels of eosinophils in emus than ostriches (Table 125.2). Eosinophils often have a bilobed nucleus with abundant small, round, red-to-pink granules and light blue cytoplasm (Fig. 125.4). The granules of eosinophil precursors are larger, and primary granules may also be present in their cytoplasm. Parasitism appears to induce eosinophilia less commonly in ratites than in mammals or certain other avian species (particularly raptors).

Basophils are found in low numbers in normal ratite blood (although they are more common than eosinophils in juvenile ostriches). The ratite basophil is slightly smaller than the heterophil and has an eccentric round to oval, nonsegmented nucleus. The basophil cytoplasm is moderate in amount and often has a distinct purple hue. The numerous dark metachromatic granules of the basophil commonly dissolve with routine Wright stain, leaving the cytoplasm with a vacuolated or reticulated appearance (Fig. 125.5). A few

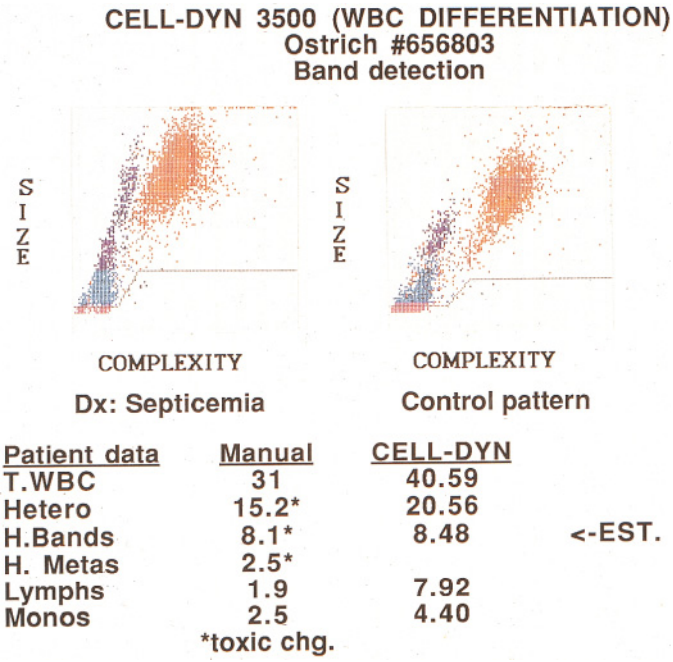

FIGURE 125.6 CELL-DYN 3500 patterns for WBC collected from a normal ostrich (right) and from an ostrich with septicemia (left). Note the orange-colored heterophil population is shifted upward and to the left, indicating the presence of immature (larger, less complex) heterophils in the septicemic ostrich. Monocytes are indicated by purple, lymphocytes by blue, and background erythrocytic debris with thrombocytes by red. The CELL-DYN analysis of ratite lymphocyte populations is consistently overestimated because of interference from similar-sized thrombocytes. Toxic heterophils (noted on the blood smear) featured hypogranularity that also produced a leftward shift in the CELL-DYN heterophil population. The heterophil band population was estimated (EST.) by the CELL-DYN analysis and appears to correlate well with the left shift noted in the manual count.

remnant basophilic granules are often present to assist cell classification. Although basophil function is unclear in ratites, basophilia is occasionally noted in hypersensitivity reactions and chronic respiratory diseases.

Lymphocyte Morphology

Lymphocytes are the second most common WBC in normal ratites, and lymphopenias are commonly associated with diseases causing increased stress. Lymphocyte morphology is similar to that of other avian species, with cells varying in size from small lymphocytes (which may be difficult to differentiate from thrombocytes) to intermediate or large lymphocytes (which may become reactive and appear similar to monocytes). The nuclear shape of small lymphocytes is round with a lacy chromatin pattern. Their cytoplasm varies in amount from scant to moderate and is usually lightly basophilic (Fig. 125.3B). This feature is quite helpful in distinguishing small lymphocytes from activated thrombocytes having clear cytoplasm. Lymphocytes are often found abutting adjacent erythrocytes, which makes their shape appear rectangular. Degenerate lymphocytes may have scant cytoplasm or cytoplasmic blebs. Occasionally, larger lymphocytes are noted with a few azurophilic granules, similar to those found in killer lymphocytes of mammals. Plasmacytoid or reactive lymphocytes may be seen in ratites, particularly during convalescent immune responses (Fig. 125.3D). These plasma cell-like lymphocytes have an eccentric round nucleus, dark basophilic cytoplasm, and a pale perinuclear Golgi zone. Mild lymphocytosis is also associated with immune stimulation, noted particularly during convalescence. Marked lymphocytosis of either small or larger lymphoid cells is suggestive of lymphocytic leukemia in ratites.[6]

Monocyte Morphology

Monocytes are found in low numbers in ratite blood, and their morphology is quite similar to mammalian monocytes. They are large cells with moderate amounts of blue-gray cytoplasm that occasionally has small discrete vacuoles. Their nuclei are pleomorphic with a chromatin pattern that is lacy and somewhat less condensed than lymphocytes. Distinct cytoplasmic granules are uncommon in ratite monocytes, although faint, dust-like eosinophilic granules are noted commonly. Differentiating monocytes from enlarged reactive lymphocytes can be challenging in ratite blood smears. Monocytosis is associated with various chronic granulomatous diseases of ratites, including mycoses, and diseases in which marked tissue necrosis occurs.

CONCLUSIONS

In the 1990s when individual ratites were valued at several thousand dollars, it was easy to justify veterinary care and extensive laboratory evaluation of individual birds. Despite this, there was a paucity of veterinary literature available concerning hematologic changes expected with ratite diseases. Hematologic evaluation can provide useful information with respect to medical evaluation of diseased ratites, no matter the economic state of the ratite industry.

AGM, aorta-gonad-mesonephros; APTT, activated partial thromboplastin time; CBC, complete blood count; EDTA, ethyelenediaminetetraacetic acid; Hgb, hemoglobin; ICM, intermediate cell mass; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCHMS-222, Tricaine methanesulfonate; MCV, mean corpuscular volume; PAS, periodic acid-Schiff; PT, modified prothrombin time; RBC, red blood cell; RVV-T, Russell viper venom time; WBC, white blood cell.

Historically, the field of fish hematology has spanned the past century as reviewed in several publications;[1,10,13,21] however, the older literature is often confusing and conflicting. Successful development of hematology as a diagnostic tool in fishes has only occurred in the past 20 years, as information concerning the function and maturation of blood cells, physiologic responses, and standardized hematologic techniques became available.

A number of factors make diagnostic hematology more challenging in fishes than in mammalian species. First, a review of the literature presents inconsistencies in the nomenclature, description, differentiation, maturation, and function of fish blood cells. Second, nucleated red blood cells (RBCs) and leukocytes overlap in size, preventing the use of automated methods to determine cell counts.[28] Lastly, the number of fish species and their diversity in morphologic form and ecologic function makes generalizations about the group difficult. The generic term "fish" includes primitive jawless vertebrates, vertebrates with cartilaginous skeletons, as well as more advanced species having bony skeletons. Bony fishes have more in common with and are more closely related to other bony vertebrates (e.g. mammals) than they are to their cartilaginous counterparts. In order to focus the discussion of this highly diverse set of animals, this chapter will be limited to bony fishes (Class Osteichthyes) that possess many similarities in blood cell morphology and function with other bony vertebrates.

HEMATOLOGIC METHODS

Hematologic techniques developed for mammalian species are generally applicable for fishes with slight modification. Most fishes respond adversely to being handled. Sedation or anesthesia before bleeding is recommended to decrease hematologic changes from the stress of restraint. A number of anesthetic agents can be effectively used with fishes. MS-222 at 100–200 mg/L is the most widely accepted, and is presently the only FDA approved anesthetic for finfish. MS-222 should be buffered with sodium bicarbonate or other suitable buffer to prevent the extreme decrease in pH of unbuffered MS-222 from causing significant alterations in physiologic and hematologic measurements. The anesthetic solution should be of sufficient concentration to induce stage 2 anesthesia (i.e. loss of equilibrium) within 20 seconds, and stage 3 anesthesia within 1

minute. The fish is bled before respiratory depression induces significant hypoxia. Anesthesia induced hypoxia can be minimized by using an aerated anesthetic solution.

Collecting a Blood Sample

Fishes can be bled from a number of sites; the most common being the caudal tail vessels. Other sites include the cuvarian duct (a vessel within the oral cavity), branchial vessels, and bleeding directly from the heart. Cardiac puncture is traumatic and should not be performed on a fish that is to be recovered after blood collection. The cuvarian duct and branchial vessels can only be sampled in large fish. Severing the tail or cutting through the musculature to expose vessels should not be used to collect blood as the sample will be contaminated with tissue fluid or other cellular elements.

Only good quality blood samples should be used for hematological evaluation. Clotted, clumped, hemolyzed, or improperly stored samples should be discarded. Fish blood hemolyzes easily and best collection results are obtained with a small (1–3 mL) syringe. Larger blood samples can successfully be collected with a vacutainer system. Blood should be transferred immediately to a blood tube containing anticoagulant to minimize clotting. Pediatric-sized tubes (0.5 mL) are an ideal size for most fishes. The choice of anticoagulant for preservation of cellular morphology appears to be species specific. Salmonid, cyprinid, and sturgeon blood cells retain morphology best with heparin, while catfish, bass, tilapia, and pacu cells preserve best in ethylenediaminetetraacetic acid (EDTA).[22,25,27,33,50] Occasionally, blood will clot in the presence of anticoagulant. Clots may be grossly visible, or thrombocytes will appear clumped when the blood film is viewed under the microscope. Use of a different anticoagulant and reducing pre-capture stress may prevent thrombocyte clumping.

Determination of Cell Counts

Reliability of the manual complete blood counts (CBCs) is one of the greatest difficulties for diagnostic hematology in fishes. Counts must be determined manually as automated methods cannot distinguish erythrocytes from leukocytes due to the overlapping size of these cells. Sources of error associated with manual counting can occur when diluting and mixing the blood, filling the hemacytometer, and during identification and counting of cells. Misidentification frequently happens when distinguishing activated thrombocytes and lysed RBCs from leukocytes. Thrombocytes are usually oval in shape but become small and round similar to a lymphocyte when activated. When erythrocytes lyse in the blood diluent, the nucleus takes up stain similar to a leukocyte. Lysed erythrocytes can be distinguished from leukocytes with practice; however, it is impossible to consistently differentiate leukocytes from thrombocytes in the hemacytometer. Leukocytes and thrombocytes are best separated and identified during the differential count on a stained blood smear.

Manually counting cells on a hemacytometer can be time consuming but provides the greatest accuracy for a CBC in fishes. A diluent should be used that differentially stains RBCs and leukocytes. Natt-Herrick's,[42] Rees-Ecker,[37] or modified Dacie's[2] diluents are effective with most fish species. Depending on the concentration of cells in the blood, a 1:100 or 1:200 dilution of blood to filtered diluent is recommended. Allow the cells to stain for 2–4 minutes before filling the hemacytometer.

As in mammals, RBCs are counted in five secondary squares of the center primary square. The raw count, multiplied by 5000 for a 1:100 dilution or by 10,000 for a 1:200 dilution, will give the number of erythrocytes per microliter of blood. The leukocyte count is frequently higher in fishes than in mammals, and leukocytes and thrombocytes are counted only in the four corner primary squares. The raw count, multiplied by 250 for a 1:100 dilution or by 500 for a 1:200 dilution, will give the number of cells per microliter of blood. This provides a combined total count for leukocytes and thrombocytes. Thrombocytes are then enumerated during the differential count on a stained blood smear.

Differential counts should be determined from good quality blood smears. Direct smears made without anticoagulant often have thrombocyte clumping which affects cell distribution and cell counts. Scan each slide before beginning the differential count to check the quality of the smear and to become familiar with the cell types present and appearance of the smear. Count leukocytes and thrombocytes until 200 leukocytes are enumerated in the monolayer portion of the blood smear. Thus, all cell types are counted except RBCs until the sum of the lymphocytes, monocytes and various granulocytes totals 200, regardless of the number of thrombocytes encountered. As thrombocytes frequently make up greater than 50% of the cells, total counts greater than 400 are common. The percentage of thrombocytes is then subtracted from the combined leukocyte-thrombocyte count determined on the hemacytometer to give the total leukocyte count and the thrombocyte count. The percentage of each leukocyte type is multiplied by the combined leukocyte-thrombocyte count to give the absolute number of each cell type.

Hemoglobin Determination

Hemoglobin is best determined using the standard cyanomethemoglobin method. Test solutions should be centrifuged before measuring the absorbance as nucleated RBCs release a flocculent material upon lysis. The released flocculent precipitate interferes with absorbance readings unless removed by centrifugation. The erythrocyte indices mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC) are calculated as in mammals.

BLOOD CELL FORMATION AND FUNCTION

Blood Cell Formation

Blood cells present in the blood of fishes vary with the species but include: RBCs, thrombocytes, lymphocytes, monocytes, neutrophils (heterophils), eosinophils, basophils, and immature forms.[10,13,57] Hematopoiesis in fishes is similar to that in mammals and occurs in two waves, primitive hematopoiesis and definitive hematopoiesis. In many fish species, development in the egg stage is brief with free swimming larvae hatching 2–3 days after fertilization. Further development including organogenesis and maturation of tissues into adult form and function occurs over the next 4–8 weeks. Primitive hematopoiesis begins while still in the egg stage or soon after hatching. Cells lying lateral to the somites in the developing larva begin to express markers for both vascular and blood elements. These cells migrate medially to form the intermediate cell mass (ICM) ventral to the notochord.[9] The ICM is equivalent to the blood islands in the mammalian yolk sac, and the cells differentiate into endothelial cells, trunk vasculature, and proerythroblasts.[9] Some fish species utilize blood islands in the yolk sac as the site of primitive hematopoiesis, while others, such as trout, utilize both the yolk sac and the ICM.[17] Proerythroblasts from these primitive hematopoietic centers enter the circulation and mature into primitive RBCs which are distinct from adult RBCs, having less cytoplasm and an elongated nucleus. Primitive RBCs contain hemoglobin and undergo globin switching from primitive embryonic chains to adult chains as do mammals.

A second site of primitive hematopoiesis, called the rostral blood islands, forms in the anterior mesoderm of developing fish. This region produces both myeloid cells and vascular elements. Myeloid cells express *pu.1*, a marker for macrophages and granulocytes. Subsets of these cells also express *l-plastin* and *mpo* that are markers for macrophages and granulocytes respectively.[9] These early phagocytes migrate from the rostral blood islands across the yolk sac and also enter the circulation. They are phagocytic and migrate to sites of infection.[9] It is not known if primitive and definitive phagocytes are produced, similar to RBCs.

Adult hematopoietic stem cells are produced in a region of the developing fish called the aorta-gonad-mesonephros (AGM). In mammals, these hematopoietic stem cells translocate to the fetal liver and bone marrow. In fishes, these cells translocate to the kidney with progenitors of all blood cell types present in the kidney tissue.[43] In some marine species, cells from the AGM also translocate to the spleen which then becomes the primary site of erythropoiesis and myelopoiesis.[15] In the developing fish, the kidney is first predominately erythropoietic. Erythroid precursors are similar to those seen in mammals and are released from the kidney into circulation at an immature stage. Reticulocytes are frequently present in fish blood preparations. Later in development of the kidney, myelopoiesis dominates and finally the kidney becomes predominately lymphopoietic. Fish lymphocytes can be divided into T, B, and nonspecific cytotoxic lymphocytes.[7,11] B cells express immunoglobulin while T cells express the T cell receptor. T cells develop and mature in the thymus, while B cells develop in the pronephros region of the kidney.[17] The origin of lymphocyte progenitors that seed the thymus has not been determined, but *Ikaros* (a hematopoietic transcription factor) positive cells in the AGM probably translocate to the thymus.

Thrombocytes are present in circulation early in development. However, the cell equivalent to the megakaryocyte, the maturation stages, and primary site of thrombopoiesis have not been identified.

Blood Cell Morphology and Function

As in mammals, RBCs contain hemoglobin and transport oxygen, albeit at much lower ambient oxygen concentrations. Fish RBCs are nucleated, are more metabolically active than their mammalian counterparts, and may play a significant role in modulating blood chemistry.[24] Reticulocytes, easily recognized by their slightly basophilic cytoplasm, are smaller cells with a more open nucleus.

Thrombocytes are involved in coagulation and clot formation. Ultrastructurally, the cells are similar to platelets, with an interconnecting canalicular system and cytoplasmic granules. Thrombocytes are activated by the same mechanisms as mammalian platelets, and they cross-react with human platelet markers. Thrombocytes have a condensed nucleus with clear or light staining cytoplasm (Fig. 126.1). Cell shape varies with the activation state, changing from spiked or oval to round as the cells activate. In anticoagulated blood, the thrombocyte nucleus may segment or remain oval.

Lymphocytes function in innate and adaptive immune responses with T, B, and nonspecific cytotoxic lymphocytes present. Lymphocytes are usually small cells with dark blue cytoplasm and a condensed nucleus (Fig. 126.2). The cells are round and frequently have pseudopods along the cell margin. As lymphocytes become reactive, they increase in size, the nucleus becomes less condensed, and they may acquire the classic plasma cell morphology.

Granulocyte nomenclature and morphology have not definitively been established for fishes and as such there are inconsistencies in granulocyte identification. The terms neutrophil and heterophil are frequently used interchangeably for cells with no visible or very fine cytoplasmic granules. Cells containing reddish cytoplasmic granules of varying sizes and shape have been called both eosinophils and heterophils. Cells with purplish cytoplasmic granules have been called both basophils and heterophils. Many reports do not contain photomicrographs of the cells, making correlation between studies difficult. Until either a consensus is reached regarding cell nomenclature or unique surface

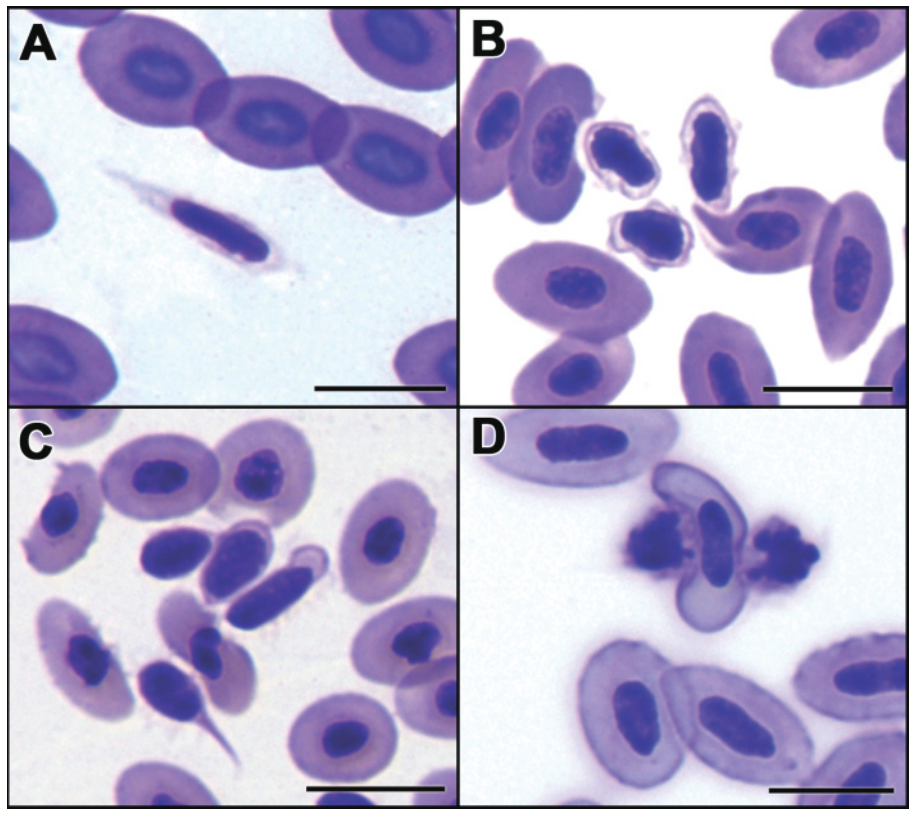

FIGURE 126.1 Thrombocytes. Thrombocyte morphology and staining can be affected by activation and anticoagulants. Cells have translucent cytoplasm and a condensed nucleus. Scale bar, 10 µm. (**C**) Cobia – *Rachycentron canadum*, direct smear, no antocoagulant; Hema 3 stain. (**D**) Striped bass – *Morone saxatilis*, direct smear no anticoagulant; Wright-Giemsa stain.

markers are identified for each cell type, nomenclature discrepancies will continue.

Granulocytes are one of the largest cells in circulation (Figs. 126.3, 126.4, and 126.5). The cytoplasm is usually a pale blue. In most species, the nucleus is open and oval to kidney bean shaped. In some species, the nucleus is segmented, possibly indicating that the cells mature in circulation before migrating into the tissues. The cytoplasm may have a grainy appearance with no visible granules, or may contain granules of variable size and shape depending on the specific cell type.

Neutrophils are involved in inflammation and the inflammatory response, and are phagocytic. They stain positive for myeloperoxidase and acid phosphatase. Functional differences between fish neutrophils and heterophils have not been determined. Eosinophils function in parasite killing and phagocytosis. Eosinophils stain PAS positive and are acid phosphatase negative. Basophils are rarely reported. It could be that basophils are just present in low numbers, or that their morphology is not well preserved with routine alcohol-based fixatives and stains. In one study basophils were best identified with lead subacetate fixative and acid toluidine blue stain.[51] Little is known about basophil function, but they are thought to be similar to mammalian basophils.

Monocytes are round cells with a round to horseshoe shaped nucleus (Fig. 126.6). The cytoplasm stains a deep blue and is frequently vacuolated. As in mammals, monocytes circulate through the blood, migrate into the tissues and become macrophages. Monocytes and macrophages are the primary phagocytic cell in fishes.[3,10]

Blood Coagulation

Blood coagulation in fishes is not well studied, but appears similar to mammalian coagulation. The majority of genes regulating coagulation are highly conserved between all vertebrates.[32] Substances that aggregate platelets or are vasoactive in mammals cause similar reactions in fishes.[13] The blood coagulation cascade contains both intrinsic and extrinsic pathways as evidenced by measurement of prothrombin time (PT), activated partial thromboplastin time (APTT), and Russell viper venom time (RVV-T).[31,55] Fishes also appear to have a similar anticoagulant pathway with the natural anticoagulants protein C, antithrombin, and heparin cofactor II present in their plasma.[31] Additionally, acute and chronic stress, such as that caused by capture or from production fish management, can cause a thrombocytosis and decrease clotting time.[6]

BLOOD VALUES IN FISHES

Previously, the main focus of piscine hematology has been to determine the effects of toxicants and altered environmental conditions on the blood analytes. Frequently only a few analytes would be measured and hematologic changes were not correlated with reference intervals or with documented pathology or disease. This lack of knowledge provided a limited database on which to base diagnostic hematology. As such, hematological changes due to stress have been fairly well characterized in fishes, but other responses are not as well documented. Current work has focused on specific responses to pathogens, correlating hematologic changes with specific tissue pathology, and standardizing reference intervals. This work has significantly advanced the field of fish hematology although much work remains, particularly to standardize the nomenclature and function of the various blood cells.

Hematologic values for a number of common fish species are listed in Table 126.1. In general, the hematocrit ranges from 20% to 45%, with higher PCV values seen in active species of fish. The hematocrit can increase artifactually from splenic contraction and from RBC swelling that occurs after the sample is collected.[19] Precapture stress or inadequate anesthesia during blood collection can exacerbate RBC swelling and significantly increase the PCV.

Hemoglobin concentrations are low compared to mammals, being 5–10 g/dL. As with the PCV, more active fishes generally have higher hemoglobin values. The MCV ranges from 150 to 350 fL. Active fish with higher oxygen demands tend to have smaller RBCs and consequently lower MCV. The MCH varies considerably between species (between 30 and 100 pg) due to differences in size of circulating RBCs. The MCHC ranges from 18% to 30%, being lower in fishes than in mammals due to the space-occupying nucleus. The developing RBC continues to increase in size and hemoglobin content with time, resulting in higher MCV, MCH, and MCHC for older cells. Additionally, there may be a variety of maturational stages present at any time resulting in a wide range for these indices.

Red blood cell counts are usually lower in fishes than in mammals and vary with the need for oxygen. Fish that have a large surface area to body mass ratio (ice fish and some larval fish) have no discernible RBCs and are able to absorb sufficient oxygen directly from the water into the plasma. Sedentary fish have values closer to $1 \times 10^6/\mu L$, whereas active pelagic fish have counts greater than $5 \times 10^6/\mu L$. Leukocyte numbers are variable but generally range from 30,000 to 100,000 cells/µL.

TABLE 126.1 Comparison of Hematological Values Determined for Various Fish Species

Species	No.	PCV (%)	Hgb (g/dL)	MCV (fL)	MCH (pg)	MCHC (g/dL)	RBC ($\times 10^6$/μL)	Reference

[a]Denotes that the range given is a reference interval; other values or ranges were determined for mixed groups of fish with various blood collection methods, time of the year, ages, sex, etc.

In most species, lymphocytes are the most abundant leukocyte present, followed by monocytes or neutrophils and eosinophils. Basophils, when present, are only occasionally seen.

In fishes, stress causes a leukopenia characterized by a lymphopenia and a neutrophilia.[7,47] Fishes also demonstrate a typical inflammatory response consisting of a neutrophilia and lymphocytosis and increased serum protein concentration.[45,49] Alterations in blood values have been noted with seasonal variation,[34,38] water temperature,[12,23] extreme pH,[8] age, and sex,[14,26] and stocking density.[22,40] Observed seasonal changes might be associated with reproductive status (i.e. spawning cycle) and not seasonal changes per se.

A few studies have begun to document alterations in hematological profiles from specific diseases. Chinook salmon infected with bacterial kidney disease increased leukocyte counts to levels above controls after 16 days.[30] Rainbow trout infected with viral hemorrhagic septicemia had a decrease in PCV, RBCs, and hemoglobin.[46] Carp infected with *Aeromonas hydrophila* had increased WBCs and decreased RBCs, PCV, and hemoglobin. Values remained altered for more than 30 days after resolution of the infection.[18] The decrease in RBC count is fairly consistent between studies, but it is unclear if it is due to altered red cell numbers or due to a change in hydration status.

Acronyms and Abbreviations

EDTA, ethylenediaminetetraacetic acid; Hgb, hemoglobin; MCV, mean corpuscular volume; PCV, packed cell volume; RBC, red blood cell; WBC, white blood cell.

Reptiles have fascinated scientists for many centuries. Some of the earliest published reptilian hematology studies in English and French language literature date to the early 1800s (reviewed by Pienaar in 1962).[36] Studies published in the past several decades have investigated the ultrastructure, cytochemistry, function, physiologic responses, and other aspects of reptilian blood cells. Interest in reptilian hematology has probably increased together with the popularity of reptiles as pets, the willingness of clients to bring their reptilian pets to veterinarians, and with increased awareness of biodiversity and conservation of reptiles.

Evaluation of blood smears and hemogram data from reptiles can be difficult for veterinarians, veterinary technicians, and other animal biologists. This difficulty arises from differences in morphology of reptilian blood cells from those of mammals, differences in the morphology of leukocytes between reptilian species, lack of robust automated cell enumeration technologies that reliably work with reptilian blood, variation in study methods, and a less robust understanding of reptilian blood physiology and hematology when compared to mammals. Therefore, proper evaluation of reptilian hemograms and blood smears requires appropriate training, experience, equipment, and laboratory methods. This chapter will briefly review different aspects of reptilian hematology. The reader is referred to the list of references at the end of the chapter for additional information, particularly some excellent reviews.[3,9,39,41,42,47,48,49]

SAMPLE COLLECTION

Obtaining blood samples from reptiles for hematologic evaluation is readily accomplished with proper knowledge of anatomy, adequate training, and practice. Blood sampling techniques, such as toenail clips, tail tip clips, and decapitation, as used in some published studies, should be avoided and should not be a substitute for proper venipuncture. Comprehensive descriptions of venipuncture techniques are beyond the scope of this chapter and are well described in the literature.[3,41,47,48]

SAMPLE PROCESSING

Detailed reviews of processing and handling of samples are reviewed elsewhere.[3,39,41,48] Despite the small volumes that are obtained from some small patients, enough blood should be available to measure total plasma solids (using a heparinized capillary tube), packed cell volume (PCV), and blood smear evaluation. Blood smears prepared from fresh, non-anticoagulated whole blood are preferred.[3] Ethylenediaminetetraacetic acid (EDTA) or lithium heparin may be used as

anticoagulant; however, EDTA may induce in vitro hemolysis of red blood cells (RBCs) in some species of reptiles, such as turtles and tortoises, and heparin anticoagulant may give a blue tinge to blood smears and induce clumping of leukocytes and thrombocytes.[3,22] Lithium heparin should be used as an anticoagulant when the same blood sample will be used for biochemical analyses because potassium or sodium heparin may interfere with determination of electrolytes.

There are several types of staining methods that can be used to stain blood smears from reptiles. Diff Quik® and similar "quick" stains are commonly used in veterinary clinical practices. Literature descriptions of blood cells were based on a variety of staining methods including quick-type stains, Wright's, Giemsa, Wright-Giemsa, Wright-Leishman, and others.

BLOOD CELL ENUMERATION

Cell enumeration in many species of mammals is routinely achieved with the use of automated cell counters.[28] These counters have been used to enumerate reptilian RBCs.[21,24,31,39,44] Unfortunately, RBCs and thrombocytes are nucleated and this interferes with the capacity of the automated cell counters to separate reptilian blood cell populations.[3] Automated cell counting technology probably can be used routinely for analysis of reptilian samples but this will involve additional research and development.

Because of the difficulties associated with enumerating reptilian blood cells in automated cell counters, the cell enumeration technologies available to practitioners and veterinary clinical pathologists have not changed significantly in many years. Hemacytometer-based techniques are routinely used to enumerate RBCs and white blood cells (WBCs) using solutions such as Natt and Herrick's.[3,39,48] These have inherent variability and limitations. The Unopette systems for RBC or eosinophil enumeration (Beckton Dickinson) were commonly used, but are no longer readily available. Estimation of WBCs or thrombocytes using a blood smear is another method that can be utilized but also has limitations.[8,21,22,50]

REFERENCE INTERVALS

Reference intervals for many species of reptiles are available but should be interpreted with care because reference intervals published by one source may vary from those published by other sources in regards to season, geographical location, collection methods, venipuncture site, captivity status, restraint methods, analytical methodology, age and/or other factors.

ERYTHROCYTES

The PCV, RBC count, and hemoglobin (Hgb) of individual animals will vary with many factors including season, ambient temperature, sex, nutritional status, and other factors.[9,49] In general, reptiles have lower numbers of circulating RBCs than birds or mammals and there is an inverse relationship between the size of the RBC and the total number of circulating RBCs.[49] Additionally, reptiles with lower mean corpuscular volume (MCV), such as lizards, tend to have higher numbers of RBCs than others such as turtles.[9,49] The average lifespan for reptilian RBCs (600–800 days) is typically greater than that of mammals and this may be due to a slower metabolic rate.[49]

Reptilian RBCs are ellipsoidal with centrally positioned nuclei (Figs. 127.1 and 127.3). The cytoplasm is orange-pink and homogeneous in appearance with most stains. The nuclear chromatin becomes denser and darker as the cell matures. Young reptiles, those undergoing ecdysis or with regenerative anemia will frequently have increased numbers of immature RBCs in blood.[3] Immature RBCs are typically less oval, have increased cytoplasmic basophilia, and have nuclei that also are less oval (Fig. 127.1). Similar to mammals, increased polychromasia is an indicator of erythroid regeneration secondary to decreases in the erythroid mass. Reticulocyte counts can be performed; however, there is very little published information on reticulocyte counts in reptiles.[43] Reptiles have punctate and aggregate reticulocytes.[43] Mitoses, binucleation, and other nuclear findings occur in reptiles with erythroid regenerative responses, inflammatory disease, post-hibernation, post-surgery, and erythroid neoplasia (Fig. 127.1).[3,16] Likewise, minimal amounts of anisocytosis, polychromasia, and poikilocytosis occur in clinically normal reptiles but may be exaggerated in disease.

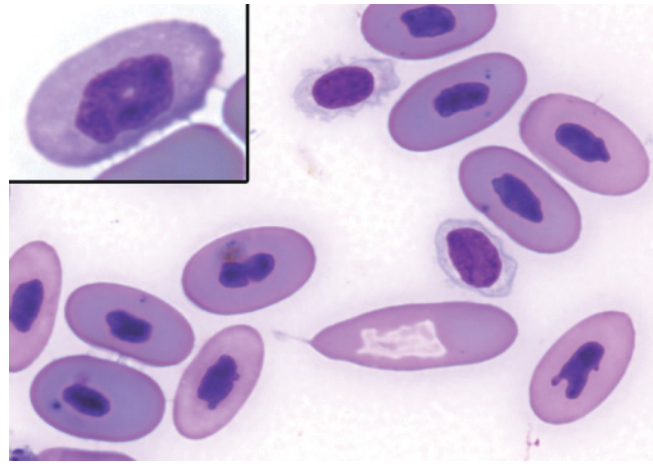

FIGURE 127.1 Blood smear from an inland bearded dragon (*Pogona vitticeps*) showing poikilocytosis. Red blood cells with irregular nuclear membranes (in particular the bottom right of the field), two thrombocytes (right and top of the field), and a tear-drop RBC lacking a nucleus (bottom right) are shown. The inset is a greater magnification of an immature RBC with a ring-shaped nucleus from the same blood smear. This slide was overstained using a quick stain. (From Reagan W, Irizarry Rovira A, DeNicola D. Veterinary Hematology: Atlas of Common Domestic and Non-Domestic Species. Ames: Wiley-Blackwell. 2008.)

Erythrophages occur with surgery and in other disease conditions.[16] Parasites, including viruses, may infect RBCs.[3,51] Single, small, round, basophilic inclusions in RBCs are found in some species of reptiles and have no pathologic significance.[3,58] These have been confused with infectious agents.

THROMBOCYTES

Reptilian thrombocytes commonly aggregate in blood smears and share some functional characteristics with mammalian platelets.[3] Thrombocytes are ellipsoidal to fusiform in shape with a centrally placed round to oval, darkly staining nucleus (Fig. 127.1). The cytoplasm is colorless to very pale blue and occasionally may contain azurophilic granules.[3] When activated, the cytoplasm may show vacuolization, and develop a spherical shape.

Information on the thrombocyte count in the blood of reptiles is limited when compared to other reptilian blood cells.[49]

LEUKOCYTES

Reptilian leukocytes frequently present a diagnostic dilemma because morphology varies, at times significantly, between reptilian species. This can lead to misclassification of reptilian cells. For example, the eosinophils of the green sea turtle (*Chelonia mydas*) have two morphologically distinct eosinophils,[58] and have been morphologically misclassified as neutrophils.[1] Reptilian leukocytes are typically classified as heterophils, lymphocytes, eosinophils, basophils, and monocytes/azurophils (Fig. 127.2). This terminology will be used here.

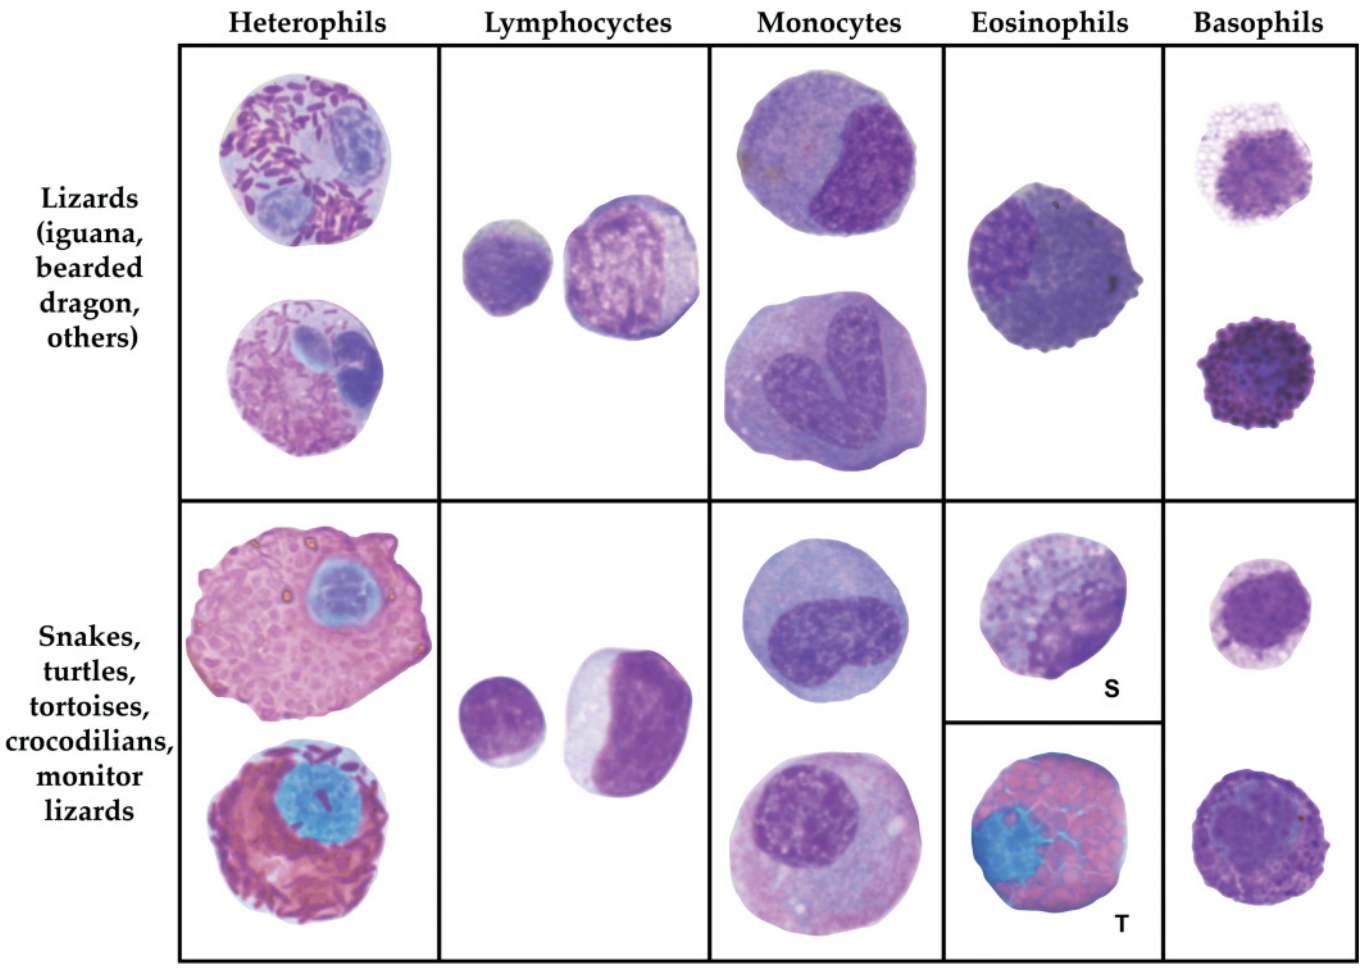

FIGURE 127.2 Overview diagram of leukocytes in healthy reptiles. S = snake; T = turtle (Adapted from Reagan W, Irizarry Rovira A, DeNicola D. Veterinary Hematology: Atlas of Common Domestic and Non-Domestic Species. Ames: Wiley-Blackwell. 2008.)

Heterophils

Functionally, the reptilian heterophil is considered analogous to mammalian neutrophils.[3] Together with monocytes, they respond to tissue inflammation quickly, and have an important function is phagocytosis.[9,32,49,54] Increases in numbers of blood heterophils may occur with inflammation and stress, and numbers also vary with season, and other factors.[3,9] Coloration and morphologic variation in granules exist between reptilian species, but, in general, granules will be spindle-shaped to elongate and have an orange-red or "muddy brown" color.[3,49] Heterophil granules in blood smears stained with "quick" stains may be less distinct than those stained with other methods such as modified Wright's (Fig. 127.3).[3] Crocodilians tend to have larger granules, although these are fewer in number than the numerous, smaller granules seen in lizards and snakes. The granules in snakes and turtles may be so numerous that granule shape will be difficult to discern. In general, the nucleus of heterophils from turtles, crocodilians, snakes, and some lizards (such as the monitor lizard, *Varanus* sp.) is round to oval while the nucleus of other lizard species, such as the green iguana (*Iguana iguana*) and the inland bearded dragon (*Pogona vitticeps*), is lobed.[9] Similar to mammalian neutrophils, reptilian heterophils exhibit morphologic changes during inflammation including left shifts and toxic changes (Fig. 127.3).

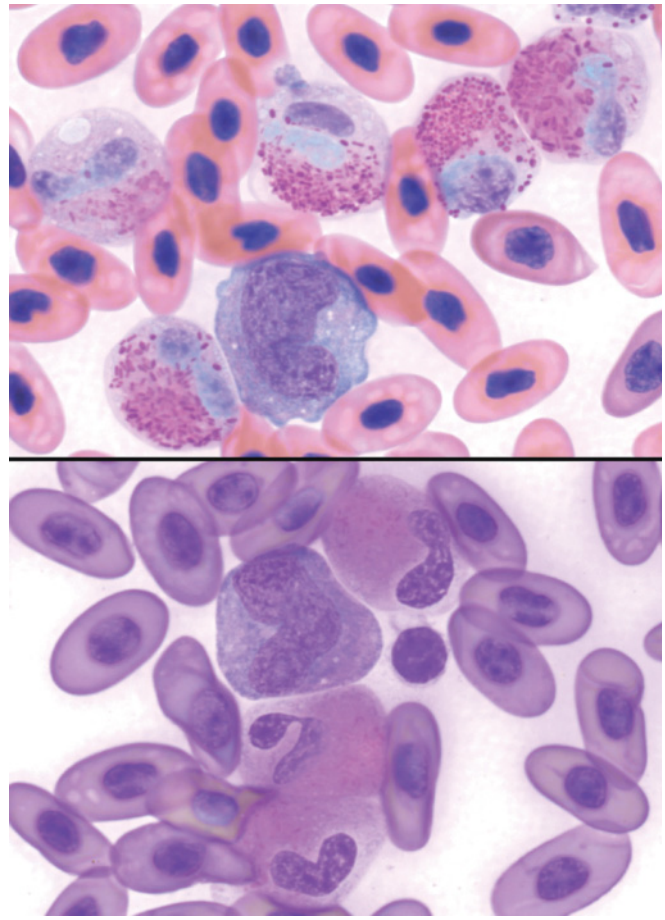

FIGURE 127.3 Blood smear from a green iguana (*Iguana iguana*). Heterophil with left shift and toxic change. Upper image: The five round cells with lobulated to oval nuclei, red round to oval granules in cytoplasm, and sometimes vacuolated are immature (i.e. left-shifted) and toxic heterophils. A large monocyte is in the bottom center of the field. Lower image: Three left shifted heterophils (top and bottom center of the field), a monocyte, and a small lymphocyte are shown. The lower image was from a blood smear stained with a quick stain; the blood smear shown in the upper image was stained with Wright's stain. (From Reagan W, Irizarry Rovira A, DeNicola D. Veterinary Hematology: Atlas of Common Domestic and Non-Domestic Species. Ames: Wiley-Blackwell. 2008.)

Eosinophils

Reptilian eosinophils are round cells with spherical cytoplasmic granules and round to lobed nuclei.[3,49] The color of the granules, shape of the nucleus, and size of the cells will vary with species. In many species of reptiles the granules of the eosinophil are bright red to orange; however, the granules of some reptilian species, such as the green iguana (*Iguana iguana*) and the inland bearded dragon (*Pogona vitticeps*), will have a blue to gray hue with Romanowsky-type stains (Fig. 127.2). Eosinophil numbers vary in relationship to multiple factors, such as species, season, and parasitic infestation.[3]

Basophils

Basophils have dark purple staining spherical granules with a slightly eccentric to centrally placed round to oval nucleus (Fig. 127.2). The nucleus is frequently obscured by darkly stained purple granules.[3] Basophils may appear vacuolated with some staining methods (Fig. 127.2). Reptilian basophils probably function in a manner similar to mammalian basophils.[3] The numbers of basophils vary with species, parasitic infestation, and other factors. In general, turtles have greater proportions of basophils than other reptilian species; however, other reptiles, such as newborn *Bothrops jararaca* snakes and some skinks, also have notable numbers of circulating basophils.[6,59]

Lymphocytes

The reptilian lymphocyte is morphologically similar to mammalian lymphocytes (Figs. 127.2 and 127.4). They are round with small amounts of basophilic cytoplasm and rarely contain azurophilic granules. Reptiles typically have small and large lymphocytes. Small lymphocytes may be confused with thrombocytes. The percentage of blood lymphocytes varies with season and other factors.[9,49] For many reptiles, lymphocytes are the most prevalent circulating cell.[49] Lymphocytosis can occur with inflammation, wound healing, viral diseases, and certain parasitic infestations.[3] Reactive lymphocytes and plasma cells rarely occur in blood and are

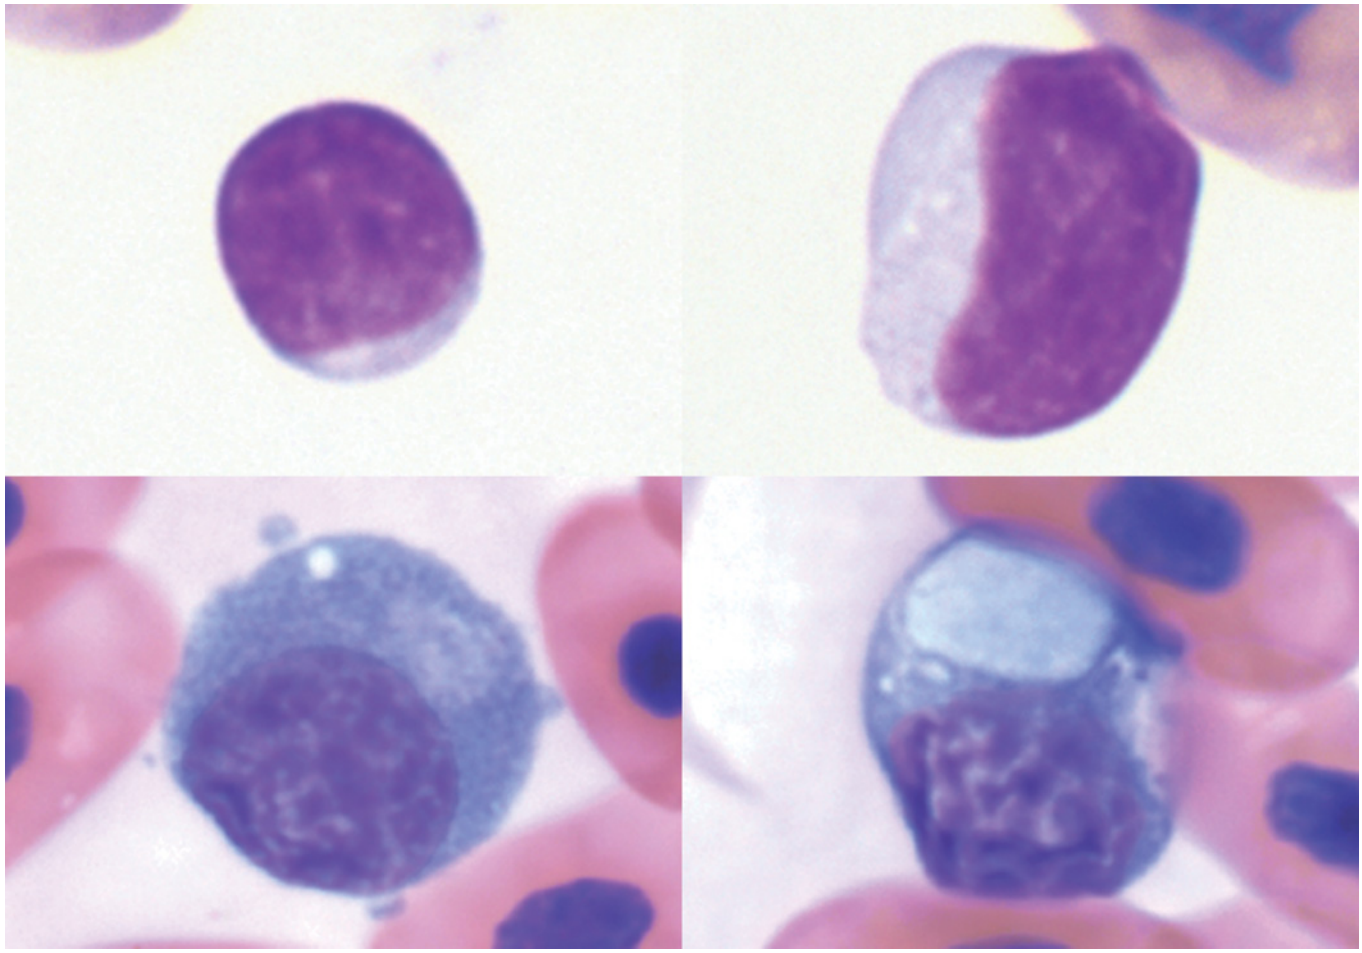

FIGURE 127.4 Representative images of lymphocytes from reptiles. The top two images are small (left) and large (right) lymphocytes from a snake (unspecified genus), and the bottom two images are from a green iguana (*Iguana iguana*). The lymphocyte in the bottom left is a reactive plasmacytoid lymphocyte, and the cell on the bottom right is a plasma cell with Russell bodies. Wright's stain. (Adapted from Reagan W, Irizarry Rovira A, DeNicola D. Veterinary Hematology: Atlas of Common Domestic and Non-Domestic Species. Ames: Wiley-Blackwell. 2008.)

similar in morphology to their mammalian counterparts (Fig. 127.4).[3]

Monocytes and Azurophils

The reptilian monocyte is similar in appearance to its mammalian counterpart (Fig. 127.2). It has moderately blue-gray cytoplasm, with or without vacuoles, and nuclei that vary from round to oval to indented.[3] However, monocytes with fine, dust-like pink (azurophilic) cytoplasmic granulation have been referred to as azurophils (Fig. 127.2). The cellular origin of this cell has been the subject of debate for a long time. Some investigators classify all azurophils as monocytes[3] while others indicate that azurophils from species such as snakes should be classified separately.[47] The clinical significance of classifying the azurophil as a separate cell type is unclear and has not been investigated sufficiently. The author prefers to group azurophils with monocytes.

HEMATOPOIESIS

There are limited numbers of studies or reviews of reptilian bone marrow hematopoiesis.[3–5,7,10,14,15,20,27,33,36,40,45,49,55–57,60] Other studies have investigated the morphology of immature RBCs in circulation or hematopoiesis in other tissues other than bone marrow. What is understood is that bone marrow is the main location for production of blood cells in adult reptiles, although extramedullary hematopoiesis may occur in other organs, such as the spleen and liver.[3,15,47] Variable amounts of active hematopoietic tissue occurs in vertebrae, long bones, ribs, carapace and plastron of turtles and tortoises, and other sites.[14,15,45] In general, the morphology of reptilian hematopoietic precursors is similar to their mammalian counterparts with obvious exceptions related to the known morphologic differences from mammalian blood cells described in the preceding section. Although bone marrow responses have not been studied as extensively as in

mammals, evaluation of reptilian bone marrow can be performed to assess hematopoietic activity in patients.[14,41] However, some studies suggest that bone marrow aspiration may be of limited value in some species of reptiles, such as desert tortoises, due to the lack of gelatinous bone marrow. In these cases bone marrow core biopsy may be necessary for adequate evaluation.[14,15] Clearly, additional investigations of hematopoietic responses and cytologic evaluation of bone marrow tissue in reptiles are needed.

CONCLUSION

The present review was intended as a brief introduction to reptilian hematology. Interested practitioners would greatly benefit from review of the current literature, training with experienced colleagues, and routine review of blood smears from reptilian patients, particularly those most frequently seen in private veterinary practices. Offering in-house hematological evaluation (including cell enumeration and other assays) to clients would be ideal if performed correctly. Furthermore, published reference intervals should be used with caution because there are many factors that influence the hemogram of reptilian patients, and there is variation in handling and analytical methods used to determine cell numbers. Tables 127.1–127.2 are a very small sample of the reptilian hemogram data that is available in the literature.

ACKNOWLEDGMENT

The author is grateful for Dr. Douglas Mader's contribution to this chapter in the previous edition.

CHAPTER 128

Hematology of Elasmobranchs

MICHAEL K. STOSKOPF

Morphologic Characterization
Protein Concentration
Response to Infectious Disease
Response to Noninfecious Disease

Acronyms and Abbreviations

ATPase, adenosine triphosphatase; Hgb, hemoglobin; PAS, periodic acid-Schiff; PCV, packed cell volume; RBC, red blood cell.

The divergence of the elasmobranches over their long evolution has resulted in over 500 species known to exist today. These species are adapted to many different ecologic niches, so variation in baseline hematologic parameters among the species of cartilaginous fishes should be expected. Unfortunately, the blood constituents of few elasmobranch species have been carefully investigated. Even less work has been published associating changes in hematologic parameters of elasmobranches to the presence of disease. Recent work by Arnold[1] has provided guidance in standardizing hematological methods for use with elasmobranch blood samples. These methods will hopefully improve the quality of material being published on these species.

MORPHOLOGICAL CHARACTERIZATION

Elasmobranchs have nucleated red blood cells (RBCs) and circulating blast cells. Mitotic figures are frequently observed and are thought to be in the RBC series, although detailed studies to confirm this are not available (Table 128.1). All principal leukocyte types are found in elasmobranch blood[1,4,15] (Table 128.2). Detailed electron microscopy and some cytochemistry studies of these cells are available.[2,3,7,8,9,10,14] Morphological evaluation of elasmobranch blood cells can be readily accomplished using routine methods. The classification of cells into heterophils, (sometimes referred to as neutrophils; Figs. 128.1 and 128.2), eosinophils (Fig. 128.3), monocytes (Fig. 128.4), lymphocytes (Figs. 128.5 and 128.6) and thrombocytes (Fig. 128.6) on the basis of cytoplasmic granule morphology and staining intensity in modified Wright-Giemsa stained smears is relatively straightforward. However, immature cells in the erythroid series are frequently erroneously counted as leukocytes. This is probably the basis for some reports of extremely high leukocyte counts with a high proportion of lymphocytes in various shark species.[24]

A major controversy remains to be resolved regarding the nature of the predominant granulocyte cell types found in elasmobranchs. Despite efforts to classify the most frequently encountered granulocytes as eosinophils, all functional evidence points to their being true heterophils with activities much like the neutrophil of mammals.[13] The question is complicated because both eosinophils and heterophils of elasmobranchs that have been studied are acid phosphatase and periodic acid-Schiff (PAS) positive.[4,7] Grimaldi found heterophilic granulocytes to be more intensely PAS and aliesterase positive and weakly ATPase positive compared to eosinophilic granulocytes that show the presence of neutral polysaccharides in the matrix but have strongly ATPase and acid phosphatase positive granules.[4] Some phagocytic activity has been demonstrated in elasmobranch heterophils.[11] A cell morphologically similar to granulocytes but without any cytoplasmic granules is frequently seen in blood of some species (M.K. Stoskopf, personal observation). It is not known if these represent a distinct cell type, are degranulated cells, or are cells that have not yet developed granules. More cytochemical studies are needed to elucidate the situation but, at present, such cells are routinely grouped with heterophils.

Elasmobranchs have efficient immunosurveillance and there is phyletic conservation of some cell mediator

TABLE 128.1 Baseline RBC Indices of Elasmobranchs

Species	*N*	Total RBC ($\times 10^6/\mu L$)	PCV (%)	Hemoglobin (g/dL)	Reference

[a]These references report very high total WBC counts indicating that there is a high probability that erythroid cells were counted as lymphocytes resulting in the high lymphocyte percentage reported.

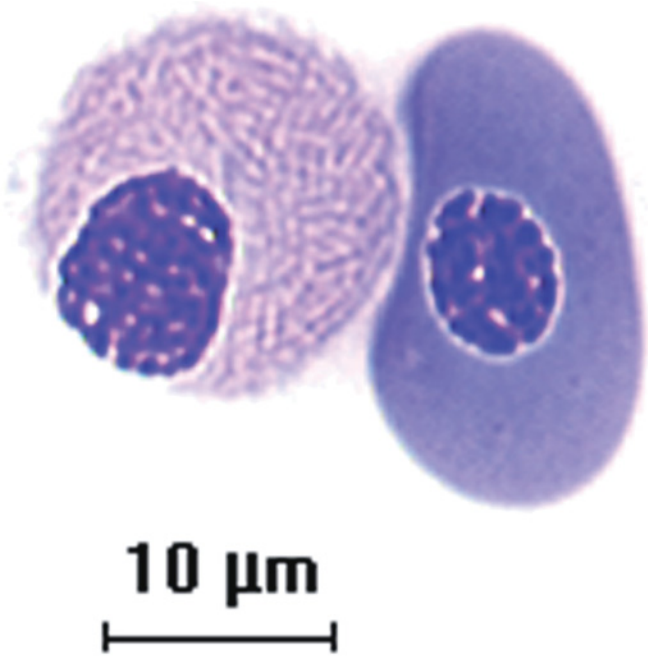

FIGURE 128.1 A heterophil (left) and an erythrocyte from a nurse shark (*Ginglymostoma cirratum*). Note the thin elongate cytoplasmic granules in the heterophil.

and regulatory products of lymphocytes and monocytes between elasmobranchs and humans.[5] Elasmobranch lymphocytes, monocytes, and thrombocytes can show weak PAS staining. Lymphocytes may also have aliesterase positive granules, while monocytes occasionally show some small PAS positive granules and weak acid phosphatase and aliesterase activities.[4] Phagocytosis has been demonstrated for elasmobranch cells considered to be monocytes but not for lymphocytes.[11] However, lymphocytes that appear to have engulfed material are seen in blood smears on occasion (Fig. 128.7).

Only a single thrombocyte cell type has been described in elasmobranchs. This is in contrast to similarly studied teleosts (*Rutilus rutilus* and *Gobio gobio*) that have two morphologic thrombocyte types.[25] The thrombocytes of elasmobranchs are rounded to spindle-shaped and originate in the spleen from prothrombocytes.[17] They contain microtubules and cytoplasmic granules that seem to correspond functionally to the mammalian platelet canalicular system.[17,25] The cytoplasmic presence of platelet factor 4, beta-thromboglobulin, and factor VIII-related antigen has been demonstrated by immunocytochemical staining. Elasmobranch thrombocytes adhere to glass, and aggregation and degranulation can be stimulated by

FIGURE 128.2 A young heterophil (near top) and a mature heterophil (below) among a group of mature erythrocytes, from a nurse shark (*Ginglymostoma cirratum*). The gradation in staining along the rubricytic series during maturation is more easily appreciated with a preliminary scan of the blood smear.

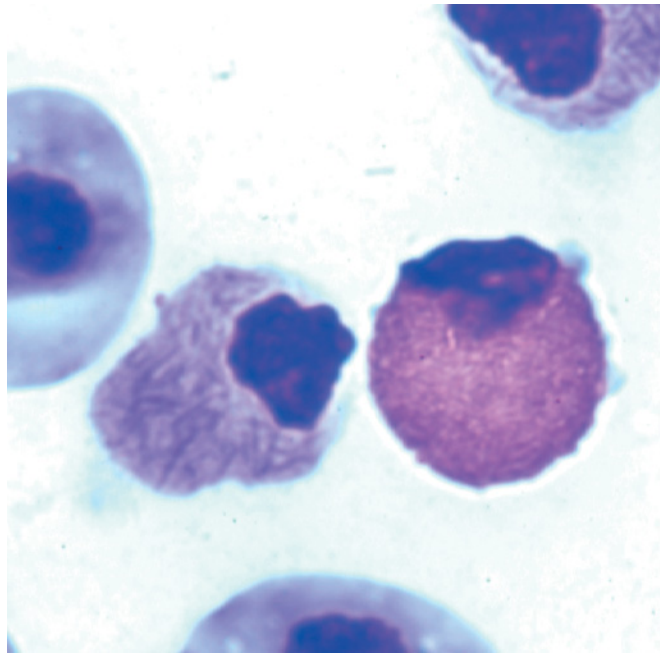

FIGURE 128.3 An eosinophil (right) and a heterophil (left) from a sandtiger shark (*Odontaspis taurus*) showing the eccentric nucleus and rounder more eosinophilic cytoplasmic granules of the eosinophil. Note the differences between the cytoplasmic granules in the heterophil compared to those in the nurse shark in Figure 128.1.

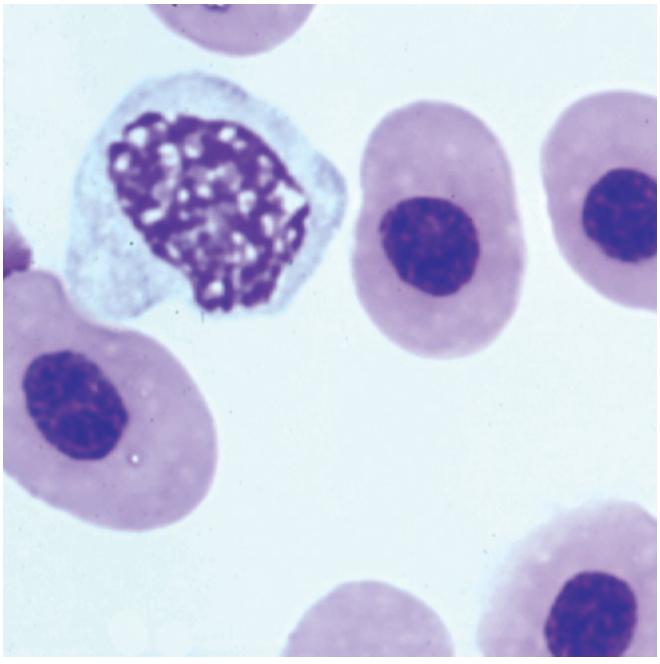

FIGURE 128.4 A monocyte from a brown shark (*Carcharhinus plumbeus*). Note the large nucleus and foamy cytoplasm of this leukocyte which is larger than found in young lymphocytes.

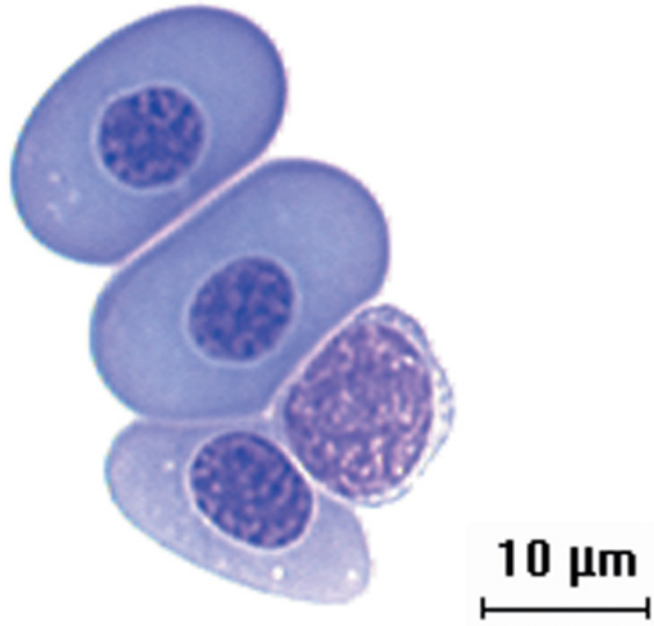

FIGURE 128.5 A large lymphocyte and two mature erythrocytes from a nurse shark, (*Ginglymostoma cirratum*).

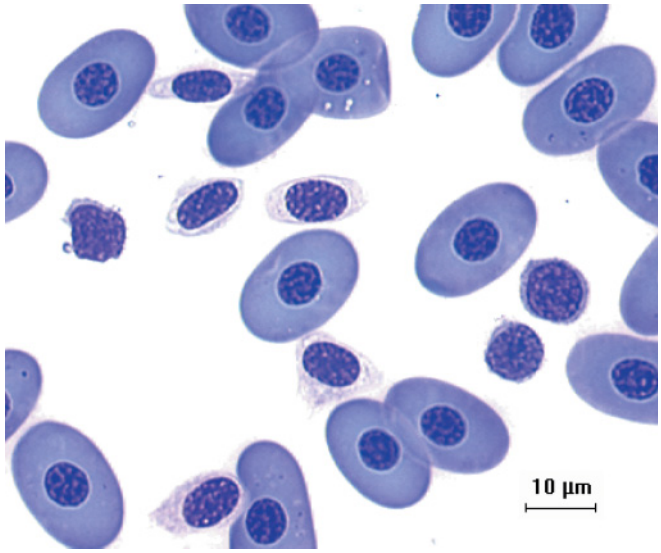

FIGURE 128.6 Five thrombocytes in various stages of maturity and three small lymphocytes from a nurse shark (*Ginglyomstoma cirratum*). Note the relatively elongate nucleus of the thrombocytes and the different staining quality of the cytoplasm of the two cell types.

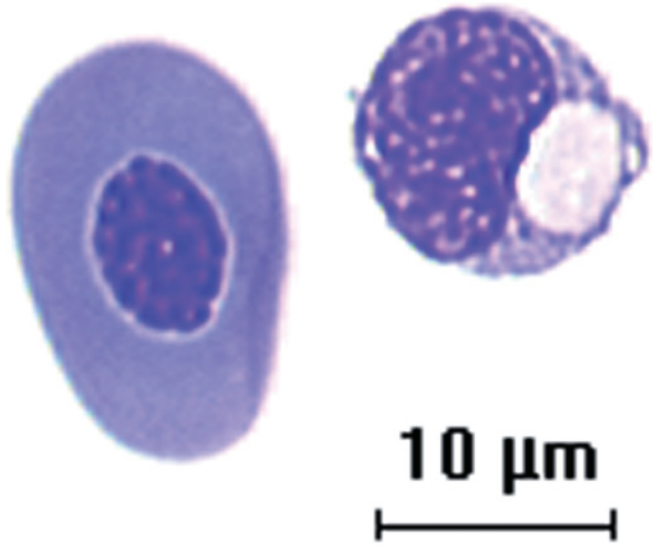

FIGURE 128.7 Lymphocyte from a nurse shark (*Ginglyomstoma cirratum*) with apparently phagocytized cellular debris.

collagen, noradrenaline, 5-hydroxytryptamine, thrombin, or adenosine diphosphate (ADP).[17] Thrombocytes contain some peripheral granules that are PAS positive and slightly ATPase positive.[4]

PROTEIN CONCENTRATION

An important methodological problem in elasmobranch hematology and clinical pathology is the determination of serum or plasma protein. Determinations made by a refractometer result in artificially high serum or plasma total protein concentrations, because of the urea nitrogen concentration that elasmobranchs maintain for the purposes of osmotic regulation. Refractometer total protein determinations are typically 2–3 times higher than automated colorimetric total protein assay results (Table 128.3).

RESPONSE TO INFECTIOUS DISEASE

Elasmobranch hematological parameters respond to infection with many of the same changes seen in mammals. Bacterial infections routinely cause marked leukocytosis, usually due to a heterophilia. A distinct left shift is difficult to demonstrate because mature granulocytes of elasmobranchs have less distinctly lobed nuclei than analogous cells of most mammals. This makes detection of immature cells less certain.

There has been little or no experience in detecting hematological changes associated with viral or protozoal diseases in elasmobranchs. Overwhelming trematode infection can be accompanied by a leukocytosis, but it is difficult to know whether this is a response to trematodes, a generalized stress response, or a response to secondary bacterial infections that can accompany heavy trematode infestations.

RESPONSE TO NONINFECTIOUS DISEASE

Stress is a frequent factor in interpretation of elasmobranch hemograms. Confinement stress appears to cause decreased red blood cell (RBC) counts, packed cell volume (PCV), and hemoglobin (Hgb) levels in spiny dogfish. In addition, a nonregenerative and, most likely, redistributional anemia develops, and serum glucose and total leukocyte count increase dramatically with confinement stress.[22] This suggests that the stress leukogram of elasmobranchs may be difficult to differentiate from a response to bacterial septicemia. The leukocytosis in both instances is primarily due to a heterophilia, and an accompanying eosinopenia in the stress leukogram may not be easily appreciated.

Some elasmobranches are found in freshwater environments and some species, such as the bull shark, move between fresh and saltwater environments as part of their natural history. These species appear to exhibit RBC swelling when exposed to acute reductions in environmental salinity beyond 50%. They respond by rapidly increasing serum urea nitrogen concentration and gradually shifting their electrolyte balances when moved acutely from freshwater to high salinity.[18] It is reasonable to assume that environmental salinity should be considered when evaluating these parameters in elasmobranches.

The other reasonably well documented noninfectious cause of hematologic changes in sharks, skates, and rays is heavy metal toxicity. Copper exposure is a frequent problem in captive animals and elasmobranchs are much more sensitive to this metal than marine

TABLE 128.3 Protein and Urea Nitrogen Concentrations of Elasmobranchs

Species	*N*	Urea Nitrogen (mg/dL)	Total Protein (g/dL)	Albumin (g/dL)	Globulin (g/dL)	Reference
Blacktip shark (captive)	2	1015	3.3	0.5	2.8	21
Brown shark (wild)	33	848 (34)	2.2	0.5	1.7	20

Tiger shark (captive, compromised)	2	1134	4.6	0.5	4.2	20

teleost fishes. A normochromic normocytic anemia with decreased total RBC count and PCV and a stable Hgb value has been documented in spiny dogfish exposed to sublethal concentrations of copper (2 ppm for 48 hours). A leukopenia and decreased serum glucose was also seen.[23] Exposure to higher copper levels (4, 6, 8, or 16 ppm) is fatal to spiny dogfish within 56 hours and causes similar anemia and falling Hgb concentrations.[23]

Zinc exposure in spiny dogfish also causes a microcytic hypochromic anemia characterized by a decreased Hgb concentration, but the PCV generally remains stable while the total RBC count is increased. This toxicity is characterized by a leukocytosis in contrast to what is seen in copper exposure. Serum glucose is also decreased.[22]

CV, coefficient of variation; CV_G, inter-individual variation; CV_I, intra-individual variation; EQA, External Quality Assessment; ISO, International Organization for Standardization; QC, Quality Control; RBC, red blood cell; SOP, Standard Operating Procedure; WBC, white blood cell.

Quality control (QC) in some aspects resembles diagnostic test validation (Chapter 130) but there are significant differences. In general, laboratory measurements for clinical purposes are performed to answer a question of consequence to patient management. Evaluating whether a test is able to answer such questions appropriately is performed through test validation procedures when introducing the test to the laboratory. A main step in this process consists of answering the question, Will the test provide results with acceptable quality for clinical decision-making? To answer this question, several sources of variation are evaluated in the step-wise approach of the validation procedure, including analytical variation, biological-physiological variation, and pathological variation. It must be concluded that analytical and biological-physiological variation is of such a magnitude that pathological variation can be detected in a clinically useful manner. The allowable level of analytical and biological-physiological variation is thus determined in part by the magnitude of the pathological variation, as a marked shift in the level of the analyte in relation to disease will allow wider margins than if the shift is only subtle and therefore more easily masked by excessive analytical variation.

Following thorough validation procedure and a decision to apply the test in a clinical setting, the question of quality shifts to, Does the test *still* provide results with acceptable quality for clinical decision-making? and this is where QC takes over from validation.

In this chapter, the major aspects of QC in veterinary hematology will be outlined. The ultimate task is to ensure that the test has an ongoing ability to detect pathological variation in a clinical useful manner. The focus will be on controlling analytical variation, as both biological-physiological variation and pathological variation are mainly patient-related and in a strict sense outside the scope of QC. However, knowledge of especially biological variation is of great benefit in the application of appropriate QC, as described later in this chapter.

QUALITY MANAGEMENT

The concept of total quality management will be described briefly to outline the role of QC within this system. Quality management has evolved through time to ensure that quality goals are fulfilled. Performing QC was added in medical laboratories in the 1960s to statistically monitor the performance of analytical processes.[20] Other aspects were added later to also include other quality characteristics, such as turnaround time and sample identification in the system, and in the 1990s a framework for continuous improvement of quality was applied.[20] This framework for quality management included the following: quality laboratory

practices (e.g. procedures and protocols), quality control, quality assurance, quality improvement, and quality planning.

Quality improvement and quality planning are tools to implement and plan changes outside the actual laboratory to correct or prevent quality problems, respectively.[20] In modern times the framework has been integrated into quality system standards, such as the International Organization for Standardization (ISO) 15189:2007 standard for medical laboratories.[11] The ISO 15189:2007 standard has been suggested as a blueprint for quality systems in veterinary laboratories.[8]

Quality management involves a holistic approach to address all identified aspects of quality, and to plan, control, intervene and improve in a continuous process. Quality control is that part of the process whereby analytical error is monitored statistically to detect errors of possible clinical importance. As a key component, it is addressed at several levels of the quality system standards.[11]

To put QC in the context of the diagnostic process, the time from sampling to delivery of results can be split into three phases: the pre-analytical, analytical and post-analytical phase. Each phase has its own palette of sources of variation that should be kept at a level with no or negligible influence on the final clinical decision based on the reported result. Where QC is limited to the analytical phase and mainly based on a statistical approach, recommendations regarding the pre- and post-analytical phases are to apply rigorous Standard Operating Procedures (SOPs), taking important sources of variation into account. Important pre-analytical factors such as the amount of sample, use of anticoagulant, timing of sample, transport, handling and sample identification should all be accounted for in the SOP.[10] For the post-analytical phase the key issue is to avoid "gross errors" that can have fatal consequence to patient management. Again appropriate SOPs are key tools, with the most important weapon against gross errors being to check and double check reports before releasing results or to allow application of smart Laboratory Information Systems.[9]

QUALITY CONTROL

Quality control itself consists of several parts that together enable the statistical control of random and systematic errors. These parts include: (1) quality control materials and methods, (2) analytical quality specifications, and (3) statistical quality control rules. All parts are necessary to perform appropriate QC, and the total efficacy of QC depends on thorough consideration in defining each part. One set of choices will not be optimal for every analyte in veterinary hematology and will not fit across veterinary laboratories, as demands on QC will vary with methodology and the use of the results. So each laboratory will have to choose in accordance with its own identified needs. It should be kept in mind that the total QC is not better than the weakest part, e.g. if a lot of effort is put into defining appropriate quality specifications and application of QC rules, it is of little use if poor or unstable QC material is used. Likewise, the use of substantial resources to establish valid and stable control material is of little use if quality specifications and control rules are poorly defined.

Quality Control Materials and Methods

Regarding QC material, it should be noted that QC should be made at several levels of the analyte, optimally at least within the normal range, close to the clinical decision level and within the pathological range. When stable QC material is available, i.e. when the analyte is stable in patient samples or sample pools, or when stable control material is provided by manufacturer, this can then be applied according to defined QC rules, as described below. However, many analytes in veterinary hematology have sub-optimal stability to allow long term use of patient or patient-like material, and alternative QC methods must be used. Alternative methods may involve performing routine validation as described in detail in Chapter 130, e.g. routine method comparison between automatic (calculated) PCV and spun (measured) PCV can be performed to detect systematic error. The use of manual leukocyte differential count to evaluate automated differential count is another example of routine method comparison used for QC purpose to detect bias, where bias is defined as the difference between results of the actual measurement and the true value. If excess imprecision is suspected, as determined by the lack of close agreement between independent results on the same analyte, fresh patient samples at various levels can be run repetitively to assess random variation and compare to specified quality goals.

Analytical Quality Specifications

Quality control must be designed to reveal clinically important systematic and random error in order to identify and eliminate the source of variation. To do this, criteria to decide whether a level of error is important or not is mandatory, without which decisions of acceptability can only be arbitrary. Nevertheless, this requirement is seemingly tough to meet in veterinary laboratories, as it has recently been identified as one of the most frequent reasons for not meeting accreditation criteria.[8] The generation of such quality specifications has also been subject to several discussions in human medicine and was the sole object of a meeting in Stockholm in 1999, resulting in a consensus statement on the setting of quality specifications in laboratory medicine.[14] It was agreed that the following hierarchy of models should be applied to set analytical quality specifications:

1. Evaluation of the effect of analytical performance on clinical outcomes in specific clinical settings.

2. Evaluation of the effect of clinical performance on clinical decisions in general:
   (a) Data based on components of biological variation
   (b) Data based on analysis of clinician's opinion.
3. Published professional recommendations
   (a) From national and international expert bodies
   (b) From expert local groups or individuals.
4. Performance goals set by
   (a) Regulatory bodies
   (b) Organizers of external quality assessment (EQA) schemes.
5. Goals based on the current state of the art
   (a) As demonstrated by data from EQA or proficiency testing scheme
   (b) As found in current publications on methodology.

It is important to make use of data ranking as high as possible in this hierarchy, as it will ensure optimal relevance of the finally established quality specification to the key question of QC, namely, Does the test provide results with acceptable quality for clinical decision-making? Only limited, if any, data at the level of "evaluation of the effect of analytical performance on clinical outcomes in specific clinical settings" are available in veterinary hematology. However, at the next level (2a), data on the biological variation of several analytes in dogs (Table 130.2, p 1028), as well as in other animal species[12] are available and should be used. A few other aspects of the ranking call for comments related to the veterinary application. There is no established tradition in veterinary medicine to define quality specifications based on the opinion of experienced clinicians, despite the high ranking of this method in the consensus statement. It has been suggested that highly relevant quality goals can be obtained by presenting well-defined case histories together with questionnaires to experienced clinicians.[18] Clinicians are asked what changes in the concentration of an analyte will cause them to change actions concerning the patient, and the laboratory must be able to detect these changes with a certain probability. Interestingly, it should be noticed that "professional recommendations from expert local individuals" ranks higher in the consensus statement than quality specifications derived from External Quality Assessment (EQA), regulatory bodies and general publications on the methodology. The higher ranking is due to the knowledge of the local expert on local needs and specific settings of the methodology, which are not included in the lower ranking methods. So although this "expert opinion" is sometimes viewed as too subjective, this subjectivity is what makes it superior to the lower ranking, more general methods of defining quality specifications.

To further exemplify application of the consensus statement, the use of data on biological variation to define quality specifications will be outlined. Studying biological variation of an analyte results in estimates of intra- (CV_I) and interindividual (CV_G) variation.[7] The derived quality specifications for imprecision and bias are set to keep these at levels negligible compared to the observed biological variation. The general consensus for analytical imprecision (CV_A) is that the desirable level should be below $0.5CV_I$, as this will keep the influence of CV_A on the total variation below 11%.[5] Criteria for an optimal level ($CV_A < 0.25CV_I$) and a minimum level ($CV_A < 0.75CV_I$) have also been agreed upon.

TABLE 129.1 Examples of Analytical Quality Specifications for Imprecision based on Different Models

Analyte	Biological variation observed in dogs $0.5CV_I$[13]	Derived for veterinary purposes from human regulatory guidelines[2]
Erythrocyte count	2.7%	±2%
Hematocrit	3.2%	±2%
Hemoglobin	3.0%	±2%
Leukocyte count	6.1%	±4%
Platelet count	NA	±6%

NA, Not assessed.

Quality specifications for analytical bias (B_A) are based on CV_I and CV_G combined, where the criteria are $B_A < 0.125(CV_I^2 + CV_G^2)^{1/2}$, $B_A < 0.25(CV_I^2 + CV_G^2)^{1/2}$ and $B_A < 0.375(CV_I^2 + CV_G^2)^{1/2}$, for optimal, desirable and minimum control, respectively.[5] This can be combined in a total allowable error (TE_{max}) approach where desirable $TE_{max} < 1.65(0.5CV_I) + 0.25(CV_I^2 + CV_G^2)^{1/2}$.[6] The total error approach will allow an overall assessment of the quality performance of the test by means of MedX charts plotting observed imprecision and bias in relation to quality specifications (Chapter 130). Table 129.1 includes examples of desirable veterinary quality specifications for imprecision derived from biological variation and human regulatory guidelines, respectively.

Statistical Quality Control (QC) Rules

When analytical quality specifications have been set up for imprecision and bias for a specific analyte, quality control rules must be defined that will detect violations of these specifications with acceptable efficacy.

Control materials, as described above, are used for this purpose. The material is analyzed in 15–20 stable analytical runs to establish a mean and standard deviation of the control material measurements. Control material provided by manufacturers of hematology analyzers or available through other commercial sources often has an assigned interval. If a control measurement falls outside this it is supposed to be rejected. It is highly advisable to establish local values for every control material, as the assigned values and limits may turn out to be sub-optimal for local QC demands, being either too insensitive or resulting in an unacceptable rate of false rejections. As for the use of cut-off values in a diagnostic set-up, there is a close relation between the

sensitivity and specificity of such QC rules, where highly sensitive rules tend to result in increased rate of false-positive rejections of analytical runs and *vice versa* (i.e. less stringent rules being too insensitive to detect critical errors). The task is to identify QC rules that will detect clinically relevant errors (according to the quality specifications) with both an acceptable probability of detecting critical errors and an acceptable risk of false rejection. Furthermore, there are no "golden QC rules" to detect both violation of quality specifications for imprecision and bias with the same efficacy. In our view, unless a method is known to have inherent risk of changing bias (e.g. by poorly defined calibration material), the primary focus should preferably be on implementing QC rules sensitive to changes in imprecision in veterinary hematology, as these will often provide sufficient control of bias also. If globally recognized standards were to be made available for veterinary analyses in the future, assessment of absolute bias would be possible, and the QC focus should be assessed on a test to test basis.

Quality Control rules can be represented by symbols in the format A_L, where A represents statistics or number of control measurements and L identifies the control limit, e.g. 1_{2S} is a control rule with one measurement and a limit of mean ± 2SD (the standard rule of the Levy-Jennings chart, where an analytical run is rejected if a measurement of the control material deviates from the established mean by more than 2SD).[19] The optimal rule depends on the quality specifications and whether focus is on detection of unacceptable imprecision or bias. Rules like 2_{2S} and 4_{1S} are sensitive to bias, where 1_{3S} and $1_{2.5S}$ are sensitive to changes in imprecision.[19] Probability of error detection and false positive rates for the different rules can be assessed by power function calculations based on the defined quality specifications and number of control materials used.[19] Based on these assessments the best rule is chosen and applied. The charting of control values over time is not different from the traditional Levy-Jennings chart, it is only the interpretation that is optimized for error detection (Fig. 129.1).

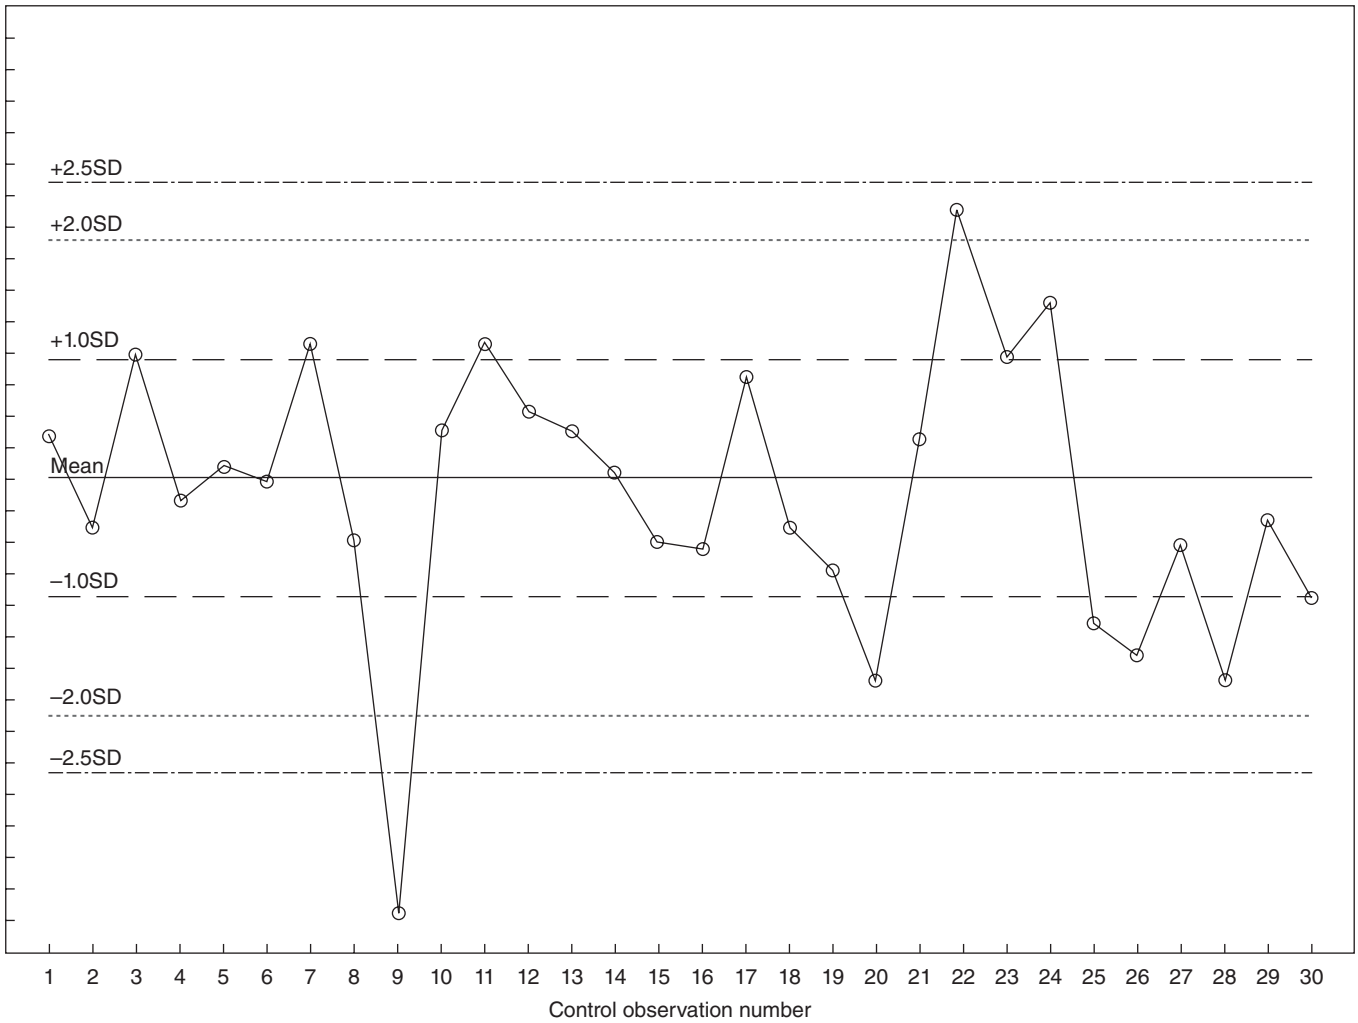

FIGURE 129.1 An example of a chart of 30 consecutive runs of a control material. Mean and standard deviation (SD) have been previously established by 20 measurements during stable performance. Values are interpreted according to chosen Quality Control Rules, e.g. if $1_{2.5S}$ is the rule then a violation is present in run 9; if 1_{2S} is the rule then both runs 9 and 22 are rejected. A rule of 10_x (10 consecutive values on the same side of mean), if applied, is sensitive to a shift in bias. Attention is therefore needed on runs 25–30, which are all below mean.

The standard rule of 1_{2S} usually results in higher, often unacceptably higher, false rejection rates and should only be used when the high sensitivity is needed. This systematic approach for QC optimization has been demonstrated for veterinary purposes also.[15] If both bias and changes in imprecision must be kept under strict control, application of multi-rule QC may be necessary.[19]

THE ROLE OF PROFICIENCY TESTING IN QUALITY CONTROL

Proficiency testing programs for veterinary hematology are available and the use thereof is highly advisable and necessary to meet general quality system criteria.[8] However, as veterinary medicine lacks globally recognized standards for uniform calibration material and as control materials are artificially stabilized for transport in the programs, results are usually only comparable within the same methods. Participation in such programs will facilitate detection of systematic errors not detectable by internal quality control methods, and it may be an indirect way to obtain a crude estimate of bias. Guidelines for assessment of human laboratory tests when proficiency testing is not available exist and some of the recommendations can be relevant for veterinary laboratories also.[3] As an example, collaborating with geographically proximate laboratories in a split-sample program may help to identify possible unacceptable differences.

THE ROLE OF MANUAL SLIDE EVALUATION IN QUALITY CONTROL

The manual microscopic evaluation of blood film slides is recognized as a very powerful diagnostic tool in veterinary hematology and its role in routine quality control is no less important.[1] However, the role shifts depending on the analyte in question and the automated methodology used. When the automated methodology is regarded as being more precise and accurate, the main role of blood film evaluation in QC is to confirm or reject results produced by automated analyzers, which can be done objectively by comparison of results (exemplified below under leukocyte differential count). If the automated analyser is regarded as inferior to the manual evaluation or incapable of analyzing the analyte in question, then the manual evaluation is regarded as the main method, and should therefore undergo its own appropriate QC.

White Blood Cell and Red Blood Cell Counts

Manual blood film evaluation will not produce estimates of total red blood cell (RBC) count reliable enough for objective quality control. The same is true for the total white blood cell (WBC) count; however, experienced evaluators will be able to detect marked leukocytosis and leukopenia with the knowledge of the hematocrit for subjective confirmation of the result from the automated analyzer.

Leukocyte Differential Count

The approved standard for evaluation of instrumental methods for leukocyte differential counts in human medicine is based on manual differentials as a gold standard.[4] So although a manual 100–200 cell differential count is seemingly mathematically unable to meet analytical quality specifications itself due to sampling variation,[16] it is a convenient qualitative tool to control automated differential counts.

If the automated analyzer used has proven to produce reliable differential counts in the specific species, the quality control will basically consist of detecting gross errors, i.e. systematic misclassification of cell types by the automated differential. The major part of variation in a manual differential count is due to the sampling of low numbers of cells (e.g. 100–200) and a rough estimate of CV_A can thus be derived from the variation of sampling proportions, where $CV_P = [(1 - p)/pn]^{1/2}$.[16]

For example, an automated differential reporting 29% lymphocytes is selected for QC (CV_A for the method is 2%). The manual differential ($n = 100$) reports 20% lymphocytes ($CV_A = [(1 - 0.20)/0.20 \times 100]^{1/2} = 0.2 = 20\%$). The combined imprecision is $CV_{combined} = (0.2^2 + 0.02^2)^{1/2} = 0.201$. The best guess of a true value is the average of the observed values [$(0.29 + 0.2)/2 = 0.245$] and the maximum difference explainable by the combined imprecision is thus: $Diff_{max} = 1.96 \times 0.201 \times 0.245 = 0.10$. With an observed difference of 0.09 = 9%, the run cannot be rejected. Due to the large inherent imprecision of the manual differential count, a difference exceeding what can be explained by the combined imprecision is a rather specific sign of a relevant systematic error.

If an automated differential is rejected, reasons for the misclassification by the automated machine should be identified and corrected, and the sample should be reanalyzed. If reasons are undetectable or uncorrectable, a result based on the manual differential can then be reported if acceptable.

If the automated analyzer has not proven able to produce reliable veterinary differentials, then the manual differential count should be regarded as the method itself, realizing the inherent imprecision of the method. The QC will then shift to consist of analyzing observer agreement.

Leukocyte Morphology

Automated analyzers are in general not yet capable of assessing morphologic characteristics of veterinary leukocytes that exceed leukocyte classification necessary for a differential count (assessment of band neutrophils and toxic changes in neutrophils are good examples). Thus leukocyte morphology evaluation relies on manual evaluation and QC on analyzing observer agreement locally and participation in proficiency testing programs that include leukocyte morphology evaluation.

Reticulocytes

Automated analyzers for veterinary purposes performing reticulocyte counts are available. Quality control of these methods can be performed by comparison of reticulocyte proportions obtained by manual evaluation, as outlined above. If automated methodology is not present and the reticulocyte count is performed manually, the QC will consist of analyzing observer agreement.

Red Blood Cell Morphology

Most analysers based on flow cytometry or impedance-based methodology can produce distributional plots of erythrocyte cell size. Several of the flow cytometry based analyzers also provide the hemoglobin content of individual cells. However, other morphological characteristics may depend on manual recognition and the QC will rely on analyzing observer agreement locally and participation in proficiency testing programs that include erythrocyte morphology evaluation.

Platelets

Platelet clumping is a main pre-analytical reason for falsely low estimates of automated platelet counts, especially in cats where a blood film evaluation is seemingly more reliable in identifying true thrombocytopenia than an automated count.[17] This calls for rigid QC of low platelet counts by manual blood film evaluation, looking for platelet clumps.[1] Some analyzers will flag the presence of platelet clumps based on distribution plots, which is seemingly specific; however, clumps can also be identified in unflagged samples (A.L. Jensen and M. Kjelgaard-Hansen, personal experience).

CHAPTER 130

Diagnostic Test Validation

ASGER LUNDORFF JENSEN and MADS KJELGAARD-HANSEN

Test Validation
- Phase 1 – Analytical Performance
  - Imprecision
    - Within-run imprecision
    - Between-run imprecision
    - Analytical goals for imprecision
  - Inaccuracy
  - Spiking recovery and linearity checks
  - Control material
  - Comparison of methods
  - Detection limit
  - Additional analysis of analytical performance
- Phase 2 – Overlap Performance
  - Initial application of the test
- Phase 3 – Clinical Performance
  - Selection of appropriate animals
  - Independent classification of the selected animals
  - Applying the test to all animals in the study population

Sensitivity and Specificity
Predictive Values
Receiver-Operating-Characteristic (ROC) Curves
Likelihood Ratios

Acronyms and Abbreviations

CV, coefficient of variation; DPR, differential positive rate; LOF test, Lack-of-Fit test; LR, likelihood ratio; MEDx chart, method evaluation decision chart; NPV, negative predictive value; P, prevalence; PPV, positive predictive value; *r*, correlation coefficient; ROC curves, receiver-operating-characteristic curves; SD, standard deviation; X_{mean}, mean value; SE, sensitivity; SP, specificity.

A primary function of the laboratory is to minimize the amount of error so that test interpretation, patient care, and/or consumer safety are not compromised. Therefore, a common task in clinical laboratories is to validate a new test or a new analyzer when it is introduced in the laboratory, assuring that test results reflect the status of the animals more than they reflect variation caused by the laboratory test itself.

Validation of diagnostic tests basically concerns reliability (Is the measurement reproducible?) and validity (Does the test measure what it is intended to measure?). This chapter presents practical procedures and statistical tests to investigate common problems in hematology laboratories, such as investigation of imprecision, inaccuracy, method comparison, detection limit and interference. Strategies for investigating how the test works when it is applied to healthy and sick animals, i.e. diagnostic sensitivity and specificity, predictive values and receiver-operating-characteristic curves, will also be outlined.

TEST VALIDATION

The very first step in test validation is to become familiar with the new test or new analyzer, both theoretically and practically. It is often useful to construct a description of the test that includes a description of the analytical procedure, including those materials and equipment necessary for an experienced analyst to obtain a test result (Table 130.1).

The next step is focused on analytical performance. This is followed by observations on how the test behaves when it is actually used on patients (overlap and clinical performance).

Phase 1 – Analytical Performance

Assessment of analytical performance should, as a minimum, include a description of the test and estimates of imprecision, inaccuracy, and detection limits for that test.

TABLE 130.1 Suggested Minimum Information for Diagnostic Tests

Intended use of the test – e.g. diagnosing a specific disease among sick animals, monitoring therapy, or screening for a specific disease among healthy animals
Outline of the analytical principle – preferably with references to the literature
Specifications of the analytical instruments and equipment
List of reagents with concentrations in appropriate SI units, source and brand name
Specimen requirements – e.g. volume, anticoagulants, and storage
Full description of all steps in the analytical procedure
Calibrating procedure and method for calculating test results
Control material with concentrations in appropriate SI units, source and brand name, control rules applied together with the probability of error detection and probability of false rejection
Safety precautions – e.g. when preparing reagents and disposing of waste
Practicability – e.g. time needed for analysis of one specimen when the analyst is not prepared for it, costs, and technical skill requirement

TABLE 130.2 Data on Biological Variation for Some Canine Hematologic Analyses

Analyte	CV_G (%)	CV_I (%)	CV_A (%)	CV_{max} (%)	TE_{max} (%)
Red blood cell count	4.4	5.4	2.8	2.7	6.3
Hematocrit	5.2	6.4	1.1	3.2	7.4
Hemoglobin	4.7	5.9	2.9	3.0	6.9
White blood cell count	12.3	12.1	3.7	6.1	14.4
Albumin	3.0	2.4	1.6	1.2	3.0
Protein	3.1	2.6	1.1	1.3	3.2
Iron	17.2	17.8	0.7	8.9	20.9
Fibrinogen	19.0	17.1	2.8	8.5	20.4

CV_G, Between-dog coefficient of variation; CV_I, within-dog coefficient of variation; CV_A, analytical coefficient of variation; CV_{max}, maximum allowable imprecision; TE_{max}, maximum allowable total error.

Imprecision

Imprecision is a measure of the closeness of a series of measurements of the same material. Imprecision is most often expressed in percent as a coefficient of variation (CV) and is usually calculated as within-run (within-day; intra-assay) and between-run (between-day; inter-assay) imprecision using the standard deviation (SD) and mean value (X_{mean}) in the formula $CV = (SD \times 100\%)/X_{mean}$. Because imprecision varies with analyte concentration, patient samples with analyte concentrations spanning the analytical range are preferred. Control material can also be used, especially when assessing the between-run imprecision in cases where the analyte is unstable.

Within-Run Imprecision This can be assessed in two ways, either from the differences between duplicate measurements obtained with a number of different samples, or from the results of several replicate measurements made on the same specimen. A practical approach is to select a number of patient specimens (e.g. 30–100) and analyze these in duplicate. The specimens are then divided into three groups (lower, middle and higher end of the analytical range) according to their analyte concentration. The mean value and the number of duplicate pairs in each group are recorded. The differences between the duplicates are used to calculate the standard deviation for each group and eventually, using the mean value of each group, the CV of each group is calculated. A statistical F-test can be used to test whether the SDs differ significantly between the groups. Alternatively, three patient samples with low, middle and high analyte concentrations are measured 10–30 times, in the same analytical run, and the mean value, SD and CV for each patient sample are calculated. A graphical picture of the imprecision (a precision profile) with the CVs on the *y*-axis plotted against the analyte concentration on the *x*-axis can be constructed when enough samples have been analyzed.

Between-Run Imprecision Not less than three patient samples with low, intermediate and high analyte concentrations are selected. The samples are analyzed in different analytical runs, e.g. twice daily over 5 days. The number of replicate measurements is recorded and the mean value, SD and CV for each sample are calculated. During the investigation period, the samples should be stored appropriately. If the analyte is unstable, control material can be used instead.

Analytical Goals for Imprecision A common rule of thumb is that imprecision CV should be below 5% for automated assays and below 10% for manual assays. A more objective was formulated by Tonks,[11] who suggested that imprecision CV should not exceed one-eighth of the width of the reference interval expressed as a percentage of the mean of the range. More recently, it has been suggested that, based on data on biological variation (i.e. within and between animal variation (CV_I and CV_G; see Table 130.2) the imprecision CV (CV_A) should be less than $0.5 \times CV_I$.[3]

Inaccuracy

Inaccuracy (also referred to as bias or systematic error) is generally defined as the agreement between the mean value of a series of measurements on the same material and the true value.

Systematic error can be subdivided into constant and proportional systematic error. Constant systematic errors are systematic deviations estimated as the average differences between the two methods. The presence of a constant systematic error indicates that one method measures consistently higher or lower in comparison with the other method. Proportional systematic error means that the differences between the two methods are proportionally related to the level of measurements.

It may be difficult to obtain a species specific specimen with a universally recognized true value and therefore, inaccuracy is often assessed using spiking recovery, linearity checks, control material, and/or comparison of analytical methods.

Spiking Recovery and Linearity Checks

In spiking recovery, the analyte concentration is measured in duplicate in patient samples before and after addition of known amounts of the analyte. Alternatively, patient samples with known analyte concentrations are mixed in various ratios and the analyte concentration in the mixtures is measured in duplicate. The percentages of the measured analyte concentrations to the expected analyte concentrations are then calculated. Ideally, these percentages should be about 100%, usually between 80% and 120%.

In linearity checks, the analyte concentration is measured in duplicate in patient samples before and after dilution with an appropriate diluent (such as physiologic saline or a zero calibrator). The relationship between the measured and the expected analyte concentrations is then investigated by regression analysis of the untransformed and logarithmically transformed data. The confidence interval of the slope of the linear regression equation should include 1, thus indicating that recovery is 100%. When necessary, data are logarithmically transformed to achieve homogeneity of the variances. The confidence interval of the slope of the logarithmic regression equation should include 1, thereby indicating that the recovery is proportional. It also worthwhile to examine whether the data follow a straight line, either by use of a simple Runs-test or by use of the more complex Lack-of-Fit (LOF) test.

Control Material

Inaccuracy can be assessed using control material having a value assigned by the manufacturer. Alternatively, one can use the mean of values assayed in specimens by participants in an external quality assurance scheme. In essence, the control material or the quality assurance specimens are subjected to replicate (e.g. 20–40) measurements. Using a one-sample *t*-test or Wilcoxon Signed Rank test, depending on whether the data are normally distributed, it is tested whether the measured mean (or median) analyte concentration differs from the expected value. The difference between the observed mean (or median) value and the expected mean value is the bias of the analytical method and it can be expressed in percentages of the expected value.

Comparison of Methods

The purpose of a method comparison study is to estimate the type and magnitude of systematic error between two methods and to judge if the two methods are identical within the inherent imprecision of both methods or within preset analytical quality specifications. A detailed approach to method comparison studies has been described.[5]

Briefly, for quantitative tests the typical protocol includes: (a) obtaining estimates of random error (CV) for both methods, (b) estimating the number of samples to be included in the method comparison experiment, (c) defining acceptable difference between the two methods, (d) analyzing the data, and (e) judging acceptability.

Estimates of random error (CV) are obtained from imprecision studies for both methods. Patient samples (e.g. 30–100) with analyte concentrations spanning the analytical range are analyzed by the two methods. Duplicate measurements on each method are preferred because outlying values are more easily identified and because the data set can be used to calculate imprecision also. The range ratio (i.e. maximum value divided by the minimum value) also indicates the number of samples to be included. If the ratio is low, the number of samples should be high and *vice versa*.

To define the acceptable difference between the two methods, two strategies can be used. The first approach is to calculate the combined inherent imprecision of both methods $(CV^2_{method1} + CV^2_{method2})^{1/2}$, or in case of duplicate measurements $[(CV^2_{method1}/2) + (CV^2_{method2}/2)]^{1/2}$. If the combined inherent imprecision is 10%, and the mean value of the two methods is 200, then the difference between the two methods is expected to be within the interval $0 \pm 1.96 \times CV \times$ mean in 95% of the measurements, that is $0 \pm 1.96(0.10 \times 200) = 0 \pm 39.2$. The second approach is to specify acceptance limits based on analytical quality specifications usually in the form of either total allowable error (TE_{max}), such as those proposed in Table 130.2, or those reported for human samples by the Clinical Laboratory Improvement Amendments (CLIA) proficiency testing criteria (for more details on CLIA, see http://www.fda.gov/cdrh/CLIA/index.html).

For analyzing the data, a plot of the results (or the means of the duplicate measurements) by one method against the other method together with a line of equality is inspected. If the data are linearly distributed and not clumped in one end of the data range, correlation analysis is performed. Then the correlation coefficient (r) is calculated. Correlation coefficients (r) higher than 0.975 (for data encompassing a small range) or 0.99 (for data encompassing a wide range) indicate that simple linear regression provides useful information about constant error and proportional error via the intercept and slope, respectively. If the intercept differs significantly from 0, then there is a constant systematic error. If the slope differs significantly from 1, then there is proportional error. If r is lower than 0.975 (or 0.99), this indicates that more data are typically needed or that other types of regression analysis should be used, e.g. Deming or Passing-Bablok regression techniques.

For judging acceptability, two approaches can be used; acceptability based on inherent combined imprecision or acceptability based on preset analytical quality specification. For the approach based on combined inherent imprecision, a difference plot is constructed by plotting the difference between the methods (A – B) on

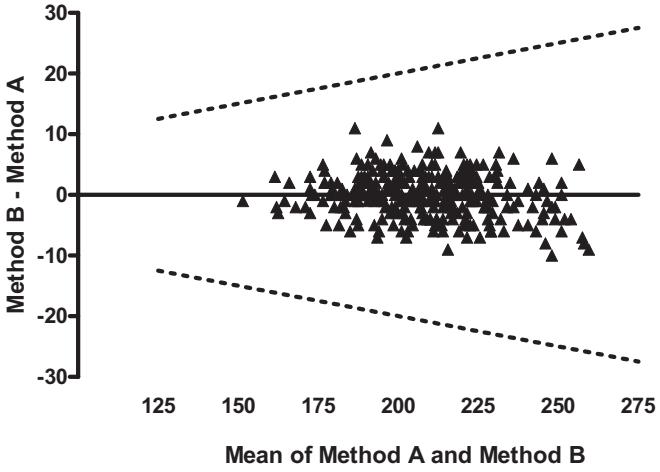

FIGURE 130.1 A difference plot together with lines representing the combined inherent imprecision of two methods. For Method A, CV is 1% and for Method B, CV is 5%. The combined inherent CV of both methods given single measurements is thus 5.1%.
At a mean value of 125, the difference between the two methods should be within the interval –12.5 to 12.5, and at a mean value of 275, the limits are –27.5 to 27.5. In this case, the two methods are identical within combined inherent imprecision since the differences are symmetrically distributed around zero and all of the differences are inside the dotted lines.

the *y*-axis against the mean of the methods [(A + B)/2] on the *x*-axis. Next, the lines representing 0 ± the combined inherent CV at different *x*-values are inserted in the plot. If the two methods are identical, the differences should be symmetrically distributed around 0, and 95% of the differences should be within the lines (Fig. 130.1). For the approach based on pre-specified criteria, the values for imprecision, inaccuracy and total error are used in a method evaluation decision (MEDx) chart.[13] This provides a simple graphical tool for comparing imprecision and inaccuracy observed for a test with an analytical quality requirement that is stated in the form of an allowable total error (Figs. 130.2A, B). Assessment can also be based on a six sigma value {Six sigma = [TE (%) – Inaccuracy (%)]/CV (%)}, where values lower than 3 indicate that the methods compare insufficiently.

Detection Limit

The detection limit can be defined as the smallest concentration that the laboratory test, with a stated probability, can distinguish from a suitable blank. A practical approach is to measure a sample with no or a very low content of the analyte (e.g. physiologic saline or a serum sample when investigating an automated blood cell counter) 20–30 times, calculate the mean value and the standard deviation (SD), and estimate the detection limit as mean value (or zero) + 2 (or 3) × SD. More precise or rigorous calculations are rarely necessary, bearing in mind that the detection limit should serve as a warning limit rather than a justification for continually using the test at its lowest analytical level.

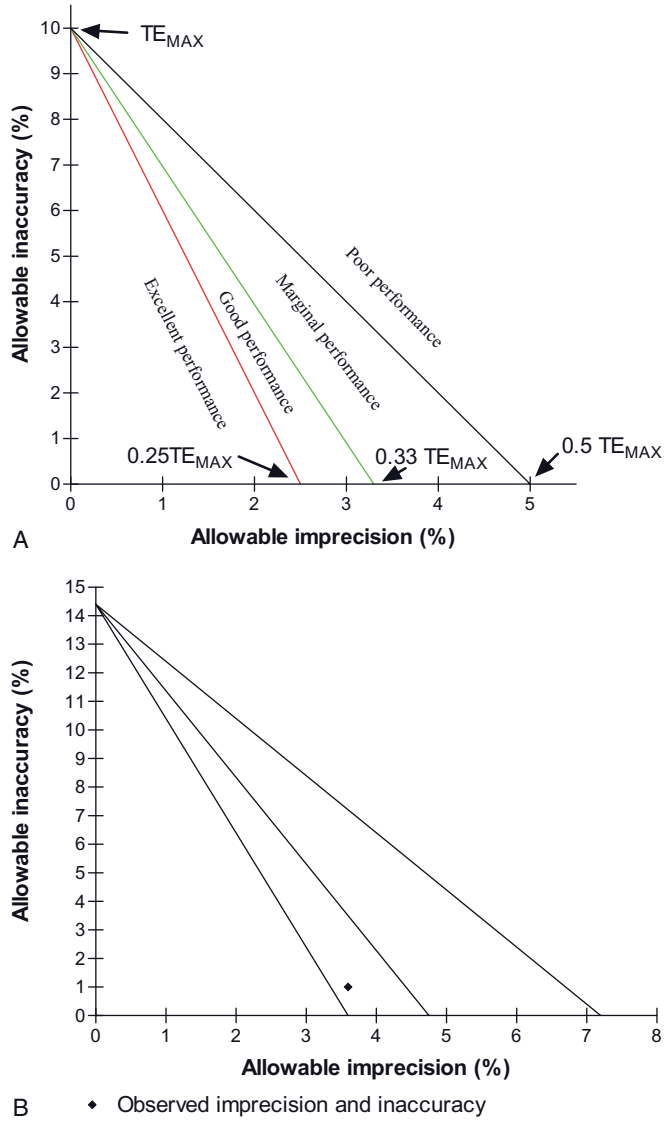

FIGURE 130.2 MEDx charts for assessing analytical performance. (**A**) MEDx chart for a test with a maximum allowable total error (TE_{MAX}) of 10%. The lines represent different currently accepted total error criteria: line marked ($0.5 \cdot TE_{MAX}$) represents the total error criterion TE_{MAX} = Inaccuracy (bias) + 2SD; line marked ($0.33 \cdot TE_{MAX}$) represents the total error criterion TE_{MAX} = Inaccuracy (bias) + 3SD; line marked ($0.25 \cdot TE_{MAX}$) represents the total error criterion TE_{MAX} = Inaccuracy (bias) + 4SD. TE_{MAX} can be calculated from data on biological variation or be estimated from CLIA proficiency testing criteria. By plotting the observed inaccuracy and imprecision of a test into its MEDx chart, the analytical performance of the assay can be classified as poor, marginal, good or excellent. (**B**) MEDx chart for total white blood cell (WBC) count with TE_{MAX} being calculated as 14.4%. Inaccuracy and imprecision were estimated for WBCs on an automated hematology analyzer as 1% and 3.6%, respectively, and using the MEDx chart, it is concluded that the test has good analytical performance.

Additional Analysis of Analytical Performance

High levels of usual blood contents (e.g. lipids, bilirubin, hemoglobin, and glucose may interfere with the laboratory test[6] and it may be useful to examine the effects of such substances in greater detail, for instance by comparing the analyte concentration in patient samples before and after addition of the different amounts of the substances. Unconjungated bilirubin and glucose can be purchased as dry matter, hemoglobin can be obtained by freezing of washed erythrocytes, and lipids can be obtained from human parenteral nutrition prescriptions. Different medications and diseases may also interfere in the test, for example, by displacing the analyte from its carrier proteins or by binding important cofactors. In most cases, it is very complicated to examine for potential interference, but significant information can be derived.[15]

Although not a topic related to analytical performance *per se*, sources of pre-analytical variation such as storage, type of anticoagulants, medication, venous site of blood sampling, etc., may significantly affect test results, and it is often valuable to investigate these sources.[7,10]

Phase 2 – Overlap Performance

Initial Application of the Test

The aim here is to compare test results in healthy animals to various groups of diseased animals. Approximately 20–30 animals in each group are tested, and the number of animals in each group, the mean or median values, SD (or 25–75 percentiles), and minimum and maximum values are recorded. A plot of the data, e.g. in a dot diagram, allows for an initial visual assessment of the degree of overlap between the groups. Unpaired *t*-tests or a Mann-Whitney U-test for unpaired observations can be used to test statistically whether test results differ between groups. If a great overlap is detected, the diagnostic value of the assay is usually so low that further evaluation is unnecessary.

It is important to remember that at this initial stage, the prevalence of the disease frequently is unrealistically high, and that animals with the disease in question may be in advanced disease stages that are easier to recognize and thus to include in the study. Furthermore, if the group of animals without the disease in question consists of healthy animals only, then the overlap of test values between animals with and without the disease in question is often further minimized.

Phase 3 – Clinical Performance

In phase 3, the clinical usefulness of the laboratory test is investigated. The outcome of this investigation can be seriously biased by simply incorporating the test under investigation into the evidence used to diagnose the disease in question. Potential sources of bias have been described.[9] To avoid biasing the outcome of this investigation as much as possible, a blind, prospective and controlled investigation fulfilling the following criteria should be used.

Selection of Appropriate Animals

The clinical usefulness must be evaluated in the relevant clinical target population, i.e. the population of animals where the disease in question is a possible differential diagnosis and to which the laboratory test is most likely to be applied later. The total number of animals should at least be greater than 40. It is very important to specify the criteria for including animals, especially because animals without the disease in question may have diseases which other users of the test do not consider appropriate differential diagnoses.

Independent Classification of the Selected Animals

The animals in the clinical target population must be classified as being with or without the disease in question independently of the laboratory test being evaluated. Criteria for establishing the diagnosis in question should be specified.

Applying the Test to All Animals in the Study Population

Ideally, but rarely practically, the test should be applied at the same point in the clinical course of the animal's disease. A very thorough description of an appropriate approach for evaluating diagnostic accuracy of tests is given by the *Sta*ndards for *R*eporting of *D*iagnostic Accuracy (STARD) steering committee.[1] Other sources of bias possibly introduced by study design and their importance have also been described.[2]

Sensitivity and Specificity

Test validation is further performed through assessment of the test sensitivity and specificity. Test results are divided into positives and negatives depending on whether or not they exceed a predefined limit, usually the upper or lower limit of the reference interval. The number of positives and negatives for each patient group (with and without the disease) are then arranged in a two-by-two table and sensitivity (SE) (the proportion of patients with the disease that tests positive) and specificity (SP) (the proportion of patients without the disease that tests negative) are calculated as follows: $SE = A/(A + C)$ and $SP = D/(B + D)$.[14]

	Disease Present	Disease Absent
Test Positive	A	B
Test Negative	C	D

The reliability of SE and SP depends on the size of the chosen population and it is therefore necessary to provide 95% confidence intervals for SE and SP. These intervals can be calculated using the normal approximation to the binomial distribution, by computer software, or they can be obtained from tables of binomial

distribution. Further, a first line assessment of the test can be performed by calculating Youdens index (Y = SE + SP – 1) and in general, the closer this value is to 1, the better the test is.

Predictive Values

For diagnostic purposes, it is of interest to know how likely the disease is when the test is positive and how unlikely the disease is when the test is negative. This information is provided by the positive predictive value (PPV) (or predictive value of a positive test or post-test probability of disease following a positive test result) and the negative predictive value (NPV) (or predictive value of a negative test or post-test probability of no disease following a negative test result).[12] Positive predictive value and NPV can be calculated using the same two-by-two table used for calculation of SE and SP if the proportion of diseased animals reflects the disease prevalence in the group of animals to which the test is to be applied. Positive predictive value is then calculated as [A/(A + B)] and NPV is calculated as [D/(D + C)], and 95 % confidence limits can be calculated as for SE and SP. In many cases, the proportion of diseased animals in the two-by-two table does not reflect the prevalence of the disease in the target animal population and therefore, PPV and NPV are calculated for disease prevalences (*P*) varying from 0 to 1 using the following formulas:

$$\mathrm{PPV} = (\mathrm{SE}\times P)/\{(\mathrm{SE}\times P)+[(1-P)(1-\mathrm{SP})]\}$$

and

$$\mathrm{NPV} = [\mathrm{SP}(1-P)/\{[\mathrm{SP}(1-P)]+[P(1-\mathrm{SE})]\}.$$

Positive predictive value and NPV can then be plotted in a graph with PPV and NPV on the *y*-axis and P and the *x*-axis. At low disease prevalences, PPV is low, and at high disease prevalences, PPV is high. The clinical approach to increased disease prevalence of the suspected disease is to obtain a history and perform a clinical examination before applying the test. In contrast, NPV is maximal at low disease prevalences and a negative test result therefore appears to be most useful for ruling out the disease at low disease prevalences.

Receiver-Operating-Characteristic (ROC) Curves

By changing the cut-off value by which test results are divided into negatives and positives, SE and SP change so that when SE increases, SP decreases and *vice versa*. The cut-off value is varied over the spectrum of test results and the resulting pairs of SE and SP are plotted in a graph (a ROC curve) with SE on the *y*-axis and (1 – SP) on the *x*-axis (Fig. 130.3).[16]

The ROC curve is used to assess the overall diagnostic accuracy of the test. This can be done visually because the better a test discriminates between diseased and non-diseased groups, the closer to the upper left-hand corner of the graph is its ROC curve situated. More formally, the area under the ROC curve (*W*) and the standard error of the area (SE_W) can be calculated using the trapezoidal rule or a computer program. The area is then compared to 0.5, which is the area under the ROC curve of a worthless test that does not discriminate between the two patient groups, by calculating a *Z* value [$Z = (W - 0.5)/SE_W$]. *Z* values above 1.96 indicate that the area under the ROC curve is significantly different from 0.5 and that the test is different from a worthless test. Two or more tests used to discriminate between two patient groups can also be compared using their ROC curves. Again, a visual assessment can be used or the areas under the ROC curves can be compared statistically. The latter is most often done by using a computer program.[4]

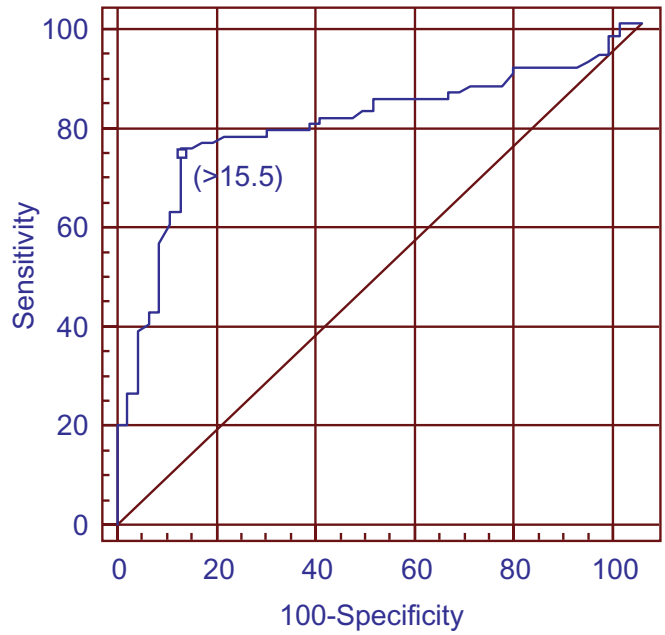

FIGURE 130.3 Receiver Operating Characteristic (ROC) curve. A ROC curve is constructed by plotting sensitivity as a function of (1 – specificity) over the range of selected cut-off values. Tests with poor performance tend towards the diagonal line. Tests with good performance tend upward and leftward. The highest sensitivity and specificity is the top-leftmost point and the cut-off value that gives this point in this plot is 15.5.

The ROC curve is a plot of SE and SP pairs for different cut-off values. From the list of SE and SP corresponding to each cut-off value, it is possible to identify the cut-off value associated with the highest SE and SP simply by calculating the differential positive rate (DPR) for each cut-off value from the formula DPR = [SE – (1 – SP)]. The cut-off value with the highest DPR is also the cut-off value associated with the highest SE and SP.

Likelihood Ratios

The ROC curve is a plot of the effect of changing the cut-off value on SE and SP. This dynamism can be described by the slope (or tangent) of the ROC curve at any single, defined, point corresponding to the cut-off value of interest. Two slopes have been defined: [SE/

(1 – SP)] and [(1 – SE)/SP]. The former is called the likelihood ratio of a positive test result (LR+), and the latter is called the likelihood ratio of a negative test result (LR–). Another definition for LR+ is the probability of obtaining a positive test result in an animal with the disease divided by the probability of obtaining a positive test result in an animal without the disease. In other words, a LR+ of 4 means that a positive test result is four times as likely to occur in a diseased animal as in a non-diseased animal. Likewise LR– is defined as the probability of obtaining a negative test result in an animal with the disease divided by the probability of obtaining a negative test result in an animal without the disease. As a general rule, a good LR+ exceeds 2 whereas a good LR– is near 0. Because likelihood ratios are derived from SE and SP, it is necessary to determine the confidence intervals of the ratio, which is a somewhat complicated procedure involving χ^2 statistics.[8]

Diagnostic test validation can be taken to yet another and more complicated phase where outcome and utility assessment are addressed. In this phase, it is assessed if a laboratory test is clinically useful by whether it successfully answers a question of consequence to patient management. To assess if measurements have a positive consequence on the case management of individuals or groups of individuals, it can be assessed if the test improves the outcome of a clinical problem, if it provides equivalent clinically useful information faster than established parameters, if it provides equivalent clinically useful information more cost-effectively than established parameters, or if measurements are done on material more easily obtained or with better stability than established methods. The difficult part here is to set criteria for outcome and quality of clinically useful information, and this is perhaps the reason why outcome and utility assessment is rarely done.

The diagnostic work-up of veterinary patients is a decision-making process. Decisions of "ruling out" or "ruling in" differential diagnoses are based on the achieved level of clinical knowledge, and the use of laboratory tests (including hematology) is an integral part of this process. Relevant tests are performed to change pre-test probability of a diagnosis to a post-test probability level, facilitating "ruling in" (increased post-test probability of a diagnosis) or "ruling out" (negligible post-test probability of a diagnosis) of one or more of the differential diagnoses. To make this decision-making process consistent, established decision criteria are essential. Optimally, these are objective and optimized to the specific clinical situation to limit false decisions with the risk of false diagnoses. Examples of specific "decision limits" can be found in human medicine, such as those defined by consensus agreement for cholesterol. A major challenge for such decision limits to be applicable across laboratories and methodologies is to ensure precision across both. One of the major prerequisites for this is traceability of calibration material to generally recognized standards, such as the CRM470 standard for human serum proteins established by the International Federation for Clinical Chemistry and Laboratory Medicine (IFCC).[1] However, such programs are rare, if not absent, in veterinary clinical laboratory medicine, making establishment of "decision limits" primarily a local task, comparable only across laboratories using the exact same methodology, at best.

Clinical decision limits are in nature dependent on the clinical objective and thus applicable for specific clinical situations only. Hence, the end result will be a demand for a vast number of decision limits in veterinary laboratory medicine. This task has not yet been encountered and decisions are therefore most often made by means of the limits of population-based reference intervals based on a distribution of reference values obtained from a reference sample group of healthy individuals. That is, the population-based reference interval describes the variation of values that can be expected in healthy animals of the population from which samples are submitted to the laboratory. The logical reasoning behind using such intervals is that a measured value outside the reference interval is unlikely to originate from a healthy individual, and will thus represent a diseased individual. This reasoning makes the use of population-based reference intervals independent of the clinical objective and more globally applicable. However, many pitfalls in this reasoning exist and population-based reference intervals should only be seen as guidelines when no better means are available[6] and not assimilated to a "clinical decision limit" optimized for a specific clinical situation.[16] The widespread lack of proper clinical decision limits in veterinary laboratory medicine should therefore be seen as an opportunity for future studies, such as studies involving Receiver Operating Characteristics (ROC) curve analysis.[8,12] Meanwhile, it should be ensured that the population-based reference intervals are applied appropriately, and the remainder of this chapter will describe different aspects of this topic. A joint guideline from the Clinical and Laboratory Standards Institute (CLSI) and IFCC on "Defining, establishing, and verifying reference intervals in the clinical laboratory" has recently been released in a new

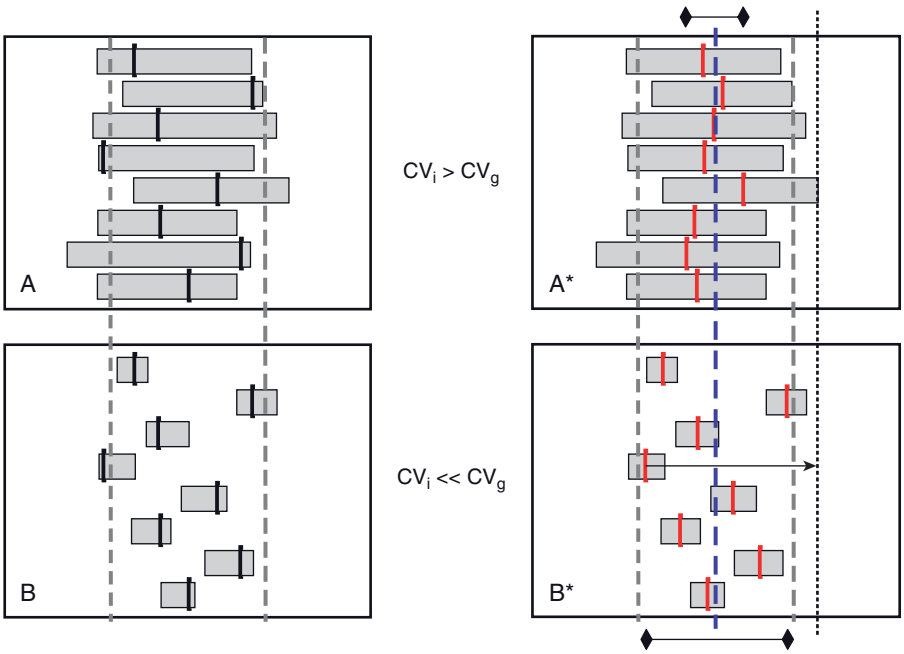

FIGURE 131.1 Single sampling of individuals in a reference sample group will not reveal the nature of biological variation, including intra- (CV_i) and inter-individual (CV_g) variation, respectively. Very different CV_i (shaded bars in A [large CV_i] and B [small CV_i]) can result in identical reference distributions of reference values (black lines) and thus in identical reference limits (broken shaded lines). It can be appreciated that the distribution of homeostatic set-points (red lines, A* and B*) are much further from the population mean (blue broken line) and with a wider range (diamond-ended lines, A* and B*) when $CV_i << CV_g$ (B*). As a result, the upper reference limit becomes an insensitive mean to detect changes, as a merely abnormal analytical result (dotted line, B*) is highly abnormal for several individuals (arrow, B*). In this case other means than population-based reference intervals should be considered for detection of changes.

edition.[3] Working groups from the American Society of Veterinary Clinical Pathology (ASVCP) and the European Society of Veterinary Clinical Pathology (ESVCP) are currently preparing a similar joint guideline for veterinary purposes (based on the CLSI C28-A3) expected to be released in the near future[7] (M. Kjelgaard-Hansen, personal communication). The guideline is a welcome opportunity to standardize how reference intervals are applied in veterinary medicine and should be applied as widely as possible.

RELEVANCE OF REFERENCE INTERVALS

The *de novo* establishment of a reference interval of high quality is very demanding, e.g. in terms of resources and manpower, and it is therefore appropriate to assess the mere relevance of a reference interval before taking on the task. Obviously, if clinical decision limits exist, as described above, these should be used and a reference interval is unnecessary. Information on biological variation of the analyte should also be considered before reference values are determined.

The width of a reference interval is mainly determined by the combined analytical, intra-individual (CV_i) and inter-individual (CV_g) variation. Analytical variation is routinely assessed and controlled by method validation and quality control. On the other hand, CV_i and CV_g remain unrevealed unless specifically designed studies are applied to the population.[5] The ratio (CV_i/CV_g), also referred to as the index of individuality, is highly relevant for assessing the relevance of a reference interval. The ratio between CV_i and CV_g cannot be detected by traditional single sampling of healthy individuals, as identical distributions can arise from very different ratios of these (Fig. 131.1). If CV_i is much smaller than CV_g, there is a marked individuality, and a population-based reference interval becomes an insensitive means of detecting pathological changes in the individual (Fig. 131.1). A ratio below 0.6 (which is not uncommon for human analytes) is generally accepted as a criterion defining population-based reference intervals as generally insensitive, and other means for detecting changes should be considered.[5] Data on biological variation in veterinary species are still limited, but such data are useful for setting standards in method validation (Chapter 130), quality control (Chapter 129) and for the assessment of applicability of reference intervals. Further studies in this area are highly warranted, and detailed descriptions on study design are available.[5]

If it is decided that a reference interval is needed and relevant for a specific analyte, then different options are available, including (1) *de novo* establishment of a reference interval, and (2) transference of a reference interval from another source.

Each option will be described below, with emphasis on the reference interval transference as this solution will be the most relevant to many veterinary laboratories, due to the cost and effort needed to accomplish *de novo* reference intervals.

ESTABLISHMENT OF REFERENCE INTERVALS (*DE NOVO*)

One of the key issues of the recent CLSI guideline (C28-A3) is how to establish a reference interval, and this guideline together with the upcoming ASVCP/ESVCP guidelines on the same topic should be consulted before starting up the process.[3] A 13-point protocol outlines the task (Table 131.1), which was recently assessed to be directly transferable for veterinary purposes.[2] It is emphasized that the primary focus should be on

TABLE 131.1 Protocol Outline for Obtaining Reference Values and Establishing Reference Intervals[3]

1. Establish a list of analytical interferences and sources of biological variability from medical and scientific literature
2. Establish selection (or exclusion) and partition criteria and an appropriate questionnaire designed to reveal these criteria in the potential reference individuals
3. Execute an appropriate written consent form for participation in the reference interval study and have the reference individual complete the questionnaire (veterinary modification: Owner's consent and completion of questionnaire)
4. Categorize the potential reference individuals based on the questionnaire findings and results of other appropriate health assessments
5. Exclude individuals from the reference sample group based on the exclusion criteria or assessments indicating a lack of good health
6. Decide on the appropriate number of reference individuals in consideration of desired confidence limits
7. Prepare, properly and consistently, the selected individuals for specimen collection for the measurement of a given analyte consistent with the routine practice for patients
8. Collect and handle the biological specimen properly and in a manner consistent with the routine practice for patient specimen
9. Collect the reference values by analyzing the specimens according to the respective analytical methodology under well-defined conditions and consistent with the routine practice for patients
10. Inspect the reference value data and prepare a histogram to evaluate the distribution of data
11. Identify possible data error and/or outliers
12. Analyze the reference values, i.e., select a method of estimation and estimate reference limits and the reference interval
13. Document all of the previously mentioned steps and procedures

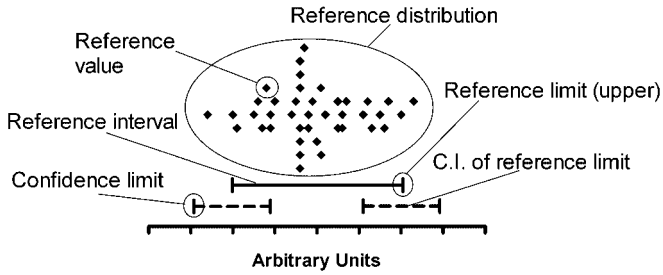

FIGURE 131.2 Nomenclature used in the establishment of reference intervals. Reference individuals (e.g. healthy dogs) are defined within the general population to comprise a reference population from which is selected a reference sample group on which are determined reference values (diamonds). These values characterize the reference distribution from which are calculated reference limits that may define the reference interval. Reference limits are determined with a certain degree of variability that can be expressed by a confidence interval (C.I.) of the reference limit, delineated by confidence limits.

sampling an appropriate reference sample group (Fig. 131.2), preferably by a direct *a priori* method, where criteria for selection, exclusion and partitioning are set before blood sampling is performed. Second, a direct *a posteriori* sampling method can be used with the only difference being that selection, exclusion and partitioning criteria are applied after actual sampling. However, the criteria have been criticized to be too theoretical and demanding,[10] which is probably the reason why they have been largely ignored in both human and veterinary clinical pathology.

A more tempting method for veterinary purposes is the indirect *a posteriori* sampling method, making use of databases and samples collected for other purposes, e.g. blood donors, health screening and preoperative samples for elective surgery. Although special care should be taken not to include large numbers of unhealthy individuals, the method has been used successfully for both veterinary and human purposes.[4,17] Collection, handling and analysis of the samples to obtain reference values should be done under conditions according to a well-defined, but routine practice under which the reference interval will later be used.

Traditionally, much focus is put on selection of statistical methods to analyze reference value data, but the number one priority in *de novo* establishment of reference intervals is to fulfill and document the sampling of the reference sample group and use of analytical methodology to obtain values. Only on a distant third priority is the choice of appropriate statistical methods to analyze the obtained data. The reason for this is that no post-sampling statistical procedures can correct for poor sampling of reference individuals, and that different choices of statistical procedures will make little difference if the reference values are of a high quality.

Statistics include outlier detection, where visual examination of a frequency distribution is a very useful tool that can be supported by other objective techniques. However, unless outliers are known to be aberrant observations, the emphasis should be on retaining rather than deleting them.[3] If the distribution of reference values is Gaussian or can be transformed to fit a Gaussian distribution, the reference interval can be assessed by parametric methods.[3,5] As the assumptions made to perform the parametric statistics are easily violated, the IFCC recommends making use of non-parametric statistics if sampling of at least 120 reference individuals is managed. A reference interval corresponding to the 95% confidence interval is easily obtained by the non-parametric approach; the n reference values are ranked and the interval is then delineated by ranks r_1 and r_2, being $r_1 = 0.025(n + 1)$ and $r_2 = 0.975(n + 1)$. Thus, in theory, a reference interval can be assessed by non-parametric methods with as few as 39 samples (as this is the lowest value of n where r_1 and r_2 will reach integer values, namely $r_1 = 1$ and $r_2 = 39$). However, it is still recommended to include at least 120 data points to assess the precision of the established reference limits.[3] Finally, an iterative method ("the robust method") has been described offering a relevant alternative to the non-parametric approach

when $n < 120$. In short, it works by initial location of median and spread of observations, and through an iterative process actual observations are down-weighted according to their distance to the central tendency. For detailed instructions on computation, which can be performed in common spreadsheets, original literature should be consulted.[11] This method can be used for skewed distributions also.

TRANSFERENCE OF REFERENCE INTERVALS

As mentioned above, at the local laboratory level, *de novo* establishment of reference intervals is largely ignored by both human and veterinary laboratories due to the associated necessary cost and efforts to do so. Here transference offers a valid alternative, which can be done appropriately by sampling only 20 reference individuals.

Transference can be done at different levels, i.e. within-laboratory (when substituting old methodologies with new ones) or with other laboratories or manufacturers as donors; however, the procedures and tools are basically the same:

1. Choose reference interval to transfer
2. Validate reference interval
3. If unsuccessful: transform reference interval by means of method comparison, if appropriate
4. Validate transformed reference interval
5. If unsuccessful: then only *de novo* establishment is left.

When choosing an external reference interval donor, the main focus should be on methodology and population used to establish the donor reference interval. The relevance of the donor reference interval increases the more these factors match, and so does the chance of a successful validation.

The validation step consists of a sequential comparison of 20 reference values with the donor reference interval, where the donor reference interval is accepted if two or fewer reference values fall outside the donor reference interval. If three or four fall outside, the procedure must be repeated with an extra 20 reference values, with the same criteria for acceptance. If unsuccessful again, then the donor reference interval is rejected (Fig. 131.3A), which is also the case if five or more values fall outside in the primary comparison.

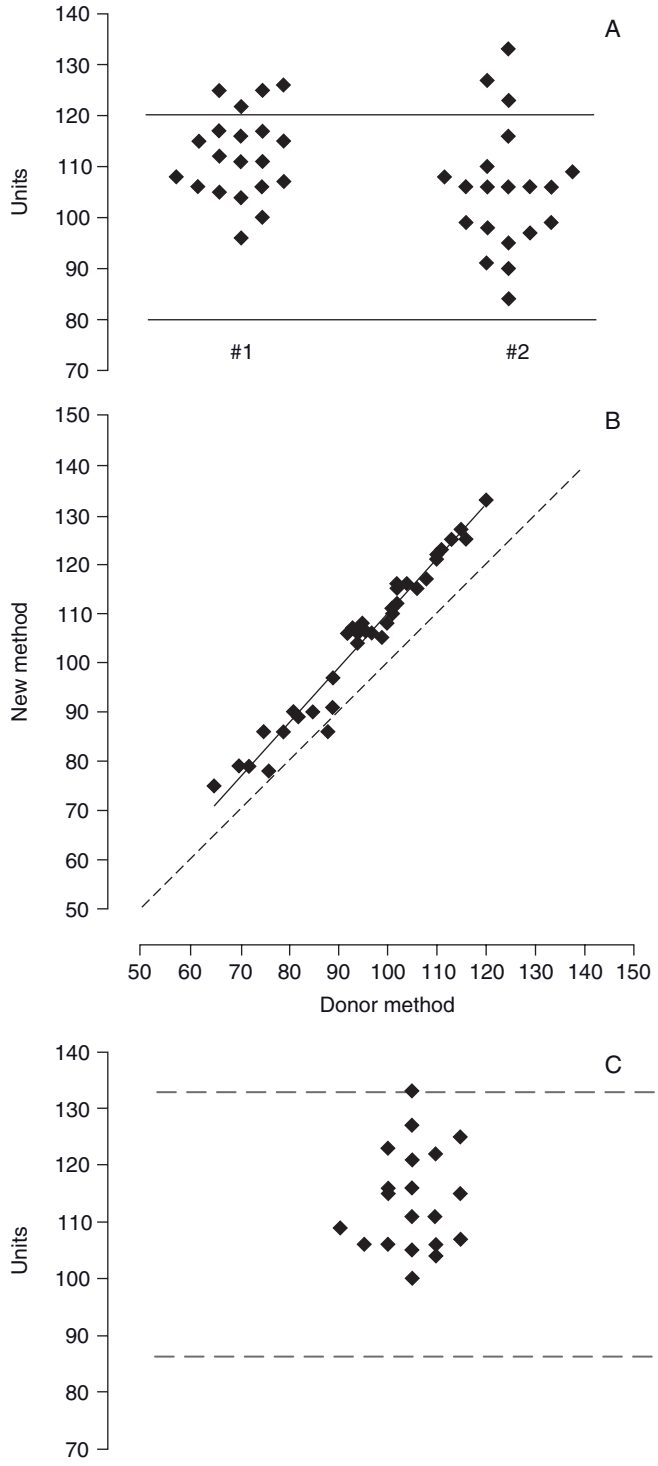

FIGURE 131.3 Validation of transferred reference intervals can be performed by sequential comparison of reference values (diamonds, $n = 20$) to the donor reference interval (black lines). If less than two values fall outside the reference interval, the donor reference interval is accepted. However, if three or four values fall outside (**A**, #1) the process must be repeated with the same criteria (**A**, #2) with a final rejection if two or more fall outside (which is the case here). If five or more fall outside in the primary comparison it will result in a final rejection of the donor reference interval. A method comparison can reveal and assess systematic bias to transform the donor reference interval to fit local methodology (**B**). In this case, the linear regression analysis result was $Y = 1.11X - 1.3$, $r^2 = 0.96$, and with 1.3 (Y-intercept) being numerically low compared to the donor reference interval [80–120] the reference limits were transformed by the regression equation [$1.11 \times 80 - 1.3$; $1.11 \times 120 - 1.3$] to the new interval [87.5–131.9]. Subsequently, the transformed reference interval must be validated as described, in this case with success as less than two reference values fall outside (**C**). The dotted line in (**B**) represents the line of agreement between methods ($Y = X$).

If the donor reference interval is from another laboratory, or the transference is between methodologies within the same laboratory, then the discrepancy may be due to a systematic bias that can be corrected by transformation. This is obviously not feasible if the donor reference interval originates from the manufacturer of the method used. Such bias can be revealed and assessed by thorough method comparison (Fig. 131.3B).[13] Care should be taken to ensure that a distribution of samples spanning the entire reference interval is used for the method comparison (these do not have to be reference samples). If a systematic bias is identified and the *Y*-intercept of the regression line is small compared to the reference interval, both the upper and the lower reference limit should be transformed by the regression equation (Fig 131.3B). The transformed reference interval must subsequently be validated as described above (Fig. 131.3C). If validation is unsuccessful, further reference values must be obtained to establish the reference interval *de novo*.

PARTITIONING OF REFERENCE INTERVALS

The global applicability of a reference interval in a population of individuals is based on the assumption of homogeneity in the population, which is an ongoing challenge to control. If homogeneity is violated in a clinically important manner, it is necessary to identify the subgroup causing the violation and create separate reference intervals for the subgroup. Several examples of such veterinary subgrouping already exist; e.g. polycythemia in Greyhounds[15] and inherent idiopathic asymptomatic thrombocytopenia in Cavalier King Charles Spaniels.[14] Clearly, more unidentified subgroups exist in the veterinary species than documented at the present time, and here the task is to be vigilant and take action when signs of subgroups appear, such as frequent outlying observations from a certain breed. Most often, the discrepancy is unidirectional (outlying observations are either systematically higher or lower than established limits) which is a sign of different means of the subgroup and general population (difference in variation would cause bidirectional discrepancy, but are infrequent and will not be described here). Several guidelines exist to determine whether the discrepancy is of clinical significance; for example, (1) if the difference between subclass means exceeds 25% of the width of the combined reference interval[18] or (2) if more than 4% of the individuals in the subgroup falls outside the established reference interval.[9] If a clinically important discrepancy is identified, a separate reference interval should be established *de novo* for the subgroup, as described above.

Current examples of existing partitioning of reference intervals are mainly based on phenotypically recognizable groupings, e.g. sex, breed, etc.; however, future partitioning may also include genotypical grouping, if these are to be characterized routinely on an individual level.

Evaluation of Bone Marrow Smears

Acronyms and Abbreviations

BM, bone marrow; BSA, bovine serum albumin; CD, cluster of differentiation; CD71, transferrin receptor; CD45, leukocyte common antigen; DioC6, dihexyloxacarbocyanine; EDTA, ethylenediaminetetraacetic acid; FACS, fluorescence activated cell sorting; FITC, fluorescein isothiocyanate; FL, fluorescence; FSC, forward scatter; EDTA, ethylenediaminetetraacetic acid; MDS, myelodysplastic syndrome; MGG, May-Gruenwald-Giemsa stain; M:E ratio, myeloid erythroid ratio; Nm, nanometer; LDS, laser dye styryl; PBS, phosphate buffered saline; PE, phycoerythrin; RBC, red blood cell; SSC, side scatter; WBC, white blood cell.

BONE MARROW COLLECTION IN DOGS AND CATS

Indications and Contraindications

Bone marrow (BM) examination is indicated for detection of abnormalities that are not recognized during the routine evaluation of a peripheral blood smear. Moreover, bone marrow collection should be performed in animals with suspected lymphoprolipherative or myeloprolipherative disease, myelodysplastic syndrome (MDS), or diagnosis and staging of hematopoietic tumors such as lymphoma, histiocytic neoplasia, multiple myeloma, or metastatic carcinoma (especially mammary carcinoma), and sarcoma. Unexplained hypercalcemia and fever of unknown origin also may raise the suspicion of paraneoplastic syndrome due to a tumor affecting the BM. Bone marrow collection is indicated in the diagnostic workup of unexplained, persistent cytopenias including nonregenerative anemias, neutropenia especially in the absence of a left shift, assessment of regeneration in thrombocytopenic animals, as well as bicytopenias or pancytopenias. The presence of abnormal cell populations in the blood, such as blasts, rubricytes in the absence of regeneration, atypical morphology of leukocytes, red blood cells (RBCs), or platelets, is also an indication for evaluation of bone marrow.

Contraindications for bone marrow aspiration include severe coagulopathies. Thrombocytopenia, however, is not a contraindication for bone marrow collection because significant hemorrhage is rarely a

problem. The risk of bone marrow infection is negligible.[15] The most important contraindication, however, is performing a bone marrow aspirate that is unnecessary.[5]

Collection of a Bone Marrow Aspirate versus Biopsy

During bone marrow aspiration for preparation of a smear, architecture of bone marrow tissue is destroyed. The advantage of this technique is that single cells are evenly spread on a slide which allows excellent evaluation of cellular morphology. Thus, bone marrow aspiration is indicated in all diseases which affect the whole bone marrow so that the aspiration is representative for the whole marrow. These include hyperplasia or hypoplasia of cell lineages, leukemia, and myelodysplastic syndromes.[15] The advantage of a biopsy is that the architecture of the bone marrow remains intact so that the relation of cellular populations to each other and to stromal cells can be evaluated.

Indications for bone marrow biopsy include:[15] (1) a bone marrow aspiration which is repeatedly not successful (punctio sicca); (2) non-diagnostic bone marrow cytology (e.g. bone marrow aplasia or hypoplasia); and (3) focal abnormalities (e.g. myelofibrosis, granulomatous inflammation, multiple myeloma, bone marrow necrosis, metastatic carcinoma). Because the need for bone marrow biopsy frequently cannot be predicted at the time of bone marrow aspiration, some clinicians routinely collect both samples.

Techniques and Locations of Bone Marrow Collection

Bone Marrow Collection in Dogs

Locations for bone marrow collection in dogs include the iliac crest (Fig. 132.1) and the anterior site of proximal humerus. In large dogs, the third, fourth, or fifth sternebra may be aspirated. In toy breeds with a small iliac crest, the trochanteric fossa of the femur can be used. Use of the sternum is associated with risk of penetrating the thoracic cavity and injuring intrathoracic organs. The iliac crest and proximal humerus are the most frequently used sites in dogs. An advantage of bone marrow aspiration at the proximal humerus is that the bone is not covered by fatty tissue, which makes marrow aspiration easier at this site in obese dogs. Moreover, there is a lower risk of hemorrhage at this localization.

FIGURE 132.1 Demonstration of iliac crest site for bone marrow collection in a dog.

Generally, BM aspiration from the iliac crest can be performed in standing, awake dogs. For BM aspiration from the proximal humerus, the dog is positioned in lateral recumbency. In anxious or aggressive dogs, sedation or general anesthesia is required. The skin over the site of collection is shaved and aseptically prepared. Approximately 1–2 mL of a 2% lidocaine solution is used for local anesthesia of all tissue layers, especially the periosteum. A 16–18 gauge × 2.5 cm Klima Rosegger, Rosenthal or Illinois sternal needle with an interlocking stylet is used for bone marrow aspiration.

For aspiration at the iliac crest, the greatest prominence of the wing of the ileum is palpated. The needle is inserted with slow rotating movements in an angle 45° parallel to the long axis of the ileum. Reaching the bone marrow may cause a brief pain reaction that confirms the location of the needle. After removal of the stylet, a 10 mL syringe is attached and approximately 0.5 mL of bone marrow is aspirated. Aspiration of a larger amount should be avoided because it results in blood dilution of the marrow specimen. Avoiding use of an anticoagulant generally yields the best results of staining; however, smears have to be prepared immediately after sampling as bone marrow coagulates rapidly. For some indications such as analysis with a hematology analyzer[2] or fluorescence activated cell sorting (FACS), the collection syringe can be rinsed with 2–3% ethylenediaminetetraacetic acid (EDTA) as an anticoagulant. EDTA solution can be prepared by injecting 0.35 mL of sterile saline in a commercially available evacuated EDTA blood collection tube that contains approximately 1.5 mg EDTA.[5] For several flow cytometric protocols, heparin is the anticoagulant of choice. However, heparin anticoagulated marrow should not be used for preparation of smears for cytologic examination as it causes significant staining artifacts. After bone marrow collection, hemorrhage is stopped by applying several layers of gauze with firm pressure for a few minutes to the aspiration site.

With exception of the sternum, core biopsy specimens are taken at the same sites as aspiration samples. The core biopsy is performed with an 11–13 gauge Jamshidi needle, a cylindrical needle with a tapered distal end and beveled cutting tip. The needle is inserted into the bone as described for the bone marrow aspiration. However, the stylet is removed after touching the cortex and the needle is advanced approximately 0.5–1 cm into the marrow cavity with an alternating clockwise-counterclockwise motion to obtain an adequate specimen. Then, the needle is removed a few millime-

ters and advanced again in a slightly different direction to secure the specimen in the needle. Finally, it is pulled out with a rotating movement. The core biopsy specimen is removed by introducing a probe through the distal cutting end. The sample is placed in neutral, buffered 10% formalin solution for histologic processing.

Bone Marrow Collection in Cats

Bone marrow collection in cats is from the iliac crest, the proximal humerus, and, occasionally from the trochanteric fossa of the femur. In cats, general anesthesia is frequently required. To obtain bone marrow aspirates from the iliac crest, the cat is positioned in sternal recumbency with hind limbs tucked alongside the body. Straight positioning is important to get bone marrow from the iliac crest. The overall collection technique is comparable to the procedures described in dogs.

BONE MARROW COLLECTION IN HORSES

The proximal rib, tuber coxae, and sternum are sites for bone marrow collection in horses.[19,22] The proximal rib contains active marrow throughout life. The rib is an easy site to reach but has several disadvantages. One disadvantage is that the bone is relatively thick and difficult to penetrate in aged horses. Another disadvantage is that the rounded surface of the rib makes it difficult to seat the needle into the bone and increases the risk of slipping off the rib and puncturing the pleural cavity. This can result in pneumothorax. The sternum is a reliable and frequently used site for obtaining bone marrow. The sternum is not covered by a large muscle mass and the bone is relatively thin at this site. Disadvantages of this site are that the sternum is awkward to reach and that the site is near the heart. The tuber coxae are only used for obtaining marrow in foals and horses less than 4 years old.[19] When the tuber coxae are used, the needle is inserted into the midportion of the tuber coxa and directed toward the opposite coxofemoral joint.

Bone marrow aspiration and core biopsy are performed in standing patients. The amount of sedation and restraint varies depending on the temperament of the patient. The skin over the site should be clipped and aseptically prepared. All tissue layers, including the periosteum, are anesthetized with a 2% lidocaine solution. A 15-gauge × 5 cm styletted Jamshidi bone marrow aspiration/biopsy needle (also called a Janus® needle) is preferred for marrow aspiration. A stab incision is made in the skin and the needle is inserted until it reaches the bone. The bone is penetrated using a slow rotational movement until the needle is firmly seated in the bone. For sternebrae, the needle is then advanced 1–2 cm further into the marrow cavity. For bone marrow aspiration, the stylet is removed and a 6 mL syringe (that can be rinsed with 2% EDTA solution) is attached. One to several quick, forceful, aspirations physically detach marrow particles and minimize hemodilution. However, forceful aspiration can result in pain with resultant jumping or kicking. An 11 gauge × 10 cm Jamshidi biopsy needle is used to obtain core biopsy specimens. The biopsy needle is advanced into the bone until it reaches the cortex. The stylet is removed and the needle is advanced 1–2 cm further into the marrow cavity. The needle is then rotated forth and back several times to loosen attachments and then is withdrawn with a rotating motion.

BONE MARROW COLLECTION IN RUMINANTS

Bone Marrow Collection in Cattle

Bone marrow aspiration smears and core biopsy specimens from adult cattle have been obtained from the sternum and dorsal end of the ribs.[11,23] The iliac crest is an unsatisfactory site because of the anatomy of the bovine pelvis. A Turkel® trephine needle (Trephine Instruments Inc., USA) has been used for bone marrow aspiration from the rib.[11] Major disadvantages of this technique include the effort needed to penetrate the bone cortex in aged animals and the risk of puncturing the pleural cavity resulting in pneumothorax. The adjustable depth control on the Turkel trephine needle helps to prevent penetration of the pleural cavity but does not eliminate the risk.

The preferred site for bone marrow collection in adult cattle is the sternum.[23,25] A 15 gauge × 5 cm styletted Jamshidi bone marrow aspiration/biopsy needle is preferred for marrow aspiration. An 11 gauge × 10 cm Jamshidi biopsy needle is used to obtain core biopsy specimens. Cows should be sedated before bone marrow aspiration. Intravenous xylazine provides adequate sedation. The aspiration site is the 3rd or 4th sternebra. This site can be located by counting the ribs starting with the last one; however, the location on the sternum coincides with an imaginary line joining the olecranon. With the cow in a standing position, a small area over the sternum is shaved and aseptically prepared and all layers of tissue, including the periosteum, are anesthetized with a 2% lidocaine solution. A stab incision is made in the skin and the Jamshidi needle is inserted (with stylet in place) until it reaches the bone. The bone is penetrated using a slow rotational movement until the needle is firmly seated in the bone. The needle should be advanced approximately 1–1.5 cm. One can frequently sense when the needle enters the marrow cavity because of a sudden reduction in resistance.

In calves, the proximal humerus is an excellent site for marrow collection. Calves can be restrained in lateral recumbency and the method described for dogs and cats can be followed. A 15 gauge × 5 cm styletted Jamshidi or Illinois sternal biopsy needle with the needle guard removed can be used for aspiration and an 11 gauge × 10 cm Jamshidi needle can be used for core biopsies.

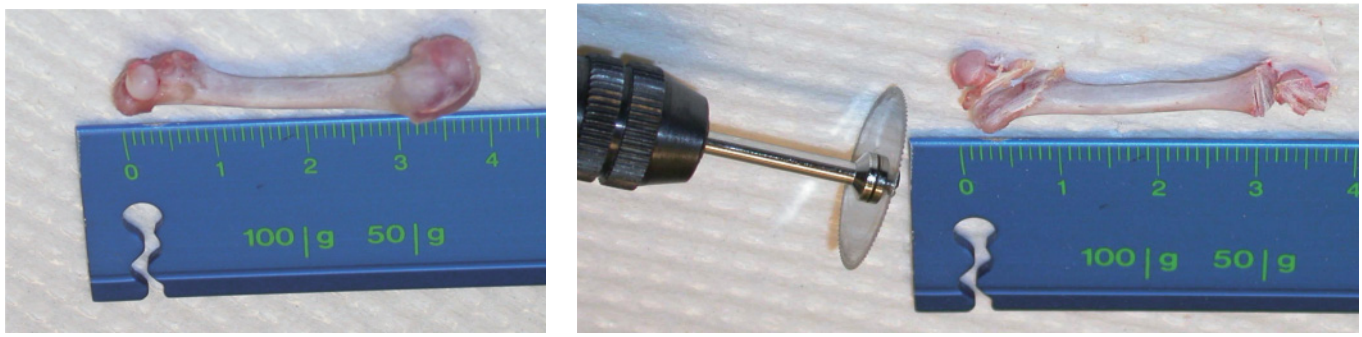

FIGURE 132.2 Bone marrow sampling procedure from the femur in rodents.

Bone Marrow Collection in Sheep

The sternum is the preferred site for bone marrow collection in sheep.[6] Sheep are restrained in a sitting position by an assistant who holds a foreleg in each hand. The 3rd or 4th sternebra is located by following the rib to its articulation. The site is aseptically prepared and anesthetized as described for cattle. A 15 gauge × 5 cm styletted Jamshidi or Illinois sternal biopsy needle with the needle guard removed can be used for aspiration. For bone marrow aspiration, the depth of penetration from the skin surface varies between 2.5 and 3.8 cm and bone penetration is approximately 0.5 cm. An 11 gauge × 10 cm Jamshidi needle can be used for core biopsies.

Bone Marrow Collection in Llamas

The sternum is the preferred site for bone marrow collection in llamas.[1] Adult llamas are sedated with xylazine and can be placed in a chute or in left lateral recumbency. The 3rd or 4th sternebra is located by following the rib to its articulation. The site is aseptically prepared and anesthetized as described for cattle. A 15 gauge × 5 cm styletted Jamshidi or Illinois sternal biopsy needle with the needle guard removed can be used for aspiration. An 11 gauge × 10 cm Jamshidi needle can be used for core biopsies.

Bone Marrow Collection in Camels

Collection of bone marrow has been described from the dorsal rib of dromedary camels.[17] Camels were sedated by intravenous administration of xylazine. A site over the 5th through 8th dorsal rib was aseptically prepared and anesthetized as described for cattle. The bone marrow needle and details of the technique were not described.

BONE MARROW COLLECTION AND PROCESSING IN LABORATORY ANIMALS

In recent years, bone marrow analysis in toxicological clinical pathology generally involves flow cytometric analysis as the primary means of bone marrow evaluation, and cytologic preparations to assess morphologic changes and abnormalities in maturation or proliferation. This approach permits quantitative analysis of bone marrow, and includes total nucleated cell counts, differential cell counts, and a myeloid : erythroid (M : E) ratio. Flow cytometry counts 10,000 cells or more, thus providing a much faster and more accurate estimate of cellular populations than microscopic assessment.

Sampling Procedures

In rodents (rat, mouse and hamster), one of the femurs is removed at necropsy and trimmed of muscular tissue. The femoral head and the distal epiphysis are cut off using a small electrical saw (Fig 132.2). In the dog and cynomolgus monkey, the fifth rib is removed at necropsy and trimmed of muscular tissue. A piece of the rib (1 cm) is cut from the articulating end with the costal cartilage (Fig. 132.3). The bone marrow tissue is flushed, approximately five times, with 2 mL PBS containing 50% fetal bovine serum using a needle and syringe (Fig. 132.4). The bone marrow cell suspension is washed and resuspended in ice-cold physiologic buffered saline (PBS) containing 0.5% bovine serum albumin (BSA). The nucleated cell count is determined using a hematology analyser and the cell concentration is adjusted to 10^7 cells/mL.

Flow Cytometry Staining Techniques

Saad et al. described a method for rat bone marrow differential cell counts using a combination of two monoclonal antibodies for the differential expression of leukocyte common antigen (CD45) and transferrin receptor (CD71).[20] This was coupled with the side scatter for cellular complexity and nucleic acid staining with LDS-751 for separation of nucleated cells from mature red blood cells (Fig. 132.5). A similar approach can also be used for monkey and mouse bone marrow analysis. Briefly, bone marrow cells are labeled with fluorescein isothiocyanate (FITC)-conjugated anti-CD45 and phycoerythrin (PE)-conjugated anti-CD71 monoclonal antibodies. The tube is incubated in an ice bath in the dark for 20 minutes followed by a washing step with PBS containing 0.5% BSA. The cell pellet is resuspended in

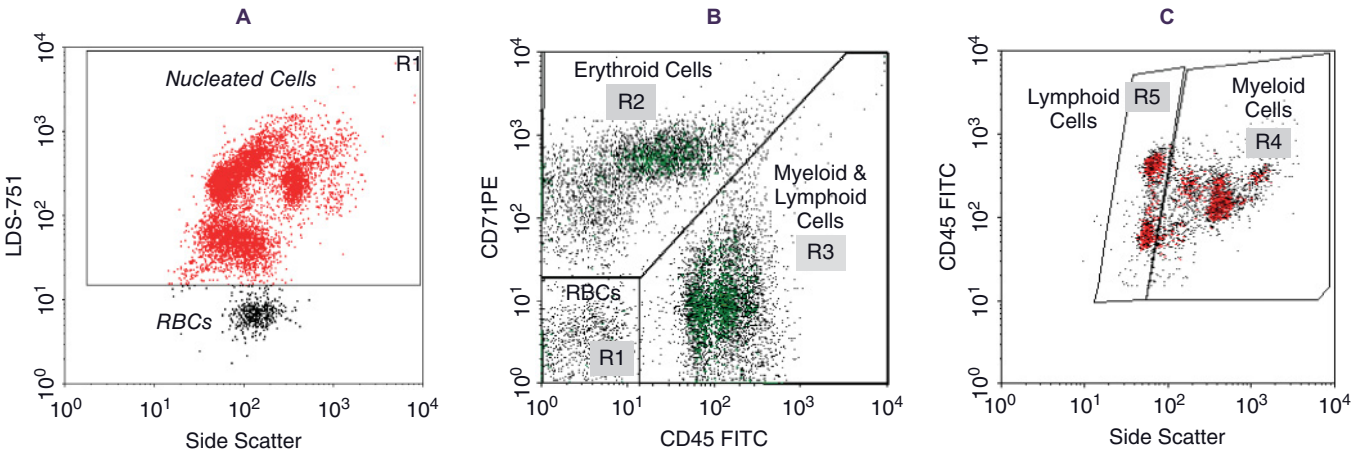

FIGURE 132.5 Rat bone marrow differential analysis using combination of CD45:FITC, CD71:PE and LDS-751 staining. Cytogram C represents events in gate R3 of cytogram B.

0.4 mL of cell fixative (1% formaldehyde). For at least 20 minutes before analysis of samples, 20 µL of LDS-751 staining solution is added. The LDS-751 staining solution is prepared by diluting 20 µL of stock solution (1 mg/mL methanol) with 3 mL PBS. The analysis is performed in a flow cytometer using an excitation wavelength of 488 nm from an argon ion laser. Data can be collected from 10,000–20,000 cells from each sample in list mode to save forward scattered (FSC) values and side scatter (SSC) in a linear scale, and FL1 (green), FL2 (orange) and FL3 (red) in a logarithmic scale. A cytogram of CD45 versus SSC can be plotted on all LDS

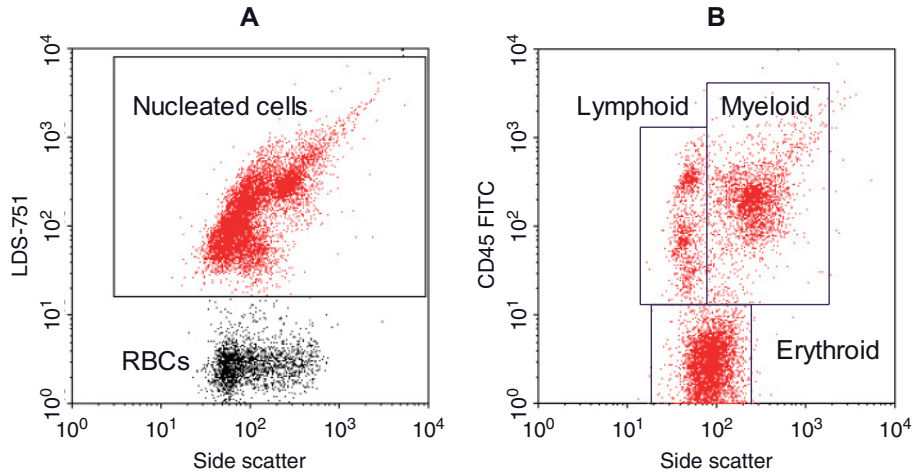

FIGURE 132.6 Dog bone marrow differential analysis using combination of CD45:FITC, cellular complexity (SSC) and LDS-751 staining. Cytogram B represents events in nucleated cells gate (cytogram A).

751-positive cells (nucleated cells) on a cytogram of LDS 751 versus SSC. Standardized gates can be used for all files and the percentages of erythroid, lymphoid and myeloid cells determined. The dog bone marrow analysis is based on cellular complexity and the expression of CD45 in combination with LDS-751 staining (Fig. 132.6).

A few other approaches on the use of flow cytometry for bone marrow analysis of laboratory animals are also described in the literature. For rodents, Martin et al.[12] described a flow cytometric method based on membrane potential using 3,3′-dihexyloxacarbocyanine iodide (DioC6) staining (Fig. 132.7). A combination of 2′,7′-dichlorofluorescein-diacetate staining (indirect myeloperoxidase staining) and monoclonal antibodies for lymphocyte subpopulations (OX52 for T-lymphocyte and OX4 for B-lymphocyte) was used by Criswell et al.[3] for the differential analysis of rat bone marrow (Fig. 132.8). Flow cytometric methods using cellular complexity and light scatter properties in combination with the expression of CD71 or CD45 have been described for rat[21] and dog[24] bone marrow evaluation. More recent work by Zhao et al.[26] described a method for rat bone marrow analysis using the combination of CD3, CD45R, CD71, and CD11b/c in combination with the DNA dye DRAQ5.

Cytology Preparations

The femur is the preferred site for bone marrow sampling of rats and mice. Usually the femur is removed promptly at necropsy and longitudinally split using a bone cutter. The following procedure allows preparation of push smear preps which allow optimal preservation and concentration of cells.[18] Alternatively, cytospin preparations can be prepared from flushed femur samples prepared for flow cytometric analysis.

Materials for Push Smear Bone Marrow Cytological Preparation

Reagents for push smear cytological preparation include: immunological grade bovine albumin, 22%,

polymerized (Median Diagnostics), several pieces of 4 cm × 4 cm square parafilm, bone cutter for sampling of longitudinally sliced femur, scissors, paintbrush no. 0 or 1 regardless of species, and glass slides. The following procedure is used:

1. Place a drop of bovine albumin fluid on several pieces of parafilm square
2. For rodent femur preparations, cut the femur lengthwise, using sharp tools
3. Pick out as much bone marrow as possible with the brush; place on parafilm next to the drop of bovine albumin fluid
4. Dip brush in albumin fluid and mix into the bone marrow to make a uniform solution
5. Place a drop of this bone marrow on 4–5 slides
6. Place another slide gently on top of the slide containing the sample and spread slides apart
7. Air dry.

Cytologic Cytospin Slides from Flow Cytometric Samples

For cytospin slides, take 100 µL of the bone marrow suspension prepared for flow cytometry and add 400 µL PBS containing 0.5% BSA. From this diluted cell suspension, 100 µL is placed in the funnel of a cytocentrifuge. The specimen is centrifuged at 50 *g* for 3 minutes and the slide is removed and air dried.

Staining Procedure for Cytologic Preparations

Wright-Giemsa or May-Gruenwald-Giemsa (MGG) staining provides optimal contrast for bone marrow cytology preparations. Rodent bone marrow requires slightly longer staining time with Giemsa staining compared with MGG stain for the best differentiation between nucleated RBCs and lymphocytes. The Giemsa stain needs to be freshly prepared just before use and care should be taken to maintain a pH of 6.8 for the phosphate buffer.

SLIDE PREPARATION AND STAINING OF CLINICAL BONE MARROW SAMPLES

Slide Preparation

Several techniques for preparing bone marrow smears in a clinical veterinary setting have been described. The most commonly used techniques are:

1. Preparation of a wedge-type smear (no anticoagulant needed)
2. Drop-squash or particle-squash preparations (require EDTA as anticoagulant).

For preparation of a wedge-type smear, several drops of the aspirated bone marrow are ejected onto a microscope slide and a spreader slide is backed into the area containing concentrated bone marrow particles. Then it is lifted off and placed on a clean slide for preparation of a wedge-type smear. Generally, up to 10–12 slides should be made.[15] For the drop-squash preparation, a drop of bone marrow is placed on a slide and gently squashed by a second longitudinally-placed slide or coverslip.[16]

Particle-squash smears are prepared from 2 drops of bone marrow that are placed on a glass slide. The slide is subsequently tilted so excess blood is drained away. Marrow particles, seen as white specks in the red marrow, can be picked up with a microhematocrit capillary tube using capillary action and are carefully transferred onto a second slide so that squash preparations can be made.[16] EDTA-anticoagulated bone marrow can also be placed in a Petri dish for collection of bone marrow particles.

Staining

After preparation, bone marrow smears are quickly air dried. Routine staining is performed with Romanowsky-type stains (May-Gruenwald-Giemsa, Wright stain). It is important to remember that bone marrow smears require a longer staining time because they are thicker and the material is often unevenly distributed. Fast stains like Diff Quik®, however, are less reliable because they do not stain chromatin structure as clearly as May-Gruenwald-Giemsa or Wright stains. Additional stains may be needed so that unstained slides should be saved. Cytochemical staining methods are discussed in Chapter 144.

EVALUATION OF BONE MARROW SMEARS

Unlike evaluation of bone marrow in laboratory animals, clinical evaluation of bone marrow is qualitative. Thus, only the proportions of cellular populations in relation to each other, their maturation, and cellular morphology are reported. For interpretation of these cytological findings, clinical signs and hematological results of the patient must be considered as they indicate the actual demand for RBCs, white blood cells (WBCs), and platelets in the blood. For instance, bone marrow with normal cellularity and a M:E ratio within the reference interval would be considered normal for a nonanemic animal but hyporegenerative for an animal with a severe anemia and no reticulocytosis.

Criteria to be evaluated in bone marrow smears include: (1) estimation of cellularity; (2) assessment of megakaryopoiesis; (3) evaluation of bone marrow iron (not in cats); (4) M:E ratio; (5) maturation cellular lineages (megakaryopoiesis, erythropoiesis, granulopoiesis, lymphopoiesis); (6) presence of dysplasic changes; (7) evaluation of other cell types (plasma cells, mast cells, macrophages, osteoclasts, osteoblasts; and (8) evidence of neoplastic cells or parasites.

While cellularity, megakaryopoiesis, stainable bone marrow iron, and the presence of atypical cell clusters are evaluated at 100× magnification, M:E ratio, maturation of cells and cellular morphology are assessed at 500× to 1000× magnification. Cellularity is estimated in

bone marrow spicules by comparing the percentage of cells to the proportion of fat tissue (cell-to-fat ratio). Normal cellularity ranges between 25% and 75% cells.[7] Cellularity is age-dependent: bone marrow spicules of growing animals contain approximately 75% cells, those of young adults 50%, and marrow spicules of older animals 25% cells. The number of hemosiderophages in the bone marrow spicules is indicative of the amount of stored bone marrow iron. Stainable bone marrow iron is increased in chronic inflammation and immune-mediated anemia; however, it is decreased in iron deficiency and in newborn or young animals.[4] In cats, however, bone marrow iron may not be readily apparent upon staining.

Quantification of megakaryopoiesis is considered to be difficult due to the irregular distribution of megakaryocytes.[10] Thus, the megakaryopoiesis should be evaluated on low power fields where the platelet precursors can be easily identified. The quantification of megakaryopoiesis can be performed by counting the number of megakaryocytes in 70–100 low power fields (100× magnification) and three slides.[15,16] Mean counts of 2.76 megakaryocytes/low power field and 1.55 megakaryocytes/low power field were obtained in one study, using drop squash and particle squash preparations, respectively.[16] Counting megakaryocytes in 20–25 spicule-containing fields achieves an acceptable variance of 20%.[14] However, the percentage of megakaryocytes is highly dependent on the technique of smear preparation and quality of the bone marrow films.[16] Therefore, megakaryopoiesis is routinely only semiquantitatively assessed. Generally, bone marrow spicules contain several megakaryocytes.[5] Normally, >70% of megakaryocytes are mature.[7] A percentage of promegakaryocytes of more than 50% suggests regeneration.[5] A predominance of promegakaryocytes is consistent with an early stage of regeneration or a maturation defect.

Proportions and maturation of erythroid, myeloid, and lymphoid cellular lineages are examined at 500× to 1000× magnification. For determination of the M:E ratio, a 500–1,000 cell differential count is recommended. Because particles have a greater percentage of granulocytes, 50% of cells from bone marrow particles and 50% from the inter-particle regions of the smear should be classified.[5] A differential cell count is indicated to document slight to moderate increases in blast cell counts that may differentiate myelodysplastic or low grade leukemic conditions from benign conditions. Alternatively, a subjective M:E ratio can be determined from the cells seen during cytological evaluation of the bone marrow smear.[5] The normal M:E ranges from approximately 0.5:1 to 2–3:1 in healthy dogs,[13] horse, cow, sheep and pigs;[9] however, broader ranges of up to 4–5:1 have been described.[8,10] A M:E of 1:2 has been reported in healthy cats.[9] Interpretation of the M:E requires consideration of bone marrow cellularity: a normal M:E in face of hypercellular marrow indicates an equal increase in both myelopoiesis and erythropoiesis. An increased M:E may be due to either a decrease in erythropoiesis or an increase in granulopoiesis, whereas a decreased M:E suggests either a granulopoietic hypoplasia or an erythropoietic hyperplasia.

The maturity of cells in the erythroid and myeloid series should also be evaluated. Normally more than 85% of cells in the granulocytic (i.e. metamyelocyte, band, and segmented cells) and erythroid (i.e. rubricyte and metarubricyte) lineages should be in the mature non-proliferative pool. Causes of immaturity in these lineages include leukemias, myelodysplastic syndromes, and immune-mediated hemolytic anemia in which erythroid precorsor cells are destroyed at a particular stage of maturation.

Hematopoietic Cell Culture

CHRISTINE S. OLVER

History of Hematopoietic Culture
Types of Hematopoietic Culture
  Progenitor Assays
  Long Term Bone Marrow Culture
  Long Term Culture Initiating Cell Assay
Growth Factors Used in Hematopoietic Culture

Acronyms and Abbreviations

BFU-E, burst-forming unit-erythroid; BMMC, bone marrow mononuclear cells; CFU, colony-forming unit; CFU-E, colony-forming unit-erythroid; CFU-GEMM, colony-forming unit-granulocyte, erythroid, macrophage, megakaryocytic; CFU-GM, colony-forming unit-granulocyte/macrophage; EPO, erythropoietin; G-CSF, granulocyte colony stimulating factor; GM-CSF, granulocyte/macrophage-colony stimulating factor; HC, hematopoietic cell; LTBMC, long term bone marrow culture; LTC-IC, long term culture initiating cell.

Hematopoietic cell (HC) culture involves the cultivation of primary cells; those that have been derived directly from the host. Sources of HC include bone marrow, peripheral blood mononuclear cells, spleen (rodents) and fetal liver (rodents). Generally, HC culture is used to study progenitor cells, which are lineage committed but morphologically indistinguishable cells. Because progenitors cannot be identified microscopically, their descendents need to be studied and identified in order to retroactively identify the progenitor. This is done by culturing in a semi-solid medium under conditions that allow a single progenitor to form a clone of differentiated cells. Thus, progenitor cells are also called colony-forming units (CFU). Hematopoietic cell culture can enumerate these progenitor cells in a crude suspension of hematopoietic tissue cells. Besides enumeration, HC culture is used to study the physiology, differentiation mechanisms and growth factor control of hematopoiesis. Additionally, liquid based HC culture is employed to establish long-term cultures that recapitulate the microenvironment of *in vivo* hematopoiesis. It is also used to expand either lineage-committed cells or undifferentiated stem cells for transplantation. This chapter describes the history of HC culture, a description of its methods and uses, the types of resulting cells, and the growth factors required.

HISTORY OF HEMATOPOIETIC CULTURE

The discovery of progenitor cells in hematopoietic tissue occurred almost 50 years ago[8] using both in vitro and in vivo assays. The colony-forming unit-spleen (CFU-S) assay was originally developed in the early 1960s[7,9] as a way to identify and enumerate bone marrow progenitor cells. The CFU-S assay provided important information on the nature of both hematopoietic progenitor cells and less differentiated (and more pluripotent) hematopoietic stem cells. Progenitor/stem cells from bone marrow mononuclear cells (BMMC) injected into lethally irradiated mice migrate to the spleen and form macroscopic colonies of variably differentiated hematopoietic cells. One cell is capable of forming a colony of 10^6 differentiated cells, indicating that the original cell is capable of massive division as well as differentiation. These assays provided evidence that these cells are of low frequency in bone marrow suspensions (1 per 10^4 bone marrow cells), have no distinctive morphologic features, have extensive proliferative and differentiation capacity, and are capable of limited self-renewal.

In vitro clonal progenitor assays were developed shortly after CFU-S assays.[1,5] Initially only granulocytic progenitors were cultured, but then conditions for erythroid colony formation were developed. A liquid

culture system permitting long term culture of bone marrow progenitors with an adherent stromal feeder layer, termed long term bone marrow culture was first developed by Dexter et al.[4]

TYPES OF HEMATOPOIETIC CULTURE

Progenitor Assays

Progenitor assays are also known as clonogenic assays (Fig. 133.1). Hematopoietic mononuclear cells (derived from blood, bone marrow, fetal liver or spleen) are cultured in a semi-solid medium so that one dividing and differentiating cell remains in one location as a colony of variably differentiated cells. For example, an erythroid progenitor will produce a colony containing varying numbers of rubriblasts, rubricytes, and metarubricytes. These colonies can be counted microscopically in the culture dishes and are identified by their particular morphology (Fig. 133.2). Mature erythroid colonies will appear orange-red because of their hemoglobin content. The semi-solid medium may consist of agar, methylcellulose, agarose, or plasma or fibrin clots. In general, larger colonies of a single type are derived from less differentiated progenitors (i.e. more proliferative potential). Also, mixed colonies (i.e. those with morphologies of more than one lineage) are derived from less differentiated progenitors (multipotential). The enumeration of progenitors from a mixture of HCs is usually done as a percentage of the original cells plated, rather than as an absolute number Table 133.1 lists and describes the various progenitors derived from progenitor cell assays.

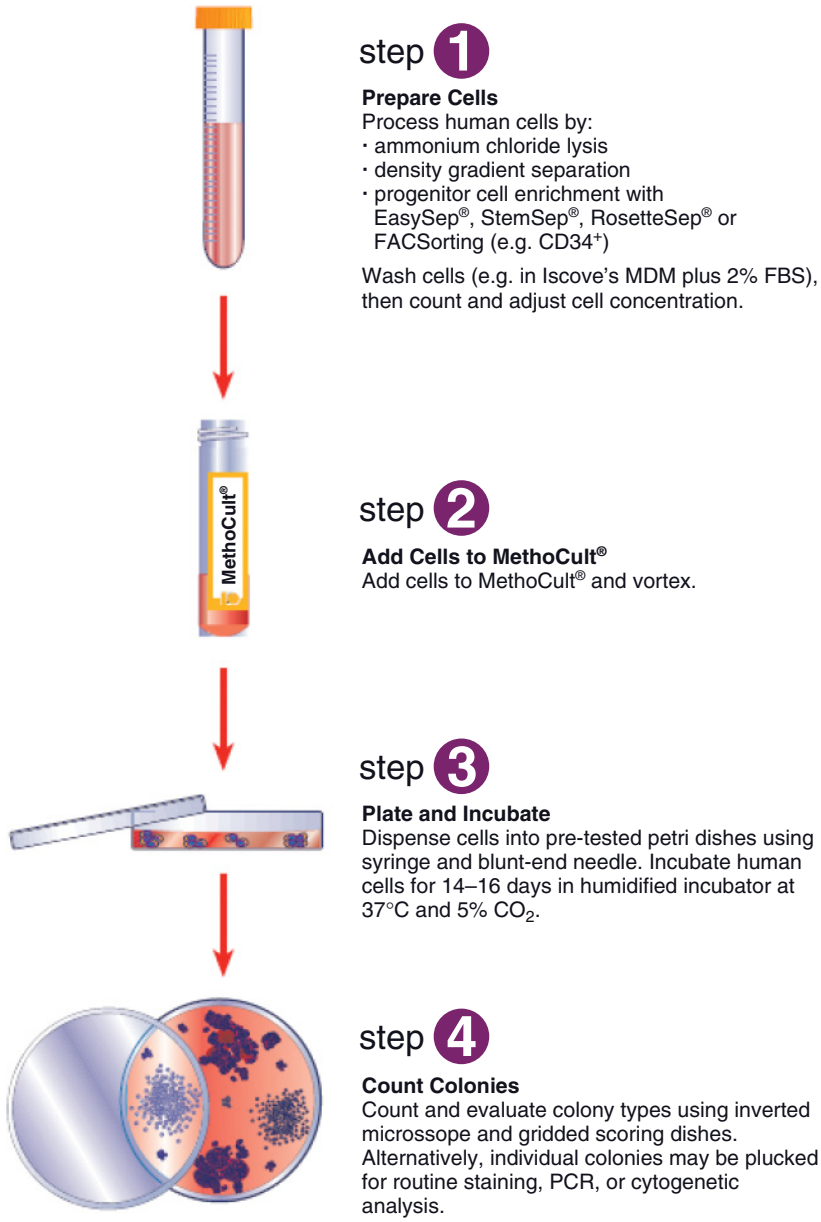

FIGURE 133.1 Schematic showing a typical progenitor assay. (Courtesy of STEMCELL Technologies.)

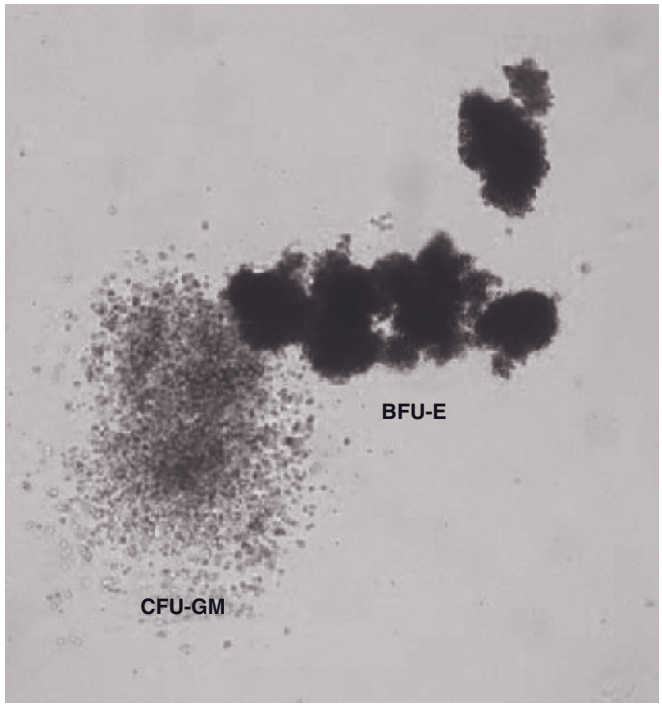

FIGURE 133.2 Photomicrograph of a CFU-GM colony and a BFU-E colony in a culture plate. (Courtesy of STEMCELL Technologies.)

TABLE 133.1 Hematopoietic Progenitor Cells and the Contents of the Subsequent Colonies

Progenitor	Differentiated Cell	Colony Size
CFU-GEMM	Granulocytes, macrophages, rubriblasts, megakaryocyte	>500 cells
BFU-E	Rubriblasts	>200 cells
CFU-GM	Granulocytes, macrophages	>20 cells
CFU-E	Rubriblasts	8–200 cells

Long Term Bone Marrow Culture (LTBMC)

This is a liquid culture system that consists of both an adherent and non-adherent cell population and recapitulates in vitro the in vivo relationships of bone marrow stromal and hematopoietic cells. Proliferation and differentiation of HCs occurs in liquid culture and production of progenitors can be assessed by culturing cells harvested from the liquid cultures in a subsequent progenitor assay. These cultures can be maintained for several months. The adherent layer consists of typical bone marrow stromal cell components, including fibroblasts, adipocytes, endothelial cells, and macrophages.[11] The cultures are initiated by a suspension of BMMCs and incubated until an appropriate stromal layer is formed. The cultures are re-infused with another BMMC suspension, and fed with media twice weekly. The cells of the microenvironment (stromal layer) produce growth factors and can support the growth of multipotent progenitor cells from which all mature hematopoietic cells are generated. Lineage-committed cells will be released from the stroma as non-adherent cells and may then be enumerated using progenitor assays.[6] LTBMC is primarily used to study the humoral and cellular mechanisms of hematopoiesis.[3]

TABLE 133.2 Some Hematopoietic Cytokines and their Functions

Cytokine/ Growth Factor	Predominant Progenitors Stimulated	Other Cells Affected
M-CSF	Macrophages	Primitive progenitors
GM-CSF	Granulocytes/macrophages	Primitive progenitors
G-CSF	Granulocytes	Primitive progenitors
IL-3	Granulocytes, macrophages, megakaryocytes, eosinophils, mast cells	Erythroid (with EPO)
Stem cell factor	Primitive progenitors in synergy with other cytokines	N/A
EPO	CFU-E to erythroblasts	Megakaryocytes (synergistic)
TPO	Megakaryocyte colonies	Primitive progenitors

Long Term Culture Initiating Cell (LTC-IC) Assay

An LTC-IC is a cell that can give rise to all of the progenitor cells described above over a 5–8 week period when cultured on an appropriate adherent "feeder cell" layer.[10] The LTC-IC assay measures the frequency of these cells by performing progenitor assays after 5 weeks in culture and then inferring the number of LTC-ICs in the original culture. The majority of CFCs are in the adherent layer.[2] The frequency of LTC-ICs in human marrow is approximately 1 per 10^4 BMMC. LTC-ICs comprise 1 in 50–100 purified human CD34+ bone marrow cells.

GROWTH FACTORS USED IN HEMATOPOIETIC CULTURE

The growth of progenitors in semi-solid medium is not autonomous and therefore a variety of "growth factors" are required for their growth and differentiation. The reader is directed to an excellent review of hematopoietic cytokines by Metcalf.[8] Each type of progenitor (e.g. CFU-GM, BFU-E, etc) responds to a certain set of growth factors, and thus many growth factors are named for the predominant lineage whose growth they stimulate. The growth factors were originally called "colony stimulating factors" (CSFs) because of this functional effect on progenitor assays. The CSFs were derived from media conditioned by immortalized cell lines or by mitogen stimulated primary cultures of mouse lung or

lymphocytes. Over a brief period of time, these growth factors were identified and cloned (Table 133.2). Although growth factors may have a predominant effect, they often synergize with other factors, or even affect the functions of mature hematopoietic cells. If growth factors are not added to the growth medium, many can be supplied using an adherent "feeder layer" of cells which produce them.

CHAPTER 134

Radiolabeling and Scintigraphic Imaging of Platelets and Leukocytes

DOUGLAS J. WEISS

Indications for Platelet and Neutrophil Scintigraphy
Platelet Scintigraphy with ^{111}In-Labeled Platelets
Alternative Techniques for Detection of Thrombi
Neutrophil Scintigraphy
Alternative Methods for Labeling Sites of Inflammation

Acronyms and Abbreviations

^{18}F-FDG, fluorine-18-fluoro-2-deoxy-d-glucose; ^{111}In, indium-111 oxine; ^{99m}Tc, technetium-99m hexamethylpropyleneamine oxime.

Platelet and neutrophil scintigraphic imaging studies have not been extensively used in veterinary medicine either in clinical medicine or in preclinical safety assessment studies. These techniques have been applied more widely in human medicine.[1,5,9,13] Older techniques consisted of ex vivo radiolabeling of platelets, neutrophils, or mixed leukocytes followed by intravenous injection. Although these techniques have been reported to be effective, they do require a somewhat lengthy sterile isolation procedure. Several alternative methods have been reported in which radiolabeled compounds that bind to platelets or neutrophils at sites of thrombosis or inflammation are injected intravenously. Many of these involve administration of labeled monoclonal antibodies.[5,12] These techniques have the advantage of considerably less pre-imaging preparation time but cannot be used for determination of platelet or neutrophil survival in the blood.

This chapter will discuss the indications for use of platelet or neutrophil scintigraphic imaging. Techniques for radiolabeling platelets and neutrophils and alternative approaches for detection of thrombi and sites of inflammation in the body will also be described.

INDICATIONS FOR PLATELET AND NEUTROPHIL SCINTIGRAPHY

Platelet scintigraphy has been primarily used for detection of thrombosis in human medicine.[1,13] Because this is less of a problem in veterinary medicine, the technique has not been extensively applied. However, the technique has been applied to detection of platelet sequestration in laminar vessels in experimental equine laminitis and in preclinical safety assessment studies.[18,19] Many experimental compounds cause thrombocytopenia as an adverse effect. Platelet scintigraphy can be used to determine the effect of the compound on platelet survival in the blood, platelet distribution in the body, platelet recirculation after discontinuing the compound, and platelet deposition in thrombi.[19] Platelet scintigraphy has been used to investigate the thrombocytopenia associated with administration of a glycoprotein IIb/IIIa peptide antagonist to dogs.[19] Administration of the peptide resulted in a reduction in platelet lifespan and removal of platelets by the spleen. Platelet scintigraphy has also been used to investigate the role of platelets in equine laminitis.[18] Near to the onset of lameness, radiolabeled platelets accumulate on the hoof wall of affected hooves. This is associated with decreased blood flow to affected hooves.

Neutrophil scintigraphy is largely used for identification and quantification of inflammatory processes.[3,5,7] Occult inflammatory processes occur in all species but are a particular problem in horses.[3,4,7,8] Most difficult to diagnose are intra-abdominal abscesses, ulcerative colitis, chronic pulmonary disease, and chronic bone and tendon inflammation that causes lameness. Neutrophil scintigraphy has been used to identify intra-abdominal abscesses, acute ulcerative colitis, and orthopedic infections in horses.[4,7,8]

PLATELET SCINTIGRAPHY WITH ^{111}IN-LABELED PLATELETS

Platelets from a variety of species including horses, dogs, and rabbits have been labeled with indium-111 (^{111}In) oxine and successfully used for platelet scintigra-

phy based on the method originally described by Thakur et al.[16,18,19] The volume of blood collected varies with the species. For horses, 250 mL of blood is collected whereas for dogs 50 mL of blood has been collected.[3,7,19] Blood is aspirated directly into Aster's acid-citrate-dextrose solution (pH 4.5; 6 parts blood to 1 part acid-citrate-dextrose solution). Blood is maintained at room temperature throughout because cooling to 4 °C permanently reduces platelet function. For horses, the blood is centrifuged at 150 × *g* for 15 minutes, whereas for dogs blood is centrifuged at 300 × *g* for 15 minutes. Platelet-rich plasma is placed in sterile tubes and centrifuged at 1,000 × *g* for 10 minutes. Thereafter, platelet-poor plasma is removed, and the platelet button is overlaid twice with 1–2 mL of modified Tyrode's buffer (pH 6.5). Platelets are resuspended in 4–6 mL of modified Tyrode's buffer. For horses approximately 1 mCi of ^{111}In oxine is added, whereas for dogs approximately 0.4 mCi of ^{111}In oxine is added.[18,19] Total counts per minute in the mixture are determined by use of a gamma particle counting instrument. The sample is incubated for 10 minutes at 20–22 °C and centrifuged at 1,200 × *g* for 10 minutes. The platelet pellet is overlaid twice with platelet-poor autologous plasma, and resuspended in autologous plasma. Total counts per minute in the sample are determined, and labeling efficiency is calculated. Labeled platelets are re-administered intravenously, usually within 2 hours after blood collection. For determination of platelet lifespan, the radioactivity in 1 mL of blood is determined at least once a day for 6 days, and results are corrected for background and physical decay and blood loss due to phlebotomy.[16,19] Linear curves of percent platelet survival are plotted against time, and platelet half-life is determined. Some curves are linear whereas other curves are logarithmic. A weighted mean method can be used to compare platelet survival between plots that best fit linear versus logarithmic regression plots.[19] Platelet survival can also be compared by determining the time for whole blood radioactivity to decrease from 100% to 50%.

Scintigraphic imaging is performed using a large field of view gamma camera. Because it is essential to keep the animal motionless for several minutes, sedation is helpful. Given a normal lifespan of 6–7 days, radioactivity is slowly cleared from the blood and accumulates primarily in the spleen within 1 week after injection. When using ^{111}In-labeled platelets to label thrombi, scans are usually done 6–24 hours after injecting the platelets for venous thrombi and 3–4 days for arterial thrombi.[12,13]

ALTERNATIVE TECHNIQUES FOR DETECTION OF THROMBI

For clinical purposes a variety of other imaging techniques are replacing specific thrombus-labeling techniques. These include ultrasonography (Doppler), magnetic resonance imaging, and computerized tomography.[10] However, specific thrombus labeling techniques still have some clinical applications. Because ^{111}In-labeled platelet labeling techniques require up to 2 hours to process the platelets, several investigators have proposed less cumbersome imaging procedures to detect thrombi. These techniques include ^{99m}Tc-antifibrin, ^{99m}Tc-annexin V, ^{99m}Tc-anti-P-selectin F(ab)2, and ^{99m}Tc-platelet glycoprotein IIb/IIIa receptor antagonist.[1,11,12,15] The details of these techniques will not be discussed here. Advantages of these procedures are a significant decrease in preparation time and a decrease in the time between injection and imaging. Imaging can usually be done within 1–6 hours after administration of the radioactive compound. Anti-P-selectin and other anti-platelet antibodies have been used to image thrombi in dogs.[14]

NEUTROPHIL SCINTIGRAPHY

Although neutrophil labeling can be used to determine neutrophil lifespan, its primary application has been for detecting sites of inflammation.[3,4,7,8] Clinically the technique has primarily been adapted for use in humans and the horse but has also been applied to other domestic animals, including sheep.[3,4,6,7,8] Neutrophils have been labeled with ^{99m}Tc-hexamethylpropyleneamine or ^{111}In-oxine. In horses, the technique can be performed quite simply by labeling mixed leukocytes after sedimentation of erythrocytes. Alternatively, pure populations of granulocytes can be isolated by use of continuous or discontinuous density gradient centrifugation. Approximately 250 mL of anticoagulated whole blood is collected from horses and erythrocytes are allowed to sediment for 20–30 minutes.[7] Thereafter leukocyte-rich plasma is removed and centrifuged at 150 × *g* for 15 minutes.[3] Plasma is removed and cells are resuspended in saline solution. Indium-111 oxine (300–400 µCi) is added and incubated for 15 minutes. The cell suspension is then washed in autologous platelet-poor plasma and resuspended in 15 mL of autologous platelet-poor plasma and reinjected intravenously. Images are collected using a large field-of-view gamma camera. Sites of inflammation are usually most visible at 24–48 hours after injection of leukocytes.[3,7]

ALTERNATIVE METHODS FOR LABELING SITES OF INFLAMMATION

Alternative techniques for labeling sites of inflammation include ^{99m}Tc-labeled anti-granulocyte monoclonal antibodies and Fab' fragments, chemotatic cytokines, and fluorine-18-fluoro-2-deoxy-d-glucose (^{18}F-FDG).[5,17] As a glucose analog, ^{18}F-FDG is rapidly taken up by sites of acute or chronic inflammation due to their increased glycolytic activity.[2,5] Each of these compounds is injected intravenously. Scans for anti-granulocyte antibodies are usually obtained 2–24 hours after injection using a gamma camera. Scans for ^{18}F-FDG are obtained within 1 hour after injection using positron emission tomographic imaging.[2,5] Although some

differences of opinion still exist among physicians, ^{18}F-FDG appears to be preferred over anti-granulocyte antibodies.

Acronyms and Abbreviations

BASO, basophil; CHCM, corpuscular hemoglobin concentration mean; CHr, reticulocyte cellular hemoglobin content; DNA, Deoxyribonucleic acid; Hgb, hemoglobin; Hct, hematocrit; LI, lobularity index; LUC, large unstained cell; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; MCVr, mean cellular volume reticulocyte; MN, mononuclear; MPC; mean platelet component concentration; MPO, myeloperoxidase; MPV, mean platelet volume; MPXI, mean peroxidase activity index; NRBC, nucleated red blood cell; PDW, platelet distribution width; PEROX, peroxidase; PLT, platelet; PM, platelet dry mass; PMN, polymorphonuclear cells; QBC, quantitative buffy-coat analysis; RBC V/HC cytogram, red blood cell volume/hemoglobin concentration cytogramm; RBC, red blood cell; RDW, red cell distribution width; RETIC Scatter ABS, reticulocyte absorption scattergram; RNA, ribonucleic acid; SLS, sodium lauryl sulphate; SMA, sequential multiple analyzer; WBC, white blood cell; WIC, WBC impedance count; WOC, WBC optical count.

INTRODUCTION AND HISTORICAL DEVELOPMENT

Counting blood cells automatically began in the 1930s with a photoelectric method using darkfield optics.[29] Later, Langerkranz proposed the use of darkfield optics or light scatter to scan hemocytometer chambers to avoid human error.[22] Instruments correlating the red blood cell (RBC) count with turbidity of cell suspensions did not gain wide acceptance because of inaccuracy and lack of practicability.[35] In the 1950s and 1960s, Coulter Electronics, Inc. and Technicon Instruments introduced analyzers able to determine one or several hematological parameters. The Coulter instrument was based on electrical impedance and the counting principle was patented, so no other manufacturer could produce such an instrument for 17 years.[35] The Technicon instrument was known as a sequential multiple analyzer (SMA) and utilized darkfield optical scanning to determine the RBC and white blood cell (WBC) counts, hemoglobin (Hgb) concentration, and hematocrit (Hct) (SMA 4®, Technicon Instruments). The Coulter Model S® additionally calculated the mean corpuscular hemoglobin concentration (MCHC), mean corpuscular hemoglobin (MCH) and mean corpuscular volume (MCV) according to well known formulas and was one of the pioneering "multiparameter" instruments. In subsequent years, more and more parameters, including platelet count, RBC distribution width (RDW), platelet distribution width (PDW) and mean platelet volume (MPV) were added to multiparameter analyzers and further technological developments, such as the combination of optical counting principle with cytochemical stains by Technicon Instruments, were introduced. In the mid 1970s Ortho Diagnostic Systems entered the multiparameter hematology instrument market and launched a cell-counting instrument which was based on laser light scatter and utilized the concept of hydrodynamic focusing. Pattern recognition systems were also developed in the 1970s, but were slow and did not improve precision of manual methods and are currently no longer manufactured.[12] Most large and in-house

hematology instruments are now capable of generating a WBC differential cell count. Methods for differentiating the WBCs vary between manufacturers, but include electrical impedance, laser light scatter, cytochemical stains, use of reagents capable of differentially lysing certain cell types, and combinations of these methods.

GENERAL PRINCIPLES OF HEMATOLOGY INSTRUMENTS

Electronic Impedance

Electronic impedance introduced by Coulter in the 1950s is still widely used in large and in-house hematology instruments. It is based on the fact that cells are poor conductors of electricity. If cells are suspended in an electrolyte solution and passed through a small aperture between two electrodes with continuous current, conductance will change. Change in conductance is sensed as a change in current, which is proportional to particle size. To count and size particles accurately thresholds have been developed. A threshold is a voltage limit with which a pulse is compared. Only pulses that exceed the threshold are sized and counted. Both a lower and an upper threshold can be defined and by manipulating the upper and lower thresholds, it is possible to produce a "window," which is a specific particle size range (Fig. 135.1).[12] In automated hematology instruments, these thresholds can be predefined (fixed) or floating. With floating thresholds, the software searches for a "valley" between two distributions and places a threshold at this location.[18]

In some hematology instruments (e.g. Sysmex E-Series®) radio frequency analysis has been combined with direct current volumetric sizing for simultaneous measurement of each WBC.[12] Radio frequency is high-frequency alternating current, which detects and sizes the cell on the basis of the overall density, including nuclear and granular density. In contrast, the direct current method sizes the entire cell, including nucleus and cytoplasm. Thus, the combination of direct current and radio frequency offers information about cell size, size of the nucleus and volume fraction of the cytoplasm to the entire cell.[41] Another possible way to improve the WBC differential cell counts is the combination of impedance technology with lysing reagents that strip away or shrink the cell's plasma membrane and cytoplasm, leaving "bare" nuclei.[12]

Light Scatter

Cells can be detected and counted as they pass through a beam of light instead of through an electrical field.[12] Although older instruments used mercury and halogen lamps, lasers are much more frequently used in modern hematology instruments. Cells passing through the beam of light cause diffraction, refraction and reflection and the scattered light is detected by appropriately placed photodetectors. With the darkfield optical method, the darkfield disc prevents light from hitting the photodetector when no cells are present. In contrast, with an absorbance channel, the photodiode receives maximum light when no cells are passing. Forward low-angle light scatter, forward high-angle light scatter, right angle scatter, and extinction offer information about cell volume, cell surface, lobularity, and granularity. Forward low-angle light scatter (1–3°) correlates with cell volume; forward high-angle scatter (4–9°) with granularity; right angle scatter (90°) with cell surface; and lobularity and extinction (0–0.5°) is a measure for cell volume.

Flow cells are made of quartz rather than glass because quartz is transparent and does not bend light that passes through.[12] Flow cells are filled with sheath fluid. The sheath fluid prevents the flow cell from being coated by reagents or cell stroma. Sheath fluid also surrounds the sample stream and facilitates laminar flow and hydrodynamic focusing (see Chapter 137). Laminar flow ensures that all particles flow through the flow cell in parallel lines and that a second fluid containing the sample does not mix with the surrounding sheath fluid.[12] Hydrodynamic focusing is needed to assure that

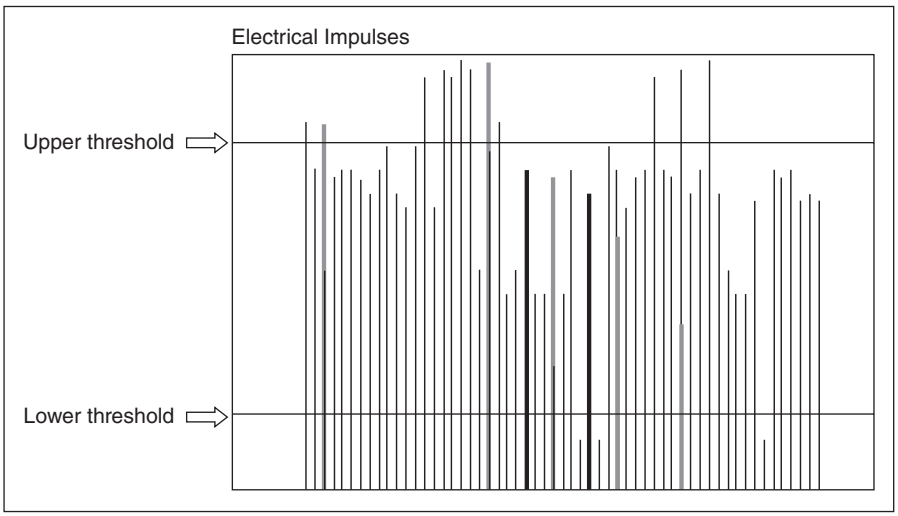

FIGURE 135.1 Diagram of electronic impedance. Number of impulses between the lower and upper threshold equals the number of particles passed through the aperture. The amplitude is proportional to the particle size.

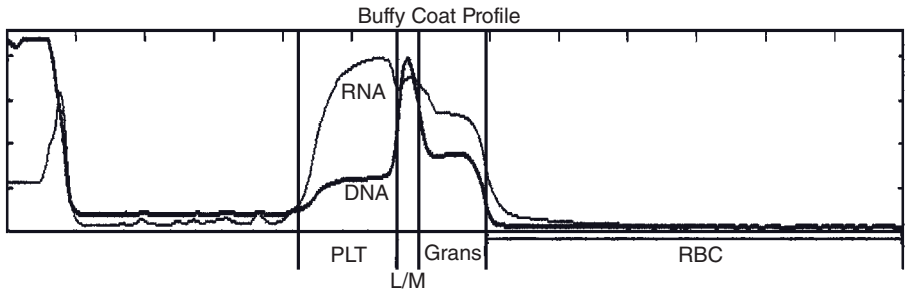

FIGURE 135.2 Buffy coat profile for a canine sample, analyzed on the QBC Vet Autoread®. Red blood cells do not fluoresce with acridine orange and thus the graph is near zero in the RBC area. The next layers are the granulocytes (Grans), which contain both RNA (thin line) and DNA (bold line). This is reflected by a hump in both lines. Below the platelets are the lymphocytes and monocytes (L/M). Because lymphocytes are smaller, they contain more DNA per volume. As a result a peak in the DNA line is visible. Platelets are at the top of the buffy coat and exhibit a DNA and RNA line. On the left edge of the graph, the free dye fluorescence and thus the DNA and RNA lines start high.

the cells pass individually through the flow cell. This is achieved by symmetrically decreasing the cross-sectional area of the fluidic channel in the flow cell and reducing the area in which the fluid is flowing. This results in faster-flowing central fluid with narrowing of the central sample stream.[12]

Centrifugal Analysis

With the centrifugal method, cells are not actually counted, but rather RBC and buffy coat layers are analyzed in centrifuged whole blood samples.[12] The method is based on the principle that different blood cells have different densities and that they sort into individual layers when spun in a microhematocrit tube. A cylindrical float (specific gravity is between that of plasma and RBCs), inserted into a capillary tube, expands the buffy coat layer. The inner surface of the capillary tube is coated with acridine orange, a fluorescent dye that stains a variety of different cellular components (DNA, RNA, lipoproteins, glycosamines): normal RBCs are not stained by acridine orange, granulocytes fluoresce orange-yellow, lymphocytes and monocytes brilliant green and platelets pale yellow. The fluorescence emitted by the cells in the tube is examined and values for WBC, PLT, MCHC, Hgb, Hct, granulocytes and lymphocytes/monocytes are reported; a characteristic buffy coat profile is generated (Fig. 135.2).

HEMATOLOGY INSTRUMENTS IN VETERINARY MEDICINE

The number of hematology analyzers available for veterinary medicine has increased steadily. In addition to large laboratory instruments, several smaller and affordable in-house instruments have been manufactured in recent years. These instruments are based on laser, impedance, or buffy coat technology and combinations of these methods. In this section we will discuss the most important analyzers.

ADVIA 120/2120® (Siemens Medical Solutions)

The ADVIA analyzers are flow-cytometry based systems, using light scatter, differential WBC lysis, and peroxidase and oxazine 750 staining to provide : (1) a complete blood cell count, (2) a WBC differential cell count, and (3) a reticulocyte count.[20] In contrast to the ADVIA 120®, the ADVIA 2120® uses a cyanide-free hemoglobin method, has a new user interface, and can be used for routine analysis of biological fluid samples in addition to blood samples.[17]

Hemoglobin Measurement

The ADVIA system has two methods of measuring Hgb: a modification of the manual cyanmethemoglobin method and a cell-based Hgb measurement. In the modified cyanmethemoglobin method, blood samples are mixed with the Hgb reagent in the Hgb reaction chamber. The Hgb chemical reaction consists of two steps: lysis of RBCs to release Hgb and formation of the reaction product, which is measured colorimetrically at a wavelength of 546 nm.[6] The cell-based Hgb measurement determines the corpuscular Hgb concentration mean (CHCM). Comparable to the MCHC it provides a measurement of the average corpuscular Hgb concentration in the sample. However, the CHCM is directly measured based on a cell-by-cell analysis, while the MCHC is a calculated parameter (Hgb/[RBC × MCV]×1000). Thus, interfering substances such as severe hemolysis or lipemia, which falsely elevate the Hgb and MCHC, will not affect the CHCM.[6]

The ADVIA 2120® analyzer can operate with a cyanide-free Hgb method. A comparison of this method to the modified cyanmethemoglobin method on the ADVIA 120® and 2120® showed a proportional bias, with overestimation of the Hgb values in dogs, cats, horses, and goats. However, the cyanide-free method was believed to be applicable in these species, provided the proportional bias is considered.[4,5]

Red Blood Cell and Platelet Measurement

The RBC and platelet cytochemical reaction consists of two steps: RBCs and PLTs are isovolumetrically sphered with sodium dodecyl sulphate. The sphering eliminates shape as a variable. In the second step RBCs and PLTs are fixed with glutaraldehyde. A pair of low-angle light scatter (2–3°) and high-angle light scatter (5–15°) signals are used to analyze RBCs. Using the Mie theory of light scattering for homogeneous spheres, low-angle light scatter is converted into cell volume and high-angle light scatter is converted into hemoglobin concentration.[6] Several histograms and cytograms are then used to determine and display RBC parameters: the RBC rate histogram shows the arrival rate of cells in the RBC/PLT channel. The RBC volume (RBC V) histogram displays the distribution of RBCs by volume. The RBC HC histogram shows the distribution of RBCs by Hgb concentration independent of cell volume, and the RBC CH histogram shows the distribution of RBCs by Hgb content. Additionally, the RBC Scatter cytogram (Fig. 135.3) is formed by plotting the high-angle light scatter (5–15°) on the *x*-axis and the low-angle light scatter (2–3°) on the *y*-axis. The RBC V/HC cytogram (Fig. 135.3) is a presentation of the RBC volume and Hgb concentration data intended for evaluating RBC morphology. The RBC Matrix then provides the cell counts and percentages for the corresponding nine regions on the RBC V/HC cytogram.[6] Based on these RBC and Hgb measurements, several other parameters are determined (Table 135.1). Additionally, morphological flags such as microcytosis, macrocytosis, and anisocytosis, as well as hypochromasia, hyperchromasia, and anisochromasia are available. Thresholds can be defined for each species.[23] Figure 135.4 demonstrates the RBC V/HC cytograms for seven different species and reflects the different thresholds, developed for each species individually.

Platelets are analyzed with a two-dimensional method: the low-angle light scatter (2–3°) signal is amplified 30 times, and the high-angle light scatter (5–15°) signal is amplified 12 times. Comparable to RBC analysis, the Mie theory of light scattering for homogeneous spheres is used to convert low-angle light scatter measurement into cell volume and high-angle scatter measurement into refractive index. Several histograms and cytograms are then utilized to determine and display platelet parameters:[6] the PLT X histogram corresponds to the *x*-axis on the PLT scatter cytogram and displays the high-angle light scatter. The PLT Y histogram corresponds to the *y*-axis on the PLT Scatter cytogram and displays the low-angle scatter. The Platelet VOL histogram of the two-dimensional PLT analysis shows the distribution of cells by volume. The Platelet PM histogram displays the distribution of platelets by platelet dry mass (PM). The platelet PC histogram demonstrates the distribution of platelets according to refractive index (platelet component concentration [PC]). Furthermore, the PLT Scatter cyto-

TABLE 135.1 RBC Parameters, Determined by the ADVIA 120/2120®

Parameter	Explanation
Mean corpuscular volume (MCV)	Mean of RBC volume histogram
Red cell distribution width (RDW)	100 × (SD of RBC volume histogram/MCV)
Corpuscular hemoglobin concentration mean (CHCM)	Mean of RBC HC histogram
Hemoglobin concentration distribution width (HDW)	SD of RBC HC histogram
Cellular hemoglobin content (CH)	Mean of RBC CH histogram
Hematocrit (Hct)	(RBC × MCV)/10
Mean corpuscular hemoglobin (MCH)	(HGB/RBC) × 10
Mean corpuscular hemoglobin concentration (MCHC)	(HGB/[RBC × MCV]) x 1000
RBC fragments	Count of RBC fragments[a]
RBC ghosts	Count of RBC ghosts[a]

[a]Determined with two-dimensional platelet analysis and displayed in the PLT scatter cytogram.

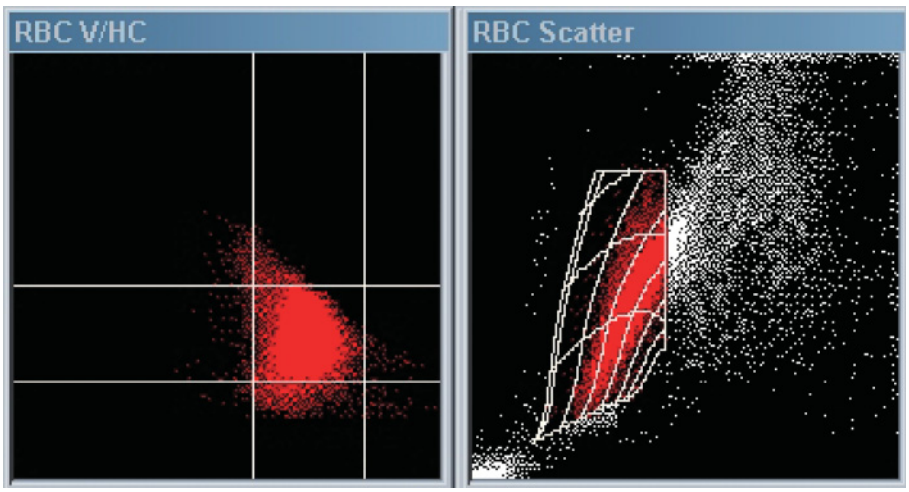

FIGURE 135.3 Red blood cell scatter cytogram and corresponding RBC V/HC cytogram of a normal dog. The RBC scatter cytogram is formed by plotting the high-angle light scatter (5–15°) along the *x*-axis and the low-angle light scatter (2–3°) on the *y*-axis. The RBC V/HC cytogram is a presentation of the RBC volume (y axis) and Hgb concentration (x axis) data intended for evaluating RBC morphology. The RBC V/HC cytogram is also called the Tic Tac Toe.

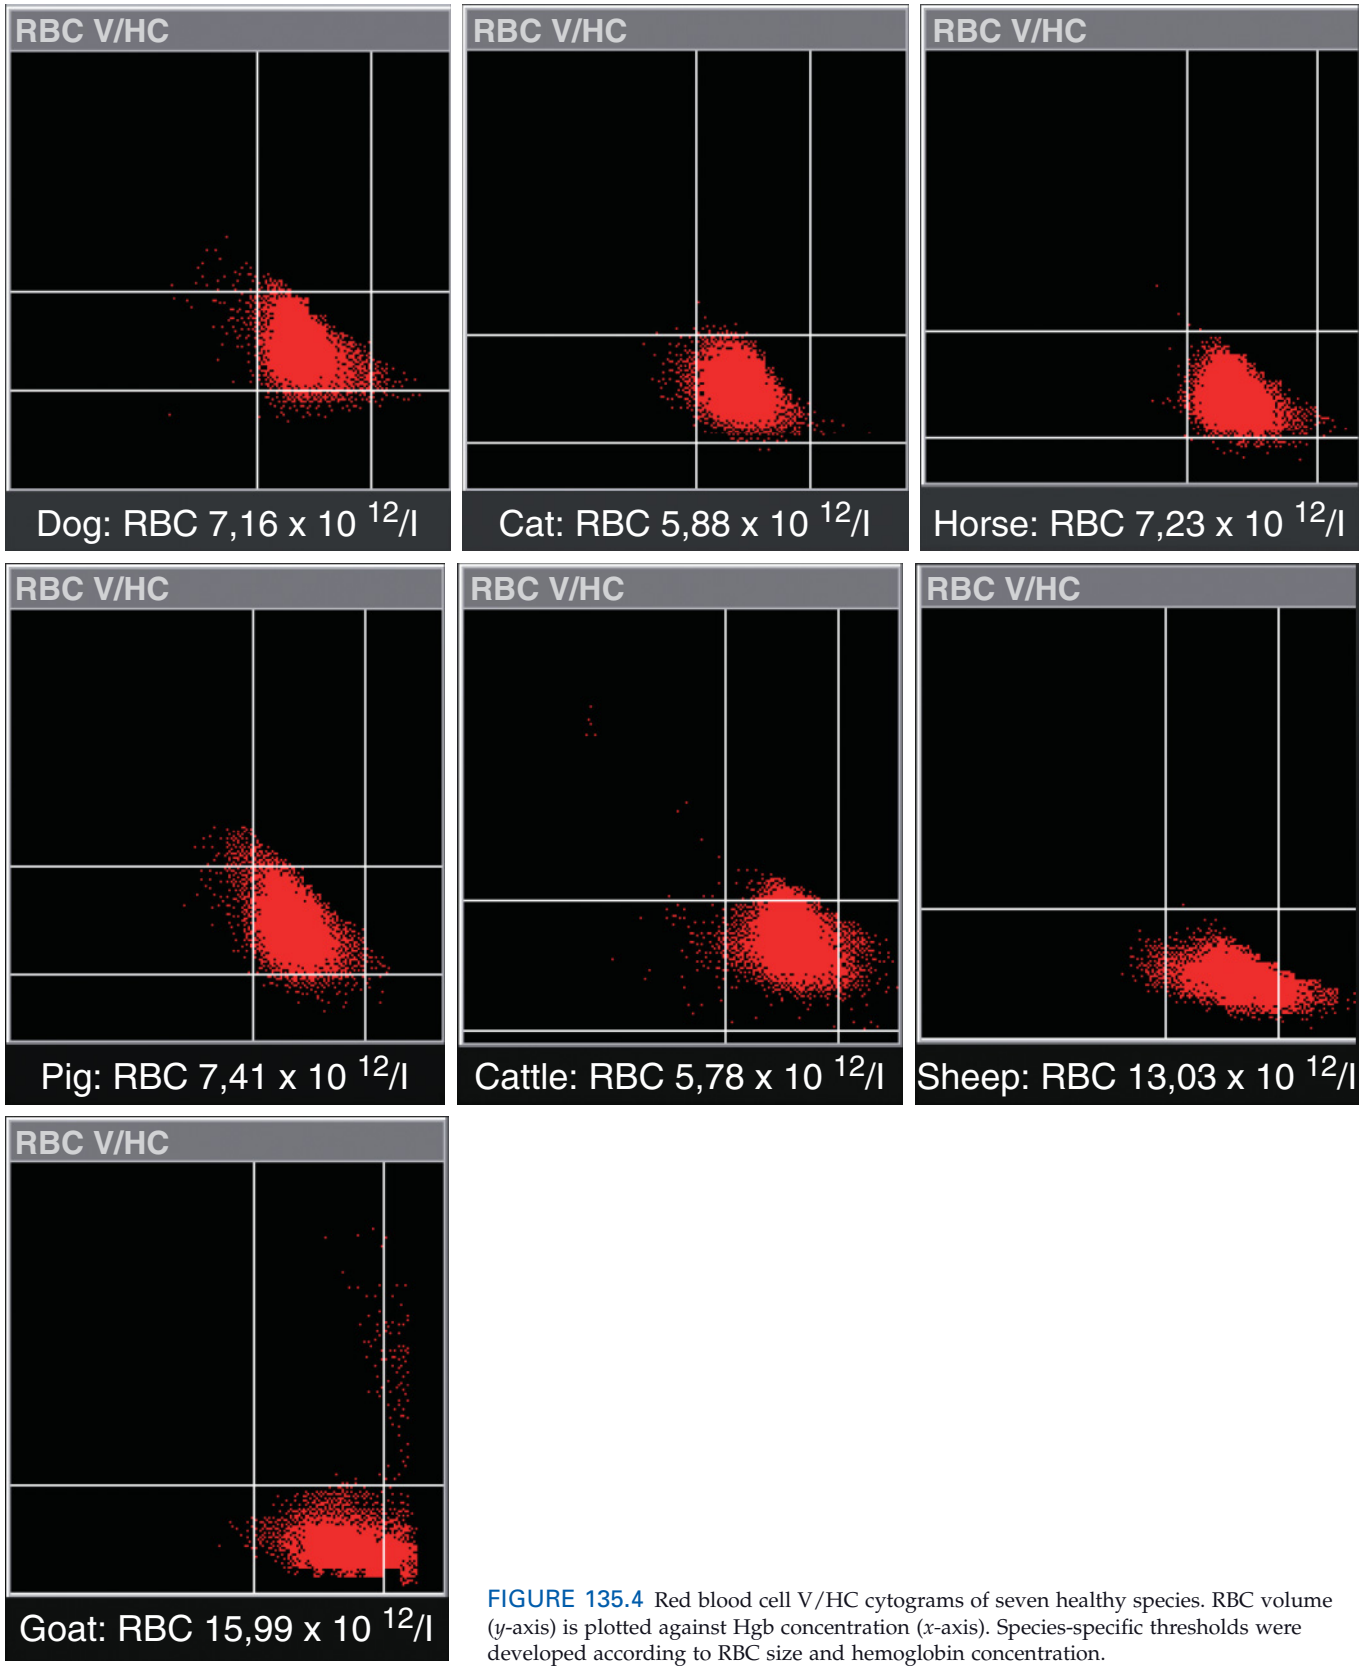

FIGURE 135.4 Red blood cell V/HC cytograms of seven healthy species. RBC volume (*y*-axis) is plotted against Hgb concentration (*x*-axis). Species-specific thresholds were developed according to RBC size and hemoglobin concentration.

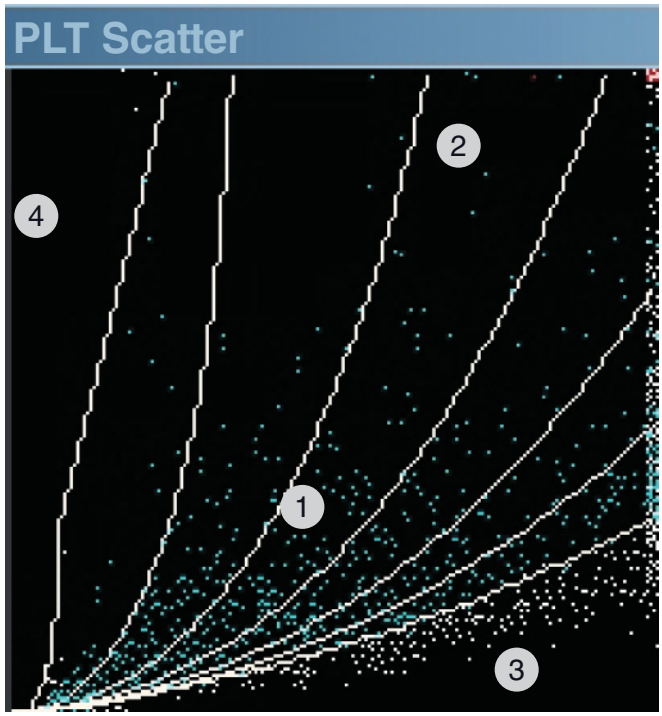

FIGURE 135.5 Platelet scatter cytogram of a healthy horse. The high-angle (5–15°) scatter is plotted on the *x*-axis, and the low-angle (2–3°) is plotted on the *y*-axis: 1, platelets; 2, large platelets; 3, RBC fragments; 4, RBC ghosts.

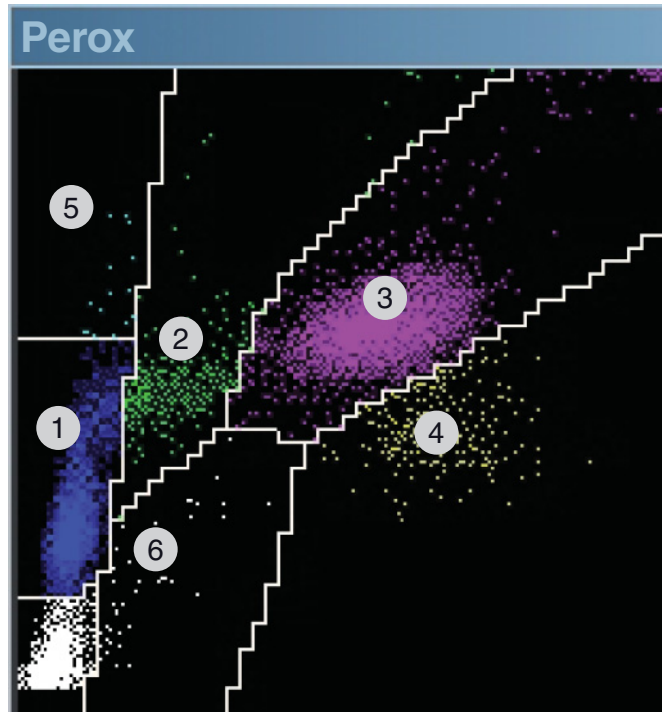

FIGURE 135.6 Perixodase (PEROX) cytogram of a healthy dog. The cells absorb light in proportion to the amount of peroxidase stain present. This is represented on the *x*-axis. Cells size is represented on the *y*-axis (cells scatter light in proportion to their size). Distinct populations are formed when the light scatter and absorption data are plotted and cluster analysis then identifies each population: 1, lymphocytes and basophils; 2, monocytes; 3, neutrophils; 4, eosinophils (except cat); 5, large unstained cells; 6, platelet clumps.

gram (Fig. 135.5) is the graphical representation of two light-scatter measurements: the high-angle (5–15°) is plotted on the *x*-axis, and low-angle (2–3°) is plotted on the *y*-axis. There is also a Platelet Volume/Refractive Index cytogram available, where the refractive index is plotted on the *x*-axis and platelet volume on the *y*-axis. Comparable to the RBC measurement, this two-dimensional platelet analysis offers many different parameters; some of them are only available for research purposes. The most important PLT parameters are shown in Table 135.2. Many of these parameters have been investigated for detection of activated platelets. A correlation has been found between an increase in P-selectin and a decrease in the mean platelet component concentration (MPC) in dogs with septic and nonseptic inflammatory diseases.[24]

TABLE 135.2 Platelet Parameters, Determined by the ADVIA 120/2120®

Parameter	Explanation
Mean platelet volume (MPV)	Mean of PLT volume histogram
Platelet volume distribution width (PDW)	100 × (SD of PLT volume histogram/MPV)
Mean platelet component concentration (MPC)	Mean of platelet PC histogram
Platelet component distribution width (PCDW)	SD of platelet PC histogram
Platelet crit (PCT)	(PLT × MPV)/10,000
Mean platelet dry mass (MPM)	Mean of platelet PM histogram
Platelet dry mass distribution width (PMDW)	SD of platelet PM histogram
Large PLT	Platelets with volumes greater than 20 fL

White Blood Cell Measurement

White blod cells are counted and differentiated with two different methods: peroxidase staining and basophil/lobularity.

In the peroxidase cytochemical reaction, RBCs are lysed and 4-chloro-1-naphthol serves as a substrate that enables hydrogen peroxide to form a dark precipitate at sites of peroxidase activity in the granules of some WBCs.[6] Neutrophils, eosinophils, and monocytes are stained based on their levels of peroxidase activity. Because lymphocytes, basophils, and large unstained cells contain no peroxidase, these cell types remain unstained. The results are graphically displayed in a PEROX cytogram (Figs. 135.6 and 135.7). The cells absorb light in proportion to the amount of peroxidase they contain. This is represented on the *x*-axis. Cells size

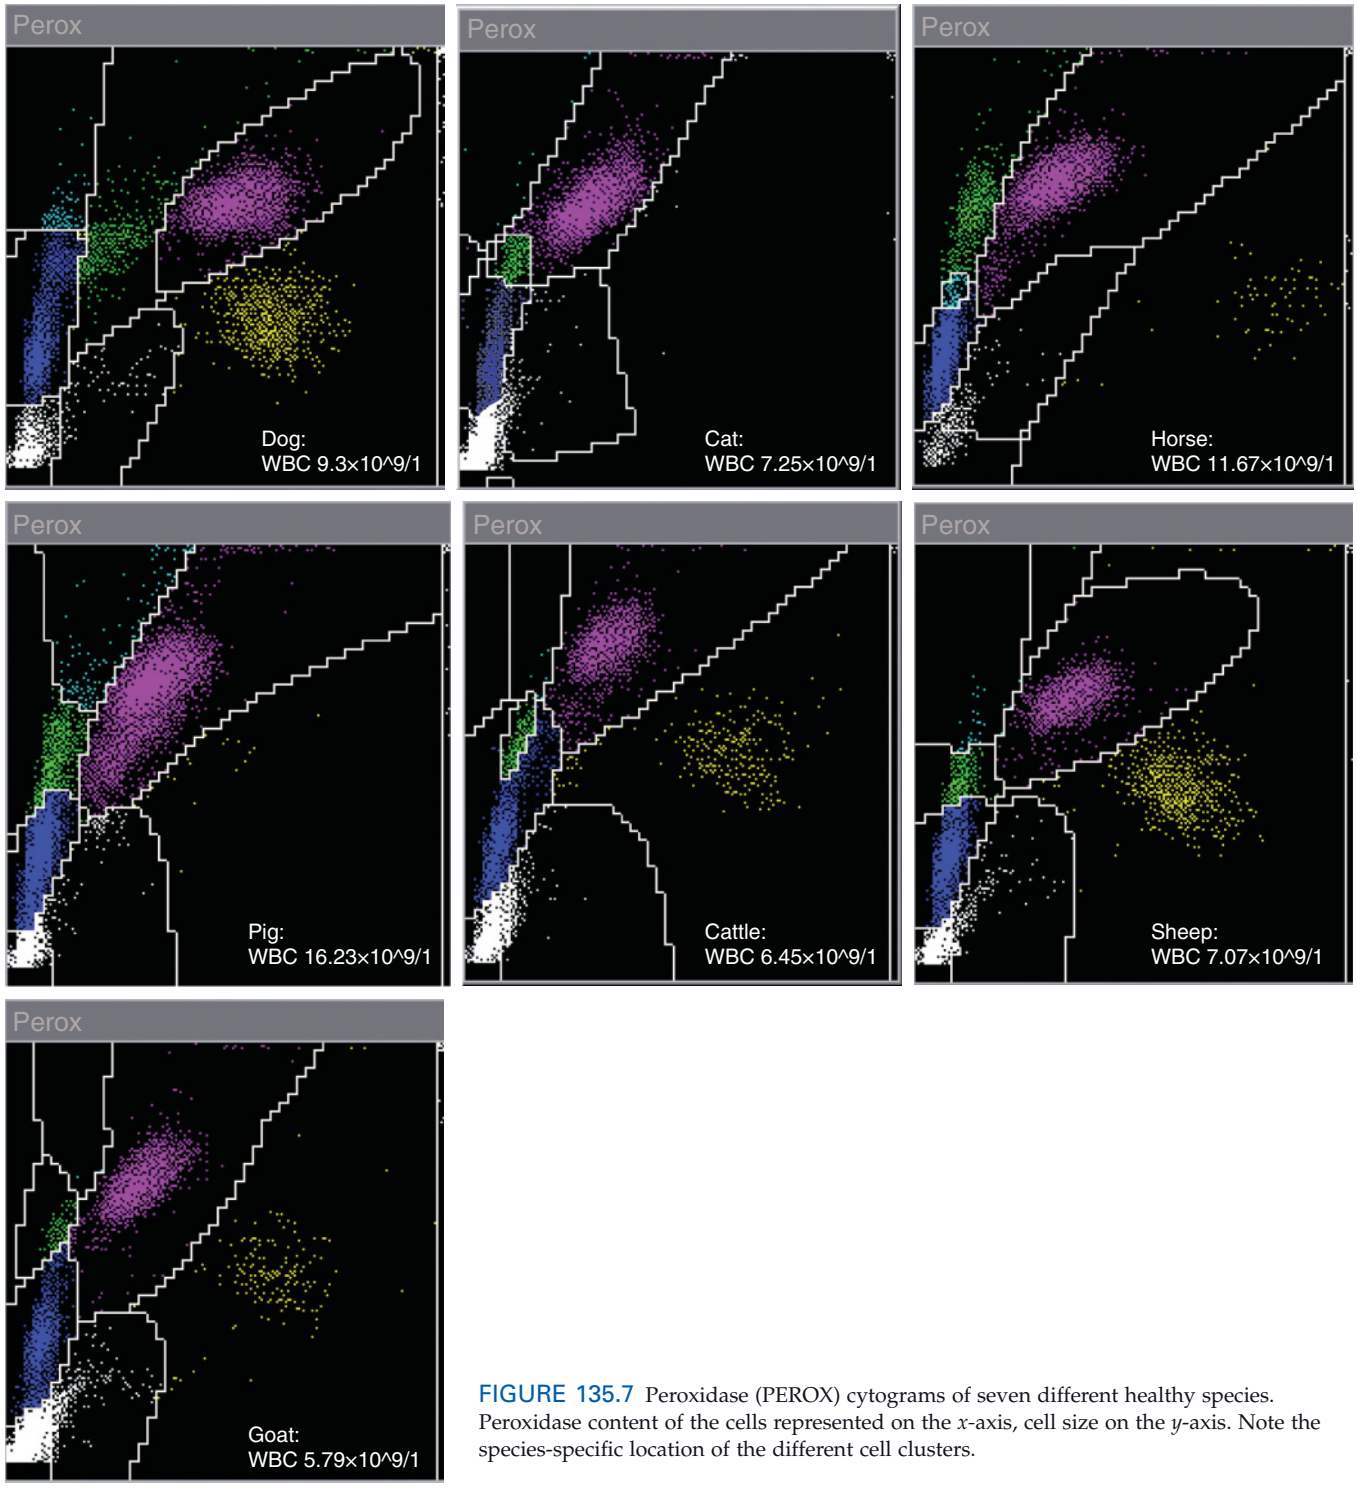

FIGURE 135.7 Peroxidase (PEROX) cytograms of seven different healthy species. Peroxidase content of the cells represented on the *x*-axis, cell size on the *y*-axis. Note the species-specific location of the different cell clusters.

is represented on the *y*-axis. Distinct populations are formed when the light scatter and absorption data are plotted and cluster analysis then identifies each population based on its position, area and density. These clusters are defined on a sample-by-sample basis. Besides a WBC count and five-part differential, including neutrophils, eosinophils, lymphocytes, monocytes and large unstained cells (LUCs), platelet clumps and mean peroxidase activity index (MPXI) are determined.

The MPXI was already available with the Bayer Technicon analyzer, the predecessor of the ADVIA 120. The system was used to identify persons suffering from myeloperoxidase deficiency (MPO).[21] In veterinary medicine, dogs with pyometra were shown to have an increase in MPXI and the authors concluded that the parameter may be an indicator of bone marrow stimulation due to local inflammation or infection.[28] An increase in MPXI was also found in septicemic foals that were neutropenic.[31] In contrast, normal MPXI values were found in septicemic foals that were not neutropenic.

Some species, (e.g. cat) have peroxidase-negative eosinophils, and eosinophils and neutrophils cannot be differentiated with the peroxidase method. Instead neutrophils and eosinophils are discriminated using the reticulocyte method (see later).

In the basophil/lobularity cytochemical reaction, RBCs and platelets are lysed and all WBCs except basophils are stripped of their cytoplasma by phthalic acid and a surfactant and by the increased temperature in the reaction chamber.[6] Low-angle and high-angle light scatter are used to categorize the stripped WBCs as mononuclear (MN) or polymorphonuclear (PMN) cells based on the shape and complexity of their cell nuclei and to distinguish the intact basophils from the smaller cell nuclei. The results are displayed in the BASO cytogram (Fig. 135.8): the high-angle light scatter (nuclear configuration) is plotted on the *x*-axis, and the low-angle light scatter (cell size) is plotted on the *y*-axis. Cluster analysis is then applied to identify each population based on its position, area, and density. Beside a WBC and basophil count, the lobularity index (LI) is determined by this method. It reflects the valley between MN and PMN cells. In case of a left shift, the valley disappears and an instrument flag is displayed (only human software).

Both methods provide a total WBC count, which are compared as part of internal quality control procedure. In general, the WBC count obtained with the basophil/lobularity method is reported.

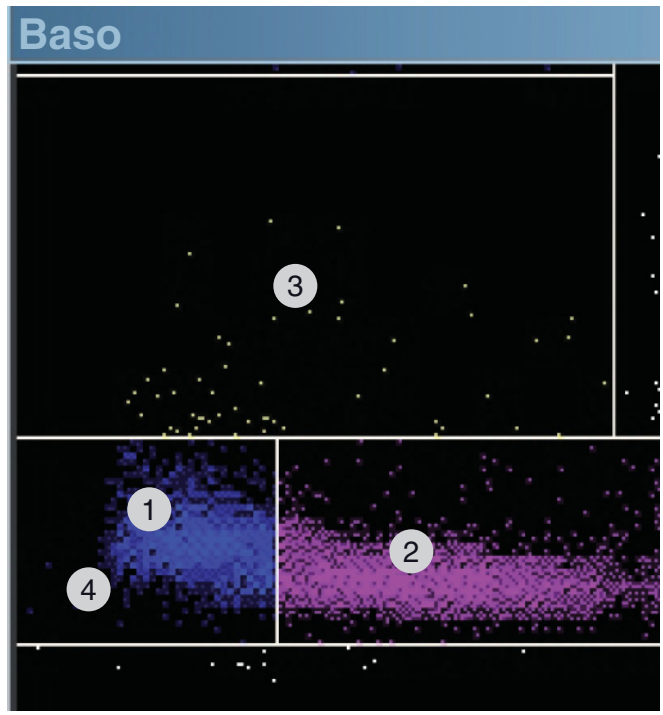

FIGURE 135.8 Basophil (BASO) cytogram of a healthy dog. The high-angle light scattergram (nuclear configuration) is plotted on the *x*-axis and the low-angle light scatter (cell size) is plotted on the *y*-axis. Cluster analysis is then applied to identify each population: 1, mononuclear WBCs (lymphocytes and monocytes); 2, polymorphonuclear WBCs (neutrophils and eosinophils); 3, basophils and lysis-resistant cells; 4: blast cell nuclei.

Reticulocyte Analysis

The cytochemical reaction for reticulocyte analysis consists of two steps: RBCs and platelets are isovolumetrically sphered and reticulocytes are differentially stained with Oxazine 750, according to their RNA content.[6] Cells are then analyzed and differentiated with the low-angle and high-angle light scatter and absorption. Low-angle and high-angle light scatter are proportional to cell size and hemoglobin concentration, and absorption is proportional to RNA content. Results are graphically displayed in the RETIC Scatter ABS cytogram (Fig. 135.9): absorption (cell maturation) is plotted on the *x*-axis and high-angle light scatter (cell size) on the *y*-axis. Determination of cell maturation allows subclassification of reticulocytes into low, medium, and high absorption reticulocytes.

There is also a RETIC Scatter cytogram available, where the high-angle scatter is shown on the *x*-axis and the low-angle scatter on the *y*-axis. Mie theory is applied to transform the low-angle and high-angle scatter signals into volume and hemoglobin concentration values.[6] In addition to the absolute reticulocyte count and the mentioned subpopulations, several other parameters are determined: the most important ones are the mean cell volume of reticulocyte population (MCVr) and reticulocyte cellular hemoglobin content (CHr). Both parameters have been used as markers of iron deficiency.[10,14,34,45] MCVr and CHr hold promise as non-invasive, cost-effective measures of iron status in the dog.[34] Fry and Kirk, using a canine model of nutritional iron deficiency, showed that several reticulocyte parameters, including CHr and MCVr, were better indicators of developing and resolving iron deficiency than were conventional hematology or biochemical indices.[14]

Beside routine hematological analyses, the ADVIA 120® and ADVIA 2120® have also been used to evaluate different body fluids and bone marrow aspirates. The results of analyses of canine bone marrow samples

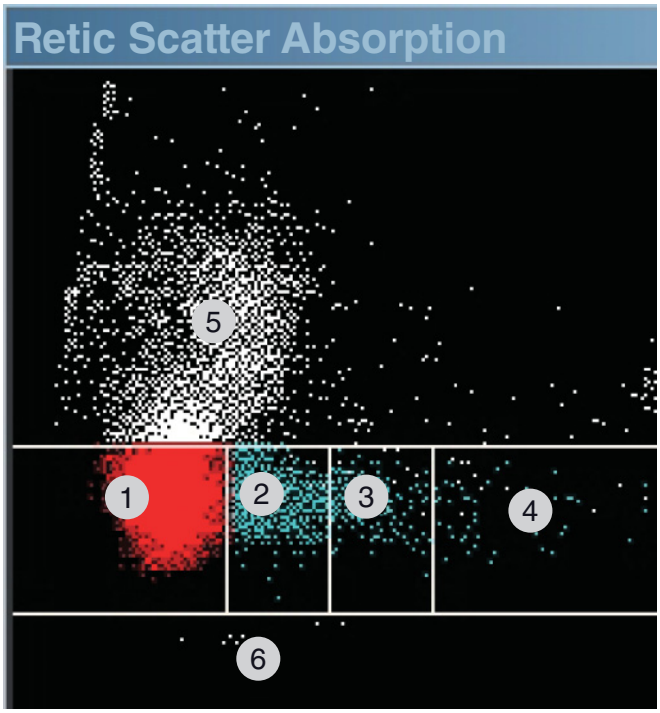

FIGURE 135.9 Reticulocyte (RETIC) scatter cytogram of a canine sample. Absorption (cell maturation) is plotted on the *x*-axis and high-angle light scatter (cell size) on the *y*-axis. Determination of cell maturation allows subclassification of reticulocytes into low, medium, and high absorption reticulocytes: 1, mature RBCs; 2, low absorption reticulocytes; 3, medium absorption reticulocytes; 4, high absorption reticulocytes; 5, coincidence events; 6, platelets.

showed that characteristic changes in the ADVIA 120® cytograms provided good preliminary information about the predominant cell population or the presence of haematopoietic neoplasia.[2] The instrument is also beneficial for the analysis of abdominal and pleural effusions and Bauer et al. showed that inflammatory effusions, monocytic proliferation and lymphoma could easily be detected. Carcinoma and mesothelial cells were classified as "mononuclear blasts."[3] Both analyzers have been evaluated for the analysis of cerebrospinal fluid.[7,33] Promising results were obtained for RBC and total nucleated cell counts and the ADVIA 2120® was useful for classifying samples with significant pleocytosis.[7]

Cell-Dyn® 3500® (Abbott Laboratories)

Another large laboratory hematology instrument widely used in veterinary medicine is the Cell-Dyn® 3500. The analyzer determines a WBC optical count (WOC) and the WBC differential cell counts in an optical flow channel. Two different electric impedance channels are used for a WBC impedance count (WIC) and for RBC and platelet counts. Hemoglobin concentration is measured spectrophotometrically.[1]

The following section highlights some important considerations about the WBC analysis on the Cell-Dyn® 3500. As mentioned above, WBCs are analyzed in two separate channels and an algorithm is applied to compare the two counts and determine which value is reported. Appropriate warning messages are also displayed. In general, the WOC is reported as the WBC count.[1]

For the WIC, RBCs are lysed and the reagent strips the cytoplasm from the WBCs. The WBC nuclei are then counted with an impedance method. Nucleated RBCs are included in the WIC.[1]

In the optical channel, four different angles of scatter are measured: forward angle light scatter (1–3 °), which correlates with the cell size, narrow-angle light scatter (7–11 °), which correlates with cell complexity, ninety-degree light scatter (70–110 °), which offers information about cell surface, lobularity, and ninety-degree depolarized light scatter, that correlates with certain types of cell granularity. These measurements allow a total WBC count, as well as a five-part differential cell count (i.e. neutrophils, eosinophils, basophils, lymphocytes, and monocytes) to be determined. Red blood cells are altered by the sheath reagent: hemoglobin diffuses out of the cell and water from the reagent diffuses into the cell. Thus, the RBC membrane remains intact, but the RBC now has the same refractive index as the sheath fluid, rendering it invisible to the laser.[1] The light scatter information is graphically presented in scatterplots: separation between MN and PMN cells is available through the ninety-degree/narrow angle scatterplot. The instrument uses dynamic thresholds to determine the best separation between the two populations. To further differentiate neutrophils and eosinophils, ninety-degree depolarized light scatter is plotted against the ninety-degree light scatter. The eosinophils scatter more 90 ° depolarized light than any other cells because of the unique nature of their granules and thus can be separated from neutrophils.[1] Finally, the mononuclear cells and basophils are separated by plotting forward-angle light scatter against narrow-angle light scatter. Basophils are included in the mononuclear clusters, because their granules are water soluble and dissolve in the sheath reagent.[1] Nucleated RBCs, unlysed RBCs, giant platelets and platelet clumps may also appear in this scattergram; however, they are excluded from the WBC count and WBC differential cell count. Additionally, several histograms are available (Fig. 135.10).

Available parameters and applicability of the Cell-Dyn® 3500 are much more limited in comparison to the ADVIA® analyzers. However, algorithmic analyses have been successfully applied to predict the ontogeny of leukemic cells in the blood of dogs and cats.[13]

Sysmex XT-2000iV® (Sysmex Europe)

The XT-2000iV® is a relatively new analyzer, combining aperture impedance and optical technologies. Red blood cells and platelets are counted in a dedicated channel using impedance combined with hydrodynamic focusing technology.[38] At the same time, the Hct is calculated via the RBC pulse height detection method:

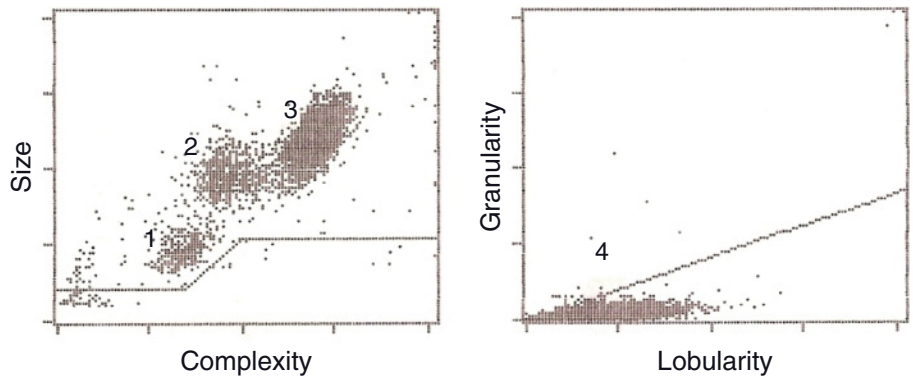

FIGURE 135.10 Cytograms for the Cell-Dyn® 3500 hematology analyzer (canine sample). On the left cytogram, cell size is plotted against complexity: 1, lymphocytes; 2, monocytes; 3, neutrophils. On the right cytogram, granularity is plotted against lobularity: eosinophils fall in the gate marked with number 4.

the intensity of the electronic pulse from each analyzed RBC is proportional to the cell volume. The analyzed pulses and the resulting RBC volumes of defined sample volume are accumulated to directly result in the Hct value.[38,39] Instead of the more commonly used cyanmethemoglobin method, the sodium lauryl sulphate (SLS) method is applied to determine Hgb conentration: the anionic detergent forms a complex with Hgb, which is spectrophotometrically measured at 555 nm.

To determine an absolute reticulocyte count and to allow analysis of stages of maturity, the analyzer applies fluorescent dye and diode laser technologies.[36] The results are displayed in the RET Scattergram (see Chapter 136), where the *x*-axis represents the intensity of the lateral fluorescent light and the *y*-axis the intensity of the forward scattered light (Fig. 135.11).[39] The same principle is used to measure platelets. It has been shown that with this technology, the instrument is capable of reliably detecting large as well as immature platelets.[25]

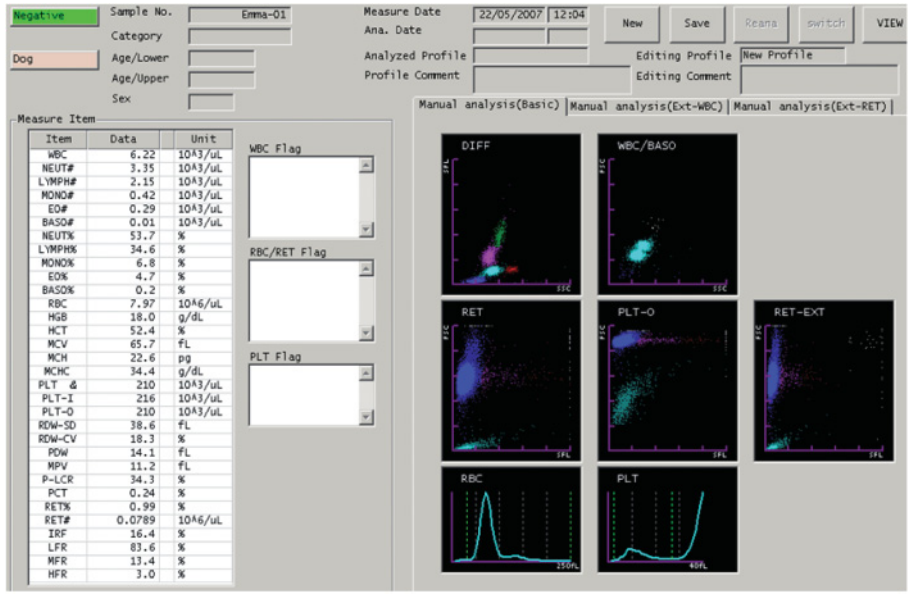
Forward-scattered light, lateral-scattered light and lateral-fluorescent light are used to determine the WBC count and WBC differential cell count. The results are displayed in a four differential scattergram, where the *x*-axis represents the intensity of the lateral-scattered light and the *y*-axis represents the intensity of the lateral-fluorescent light (Fig. 135.11).[37] In a second scattergram (WBC/BASO), lateral-scattered light is displayed on the *x*-axis, with forward-scattered light on the *y*-axis (Fig. 135.11).[37] In contrast to the other large laboratory hematology instruments, manual re-gating is possible with the Sysmex XT® analyzer. To the authors' knowledge, results of comparison studies concerning the accuracy of the Sysmex Analyzer are available only in abstract form. Our experience indicates that the system is relatively easy to use, and gives reliable results. Further studies are needed to determine the usefulness of the manual re-gating feature for WBCs. One study reports that the instrument can be used to determine total nucleated cell counts on body fluids of dogs and cats.[30]

In-House Hematology Instruments

The point-of-care hematology instrument market is currently in flex, with frequent introductions of new instruments and enhancements. The decision about the type of system to be used depends not only on instrument accuracy and precision, but on other factors including costs, maintenance, ease of use, desired parameters, and the number of samples to be analyzed. The majority of the instruments use impedance technology to determine WBC, RBC, and platelet counts and parameters. A few instruments are available that apply laser technology to determine cell counts or at least the WBC differential cell count. Buffy-coat analysis is still used in one instrument (IDEXX VetAutoRead™, IDEXX Laboratories). Available parameters also vary between the different systems: two-, three- or five-part differential WBC counts and the ability to measure absolute reticulocyte counts are the most important differences between the analyzers.

Several studies concerning the accuracy of in-house instruments have been published.[8,9,11,15,16,19,26,27,32,40,42–44] Comparing the results of the different investigations is difficult, because various reference/comparative methods, as well as different statistical methods have been used. Furthermore, many evaluations are only available in abstract form. In general, the point-of-care analyzers appear to perform well in comparison to the different reference or comparative method.[8] There are some limitations, especially for the WBC differential cell counts and platelet counts. However, automated differential WBC counts, in a clinical setting, need to be verified no matter which automated instrument is used. Thus, with the currently available in-house instruments, accuracy seems not to be a major factor in selecting an instrument. Instead, as mentioned above, costs, maintenance, ease of use, desired parameters, and number of samples to be analyzed are more important considerations.

Besides assuring the accuracy of instruments, manufacturers must train users appropriately concerning



Item	Data	Unit

FIGURE 135.11 Routinely available data report of the Sysmex XT-2000iV® (canine sample). On the left, the numerical data and on the right the graphical report including cytograms: Diff, WBC/Baso, Ret, PLT-O, Ret-Ext and histograms: RBC and PLT.

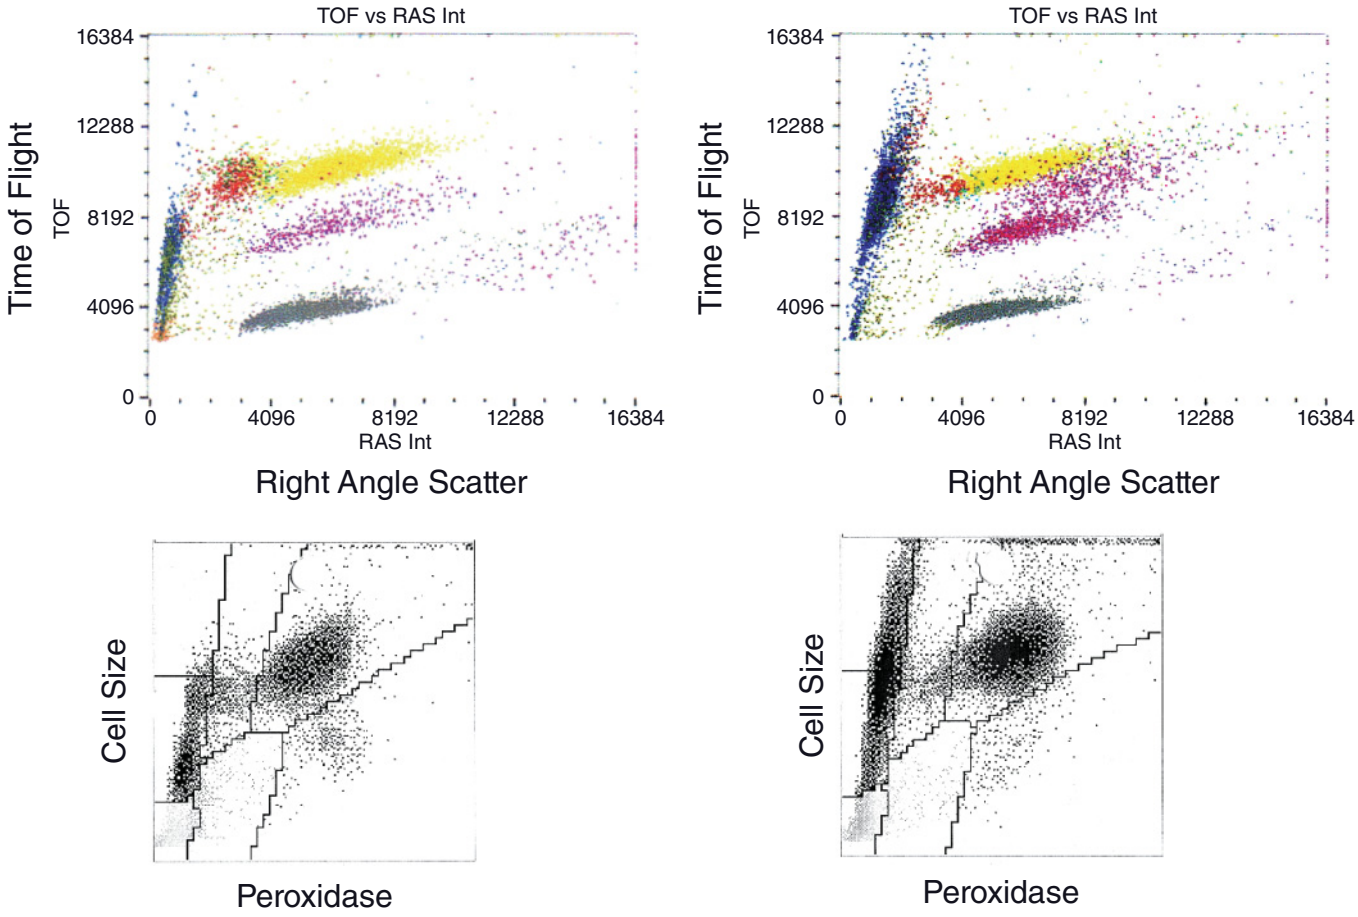

FIGURE 135.12 Cytograms of the LaserCyte® and ADVIA 120® for a hematological unremarkable sample (left) and a sample with a significant number of circulating lymphoblasts (right). The two scattergrams on the top are generated by the LaserCyte® and time of flight is plotted against right angle scatter: the blue population represents the lymphocytes. The two PEROX cytograms on the bottom are of the same samples, analyzed with the ADVIA 120®. The LaserCyte® scattergrams of the sample with lymphoblasts clearly reveals that the lymphocyte population is enlarged with numerous events scattering upwards. This is comparable to the PEROX scattergram of the ADVIA 120® with events spreading into the large unstained cells (LUC) gate.

operation, maintenance, quality-control procedures, troubleshooting, and most importantly, result verification. Result verification can be achieved in different ways: flagging of inaccurate results, assessment of graphical reports, and blood film evaluation. All hematology analyzers have the capacity to display error messages. The number of error messages and explanations provided by the manufacturer about the underlying causes for showing these messages vary greatly. Our own investigations revealed that up to 89% of test results are marked with an error message.[8] Usefulness of the these messages is very limited, because many accurate results are marked with an error message and, in contrast, many samples with inaccurate results are not detected.[8] Thus, using error messages for result verification is currently not recommended. The impedance-based in-house instruments typically display histograms for WBCs, RBCs and platelets. A notable exception is the LaserCyte® (IDEXX Laboratories). This is a purely laser-based instrument, which also generates several scattergrams and histograms. Preliminary experience is promising concerning the usefulness of these scattergrams for verification of the WBC differential cell counts. Figure 135.12 shows the ADVIA 120® and LaserCyte® scattergrams of a normal canine blood sample and a sample with significant numbers of medium-sized lymphoblasts. In the displayed scattergrams of the LaserCyte®, time of flight is plotted against right-angle scatter and the blue population represents the lymphocytes. Comparing the scattergrams of the normal canine sample and the sample with circulating lymphoblasts, the lymphocyte population is enlarged with numerous events scattering upwards. This is comparable to the PEROX scattergram of the ADVIA 120® with events spreading into the large unstained cells (LUC) gate. However, prospective studies about sensitivity and specificity of scattergrams and histograms to recognize inaccurate results, as well as morphological changes (e.g. left shift, toxic changes, RBC poikilocytosis) are currently lacking. Therefore, blood smear evaluation remains essential for result verification and is currently needed for every sample analyzed on an in-house instrument.

Reticulocyte and Heinz Body Staining and Enumeration

HAROLD TVEDTEN and ANDREAS MORITZ

Reticulocyte Staining and Counting
- Manual Methods
- Automated Methods
- Reporting Methods
- Other Indicators of Reticulocyte Status
- Reticulocyte Interpretation (see Chapter 24)

Heinz Body Staining and Counting
- Manual Methods
- Species Variations
- Interpretation of Heinz Bodies (see Chapters 24 and 36)

Acronyms and Abbreviations

Advia, Advia® 2120, 120 or 2120I; AO, acridine orange; BCB, brilliant cresyl blue; CH retic, hemoglobin concentration reticulocyte; CHr, cell hemoglobin of reticulocytes; EDTA, ethylenediaminetetraacetic acid; LaserCyte, IDEXX Laboratories LaserCyte® hematology analyzer; MCV retic, mean corpuscular volume reticulocyte; mRNA, messenger ribonucleic acid; NMB, new methylene blue; RBC, red blood cell; Sysmex, Sysmex XT® 2000 iV; TO, thiazole orange.

This chapter describes technical aspects of enumeration of reticulocytes and Heinz bodies. Interpretation of results is described in Chapter 24 and other chapters. Evaluation of reticulocytes and Heinz bodies occurs when blood is stained with a supravital dye, that demonstrates ribosomal material in reticulocytes and precipitated hemoglobin in Heinz bodies. Manual staining and counting of reticulocytes may be performed even in small clinics but is time consuming and subjective. Automated hematology instrument enumeration of reticulocytes is more precise and rapid and preferred for laboratories with appropriate instrumentation. Reticulocytes vary in appearance and number in various species of animals. Feline punctate reticulocytes have too little RNA to be detected by currently available automated veterinary hematology systems (i.e. Advia 2120®, Sysmex XT 2000 iV®) and must be counted manually on stained blood smears. Birds and reptiles have nucleated erythrocytes and variable numbers of ribosomes which can confuse identification and enumeration.

Heinz body evaluation is usually based on manual counting of the percentage of red blood cells (RBCs) that contain Heinz bodies in stained smears. The clinically important measurement of total mass of precipitated hemoglobin (i.e. Heinz body material) does not consistently correlate with the percentage of RBCs containing Heinz bodies. The size and number of Heinz bodies should be considered in interpretation of severity of the change.

RETICULOCYTE STAINING AND COUNTING

Reticulocytes are the stage in the maturation of erythroid cells between the metarubricytes and mature RBCs. The basic principle of different methods identifying reticulocytes is to stain mRNA in ribosomes of reticulocytes so that they can be differentiated from mature RBCs and nucleated RBCs. In automated systems, the reticulocytes may be further divided into two or three subgroups based on the relative amount of mRNA they contain. Those with most mRNA are considered younger reticulocytes.

Based on the system of detection, a definition is required of how much mRNA or number of dots of ribosomal material is needed to classified an RBC as a reticulocyte. Punctate reticulocytes are frequently not detected by automated hematology systems. Even with manual reticulocyte counting, erythroid cells with only

1–2 dots of ribosomal material are not classified as reticulocytes.

Specimens for reticulocyte quantification are anticoagulated blood, usually in ethylenediaminetetraacetic acid (EDTA). Specimens are suitable if stored at room temperature for up to 48 hours and likely up to 4 days at 4 °C. Specimens should be free of clots, hemolysis or other gross defects. Sample-induced errors in reticulocyte counting include Howell-Jolly bodies, basophilic stippling, blood parasites, large platelets with abundant RNA, and factors that affect determination of the total RBC count.

Manual Methods

RNA is a polyanion and can be stained with many cationic dyes including brilliant cresyl blue (BCB), new methylene blue (NMB), acridine orange (AO), thiazole orange (TO), azure B, auramine O, oxazine 750 and pyronine Y. The two stains used most frequently for manual counting of reticulocytes in blood smears are new methylene blue (1% NMB in saline plus 1.6% potassium oxalate) and brilliant cresyl blue (1% in saline). Equal amounts of blood and stain are mixed and allowed to stand at room temperature: 10 minutes for NMB and 15–30 minutes for BCB. One may increase the proportion of blood if the animal is very anemic. The mixture is remixed and blood smears are made. Counterstaining with a Romanowsky's stain (e.g. Wright-Giemsa) gives a darker reticulum with BCB. For birds, mix 3 drops NMB to 1 drop EDTA blood and allow to stand at room temperature for 10 minutes before making the smear.

Microscopic evaluation of 1000 stained non-nucleated erythroid cells is used to determine the percentage of reticulocytes. That percentage multiplied by the absolute erythrocyte count gives the absolute reticulocyte count per given volume (microliter or liter). Other granular material may be present and should be recognized. Heinz bodies stain a lighter blue than the more purple reticulocyte granules.

Reticulocytes are defined as RBCs that contain more than 2 dots of ribosomal material. Identification of the division between feline aggregate and punctate reticulocytes is more difficult and subjective (Fig. 136.1). Tvedten defines aggregate reticulocytes as having more than 15 dots or as RBC having one or more aggregates of dots. Reticulocytes counted in birds should be the ring form reticulocyte, in which aggregates of ribosomes are arranged in a ring around at least half of the nucleus. These correlate best with polychromasia in birds.[4]

Automated Methods

Automated systems have better precision and accuracy than manual methods because much larger numbers of cells are enumerated, inter-observer variation is avoided and variation in staining quality such as stain precipitates and staining intensity is minimized. Time needed to perform the test is greatly decreased; therefore reticulocyte evaluation becomes routinely available. The coefficient of variation for manual counting of reticulocytes may be 8–23% while for flow cytometric counting it may be less than 3%; however, stains and detection methods may result in variability in sensitivity and specificity.[9]

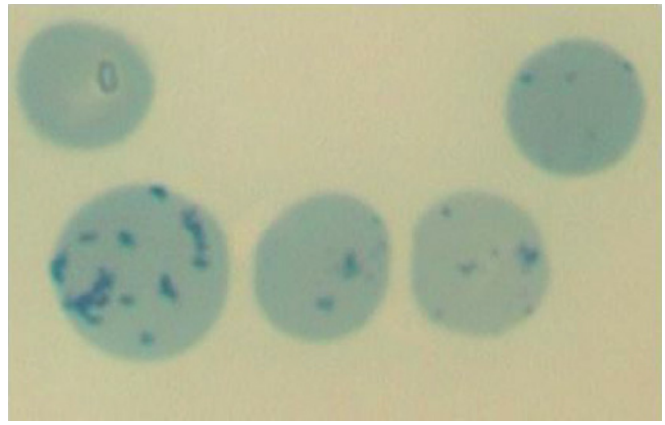

FIGURE 136.1 Feline reticulocytes illustrated are three punctate reticulocytes on the right, an aggregate reticulocyte on the lower left and an erythrocyte (with an artifact) on the upper left. The upper right punctate reticulocyte has three dots (ribosomal material) and it therefore just makes the definition of a reticulocyte.

Automated veterinary instruments, designed for reference laboratories and validated to enumerate canine, feline, and equine reticulocytes, include the Sysmex® and the Advia®.[5] Two in-clinic hematology instruments (IDEXX LaserCyte® and Oxford Science ForCyte®) have been evaluated for reticulocyte counting in dogs and they had fair correlation coefficients compared with the Advia®, and moderate random error for canine reticulocyte counting.[1] The LaserCyte® compared well with the Advia® for feline reticulocyte counts.

The Sysmex XT 2000 iV® uses fluorescence flow cytometry with a semiconductor laser for enumerating reticulocytes. Cells are stained with polymethime, a fluorescent stain, which is optimized to stain RNA.

Other stains, such as TO, AO, and auramine O, are used for flow cytometery.[2] Perkins and Grindem[9] showed that of these three dyes, TO best identified distinct peaks corresponding to aggregate and punctate reticulocytes from cats, while using a dedicated reticulocyte cytometer, the Sysmex R-1000®, and a software package, Retic-count® (Becton-Dickinson Immunocytometry Systems, Sana Jose, CA). Thiazole orange was brighter than auramine O or AO, but required longer incubation times, and the commercially prepared reagent was expensive. Punctate reticulocytes appeared as a widened RBC peak or a shoulder off the mature peak. Aggregate reticulocytes formed a separate peak. Indistinct separation of the punctate reticulocytes required a standardized protocol and use of template histogram regions. Percentages of automated counts matched fairly well manual count results, with a cor-

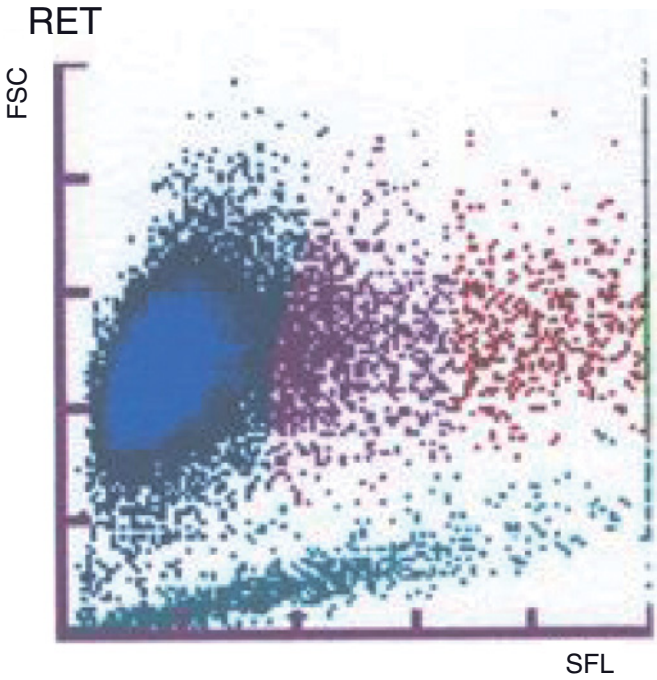

FIGURE 136.2 Reticulocyte dot plot from a cat with Sysmex XT 2000 iV® graphics. Example of marked reticulocytosis (10.3%). Mature RBCs are blue. Reticulocytes are purple and red and extend to the right of the RBCs. Platelets form the linear group of blue-green dots at the bottom. FSC, forward scatter; SFL, side fluorescence which is associated with RNA content.

relation coefficient of 0.72 with aggregate and 0.58 with manual punctate counts.[9]

The automated reticulocyte analysis of the Advia® uses a reagent solution formulated to maintain pH 7.4 as a preferred value, with an osmolality preferably about 292 ± 5 mOsm. At these pH and osmolality ranges, the concentration of the cationic dye, oxazine 750, required for RNA staining is preferably about 9.0 µg/mL to about 10.5 µg/mL. The buffer enhanced penetration results in the dye staining RNA in the reticulocytes in about 20–30 seconds or less. The concentration of dye in the reagent of the method minimizes non-reticulocyte staining of mature RBCs which leads to a good signal separation from the background noise.[14]

Sysmex® canine reticulocyte counts had high correlation (r = 0.90) with manual counts.[5] Sysmex® reticulocyte counts in cats (Fig. 136.2) correlated well with manual aggregate reticulocyte counts (r = 0.86) but not with manual punctate reticulocyte counts (r = 0.50). A mean positive bias of the Sysmex® reticulocyte count over the manual aggregate count was about 6% (range –2% to +19%). This suggested that some punctate reticulocyte were included with the Sysmex® automated reticulocyte count. Equine reticulocytes are detected by the Sysmex® but too few were seen in manual reticulocyte counts to validate any accuracy. The highest absolute reticulocyte counts were seen in horses with highest RBC counts and in foals.[5]

The Advia 2120® automated reticulocyte counts (Fig. 136.3) had excellent correlation to manual reticulocyte counts in 32 dogs (r = 94, slope 0.98) and feline aggregate reticulocyte counts in 33 cats (r = 94, slope 1.16) (unpublished data). However, there was poor correlation with feline punctate reticulocytes. Equine reticulocytes are detected by the Advia®.[12]

The LaserCyte® uses NMB to stain reticulocytes. Reticulocytes are then differentiated from RBCs by different extinction and laser light scatter. The LaserCyte® was compared to Advia® and manual reticulocyte counting in 250 anemic dogs in which two-thirds had a regenerative anemia defined by more than $60 \times 10^3/\mu L$ reticulocytes on manual counts.[13] Weissert et al. found a good correlation (r = 0.66–0.72) but a negative bias combined with a proportional error for the LaserCyte® absolute reticulocyte count compared to the manual and Advia® methods. Thus they recommended instrument specific cut-off values for the LaserCyte® to separate nonregenerative from regenerative anemia which have reticulocytes of $<35 \times 10^3/\mu L$ or $>75 \times 10^3/\mu L$, respectively.[13]

Reporting Methods

Reticulocytes are reported both as a percentage of non-nucleated RBCs and absolute number per liter or microliter. The absolute number of reticulocytes is recommended for interpretation. However, the total RBC count is needed to calculate the absolute count (RBC × percent reticulocytes; see Chapter 22).

Other Indicators of Reticulocyte Status

The Advia® identifies the volume and hemoglobin concentration of each individual RBC analyzed and keeps track of which cells are reticulocytes (Fig. 136.4). Thus the instrument can report reticulocyte size (MCV retic) and hemoglobin concentration (CH retic) by summation of individual results. CH retic and MCV retic have been shown to be sensitive indicators of iron deficiency and response to therapy in dogs (Fig. 136.4).[3]

Note in Figure 136.4 that the reticulocyte cluster in RTC SCAT ABS in the upper left is lower than the cluster in Figure 136.3 as the reticulocytes in iron deficiency are relatively smaller (more microcytic) than normal reticulocytes. Reticulocytes in iron deficiency are still relatively macrocytic and hypochromic compared to the patient's own erythrocytes (Fig 136.4). Note the blue colored reticulocytes in the RTC volume and RTC HC histograms at the lower right are more macrocytic and hypochromic than the RBCs indicated by the red peak. Reticulocyte volume (MCVr) was 65.5 fL and cell hemoglobin of reticulocytes (CHr) was 15.4 pg. Reticulocyte indices may be monitored for response to treatment. For example, when assessing values after experimental iron replacement in iron deficient dogs, the MCVr increased from 65 fL before iron treatment to 82 fL after 11–12 days of iron supplementation, and CHr increased from about 16 pg up to 22 pg.[3]

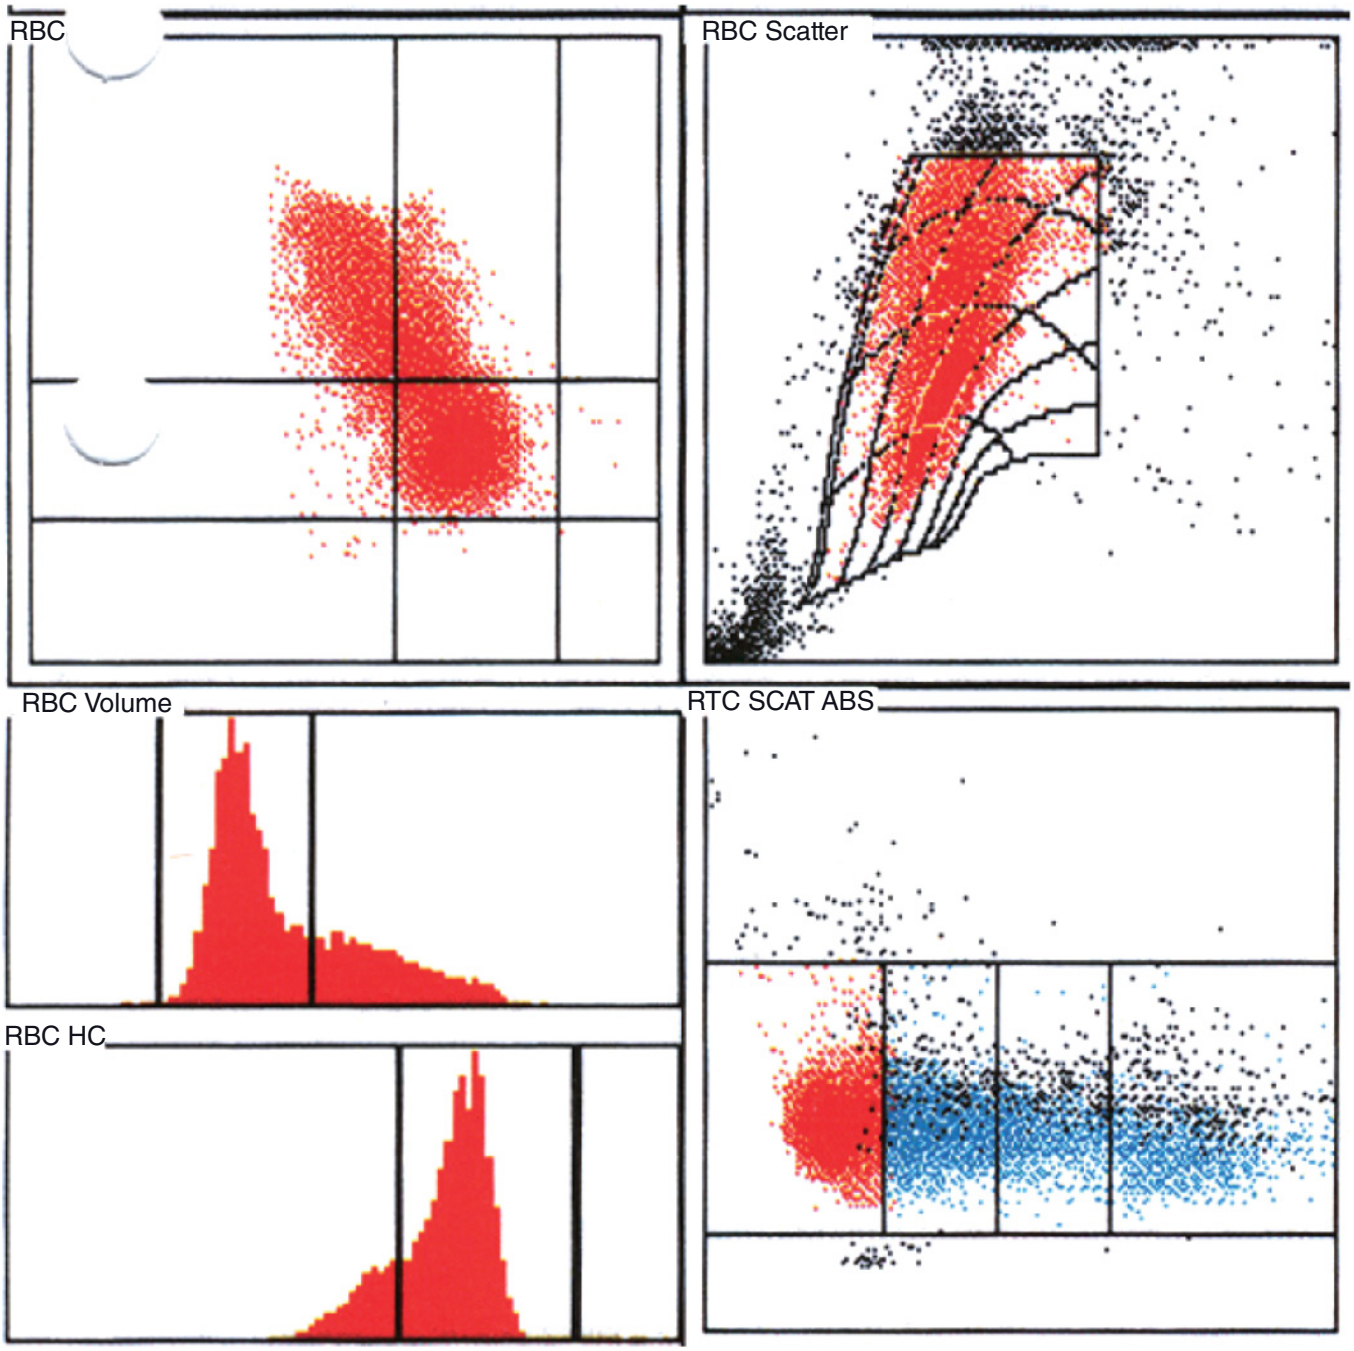

FIGURE 136.3 Advia 2120 graphics of a dog with a regenerative anemia and 21% reticulocytes. The lower right box shows reticulocytes as blue dots extending to the right of mature RBCs (red). The reticulocytes are divided into three groups based on RNA content. Those to the far right have the most RNA. The other four graphics show RBCs analyzed by size and hemoglobin concentration. These illustrate distinct populations of mature normocytic normochromic RBCs and immature macrocytic hypochromic RBCs.

HEINZ BODY STAINING AND COUNTING

Heinz bodies are formed from denatured, precipitated hemoglobin resulting from oxidative damage. Oxidation of sulfhydryl groups cause permanent damage and sulfhemoglobin formation (see Chapter 36).

Manual Methods

Heinz bodies may be seen on blood smears routinely stained with Romanowsky stains if they are large enough to bulge from the surface of the RBC or if they appear lighter and somewhat refractile compared to the rest of the hemoglobin in the RBC. Heinz bodies are

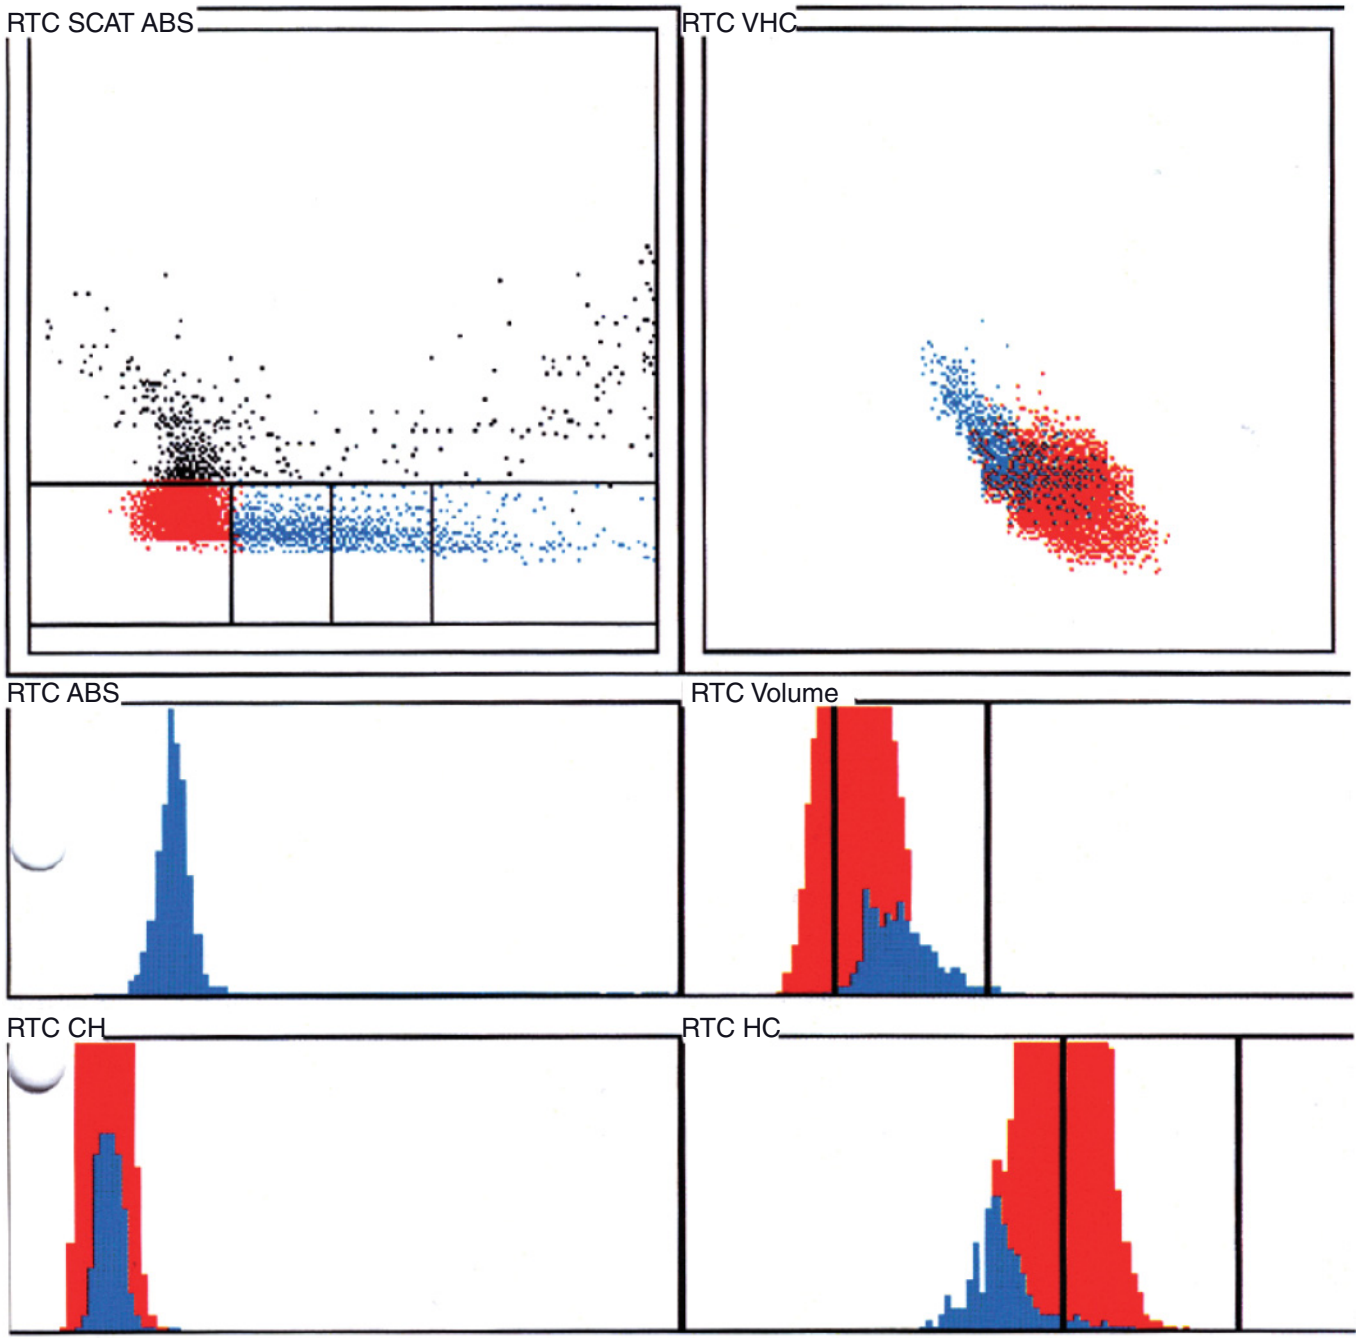

FIGURE 136.4 Advia 2120® reticulocyte graphics from a dog with iron deficiency. Note the reticulocyte (RTC) cluster in RTC SCAT ABS cytogram (upper left) is lower than the cluster in Fig. 136.3 reflecting that reticulocytes in iron deficiency anemia are smaller than normal reticulocytes. The RTC VHC cytogram, RTC volume histogram, and RTC HC histogram on the right show the blue reticulocytes were macrocytic and hypochromic when compared to mature RBCs.

clearly seen in ghost cells as hemoglobin colored bodies attached to the RBC membrane. Heinz bodies are best evaluated on blood smears stained for enumeration of reticulocytes (e.g. NMB- or BCB-stained smears). For birds, mix 2 drops NMB with 1 drop fresh EDTA blood and allow to stand at room temperature for 30 minutes before making the smear.[6]

Heinz bodies stain a lighter blue than ribosomes in reticulocytes. Heinz bodies may be small and numerous, and may be mistaken for reticulocytes. This erroneously affects the reticulocyte count and fails to detect the presence of Heinz bodies. Howell-Jolly bodies are nuclear remnants, stain a darker purple, and have a more distinct border than Heinz bodies. Howell-Jolly

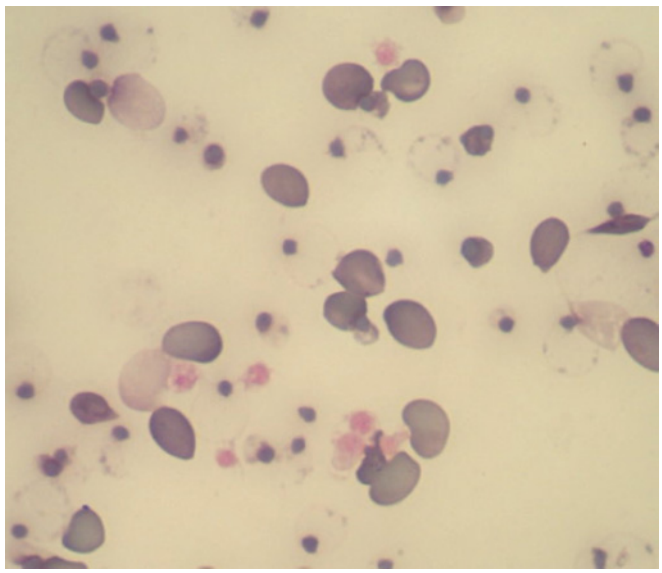

FIGURE 136.5 Modified Wright's-stained blood smear of a cat with onion toxicity. Many round Heinz bodies about the same color as hemoglobin are in ghost cells (lysed RBCs). One large Heinz body is usually seen in cats but small granular Heinz bodies are seen attached to membranes of some lysed RBCs.

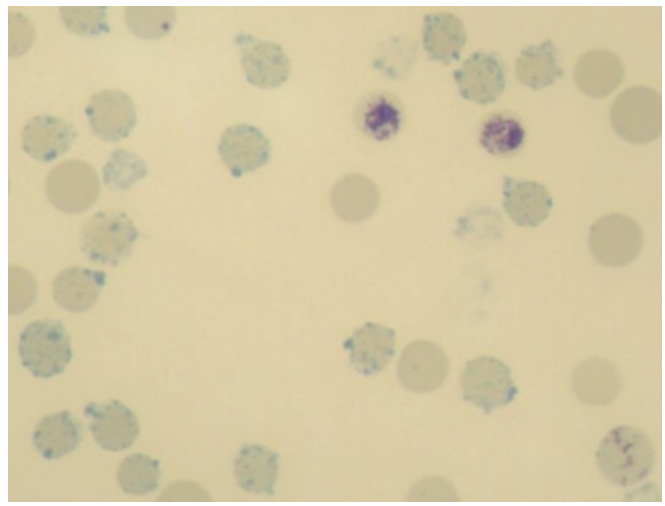

FIGURE 136.6 Brilliant cresyl blue-stained blood smear of a dog with onion toxicity. There are only two reticulocytes with dark blue-purple granules in the upper right. Most of the RBCs have many Heinz bodies which are lighter blue-stained granular bodies.

bodies are usually too few in number to cause much error in manual Heinz body enumeration.

The total mass of precipitated hemoglobin (Heinz body material) is reflective of the magnitude of toxic injury; therefore the report should also indicate whether Heinz bodies were small or large, how much granular Heinz body material was also in the RBC and how much other damage to RBC was seen. Blood turbidity may be measured to estimate the amount of Heinz body material.[7]

Oxidative toxins that form Heinz bodies also cause other changes such as methemoglobin formation, eccentrocytes, ghost cells, and pyknocytes. These other disease changes (and the presence of Heinz body induced artifacts, see below) should be checked for before a final hematology report is released from the laboratory. The presence and amount of those changes should be included in the report. The pattern and amount of change in Heinz bodies, eccentrocytes, and methemoglobin varies with different oxidative toxins and species.[8]

Heinz bodies in the blood sample may cause artifacts such as false increases in MCH and MCHC when determined by in laser hematology instruments, increased hemoglobin concentration when determined by spectrophotometric methods, and increased leukocytes in the basophil channel of the Advia® or earlier H-1® instruments (see Fig. 24.3, p. 156).[10] The increased MCH and MCHC is due to increased optical density of RBCs containing Heinz bodies in the laser system of the Advia®. Heinz bodies interfere with the spectrophotometric measurement of hemoglobin by interfering with light transmission through the sample. This results in an overestimation of hemoglobin concentration. Heinz bodies in ghost RBCs in a cat gave a very erroneous basophil count of 69,750/µL (Fig. 136.5).

Species Variations

The size of Heinz bodies varies greatly. Heinz described them as 1–2 µm in diameter in dogs, rabbits and guinea pigs, but largest in cats, in which they may be up to one-third the diameter of the RBC.[11] Heinz bodies in cats are predominately distinct, large round structures (Fig. 136.5). However, in dogs and other species they may be multiple, small granular bodies that can be mistaken for reticulocytes (Fig. 136.6).

Acronyms and Abbreviations

FACS, fluorescent activated cell sorter; RBC, red blood cell; WBC, white blood cell.

Flow cytometry has emerged as a major technology that is now an essential component of veterinary clinical laboratories.[9] Flow cytometric technology has been incorporated into hematology analyzers (see Chapter 135). This technology has facilitated more precise evaluation of red blood cell (RBC) size and hemoglobin content, determination of an automated white blood cell (WBC) differential cell count, and determination of several platelet parameters including detection of activated platelets. Flow cytometers, not associated with hematology analyzers, are also becoming an integral part of veterinary clinical laboratories, particularly in the area of preclinical safety assessment. These instruments are flexible and can be adapted to many cell and particle systems in which a single cell suspension can be produced and in which appropriate monoclonal antibody or specific cytofluorescent stain is available. Creating a single cell suspension is a relatively simple matter for most hemolymphatic tissues, including blood, bone marrow, lymph node, and spleen. Somewhat more complex processing, including mincing and protease digestion, is required to create single cell suspensions from solid tissues.[2,6] The availability of species-specific monoclonal antibodies for domestic animals has limited the application of flow cytometry in veterinary medicine. However, the number of monoclonal antibodies available for cattle, sheep, pigs, horse, cats, and dogs from both commercial and private sources has expanded dramatically in recent years and many cross-reacting antibodies are also available.

INSTRUMENTATION

Flow cytometry is defined as a technology that measures multiple characteristics of cells or particles as they pass through a light source in a fluid stream.[1,2,11] In addition to cells, flow cytometers can detect chromosomes, proteins, or molecules if they are attached to a particle such as a microsphere. A fluorescent activated cell sorter (FACS) is a flow cytometer that has the capacity to separate fluorescently-labeled cells from a mixed cell population. Most bench top flow cytometers do not have the capability to sort and are dedicated to analytical methods that measure light scatter and emitted fluorescent light.[2,11]

Essential Components of Flow Cytometers

Analytical flow cytometers and cell sorters use a combination of fluidics, optics, electronics, and computer components in their analysis (Fig. 137.1). In the fluidics

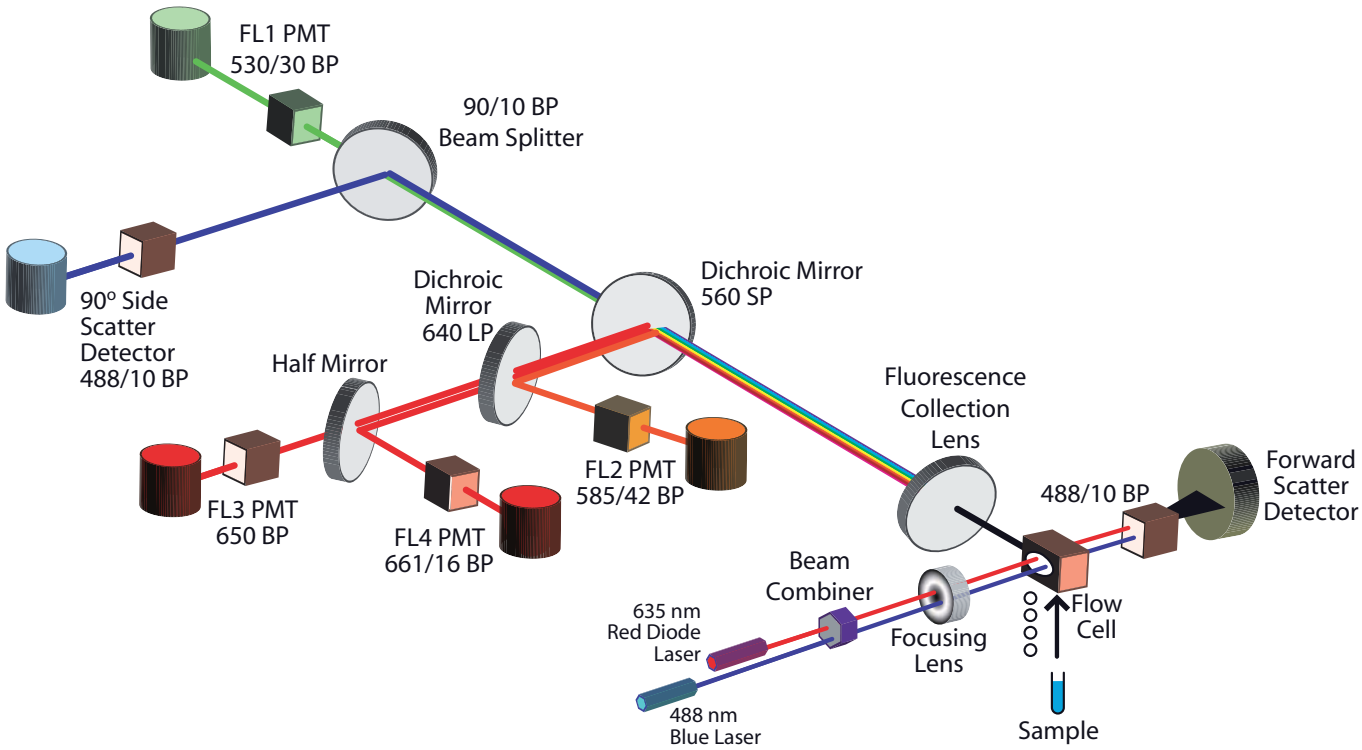

FIGURE 137.1 Schematic of the basic optical and detection components of a flow cytometer. PMT, photomultiplier tube; LP, light path.

system, cells suspended in a physiologic solution are mixed with a sheath fluid that is supplied in a pressurized reservoir. For most mammalian cells, the sheath fluid consists of a phosphate-buffered saline solution. The cell sample stream is at a higher pressure than the sheath fluid. As a result, the sample stream becomes a core in the sheath fluid, which is referred to as coaxial flow. This type of flow permits the cells in the sample stream to intersect the laser one cell at a time. This process is called hydrodynamic focusing. The pressure applied to the sample stream can be adjusted to alter the alignment between the cells and the laser beam. Increasing the sample pressure increases the flow rate by increasing the width of the sample core stream.

The optics component of the flow cytometer consists of a laser and a series of lenses to focus the beam. The number of lasers in a flow cytometer is critical to the number and type of fluorochromes that can be detected by the instrument. Argon gas is commonly used as the excitation laser. The energized light produced by these lasers emits at 488 nm. Many fluorochromes absorb at 488 nm light and emit light in the green (535 nm), orange (585 nm), and red spectrum (630 nm). However, ultraviolet (UV) sensitive or far-red fluorochromes require excitation lasers that emit light in the UV (300–400 nm) or far-red (630 nm) range. Other flourochromes emit at a different wavelength and thus require separate detectors. The number of lasers, optical filters, and detectors determines the overall capacity of a given flow cytometer. Typical bench top systems, such as Becton Dickinson's FACSCalibur (Becton Dickinson, San Jose, CA), have two lasers (argon and red diode) and four fluorescent detectors, thereby providing the possibility of four-color analysis. A typical optical bench from a two laser, four-color flow cytometer is depicted in Fig. 137.1.

Becton Dickinson's newer design in the FACSAria consists of an octagon arrangement of fluorescent detectors (photomultipler tubes) that allow up to four lasers and 14 multicolor parameters.

Light signals detected by the detectors are converted to electronic voltage pulses. Forward-angle light scatter is converted to voltage pulses by a photodiode. Side-angle scatter and fluorescent light signals are converted to voltage pulses by photomultiplier tubes. Finally, voltage pulses are converted to a digital output and transferred to a computer.

Basic Principles of Light Scatter and Fluorescence

As cells pass single file through the laser bean, flow cytometers are capable of measuring two types of light scatter as well as detecting fluorescence.[2,11] Forward-angle scatter light is laser light diffracted around the cell and is proportional to the size or volume of the cell. Light scatter in a 90° angle (side-angle scatter) is proportional to the internal complexity (i.e. granularity) of the cell. Based on these light scatter features, cells can be graphically displayed and separated based on their size and granularity. This is the principle used by laser-based clinical hematology analyzers to perform WBC differential cell counts (Fig. 137.2).

In addition to forward-angle and side-angle light scatter, flow cytometers are able to detect fluorescent

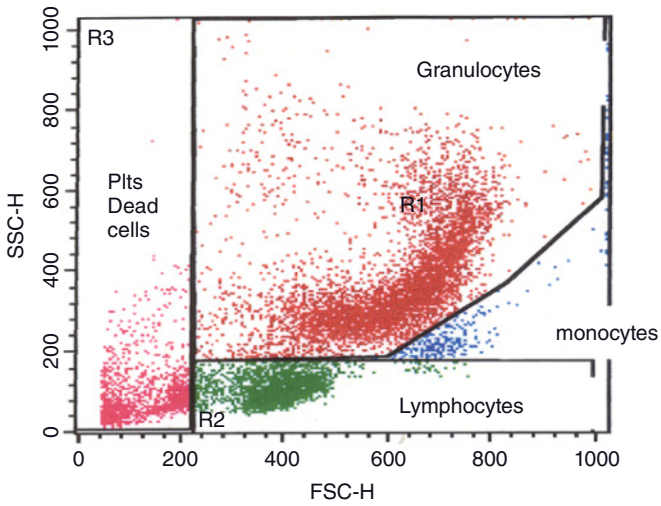

FIGURE 137.2 Forward-angle (FSC-H) versus side-angle (SSC-H) light scatter dot plots of blood leukocytes with gating used to perform differential WBC counts.

labels on cells. Depending on the capabilities of the flow cytometer, several fluorochromes can be detected simultaneously. This approach provides for identification of lineage-specific markers on a subset of cells in complex mixtures of cells or for detecting altered physiologic (i.e. activation) or pathologic (i.e. neoplastic, apoptotic) states of cells.

Principles of Cell Sorting

Cell sorters are flow cytometers that have the capacity to isolate a subpopulation of cells. Cell sorters have a nozzle tip that oscillates the sample core stream resulting in a stream that breaks up into droplets. Each droplet contains a cell. Typically the cell to be sorted is fluorescently labeled. As the droplets pass through the laser, the fluorescent label is detected and the droplet will be charged either positively or negatively by a charging electrode. Charged droplets travel toward positively or negatively charged high voltage platinum plates into a collection system (test tube, 96-well microtiter plate, glass slides etc.).[2,11] The major advancement in recent years is ease of operation. The operation of current bench top analytical flow cytometers is relatively simple and permits opening access to multiple users once they have had some training. State of the art cell sorters still require a dedicated trained operator to operate and maintain the equipment.

SAMPLE PREPARATION

Collection and processing protocols vary with the cell type and assay method used.[2,18] When analyzing blood cells, it is possible to analyze a whole cell sample and then focus (i.e. "gate on") on the cell population of interest. Alternatively, the cell population of interest can be isolated before analysis. Both approaches have advantages and disadvantages. Isolating a cell population can be time-consuming and can introduce artifacts (e.g. cell activation, aggregation, altered cell size or shape, or even cell death). Alternatively, identifying a subpopulation of cells may require additional steps such as addition of one or two fluorescently-labeled monoclonal antibodies. Therefore, the blood cell collection and processing technique should be carefully researched to determine the most suitable method for a particular application.

White blood cells or WBC subpopulations can be isolated using density gradient centrifugation, or whole blood specimens can be used. Presently, the whole blood method is used most frequently because it is faster and easier to perform and avoids cellular alterations associated with density gradient centrifugation. Red blood cells can be removed by addition of an RBC lysis buffer. Commercially available lysis buffers come with a cell fixative added. Fixation prevents activation and clumping of WBCs and does not adversely affect binding of most antibodies. If tests of neutrophil function are performed, whole blood may be preferred to prevent in vitro neutrophil activation during processing (see Chapter 141). Red blood cells can be analyzed using anticoagulated whole blood or RBCs collected from the RBC layer of cells after centrifugation of whole blood. Bone marrow and solid tissue require somewhat more elaborate processing procedures (see Chapter 132). Platelet-rich plasma is most frequently used for platelet analysis. Platelet-rich plasma is prepared by low speed centrifugation of anticoagulated whole blood. Platelets become activated and clump when pelleted. Therefore, platelet function must be inhibited for most flow cytometric applications. Various methods of platelet function inhibition, including paraformaldehyde fixation, addition of prostaglandin E1, and lowering pH to 6.5, have been used.

SAMPLE PROCESSING

A large spectrum of flow cytometric tests have been described for analysis of blood cells. A basic method of preparation is common to most assays. In general, these techniques involve incubation of cells, typically for 30 minutes, with a monoclonal antibody or fluorochrome stain directed against a cellular antigen of interest. If this antigen is inside the cell, cells may need to be permeabilized to permit the marker to enter the cell. If the monoclonal antibody is labeled with a fluorescent dye, the cell suspension is washed, resuspended in buffer solution, and analyzed. If the primary antibody is not labeled, a labeled secondary antibody, typically an anti-mouse immunoglobulin antibody is added. The secondary antibody binds to the first antibody in proportion to the amount of primary antibody that is bound. After removing excess unbound secondary antibody by washing, the specimen is analyzed. The number of cell washes used varies between investigators.

Samples should always be inspected grossly or microscopically for cell clumps. Cell clumps can readily plug flow cytometers. Clumping of the sample can be

greatly reduced by adhering to optimal cell concentrations of no greater than 1×10^6 cells/mL. Cell clumps can be removed from samples by filtering the sample through special filters with 30 µm pores that are designed to fit into tops of 6 mL tubes.

CHOICE OF ANTIBODY AND FLUOROCHROME

The spectrum of species-specific and cross-reacting antibodies available for species of interest to veterinary medicine has increased dramatically in recent years. The choice of antibody for cell labeling is of critical importance to successful flow cytometric procedures. Some antibodies work well for flow cytometric procedures while others do not. Many commercially available antibodies have been tested for use in flow cytometric applications. A partial list of several references that have used species-specific and cross-reactive antibodies is available in Chapter 4. If the antibody has not been tested in the species of interest, the commercial antibody should be tested at serial dilutions to determine the optimal titer at which the nonspecific binding is minimum, specific antibody binding is maximum, and therefore the fluorescence signal-to-noise ratio is at its highest.[3] Binding of some antibodies to cells may be affected by processing conditions such as cell fixation, while other antibodies may not be affected. Many antibodies are nonspecifically taken up by dead and dying cells resulting in false positive labeling.

The choice of fluorochrome is also important. The choice is limited to which fluorochrome the excitation lasers can excite. Users should always verify before purchase that the fluorochrome of interest can be excited by the exciting lasers. Fluorescein is a commonly used label that has the advantage of being highly stable; however, it has high background fluorescence. The red emitters (e.g. PerCy5, PerCP), are somewhat less stable but have a lower background fluorescence.

SAMPLE ANALYSIS

A few general comments about operation of flow cytometers will be presented. Cells are typically initially displayed as forward-angle versus side-angle light scatter dot plots. Most frequently, side scatter (i.e. granularity) is on the *y*-axis and forward scatter (i.e. size) is on the *x*-axis. Voltages are adjusted by the operator until the cells of interest are centered in the dot plot. Although it is logical to think that each dot on the dot plot identifies one cell, each dot actually identifies all cells with the same scatter properties. Therefore, one dot could represent one cell or many cells. Gates can be set around cell population of interest to quantify them.

If cells are fluorescently labeled, fluorescence can be detected in a separate plot. Fluorescence intensity (on a log scale) is usually plotted against forward-angle light scatter. Histogram plots or dot plots can be used. The most critical determination to be made is that of which cells are fluorescing. This is complicated by the fact that all cells have some level of background fluorescence and the apparent fluorescent intensity of a cell population can be changed by adjusting the gain setting of the instrument. Some fluorescent labels have a relatively high level of background fluorescence that is greater if samples have been exposed to light. Background fluorescence is relatively high for fluorochromes that are green, yellow, and orange emitters. Alternatively, red emitters have comparatively low background fluorescence. To help the operator set a gate between fluorescent and non-fluorescent cell populations, several controls should be used. These include a negative control incubated with an irrelevant isotype-matched control antibody and positive-labeled control. The negative control specimen frequently cannot be adjusted to zero because of nonspecific antibody binding and autofluorescence, so values are typically adjusted to a value of <10 channel units. If a positive control is not available, fluorochrome-labeled beads can be substituted in some applications.

If two or more fluorescent markers are used in a single sample, the emission spectra of the fluorochromes may overlap. For example, if cells are labeled with fluorescein (FL1 emission peak at 530 nm) and phycoerythrin (FL2 emission peak at 575 nm), the detector for fluorescein will detect some of the phycoerythrin in the sample and vice versa. To compensate for this overlap of fluorescence, the operator puts a sample in labeled only with fluorescein (green fluorescence) and adjusts the FL2 detector to subtract out the percentage of fluorescein that is detected (i.e. typically to <10 channel units). A sample labeled only with phycoerythrin is then added and the FL1 detector is adjusted remove the phycoerythrin that is detected.

After this quality control procedure is performed, a dual-labeled or multi-color sample can be acquired and analyzed with confidence and accuracy. There is software available that will allow the user to compensate for fluorescence overlap after acquisition (WinList™ Verity Software).

Threshold setting permits the operator to set a limit below which data will not be detected. Setting a higher forward-angle and side-angle light scatter threshold eliminates small particulate debris and/or platelets from the analysis. If the threshold is raised to 200, platelets will be excluded from acquisition or analysis of the preparation. Threshold setting for fluorescence intensity eliminates nonspecific fluorescence. Threshold settings frequently improve the results obtained.

INSTRUMENT MAINTENANCE

Technical advances in design and computerization of flow cytometric instrumentation has opened the use of these instruments to multiple users including laboratory staff, researchers, and graduate students. Flow cytometers are highly adaptable to many different techniques and the operator has great flexibility in manipu-

lating the appearance of the computer-generated graphics and the final results obtained. As such, the operator has the capacity to produce valid or nonsensical results.

All results obtained are dependent on the quality of routine maintenance, calibration, and troubleshooting. While it is possible to have multiple people operating a particular flow cytometer, it is essential to have one responsible person in charge of calibration, maintenance, and troubleshooting. Maintenance and calibration are instrument dependent and will not be discussed in detail here. In general, they involve daily calibration using fluorescent beads, a checklist of routine maintenance, a troubleshooting guide, a protocol for start up and shut down each time the instrument is used, and a maintenance contract with the manufacturer.

APPLICATIONS IN VETERINARY CLINICAL LABORATORIES

The potential applications of flow cytometry are diverse.[15] In this chapter, we will list some techniques that provide clinically relevant data or provide more valid or more quantifiable data than are presently available. Some of these tests are discussed in more detail in other chapters in this book.

Erythrocyte Applications

Major applications of flow cytometry to RBCs include determination of RBC indices on individual cells, determination of reticulocyte count and reticulocyte maturation index, and determination of anti-RBC antibody binding.

Erythrocyte Indices

Newer flow-based hematology analyzers determine the size and complexity of individual RBCs and provide RBC histograms. This provides much more clinically relevant information than previous measures of RBC indices (see Chapter 135).

Reticulocyte Count and Reticulocyte Maturation Index

The manual method of reticulocyte counting is relatively imprecise, with coefficients of variation of 8% to 23% reported for dog blood.[12] Flow cytometry is a more precise method for reticulocyte counting. The technique is discussed in Chapter 136.

Erythrocyte-bound Immunoglobulin

The direct anti-globulin (i.e. Coombs') test has been routinely performed in veterinary laboratories. However, the sensitivity is relatively low being in the range 48–58% when performed by the standard tube method (see Chapter 140).[10,23] More recently, flow cytometric techniques have been developed for detection of erythrocyte-bound immunoglobulin in dogs and horses.[10,23] In two studies, this resulted in sensitivity of 92% for diagnosis of immune-mediated hemolytic anemia. In this technique, washed RBCs were incubated with fluorescein isothiocyanate (FITC)-labeled sheep-antidog IgG, FITC-labeled goat-antidog IgM, or FITC-labeled goat-antidog C3. Cells were washed, resuspended and fluorescence analyzed in a flow cytometer. These results indicate that the flow cytometric test is more sensitive that the Coombs' test, but may also be somewhat less specific.

Platelet Applications

Clinical applications of flow cytometry for evaluation of platelets include quantitation of immature (i.e. reticulated) platelets, detection of anti-platelet antibody, and detection of activated platelets. Immature platelets have been quantified in blood from humans, dogs, and horses in much the same way that reticulocytes are analyzed.[13,22] Immature platelets contain greater RNA content compared to mature platelets and this residual RNA can be quantified by incubating platelets with the fluorescent stain thiazole orange. The percentage of platelets with increased fluorescence intensity can then be determined (see Chapter 135).[22]

Flow cytometry has been used to detect anti-platelet antibody in a manner similar to that for detection of anti-RBC antibodies.[7] This test method is discussed in Chapter 140.

A variety of flow cytometric tests have been developed to detect circulating activated platelets. These include binding of fibrinogen to platelets, binding of monoclonal antibodies to activation-dependent markers on the platelet surface, detection of platelet microparticles, detection of platelet shape change, and detection of platelet-leukocyte aggregates (see Chapter 142).[1,4,21] Activation markers detect conformational changes in surface proteins (e.g. activated glycoprotein IIbIIIa), translocation of granule-associated proteins to the platelet surface (e.g. P-selectin, glycoprotein 53, dense granule membrane protein), or binding of secreted proteins to the platelet surface (e.g. thrombospondin). The activation-associated conformational change in glycoprotein IIbIIIa can be detected by quantifying fibrinogen bound to the platelet surface or by addition of antibodies that specifically react with activation-associated binding sites. Few antibodies are available for use in animals. Anti-human fibrinogen cross-reacts with cat, horse, and pig, but not with dog.[4,21] A monoclonal antibody that recognizes a receptor-induced binding site on canine fibrinogen has been described.[1] A monoclonal antibody that reacts with canine P-selectin also has been described.[4]

Platelet microparticles can be measured as an indication of platelet activation. Platelet microparticles are vesicles derived from the plasma membrane of activated platelets. Platelet microparticles can be detected by centrifuging citrate-anticoagulated blood at

10,000 × *g*.[24] Centrifugation results in nearly complete removal of platelets. The platelet-poor plasma is then incubated with a platelet membrane-specific antibody, such as anti-glycoprotein IIbIIIa. Thereafter, the number of fluorescent particles is quantified. Increased numbers of platelet microparticles have been reported in pigs during experimental endotoxemia.[5]

Activated platelets adhere to leukocytes.[21] Adhesion is through expression of P-selectin (i.e. CD 62) on the surface of activated platelets and its interaction with platelet-specific glycoprotein ligand on the surface of leukocytes. P-selectin is normally expressed on the internal surface of alpha granules but, upon degranulation, is transported to the platelet surface. Activated platelets primarily bind to neutrophils and monocytes. The test is usually done using heparinized whole blood, because platelet-leukocyte adhesion is calcium dependent.[21] Prostaglandin E1 can be added to prevent post-collection platelet activation.[21] The assay is based on fluorescent labeling of platelets in whole blood or more frequently in whole blood after erythrocyte lysis. Cells are then displayed as forward-angle versus side-angle scatter plots, and the neutrophils and/or monocyte populations are gated and analyzed for fluorescence intensity. Fluorescence of leukocytes is an indication of binding of platelets to the leukocyte surface. Increased numbers of platelet-neutrophil aggregates have been identified in horses during intensive treadmill exercise[20] and in ponies during the prodromal stages of alimentary laminitis.[21]

Leukocyte Applications

A variety of flow cytometric tests have been described for evaluation of leukocytes. Of these, analysis of lymphocyte subtypes and immunophenotyping of hemic neoplasia have found clinical applications.[6] Neutrophil function tests have been described and have been used extensively for research studies but it is unclear if these tests will find clinical applications other than detection of the relatively rare hereditary neutrophil function defects (see Chapter 141).

Immunophenotyping of Leukocytes

Immunophenotyping of leukocytes involves the use of antibodies and fluorochrome reagents to identify specific cell types in blood, bone marrow, or solid tissues. Fluorochromes are generally not species-specific and, therefore, can be used for a variety of species. Alternatively, antibodies that detect specific markers on cell membranes tend to be species-specific. This technique is particularly useful in performing differential cell counts on bone marrow (see Chapter 132), in classifying myeloproliferative and lymphoproliferative diseases (see Chapter 143), and in evaluating immune dysfunctions associated with lentivirus and feline immunodeficiency virus infections (see Chapter 55) and associated with ricketsial and autoimmune diseases (see Chapters 33 and 34).

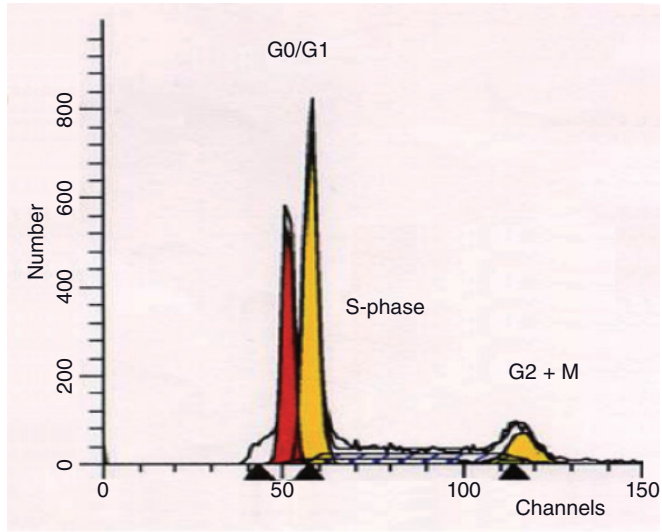

FIGURE 137.3 Analysis of DNA ploidy and cell cycle determination by use of flow cytometry. Peritoneal fluid from a horse was analyzed. Yellow peaks represent aneuploid DNA that is an indication of tumor-associated alterations in chromosome number.

Determination of Clonality and DNA Ploidy

In addition to evaluation of the immunophenotype of potentially neoplastic populations, markers of clonality and DNA ploidy can be determined as indicators of malignancy (see Chapter 143). Clonality is an indication that cells are progeny of a single cell and therefore likely represent a malignant population. For B-cell malignancies, the exclusive presence of kappa or lambda immunoglobulin light chain rather than a mixture of the two indicates clonality. Likewise, the presence of a specific T cell receptor rearrangement indicates clonality of T cell malignancies. DNA ploidy and cell cycle analysis can also be used to identify malignant cells (Fig. 137.3). Peaks in DNA histograms, in addition to the normal diploid peak, are an indication of tumor-associated alterations in chromosome number. Cellular DNA is usually stained with the fluorochrome propidium iodide.[11]

Evaluation of Neutrophil Function

A variety of flow cytometric tests have been described to define neutrophil function (see Chapter 141). These tests include oxidative metabolism,[2] phagocytosis, degranulation, activation markers, surface expression of secreted granule contents, shape change, F-actin content, and opsonization.

Bone Marrow Applications

Flow cytometric techniques have been used to determine bone marrow total and differential cell counts, determine megakaryocyte maturation, quantify the rate of cell proliferation, and detect and differentiate leukemias and myelodysplastic syndromes. Several

approaches have been used to perform bone marrow differential cell counts. Rat bone marrow differential cell counts were done after labeling cells with the fluorochrome 2′,7′-dichlorofluorescin-diacetate.[3] This reagent preferentially labels peroxidase-positive cells. In the presence of hydrogen peroxide, peroxidase converts 2′,7′-dichlorofluorescin-diacetate to the fluorescent dichlorofluorescein compound. The technique is relatively simple. Anticoagulated marrow samples are incubated with 2′,7′-dichlorofluorescin-diacetate for 15 minutes, hydrogen peroxide is added and incubation is continued for an additional 15 minutes. Marrow specimens are analyzed as log green fluorescence versus forward-angle light scatter plots. When compared to manual differential cell counts, this technique was able to identify populations of proliferating and mature myeloid cells, proliferating and mature erythroid cells, and megakaryocytes.[3] The technique was not able to differentiate lymphoid cells from mature erythroid cells. Therefore, the technique was combined with the use of monoclonal antibodies to detect B and T cells. Bone marrow of several species has also been analyzed by use of the lipophilic cationic dye 3,3′-dihexyloxacarbocyanine iodide.[8] The technique was simple, involving incubation of bone marrow aspirate material with the dye for 30 minutes and analysis as log green fluorescence versus forward-angle light scatter plots. Populations of mature and immature myeloid cells, mature and immature erythroid cells, and lymphocytes were detected. The technique gave acceptable differential cells counts for mouse, rat, dog, and cynomolgus monkey.[8]

Canine and feline bone marrow was evaluated by use of forward-angle versus side-angle light scatter plots.[16,19] This relatively simple approach gave acceptable identification of mature and immature granulocytes and mature and mature erythroid cells, but failed to identify lymphocytes or monocyte/macrophages. Identification of subpopulation within the bone marrow was further refined through use of lineage-specific monoclonal antibodies.[17] Canine bone marrow was also evaluated by labeling bone marrow with anti-dog CD45 and analyzing cells in scatter plots as side-angle light scatter versus fluorescence intensity.[18] Populations of mature granulocytes, myeloblasts, erythroid precursors, lymphocytes, and monocyte/macrophages were identified.

A method for bone marrow total and differential cell counts in preclinical safety assessment studies for rats, mice, monkeys and dogs is described in Chapter 132. It involves using a combination of anti-CD45 and anti-transferrin receptor (CD71) antibodies. This is coupled with side scatter for cellular complexity and nucleic acid staining with LDS-751 for separation of nucleated cells from RBCs.

Megakaryocyte ploidy can be analyzed by use of flow cytometry. Megakaryocytes are labeled with a megakaryocyte-specific monoclonal antibody and DNA is labeled with propidium iodide. Monoclonal antibody-associated fluorescence is used to identify megakaryocytes and the intensity of propidium iodide staining varies directly with the number of nuclei present in the cells.

Proliferative activity of bone marrow has been measured by use of the fluorescent DNA stain propidium iodide or by staining with bromodeoxyuridine.[14] Mitotic activity causes slight variations in the DNA content of cells that result in altered fluorescence. Bromodeoxyuridine is incorporated into mitotic cells. An anti-bromodeoxyuridine antibody is needed for flow cytometric analysis. Both the frequency of mitosis and the stage of mitosis can be determined. The proliferative rate of a specific population of bone marrow cells can be determined by labeling the population with a specific monoclonal antibody and with propidium iodide.[14]

Cytopathology Applications

Flow cytometry has been used to analyze cell from tissues other than blood and bone marrow. Techniques for creating a single cell suspension vary with the tissue studied.[6] Because of the extensive processing required for some tissues, staining and examination of cells before analysis is essential to establish that the cell type of interest is present and that the cells are intact. Flow cytometry has been applied to evaluation of cytologic tissue from many tissues including lymph node, urine, semen, breast, lung, liver, pancreas, and endocrine tissue.[6] Flow cytometric analysis has been used almost exclusively for detection and differentiation of malignancies (Fig. 137.3). The only test frequently applied to cytologic specimens is DNA analysis for aneuploidy and proliferation rate. However, tests for clonality and cell lineage determination have been applied to lymph node aspirates.[6]

CONCLUSION

Flow cytometric technology has been incorporated into conventional hematology analyzers, and as such has become part of many veterinary clinical laboratories. Flow cytometers, not associated with hematology analyzers, are in routine use in preclinical safety assessment laboratories, research laboratories, and in some clinical laboratories. As instrumentation, reagents, and demand for flow-based testing continue to advance, use of these instruments should continue to increase.

Acronyms and Abbreviations

ACT, activated clotting time; Ag, antigen; APC, activated protein C; APCR, activated protein C resistance; α2-AP, alpha-2-antiplasmin; aPTT (or PTT), activated partial thromboplastin time; AT, antithrombin; Ca^{2+}, calcium ions; DDAVP, 1,8-desamino-d-arginine vasopressin or desmopressin; DIC, disseminated intravascular coagulation; EDTA, ethylenediaminetetraacetic acid; ELISA, enzyme linked immunosorbent assay; F 1+2, prothrombin fragment F 1+2; FVII, coagulation factor VII, and so on; FXa coagulation factor X activated, and so on; FII, prothrombin, FI, fibrinogen; FDPs, fibrin/fibrinogen degradation products; FM, fibrin monomers; FPA, fibrinopeptide A; FPB, fibrinopeptide B; HMWK, high molecular weight kininogen; HS, heparin sulfate; INR, international normalized ratio; ISI, International Sensitivity Index; IV, intravenous; LMWH, low molecular weight heparin; NPT, near patient testing; PAI-1 or 2, plasminogen activator inhibitor 1 or 2; PC, protein C; PL, phospholipids; pNA, para-nitroaniline; PPP, platelet-poor plasma; PR, prothrombin ratio; PS, protein S; PT, prothrombin time; SF, soluble fibrin; SLE, systemic lupus erythematosus; TAT, thrombin anti-thrombin; TEG, thromboelastography; TF, tissue factor; TM, thrombomodulin; t-PA, tissue plasminogen activator; TT, thrombin time; UFH, unfractionated heparin; u-PA, urokinase plasminogen activator; VWD, von Willebrand disease; VWF, von Willebrand factor.

METHODOLOGY OF PLASMA BASED HEMOSTASIS TESTS

Blood Sampling

Proper blood sampling is critical to hemostasis investigation in all species. Ideally, drawing the blood into a plastic syringe containing the appropriate amount of citrate for the volume of blood should be used. As this procedure is not always easy to perform, blood is drawn and then transferred to the citrate tube. Blood sampling through non-heparinized catheters may be done, if necessary, after flushing the catheter with at least 5 mL of saline solution (or six times the catheter dead space) and then discarding the first 5 mL of blood collected.[114]

Blood sampling through heparinized catheters generally should be avoided, though a flush and discard procedure as above in healthy dogs produced similar results as samples collected from direct venipuncture.[93]

As a general rule, care should be taken to minimize platelet or coagulation and fibrinolytic system activation. Blood should be collected by atraumatic venipuncture on the first attempt, allowing a free flow into the syringe and avoiding unnecessary vacuum as turbulence may activate platelets. If collection is difficult, as in the case of sampling through a hematoma or exiting and re-entering the vein, a new vein site should be selected. Discarding a few drops of blood or using two tubes (the former for other purposes, the latter for coagulation studies) could be standardized, but this is not necessary if a clean venipuncture is obtained.[133]

In the plasma based assays, the sample is citrated plasma that is harvested either from siliconized glass or plastic tubes. In humans, statistically significant differences in test results have been documented in comparisons of plastic versus glass tubes, but these differences are small and rarely of clinical importance.[70] The blood collected should be anticoagulated with trisodium citrate at an anticoagulant to blood ratio of 1:9 (by using 3.2% or 3.8% citrate tubes according to the laboratory preferences). Minimal influence on assay results in healthy dogs or dogs with hereditary hemostatic disorders have been documented using these two citrated formulated tubes.[108,135]

It is important to maintain the 1:9 citrate to blood volume ratio. Overcitrated samples (e.g. in case of erythrocytosis where there is less plasma with the same amount of citrate) may have reduced coagulation activity or prolonged times because of the excess of citrate. Undercitrated samples (e.g. in case of severe anemia where there is more plasma with the same amount of citrate) may be hypercoagulable or show reduced times. Even the hematocrit of the sample may influence the hemostatic assays, and the correction of the citrate amount has been suggested in humans according to the following formula: citrate volume in mL = 0.002 × (100 − hematocrit value) × volume of collected blood.[83,114,130,133]

It has been shown recently that EDTA samples can be considered as a possible suitable alternative to citrated samples for some hemostasis testing. Assays should be performed as soon as possible after the sample collection, and appropriate reference intervals are needed.[23,42]

Sample Processing and Storage

After confirming the absence of any clots in the sample, the citrated blood should be centrifuged for 10–15 minutes at 1500 × *g*. The general recommendation is to centrifuge and remove the plasma within 1 hour and test it within 4 hours from the drawing. The supernatant platelet-poor plasma should be transferred to plastic tubes by using plastic pipettes.[114] Recently, it has been documented that is possible to analyze human blood specimens for several coagulation assays in the original collection tube after 24–48 hours, without observing clinically relevant changes.[166]

Storage of canine citrated plasma samples collected from healthy animals yielded stable hemostasis results for 48 hours when stored at 24 °C (even better than samples kept at 4 °C), except for a mild decrease of fibrinogen at 24–48 hours. This evidence is important for samples that should be shipped to a referral laboratory. Similar studies are lacking in other species.[39]

In the case of frozen plasma samples it is advisable to test them promptly after thawing, and the process of thawing should be rapid to minimize cryoprecipitate formation.[133]

Coagulometers

Coagulometers can be manual, semiautomatic, or automatic devices (Fig. 138.1) depending on the operational procedure available in the laboratory. Manual coagulation testing, such as the tilt tube or manual hook method, are seldom used.[67]

Introduction of semi or fully automated coagulometers has improved precision, reduced operator variability, and has resulted in significant cost and time savings. These coagulometers employ various physical clot detection methods such as mechanical by a steel ball, turbidimetry, and nephelometry or light scatter, or a combination of the above methods.[56,68,129]

In the coagulometer using mechanical end-point detection, the sample and reagents are dispensed into a cuvette, which holds a disposable little steel ball. The ball rotates and a magnetic sensor detects the change of the magnetic field, which occurs when the forming fibrin strands interfere with the rotation of the ball.[56,67,104,151]

The coagulometer using optical end-point detection of fibrin is based either on turbidimetry or nephelometry (detection of light scatter). In addition to the clotting assays, the detectors can also be used for turbidimetric immunochemical assays, and, in the case of turbidimetry, the use of specific filters in combination with the light source of the instrument allows chromogenic assays to be performed. The time elapsed until the

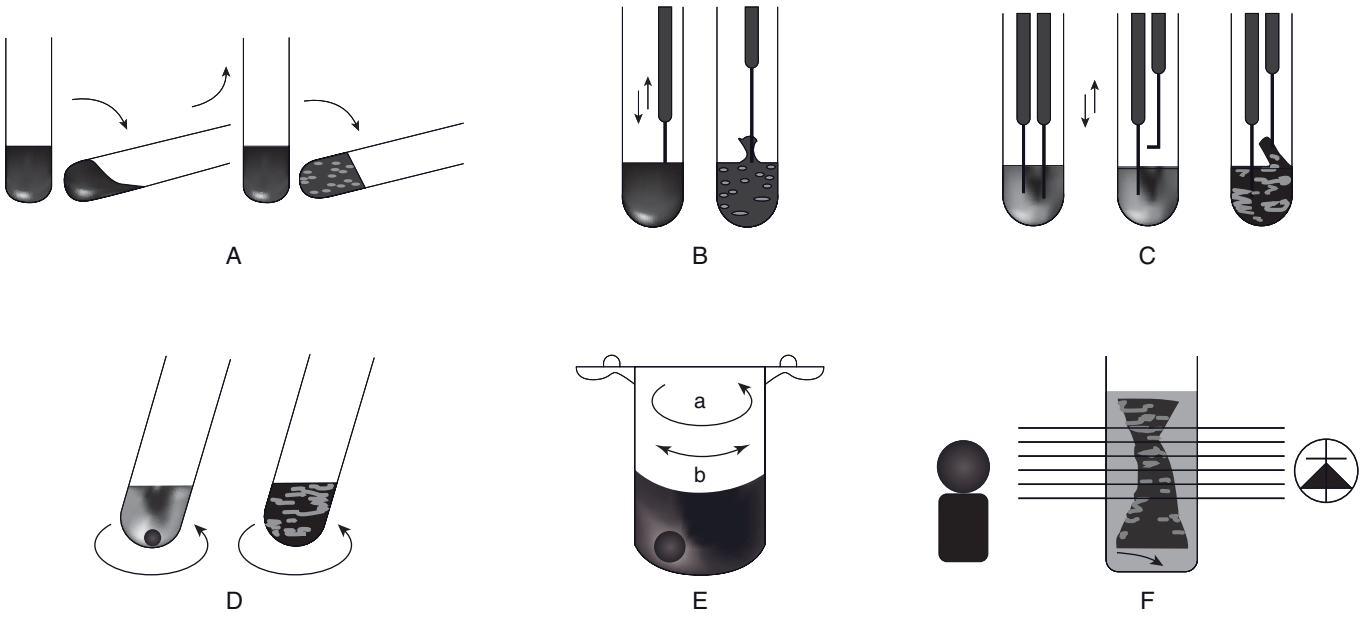

FIGURE 138.1 Clot Detection Methods. (**A**) The manual tilt tube method provides a visual clot endpoint.[121] (**B**) The manual hook method uses a hook to lift the clot out of the sample, indicating the endpoint.[68] (**C**) The hook mechanical coagulometer.[129] It employs two electrodes. Before clot formation, the electrical circuit is made with both electrodes immersed in the plasma sample (left) and interrupted when the hook is lifted (center). When the clot is formed (right) the fibrin clot maintains the conductivity and the endpoint time is recorded. (**D**) The ball coagulometer, rotational technique. The steel ball is kept stationary both by gravity and a magnet at the bottom while the tube is rotating. During clot formation the electromagnet detects the change of the magnetic field, which occurs when the forming fibrin strands interfere with the movement of the ball on one side. (**E**) The ball coagulometer, oscillational technique. The steel ball is oscillated in the tube with the plasma sample. The ball movement is secured by a magnet. When the fibrin clot forms the ball stops moving and the endpoint time is recorded. (**F**) Clot detection in an optical and mechanical coagulometer. The source of light (tungsten lamp) at the left is continuously adjusted to give a constant voltage at the photodiodes located at the right. When the voltage change exceeds predetermined limits, the clotting time is recorded.

signal begins to change is the "clotting time." Depending on the instruments, different algorithms are used for the calculation of the end-point and the threshold is set at different ways, e.g. end-point is set when a total change of absorbance/scatter of 50% has been reached or when the time for a predefined change of absorbance has occurred.[56,67,104,151]

All clot detection methods have their limitations – optical devices suffer when lipemic or icteric samples are used, while mechanical devices are critically influenced by lipemia.[56,67,104, 151]

Clotting Assays

Clotting or chronometrical assays, usually performed with a coagulometer, are still the most often used tests for hemostasis in veterinary medicine. Indeed, these tests are mostly used for preoperative screening, evaluating an animal suspected of having a coagulation disturbance, for monitoring therapy, and to screen function of entire pathways or of the individual components of the pro- and anticoagulant pathways.[31,43,151]

A clotting assay measures the time in which the mixture of sample and reagents starts to clot, after addition of a starting reagent. For precision reasons, clotting assays should be developed so that the clotting times are in the typical measuring ranges of more than 5–6 and less than 30–50 seconds. If the assays are be adapted to optical analyzers, agents which improve the optical clot opaqueness may be used in order to enhance the signal.[31,43,104,151]

Activators

Coagulation factors in plasma are usually inactive and require proteolytic activation. The activators of choice are: unphysiological substances such as silica, kaolin, and celite; physiological substances such as tissue extracts or purified or recombinant activated coagulation factors; or specific snake venom derived enzymes. Several of the enzymatic steps require not only the activated coagulation factors, but also an activated co-factor, phospholipids (PL) and Ca^{2+}. This means that a very complex mixture of relatively unstable proteins, which are sometimes difficult to purify and to activate themselves, needs to be stabilized. The use of highly specific snake venom enzymes, derived from the venom of many species, is often a better approach than the use of natural activators. These products are often resistant against the plasma protease inhibitors or direct anticoagulants of the patient plasma. Further, many are not dependent on co-factors, not even on Ca^{2+}.[31,43,104,151]

Chromogenic and Fluorogenic Substrates

The introduction of synthetic chromogenic substrates was a milestone in coagulation tests. The chromogenic assay allows a direct determination of the activity of an enzyme or protease inhibitor. They are very much related to the typical enzymatic assays in clinical chemistry and therefore easily automated. The principle briefly outlined is based on a peptide (2–4 amino acids) which is combined with a chromophore, e.g. *para*-nitroaniline (pNA) behind the cleavage site. The chromophore is coupled to the peptide by a peptide-like bond and shows an absorbance maximum at shorter wavelengths (380–405 nm) than the free chromophore. Proteases cleave the peptide, which leads to the liberation of the chromophore. Measured at an appropriate wavelength, the change of absorbance is a direct function of the activity of the enzyme.[31,43,56,104,151]

In addition, fluorogenic substrates are also used. Commonly the fluorogenic group is 7-amino-4-methylcoumarin, which shows maximum fluorescence emission at 440 nm. Fluorogenic substrates allow the development of more sensitive assays than chromogenic ones, e.g. detection of trace amount of proteases. For both methods the peptide sequence of the substrate determines the specificity and sensitivity of the assays.[31,43,56,104,151]

Assay Systems with Chromogenic Substrates

Usually the concentration of the chromogenic substrate is chosen so that a linear cleavage is obtained for at least the first 30–60 seconds, producing a kinetic assay. This means that the development of color is followed over time and should be linear, before the reaction rate decreases when the substrate is exhausted. Turbidity formation induced by fibrin generation during the assay can interfere with the photometric detection.[31,43,56,104,151]

Immunochemical Methods

Generally, immunochemical tests detect the concentration of an analyte, and cannot easily discriminate between active and inactive forms. Using specific antibodies (monoclonal or polyclonal) the detection of reaction products such as activation peptides, enzyme-inhibitor complexes or breakdown products can provide information on ongoing activation of hemostasis.[56,104,151]

The major techniques are the automated latex enhanced turbidimetric assays and the manual agglutination tests. The principle of both is basically the same: in the presence of antigen, antibody coated particles form agglutinates of large molecular size which show either a visible formation of large particles or a change in the turbidity of the suspension, which can be detected by photometry. A widely used method is the enzyme linked immunosorbent assay (ELISA) or its variant (sandwich technique).[56,104,151]

COAGULATION SCREENING TESTS

Prothrombin Time

The prothrombin time (PT) was introduced as an assay for prothrombin in plasma samples before many of the other factors that participate in coagulation reactions were identified.[121] It is a widely used screening test for the function of the extrinsic pathway. The test is sensitive for deficiencies of FVII, FX, FV, prothrombin (FII), and for fibrinogen (FI). The sensitivity for the latter two factors, FII and FI, is less pronounced than for the other factors. In man, the PT is often used for monitoring oral anticoagulants (vitamin K antagonists) and as a screening test to identify acquired or inherited deficiency or rarely occurrence of inhibitors.[89,112,151]

The PT test is performed by adding tissue thromboplastin (or TF) and Ca^{2+} to citrated plasma and measuring the time for clot formation. It can be performed either manually by the tilt tube method or mechanically by use of a fibrometer or a photo-optical instrument. The PT reagent used in the testing provides the tissue thromboplastin and Ca^{2+}.[89,151]

Currently three types of thromboplastin reagent are used, which can differ in several aspects such as factor sensitivity, lot to lot consistency, and absolute values of the clotting times. These types include: (1) recombinant PT reagents (recombinant tissue factor, Ca^{2+}, PL, buffer, stabilizers), (2) tissue thromboplastins (relatively crude extracts of thromboplastin-rich tissue, either from rabbit brain or human placenta, and Ca^{2+}), and (3) combined thromboplastin (tissue thromboplastin, e.g. from bovine brain, diluted into a fibrinogen fraction, usually adsorbed bovine plasma, and Ca^{2+}). The necessary Ca^{2+} is added to the reagent either at the time of manufacture or prior to testing.[89,151]

The PT test can be performed as either a one-stage or a two-stage assay although the one-stage procedure is the most widely used and preferred. Thromboplastin reagent (0.2 mL) is warmed at 37 °C then forcibly added to plasma (0.1 mL) which also has been heated to 37 °C, and a timer is started. As soon as the clot forms indicating fibrin formation, the timing stops and the time is recorded to the nearest one-tenth of a second. The expected normal range for a PT is dependent on the type of reagent used.[89,151]

The results of the prothrombin time assay are usually reported in seconds (Table 138.1). The international normalized ratio (INR) generally used in humans is seldom utilized in veterinary science, although it has been applied in some experimental studies.[86,107]

In veterinary diagnostics, the higher activity of several coagulation factors involved in the pathways of hemostasis explored by the PT assay have led to suggestions to increase the results up to 10–15 seconds, similar to those results reported in humans.[65,165] This could be done by diluting the plasma citrate samples (from 1:20 to 1:40)[105] or the thromboplastin reagent[31] and/or by adding an established amount of human fibrinogen.[105] These procedures can increase the sensi-

TABLE 138.1 Ways of Reporting Prothrombin Time Values[67]

Unit name	Definition	Notes
Seconds	Clotting time	Reagent, batch and instrument dependent
Prothrombin ratio (PR)	Ratio of clotting times of sample divided by clotting time of normal plasma	Reagent and instrument dependent; comparison between reagents cannot be possible
Percent activity (%)	Clotting time is related to a calibration curve obtained by dilution of normal plasma or with appropriate calibrators	Reagent dependent; technical error may occur; PT% values may differ between reagents; algorithm for calibration curve is not standardized
International Normalized Ratio (INR)	PR corrected by the ISI (International Sensitivity Index) value	Recommended for oral anticoagulation therapy control

tivity of the test in the dog,[105] in the cat[100] and in the horse.[41]

Prolongation of the PT test result can have several causes. It can be due to a reduced production of functional factor or to reduction of a combination of functional factors in both the extrinsic system and common pathway. Disorders where this can occur include liver failure, rodenticide intoxication by vitamin K antagonist, malabsorption, increased globulin levels (i.e. canine multiple myeloma or leishmaniasis), and congenital factor deficiency (factors VII, II, I).[31,89,151]

A prolongation of PT results can also be induced by consumption or loss of plasma factor in disorders such as disseminated intravascular coagulation (DIC) or primary hyperfibrinolysis, and during thrombolytic therapy or chemotherapy.[38,89,106] In addition, prolongation of the PT result can be induced by the presence of inhibitors or substances that interfere with fibrin polymerization, such as a heparin IV bolus. Finally, prolongation of the PT can derive from improper collection of blood (underfilled tubes) or can be seen in patients with elevated hematocrits, which alters the ratio between citrate and plasma (excess of citrate).[73,89]

The degree of prolongation is inversely correlated with the factor plasma level, but a normal PT does not exclude a factor deficiency. It should be noted that the extrinsic pathway is less sensitive to reduced factor levels in comparison to both common and intrinsic pathways.[89,151]

Shortening of the PT can also occur, but PT results shorter than the reference ranges have not been consistently correlated with any clinical situation except hyperfibrinogenemia.[74] It should also be noted that lipemic and icteric samples can shorten the PT results in dogs.[109]

Activated Partial Thromboplastin Time

The activated partial thromboplastin time (aPTT, sometimes abbreviated as PTT) is a screening test for the intrinsic system and common pathway. The name "partial thromboplastin" means that the reagent contains PL but no TF, in this way activating only the intrinsic system. "Activated" means that reagents contain substances that can accelerate the coagulation reaction and shorten the time to produce the fibrin clot.[90,112]

The aPTT assay is performed by adding to platelet-poor plasma (PPP) factor XII activator, PL, and Ca^{2+} (as calcium chloride, 20 or 25 mM). Factors I, II, V, VIII, IX, X, XI, XII, prekallikrein (Fletcher factor) and high molecular weight kininogen (HMWK) are measured. An abnormal aPTT result might indicate the presence of an acquired inhibitor or a deficiency in any of the coagulation factors except FVII and FXIII.[90,112,151]

The aPTT reagents are even more diverse and unstandardized than PT reagents. Commonly used activators are ellagic acid, kaolin, micronized silica and celite. All of these are used in aPTT reagents and serve the same function of activating the clotting mechanism. Phospholipids are platelet substitutes and accelerate the reactions involved. Sources of PL are rabbit brain, cephalin (dehydrated rabbit brain), bovine brain, and soybean. Usually only mixtures with different types of PL, including the negatively charged phosphatidyl serine, are used. It is the combination of contact activator, PL, calcium chloride molarity, ionic strength, buffer systems, and the stabilizers of the reagents, which determines the reagent properties.[90,112,151]

A suspension of activator and partial thromboplastin (aPTT reagent) (0.1 mL) is warmed at 37 °C for 2–5 minutes together with 0.1 mL of a citrated plasma sample. A timer is started as 0.1 mL of calcium chloride solution (37 °C, 0.025 M) is added. As soon as the clot forms indicating fibrin formation, the timer is stopped and the time is recorded to the nearest one-tenth of a second.[90,112]

In animal testing, the normal values should range from 10 to 20 seconds, taking into account the different concentration and activity of coagulation factors involved in aPTT, which are known to be species-specific.[65,79,165]

The normal range of the aPTT is strongly reagent and instrument dependent, but a significant role is played by the pre-analytical phase. Each laboratory should determine its own normal reference ranges (sometimes for each new lot of reagent).[90,112,151]

Prolongation of the test result can have several pathogenic mechanisms. It can be caused by a reduced production of each factor or by a combination of factors in the intrinsic and common pathway. The list of disorders includes liver failure, rodenticide intoxication by vitamin K antagonist, malabsorption, increased globulin levels (i.e. canine multiple myeloma or leishmaniasis), congenital factor deficiency (factor VIII, IX, XI,XII,

prekallikrein, HMWK, X, V, II, I), and congenital deficiency of von Willebrand factor (VWF) (aPTT can be slightly prolonged due to the reduced half life of factor VIII).[90,106,151]

Prolongation of aPTT results can also be induced by consumption or loss of plasma factors seen in disorders such as DIC or primary hyperfibrinolysis, or with thrombolytic therapy or chemotherapy.[38,90,106,151]

In addition, a prolongation of aPTT result can be induced by the presence of inhibitors or substances that interfere with fibrin polymerization such as heparin, heparin-like substances, lupus anticoagulant, and autoantibody against one of the coagulation factors involved in the aPTT.[90,151]

Finally, prolongation of aPTT, similar to PT, can result from improper collection of blood (underfilled tubes) or from patients with an elevated hematocrit, which alters the ratio between citrate and plasma (excess of citrate).[73,117]

Shortened aPTT results can occur, and may be related to the presence of activated coagulation factors. Attention should be paid to accurate and appropriate blood sampling.[90,112] Indeed, highly hemolytic canine samples can shorten the aPTT results.[109]

Reagents used for aPTT show variable factor sensitivity, especially for FVIII and FIX deficiency. Sensitivity depends strongly on the accuracy of the selected cut-off values for interpretation of normal ranges. Clinically significant deficiencies with levels below 30% are usually identified.[94,95]

Thrombin Time

The thrombin time (TT or thrombin clotting time) is a simple screening test for both the fibrinogen conversion to fibrin and fibrin polymerization. The TT is inversely proportional to the fibrinogen level. This test can detect dysfibrinogenemia, heparin and excess of fibrin/fibrinogen degradation products (FDPs).[40,151]

This test reflects two different reactions: the cleavage by thrombin of fibrinopeptides from fibrinogen to produce fibrin monomers and the polymerization of fibrin monomers into the fibrin polymer, which is identified as a fibrin clot.[40,151]

The TT test is performed by adding a relatively low to moderate concentration of thrombin (bovine or human) into citrated plasma. Thrombin cleaves fibrinogen, releasing fibrinopeptide A (FPA) and B (FPB), and converting fibrinogen into fibrin clot. The clotting time is related to the fibrinogen concentration and quality and to the presence of AT. The test is strongly method-dependent.[40,112,151]

The prolongation of the test can be caused by reduced levels of fibrinogen, presence of heparin or heparin-like substances, elevated FDPs, and monoclonal paraprotein, dysfibrinogenemia, and hyperfibrinogenemia.[28,40,106,151]

Shortened TT results are rare. Improper sample collection/manipulation and storage need to be considered; indeed lipemic and hemolytic samples can shorten the TT results in dogs.[109]

Reptilase® Time

The Reptilase® time (batroxobin) test is based on the use of a thrombin-like snake venom protease which is able to clot fibrinogen. However, in contrast to thrombin, batroxobin cleaves only FPA and has no activity directed against other thrombin substrates such as FV, FVIII, etc. This test is not inhibited by AT and heparin and can be used to investigate fibrin polymerization in the presence of heparin. The assay is not commonly used in current veterinary diagnostics.[151] The Reptilase® time is prolonged in afibrinogenemia, severe fibrinogen deficiency, dysfibrinogenemia and in the presence of relatively high levels of FDPs.[151]

DETERMINATION OF FIBRINOGEN AND INDIVIDUAL COAGULATION FACTORS

Fibrinogen

Several techniques to assay fibrinogen are available as functional or immunochemical methods, including total clottable fibrinogen, thrombin-initiated clotting rate, thrombin-initiated turbidimetry or light scattering, salt precipitation and fibrinogen antigen measurement.[12,43,113,151]

The most commonly used assay is the thrombin-initiated clotting rate, modified by Clauss.[25] This method is based on the rate of clot formation in diluted citrated plasma following the addition of a high concentration of thrombin solution. In this way high concentrations of thrombin minimize interference by heparin therapy, while diluted citrated plasma reduces interference by high levels of FDPs, as happens in DIC. However, high levels of FDPs can interfere and lead to falsely low values for fibrinogen, as documented in dogs.[25,97,103,113]

Another assay is based on the increase of turbidity during the PT test, which is directly proportional to the concentration of clottable fibrinogen and could be detected by nephelometry or turbidimetric end-point detection. Therefore the PT derived fibrinogen assay correlates well with the Clauss method, with the exception of patients with elevated levels of FDPs. Here, the PT derived fibrinogen is usually higher than the Clauss assay, but is probably more accurate.[12,67,151]

A kinetic assay for fibrinogen is available which employs batroxobin, which generates a pseudo-linear increase of turbidity. This method has a wide range, an excellent precision and can be easily be adapted to automated coagulometers or clinical analyzers.[12,67,151]

The antigen assay for fibrinogen, belonging to the immunochemical methods, measures the quantity of fibrinogen and does not discriminate between clottable fibrinogen and inactive or degraded forms. This assay may produce significantly higher values of fibrinogen in the presence of high concentrations of FDPs. Unfortunately, it appears that this assay will have limited use in veterinary medicine until species-specific antibodies are available.[111,122]

The estimation of fibrinogen by the heat-denaturation method correlates well with chronometric proce-

dures, except during acute-phase reactions.[19,92] Some studies comparing several assay methods have been done in dogs.[102]

Hypofibrinogenemia can be observed in DIC, hyperfibrinolytic syndrome, liver disease, inherited hypofibrinogenemia, dysfibrinogenemia, multiple myeloma, and with thrombolytic therapy or with the presence of monoclonal paraproteins. Hyperfibrinogenemia can be seen in acute phase responses, with glucocorticoid administration, and with pregnancy.[12,151]

Sources of analytical error can be: over- or underfilling of collection tubes, lack of citrate volume correction for high hematocrit, use of the wrong anticoagulant and heparin contamination.[12]

Coagulation Factor Assays: FII, FV, FVII, FVIII, FIX, FX, FXI, and FXII

Clotting Assays

Specific clotting factor assays are generally used to diagnose inherited or acquired hemorrhagic disorder, or to explain PT or aPTT prolongation. Although specific chromogenic assays for many of the individual coagulation factors are available, clotting assays are the preferred methods for coagulation factor assays. With this principle the activity of several coagulation factors can be determined in a modified PT (for FVII, FX, FV, FII) or aPTT (for FXII, FXI, FIX, FVIII, and FV also) test, in combination with a factor deficient plasma reagent. A factor deficient or substrate plasma contains all but the factor to be assayed. The most important quality criteria for the factor deficient plasma reagents (either immunoadsorbed or congenital) are a very low or undetectable level of the factor which is to assayed, high activity of all other factors and a steep calibration curve (prepared with pooled plasma of the same species where the test is applied) which allows a good discrimination between normal and abnormal.[31,58]

In veterinary diagnostics, this type of assay system assumes that there is sufficient structural homology between the human proteins and those of other species, so that they can react interchangeably in the thrombin-generating pathway. Consequently, human plasma reagents are generally used. However, this type of assay is not necessarily reliable when the absolute activity for a non-human species is being determined. For example, striking differences in structural homology have been pointed out for sheep and cattle plasma.[43,65]

The plasma under investigation is diluted (1:5 or 1:10) into the deficient plasma. The degree of correction of the very long clotting time of the deficient plasma is proportional to the activity of the specific factor in the sample. The assay is calibrated by running dilutions of a standard or calibrator, which for animal studies is the pooled plasma. The calibration curve gives a straight line over a wide range in a double logarithmic plot.[58,151]

Factor assays that depend on a clot as the end-point of reaction are inherently quite variable, with inter-assay coefficient of variation in the range 10–15%. Not all combinations of deficient plasma and PT and aPTT reagent work equally well. The quality of the deficient plasma and the factor sensitivity of the reagent play significant roles.[58,151]

The reference interval for each factor level is expressed as percent of normal pooled plasma concentration. By definition, normal plasma contains 100% (1 unit/mL) of each factor. The reference interval is approximately 60–140%.[58,151]

It has been pointed out that the type of commercial prothrombin time reagents and methods used are critical in equine or canine plasma evaluation for FII, FV, FVII, and FX deficiencies.[43,96,97,99,101] Conversely, most commercial aPTT test kits are sensitive as screening tests for factor VIII and IX deficiencies in canine plasma.[94,95]

Assays for Inhibitors

Because acquired causes of factor deficiencies are generally more common than hereditary causes, a patient found to have a factor deficiency should be evaluated for possible acquired etiologies. Differentiating between true deficiencies and inhibitor occurrence is the second step to correctly approach these patients. A description of inhibitors and their testing is provided below.[67]

Lupus Anticoagulant Historically these inhibitors were noted in patients with systemic lupus erythematosus (SLE), but later it was evident that they were not restricted to patients with SLE, and that they do not have an anticoagulant effect in vivo. Despite aPTT prolongation, patients with this inhibitor had increased risk for various thrombotic sequelae. The evidence that the mechanism of disease was due to antibody that binds to the phospholipid in the aPTT reagent caused the antibody to be renamed "antiphospholipid antibody." Presence of an inhibitor, such as lupus anticoagulant, has been rarely demonstrated in veterinary species but it is likely that its occurrence is underestimated.[139]

The presence of an inhibitor, such as lupus anticoagulant, can cause artifactual decreases in the in vitro factor level. Therefore, the laboratory should perform factor assays at multiple dilutions (three minimum). At higher dilutions, the inhibitor interference will decrease due to dilution of the inhibitor.[59,151]

This assay is done by mixing patient's plasma and an equal volume of normal plasma, noting aPTT results immediately and after 1 hour of incubation at 37°C. A significant factor deficiency is suggested if the test normalizes. If the test remains altered or increased, the inhibitory substance is confirmed. Partial correction is not uncommon in human samples and this presentation can be difficult to interpret even with more detailed studies. To confirm that reduction of phospholipid is the cause of aPTT prolongation, additional study is needed. In this case a modified aPTT or PT or Russell viper venom time with dilute phospholipid is used. A suitable control plasma is either tested in parallel or

reference intervals are determined with plasma from healthy donors.[59,151]

Factor VIII Acquired Inhibitor Some hemophilic patients who have been transfused with products containing FVIII have developed antibodies against FVIII, which inactivates the transfused factor. The predisposition to inhibitor development is genetically based. This happens in humans and rarely in dogs.[44,141]

A quantitative determination of the inhibitor titer can be made in specific clotting assays such as the "Bethesda assay" or the "Oxford" or "Nijmegen" assay for FVIII or for other coagulation factors. In these assays normal plasma is incubated with different dilutions of the sample or a normal control. The inhibitors inactivate the FVIII of the normal plasma after an incubation step of 2 hours at 37°C. The residual activity in the samples is determined and the inhibitor titer is calculated, i.e. a titer of 1.0 is defined as the inhibition of 50% of FVIII in the normal plasma.[4,151]

Factor IX and XI Acquired Inhibitors Repeated blood product transfusions can cause acquired inhibitors of FIX and FXI. These are very rare situations in veterinary medicine, with one case report in a cat described.[37]

Monoclonal Paraproteins Multiple myeloma is a well-described disorder in veterinary medicine. It is a clonal proliferation of plasma cells or their precursor in bone marrow. These cells are characterized by the production of monoclonal or more rarely biclonal gammaglobulins that can interfere with fibrin polymerization.[128]

Actually, the mechanisms by which multiple myeloma cause hemostatic alterations and bleeding tendency are numerous: interference between VWF and glycoprotein Ib binding, decreased production of coagulation factors, production of both lupus anticoagulant and heparin like substances, specific inhibitor of factor VIII, and thrombopathia.[45,66,140]

Heparin Canine mast cell neoplasia can produce a hemorrhagic paraneoplastic syndrome due to the production of heparin by neoplastic cells. Both TT and aPTT are prolonged and canine patients show a hemorrhagic tendency and dehiscence of healing wounds.[57]

Chromogenic Assays

For the evaluation of several coagulation factors, chromogenic assays may be superior (and cheaper) when better resolution in the high range is required. The high sensitivity of the chromogenic methods allows a higher sample dilution, which eliminates several problems connected with inhibitors, which might interfere with the clot-based methods.[43,151]

The determination of FX is one of the most traditional chromogenic substrate methods. The activation of FX in the sample made with the FX activating enzyme from Russell viper venom is directly detected by a chromogenic substrate such as Pefachrome® Xa.[43,151]

The determination of FVIII by chromogenic methods is the most widely used assay, especially in human medicine. Indeed, it is the method of choice during the monitoring of substitution therapy using recombinant or monoclonal purified FVIII concentrates. As FVIII is not an enzyme, it catalyzes the activation of FX by FIXa in the presence of PL and Ca^{2+}. The amount of FXa which is generated is directly proportional to the activity of FVIII in the sample. Methodological factors can lead to systematic differences between the clotting assay and the chromogenic method, but can be overcome by careful standardization of the test systems and by use of appropriate calibrators.[5]

A chromogenic assay for FIX has been described in which FIXa, previously activated by FXIa, activates FX in the presence of a saturating amount of FVIIIa. The activity of generated FXa is directly proportional to the activity of FIX.[47]

The determination of FVII should be performed in a coupled assay as FVIIa is a poor "amidase" and does not hydrolyze synthetic substrates effectively enough for a direct assay. In the sample FVII is activated with TF, PL, and Ca^{2+}. The complex FVIIa-TF activates the FX in the reagent. The FXa can be detected with a chromogenic substrate, such as Pefachrome® Xa.[151]

The chromogenic assays have been shown to be effective in estimating FVII, FVIII, FIX and FX in horses and in a few other species.[43,143]

Finally, immunoassays (antigen assays) are commercially available in man for FVII, FVIII, FIX, and FX. Unfortunately, it appears that these assays will have limited use in veterinary medicine until species-specific antibodies are available.[111,122]

It should be pointed out that factor deficiencies can be quantitative or qualitative. In quantitative disorders, the factor level determined by routine PT- or aPTT-based methods (functional activity assays) is similar to the result obtained by immunological (antigen) assays. In qualitative disorders, the PT- or aPTT-based (functional) assay result is decreased, but the antigen level is normal or significantly higher than the functional level, indicating the presence of a dysfunctional protein.[151]

Determination of von Willebrand Factor

The analysis of VWF is quite complex as several subtypes of this disease are known (Chapter 81). The most often performed assays in veterinary science include:

1. determination of the concentration of VWF antigen (Ag), by means of immuno-turbidimetric assay and ELISA[3,9,10,62,78,131]
2. VWF subunit pattern analysis, by means of agarose gel electrophoresis and immunoblot[67]
3. determination of activity using agglutination of fixed or fresh platelets induced by ristocetin, botrocetin, or collagen, and measuring the agglutination that has occurred by an aggregometer.[64]

Alternatively, immunoassays have been designed to assess VWF function. The collagen-binding assay is

an ELISA in which collagen is the antigen. If VWF is functional, it binds to collagen and is subsequently detected.[151]

Repeated testing is often required, because both VWF and FVIII become elevated above baseline during acute phase reactions, including even minor illnesses, injury, stress, or pregnancy. An elevation of a low or borderline value for VWF into the normal range during any of these conditions often masks the diagnosis of VWD. It should be noted that when VWF is markedly decreased, the FVIII level can also become very low, which prolongs the aPTT. In most VWD patients, the disease is mild or moderate and the aPTT is therefore normal.[88,110]

Finally, it should be pointed out that currently diagnosis of VWD can be performed in many dog breeds by means of molecular testing.[17,69,124]

TESTS FOR THROMBOPHILIA

Antithrombin

Antithrombin (AT) (previously antithrombin III or ATIII) seems to be one of the most important physiologic protease inhibitors in plasma involved in the regulation of blood coagulation. Antithrombin is a protein produced mainly by hepatocytes and partially by endothelial cells. Its main function is to bind to thrombin, forming a 1:1 stoichiometric complex and preventing the conversion of fibrinogen to fibrin. In addition, the AT action is similar against other activated factors (FXIIa, FXIa, FIXa, FXa and partially FVIIa). This inhibitory effect of AT is catalyzed by heparin and by proteoglycans such as heparin sulfate (HS), which may be present in high concentrations locally at the endothelial surface.[52,125] Due to its cofactor role in heparin therapy, AT is a frequently ordered assay in thrombophilia, DIC and during heparin therapy.[16,48,120,123,142] In veterinary clinical practice, chromogenic assays are primarily used to measure AT, as they show a low interassay coefficient of variation.[36,152] In the chromogenic assay AT is determined using FXa or thrombin in the presence of a saturating concentration of heparin (heparin cofactor method). This is the preferred method of testing as assays using thrombin are available but FXa is not inhibited by heparin cofactor II and is more stable. The general principle is based on an inhibition phase in which FXa excess is reacted with AT in the presence of heparin to give an inactive FXa-AT complex plus a residual FXa. The FXa residual reacts with the chromogenic substrate to give a color which can be measured spectrophotometrically.[35,60,151] The values of AT are reported as percent of activity compared to either a species-specific or human plasma pool considered to have 100% activity. Consequently, reference and reported values vary with the species used for the reference pool in relationship to species differences in AT activity.[16,48,120,123]

Inherited deficiencies of AT, a common cause of spontaneous or recurrent venous thromboembolic events in humans, are not reported in veterinary species. In clinical veterinary practice acquired plasma variations of AT are more frequently observed (see Chapter 87).

Protein C

Protein C (PC) is a vitamin K-dependent plasma protein synthesized in the liver. The binding of thrombin to thrombomodulin (TM) converts the bound thrombin from a procoagulant enzyme to an anticoagulant enzyme that converts the PC zymogen to the anticoagulant serine protease renamed "activated protein C" (APC). This surface-dependent reaction is enhanced by the endothelial cell protein C receptor that binds PC. Protein C testing may be of value in the determination of pre-thrombotic or hypercoagulable conditions.[33,34,154]

The currently performed methods are either functional or immunochemical. The functional assays are either clotting or chromogenic substrate based assays.[26,149,151]

The PC clotting assay is performed in a way similar to the assays for the individual coagulation factors. The sample is pre-diluted into PC deficient plasma which is prepared by immunoabsorption. In the activation phase, the PC in the sample is activated by Protac® (a snake venom based PC activator from *Agkistrodon contortrix*). The inhibiting effect of PC is detected via the aPTT. The prolongation of the clotting time (caused by inactivation of FV and FVIII) is proportional to the activity of PC in the patient plasma. This assay can easily be automated and the quality of PC deficient plasma is important.[26,149,151]

In the dog it has been demonstrated that Protac® does not stimulate the production of activated PC activity in canine plasma detectable by clotting assays. Molecular differences in the canine PC molecule are hypothesized to prevent formation of the stoichiometric complex of venom extract, aPTT reagent, and canine protein thought to be essential for the PC-activating function of the Protac®.[63]

The PC chromogenic assay is based on the activation of PC by Protac® to give APC, which reacts with the chromogenic substrate to give a color by means of pNA that can be measured spectrophotometrically. This assay is very simple, specific, easy to automate and shows an excellent precision.[26,149,151]

The immunochemical determination of PC by means of automated turbidimetric agglutination tests and ELISA is less important than the functional method.[26,149,151] An antigenic assay has been developed in the horse which shows poor correlation with the clotting method. The values are reported as percent of activity or antigen relative to a reference plasma pool considered to have 100% activity or antigen.[6,157,158]

Activated protein C resistance (APCR), a reduced anticoagulant response of a plasma sample to APC, is an important risk factor for thrombosis in man.[67,149,151] Activated protein C resistance is assayed via a modified aPTT in the presence and absence of APC. Prothrombin time and snake venom-based tests have also been

described. Unfortunately, no literature is available in veterinary science about the use of APCR testing.[67,151,154]

Protein S

Protein S is one of the vitamin K-dependent coagulation proteins and its main function is to enhance the anticoagulant activity of APC as cofactor. In human medicine, deficiencies of PS are associated with inherited thrombotic disease.[26,149,151] In veterinary science, no references are available on clinical applications for the assay. A study examining the effects of bovine protein S and bovine APC on fibrinolysis in human plasma has been published.[154]

TESTS FOR THE MONITORING OF ANTICOAGULANTS

Anticoagulant drugs are widely used for prophylaxis and treatment of thromboembolic disorders and in DIC. Strict monitoring and dose adjustment according to the results of appropriate tests are necessary in order to prevent bleeding or thrombosis. Monitoring can either be performed in the laboratory or by near patient testing (NPT) with appropriate devices. Testing in the laboratory is performed on citrated plasma whereas NPT can be performed directly on non-anticoagulated whole blood or with citrate added.

Activated Clotting Time

The ACT or activated coagulation time is a "bedside" clotting or a point-of-care test. It is similar to the principle of aPTT with the difference that the ACT is activated with a contact activator without the addition of PL and Ca^{2+}.[67,91,151]

Activated clotting time testing is very simple, using whole blood that immediately after collection is transferred to a special tube containing an activator of coagulation, such as celite (diatomaceous earth), kaolin, or glass particles. These activate the intrinsic pathway of coagulation, causing the blood to clot. The tubes require accurate mixing and the specimen cannot be stored.[20,46,49,91,163]

For methods that use cartridges rather than tubes, whole blood may be collected into a plastic syringe or tube and then immediately transferred into the cartridge.[55,91] In the test tube method, a visual inspection can be performed to detect clot formation, which can lead to inaccuracy. Alternatively, a specialized coagulation analyzer, which detects the clot formation by the mobility of a magnet inside the blood test tube, can be used. Mechanical, electrical or light devices, or cartridge methods can detect clot formation.[91,150]

The ACT is less precise than the aPTT, and lacks high correlation with the aPTT or with heparin anti-FXa levels. The ACT is influenced by a number of variables, including platelet count, platelet function, lupus anticoagulants, factor deficiency, room temperature, hypothermia, and hemodilution. The various methods are not standardized, and therefore, results obtained are not interchangeable.[91]

Activated Partial Thromboplastin Time

The aPTT assay described in detail earlier can be useful for the monitoring of heparin in the lower concentration range. However, as a screening test, aPTT is not only influenced by anticoagulant concentration but also by a variety of other factors; for example, the unfractionated heparin (UFH) assessment shows a pronounced reagent dependency.[18,98]

Heparin Assays

Synthetic substrate based assays are widely used for the specific determination of heparin, especially when low molecular weight heparin (LMWH) is used.[67,151] Heparin is determined via its accelerating function in the inhibition of FXa (anti-FXa activity) or thrombin by AT. The stimulation of AT inhibition of FXa by LMWH or degraded forms of UFH favors the pathway via FXa. FXa has also the practical advantage that is a relatively stable enzyme. The test is based on two principal steps:[67,151] the inhibition phase where an excess of FXa plus AT in the presence of heparin in the sample gives FX-AT inactive forms, and the FXa residual molecules detection phase where FXa residual molecules react with a chromogenic substrate and give a color via pNA that is detected spectrophotometrically.

The test can either be arranged as a kinetic or endpoint version. There are several modifications of this general principle. Some tests use a saturating concentration of AT in the reagent; others are based on the endogenous AT in the sample. Whereas the first modification determines the "total heparin" the latter determines the AT-heparin complex.[67,151]

Chromogenic heparin assays can be easily automated and are especially useful for the monitoring of LMWH for which no routine clotting assay (such as aPTT) is available. In addition, the assay shows no interference by FDPs, aprotinin or elevated FVIII values, which have a strong impact on the aPTT or ACT tests.[67,151]

The calibration of heparin assays can vary since several manufacturers recommend calibration with the same brand of heparin used for therapy. The measuring range for most commercial assays is from 0 to 1.0 anti-FXa U/mL, while the therapeutic range is usually between 0.3 and 0.7 anti-FXa U/mL. Extensive studies have been conducted in canine and feline medicine assaying the several commercial kits available.[18,30,98,127]

FUNCTIONAL TESTS FOR FIBRINOLYSIS

Chromogenic substrate tests brought fibrinolysis function tests into practical laboratory settings. Previously, fibrin plate lysis assays, the euglobulin lysis time and similar complicated and time-consuming tests were used by only specialized laboratories.[13] In man, tests are available for measurement of

plasminogen, alpha-2-antiplasmin (α2-AP), plasminogen activator inhibitor 1 (PAI-1), and tissue plasminogen activator (t-PA).[13,145,146,147,151] Unfortunately, these assays are costly and used primarily for research purposes in veterinary medicine, with limited veterinary practice application.[75,76]

Plasminogen

Plasminogen is the inactive precursor of the enzyme plasmin, which is the primary catalyst of fibrin degradation. The assay for plasminogen utilizes the interaction of plasminogen with streptokinase, a bacterial protein. In veterinary science, urokinase instead of streptokinase is used for both dogs and horses. The complex of plasminogen and urokinase has enzymatic activity and hydrolyses the chromogenic substrate, releasing a colored-compound. This complex is not inhibited by alpha-2-macroglobulin and the fast acting α2-AP. An assay which would simply convert plasminogen directly into plasmin is not possible in plasma, because free plasmin is immediately neutralized by α2-AP.[36,75,145,156]

For the plasminogen assay, aliquots of standard plasma, control plasma, and the patient's test plasma are dispensed into reaction tubes. Streptokinase (urokinase in dogs and horses) is added in excess, so that virtually all the plasminogen in the sample is in the complex form with plasmin-like activity. Following a short incubation period, the appropriate chromogenic substrate is added and the reaction is allowed to proceed. After 0.5–5 minutes the reaction is stopped with acetic acid and the color is assessed at the appropriate wavelength.[67,145,146,151,156]

Acquired abnormalities of plasminogen are encountered far more commonly than inherited deficiencies. A low concentration of plasminogen can be caused by increased consumption (DIC, thrombolytic therapy) and decreased production (liver failure).[67,145,146,151]

Alpha-2-Antiplasmin

Alpha-2-antiplasmin is the primary plasmin inhibitor in plasma and thus an important regulator of fibrinolysis. It is synthesized by hepatocytes, although the kidney may be another contributing source. Evaluation of the concentration of α2-AP may be useful in patients with thrombophilia, unexplained bleeding and DIC.[87]

Chromogenic assays for plasma α2-AP have replaced other test methods (esterolytic, fibrin plate lysis) previously employed. Immunologic methods for the measurement of α2-AP are also available, but it is preferable to assess enzymatic activity rather than the total mass, at least as an initial assay. Many inhibitors in plasma can react with plasmin, but α2-AP is the only extremely fast acting inhibitor. Due to the rapid inactivation of plasmin by α2-AP, the inhibition and detection phase can be started almost simultaneously, which helps to improve specificity against slower acting plasmin inhibitors in the plasma. The test includes an inhibition phase where an excess of plasmin links to α2-AP in the sample. The residual plasmin left reacts with the chromogenic substrate, releasing a colored-compound.[75,145]

Acquired abnormalities of α2-AP are encountered far more commonly than inherited deficiency. Low concentration of α2-AP can be caused by increased consumption (DIC, thrombolytic therapy) and decreased production (liver failure).[67,145,151]

Plasminogen Activators

There are two types of plasminogen activators: tissue-type plasminogen activator (t-PA) and urokinase-like plasminogen activator (u-PA). Both types are serine proteases that have high specific activity in converting plasminogen to plasmin.[146]

Though t-PA is a relatively good amidase which can be easily determined in purified preparations with specific chromogenic substrates, its low concentration in plasma requires an indirect approach. One molecule of t-PA can activate multiple molecules of plasminogen and a massive amplification is obtained. Therefore the determination of the low concentrations of t-PA, which are usually found in plasma, is possible in an amplification system via plasminogen and catalyzed by soluble fibrin (in the form of cyanogen bromide cleaved fibrinogen).[146,151]

Increased levels of t-PA can be caused by liver cirrhosis, acute promyelocyte leukemia, and in the reperfusion phase of liver transplantation (both only in humans). Decreased levels of t-PA can be caused by trauma, surgery, pregnancy, and thrombotic thrombocytopenic purpura.[146,151]

Plasminogen Activator Inhibitor 1

Plasminogen activator inhibitor 1 is produced by endothelial cells, platelets and hepatocytes. In plasma, PAI-1 circulates in complex with vitronectin, which may protect it from inactivation. It is the primary physiologic inhibitor of plasminogen activation in blood, targeting both u-PA and t-PA. The measurement of its plasma level therefore provides important information as to the balance between profibrinolytic and antifibrinolytic factors. Elevations of PAI-1 may be associated with a predisposition to thrombosis, whereas deficiency of PAI-1 on an inherited basis has been associated with a bleeding disorder.[77]

The determination of PAI-1 is technically complicated. In blood PAI-1 circulates in three major forms: inactive (20%), or "latent", PAI-1; active PAI-1 (60%); and PAI-1 in complex (20%) with t-PA. PAI-1 can be assayed using both functional and immunologic methods. For both methods, sample collection is a crucial point.[72,77,151]

A simple direct inactivation assay via t-PA or u-PA is not sensitive enough for plasma because the concentration of PAI-1 is quite low. Typically an amplification step which utilizes the u-PA or t-PA mediated activation of plasminogen is used. The generated amount of plasmin, which is inversely proportional to the PAI-1 activity in the sample, is detected with a plasmin spe-

cific chromogenic substrate. Another difficulty is the direct or indirect interference by α2-AP or alpha-2-macroglobulin. These inhibitors can be inactivated by acidification, oxidation or snake venom enzymes. When t-PA is used, soluble fibrin or cyanogen bromide derived fibrinogen peptides (as part of the reagent) are required as a stimulator for the amplification step. The u-PA based methods are technically somewhat less complicated and can be adapted to fully automated analyzers.[72,75,146,147]

TESTS FOR HEMOSTASIS ACTIVATION

The majority of tests for the detection of hemostasis activation are based upon immunochemical methods. Monoclonal antibodies, which are able to discriminate between activated, non-activated, inhibitor-bound or inactivated forms of analytes are very useful. Using assays such as ELISA, automated fluorescence immunoassay or turbidimetry, activation markers have found increased applications in many referral laboratories. Manual latex agglutination assays are also used with reliability in veterinary practices.

D-Dimer

D-Dimer is a neoantigen formed when thrombin initiates the transformation of fibrinogen to fibrin; it is derived from plasmin digestion of cross-linked fibrin.[22,134,137]

This analyte is determined with a monoclonal antibody-based assay. Turbidimetry, manual latex agglutination, fluorescence immunoassay, and ELISA are the available methods. The manual agglutination method is less sensitive than automated methods or ELISA and may show a high degree of variability. Since D-dimer is not a standardized analyte, different assays may show discrepant results depending on the specificity of the antibodies and the calibration material which is used. Results are reported as µg/mL or ng/mL or µg/L.[22,134,137]

Assays based on latex agglutination can estimate semiquantitatively[29,116,137] or qualitatively[50,51] the D-dimer concentration in dogs. The immunoturbidimetric assay is currently the gold standard for D-dimer concentration assessment in dogs and cats, and can use citrated plasma that has been stored for up to 1 month.[16,22,39,115,134] In the horse, a comparative study for the assessment of several assays for D-dimer concentration has been performed, establishing the validated use of latex agglutination methods over the immunofiltration card test.[138]

Fibrin/Fibrinogen Degradation Products

The determination of FDPs is a valuable tool for the detection of fibrinolytic activation, allowing an estimation of the relative proportion of fibrinolysis and fibrinogen breakdown, especially for clinical investigations in dogs, cats and horses.[11,21,136,138]

Traditional methods with polyclonal antibodies against FDPs initially required special blood collection tubes, which contained either thrombin or thrombin-like snake venom (Botrox atrox) for clotting the blood. The assay can now be performed on citrated plasma samples, which are easier to collect and give fewer false positive results.[21,136,138]

In the assay, patient plasma is mixed with latex particles, which are coated with monoclonal anti-FDP antibodies. If FDPs are present in the plasma, the latex particles agglutinate as FDPs bind to the antibodies on the particles. The technician can detect these large agglutinated clumps visually. Various dilutions of patient plasma can be tested to provide an estimation of the FDPs titer in a semiquantitative result format. The results are usually reported in µg/mL, ng/mL or µg/L.[11,21,136,138]

Thrombin Anti-Thrombin Complex

The thrombin anti-thrombin (TAT) complex is an indicator of the inhibition of thrombin by its natural inhibitor AT. In the ELISA for TAT, a thrombin specific capture antibody binds the TAT complex. After a washing step, a second antibody detects the AT moiety of the complex in a color reaction. The values are reported in µg/L or ng/mL.[151] The assay has been applied in horses[142,144,155], dogs[84] and in other laboratory animal species.[122]

Prothrombin Fragment F 1+2

Prothrombin fragment F 1+2 (F 1+2) is released from prothrombin after activation by the prothrombinase complex. While TAT represents a group of activation markers, characterized by complex formation between an active enzyme and an inhibitor, F 1+2 detects activation by prothrombinase. It represents the FXa activity in vivo.[7,122,151]

Fibrinopeptide A

The FPA is a circulating amino acid peptide released from fibrinogen upon cleavage by thrombin.[148] The first generation of assays was based on separation of FPA and fibrinogen or larger FDPs by adsorption to bentonite. The detection of FPA in the bentonite supernatant was made with polyclonal antibodies directed against fibrinogen. Since then, monoclonal antibodies against FPA have been developed and the detection is based upon ELISA.[122,151]

Soluble Fibrin

Like FPA, the determination of soluble fibrin (SF) or fibrin monomers (FM) is also direct evidence for thrombin formation in vivo. While FPA or TAT are cleared rapidly from the circulation, SF is present in plasma for several hours. The determination of SF with ELISA makes use of specific monoclonal antibodies

directed against the N-terminus in fibrin, formed when fibrinogen is cleaved by thrombin. Sample pretreatment using a chaotropic agent (a substance which disrupts the three dimensional structure in protein macromolecules) may be used. Generally, the results for SF and F 1+2 tend to be very similar.[53,80,151]

The determination of SF can be performed by chromogenic substrate based assays, which use the potentiating effect of SF on the activation of plasminogen by t-PA. The activity of plasmin that is generated is proportional to the concentration of soluble fibrin. FDPs may also stimulate this reaction. Care has to be taken since FM may bind to plastic surfaces of the cuvettes.[151] Recently, a latex immunoturbidimetric assay for SF has been validated in man.[53]

THROMBOELASTOGRAPHY

The acknowledgement of the cell-based model of hemostasis (Chapter 84) has forced a paradigm shift in the theoretical perception of the biochemistry of hemostasis. It has challenged the traditional view of the intrinsic and extrinsic pathways in the cascade model of coagulation as accurate models of the complex physiology and pathophysiology of hemostasis in areas other than specific factor deficiencies.[27,85] It is both rationally and intuitively appropriate to apply unconventional coagulation assays, which include both plasma and cellular blood components in the analysis, to diagnose and monitor patients with abnormal hemostasis. Whole blood contains all the intravascular factors and cells participating in physiologic and pathologic hemostasis, incorporating TF and PL-bearing cells. Whole blood assays such as thromboelastography (TEG) may provide a more truthful reflection of in vivo hemostasis than the traditionally used plasma based hemostasis assays.

Method

TEG is not a new method, but its potential use in assessing hemostatic disorders has resurfaced after it was reintroduced with new software and activators, allowing for rapid, qualitative and quantitative assessment of hemostatic function.[54] TEG is applied to whole blood, which enables a unique combined evaluation of both the plasma and cellular components of coagulation.[82] Originally the assay was performed on unstabilized fresh blood within 4–6 minutes of patient sampling, requiring the TEG machine to be in close vicinity to the patient. However, in a larger hospital environment with centralized laboratory facilities, an assay with such a short transfer time is rarely practical.[82] In order to increase the time span from patient sampling to analysis, it was therefore proposed that whole blood stabilized in 3.2% citrate be used instead, with re-calcification immediately before analysis.[24]

As with other coagulation analyses, blood samples for TEG analysis should be collected in a standardized manner and it is recommended that samples are handled without delay after receipt in the laboratory. Additionally, studies in both humans and dogs have indicated that a set time point post sampling (e.g. 30 minutes) should be used for serial measurements (Table 138.2).[161,164]

In veterinary medicine, TEG analyses are almost always performed on citrated whole blood samples, but plasma samples can be assayed as well.[160] There are two different commercial machines on the market, the ROTEM produced by Pentapharm in Germany and the TEG, which is produced by Haemoscope (Fig. 138.2). Both machines function on the same principle, namely

FIGURE 138.2 The TEG 5000 in a laboratory setting.

the gradual binding of a pin to the sides of a cup during clot formation. The main difference between TEG and ROTEM is that in the TEG it is the cup that oscillates and in the ROTEM it is the pin. The following is a description of the TEG method, since it is the most common.

The blood sample is loaded into a pre-warmed (37 °C) oscillating sampling cup containing calcium, and the cup is raised into contact with a disposable pin. The pin is connected to a torsion wire within the instrument. The cup oscillates slowly from side to side, and as a clot starts to form, fibrin strands begin to bind the cup and pin together. As clotting is amplified and propagates, more and more fibrin is formed, which causes the amplitude of the pin's rotation to increase. The rotation of the pin is transmitted via the torsion wire to a computer which continually monitors the amplitude of the pin's oscillation. As the clot develops the computer displays a representative tracing, which begins as a straight flat line, which upon initiation of clot formation separates into two divergent lines. Data measurement can continue for up to 3 hours, and thus can include not only evaluation of the kinetics of the initiation and amplification phases of coagulation, but also assessment of strength and stability of the formed clot (Fig. 138.3).

Three types of standard TEG assays have been evaluated in veterinary medicine: native (no activator), human recombinant tissue factor activated (Innovin, Dade Behring) and kaolin activated (Haemoscope). The simplest way to perform a TEG analysis is without the use of an activator (native TEG), which offers the opportunity to evaluate the blood clotting process without the interference of any form of exogenous substance that may affect clotting. The benefit of this approach is that it is simple and inexpensive to use. The disadvantage is that there is a prolonged lag time from start of the assay and until first clot formation. Furthermore there may be an issue of increased analytical variation, although this has yet to be confirmed in veterinary medicine. In order to reduce lag time, increase sensitivity and minimize analytical variation, two different activators have been applied in veterinary medicine. Kaolin is a commercially available, "ready to use" reagent that is used to reflect the ability of blood clotting initiated via the intrinsic coagulation cascade. Tissue factor (TF), on the other hand, reflects ability of blood clotting initiated via the extrinsic coagulation cascade. The appealing aspect of TF is that it potentially reflects the physiological initiation of coagulation as it is perceived to take place in the cell based model of hemostasis. Unfortunately the TF assay is not commercially available, and therefore somewhat more laborious to perform since the reagent has to be pre-diluted.

Irrespective of which activator and reagent are used, it is well established that the reference intervals are not interchangeable at the present time; therefore each laboratory has to individually establish their own reference intervals.

Clinical Application

The ability of a laboratory assay to reveal and correlate to clinical phenotype is crucial for rational hemostasis

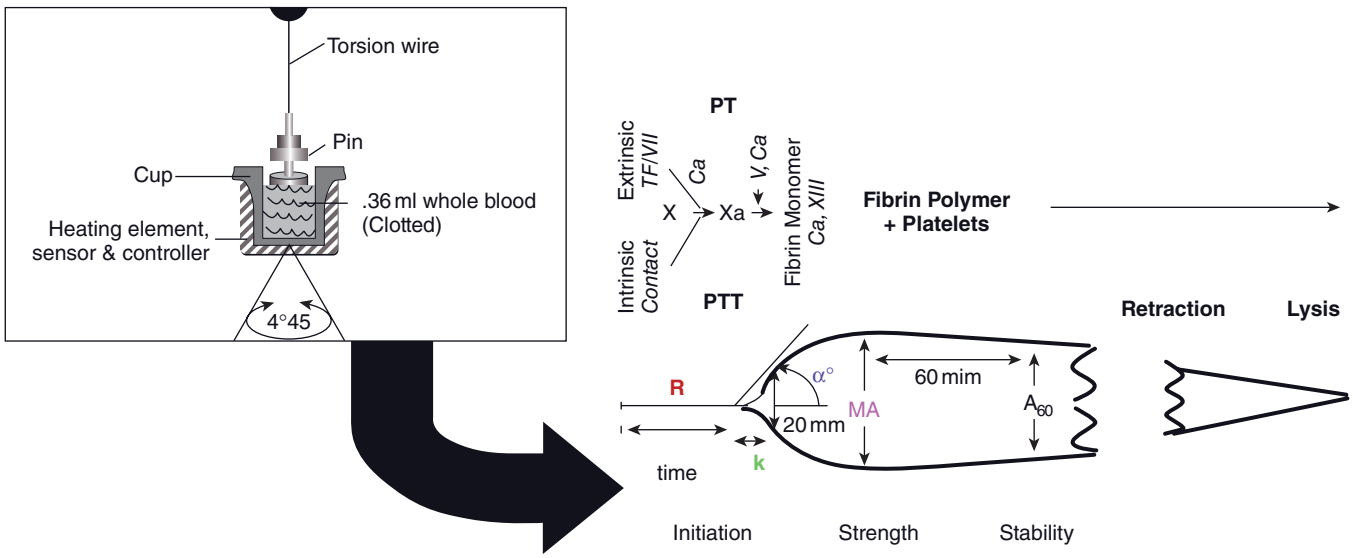

FIGURE 138.3 Example of TEG tracing with most common parameters and relationship to plasma based coagulation assays. R is the reaction time and represents the time of latency from the time that the blood was placed in the TEG analyzer until a preset fibrin formation is reached, measured as an increase in amplitude of 2 mm. The clotting time (K) is the time to clot formation time measured from the end of R until an amplitude of 20 mm is attained, and is a measure of the time it takes from initial clot formation until a predetermined clot strength is reached; α (or angle) represents the rapidity of fibrin build-up and cross-linking; MA, maximum amplitude; A_{60}, amplitude at 60 min; PT, prothrombin time; PTT, activated partial thromboplastin time; TF, tissue factor; Ca, calcium; VII, factor VII; X, factor X, Xa, activated factor X.[161] (Modified from Wiinberg B, Jensen AL, Rozanski E, et al. Tissue factor activated thromboelastography correlates to clinical signs of bleeding in dogs. Vet J 2009;179:121–129, with permission. ©Oxford University Press.)

monitoring. The ideal hemostasis assay should therefore be able to identify both biochemical and cellular abnormalities in the hemostasis system and at the same time correlate to the clinical signs of the patient. Thromboelastography offers a welcome opportunity for point of care evaluation of overall hemostatic capability and could potentially provide clinicians with an improved ability to diagnose, monitor and predict therapeutic response in animals with bleeding and/or procoagulant and thrombotic disorders. Consequently, TEG analysis has the potential to aid in the diagnostic workup of patients with abnormal hemostasis and supplement the information received from traditional coagulation assays, such as PT, aPTT, D-dimer, and fibrinogen assays. Figure 138.4 depicts TEG tracings of the different states of hemostasis as they have been reported, mainly in humans, but also in animals.[32,82]

Thromboelastography has been used in several veterinary studies so far, both clinical and ex vivo. The studies have mainly included pigs, dogs and cats, but also horses and alpacas have been studied and the results published.[2,8,119,153,161] Several other species have been studied at research institutions, but the data have not been published.

A recent study in dogs demonstrated that TF activated TEG (TF-TEG) is able to correctly identify dogs with clinical signs of bleeding with both higher positive and negative predictive values than the conventional coagulation profile consisting of aPTT, PT, D-dimer, fibrinogen and platelet count, which are widely used in veterinary medicine.[162]

In another study examining the application of TF-TEG as an aid in the diagnosis of DIC in dogs, it was demonstrated that TEG can be used to distinguish between different stages of DIC. Thus TEG as a test of global hemostasis may potentially provide an option for more individually tailored treatment plans for patients with DIC.[159]

In a study where TF-TEG was used to examine the overall hemostatic state in dogs with a variety of neoplasias, 28 out of 49 dogs (57%) had abnormal TEG results. Overall, a total of 22 out of 49 dogs could be characterized as hypercoagulable (45%), and six were characterized as hypocoagulable (12%). The results confirm that a majority of dogs with malignancy have hemostatic dysfunction, but most importantly, it was documented for the first time that the most common abnormality is hypercoagulability.[71]

Thromboelastography has traditionally been used in humans to monitor hemostatic function during surgery and to optimize blood product selection and usage. The use of TEG as a transfusion guide seems to have a large potential in veterinary medicine, as it is intuitively easy to perform and interpret (Fig. 138.5). Furthermore, it has the potential to significantly optimize blood product usage and efficacy. But TEG also has the potential to test the efficacy of different types of medication in vitro.[132]

A veterinary example of this is found in an in vitro study, where heparinase modified TEG was investigated as a possible method to evaluate the effect of therapy with the low LMWH dalteparin in dogs.[61] The results show that spiking citrated canine whole blood with increasing doses of dalteparin significantly and dose dependently affects all TF-activated TEG parameters. In contrast to this, it was observed that when using kaolin as an activator there was almost no measurable dalteparin effect.[61]

Long-term corticosteroid therapy has been associated with an increased risk of thromboembolic complications in dogs, and TEG has been used in a small prospective pilot study in an attempt to detect the development of a hypercoagulable state in Beagles receiving oral prednisone.[126] Further studies are needed to determine the underlying mechanisms of this hypercoagulability.

Recently TEG has also been used to monitor the antiplatelet effect of various non-steroidal anti-inflammatory drugs and clopidogrel.[14,15]

These last four studies emphasize a unique feature of the TEG assay, which suggests that it could be uti-

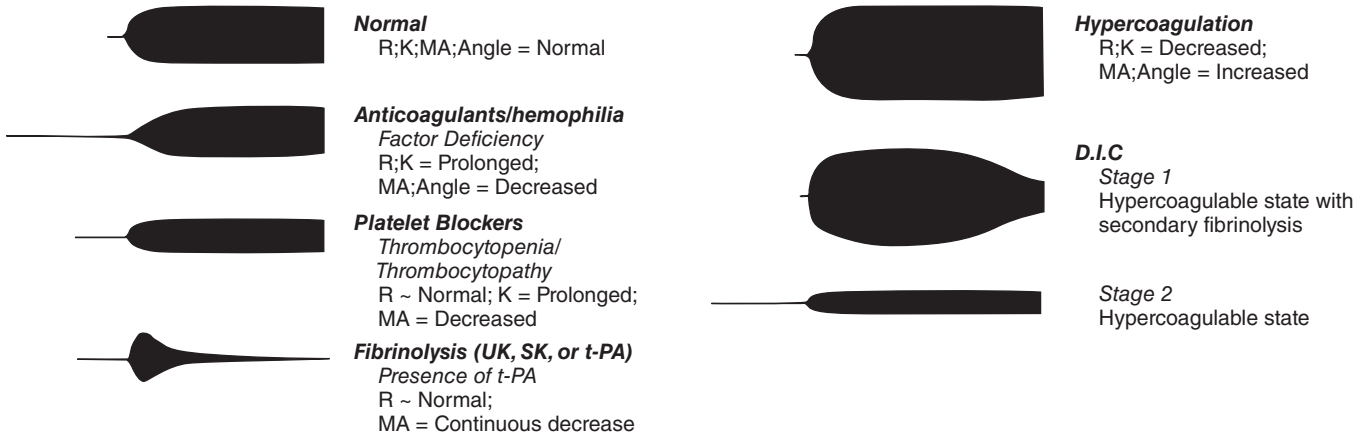

FIGURE 138.4 Pattern recognition chart of TEG tracings, compiled from human research (from Haemoscope Corporation, with permission). R, reaction time; K, clotting time; MA, maximum amplitude; t-PA, tissue plasminogen activator; DIC, disseminated intravascular coagulation.

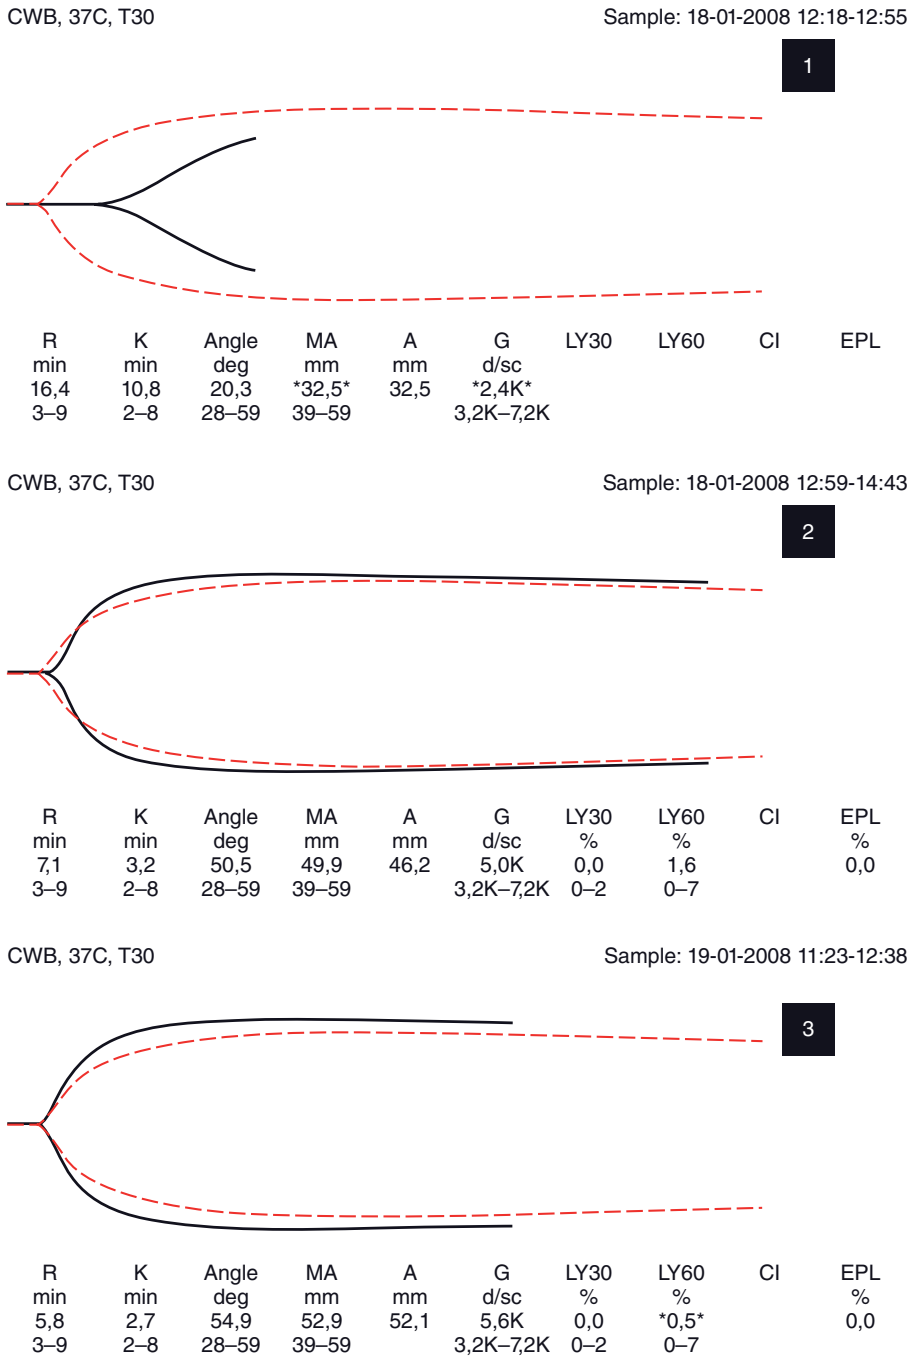

FIGURE 138.5 Clinical example, where TEG is used to guide transfusion therapy. (**1**) Patient sample **pre-treatment**. Prolonged R, K with decreased angle and slightly decreased MA, demonstrating coagulation factor deficiency. (**2**) Patient sample **pre-treatment** added fresh frozen plasma in vitro at a dosage equivalent to 10mL/kg. The results show normalization of all TEG parameters, indicating good effect of treatment. (**3**) Patient sample **post-transfusion** with 10mL/kg fresh frozen plasma. The results are very similar to the projected effect of treatment. R1, reaction time; K, clotting time; MA, maximum amplitude.

lized in targeting therapy of the patient towards normalization of their TEG tracings and thereby tailor dosage to meet the requirements of the individual patient.

In other species, TEG has been used in studies on cats with cardiogenic arterial thromboembolism, and has evaluated the effects of LMWH and UFH therapy in cats with and without cardiac disease.[1] Thromboelastography has also been used to detect platelet dysfunction in a horse and to evaluate the hemostatic response in pigs undergoing pericardiectomy.[81,118]

CHAPTER 139

Clinical Blood Typing and Crossmatching

K. JANE WARDROP

Blood Typing (see Chapter 92)
- Laboratory Testing and Submission
- Blood Typing in the Dog
- Blood Typing in the Cat
- Clinical Blood Typing Methods
- Blood Typing in Large Animals

Crossmatching (see Chapters 95 and 98)
- Indications and Limitations
- Crossmatching in Large Animals
- Standard Crossmatching Procedure
- Crossmatching using Gel Tubes

Acronyms and Abbreviations

ACD, acid citrate dextrose; EDTA, ethylenediaminetetraacetic acid; IAT, indirect antiglobulin test; NI, neonatal isoerythrolysis; RBC, red blood cell.

Blood typing and crossmatching are techniques used in the selection of blood components before transfusion. When blood typing is performed, antisera or other reagents are used to identify specific red blood cell (RBC) antigens. In crossmatching, antibodies are detected by reacting donor sera and donor RBCs with recipient sera and recipient RBCs. The primary purpose of this pretransfusion testing is to ensure that the transfused RBCs have optimal survival when transfused and do not cause harm to the recipient.

Pretransfusion testing in humans generally involves a type and screen procedure. This consists of an initial typing for ABO and Rh antigens and detection of patient antibody by mixing patient serum with commercially available reagent RBC that contain known antigens. An indirect antiglobulin test (IAT) is used during this antibody screen. When no clinically significant antibodies are detected, an immediate spin crossmatch, in which serum is mixed with saline-suspended RBCs and centrifuged immediately, can be performed to ensure ABO compatibility. If clinically significant antibodies are found, RBCs that lack the corresponding antigens are used, and an IAT crossmatch is performed. The IAT is best for detecting IgG antibodies. Use of a low-ionic-strength saline solution in the IAT further enhances its sensitivity. Techniques using microplates, solid-phase systems, and microtubes, where antiglobulin reagent is contained within a matrix of Sephadex or glass microbeads, have also been developed.[8]

Blood typing and crossmatching can also be used before transfusion in most domestic animals. The development of veterinary blood banks for animals and an increased awareness of the benefits of transfusion have resulted in increased availability and use of blood products, especially whole blood, packed RBCs, and plasma. Transfusions performed with untyped or uncrossmatched blood can sensitize recipients to future transfusions or can result in reactions that range from enhanced removal of the transfused RBCs to death of the patient. Pretransfusion testing in veterinary clinical practice is frequently less complex than that performed in the human field, largely because of a lack of appropriate reagents.

BLOOD TYPING

Laboratory Testing and Submission

Blood typing of some animal species can be performed in commercial veterinary laboratories. A partial listing of these laboratories is provided (regional veterinary diagnostic or clinical pathology laboratories may also offer these services and can be contacted).

1. Animal Blood Resources International (dogs, cats)
   4983 Bird Drive
   Stockbridge, MI 49285
   517-851-8244

2. Equine Parentage Testing and Research Lab (horses)
   102 Animal Pathology Bldg.
   University of Kentucky
   Lexington, KY 40546-0076
   859-257-3656
3. Hematology Laboratory (horses)
   Room 1012, Veterinary Medical Teaching Hospital
   One Garrod Drive
   University of California
   Davis, CA 95616
   530-752-1303

To perform blood typing, laboratories usually require the submission of either ethylenediaminetetraacetic acid (EDTA) or acid citrate dextrose (ACD) whole blood. Serum also may be required for antibody testing.

Blood Typing in the Dog

Canine RBC antigens are primarily identified by use of polyclonal antibodies generated through canine alloimmunization. DEA 1.1, an antigen capable of producing acute hemolytic reactions in sensitized animals, can be identified with a monoclonal antibody.[1] DEA typing for dogs varies, depending on the laboratory used, with some laboratories only typing for DEA 1.1, and others typing for DEA 1.1, 1.2, 3, 4, 5, and 7. Other RBC antigens may be present; however, lack of available antisera prohibits or prevents their identification. This is true for both well known antigens and newly discovered antigens. For example, DEA 6 and 8 are common antigens (DEA 6 is present in 99% of dogs; DEA 8 may be present in 40% of dogs) identified in dogs. Lack of available antisera prevents their identification by most typing laboratories. The *Dal* antigen is a newly discovered RBC antigen of dogs, and its frequency is unknown;[2] typing sera for this antigen also is commercially unavailable.

Blood Typing in the Cat

The best characterized blood-group system in cats is the AB system. This system consists of three blood types, A, B, and AB. Type A is the most frequent blood type, occurring in more than 95% of domestic short-hair and long-hair cats in the United States. Type-B blood occurs in less than 5% of domestic short-hair and long-hair cats; however, the frequency of type A and B in cats varies with the breed of cat and the geographic location.[5,6] For example, as many as 45% of Exotic and British Short-hair cats and Cornish and Devon Rex cats have the B blood type. Type-AB cats are rare. Most laboratories type for both the A and B antigen in cats.

All type-B cats older than 3 months of age have high titers of anti-A antibodies. These antibodies act as strong hemolysins and hemagglutinins.[4] Type-B cats transfused with type-A RBCs have a significant hemolytic transfusion reaction, and type-A or -AB kittens born to type-B queens are at risk of developing neonatal isoerythrolysis. Cats that have type-A blood have weak anti-B alloantibodies that produce a delayed transfusion reaction characterized by premature removal of transfused cells. Type-AB cats have no alloantibodies in their plasma.

Recently, a newly recognized, non-AB blood group RBC antigen was described in domestic short-hair cats, and was called the *Mik* red cell antigen.[14] The absence of this antigen was found to be associated with naturally-occurring anti-*Mik* alloantibodies, capable of eliciting a hemolytic transfusion reaction.

Clinical Blood Typing Methods

Typing of dogs and cats has been simplified for clinical use by production of commercial typing kits. Typing cards (DMS Laboratories, Inc., Flemington, NJ) contain monoclonal antibody or reagent (*Triticum vulgaris* lectin for blood type-B cats) that has been lyophilized onto the card wells. A small amount of diluent and patient EDTA whole blood is added, and the card is rocked for approximately 2 minutes. Agglutination indicates a positive response (Fig. 139.1). Control wells are included with the canine typing cards to aid in reading the reac-

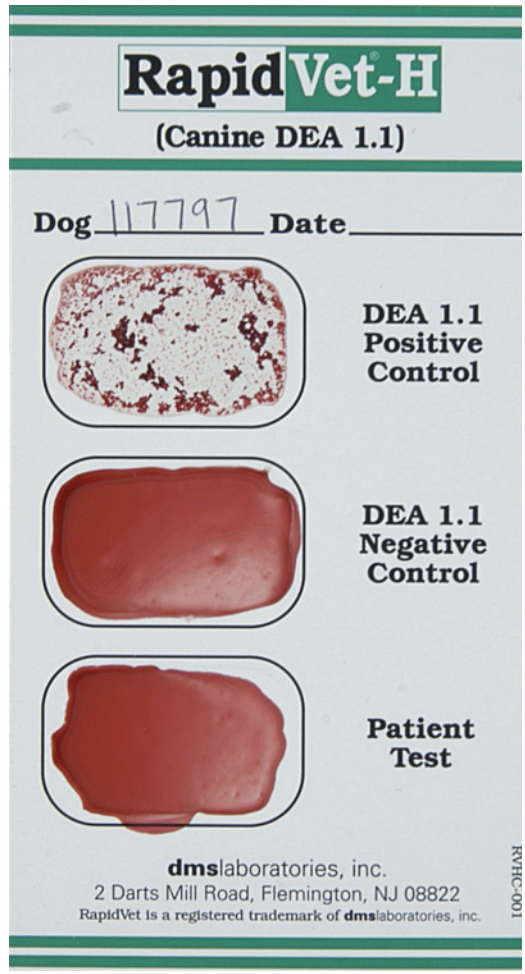

FIGURE 139.1 An example of a canine DEA 1.1 blood-typing card, with positive and negative control wells. The canine patient blood shows no agglutination, and is DEA 1.1 negative.

tions. For the dog, cards are available that type for DEA 1.1. Cats that have type A, B, or AB can be identified using the feline blood-typing cards. The advantage of these cards lies in their speed and simplicity. DEA 1.2 positive dogs may produce false-positive DEA 1.1 reactions on the card assay.[7] The anti-A antibody agglutination reaction of type AB-positive cats may be weak when using the feline blood typing cards.[11]

Typing gels are also available for the typing of DEA 1.1 in dogs and A, B, and AB in cats (Diamed AG, Morat, Switzerland). Gel tubes contain a monoclonal antibody in a gel matrix. Antigen-antibody reactions cause agglutinates to form that then become trapped within the gel. Free RBCs pass though the gel and form a button at the bottom of the tube (Fig. 139.2). The microtubes are bound to small cards, necessitating a special centrifuge for their accommodation. Control tubes that contain gel without antibody are included to detect potential false positive reactions due to autoagglutination.

The newest test for blood group determination in dogs and cats uses a membrane dipstick technique (Alvedia®, Villeurbanne, France) In this test, RBCs mixed with a buffer are allowed to migrate on a membrane that contains monoclonal antibodies against DEA 1.1, or against feline type A and B. In a positive reaction, RBCs will agglutinate with the antibodies and form a visible line on the membrane (Fig. 139.3).

FIGURE 139.2 An example of a canine DEA 1.1 gel test. From the left, tubes 1 and 3 are negative control tubes, tube 2 shows a negative reaction in a canine patient, tube 4 shows a positive reaction in a canine patient, and tubes 5 and 6 are unused.

Blood Typing in Large Animals

Blood typing for large animals is best performed by a commercial veterinary laboratory. Blood typing cards or gels are not available. Blood typing in large animals can be complex. For example, 34 different erythrocyte antigens from seven blood groups have been identified in horses.[10] Cattle have at least 11 blood-group systems; sheep have seven.[10] This means that identification of a blood donor with identical alloantigen and antibody profiles is difficult, if not impossible. Compatibility testing in these species, however, can be used to help avoid severe transfusion reactions by identification of existing antibodies. Alloantigens Aa and Qa are the most immunogenic of the equine RBC antigens and are responsible for the majority of equine neonatal isoerythrolysis (NI) cases.[13,15] Mares that lack Aa and Qa are at risk of producing antibody to them upon exposure. Mares known to be at risk, either because of blood type or because of previous foaling of an affected foal, can have sera tested for antibody before foaling.

CROSSMATCHING

Indications and Limitations

Blood typing permits the identification of RBC antigens in a patient. It does not allow the detection of antibodies between a patient and a potential blood donor. In a clinical situation this is generally determined by crossmatching. Even in animals that have been blood typed, crossmatching should be performed to detect antibodies against RBCs.

Crossmatching does have its limitations. A compatible crossmatch does not necessarily indicate that the donor and recipient have the same blood type, merely that antibodies against RBCs cannot be detected. Also, the crossmatch technique may lack the appropriate sensitivity to detect some antibodies; thus it is possible to

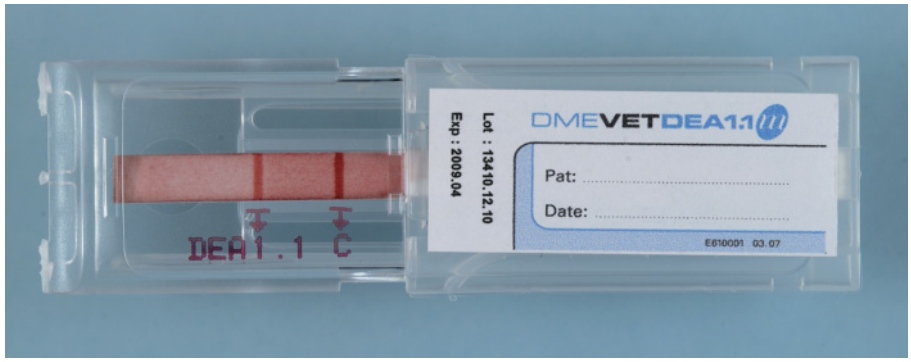

FIGURE 139.3 An example of a canine DEA 1.1 membrane dipstick test. The presence of a red line by the "DEA 1.1" arrow indicates a positive reaction. The red line by the "C" arrow is a control line that indicates the test has been run successfully.

have a compatible crossmatch and still have increased removal of the transfused cells. A standard crossmatch does not detect platelet or granulocyte antibodies. It cannot predict some types of transfusion reactions, such as urticarial reactions. Nevertheless, crossmatching can be a useful technique and should be performed before transfusion. Ideally, crossmatching should be performed before all transfusions; however, where this is not possible, it should certainly be performed before those transfusions in which the recipient has a history of previous blood exposure. Crossmatching should always be performed before feline transfusions, regardless of the previous transfusion history, because of the presence of naturally-occurring antibody in the cat and the serious consequences of transfusing type-A blood into a blood type-B cat.

Crossmatching in Large Animals

Crossmatching in large animals generally requires both a saline-agglutinating technique and a technique that can detect hemolysis. Agglutination tests can be performed by most veterinary practices; however, the hemolytic tests require the addition of exogenous complement, usually provided by rabbit or guinea pig serum.[12] This serum is diluted or adsorbed first with RBCs of the species to be tested, to remove the natural heterolysins and heteroagglutinins present in the rabbit or guinea pig serum. Consequently, detection of hemolytic antibodies is usually confined to the veterinary laboratory.

One crossmatching technique used in the identification of mare antibody in cases of suspected NI is the jaundiced foal agglutination test.[10,13] In this test, colostrum from the mare is reacted with RBCs from the foal. The colostrum can also be tested with potential donor blood. Serial dilutions (1:2–1:128) with saline of colostrum are made, and one drop of EDTA foal blood is added to 1 mL of the dilution. Blood is also added to a saline control tube that lacks colostrum. The tubes are centrifuged and judged for agglutination. Positive reactions at dilutions of 1:16 or greater are considered significant in horses.

Standard Crossmatching Procedure

The crossmatching procedure described in Table 139.1 is a saline-agglutination crossmatch commonly performed by many veterinary laboratories. Some laboratories also use an IAT in this procedure, adding species-specific Coombs' reagent after the initial RBC or sera reactions have been interpreted. Antisera-treated RBCs are washed in saline, the Coombs' reagent is added in an amount and dilution determined by the manufacturer, and the mixture is incubated. The mixture is then centrifuged and the sample is checked for agglutination. A saline replacement technique is useful to detect rouleaux in species such as horses and cats, in

TABLE 139.1 Crossmatching Procedure

1. Obtain an anticoagulated (EDTA) and/or non-anticoagulated specimen of blood from both patient and donor. The EDTA tube will serve as the source of RBC (antigen), and the non-anticoagulated tube will serve as the source of serum (antibody).
2. Centrifuge and separate plasma or serum from RBC.
3. Wash RBC by adding saline or phosphate buffered saline (PBS) to a small amount of packed RBC, mixing, and centrifuging. Decant the saline and repeat 3 times, filling the tubes with saline, mixing, centrifuging, and decanting.
4. After last wash, decant supernatant and resuspend cells with saline to give a 2–4% ("weak" tomato juice) suspension of RBCs. The suspension may also be calculated; for example, 0.1 mL blood in 2.4 mL saline gives a 4% suspension.
5. Make the following mixtures by adding the indicated amount of the well–mixed RBC suspension and serum to 12 × 75 mm tubes:

Major crossmatch: 2 drops patient sera, 1 drop donor 2–4% RBC
Minor crossmatch: 2 drops donor sera, 1 drop patient 2–4% RBC
Include controls: 2 drops patient sera, 1 drop patient 2–4% RBC
2 drops donor sera, 1 drop donor 2–4% RBC

6. Incubate tubes 15–30 minutes at 37°C.
7. Centrifuge for 15 seconds (3400 rpm/1000 × *g*).
8. Read tubes:
   Macroscopic: Examine tubes first for hemolysis. Then rotate tubes gently and observe cells coming off the red cell "button" in the bottom of the tube. Rotation of the control tubes prior to or simultaneously with rotation of the other tubes allows for optimum comparison of reactions. In a compatible reaction, i.e. where there is no antigen-antibody reaction, the cells should float off freely, with no clumping/hemagglutination (compare to the control tubes). Rouleaux formation can be falsely interpreted as a reaction. If rouleaux formation is suspected, a saline replacement technique can be used. Proceed to the microscopic examination in those tubes with weak or no obvious reactions.
   Microscopic: After tubes have been viewed macroscopically, place a drop of the cells/sera mixture on a slide, apply a coverslip and examine microscopically. The RBC should normally appear as individual cells, with no clumping or rouleaux formation.

which rouleaux formation is common and can be erroneously identified as agglutination in the crossmatch procedure. Steps in the saline replacement technique[3] are as follows:

1. Recentrifuge the serum or the RBC mixture when rouleaux formation is suspected.
2. Remove the serum.
3. Replace the serum with an equal volume of saline (two drops) and gently mix.
4. Centrifuge the saline or the RBC mixture at $1000 \times g$ for 15 seconds.
5. Resuspend the saline or the RBC mixture and observe for agglutination.

Rouleaux disperse when suspended in saline, whereas true agglutination remains.

Grading of reactions or antibody titration can also be performed.[3,9]

Crossmatching Using Gel Tubes

Crossmatching using gel microtubes has been described for both the dog and the cat.[2,14] The procedure uses saline gel microtube test cards (ID card "NaCl, enzyme test and cold agglutinins," Diamed AG, Morat, Switzerland) that contain a neutral dextran-acrylamide gel. For the major crossmatch, a 0.8% suspension of donor RBCs is prepared, using a modified low ionic strength saline solution (LISS, ID-Diluent "Vet 2," DiaMed AG, Morat, Switzerland). Patient plasma and the donor RBC suspension are added to the gel tubes, incubated for 15 minutes at 37°C, and centrifuged in a special centrifuge designed to accommodate the typing cards. The crossmatch can also be performed using gel microtubes containing anti-canine globulin (ID-gel test anti-canine globulin, Diamed AG, Morat, Switzerland). A larger tube gel crossmatching kit that uses a standard centrifuge is also commercially available (DMS Laboratories, Inc., Farmington, NJ).

Blood typing and crossmatching are valuable techniques that must be considered before transfusion in all species. Although some testing should be performed in specialized veterinary laboratories, other tests, such as saline-agglutinating crossmatching and DEA 1.1 and feline AB blood typing can be performed in most clinical veterinary practices and provide information that aids in the safe selection of blood components.

Acronyms and Abbreviations

ANAs, antinuclear antibodies; DAT, direct antiglobulin test; dsDNA, double-stranded DNA; ELISA, enzyme-linked immunosorbent assay; FITC, fluorescein-isothiocyanate; IAT, indirect antiglobulin test; ID, immunodiffusion; IIF, indirect immunofluorescence; IMHA, immune-mediated hemolytic anemia; IMN, immune-mediated neutropenia; IMT, immune-mediated thrombocytopenia; MCTD, mixed connective tissue diseases; PBS, phosphate buffered saline; PF3, platelet factor 3; PF4, platelet factor 4; PSAIg, platelet surface-associated immunoglobulins; RBC, red blood cell; RNP, ribonucleoproteins; SLE, systemic lupus erythematosus.

Immune-mediated hematologic diseases occur with some frequency in veterinary medicine. Immune-mediated hemolytic anemia (IMHA), immune-mediated thrombocytopenia (IMT), immune-mediated neutropenia (IMN), and disorders such as lupus erythematosus have all been previously described (see Chapters 33–35, 41, 54, and 78). Testing typically involves detection of antibody directed against cellular antigens. This chapter will describe specific tests available for the above named diseases.

COOMBS' TEST

The Coombs' test, also known as the antiglobulin test, is used to detect antibody and complement on the surface of red blood cells (RBCs). The test is frequently used in diagnosis of IMHA. In this disease, antibodies directed against the RBC surface cause premature destruction of the RBC: these are often incomplete antibodies that sensitize or coat RBC but fail to agglutinate them without addition of potentiators to alter the RBC zeta potential or without the addition of antiglobulin reagent. Most incomplete antibodies are IgG and are thus detected by anti-IgG serum (as contained in antiglobulin reagent). A few IgM antibodies also can be incomplete. These incomplete antibodies produce antibody-dependent complement activation; thus antiglobulin reagents are also designed to react with complement components on the red cell surface, with the main components detected being C4 and C3. Polyspecific reagents for veterinary use typically contain anti-IgG, anti-IgM, and anti-C3. Monospecific reagents are also available.

Methodology

Two forms of the antiglobulin test are used in veterinary medicine: the direct antiglobulin test (DAT) and the indirect antiglobulin test (IAT). The DAT, that detects immunoglobulin and/or complement bound directly to RBC, is used to evaluate IMHA patients. The IAT detects the presence of unbound antibody in the serum and is not typically used in IMHA cases. An example of a tube procedure for the DAT is described in Table 140.1. In this procedure, the addition of antiglobulin reagent to the RBC with bound immunoglobulin or complement causes agglutination to occur (see Fig. 33.5).

The antiglobulin test can also be performed using microdilution plates, which allows for a greater number

TABLE 140.1 Direct Antiglobulin Test (DAT) Tube Technique

1. Place 1–2 drops of a 2–5% RBC suspension in a 10 or 12 × 75 mm test tube.
2. Wash 3–4 times with normal saline or with phosphate buffered saline (PBS). Thoroughly decant the last wash residual in order to avoid dilution or neutralization of the antiglobulin reagent.
3. Immediatedly add antiglobulin reagent in amounts and as diluted per manufacturer's guidelines. Standard dilutions for canine antiglobulin are 1:2, 1:4, and 1:8. Prepare a negative control tube by adding saline instead of reagent to a tube.
4. Incubate tubes according to manufacturer's directions.
5. Centrifuge, gently dislodge red cell button and record agglutination reactions observed as the cells come off the button. If no agglutination is apparent, a small amount of the tube contents can be placed on a slide and examined microscopically.
6. If available, add IgG-sensitized red cells (known as "check" cells) to nonreactive (unagglutinated) tests. Centrifuge and examine for agglutination.
7. If a positive DAT is obtained, monospecific reagents (if available for the species) can be used to determine whether immunoglobulin or complement (or both) are present. Freshly washed cells must be used for this step.

of dilutions of antiglobulin reagent and uses smaller volumes of reagent and RBC per well. The use of multiple dilutions has been shown to increase test sensitivity.[48]

Diagnostic Significance

The antiglobulin test today is most commonly used in veterinary medicine in the diagnosis of IMHA. The use of the antiglobulin test as an aid in the diagnosis of IMHA in dogs was first described by Miller et al. in 1954, and subsequently by Lewis et al. in 1963.[37,44] Direct antiglobulin test positive hemolytic anemia was first described in cats in 1973 by Scott et al.[54] Several studies on the use of the antiglobulin test in detecting IMHA in the horse have been described.[38,40,43]

Sensitivity of the antiglobulin test in detection of IMHA is moderately low, with sensitivity as low as 48% reported in dogs.[26] False negative test results may be secondary to factors such as incomplete washing of RBCs, insufficient RBC-bound antibody, elution of Ig or C3, or to a prozone effect.[48,63] Interestingly, positive results in the absence of IMHA can also occur. One study described a high incidence of C3b bound to RBC in dogs with infections, inflammatory disorders, and myeloproliferative and lymphoproliferative diseases.[56] Hemolytic disease in these dogs was minimal or absent. The positive DAT was felt to be useful in dogs with signs of hemolytic disease, but needed to be interpreted with caution in other conditions. In another study using cats, 16 of 20 anemic cats were DAT positive. Eleven of the 16 were FeLV positive, and the remaining five positive cats had inflammatory disease or hemoplasmosis. Conservative interpretation of a positive test in the absence of hemolysis was recommended.[13]

Alternate Technologies for Antiglobulin Tests

Alternate test modalities have been developed to enhance test sensitivity. Most of the alternate technology associated with antiglobulin testing has been designed to either increase the sensitivity of the test or to lessen the subjectivity associated with assessment of agglutination. Enzyme-linked antiglobulin tests appear to enhance sensitivity, but are difficult to perform and also decrease the specificity for IMHA.[3,27] Flow cytometry has been shown to be a sensitive diagnostic technique for IMHA in dogs and horses, with some decrease in specificity.[51,67] However, the test necessitates the availability of a flow cytometer in the laboratory. Antiglobulin gel tests incorporate antiglobulin into a gel matrix. An RBC suspension is dispensed into the reaction chamber of a microtube containing the gel, and tubes are incubated and centrifuged. The microtubes may be held together in a small plastic card, which necessitates a specific centrifuge. Red blood cell agglutinates become trapped and remain stable in the gel, while free RBCs pass through and form a button at the bottom of the tube. The end-point reactions are more stable than conventional tube agglutination reactions. Strong positive reactions remain at the top of the gel, while RBCs involved in negative reactions pellet to the bottom. A gel antiglobulin test is available for dogs (DiaMed, Switzerland); however, comparison studies between this canine gel test and other types of antiglobulin testing are lacking.

ANTINEUTROPHIL ANTIBODY TESTS

IMN has been described in dogs, cats, and horses.[7,12] The disease is frequently diagnosed by exclusion of other diseases known to cause neutropenia, supportive bone marrow findings, and by response to corticosteroids. Direct diagnosis of IMN involves detection of antineutrophil antibody; however, antineutrophil antibody tests are not widely available. Previous techniques for detection have included leukoagglutination, phagocytic inhibition, indirect immunofluorescence, and flow cytometry.[64] In one study, an indirect leukoagglutination test was used to determine antineutrophil antibodies in two giant Schnauzers.[62] The sera of these neutropenic dogs were incubated for 30 minutes at 37°C with saline washed buffy coat cells harvested from the patient's blood. The cells were rewashed, incubated with antiserum to canine IgG, IgM, and C3, resuspended, and applied to glass slides. The slides were stained and viewed with a microscope. Serum from the patients but not from a control dog demonstrated agglutination of the patient's neutrophils, and a tentative diagnosis of IMN was made. A leukoagglutination method has been described in the cat, but the technique used was deemed difficult and fraught with interpreta-

tive problems.[10] An indirect immunofluorescence test, using paraformaldehyde-fixed cat neutrophils incubated with patient serum and tagged with fluorescein isothiocyanate (FITC) conjugated antiglobulin was described for cats, but failed to identify any antineutrophil antibody in 55 feline neutropenic patients.[10] A phagocytic inhibition test has been described in the horse as a method for detection of IMN.[25] In that test, the presence of neutrophil antibody in patient serum was indicated by inhibition of normal neutrophil phagocytic activity, but the assay was felt to be relatively insensitive.

Both direct and indirect flow cytometry are described as being the most sensitive tests for antineutrophil antibodies. A flow cytometric method using unfixed equine neutrophils treated with rabbit antineutrophil serum and fluorescein-conjugated goat anti-rabbit IgG antibodies has been described.[24] In the dog, patient serum was incubated with paraformaldehyde-fixed neutrophils and subsequently incubated with fluorescein conjugated rabbit anti-dog IgG.[65] Factors such as alloantibodies, immune complexes, or neutrophil donor variation did not appear to be present. Use of this test in 12 dogs with neutropenia demonstrated antibody in five out of six dogs with a clinical diagnosis of IMN and lack of antibody detection in six out of six dogs with neutropenia associated with other diseases.[64]

ANTIPLATELET ANTIBODY TESTS

IMT has been described in dogs, horses, and rarely in cats, and the pathologic mechanisms are described in more depth in Chapter 78.[28,33,41] The disease may be primary (idiopathic), or secondary to a variety of underlying conditions caused by infectious agents (primarily tick borne), neoplasia, or associated with drug administration.[33] In dogs with primary IMT, the platelet reactive antibodies are frequently reported to be of an IgG class and have been identified to be directed against the platelet surface glycoprotein gpIIb/IIIa (CD41/CD61), the fibrinogen receptor antigen.[35,55] As a consequence, the antibody-coated platelets are rapidly cleared by macrophages in spleen or other tissues.[69] In secondary IMT, platelet destruction can be consequent to binding of immune-complexes to platelet Fc receptors, exposure of new antigens after membrane damage, nonspecific adsorption of foreign antigens (i.e. drugs), or newly generated antigens produced during the course of infectious or neoplastic diseases.[33,53,69] Several techniques have been developed to detect platelet surface-associated immunoglobulins (PSAIg) in primary IMT.[53] Initial methods to identify antibodies bound to platelets of human patients with IMT measured the total IgG concentration in platelet lysates.[11,34] These methods are not considered appropriate anymore, because subsequent studies identified the capacity of platelets and megakaryocytes to internalize plasma proteins into alpha granules including large amounts of IgG.[11,34]

Early assays to detect platelet antibodies in dogs mainly consisted of the platelet factor 3 (PF3) test and a direct immunofluorescent test to identify antibodies on megakaryocytes in bone marrow. The PF3 test was an example of a functional assay in which binding of platelet antibodies induces the release of PF3 and alters the clotting time.[23,61] The PF3 test lacks diagnostic specificity and is no longer used.[23,33] The direct immunofluorescent test for megakaryocytes is infrequently requested because it requires a bone marrow aspirate and has variable sensitivity.[33]

Indirect methods to detect serum antibodies that have binding specificities for platelets (platelet bindable antibodies) and direct methods to detect PSAIg have been described using enzyme-linked immunosorbent, immunoradiometric, and immunofluorescent (microscopy or flow cytometry) labeling techniques.[30,34,42,55,69] Indirect assays to detect antiplatelet antibodies in canine serum are infrequently used, because levels of circulating platelet bindable antibodies are typically low; therefore diagnostic sensitivity of the test is low (average sensitivity reported to be 60%).[29,30,36,42] Radioimmunoprecipitation methods described in dogs with primary IMT have identified specific autoreactive antibodies, but are laborious and not routinely available.[35,55]

Direct assays using flow cytometry to detect PSAIg are the most common methods currently in use for dog, horse, and cat blood samples.[28,33,41,69] At the Immunology Laboratory at Kansas State University College of Veterinary Medicine, platelet-rich plasma is prepared from EDTA anticoagulated samples and unbound immunoglobulins are removed by three washes in Tyrode's buffer. A species-specific FITC-conjugated monoclonal antibody against canine or feline IgG (polyclonal antibodies specific for equine IgG, IgM, and IgA are used for horses) is incubated with an aliquot of washed platelet suspension. Ten thousand platelets are counted and their signals recorded by the flow cytometer. The percentage of platelets coated with Ig is defined by the proportion of counted platelets that produces fluorescent signals above the background. The background represents the nonspecific binding of proteins to the platelet surface and is determined by the reaction of a FITC-conjugated isotype control antibody (Fig. 140.1).[69] Direct immunofluorescent assays for IMT have a high diagnostic sensitivity (90–95%) and a low diagnostic specificity.[33]

It is important to mention that these direct labeling techniques are used to identify the presence of surface-associated immunoglobulins on platelets and do not identify autoantibodies specific to platelet glycoproteins. Therefore, the sensitivity and specificity of any method for the detection of PSAIg should refer to its ability to detect immunoglobulins on the platelet surface, rather than correlating with the subjective clinical probability of primary IMT.[11,22,53] The diagnosis of primary IMT, in both human and veterinary medicine, is still based on the clinical impression, the exclusion of known causes of thrombocytopenia, and response to treatment.[22,55,61] The detection of PSAIg, hence, is not

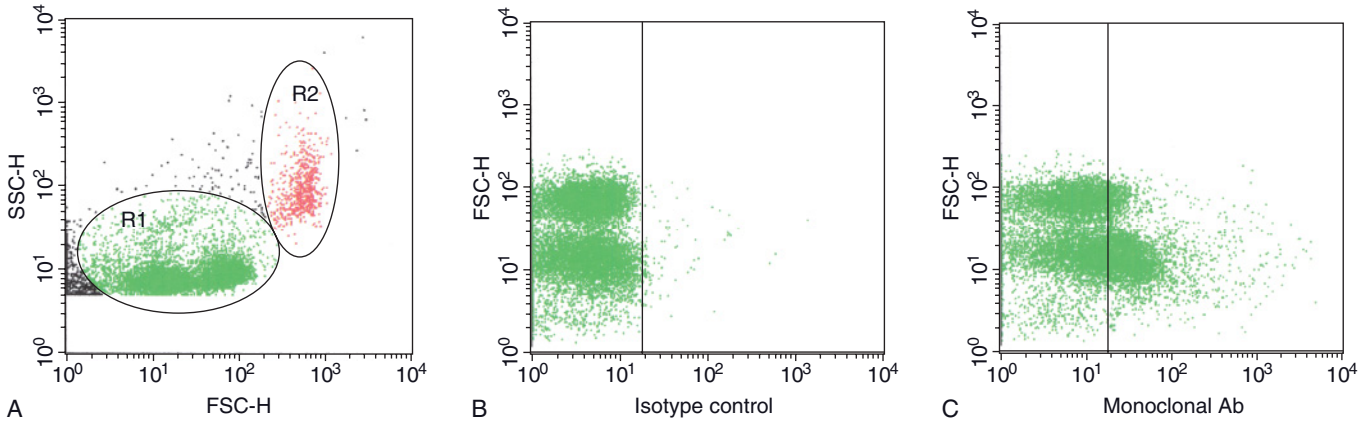

FIGURE 140.1 Dot plot results of the flow cytometric direct immunofluorescent test to detect PSAIgG on canine platelets. Each dot represents platelets/cells in a concentrated preparation of platelet-rich plasma (PRP). (**A**) Scatter plot of PRP demonstrates that the size and complexity of platelets (R1) is less than that of contaminating RBCs (R2) (SSC-H, side scatter height or complexity; FSC-H, forward scatter height or size). Two fairly distinct populations of platelets of different sizes are noted. (**B**) FSC-H versus fluorescence plots gated on platelets (R1) incubated with an isotype control antibody (FITC-labeled mouse IgG) which demonstrates background fluorescence to the right of the vertical line (1% of the gated platelet population); (**C**) FSC-H versus fluorescence plots gated on platelets (R1) incubated with a monoclonal antibody specific to canine IgG; platelets shifted to the right of the vertical line (42% of the gated platelet population) demonstrate binding of the fluorescent monoclonal antibody to platelet-bound IgG (PSAIgG).

pathognomonic of primary IMT and true-positive results are also found in other disorders with concurrent immune-mediated platelet destruction (secondary IMT). For this reason, the American Society of Hematology first defined the detection of PSAIg inappropriate and unnecessary in primary IMT patients.[16,22] However, more recent literature suggests that PSAIg assay could be useful as a screening test for primary IMT due to its high sensitivity.[22,61] A negative result, in fact, rules out an immune-mediated mechanism as the basis of the platelet destruction, whereas positive results must be confirmed by more specific assays, such as the monoclonal antibody-specific immunomobilization of platelet antigen assay (MAIPA), which is available in human medicine.[6,22,33,36]

A major disadvantage to the PSAIg assays is the poor stability of the sample that can lead to false positive results.[29,68,69] In fact, platelets can be activated by an improper blood drawing, poor sample handling (i.e. unnecessary agitation of the tube), low storage temperature, prolonged length of time between blood draw and sample preparation (storage time) and centrifugation steps, with subsequent exposure on the platelet surface of IgG contained within the alpha granules.[11,31,34,47,68–70] In the flow cytometric PSAIg test, platelet shape changes can be evaluated as an indicator of activation. When activated, the platelet population (forward-scatter versus side-scatter plots) spreads from the normal well-defined oval shape to an elongated and narrower scatter plot (Fig. 140.2).[47]

Flow cytometry methods using whole blood samples have been proposed as alternative methods to minimize in vitro platelet activation that occurs during the preparation of platelet-rich plasma.[59] However, a prolonged contact with leukocytes before platelet separation can trigger platelet activation.[31,59] Because the principal sources of platelet activation occur in a pre-analytical phase and are neither predictable nor trackable (i.e. shipment condition), positive results must be interpreted with caution and in the context of clinical and supporting laboratory findings.

ANTINUCLEAR ANTIBODY TEST

Antinuclear antibodies (ANAs) are a heterogeneous population of antibodies reacting against self nuclear components.[32,66] The identification of ANA specificities in humans is of diagnostic and prognostic value since particular autoimmune disorders are associated with the presence of specific autoantibodies.[32] The indirect immunofluorescence (IIF) assay is the most frequently used screening test for detection of circulating ANAs in both human and veterinary medicine.[21,32] Briefly, serial dilutions of serum from patients are applied to nuclear-rich tissue substrates fixed on glass slides, either rat liver sections or human monolayer epithelial cells (e.g. Hep-2, HeLa, Vero).[18,21] A secondary anti-species-specific antibody, typically conjugated with FITC, is applied to the sections, and the slide is then washed, after incubation, to remove unbound antibody. A specific ANA reaction is identified if the fluorescent staining is specific to the tissue substrate nuclei using fluorescence microscopy (Fig. 140.3).[21,32,50]

In humans beings, the pattern of nuclear fluorescence suggests the type of antibodies present and guides in selecting additional tests for the detection of antigen specificity and disease association. A homogeneous or peripheral nuclear staining usually reflects the presence of antibodies directed against chromatin constituents, such as double-stranded DNA (dsDNA) or histones. In people this is characteristic of systemic lupus erythema-

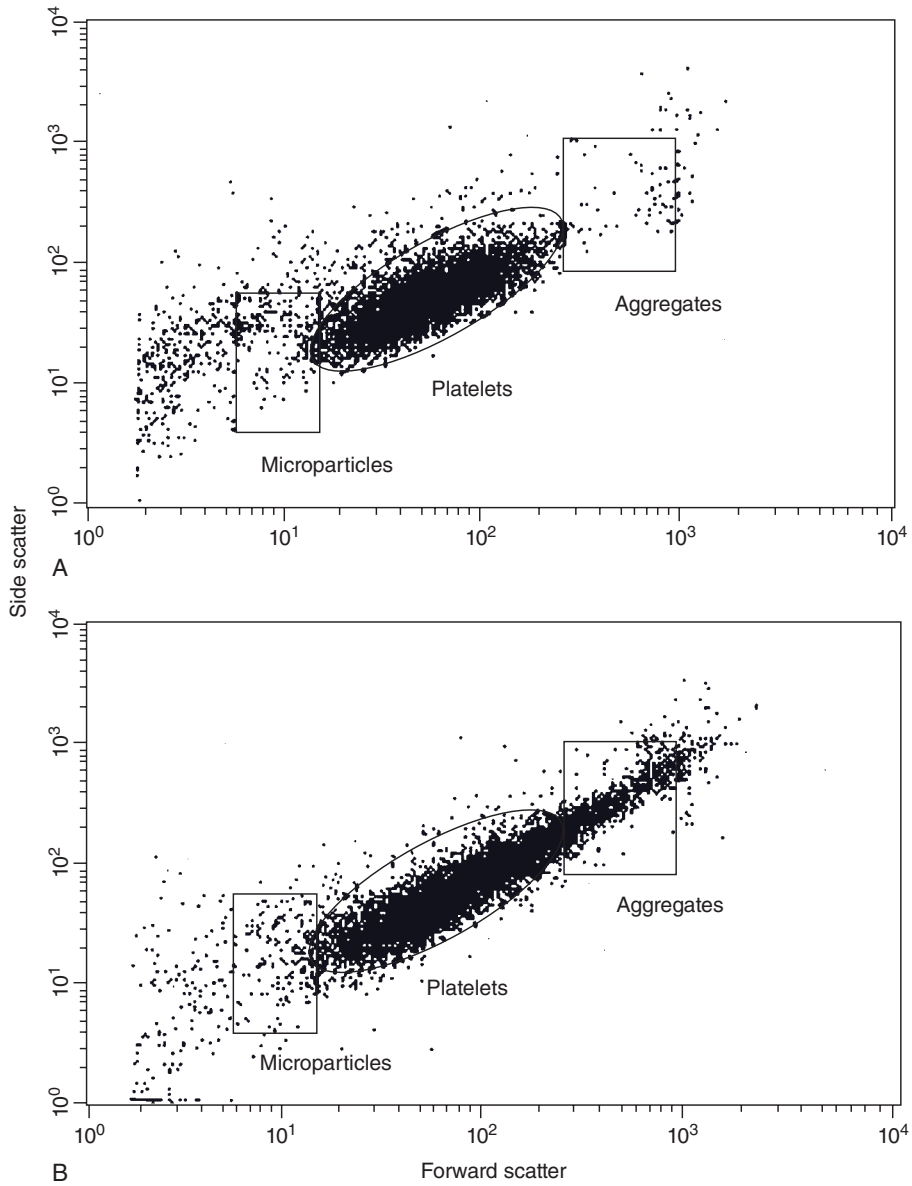

FIGURE 140.2 Forward-angle versus side-angle light scatter plots. (**A**) The scatter of non-activated platelets is a characteristic well-defined oval shape. (**B**) Platelets activated with 20 ng/mL phorbol myristate acetate. The platelet population spreads to form an elongated and narrower scatter plot. Platelet fragments (microparticles) and platelet aggregates are produced upon activation and are discernible as two distinct populations with a lower and higher forward scatter, respectively. (Reproduced from Moritz A, Walcheck BK, Weiss DJ. Flow cytometric detection of activated platelets in the dog. Vet Clin Pathol 2003;32:6–12, with permission.)

tosus (SLE) or drug-induced lupus. The speckled staining is the most frequently identified pattern but is not specific for a particular autoimmune disease. In human beings it is seen in the presence of antibodies to non-DNA components such as ribonucleoproteins (U1-RNP), Scl-70, Smith antigen (Sm), and Sjögren's syndrome sicca antigens A and B (SS-A, SS-B), that are associated with mixed connective tissue diseases (MCTD) and SLE, scleroderma, SLE, and Sjögren's syndrome sicca complex, respectively. The centromere and nucleolar stainings are more often associated with scleroderma, polymyositis, and other connective tissue diseases. In the majority of the cases of IIF positivity, serum samples are further analyzed for the determination of the specificity of the auto-reactive antibodies.[32] The most common secondary tests used include enzyme-linked immunosorbent assay (ELISA), immunodiffusion (ID), radioimmunoassay and immunoblot.[32,66] The double immunodiffusion technique of Ouchterlony has been used in dogs with positive immunofluorescence for ANAs.[19] The serum tested diffuses toward lyophilized mammalian nuclear antigens and forms a visible line where the immune complexes precipitate. Specific human sera reactive to predetermined extractable nuclear antigens are used to establish the specificity of the precipitating canine sera.[19]

The application of ANAs in veterinary medicine is still restricted to the diagnosis of SLE.[21] The lupus ery-

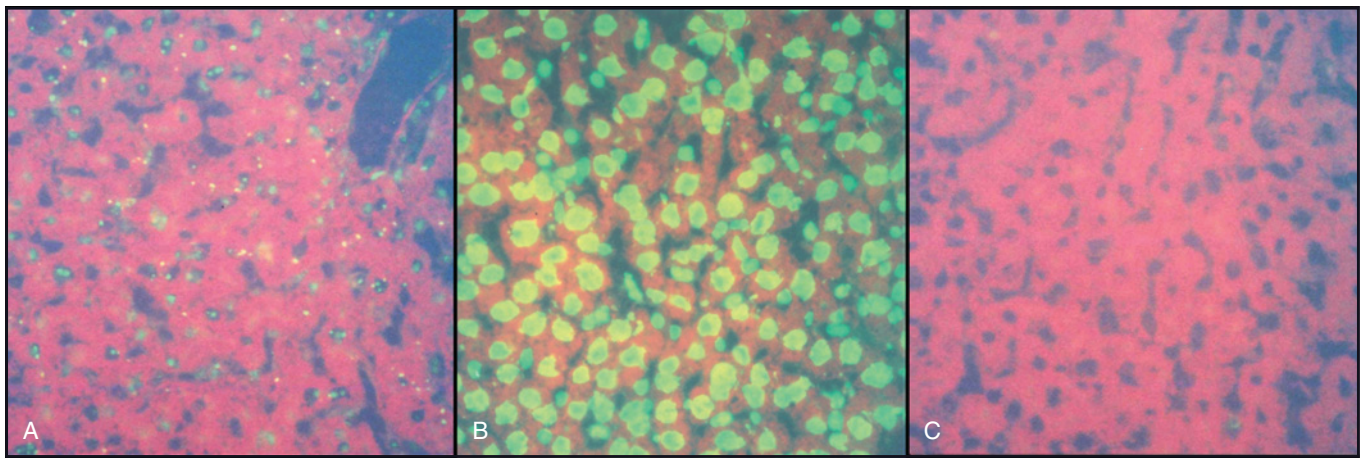

FIGURE 140.3 Antinuclear antibody patterns of canine serum reacting in the immunofluorescence test using rat liver substrate. Three separate canine serum samples reacted with FITC-conjugated anti-canine IgG to produce (**A**) a nucleolar staining pattern of hepatic cells; (**B**) a diffuse nuclear staining of hepatic cells; and (**C**) no specific staining of nuclear material. (Reproduced from Paul S, Wilkerson MJ, Shuman W, et al. Development and evaluation of a flow cytometry microsphere assay to detect anti-histone antibody in dogs. Vet Immunol Immunopathol 2005;107:315–325, with permission.)

thematosus cell test (LE test) also has been used to diagnose this disorder, but the test has a high incidence of false negative and false positive results, and is uncommonly used (see Chapter 54). SLE is rarely reported in cats and horses, and lack of comparative data makes difficult the interpretation of ANA titers.[15,18,60] Antinuclear antibody titers in cats diagnosed with SLE are usually low (below 1:40) and overlap with the titers of healthy subjects. Furthermore, titers as high as 1:100 can transiently be found in both FeLV and FIP positive cats.[18,60]

In dogs, a positive ANA titer is expected in 97–100% of cases of SLE, but the sensitivity of immunofluorescence varies between laboratories and substrate employed.[8,18] Antinuclear antibodies can also be produced in many inflammatory and infectious diseases, and a positive immunofluorescence result must be interpreted in the context of clinical signs and laboratory data.[21,58] Therefore a positive ANA test is listed in the revised American Rheumatism Association diagnostic criteria for people adapted for dogs, but should not be considered the sole criterion for the diagnosis of SLE.[9,21]

Positive ANAs have been described in dogs with non-autoimmune disorders such as in atopic dermatitis, onychodystrophy, and black hair follicular dysplasia, and in subjects sero-positive for *Bartonella vinsonii* subsp. *berkhoffii*, *Ehrlichia canis*, or *Leishmania infantum*.[17,18,49,58] Dogs with non-primary immune-mediated disorders tend to have low positive titers (91% ≤ 1:256), but positive titers up to 1:4000 occasionally can occur in dogs.[8,17,21,46,58] In contrast, higher immunofluorescence titers were found to be clearly correlated with signs of autoimmune diseases (1:100 on Hep-2)[21] and titers ≥1:640 were considered to be a good predictor of immune-mediated diseases in dogs.[57] Positive titers can also be found in healthy dogs, especially when cryopreserved sections of rodent liver are employed.[18,21] The appropriate threshold titer of positivity must be determined in each laboratory based on a control population and the type of substrate.[20] In general, high titer cut-offs (e.g. 1:100) are required with rat liver substrates to decrease the number of false positive results.[21] Hansson et al. found the Hep-2 substrate to be superior to rat liver sections not only for its high specificity (no false positives at 1:25 dilution in 100 healthy dogs), but also because it provides an easier and more consistent pattern discernment.[21] Using Hep-2 slides, two major patterns are recognizable in dogs: the homogeneous, characterized by an intense fluorescence staining of the chromosomal area in mitotic cells; and the more commonly occurring speckled pattern, chromosome-negative.[21] An association between homogeneous immunofluorescence pattern and SLE has been reported to occur in dogs, analogous to humans.[19] However, Hansson et al. failed to demonstrate an association between speckled immunofluorescence patterns and specific canine autoimmune diseases.[19] Likewise, a correlation between immunofluorescence patterns and ANA specificities was not found when the sera were analyzed with Ouchterlony ID, immunoblot, and ELISA, even if reacting bands were exclusively found in speckled patterns.[66] These results are possibly due to the lack of well-defined diagnostic criteria for the different autoimmune diseases in dogs and their overlapping clinical signs.[19,20] Furthermore, several canine auto-antigens differ from human antigens and are absent in the commercially available extracts made for the examination of human sera.[18,19,66]

In contrast to humans beings, the majority of ANAs in dogs are not directed against nucleic acid in native dsDNA but against nuclear proteins such as histones and RNP.[19,45] Autoantibodies against several individual histones (H1, H2A, H3 and H4) are increased in canine SLE whereas antibodies to histone-DNA complexes are rare.[8,45,66,50] Some anti-RNP autoantibodies are found in

both human and canine ANA-positive samples, such as antibodies directed against the proteins U1-70K, RNP A, RNP C, Sm, and SS-A.[8,45] Other autoantibodies, such as the so-called anti-type 1 (anti hnRNP G) and anti-type 2, are confined to dogs and many are yet to be identified.[19,45,66]

INVESTIGATION OF DRUG-INDUCED AUTOANTIBODIES

Drugs can induce the formation of antibodies, either against the drug itself, against intrinsic cellular antigens modified by the drug, or against both (see Chapters 15 and 16). This has been most frequently described with drug-induced immune hemolytic anemia in humans.[2,14] Drug-dependent antibodies require that the drug be present. Drug-independent antibodies react similarly to true autoantibodies (i.e. no drug is needed to demonstrate the presence of antibody). Drugs can bind loosely or firmly to cell membranes and antibodies may be made to (1) the drug itself, necessitating drug binding for in vitro detection; (2) cell membrane components; or (3) part drug, part membrane components, producing an in vitro reaction typical of an immune complex mechanism.

Method of Antibody Detection

Drug-induced anti-RBC antibodies in human are usually associated with a positive DAT. For further investigation of suspected hemolysis due to drug-dependent antibodies, special methods are used. As an example, for detection of antibodies to penicillin, drug-treated RBCs are prepared. Washed, packed group O RBCs are incubated for 1 hour with penicillin dissolved in a barbital buffer. The cells are then washed and stored in PBS. An aliquot of untreated RBCs in the same buffer is also prepared. The patient serum is mixed with a 5% saline suspension of the drug-coated cells and incubated at 37°C for 1 hour. The sample is then centrifuged, and examined for hemolysis or agglutination. The cells are also tested by an indirect antiglobulin technique.[5] For demonstration of immune-complex formation involving drugs, the patient serum is incubated with a suspension of the drug in question. The mixture is then added to enzyme-treated group O RBCs, incubated, and centrifuged and examined as described for the drug-coated cells. A similar test for antibodies directed against drug metabolites has been described.[5] Drug-independent antibodies react similarly to most IMHA cases, with a positive DAT test result.

Diagnosis of drug-induced immune granulocytopenia or thrombocytopenia is generally considered when there is a temporal association of the drug and the cytopenia, rather than by actual detection of antibody in the presence of drug. An exception would be heparin-induced thrombocytopenia, a condition described in human patients receiving unfractionated or low molecular weight heparin. Immunogenic complexes formed by heparin and platelet factor 4 cause antibody formation, and these anti-heparin/PF4 antibodies can be detected with commercially available immunoassays.[1]

Drug-Induced Hemolytic Disease in Veterinary Medicine

Drug-induced immune hematologic disease has been poorly documented in veterinary medicine, with most reports showing a temporal association of a drug with hematologic disease, but no actual testing for drug associated antibody. Penicillin induced hemolytic anemia has been described in horses.[4,39,52] The Coombs' test was positive in these horses, and their sera produced agglutination of penicillin-coated RBCs. In one horse, anti-penicillin antibody titers decreased progressively throughout the period of observation.[52]

Acronyms and Abbreviations

BAL, bronchoalveolar lavage; C5a, complement component C5; CAT, catalase; CV, coefficient of variation; DCF, 2,7-dichlorofluorescein; DHE, dihydroethydium; DNA, deoxyribonucleic acid, EDTA, ethylenediaminetetraacetic acid; F-actin, filamentous polymeric form of actin; FMLP, N-formyl-methionyl-leucyl-phenylalanine; G-actin, globular monomeric form of actin; H2-DCFDA, dichlorodihydrofluorescein diacetate; LTB4, leukotriene B4; MCLA, methyl cypridina luciferin analog; NADPH oxidase, nicotinamide adenine dinucleotide phosphate oxidase; NBT, nitroblue tetrazolium salt; PAF, platelet activating factor; PMA, phorbol myristate acetate; RBC, red blood cell; ROS, reactive oxygen species; SOD, superoxide dismutase; TdT, terminal deoxyribonucleotidyl transferase; TNF-α, tumor necrosis factor alpha; TUNEL, terminal deoxyribonucleotidyl transferase-mediated dUTP nick-end labelling; ZAS, zymosan activated serum.

Neutrophils play an important role in nonspecific immunity as the first defense against microbes, mainly of bacterial and fungal origin. Deficits in neutrophil function lead to increased susceptibility to infectious diseases, and have been reported in both congenital and acquired diseases (see Chapter 42).

Nonspecific immunity in vivo is related not only to neutrophil function but also to several conditions, including vasopermeabilization, priming and opsonization, cytokines, complement factors, soluble mediator secretion, and interaction between neutrophils and extracellular matrix or other inflammatory and endothelial cells. Testing neutrophil function in vivo is quite complex and does not permit discrimination between direct and indirect alterations; thus in vitro tests, that are more standardized, are more useful in most pathological conditions and allow testing the direct effect of different substances, drugs, and activators on neutrophils.

SPECIMEN, STORAGE AND NEUTROPHIL ISOLATION

Theoretically, a purified population of neutrophils supplies more definitive informative information about functional abnormalities. However, isolation techniques are reported to activate cells;[4] thus, sometimes, it is preferable to use techniques requiring whole blood (such as flow cytometry or chemiluminescence) in order to limit manipulation and activation of cells. Neutrophils from milk, exudates, and bronchoalveolar lavage (BAL) fluid can also be tested. Peripheral blood or fluids must be collected in anticoagulated tubes. Definitive studies on the influence of different anticoagulants on neutrophil function in animals are not available but heparin is generally preferred, especially when in vitro activation of neutrophils is desired. However, EDTA as well as acid-citrate-dextrose and citrate are often used as good alternative choices in many studies in dog, pig

and ruminants. Analysis can be delayed for up to 24 hours after collection, even though the samples should ideally be processed within 4 hours. Samples should be stored at room temperature. In order to avoid neutrophil activation, plastic instead of glass tubes should be used and sterility of all solutions should be carefully maintained.

Neutrophil Isolation by Lysis

The simplest methods of preparation of blood leukocytes is osmotic lysis of red blood cells (RBCs), adding distilled water to an aliquot of whole blood followed by restoring isotonicity with a hypertonic solution. Red blood cells are mechanically ruptured while leukocytes are more resistant, and RBC membrane debris is removed by washing steps. This technique is very simple but it does not allow isolation of leukocyte subpopulations and the percentage of purity of neutrophils is similar to that of whole blood. On the other hand, the method induces only minimal activation of neutrophils. A modification of this technique is the method described by Carlson and Kaneko[1] and has been widely used in ruminants. It involves osmotic lysis after removal of the buffy coat that containing most of the mononuclear cells. The method yields a high percentage of granulocytes, but eosinophils cannot be separated from the neutrophils. The method does not provide good purity and recovery in non-ruminant species.

Red blood cell lysis can also be performed by means of chemical solutions such as tris-buffered ammonium chloride. Unfortunately, this technique frequently interferes with some neutrophil functions or induces apoptosis; therefore it should be limited to flow cytometric evaluation of membrane antigens.

Sedimentation Techniques

Neutrophils can be enriched by adding an equal volume of dextran solution to whole blood. Dextran is a polysaccharide solution that induces rouleaux formation by increasing sedimentation of RBCs and mononuclear cells. After 30 minutes the granulocyte-rich supernatant is collected, centrifuged, and washed. This method has been described in humans and dogs,[13,34] as a single step or followed by gradient centrifugation and it is particularly useful in small animals because it requires a minimal amount of blood. However, isolated cells are characterized by low purity and dextran can partially influence neutrophil function.

Gradient Centrifugation Techniques

Several isolation techniques use colloidal suspensions at different densities to concentrate cells according to their specific gravity. Continuous gradients have been used, but discontinuous gradients are more feasible and adaptable to routine isolation of cell populations. The most frequently used technique in veterinary medicine is separation using a gradient of discontinuous Percoll® silica particles coated with polyvinyl pyrrolidone. For canine neutrophils, two different densities (1.092 and 1.071 obtained by using 74% and 55% of Percoll respectively) are layered and leukocyte suspensions are put on the top of the tube.[37] After centrifugation, a neutrophil-rich band is easily recognizable at the interface between two different densities (Fig. 141.1). This layer can be removed and after washing provides a very pure population of neutrophils. The method can be adapted to different species by adjusting the densities of Percoll: in swine 65% and 55%; in bovine 70% and 50%; and in the horse 75% and 60% concentrations of Percoll can be used. The main advantage of this technique is the high purity and recovery of neutrophils, especially in healthy animals. However, cell densities frequently vary with physiologic and disease conditions, which could lead to failure to isolate atypical or activated cells.[26]

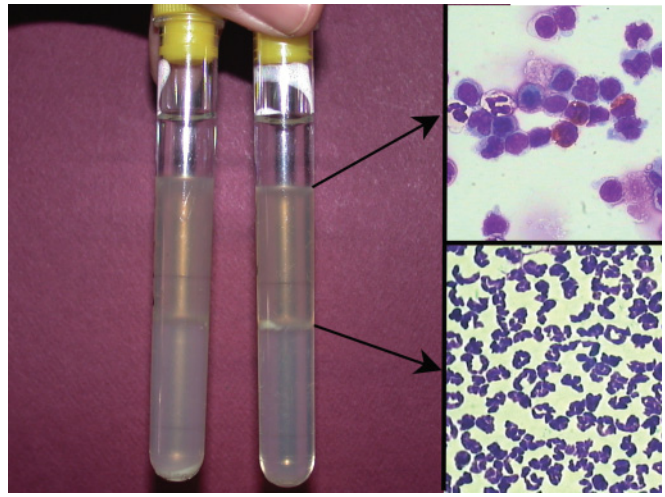

FIGURE 141.1 Isolation of blood neutrophils using a discontinuous Percoll gradient. After centrifugation a neutrophil-rich band is located at the interface between the two Percoll densities. (Courtesy of V. Spagnolo.)

A similar technique uses another commercially available polymer, Ficoll-Paque®, which is able to separate mononuclear cells and platelets (at the top) from granulocytes and RBCs (in the bottom of the tube) after centrifugation. This method is widely used in human medicine but it does not provide advantages in veterinary medicine in comparison with Percoll gradients.

Finally, an interesting method using a discontinuos metrizamide gradient has been developed and reported to isolate bovine neutrophils with high purity and yield.[6] This technique is reported to minimally interfere with neutrophil function but it has not been widely used.

Magnetic Beads Separation

Recently, separation methods using magnetic beads have been developed in cattle.[25] Briefly, magnetic beads are labelled with anti-bovine neutrophil monoclonal antibodies and then incubated with leukocyte suspen-

sions. Leukocytes bound to the beads are then captured using the magnetic system while unbound cells (mononuclear and other granulocytes) are eluted and discarded. After removal of the magnetic field, collected neutrophils show a high percentage purity and yield that makes the method useful. However, this technique requires neutrophil-specific antibodies that do not recognize other polymorphonuclear cells. Moreover, incubation with some antibodies could induce activation of neutrophils, thus influencing function tests. For these reasons, antibodies should be chosen carefully.

CLASSICAL TECHNIQUES FOR EVALUATION OF THE PHAGOCYTIC PROCESS

Many different techniques are described for evaluation of phagocytosis, some of which are able to evaluate the whole phagocytic process while others are used to discriminate single steps of phagocytosis (i.e. rolling, adherence, random migration and chemotaxis, particle uptake and killing). Tests for a specific step of phagocytosis are useful because many diseases or conditions lead to alterations in a single function without perturbing the whole phagocytic process. On the contrary, tests for the whole phagocytic process are easier to perform and give a more complete picture of complex interactions with nonspecific immunity. Thus a panel of tests for simultaneous evaluation of different steps of phagocytosis is strongly recommended in order to correctly assess neutrophil function.

Cellular Movement and Chemotaxis

The simplest technique to evaluate cellular movement is microscopic detection of conformational changes of neutrophils after activation. Activated neutrophils show a bipolar configuration within a few minutes after exposure to activating agents with a gradual return to a spherical shape.[29] However, this method is difficult to standardize and does not distinguish spontaneous motility, random migration (chemokinesis), and directional migration (i.e. chemotaxis). Many chemoattractant substances have been recognized but some of them (interleukin-8, zymosan-activated serum [ZAS], casein, LTB4, C5a, TNF-α, PAF and formylated peptides such as FMLP) are more commonly used in chemotactic tests. However, some species differences have been recognized. Neutrophils from cows, pigs, and cats do not respond to formylated peptides and those from dogs require a priming agent in order to express enough receptor for such substances.[11]

A frequently used method to test chemokinesis and chemotaxis is the migration assay using a modified Boyden chamber.[36] Briefly, suspensions of isolated neutrophils are put into the upper wells of a migration chamber while chemoattractant is added in the lower well. For evaluating random migration the addition of chemoattractant in the lower well is omitted. Two different methods have been described based on the type of filter used between the two wells:[31]

Method 1 In the leading front method (Fig. 141.2) a 150 µm thick cellulose nitrate filter is used. The chamber

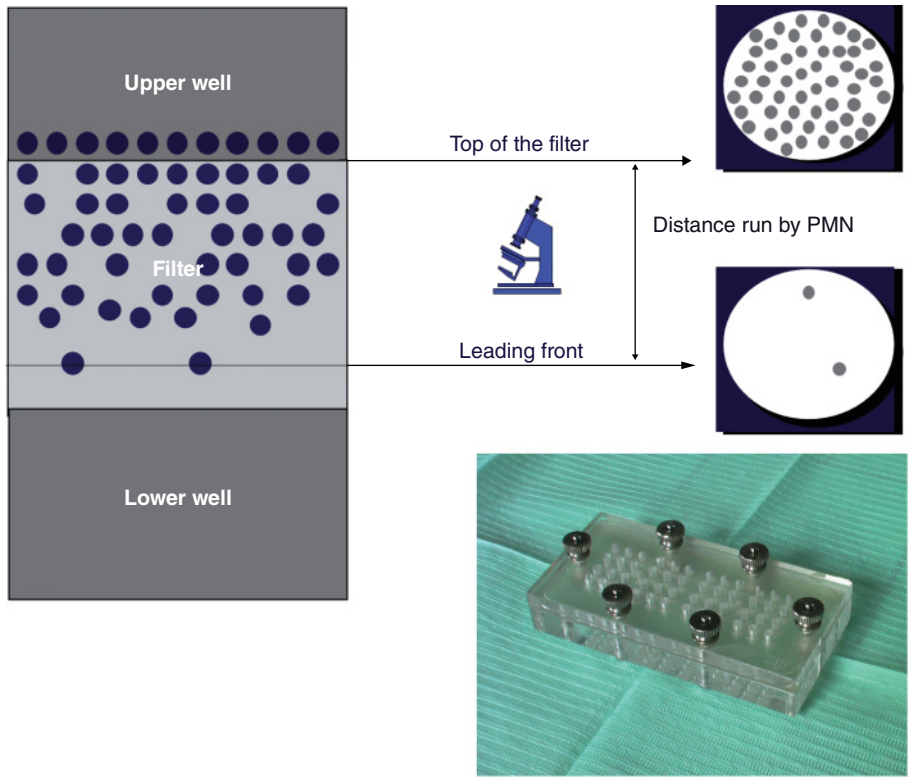

FIGURE 141.2 Evaluation of chemotaxis in a Boyden chamber, using the leading front method. Neutrophils migrate from the upper to the lower well (toward a chemoattractant) through a cellulose nitrate filter. The distance travelled by the cells is evaluated after staining the filter, using the fine adjustment on the microscope.

is incubated for 30 min at 37 °C in humified, 5% CO_2 atmosphere, and then the filter is removed, fixed, stained, dehydrated, clarified in xylene, and mounted on a glass slide. Cellular movement is evaluated by measuring the distance between the top of the filter and the leading front, where the two last cells are in focus.

Method 2 In the lower surface count method a thin (12 µm) polycarbonate filter with a pore size of 2.0 µm diameter is used. After incubation the filter is removed and the number of cells that pass through the filter is enumerated in the lower well, using a cell counter or a spectrophotometric method.[8] Cells attached to the lower surface of the filter are counted after wiping the upper surface of the filter and staining with Wright's stain.

These two methods provide different data on neutrophil chemotaxis but, according to some investigators, both methods are strongly influenced by the degree of adherence and gravity.

Thus, assays to evaluate chemotaxis in a collagen gel matrix[5] or under-agarose[17] have been developed. The collagen gel matrix assay consists of a visual assay obtained by two capillary tubes with their ends covered by a dialysis membrane and connected by a polyethylene tubing sleeve. The compartment formed between the ends of the two tubes is filled with a solution of monomeric collagen and put under a microscope. Cell movements are recorded microscopically after addition of cell suspension and chemoattractant. This technique is quite complex but it allows study of neutrophil movement step-by-step in a microenvironment similar to an in vivo system.

The under-agarose technique is a quite simple, inexpensive and widely used method based on the preparation of a gel matrix in a teflon chamber. Wells are cut in the gel and cell suspensions are added to the wells. Different chemoattractants can be put in separate wells and in some cases chemoattractant is omitted in order to evaluate spontaneous motility. After incubation, agarose is flooded with methanol, followed by 35% formaldehyde in order to harden the gel and, after staining, the migration distance run by neutrophils toward the chemoattractant well is evaluated by microscopy.

Finally, some authors[24] have suggested a more complex method that requires a culture system made of successive layers of collagen, fibroblasts, collagen, and a confluent monolayer of epithelial cells coated on a porous membrane. Cells are put at the basal side of the membrane and cells passing over the epithelial layer towards chemoattractant stimuli are counted. This technique is particularly useful for studying chemotaxis and diapedesis of neutrophils during infection in the mammary gland, but it is quite difficult to perform and to standardize.

Adherence

Assays for evaluation of adhesive capability of neutrophils could be schematically divided into two groups: (1) those evaluating adherence to inert substances, such as polysaccharides, nylon fibers, glass, or plastic, and (2) those that measure adhesiveness to biological structures, such as endothelial cells, monolayers, or cell culture systems. The latter assays reproduce interactions between neutrophils and biological barriers in a more complex way, similar to that which occurs in vivo. However, they are strongly influenced by extragranulocytic factors; thus most of these techniques are difficult to standardize and lack reproducibility.

Techniques that evaluate adherence to inorganic substances have been developed using column or microtiter plates. Briefly a borosilicate glass column can be filled with packed Sephadex or nylon fibers and neutrophil suspensions are percolated through the column. The percentage of adhered cells is then calculated by counting and subtracting the recovered cells. Different stimulators or substances can be used. All of these methods lack precision; thus it is strongly recommended that these tests be done in triplicate. Assays in microtiter plates are performed by adding suspensions of neutrophils in flat bottom wells together with different activators or inhibitors, and they are useful for testing the influence of different substances on neutrophil adhesiveness. Nonspecific adherence to plastic wells or adherence after activation with an activation agent (e.g. phorbol myristate acetate [PMA] or zymosan activated serum [ZAS]) can be evaluated. In order to remove nonspecific activation due to contact with plastic wells, pre-coating of some wells with gelatin can be performed. After incubation and washing to remove non-adherent cells, the percentage of adhered cells is evaluated by microscopic count using an inverted microscope. Otherwise neutrophils can be lysed and indirectly evaluated by means of chemical or fluorometric methods. Fluorometric labelling with calcein[16] or colorimetric methods to quantify myeloperoxidaes or acid phosphatase are commonly used.[22] Results should be reported as the number of adhered cells compared to a standard curve obtained by different dilutions of neutrophils from the same animal. Assays in microtiter plates are more reproducible compared with those in columns and require smaller amounts of blood; thus they are more applicable for small animals.

Many assays have been reported to test adhesive capability of neutrophils to cell layers or tissues. The simplest methods use cultured endothelial cells packed into an adherence column instead of nylon fibers or Sephadex. Other techniques using monolayer of cultured cells of different origin (endothelial, fibroblasts, myocytes) have been reported. Target cells may be isolated from fresh tissues and cultured on a coverslip until confluent. An adhesion assay chamber is obtained by adding a second coverslip separated from the monolayer by a rubber O-ring. Neutrophils are added in this incubation chamber and adhesion is evaluated by a visual method, using an inverted microscope equipped with phase-contrast optics. The number of neutrophils remaining on the slide, after washing away the non-adherent cells, is enumerated. This technique reproduces the complexity of interactions between neutrophils and tissue cells and is very useful for studying the pro-

duction of cytokines by endothelial or mesenchymal cells, or the mechanism of interaction between neutrophil adhesion molecules and their ligands. However, the technique is difficult to perform, lacks reproducibility, and is influenced by extra-neutrophilic factors.

Particle Uptake

The capability of neutrophils to phagocytize particles can be evaluated by visual, spectrophotometric or flow cytometric assays. Many different particles can be used, including latex beads, yeasts (*Saccharomyces* or *Candida*, for instance), and bacteria (*Escherichia coli* or *Staphylococcus aureus*). Particles are incubated on a glass slide with a suspension of isolated neutrophils; then ingestion is stopped by adding an ice-cold isotonic solution, and phagocytosis is evaluated by various methods. The simplest method is microscopic evaluation of the percentage of cells that have phagocytized particles, after staining adherent cells. In some assays, particles can be pre-labelled with a fluorescent dye (fluorescein isothiocyanate or acridine orange) and the mean number of ingested particles per neutrophil determined using a fluorescence microscope. Fluorescence of non-ingested particles is inactivated by treating the cellular suspension with trypan blue solution.[34] The main problem with this technique is that results are strongly affected by adherence to the glass slides; therefore assays using neutrophil suspensions in tubes or flasks have been developed.[27]

Another interesting technique uses polystyrene latex beads (1.09 µm diameter).[21] After incubation, non-ingested particles are removed by centrifugation and the supernatant is discarded; then neutrophils are ruptured and ingested latex particles are solubilized with 1,4-dioxan. The amount of latex is indirectly determined in a spectrophotometer at 255 nm. This method is very simple, inexpensive and rapid, but it does not permit determination of the percentage of neutrophils phagocytizing particles.

Finally, in some assays ingestion has been evaluated after labeling bacteria with radioactive materials followed by evaluation of the quantity of radioactivity in cell suspension.[19] However, this technique is very complex and expensive and requires handling of radioactive materials.

Killing

Many assays have been developed to evaluate bactericidal activity of neutrophils. These have been divided into three groups:

Group 1 This group includes techniques that evaluate residual viability of bacteria incubated with neutrophil suspensions. These assays are easy to perform and can be applied to whole blood. The method consists of incubation of a suspension of live bacteria with neutrophil suspensions and serum in order to allow opsonization. After incubation, bactericidal activity is determined by counting colony-forming units, after cultivation in blood agar plates, or by enumerating bacteria using a spectrophotometric assay after addition of a tetrazolium compound.[28] Live bacteria reduce tetrazolium to red-purple formazan while dead bacteria do not. Results are compared to a standard curve obtained with a known number of live bacteria.

Group 2 This group includes techniques that quantify neutrophil lysosomal enzymes. Many assays have been developed to quantify activity of lysosomal enzymes (myeloperoxidase, lysozyme, lactoferrin, cationic proteins, neutral proteases, acid hydrolases, and proteases) after neutrophil lysis. Most of them utilize colorimetric or ELISA methods that can be performed using a spectrophotometer or a microtiter plate reader.

Group 3 This group includes techniques that quantify the production of oxygen compounds produced by respiratory burst. Neutrophils generate reactive oxygen species (ROS) that play an important role in bactericidal activity. Many ROS are involved but superoxide anion is the precursor. Several assays have been developed to test the oxidative burst of neutrophils. Most of them are performed in multiwell microplates. Neutrophil suspensions are incubated in the presence of activators (such as PMA or zymosan) and after incubation, different methods to measure ROS production can be used. Intracellular and extracellular ROS production can be made by pre-treating cell suspensions with the NADPH oxidase inhibitor diphenyleneiodonium chloride (DPI) or with superoxide dismutase (SOD) or catalase (CAT), which are superoxide and hydrogen peroxide scavengers, respectively. These substances do not cross cell membranes; therefore they inhibit only extracellular ROS.

A rapid assay to detect respiratory burst activity evaluates the capability of neutrophils to reduce nitroblue tetrazolium salt (NBT) to formazan with production of a reddish-purple color that can be quantitated spectrophotometrically.[14] Recently, a microplate assay to measure ROS production in bovine neutrophils has been described.[18]

In the cytochrome *c* reduction assay, ferricytochrome *c* is added to wells and is reduced by superoxide. Changes in absorbance at 550 nm are spectrophotometrically evaluated at 10 minute intervals. This assay is reported to be a specific indicator of extracellular superoxide production.

Chemiluminescence can be evaluated by addition of methyl cypridina luciferin analog (MCLA). After addition of MCLA, decrease of chemiluminescence is measured at 10 minute intervals using a microplate luminometer. The assay is reported to be a specific indicator of superoxide production.

A commercially available test (Amplex-Red-dependent fluorescence) consists of a reaction mixture (resorufin and horseradish peroxidase) that is added to neutrophils. Samples are evaluated in a fluorimeter at an excitation wavelength of 530 nm and an emission wavelength of 590 nm. The test detects extracellular hydrogen peroxide. Other fluorescent assays include the dihydroethydium (DHE) and dichlorodihydrofluorescein diacetate (H2-DCFDA) fluorescence assay, and the luminol and isoluminol chemiluminescence assay.

All of these assays are suitable for detection of neutrophil oxidative burst in the bovine. Intra-assay repeatability is good; however, variability is high. The luminol assay has the lowest interassay coefficient of variation (CV) while other tests such as cytochrome *c* reduction, Amplex Red and DHE have high interassay variability (CV > 30%).

In dogs, studies using evaluation of ROS production using cytochrome *c* reduction,[2] luminol chemiluminescence,[34] H2-DCFDA,[20] and NBT reduction[7] have been reported.

FLOW CYTOMETRIC TESTS FOR NEUTROPHIL FUNCTION

The previously described measurements of neutrophil function using physical, microscopic, or chemical methods remain time-consuming. Moreover, because phagocytosis is due to sequential activation of multiple steps (rearrangement of cytoskeleton, chemotaxis and adherence, degranulation, and production of oxygen radicals) and alteration in any single step could influence the whole process, a panel of assays is usually applied. This requires large numbers of neutrophils that are difficult to obtain from small or diseased animals. Flow cytometric assays for testing neutrophil function have significant advantages when compared to classical ones: they are very rapid to perform, require small numbers of cells (at least 50–100 times fewer than conventional assays) and, using gating techniques, can be applied on heterogeneous populations of cells such as whole blood, avoiding neutrophil isolation that could induce significant activation of cells. Flow cytometry measures fluorescence and light scatter signals through a laser source (see Chapter 137). Using gating and multicolor techniques, cell populations can be resolved and analysis restricted only to cells of interest. Many different flow cytometric assays have been described in human medicine[35] but only a limited number have been validated and utilized in veterinary medicine.

Cytoskeletal Actin

Actin is a major cytoskeletal protein of neutrophils and can be found in a globular monomeric form (G-actin) and a filamentous polymeric form (F-actin). During activation, G-actin changes into F-actin and accumulates at the periphery of the cells. This process is involved in adhesion, deformability, and cellular movements. Dysfunctions in actin dynamic polymerization have been linked to susceptibility to infectious diseases.

Flow cytometric detection of F-actin can be assessed using the fluorochrome NBD-phallacidin. Whole blood cells are activated, then cells are fixed with 3% paraformaldehyde and RBCs are lysed. Leukocytes are permeabilized and stained with fluorochromes. In the flow cytometer, fluorochromes within neutrophils are excited with standard laser light and emit green fluorescence. The amount of fluorescence is correlated with F-actin content. This technique has been used in cattle, where increases of F-actin were found after neutrophil activation.[12]

Surface Adhesion Molecules

Flow cytometric assays for neutrophil adhesion are mainly based on detection of adhesion molecules on the cellular surface. Adhesion molecules may be divided into two groups: the selectin family that establishes a weak association of neutrophil with endothelial cells, and the integrin family that interacts with the immunoglobulin superfamily on endothelial cells, resulting in a firm bond that allows neutrophil diapedesis. The expression of adhesion molecules can be readily quantified using monoclonal specific antibodies. Whole blood is preferable in order to avoid neutrophil activation during the isolation technique. After labeling cells with fluorochrome-conjugated antibodies, the expression of membrane surface molecules is evaluated on gated neutrophils and expressed as mean (or median) fluorescence channel units. Integrins increase on neutrophil cell membranes after activation due to externalization of adhesion molecules from cytoplasmic granules (Fig. 141.3). On the contrary, expression of selectins on the cell membrane of activated cells is controversial.

This assay is simple and rapid but requires careful standardization of procedures, number of cells, and titration in order to work with a large excess of antibody. In veterinary medicine many studies using this technique have been reported, with particular attention given to canine and bovine adhesion molecules.[3,10,15,30,32,33]

Phagocytosis

Many different assays to quantify neutrophil phagocytic capabilities have been described. These methods entail incubating whole blood with fluorescently conjugated particles of different origin (inorganic beads, bacteria, yeast). The amount of fluorescence is taken as an

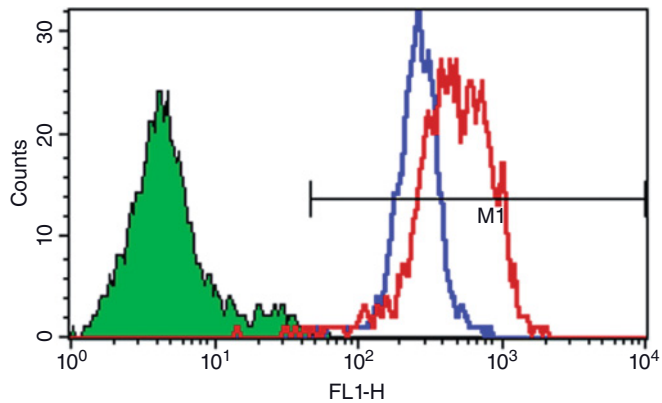

FIGURE 141.3 Flow cytometric evaluation of membrane integrin CD11b in bovine neutrophils. LPS-activated neutrophils (red line) express increased fluorescence compared to non-activated neutrophils (blue line). Shaded line indicates isotypic control.

indicator of phagocytic activity (Fig. 141.4). Heparinized whole blood is used because other anticoagulants chelate Ca^{2+} that is necessary for phagocytosis. A major limitation is that nonspecific adherence to the neutrophil membrane can cause an overestimation of phagocytosis. This aspect could be partially limited by quenching fluorescence of non-phagocytized particles using a quenching solution such as trypan blue or crystal violet. Alternatively, a control sample can be incubated at 4 °C that inhibits phagocytosis and allows quantitation of nonspecific adherence.

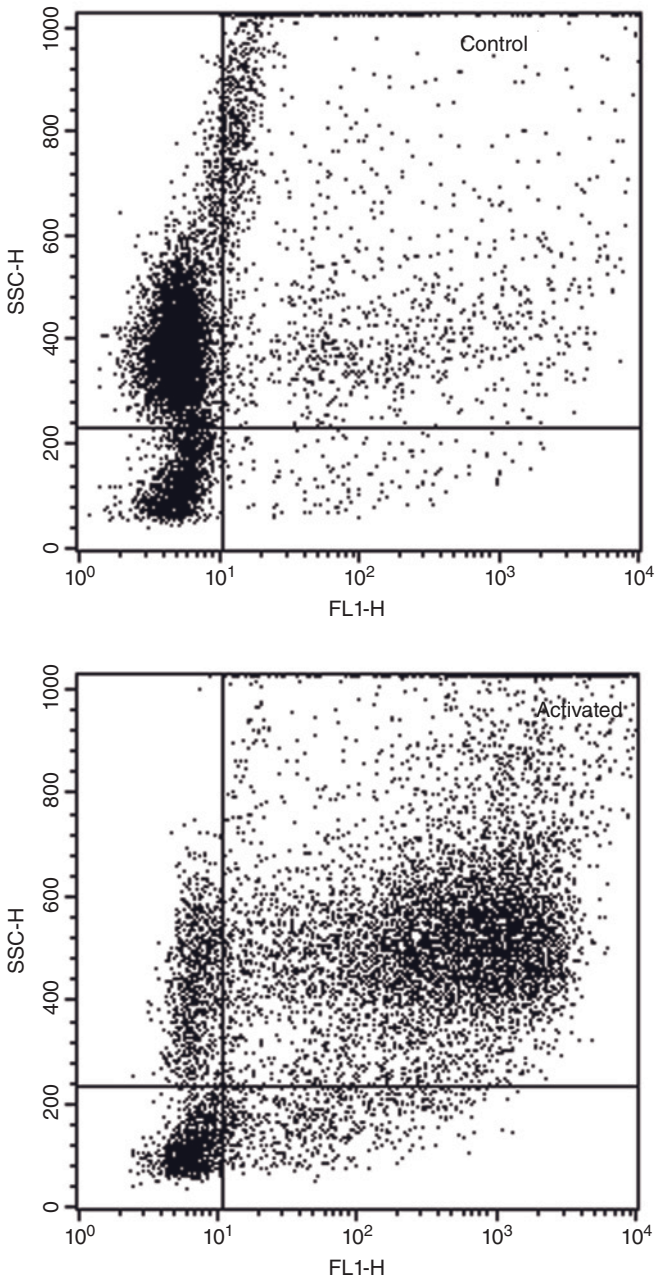

FIGURE 141.4 Flow cytometric evaluation of phagocytosis of fluorescein-labeled *Escherichia coli*. A high percentage of neutrophils shows fluorescence due to bacterial ingestion. In the control sample, phagocytosis is inhibited by incubating cells at 4 °C.

An interesting variant of this method allowing simultaneous evaluation of phagocytosis and oxidative burst has been described in cows,[23] dogs, cats, and horses. The technique couples evaluation of ROS production using a green fluorescent dye (dihydrorhodamine 123 or 2,7-dichlorofluorescein [DCF]) with ingestion of propidium-conjugated bacteria that emit a red fluorescence. A double color analysis allows easy measurement of particle uptake and oxidative burst activity simultaneously. Recently, commercially available flow cytometric assays have been validated for the bovine species, and show good agreement with other classical methods.[9]

Reactive Oxygen Species Production

Many flow cytometric tests to measure ROS production have been developed. One of the most frequently used is the DCF assay. The acetate form enters the cells and is oxidized mainly by hydrogen peroxide giving a green fluorescence. A similar technique uses dihydrorhodamine 123 which is converted to the fluorescent rhodamine 123. The benefits of flow cytometric techniques versus conventional ones are that they are rapid, they use small sample volumes, and whole blood samples can be used. However, eosinophils, that are not differentiated based on scatter properties, are capable of an oxidative burst; thus results on whole blood must be carefully evaluated in animals with hypereosinophilia.

APOPTOSIS

The study of neutrophil apoptosis, or programmed cell death, is another challenging area of neutrophil function. Neutrophils are characterized by a very short lifespan. Evaluation of neutrophil apoptosis is interesting because many different cytokines and also substances produced by pathogens may influence the rate at which neutrophils undergo apoptosis and/or necrosis.

Many assays, using conventional and flow cytometric techniques, have been developed to test neutrophil apoptosis. Conventional techniques mainly use cytochemical stains or colorimetric evaluation of proteases involved in the apoptosis process (i.e. caspase-3). Flow cytometric techniques have the advantage of assessing apoptosis in a large number of cells and are rapid and easy to perform. Many different assays have been developed that can evaluate the following:

1. Scatter properties Apoptotic cells lose water and decrease granularity. This aspect can be easily identified by decreases in both forward and side scatter. However, this method can not distinguish between apoptotic and necrotic cells.
2. DNA content The content of DNA can be evaluated using the fluorescent dye propidium iodide (or other dyes such as acridine orange, ethydium bromide, Hoechst 33342, or actinomycin D) after cell permeabilization. Apoptosis results in DNA frag-

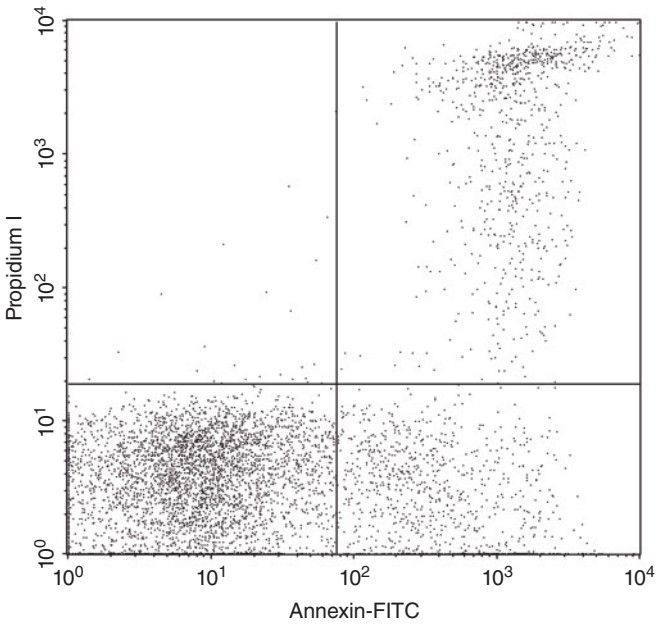

FIGURE 141.5 Flow cytometric evaluation of neutrophil apoptosis using double labeling for annexin V and propidium iodide. Cells in early apoptosis are detectable in the lower right quadrant while necrotic cells are in the upper right quadrant. (Courtesy of M.E. Gelain.)

mentation; thus the detection of cells with less DNA content than normal diploid neutrophils is suggestive of apoptosis or necrotic cells.

3. Surface markers of apoptosis Annexin V is a polypeptide that exhibits a strong affinity for phosphatidylserine molecules that are present only on the inner layer of cell membrane in viable cells. During apoptosis phosphatidylserine residues are exposed on the cell membrane. Early apoptotic neutrophils and necrotic cells can be easily detected by double labeling cells with fluorescent-conjugated Annexin V and propidium iodide that enters only necrotic cells (Fig. 141.5).
4. Terminal deoxyribonucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL) The principle of this assay is that, during apoptosis, terminal deoxyribonucleotidyl transferase (TdT) adds nucleosides to the free 3′ ends produced from DNA cleavage. Neutrophils are permeabilized and incubated with biotinylated nucleosides and TdT; after washing fluorescent-conjugated streptavidin that binds to the biotin is added and the number of cells in apoptosis is detected using a fluorescent microscope or flow cytometer. This assay is one of the more widely used methods to detect apoptosis. However, nonspecific positivity in necrotic cells is reported; thus it should be combined with one or more other techniques.

ADAMTS13, *a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13* also known as *von Willebrand factor-cleaving protease* (VWFCP); ADP, adenosine diphosphate; ATP, adenosine triphosphate; BMBT, buccal mucosal bleeding time; CADP, cartridges coated with collagen and ADP; CEPI, cartridges coated with collagen and epinephrine; CT, closure time; DDAVP, desmopressin acetate (1-(3-mercaptopropionic acid)-8-d-arginine vasopressin monoacetate (salt) trihydrate); FITC, fluorescein-isothiocyanate; GPIb, glycoprotein; GPRP, synthetic peptide Gly-Pro-Arg-Pro; LTA, light-transmission aggregation; MPC, mean platelet component concentration; NSAID, non-steroidal anti-inflammatory drug; OMT, oral mucosal bleeding time; PAF, platelet activating factor; PFA-100®, platelet function analyzer; PPP, platelet-poor plasma; PRP, platelet-rich plasma; SPD, storage pool disease; VWF, von Willebrand factor.

Tests of platelet function have been used in multiple ways in both clinical and research settings. In veterinary medicine they have primarily been used for diagnosis of bleeding disorders, and to predict bleeding risk associated with invasive procedures. More recently, platelet hyperfunction has been found to be an important aspect of many disease processes, and assays that can detect platelet hyperactivity and possibly predict thrombosis have increasingly gained interest. Table 142.1 lists currently available platelet function tests described in this chapter.

This chapter discusses currently available tests of platelet function, their advantages and drawbacks, and their utility in veterinary clinical and research settings. The chapter is focused on tests with published data in the veterinary literature, and does not provide a discussion of all available tests of platelet function.

BUCCAL MUCOSAL BLEEDING TIME

The bleeding time is one of the oldest tests still in clinical use. The buccal or oral mucosal bleeding time (BMBT or OMT) has been the classic in vivo test to evaluate primary hemostasis in veterinary medicine (Table 142.2), although other types of bleeding time tests have been evaluated.[46] The template bleeding time has been reported to have poor reproducibility in horses, with coefficients of variation ranging from 26.8% to 45.5%.[52] The BMBT or OMT is performed by evaluating hemorrhage from a standardized incision in the oral mucosa using a disposable, single-use, spring-loaded lancet.[21]

The BMBT has been used to screen patients preoperatively,[30] to find a cause of bleeding in an actively bleeding patient, to determine if an individual has a

TABLE 142.1 An Alphabetical List of Tests of Platelet Function Described in Chapter 142 With Reference to the Veterinary Literature

Name of Test	Principle	Clinical Applications	Reference
Bleeding time	In vivo cessation of blood flow	Screening POC test	5, 21, 46, 51, 52
Flow cytometry	Measurement of platelet glycoprotein and activation markers by fluorescence	Diagnosis of platelet glycoprotein defects, detection of platelet activation in vivo or in response to agonists	4, 24, 28, 29, 38, 43, 47, 54, 56, 64
Full blood count	Automated impedance or flow cytometry-based analysis of cells	Abnormalities in platelet number, size, and distribution. Platelet density value now available as POC measure of platelet activation	44
Light transmission aggregometry	Low shear platelet-to-platelet aggregation in response to agonists	Diagnosis of a wide variety of acquired and inherited platelet defects	10, 42, 50
PFA-100®	High-shear platelet adhesion and aggregation during formation of a platelet plug	Detection of some inherited and acquired defects in primary hemostasis. Highly dependent on von Willebrand factor	7, 11, 40, 41, 53
Whole blood aggregation	Change in impedance in response to platelet agonists	Diagnosis of a wide variety of acquired and inherited platelet defects	23, 55

TABLE 142.2 Normal Bleeding Times Reported in Different Companion Animal Species

		Normal Bleeding Time (seconds)			
Animal Species	No.	Mean ± SD	Range	Method	Reference
Dogs	34	157 ± 29		Buccal mucosal	21
Dogs (Greyhounds)	61	129.5 ± 44.2		Buccal mucosal	51
Cats	14	114 ± 30		Oral mucosal	49
Horses	20	342 ± 114	136–894	Template	52

hereditary primary hemostasis disorder, or to evaluate drug effects.[2,5,21,49] In dogs with von Willebrand disease, the BMBT is reported to be prolonged 85–100% in affected dogs; however, most of these reports consist of small numbers of cases.[8,5,21] Administration of desmopressin and cryoprecipitate has been reported to significantly shorten the BMBT, and the test, therefore seems to offer a cost-effective method of treatment evaluation for dogs with von Willebrand disease.[8,9] The BMBT is also prolonged in dogs with thrombocytopenia, and severe azotemia.[21] In a series of coagulation factor deficient dogs the BMBT has been reported to be normal.[5] Considerable variability between BMBT measurements in Greyhounds has been found; for example, values may differ by up to ±2 minutes.[51] The BMBT has been found to correlate weakly with surgical blood loss in dogs;[30] however, its value as a routine preoperative screening test in both human and veterinary medicine is debatable.[21,31] Clearly, more prospective research involving larger populations of animals affected by primary hemostatic disorders is needed before conclusions can be reached regarding sensitivities and specificities, the biological variability and the use of the BMBT as a preoperative screening tool in veterinary medicine. However, because other more sensitive tests of platelet function are not widely available, the BMBT may still have a place in veterinary practice as a screening tool for disorders of primary hemostasis.

PLATELET AGGREGATION

Platelet aggregation is the historical "gold standard" for testing platelet function defects, although this position is now being challenged by novel methods. The original platelet aggregation method in platelet-rich plasma (PRP) was described in 1962 by Born, and consisted of an absorptiometer with experiments performed at room temperature.[1] Platelet aggregation is currently being performed in PRP at 37°C using a spectrophotometer, or in whole-blood using an electrical impedance method. The aggregation pattern is classically evaluated in response to addition of an exogenous platelet agonist.

Light-Transmission/Optical Platelet Aggregation

Light-transmission aggregation (LTA) is measured in a spectrophotometer attached to a chart recorder or a computer with relevant software. The instrument is

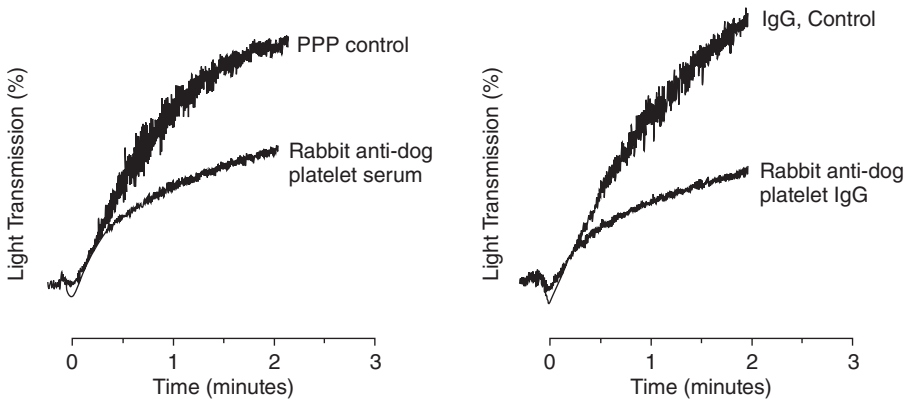

FIGURE 142.1 Aggregation response to thrombin after addition of rabbit anti-dog platelet antiserum and IgG to normal dog platelets. (Reproduced from Kristensen AT, Weiss DJ, Klausner JS. Platelet dysfunction associated with immune-mediated thrombocytopenia in dogs. J Vet Int Med 1994;8:323–327, with permission.)

standardized for each subject using PRP set as 0% aggregation and autologous platelet-poor plasma (PPP) set as 100% aggregation. As platelets aggregate in response to the addition of an exogenous platelet agonist, the sample becomes more clear and an increase in light transmission through the test sample is recorded (Fig. 142.1).

Platelet aggregation responses can be evaluated as the percent maximal aggregation response when compared to PPP, or as the rate of aggregation, calculated as the slope of the aggregation curve.

Light-transmission aggregation is a very useful technique for identification and diagnosis of platelet function defects. By using large panels of agonists at various concentrations, it is possible to obtain a large amount of information about many different aspects of platelet function.[66] However, LTA is relatively nonphysiological because platelets are separated from other blood components and aggregated under low shear conditions during the test—conditions that do not accurately mimic platelet adhesion, activation, and aggregation in damaged vessel walls.

Light-transmission aggregation can be affected by a variety of analytical and preanalytical variables. Venipuncture should be performed carefully using a 19- to 21-gauge needle and a central vein (e.g. jugular) with minimal stasis. Some laboratories do not consider evacuated collection tube collected blood as suitable for aggregation measurements due to ex vivo artifactual activation of platelets by the shear force of the vacuum. However, other laboratories use these tubes without causing significant ex vivo platelet activation.[37] Sodium citrate (0.102 mol/L, 0.129 mol/L, buffered and nonbuffered) at a ratio of nine parts blood to one part anticoagulant is the typical anticoagulant for platelet aggregation testing. Very low hematocrit values can affect aggregation values, as the final plasma concentration of the anticoagulant will be low compared to samples with normal hematocrit, with a higher concentration of free calcium available in the plasma.[15]

There are a variety of opinions on whether or not it is necessary or beneficial to standardize the platelet count of the PRP used in platelet aggregation assays.[33,63] Some report that aggregation responses can vary in relation to platelet count, and it is recommended that platelet counts be standardized.[20] However, mixing PPP with PRP could influence aggregation results because PPP may contain substances released from platelets and other blood cells during the centrifugation process that may influence platelet function.[32]

Impedance/Whole Blood Platelet Aggregation

Platelet aggregation may be carried out in a whole blood system using electrical impedance. The impedance method can be used with either PRP or whole blood, although the whole blood method is the most widely used. This method measures an increase in impedance across two electrodes placed in the anticoagulated blood as activated platelets accumulate on them.[19] Whole-blood aggregation has many advantages, including use of smaller blood volumes, immediate analysis of samples without manipulation, and no loss of platelet sub-populations or platelet activation during centrifugation.

Platelet Agonists

Adenosine Diphosphate

Adenosine diphosphate (ADP) is a weak platelet agonist, and was the first known low-molecular-weight platelet aggregating agent. In human platelets, it induces shape change and reversible aggregation. The secondary aggregation sometimes observed after stimulation of PRP with ADP is caused by secretion of dense granule constituents triggered by synthesis of thromboxane A_2. Although a weak agonist in itself, ADP plays a key role in platelet function by amplifying platelet responses induced by other platelet agonists.

There is considerable interspecies difference in platelet aggregation responses to various agonists; however, platelets from most species appear to respond to stimulation by ADP at concentrations between 5 and 25 µmol/L.[42,50,55] One exception is in canine whole blood, where ADP does not give consistent aggregation responses, possibly due to degradation of ADP by red blood cells and white blood cells.[23,45]

Collagen

Collagen, either of bovine or equine tendon origin, is typically the strongest of the agonists used in clinical laboratories. Collagen-induced platelet aggregation usually has a lag phase, during which the platelets adhere to the collagen fibrils and undergo shape change and release granule contents. Canine platelets have been reported to respond in a dose-dependent manner to 1–20 µg/mL collagen.[23,42] Platelets from horses, cows, pigs, buffalo, and sheep all responded to collagen in one study, with equine platelets being the most sensitive to collagen.[50]

Arachidonic Acid

Arachidonic acid is converted to thromboxane A_2, a potent platelet agonist, when reacting with cyclooxygenase. The aggregation response induced by arachidonic acid is completely inhibited by aspirin in humans. There are reports of variable platelet responses to arachidonic acid in the veterinary literature, and this agonist may, therefore not be of as great value for testing aspirin and other non-steroidal anti-inflammatory drug (NSAID) effects on animal platelets.[10,23,50] Pelagalli[50] showed that arachidonic acid was less effective than ADP, collagen, or platelet activating factor (PAF) in inducing aggregation of PRP from horses, buffaloes, pigs, and sheep, although a maximal aggregation response was achieved at 7.5 mmol/L. The use of arachidonic acid as an agonist in canine platelet aggregation experiments has been controversial. Jüttner[23] found no response to arachidonic acid at 0.5 mmol/L and 1 mmol/L in any dogs tested, whereas others have found that canine platelets aggregate in response to arachidonic acid.[13,55] One study found that the variable platelet responses to arachidonic acid were breed-dependent,[10] and it has been suggested that the differences in sensitivity to aracidonic acid in dogs may be because of inherited differences in intracellular signaling pathways.[22]

Epinephrine

Epinephrine is the most erratic and unreliable of the agonists for platelet aggregation. Epinephrine is usually regarded as ineffective by itself as an aggregation initiator, but has been used to enhance aggregation responses of other platelet agonists.

Thrombin

Thrombin is a very potent platelet agonist and in addition cleaves fibrinogen to form a fibrin clot in plasma, which makes it a very difficult agonist to use for platelet aggregation testing. The synthetic peptide, Gly-Pro-Arg-Pro (GPRP), inhibits thrombin-induced fibrin polymerization while not inhibiting platelet aggregation responses.[42]

Platelet Secretion Techniques

Platelet dense granule release can be evaluated in a specialized aggregometer, called a lumiaggregometer, simultaneously with the aggregation response. Lumiaggregation is based on the conversion of ADP, released from platelet dense granules, to ATP. This ATP then reacts with the firefly lantern extracts (luciferin and luciferase), generating adenyl-luciferon. Light is emitted when oxidation of adenyl-luciferon occurs. An ATP standard is used to calibrate the signal. Studies of platelet secretion allow the assessment not only of platelet aggregation but also of granule secretion. This is useful in the diagnosis of platelet disorders such as storage pool disease and release defects, especially in cases where animals have clinical bleeding with normal aggregation tracings.[63]

Platelet Aggregation in Clinical Disorders

Platelet aggregation has been used in the evaluation of both inherited and acquired diseases. Animals with Glanzmann thrombasthenia have a defect involving glycoprotein complex IIb-IIIa (integrin αIIbβ3). The integrin αIIbβ3 is required for platelet aggregation, and the diagnostic features of Glanzmann thrombasthenia are absent aggregation to virtually all physiologic agonists, and an abnormal clot retraction.[3] Storage pool disease (SPD) is characterized by defective secretion of adenine nucleotides. Animals with dense-granule SPD may have impaired platelet aggregation response to ADP and collagen or normal platelet aggregation.[6] The SPD associated with Chediak-Higashi disease causes impaired platelet aggregation response to collagen and a virtually absent release of adenine nucleotides, measured by lumiaggregation.[18] See Chapter 82 for a more detailed description of inherited platelet disorders.

Acquired platelet function defects detected by platelet aggregation have been described in uremia, immune-mediated thrombocytopenia, laminitis, infectious diseases, malignancies, heart disease, and drug-related disorders.[25,42,45,48,58] These disorders are discussed in detail in Chapter 83.

PLATELET FUNCTION ANALYZER – PFA100®

Because of several disadvantages of the bleeding time as a screening test for platelet dysfunction in clinical practice, several newer alternative technologies have been developed. The most widely used in veterinary medicine is the platelet function analyzer (PFA)-100® (Dade-Behring, Deerfield, IL). The test is a modified bleeding time and is based on the three phases of platelet function: adhesion, aggregation, and secretion.

Test Principle

The PFA-100 test is performed by pipeting 0.8 mL of citrated whole blood into a disposable cartridge. The blood sample is then drawn, under a constant vacuum,

FIGURE 142.2 The PFA-100® instrument (Dade-Behring).

through a capillary tube and an aperture 150 µm in diameter. The membrane is coated with collagen and epinephrine (CEPI) or collagen and ADP (CADP). Activation of platelets and adhesion to the membrane is caused by the high shear rates (4000–5000 s^{-1}) generated in the PFA-100 system and is mediated via a platelet surface glycoprotein Ib-von Willebrand factor (GPIb-VWF) interaction. Subsequent release of platelet granule contents and the presence of collagen and epinephrine or ADP on the membrane result in platelet aggregation. When the aperture is occluded by aggregated platelets, blood flow through the membrane stops. This is referred to as the closure time (CT) (Fig. 142.2).[26] Normal reference intervals for CT have been reported to be 53–98 seconds for CADP-CT and 92 to >300 seconds for CEPI-CT in dogs,[40] and 61–116 seconds for CADP-CT and 159 to >300 seconds for CEPI-CT in horses.[53] It is generally recommended that each laboratory establishes its own normal range for CT in both cartridge systems of the PFA-100. Ideally, normality should be established by parallel platelet aggregation studies and measurement of VWF activity. The normal range must be established using the same concentration of sodium citrate that is routinely used in the institution (see below).

Factors Affecting Closure Time

PFA-100 CTs are sensitive to both platelet number and function. In dogs there is an approximate linear relationship between CT and platelet count below 150×10^9/L.[41] However, no association has been found between platelet count and CT in Cavalier King Charles Spaniels with idiopathic inherited macrothrombocytopenia, probably reflecting a normal total circulating platelet volume in these dogs.[59]

Closure time also increases with decreasing hematocrit in humans and dogs.[27,41] The exact threshold at which the CT is affected will probably vary between species. In dogs a prolongation of the CT is seen at hematocrit values below 30–40%.[7,41] Plasma levels of VWF are an important determinant of CT in the PFA-100, because platelet aggregation at high shear rates is highly dependent on VWF. In humans, it has recently been shown that plasma VWF levels modulate PFA-100 CT to a greater extent than intrinsic platelet function.[16] An association between PFA-100 CT and VWF has been shown in healthy dogs,[57] and in dogs with inherited,[7,41] and acquired[58] von Willebrand disease.

The concentration of anticoagulant is an important determinant of CT in humans and dogs. Test times are longer in 0.129 mol/L (3.8%) citrate than in 0.109 mol/L (3.2%), probably due to greater calcium chelation. In dogs, the PFA-100 CT appears to be stable up to 8 hours after the blood sample is collected,[40] although testing within 2 hours is generally recommended. The manufacturer of the PFA-100 currently recommends testing within 4 hours for humans.

Detection of Platelet Function Defects

The PFA-100 system has been designed for use in humans, and there has been some concern about use of the CEPI cartridge in veterinary medicine. Very long CTs and non-closure (>300 seconds) have been reported in a substantial proportion of healthy, unmedicated dogs and horses.[7,41,53,59] It has been suggested that subjects with CEPI-CT > 300 seconds may have an aspirin-like defect; however, normal plasma thromboxane B_2 levels have been demonstrated in dogs with CEPI-CT > 300 seconds.[45] Epinephrine does not consistently cause platelet aggregation in dogs,[10] whereas in humans epinephrine causes primary aggregation, and this is the most likely cause for the apparently false-positive CEPI-CTs found in dogs and horses.

Hypofunction

The sensitivity of the PFA-100 for detecting von Willebrand disease in humans is very high.[12] In two small case studies of dogs with von Willebrand's disease (see Chapter 81), all affected dogs had prolonged CADP-CT, suggesting a similar high sensitivity.[7,41] Callan and Giger[7] have reported a sensitivity of 95.7% and specificity of 100% for detecting primary hemostatic disorders (thrombocytopenia, thrombopathia, and type 1 von Willebrand disease) using the CADP cartridge; sensitivity was 95.7% and specificity 82.8% using the CEPI cartridge. The PFA-100 has utility in monitoring responses to DDAVP in dogs with type 1 von Willebrand's disease, where partial correction of

CT typically is obtained. DDAVP administration has been found to significantly shorten the CADP-CT but not the CEPI-CT. The PFA-100 CADP cartridge, therefore appears to be useful in monitoring the response.[8]

Very few studies have documented the utility of the PFA-100 in detecting congenital platelet function disorders in animals. Callan and Giger[7] found that five out of six dogs with unspecified thrombopathia had prolonged CADP-CT, and a case report has described prolonged CADP-CT in a horse with Glanzmann thrombasthenia.[35] In humans, the PFA-100 is sensitive to the presence of Glanzmann thrombasthenia (GPIIb-IIIa deficiency), Bernard-Soulier syndrome (GPIb-IX-V deficiency), and patients with δ-storage pool deficiency and primary secretion defects.[14] However, the International Society of Thrombosis and Haemostasis working group on the PFA-100 has recently recommended use of the PFA-100 be restricted to research studies and prospective clinical trials, due to insufficient sensitivity or specificity.[17]

Assessment of acquired platelet dysfunction by the PFA-100 has to some extent been described in veterinary medicine. Both the CADP-CT and CEPI-CT appear to be prolonged by acetylsalicylic acid in dogs and horses.[41,53] This is in contrast to humans, where the CT will be prolonged with the CEPI cartridge, but normal (or near-normal) with the CADP cartridge.[36] Dogs experimentally loaded with endotoxin had shortened CT at 0.5 hours and prolonged CT 48 hours after inoculation. The initial shortened CT may reflect hemoconcentration more than actual platelet hyperfunction.[65] Dogs with heart diseases causing high-velocity blood flow (mitral valve regurgitation and subaortic stenosis) and an acquired type 2A von Willebrand disease have prolonged CADP and CEPI CT (Fig. 142.3). The mechanism has been suggested to be enhanced cleavage of VWF high-molecular weight multimers by ADAMTS13, a plasma metalloprotease acting on VWF preferentially under conditions of high fluid shear stress.[57,58] A similar acquired defect with prolonged CT has been found in humans with aortic stenosis.[60]

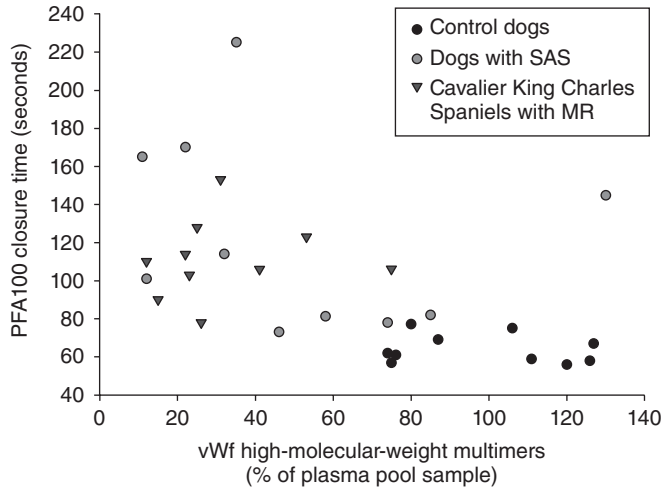

FIGURE 142.3 Platelet function analyser closure times shown as a function of percentage high-molecular-weight von Willebrand Factor multimers (sample relative to pool ratio) (Spearman's rank correlation coefficient; $r = -0.62$, $P = 0.0003$). SAS, Subaortic stenosis, MR, mitral regurgitation. (Reproduced from Tarnow I, Kristensen AT, Olsen LH, et al. Dogs with heart diseases causing turbulent high-velocity blood flow have changes in platelet function and von Willebrand factor multimer distribution. J Vet Int Med 2005;19:515–522, with permission.)

Hyperfunction

It is unclear whether shortening of the PFA-100 CT truly reflects platelet hyperfunction/increased activity, because there is lack of data that links shortened CT to clinical evidence of thrombosis or thrombosis-related outcome. Shorter CTs have been associated with ST elevation myocardial infarcts in human patients, but data are lacking in veterinary medicine. Greyhounds have been found to have shorter CT compared to other dogs; however, this could be linked to the higher hematocrit found in this breed.[11]

FLOW CYTOMETRY

Flow cytometry is a versatile tool for study of platelet function, that can be used for multiple purposes in veterinary medicine. Flow cytometry may be used to: (1) measure the activation state of circulating platelets and their reactivity (by activation-dependent changes in the platelet surface, leukocyte-platelet aggregation, and pro-coagulant changes on the platelet surface); (2) diagnose specific platelet function defects (see Chapters 82 and 83); (3) monitor thrombopoiesis by quantifying reticulated platelets; (4) measure platelet count (see Chapter 77); (5) assess anti-platelet drug effects; and (6) perform assays used for research purposes. Only measurement of the activation state of circulating platelets and their reactivity will be described in this section.

Flow cytometry measures specific characteristics of cells as they flow through a flow chamber, and through the focused beam of a laser. The cells can be fluorescently labelled, typically with a fluorescently conjugated antibody, or can be analysed unlabelled. When labelled cells pass through the laser, the laser light activates the fluorophore at the excitation wavelength, and the emitted fluorescence as well as the light scattering properties of each cell are detected. The intensity of the emitted light is directly proportional to the antigen density of the cell (see Chapter 137).

Flow cytometric assays evaluating platelet function can utilize washed platelets, PRP, or whole blood. Use of washed platelets or PRP is potentially susceptible to artifactual in vitro activation as a result of separation procedures. Use of whole blood requires a minimum of two antibodies, each conjugated with a different fluorophore: a platelet identifying antibody, to separate platelets from other cells in the blood, together with a "test" antibody recognizing the antigen to be measured. Physiologic or non-physiologic agonists can be used to

assess platelet reactivity. Samples can be stabilized by fixation before or after addition of antibodies. Relevant isotope-matched antibodies are used as negative controls.[39]

There are many advantages to flow cytometric analysis of platelet function. Both the activation state of circulating platelets and the reactivity of platelets can be assessed; only minute volumes of blood are needed; and the evaluation of function of platelets with severe thrombocytopenia and/or anemia is possible. The application of flow cytometry for evaluating platelet function in veterinary medicine is limited by the lack of commercially available species-specific monoclonal antibodies. Some platelet antigens, (e.g. integrin αIIbβ3), appear to be widely preserved across species, and most anti-human antibodies directed against this antigen are cross-reactive.[35,54,56]

Measurement of Platelet Activation

The activation state of circulating platelets can be judged by binding of an activation-dependent monoclonal antibody in the absence of an agonist. Inclusion of exogenous agonists allows analysis of the reactivity of platelets in vitro. Activation of platelets results in a specific functional response, such as a change in surface expression of a receptor or other antigen or bound ligand. In addition, flow cytometric detection of leukocyte-platelet aggregates and procoagulant platelet-derived microparticles, that are sensitive markers of platelet activation in humans, have been investigated as markers of platelet activation in veterinary medicine (Table 142.3).[39]

Activation-Dependent Platelet Surface Changes

Markers of platelet activation include activation-dependent conformational changes in integrin αIIbβ3, exposure of granule membrane proteins, such as P-selectin, platelet surface binding of secreted platelet or plasma proteins (i.e. fibrinogen), and development of a procoagulant surface (assessed by Annexin V binding). The most widely used in veterinary medicine are detection of platelet surface P-selection expression, binding of fibrinogen, and development of a pro-coagulant surface.

In dogs, horses, and pigs, methods to assess platelet activation by assessing platelet surface P-selectin expression have been described.[28,38,43,54,56,64] Increased platelet surface P-selectin expression has been demonstrated in dogs with inflammatory disease,[44] and with immune-mediated hemolytic anemia (see Chapters 33 and 83).[61]

Assessment of fibrinogen binding has been described in dogs using a monoclonal antibody that recognizes a receptor-induced binding site (RIBS) on canine fibrinogen.[4,56] Moreover, exogenous FITC-labelled fibrinogen binding as a marker of platelet activation has been described in dogs.[56] Binding of an anti-fibrinogen antibody as a marker of platelet activation has been described in horses and pigs.[24,29,47]

Development of a pro-coagulant surface can be assessed by binding of the protein Annexin V to phosphatidylserine exposed on the platelet surface. This has been described in dogs and horses.[24,64] Phosphatidylserine exposure combined with bound α-granule proteins and calcium permeability identify coated platelets, a subpopulation of platelets that are highly pro-coagulant. Annexin V measurement is independent of species, because it is a placental protein and not an antibody directed against a specific epitope.

Leukocyte-Platelet Aggregates

Leukocyte-platelet aggregates are formed via interaction between P-selectin exposed on the surface of activated platelets and the P-selectin glycoprotein ligand 1 counter receptor on the leukocyte surface.[39] Detection of leukocyte-platelet aggregates has been described in dogs (Fig. 142.4) and horses,[54,56,64] and increased neutrophil-platelet aggregates has been associated with laminitis in ponies.[62]

TABLE 142.3 Application of Flow Cytometry to the Study of Platelet Activation

Activation-dependent platelet changes	Method	Reference
Surface P-selectin exposure	Binding of monoclonal antibody AC1.2, 1E3, MD6 (dogs)	43, 56, 64

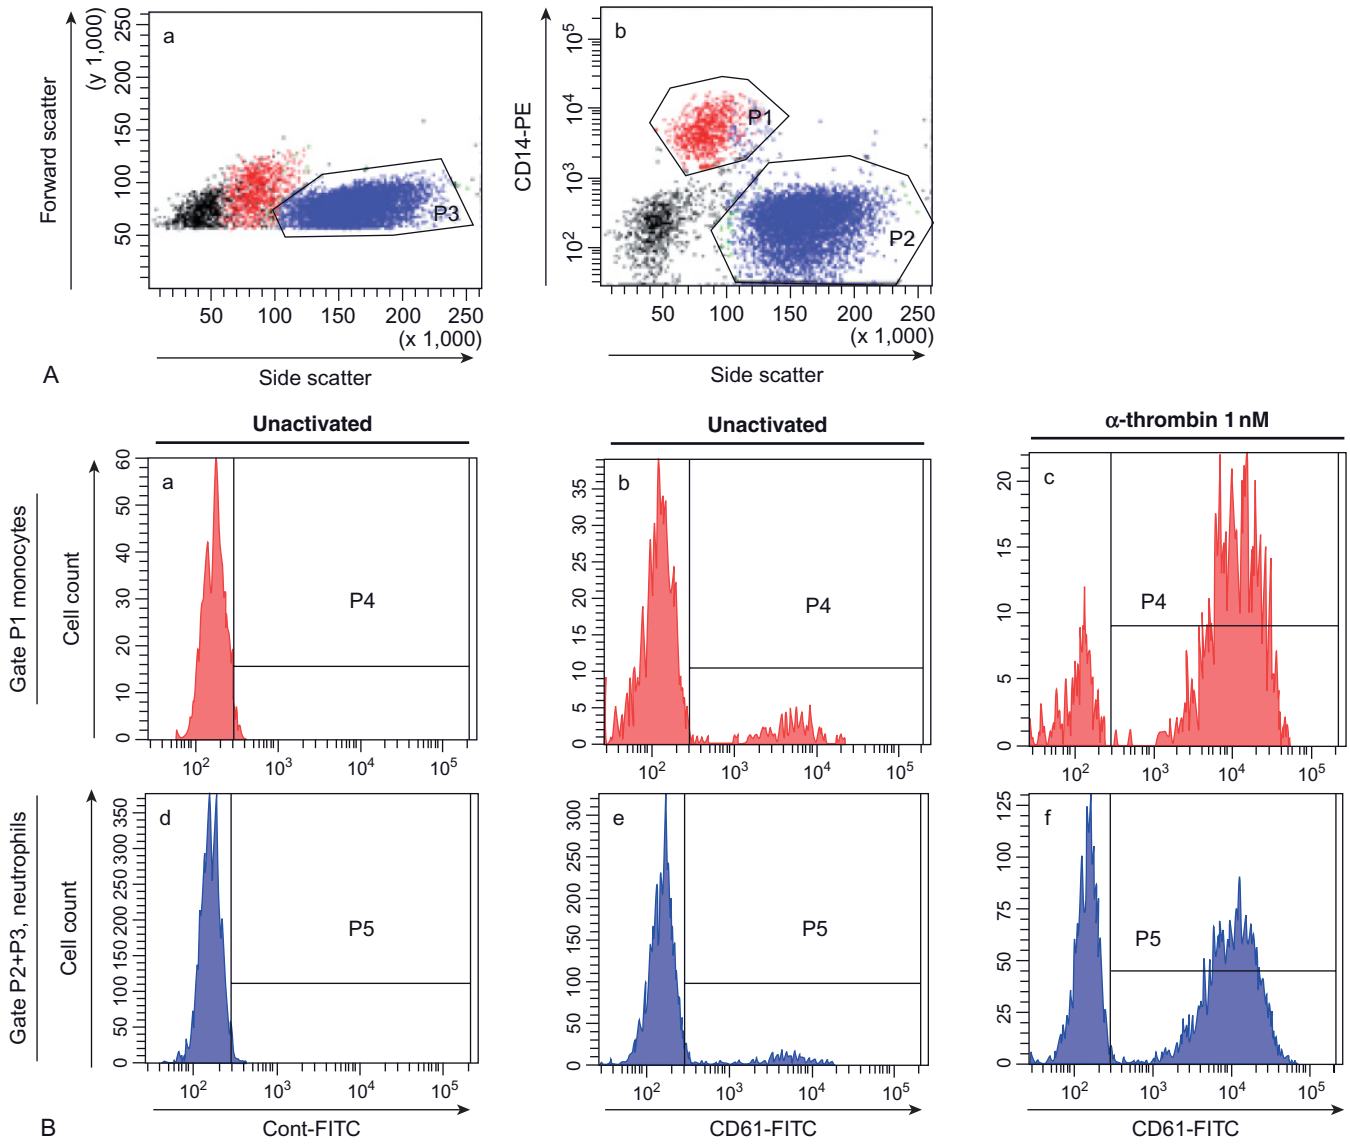

FIGURE 142.4 Flow cytometry gating logic for the detection of leukocyte-platelet aggregates in canine whole blood. (**A**) Monocytes and neutrophils were gated by a combination of light scattering and CD14-PE fluorescence. Bright CD14 and 90° (side) light scatter define monocytes (P1), dim CD14, forward and 90° light scatter define neutrophils (P2 and P3). (**B**) Histograms are used to quantify leukocyte-platelet aggregates by percent CD61-FITC positive cells and CD61-FITC mean fluorescent intensity from P1 cells, monocytes (**B-a, B-b, B-c**) and P2 and P3 cells, neutrophils (**B-d, B-e, B-f**). Gates P4 and P5 are adjusted such that they include 1% of the isotype-control stained (Cont-FITC) population (**B-a, B-d**). Unactivated samples had 9.6% monocyte-platelet aggregates (**B-b**), and 7.5% neutrophil-platelet aggregates (**B-e**). Activation with 1 nM α-thrombin gave 84.2% (**B-c**) and 59.7% neutrophil-platelet aggregates (**B-f**). (Reproduced from Tarnow I, Kristensen AT, Krogh AKR, et al. Effects of physiologic agonists on canine whole blood flow cytometric assays of leukocyte-platelet aggregation and platelet activation. Vet Immunol Immunopathol 2008;123:345–352, with permission.)

Automated Measurements

Mean platelet component concentration (MPC) has been investigated as an automated measurement of platelet activity. The MPC estimates the refractive index of platelets. When activated platelets degranulate, the density decreases and the MPC decreases.[34] Decreased MPC has been associated with inflammatory disease in dogs, with a significant inverse correlation between platelet surface P-selectin expression and MPC.[44]

FUTURE ASSAYS

Recent abstracts indicate that thromboelastography, including platelet mapping assays, calibrated automated thrombograms, point of care aggregation based assays (VerifyNow, Accumetrics, San Diego, CA), and single platelet detection based assays (PlateletWorks, Helena Laboratories, Beaumont, TX) will likely become future tools for testing the contribution of platelets to the hemostatic process.

Clonality Testing or Immunophenotyping in Lymphoid Leukemia and Lymphoma – Which to Choose?

Acronyms and Abbreviations

ALL, acute lymphocytic leukemia, AML, acute myeloid leukemia; CLL, chronic lymphocytic leukemia; ICC, immunocytochemistry; Ig, immunoglobulin; IHC, immunohistochemistry; LGL, large granular lymphocyte; PARR, PCR for antigen receptor rearrangements; PCR, polymerase chain reaction; TCR, T cell receptor.

IMMUNOPHENOTYPING

There are over 40 categories of human lymphomas and leukemias. Although these different subtypes were originally defined by histologic and/or cytologic appearance and clinical behavior, it is now possible to define the majority of these different categories based on the array of proteins expressed on the cell surface using immunophenotyping. Many antibodies are now available for similar work in dogs, and a more limited panel is available for cats.

All immunophenotyping methods utilize monoclonal antibodies specific for cell surface or cytosolic proteins, either directly conjugated to fluorescent proteins or enzymes that catalyze a color change, or detected using secondary reagents specific for the monoclonal antibodies. Immunohistochemistry and immunocytochemistry (IHC and ICC) are used with cells on slides – either paraffin embedded tissue biopsies or cytology preparations. Although IHC is an essential component of evaluating lymph node biopsies, it will not be discussed here. Flow cytometry provides more flexibility than ICC and will be the focus of this chapter.

Indications

In hematologic malignancy, flow cytometry can be used to accomplish two general goals: to determine if the patient has lymphoma or leukemia, and to determine what type of lymphoma or leukemia is present. Hematologic malignancy can present with a very wide range of clinical symptoms, but flow cytometry is generally indicated in only two: (1) when there are more cells present than are expected (for example lymphocytosis); (2) when there are cells with a cytologically malignant appearance. Table 143.1 gives guidelines for specific situations where flow cytometry may be useful and where it is not likely to be useful. These are just guidelines, however, and as more antibodies become available there may be additional indications. It is also important to contact the laboratory to which you are considering submitting flow cytometry because some

TABLE 143.1 Clinical Indications for Performing Flow Cytometry, and Situations Where Flow Cytometry is Not Informative

	Blood	Masses/Lymph Nodes	Bone Marrow	Cavity Fluids
Indicated	Lymphocytosis Cytologically abnormal cells	Lymphadenopathy Mediastinal masses	Cytologically abnormal cells Increased lymphocyte count	Increased lymphocytes Cells with aberrant morphology suggesting lymphoid or myeloid origin
	Monocytosis	Splenomegaly with cytologic suspicion of lymphoma		
Not indicated	Neutrophilia[a]	Metastatic disease from non-lymphoid tumors[b]	Increased plasma cells or monoclonal gammopathy[c]	Transudates with few cells
	Eosinophilia[a]	Primary tumors of non-lymphoid origin	Loss of a lineage or myelofibrosis	Suspected septic process
	Thrombocytosis	Highly reactive nodes		Suspect carcinoma/reactive mesothelial cells[b]
	Polycythemia Cytopenias			

[a]Neutrophils from patients with CML and reactive neutrophilia have the same phenotype. The immunophenotype of canine eosinophils has not been described.
[b]The use of flow cytometry to detect non-lymphoid tumors in lymph nodes and cavity fluids (such as melanoma in a lymph node, carcinoma in a pleural effusion) has not been reported. As antibodies that detect these tumors become available and tested, however, flow cytometry will be an important application for this purpose.
[c]The immunophenotype of canine plasma cells has not yet been described. Therefore, flow cytometry will not be able to distinguish reactive from neoplastic plasma cells (the clonality assay will be useful in these cases).

laboratories may have additional capabilities that have not yet been reported in the literature.

Preparation of Samples

Detection of cell surface antigens by flow cytometry requires cells to be viable when they are stained. Therefore, when cells are prepared steps must be taken to ensure they remain viable until they are processed. Peripheral blood and bone marrow samples can retain reasonable viability for several days when kept refrigerated, but samples from effusions, or aspirates of lymph nodes or masses are less hardy.

The author's laboratory recommends the following procedures be followed when collecting samples for flow cytometry:

Blood and Bone Marrow

Collect these samples in EDTA and ship overnight with a cold pack. Testing within 2–3 days of taking the sample is preferred, but in some cases, blood samples can remain sufficiently viable for 5 days.

Aspirates and Cavity Fluids

It is essential that tissue aspirates and cavity fluids with low protein (<5 mg/dL) be placed in medium with serum in order to preserve viability. Roswell Park Memorial Institute (RPMI) medium, Dulbecco's modified Eagle's medium (DMEM) or similar cell culture media with 10% fetal bovine serum are ideal. This can usually be found in a university setting. In private practices where this is not available, put 0.5–1 mL of 0.9% saline (LRS, Norm R or Norm M may also be used) into a test tube or red top tube without anticoagulant. Add serum from an animal of the same species (this can be the patient, but it does not have to be) so that the serum is approximately 10% of the total fluid volume. These samples should be shipped with a cold pack overnight and tested as soon as possible. The author has found that this method maintains viability for 2–3 days.

The specific method of preparing cells for analysis differs between laboratories. The simplest is to treat all samples with hypotonic lysing solution to remove erythrocytes and then stain cells immediately. This is the most common method described by the various laboratories which report flow cytometry results.[24,26–28,31,34,39,50,51,53,54] An alternative is density gradient centrifugation for removing erythrocytes, dead cells and platelets. However, this is more time consuming and may result in selective loss of some cell subsets, and is no longer often used.

Antibody Panels

Each laboratory that offers this test uses different combinations of antibodies, and a different approach to immunophenotyping. The goal of designing an antibody panel is to be able to detect cells with an abnormal phenotype, suggesting malignancy in cases where the diagnosis is not clear, and to determine the lineage of malignant cells. Because there is presently no standardization of antibody panels in either veterinary or human medicine, it seems reasonable to follow the most recent recommendations of a consensus panel on phenotyping human hematopoietic malignancies.[12,55] Each laboratory should develop its own panels based on the experience of that laboratory, the most current literature, the technology available to that laboratory (the nature of the

flow cytometer) and the array of antibodies available. A minimum panel for canine malignancies should include antibodies to cell surface proteins found on T cells (CD3, CD4 and CD8), B cells (CD21), CD34 (a stem cell antigen that is considered diagnostic for acute leukemia), CD45 (a pan-leukocyte antigen), and CD14 (for identification of monocytes). A detailed description of these antigens is given in Chapter 4. Antibodies to cytoplasmic CD3e and CD79a, which require permeabilization for staining,[43,47] are essential for determining the phenotype of acute leukemias, because these immature neoplasms often do not express surface antigens. The repertoire of antibodies available for cats is frustratingly limited. Directly conjugated antibodies to CD4, CD5 and CD8 are commercially available, and many anti-B cell antibodies react with feline cells, including anti-canine and anti-human CD21,[32] as well as an antibody to murine B220 (A.C. Avery, unpublished observations). In addition, the antibodies used to detect cytoplasmic CD3e[10] and CD79a react with virtually all species, so these could be used in cases of suspected acute leukemia to determine lineage.

It is the author's opinion that the use of commercially available, directly conjugated antibodies is preferable for two reasons. First, when a small number of commercial sources are used, quality control and reagent preparation become less of a variable between laboratories. Second, the use of directly conjugated antibodies, which are more easily prepared by commercial suppliers than individual laboratories, allows for multiparameter flow cytometry, which is essential for identifying cells with an abnormal phenotype. In addition, reagents such as propidium iodide or 7-amino-actinomycin D (7-AAD) to exclude dead cells should always be included in flow cytometry studies when staining for surface antigens, because dead cells can bind antibodies nonspecifically, or are permeable to intracellular staining where some antigens are even in the absence of surface expression.[35]

Reporting Flow Cytometry Results

Following the lead of consensus recommendations for human lymphoid malignancies,[55] a useful approach to reporting would include both objective data (percentage of cells expressing informative markers, or in the case of peripheral blood, total number of cells expressing those markers per microliter), as well as a subjective description of the study and interpretation of the findings. Any reporting of values should be accompanied by reference ranges established by the laboratory; either percentages of different lymphocyte subpopulations for samples of bone marrow and lymph nodes, or absolute numbers of each cell type for peripheral blood. A small number of reference ranges for blood, bone marrow and lymph nodes have been published.[17,42,53]

Reactive Versus Neoplastic

Two criteria can be used to establish that a population of cells are malignant: (1) The presence of cells with an aberrant immunophenotype, and (2) in cases where the cells are lymphocytes, an expansion of lymphocytes with a homogeneous phenotype (for example all of the lymphocytes are B cells). We have suggested the following criteria for establishing that a population of lymphocytes in canine peripheral blood is malignant when such a determination by cytology is ambiguous,[54] but similar guidelines have not yet been suggested for distinguishing reactive from neoplastic processes in lymph nodes:

1. A lymphocyte count above the reference range for the submitting laboratory or clinic, and one of the following:

2a. 80% of the lymphocytes have a single phenotype), or

2b. 60% of the lymphocytes have a single phenotype and a positive clonality assay (PARR assay or PCR for antigen receptor rearrangements), or

2c. Presence of lymphocytes with an aberrant phenotype for peripheral blood.

One well-established exception to the notion that homogeneous expansion of lymphocytes is diagnostic for malignancy is the observation that *Ehrlichia canis* infection also induces the exclusive expansion of CD8 T cells (large granular lymphocytes (LGL)) in a minority of chronic infections.[19,48] Therefore if *E. canis* infection is a consideration, serology should be used to rule out this disease in cases of CD8 T cell expansion up to 30,000 cells/μL.

Cells can be considered to have an aberrant phenotype if the particular constellation of antigens they express is not found in normal or reactive processes, or not found in significant numbers. Aberrant phenotypes for dogs reported in the veterinary literature include: T cell leukemias/lymphomas that have lost express of CD45,[54] co-expression of CD4 and CD8 on the same T cells, which indicates the presence of thymoma when found in a mediastinal mass aspirate,[24] or lymphoma/leukemia when found in peripheral lymph node aspirates or peripheral blood,[46,53] expression of CD3 and/or CD5, but not CD4 or CD8,[46,54] the expression of CD79a but not CD21 in B cell lymphomas,[53] and the expression of CD34 on acute leukemias.[36,47,54] Therefore, the presence of these cells can be considered strong evidence supporting the diagnosis of lymphoma or leukemia.

There is significantly less information available for feline leukemia/lymphoma. Large granular lymphocytic leukemias in cats represent blood involvement secondary to intestinal lymphoma.[30] These tumors were most often CD8 T cell and CD3e positive, with variable levels of CD5 expression. Anecdotal experience from our laboratory and others[56] suggests that the majority of feline chronic lymphocytic leukemias are CD4+. We have also found that a subset of feline CLL express CD5 but not CD4, or only low levels of CD4. Clearly, however, a greater array of reagents would be very useful in the diagnosis of feline leukemia and lymphoma.

Persistent mature neutrophilia, monocytosis or eosinophilia often suggests a diagnosis of chronic myelog-

enous, myelomonocytic or eosinophilic leukemia. None of these conditions can be diagnosed by flow cytometry with currently available antibodies, because the normal cellular counterparts of these leukemias have the same immunophenotype as the leukemic cells.

Lineage Determination

Lymphocytic or Myeloid Origin Leukemia?

Leukemias of mature leukocytes (lymphocytes, neutrophils, monocytes) do not pose a dilemma for lineage determination because they each have a characteristic cytologic appearence. Leukemias of immature cells, however, can be more of a challenge. Four separate studies used failure to express lymphoid surface markers (CD3, CD8, CD21) or cytoplasmic CD3e or CD79a, in addition to the presence of characteristic morphology, to make the diagnosis of AML in dogs.[39,43,46,47] The expression of cell surface CD14, CD4, CD11b, CD11c and neutrophil surface antibody (NSA), and/or intracellular expression of myeloperoxidase (MPO) and MAC387, have also been used, together with the above criteria, to establish a myeloid lineage.[43,46,47] Conversely, staining with one of the lymphoid lineage markers described above, or positive staining for cytoplasmic CD3 or CD79a is considered diagnostic for lymphoid leukemia.

Acute or Chronic Leukemia?

Leukemic processes with >20% or 30% blasts in the peripheral blood or bone marrow are considered acute leukemias (Chapter 65).[20] More recently, CD34 expression has been recognized as diagnostic for acute leukemia[43,47,54,56] but the absence of CD34 expression does not rule out acute leukemia. Villiers et al. described 8 cases of acute myeloid leukemia, and provided a thorough description of their cytologic and criteria for making this diagnosis (>30% blasts in the peripheral blood or bone marrow, characteristic morphology). Two of these cases were CD34 negative.[47] Vernau et al. suggested that acute LGL leukemia is also CD34 negative, but the criteria used for the diagnosis in these cases were not given in detail.[46] Presently, then, expression of CD34 can be considered diagnostic for acute leukemia, but absence of CD34 does not rule out AML. More detailed studies of CD34 expression on suspected ALL is warranted.

Leukemia or Lymphoma?

This is a question frequently posed by clinicians in the face of peripheral lymphocytosis, and the answer can impact treatment decisions. At present there is no way to make this distinction by immunophenotyping alone, but immunophenotyping can contribute to this decision. In our study of 99 cases of lymphocytosis, all cases fell into one of three main groups; CD34+ and negative for other surface markers (intracytoplasmic staining was not performed), B cells expressing CD21, and T cells that were CD4–CD8+CD3+ or CD4–CD8–CD3+. CD4+ lymphocytosis is extremely rare. CD34-expressing tumors behaved clinically like acute leukemias, with their attendant poor prognosis. Lymphocytosis involving small cells with a mature B cell immunophenotype behave clinically like chronic lymphocytic leukemia.[54] Lymphocytosis involving T cells with a mature CD8+ phenotype and an initial lymphocyte count of less than 30,000 cells/μL also behaves clinically like CLL. Therefore, it seems reasonable to favor a diagnosis of chronic lymphocytic leukemia in these two situations. Cases involving large B cells or T cells and a high initial lymphocyte count may be more difficult to classify based on immunophenotype alone. These behave more aggressively, and using other criteria may be classified as acute leukemia or stage V lymphoma.

CLONALITY

Principles of Testing

Clonality testing refers to the process of determining if a population of cells is derived from a single parental clone, or if that population is heterogeneous. Clonality testing in lymphocytes is based upon the observation that during the course of an immune response a diverse array of lymphocytes are activated. Normal lymphocyte differentiation is dependent upon the rearrangement of genes encoding antigen receptors – Ig and TCR genes.[5,13,21] During this process (Fig. 143.1) nucleotides are trimmed or added between genes as they recombine, resulting in significant length and sequence heterogeneity within the complementarity determining region 3 (CDR3). The end result of this differentiation is a diverse population of lymphocytes with virtually limitless antigen specificity and a large variety of CDR3 sequences and lengths.

Lymphocytes which are the product of division by a single parental cell will have CDR3 regions of the same length and sequence. Uniform CDR3 length can be established by amplifying DNA from the cells of interest with PCR primers directed at conserved regions of the V and J gene segments of Ig and TCR genes (schematically depicted in Figure 143.1). Amplified DNA is then separated by size using one of a variety of methods, including polyacrylamide gel electrophoresis and GeneScan analysis. The presence of a dominant single sized product indicates the presence of a group of lymphocytes that share an identically sized CDR3 region, i.e. that are clonally expanded. The presence of many sized products suggests a polyclonal population of lymphocytes.

In human medicine, determination of clonality is the test of choice if other diagnostics are ambiguous.[37] Clonality testing is now also available for dogs on a routine basis. We have named this assay the PARR assay (PCR for antigen receptor rearrangements) to distinguish it from other methods of clonality testing, but it is important to note that the term PARR does not appear in literature describing the assay in human

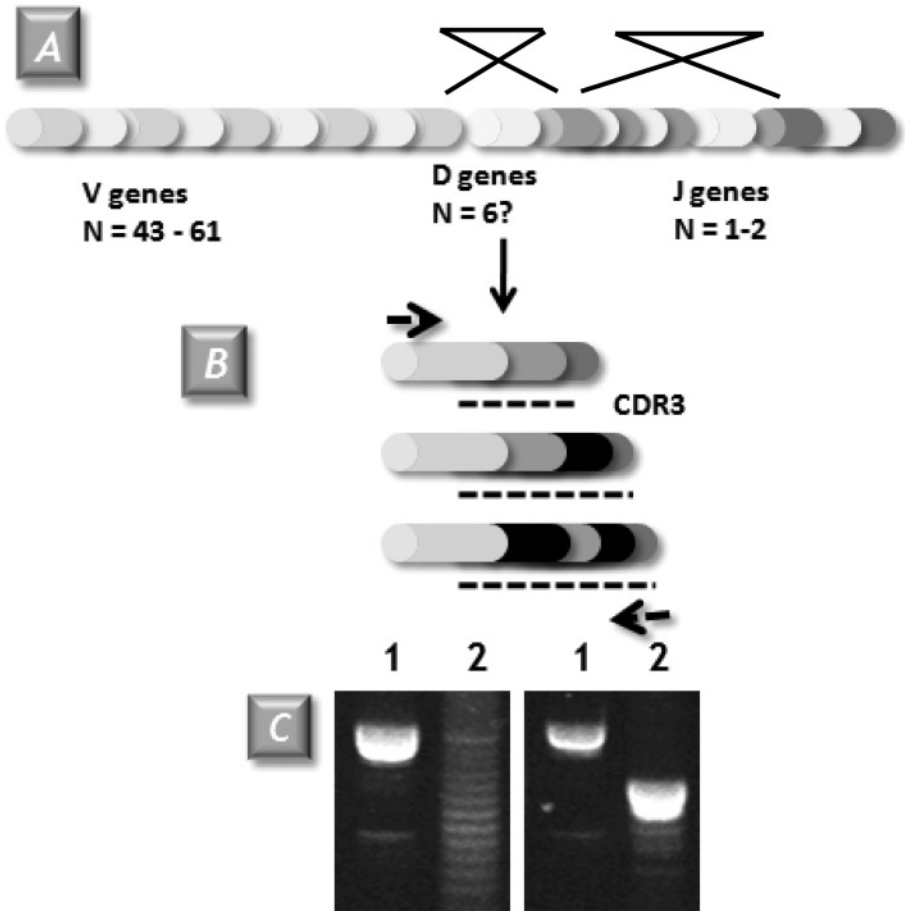

FIGURE 143.1 Immunoglobulin gene rearrangement results in CDR3 regions of variable sizes. (**A**) DNA (white) between V region genes (light gray) and D region genes (medium gray), and between D region genes and J region genes (dark gray) loops out to bring V, D and J gene segments together. (**B**) The CDR3 region (dashed line) is the result of recombination between V, D and J region gene segments. The length of this region varies between B cells because nucleotides are added (black segments), and end to end joining between V, D and J genes is imprecise. Polymerase chain reaction primers placed outside of CDR3 (arrows) in the conserved area of the gene will amplify intervening DNA resulting in different sized products from different B cells. (**C**) Polyacrylamide gel electrophoresis of PCR products from a dog with reactive lymphoid hyperplasia (left) and from a dog with lymphoma (right). The first lane of each panel shows amplification with primers specific for a control gene (any non-antigen receptor gene) as a positive control for DNA. The second lane shows DNA amplified with immunoglobulin primers. DNA from the dog with lymphoid hyperplasia yielded multiple faint PCR products. DNA from the dog with lymphoma yielded a single sized product. Similar principles apply to TCR gamma genes, except that these genes lack D regions.

patients. The first large scale study of this technique was reported by Burnett et al,[8] following earlier studies that demonstrated the presence of clonally rearranged TCR genes in canine malignancy.[15,18,46] A number of laboratories have reported versions of the assay.[6,8,22,38,46,57,58]

Each laboratory performing this test uses slightly different primer sequences,[6,8,22,38,46,57,58] but all laboratories use primers which anneal in the framework 3 region of Ig and TCR V genes, and to the 3′ end of Ig and TCR J genes. The TCR gamma gene is used for this assay despite the fact that the majority of T cells express the α/β T cell receptor protein, because in the thymus, the TCR gamma gene rearranges before the TCR beta gene. If this rearrangement is not productive (which is true the majority of the time), the T cell will go on to rearrange TCR beta, but the rearranged TCR gamma gene remains[29] and can still be used as a marker of clonality. Early studies in human patients found this assay to be more sensitive than detection of TCR beta rearrangement,[14,40,41] and therefore TCR gamma was also used in the development of the assay for canine and feline patients. Sequencing of feline TCR gamma[49] and Ig genes[52] has been reported and used clinically[9] but these assays are less well developed.

Obtaining and Shipping Samples

Virtually any source of cells can be used, including cytology slides regardless of whether they are stained or not. In addition to stained slides, aspirates from masses or nodes can be squirted directly into an EDTA tube with the addition of other liquid. The appropriate sample to submit for clonality testing is the tissue con-

taining the suspicious cells: testing of peripheral blood in cases where there is no obvious blood involvement is significantly less sensitive than testing the suspicious lymph node,[25] mass or cavity fluid.

The only sample type not used by our laboratory is DNA derived from formalin fixed, paraffin embedded tissues. The process of formalin fixation substantially decreases the quality of the DNA, and different sensitivity and specificity parameters must be developed for this sample source. Useful information can come from the analysis of formalin fixed samples, however, and this testing is performed in some laboratories.[44]

Quality Control

As with all PCR-based assays, negative controls that include all elements of the PCR reaction except the DNA to be tested are essential to demonstrate there is no contamination. In addition, it is also important to establish that there is sufficient DNA in a particular clinical sample for detection in order to make both negative and positive results meaningful. While insufficient DNA may result in false negative results, it can also lead to false positives which are sometimes termed "pseudoclonal." Although it may seem paradoxical, in a sample of low cellularity or poor quality DNA (such as formalin fixed samples), the intact DNA that is present may be from only a small number of cells. In these cases, amplification will seem to yield a clonal result because few Ig or TCR genes are present to bind the primers.[16]

There are at least two ways to control for this phenomenon. Some groups carry out all analyses in duplicate[44] because pseudoclonal PCR products are often not repeatable. Our laboratory prefers to amplify a non-antigen receptor gene as a positive control for DNA (Fig. 143.1).[8] This indicates there is sufficient DNA present, and therefore validates negative results obtained with Ig and TCR primers.

Sensitivity and Specificity

When first developed, clonality testing in people[1,2,4,14] had sensitivity similar to what we currently achieve in dogs: 75–80%. The addition of detection of light chain gene rearrangement has increased the sensitivity to close to 100%.[45] Specificity values for the assay in human patients are harder to find. In one, 80 cases of atypical or benign lymphoid hyperplasia were tested for clonality, and in all cases where a clonal population of T or B cells was detected (n = 5), the patients went on to develop malignancy within 2 years.[33] This finding suggests that clonality testing is able to detect malignancy before conventional diagnostics.

In veterinary medicine, clonality testing almost certainly differs in sensitivity and specificity between laboratories, and these values need to be established by each institution offering the assay. Our laboratory detects approximately 75% of histologically or cytologically confirmed lymphomas, when the assay is carried out on the cells in question (based on testing of approximately 800 cases). Lack of a clonally rearranged antigen receptor on a confirmed case of lymphoma or leukemia can have several explanations: (1) the genes involved in the antigen receptor rearrangement in this tumor are not detectable by our primers (details of V and J region TCR and Ig genes in dogs have been previously described[11,38,57]); or (2) there is no antigen receptor rearrangement because the tumor is NK in origin; or (3) the tumor is derived from an early lymphocyte precursor. These types of tumors may be characterized by flow cytometry. PARR negative malignancies do not appear to have a different prognosis than PARR positive malignancies.[25]

In order to determine the specificity of a positive finding, we tested a series of 72 cases with clinical conditions other than lymphoid malignancy and found a false positive rate of 8%.[7] The most common reason for detecting a clonal T cell population in a dog without neoplasia is *E. canis* infection, a phenomenon that has also been reported in the literature.[8,46] Each case of *E. canis* was diagnosed by serology, responded to therapy and was healthy at a minimum of 8 months follow-up. Rarely, cases of Lyme disease, bartonellosis and Rocky Mountain spotted fever have been associated with clonal B cell expansion, but this finding is unusual (A.C. Avery, unpublished results). Leukemias with a suspected or confirmed myeloid origin were excluded from this case series because in people[23] and in dogs[8] acute myelogenous leukemias (AML) can have aberrantly rearranged lymphocyte antigen receptor genes.

Interpretation of Results

Possible results of a clonality assay include: no amplification of DNA using TCR or Ig primers, amplification of one or two products (clonal amplification), amplification of three or more products that are not regularly spaced in size (oligoclonal), amplification of a range of PCR products that are evenly distributed with regard to size (polyclonal). Samples from non-lymphoid tissues tend to yield the first kind of result (no PCR products except the positive control). This is because the distance between two primers annealing to un-rearranged Ig or TCR genes is too long to successfully amplify PCR product. Samples from normal or reactive lymphoid tissue tend to yield polyclonal PCR products.

One or two PCR products indicate the presence of one or two clonal populations of lymphocytes: a single tumor can have rearrangements of antigen receptor genes on both chromosomes. Oligoclonal amplification is more difficult to interpret. In our experience (A.C. Avery, unpublished observations), T cell lymphomas unambiguously diagnosed by cytology or histology often have multiple clonal PCR products. This observation has also been reported in certain kinds of human T cell lymphomas.[3] The explanation for these findings is not clear, but includes the possibility of ongoing gene rearrangement during tumor progression, or a process that involves malignant transformation of more than one T cell precursor simultaneously. Sequencing of these clonal PCR products may help clarify this issue.

CLONALITY TESTING OR IMMUNOPHENOTYPING IN LYMPHOID LEUKEMIA AND LYMPHOMA – WHICH TO CHOOSE?

Each laboratory that provides these diagnostic tests may have different recommendations, but in general, because immunophenotyping provides substantially more information than clonality testing, we recommend clonality testing only in cases where the cytologic or histologic diagnosis is ambiguous. When there is a definitive or highly probable diagnosis of lymphoma or leukemia, immunophenotyping by flow cytometry should virtually always be able to confirm neoplasia by detecting cells with an aberrant phenotype or a homogeneous expansion of lymphocytes. In addition, any peripheral blood samples with an elevated lymphocyte count should be assessed by flow cytometry, because this assay will provide both a diagnosis and in many cases a prognosis for the canine patient.[54]

Acronyms and Abbreviations

ACH, acetylcholinesterase; ACP, acid phosphatase; ALL, acute lymphoblastic leukemia; ANAE, alpha naphthyl acetate esterase; ANBE, alpha naphthyl butyrate esterase; βG, β-glucuronidase; CAE, chloroacetate esterase; LAP, leukocyte alkaline phosphatase; NK, natural killer; NSE, nonspecific esterase; OEN, omega-exonuclease; PAS, periodic acid-Schiff; PER, peroxidase; SBB, Sudan black B; TB, toluidine blue.

GENERAL PRINCIPLES OF CYTOCHEMISTRY

Cytochemistry is the use of special stains in the microscopic examination of cellular constituents such as lipids, carbohydrates, and enzymes.[57] These stains may detect differences between normal cell types and identify the lineage of poorly differentiated blast cells (see Section V on Hematologic Neoplasia). Cytochemistry is ideal as a diagnostic technique because it involves minimal cost and is readily performed at diagnostic referral centers. This technique may be used with hemolymphatic tissues (blood, bone marrow, lymph nodes, spleen, and thymus) or with liver. These specimens may include fresh imprints or aspirates, frozen tissues,[79] or plastic-embedded tissues.[8] In contrast, paraffin-embedded tissues may not be stained for nonspecific esterase (NSE) activity because the enzyme is unstable during tissue processing. In addition to light microscopic preparations, cytochemical staining also has been applied to electron microscopic specimens.[6,49]

To ensure proper sample handling, the clinician should contact the laboratory performing the cytochemical staining before submitting materials. Multiple unfixed slides usually are preferred so a panel of stains can be performed. During cytochemical staining, appropriate control slides are used as positive and negative stain markers to assure quality control for the procedure(s). Although cytochemistry is applicable to the cells of various species, it is noteworthy that incubation times, staining patterns, and the presence of substrates may differ, even among the various avian, reptile, and fish species.

GENERAL CONSIDERATIONS FOR STAINING NEOPLASTIC HEMATOPOIETIC CELLS

The first step in the identification and classification of hematopoietic neoplasia is a morphologic characterization of the poorly differentiated blast cell population

and accompanying cells. This may be followed by special tests to better define the cell of origin. Poorly differentiated cells are indistinguishable by morphology alone but may be better identified by their cytochemical characteristics. This is critical for acute leukemias and especially useful in domestic animals like the dog, cat, and horse. The use of cytochemical staining can improve the diagnosis and sometimes change the initial morphologic interpretation.[27,28,35]

The general premise of cytochemistry for hematopoietic malignancies is that the neoplastic cells contain the same enzymes or cellular products as are found in cells from healthy individuals. However, occasional irregularities may occur related to the altered development of neoplastic or dysplastic cells. Cytochemical staining is best interpreted when a panel rather than one or two stains are performed, since discrepancies may occur with neoplastic cells.

In general, lymphoid cells do not stain with many cytochemical stains. However, negative staining does not automatically indicate a lymphoid neoplasm. Rather it may represent an undifferentiated myeloid malignancy. Stain intensity is often very weak or absent in the most undifferentiated cells because they contain few of the necessary enzymes or cellular constituents found within lysosomal granules, cytoplasm, or the plasma membrane. On the other hand, some enzymes such as myeloperoxidase found in the primary granules of granulocytes are present to a greater extent in the earlier stages. In cytochemistry, it is best to interpret the results of positive staining rather than the lack of staining. Positive staining is meaningful, whereas negative staining leads to uncertainty.

In addition to stain intensity, the pattern of staining may be diagnostic. T-lymphocytes bearing focal lysosomal granules often produce a focal or discrete localization of NSE enzyme activity compared with the diffuse or granular nature found in some nonlymphoid cells. Lymphoid cells are best classified using immunologic markers, but lineage- and species-specific monoclonal antibodies may be limited in availability or by cost. Therefore, limitations using immunomarkers supports continued use of cytochemical staining techniques for T-cell identification.[83]

In the interpretation of staining data, additional factors are considered. One factor is the species involved. Reactions seen within one species cannot be extended readily to other species. For example, feline eosinophils normally do not stain with either peroxidase (PER) or Sudan black B (SBB), whereas these stains can be used in the eosinophils of other species.[45] Another factor involves the extent of staining within the sample. The percentage of stained blast cells in the bone marrow should be sufficient to establish a positive reaction with a given stain. Generally, this is greater than 3%. In the case of PER or SBB, greater than 3% of the blast cells present should be positive to identify human myeloblastic leukemia (without maturation).[9] It is best to count a minimum of 200 bone marrow cells when calculating this figure to avoid an over- or underestimation. A simplified classification of acute leukemias using cytochemical staining is shown in Fig. 144.1.

REACTIONS OF NORMAL HEMATOPOIETIC CELLS

A summary of normal cell reactions for selected stains in several animal species is provided in Table 144.1.

Neutrophils/Heterophils

Primary or azurophilic lysosomal granules contain myeloperoxidase. Peroxidase (PER) activity is readily demonstrated from the promyelocyte stage through mature segmented forms (Figs. 144.2A, B). In electron

microscopic preparations, PER activity also may be visualized in the nuclear membrane, rough endoplasmic reticulum, and Golgi apparatus of myeloblasts.[45] Peroxidase reactivity generally is absent in heterophils of rabbits, certain birds, and reptiles.[3,53,101] Iguana heterophils, in contrast to many reptiles, have a significant positive PER reactivity.[37] Neutrophils with eosinophilic prominence, such as those of the manatee, possess myeloperoxidase and stain intensely.[53]

Secondary or specific granules contain lipids, which stain positively with Sudan black B (SBB) (Fig. 144.3A). Sudan black B staining is found to a lesser extent within primary granules (Fig. 144.3B). Because both primary and secondary granules stain with SBB, all stages of neutrophil maturation are detected.

Primary and secondary neutrophilic granules also contain chloroacetate esterase (CAE) activity (Figs. 144.4A–C). The cytochemical stain technique detects enzymatic activity, producing moderate to strong reactions in all maturation stages of neutrophils (Fig. 144.5).

Leukocyte alkaline phosphatase (LAP) is found predominantly in the secondary granules of neutrophils of most species including humans, horses, rabbits, and ruminants (Fig. 144.6). However, this enzyme is absent in more mature neutrophils of dogs and cats. Equine and caprine neutrophils stained for NSE activity may show variable reactivity; neutrophils from most other species are cytochemically nonreactive.[45,95]

Acid phosphatase (ACP) activity is present in the primary granules of neutrophils. Enzymatic activity is higher in immature neutrophils than in bands or segmenters. Stain reactivity, however, is of modest intensity.

Eosinophils

The PER that is present in eosinophils differs both structurally and biochemically from that found in neutrophils and megakaryocytes. This enzyme is present in the matrix of large eosinophilic granules but not within the crystalloid core (Fig. 144.2A). Unlike eosinophils of most species, feline eosinophils do not stain with either PER or SBB techniques. However, PER and SBB reactivity may be observed in avian and reptilian

eosinophils.[3,5,64] In general, eosinophils do not stain with CAE technique; however, reactivity has been observed in green turtle and koi eosinophils.[94,101] Nonspecific esterase activity is absent in canine and feline eosinophils, but occasionally may be observed in equine and ruminant eosinophils.[45] Both alpha naphthyl butyrate esterase (ANBE) and alpha naphthyl acetate esterase (ANAE) activities are noted to be strong in elephant eosinophils (see Chapter 120). Eosinophils, especially those of the cat, stain strongly for ACP activity in the intergranular areas. Enzymatic activity is present in both canine and feline eosinophils and is tartrate-resistant.[27,28] Leukocyte alkaline phosphatase activity is found intracellularly between the specific granules of eosinophils (Fig. 144.5). The strongest reactivity occurs within the eosinophils of the horse. Specific eosinophil stains, such as Luna[59] and Luxol fast blue[106] also have been helpful in cell identification.

Basophils

Basophils are negative for SBB and PER reactivity. Feline and possum basophils may demonstrate occasional positive reactions with LAP activity.[20,45] The CAE technique produces a moderately positive reaction in canine and feline basophils, whereas bovine and equine basophils are weakly positive for enzyme reactivity. Basophils of the dog, cat, horse, and cow are negative for NSE activity. Acid phosphatase activity occasionally may be observed in canine and feline basophils; enzymatic activity is tartrate-resistant.[27,28]

Alcian blue stains positively for the sulfated mucosubstances in basophil granules of many species.[78] Omega-exonuclease (OEN) activity is present in basophils and mast cells of dogs and cats (Fig. 144.7A, B), but it is absent in both equine and bovine basophils.[47,78] Toluidine blue (TB) staining may be metachromatic (purple) for basophil granules of domestic animals under acidic conditions, but this characteristic is not observed at neutral pH.[53] Toluidine blue staining also has been demonstrated in basophils from the alligator and desert tortoise.[3,64]

Monocytes/Azurophils

Monocytes and azurophils of some species show diffuse, weakly positive reactivity for SBB and PER (Fig.

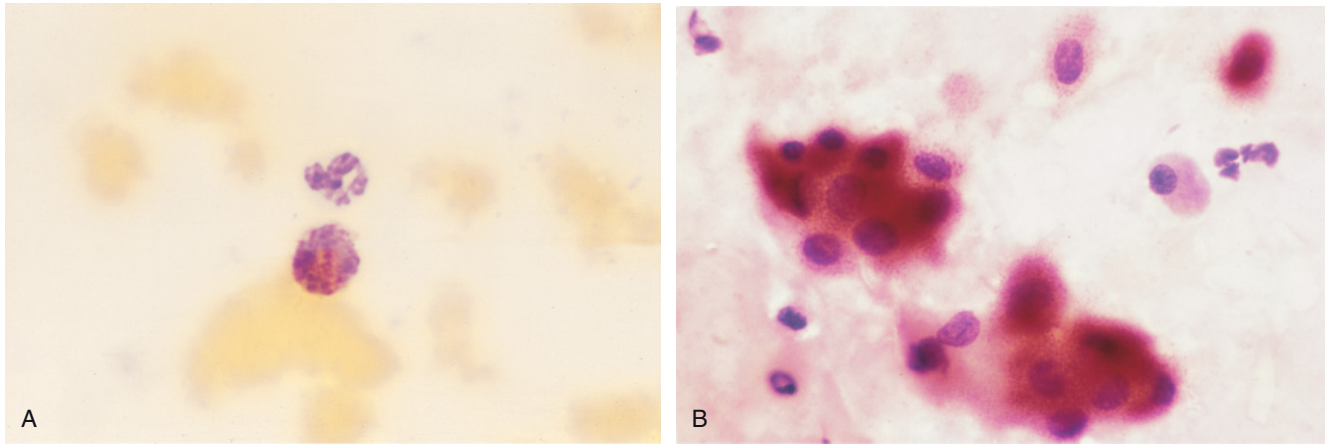

FIGURE 144.7 (**A**) Positive stain reaction with OEN in a feline basophil. Blood. × 100 objective. (**B**) Strong cytoplasmic staining of cells from a canine mast cell tumor with OEN. Skin mass cytology. × 100 objective.

144.5).[2,4,11] Peroxidase activity may be more evident when copper nitrate is used to intensify the enzymatic reaction within the lysosomes. Generally, monocytes do not contain CAE activity; however, trace positive reactivity may be observed in bovine, equine, ovine, caprine monocytes[45] as well as the bilobed monocyte of elephants (see Chapter 120). Nonspecific esterase is present in cells of monocytic origin, resulting in diffuse, finely granular reactivity (Fig. 144.5) that is most intense in macrophages.[42,103] Nonspecific esterase reactivity (Fig. 144.8) is inhibited with sodium fluoride due to the presence of the enzymes on the plasma membrane.[13,25] Acid phosphatase reactivity is present in a diffuse manner, similar to that observed for NSE. Acid phosphatase reactivity is of moderate intensity in monocytes and increases with maturity into macrophages. Leukocyte alkaline phosphatase may be found in canine monocytes and monoblasts (Figs. 144.5 and 144.9) Monocytes in koi, an ornamental carp, are noted to have NBE as well as beta glucuronidase (βG) activities.[94]

Lymphocytes

Traditionally, lymphocytes lack reactivity to many of the cytochemical techniques used to identify granulocytic and monocytic cells. Peroxidase activity is absent, although rare cases in human medicine exhibit PER expression as detected by molecular studies.[41] Leukocyte alkaline phosphatase activity may be observed in a B-cell subtype associated with the mantle zone of lymph nodes in dogs.[79] Stain reactivity presents in a fine, diffusely granular pattern involving the plasma membrane. Chloroacetate esterase reactivity is rare in lymphocytes (Fig. 144.4B), but weak staining has been reported in bovine and equine lymphocytes[45] as well as in elephant lymphocytes (see Chapter 120). Occasional punctate staining has been associated with non-T-cell large granular lymphocytes in people.[39] Nonspecific esterase activity results in a focally discrete staining reaction within the intracellular organelles of normal and neoplastic lymphocytes from humans, dogs, cats,

cattle, horses, sheep, elephants (see Chapter 120), and chickens. This focal staining has been associated with lymphocytes of a T-cell origin.[6,25,27,28,39,75,98,102,104] Cells consistent with canine natural killer (NK) cell activity have weak, focal staining with the NSE and periodic acid-Schiff (PAS) techniques.[54] Weak PAS staining has been demonstrated in lymphocytes from cattle, dogs, horses, and sheep.[45] Positive reactivity for ACP has been observed in canine NK cells with and without tartrate incubation (Fig.144.10).[54]

Platelets and Megakaryocytes

Platelets contain a specific PER that is only apparent in ultrastructural preparations (not in light microscopic specimens). This specific PER is present within the endoplasmic reticulum and nuclear membrane of megakaryocytes and within the tubular system of the platelets. Slight CAE reactivity in canine and feline megakaryocytes has been reported, similar to that observed in human cells.[27,28] Periodic acid-Schiff staining is often apparent within platelets and megakaryocytes of many animal species, including thrombocytes of birds and reptiles (Fig. 144.11).[64,88] Positive reactivity to LAP- or SBB-staining techniques has not been demonstrated within platelets. Megakaryocytes and platelets may exhibit reactivity for NSE; these reactions are mildly to totally inhibited with sodium fluoride.[36] Both megakaryocytes and platelets are strongly reactive for ACP activity. Synacril black AN, a textile dye,[51] selectively stains acid mucopolysaccharides found in the megakaryocytic cytoplasm (Figs. 144.12A, B); metachromatic staining is observed. Acetylcholinesterase is another marker that primarily identifies megakaryocytes and platelets in dogs, cats, and rats.[48]

Erythroid Cells

Reactivity of erythroid cells to routine cytochemical stains is observed infrequently. Examples include a diffuse blush of positive reactivity due to endogenous PER activity. Similar observations occur with SBB cytochemistry. Acid phosphatase, βG, PAS (Fig. 144.11), and ANBE techniques may result in diffuse granular staining of various stages of erythroid precursors.[27,28,96]

Mast Cells

Canine and feline mast cells exhibit variable reactivity with the CAE, PAS, alcian blue, toluidine blue, and OEN (Fig. 144.7B).[47] Mast cells, like basophils, are negative for PER and SBB reactivity. Leukocyte alkaline phosphatase activity is not present in canine and feline mast cells, whereas ACP reactivity results only in weak staining. Nonspecific esterase reactivity may have variable intensity in mast cells from some species like the pig, dog, and cat.

CYTOCHEMICAL STAINING PRINCIPLES AND APPLICATION

A listing of selected cytochemical stains and the methodology used by the author can be found in the previous edition of this book.[80] Other methods and kits may be used for a similar result including double staining techniques (Fig. 144.5). The cytochemical principle and application for each of the techniques will be further described below and shown in Tables 144.2 and 144.3.

Myeloperoxidase

This cytochemical technique is used as a marker for myeloid cells, particularly neutrophils, eosinophils, and monocytes (Fig. 144.2A). The PER enzymes are sensitive to tissue processing. Therefore, enzymatic reactivity is demonstrable only in fresh tissues and not in paraffin-embedded tissues. Peroxidase reactivity diminishes over time, especially in samples older than 2 weeks of age. Peroxidase reactivity may be less intense if smears are over 3 days old.[35] The most sensitive method to detect PER activity involves benzidine compounds that are potentially carcinogenic.[50] Copper salts enhance the benzidine reaction producing a gray-black product rather than an orange-brown result. An acceptable alternative substrate to diaminobenzidine tetrahydrochloride is 3-amino-9-carbazole.[46]

The blast cells within the bone marrow should stain positive with PER for the following subtypes of acute myeloid leukemia: myeloblastic leukemia (with or without maturation), myelomonocytic leukemia, and erythroleukemia. Rare positive staining in monoblastic leukemia (without maturation) is possible. The intensity of staining within mature neutrophils reflects the level of activity within myeloblasts. There is a deficiency of PER activity for myelogenous leukemia in human medicine but during remission following chemotherapy, the activity increases and can be better detected in the mature neutrophil. Therefore monitoring PER activity may provide prognostic information regarding the efficacy of treatment in people.

Lymphoid malignancies traditionally lack PER reactivity; however, occasional reports in human medicine have identified molecular expression of the enzyme.[41] There are no known reports of PER expression in veterinary cases of acute undifferentiated leukemia, basophilic leukemia, megakaryoblastic leukemia, acute lymphoid leukemia, lymphoma, histiocytic sarcoma, or mast cell neoplasia. Peroxidase staining was helpful in the diagnosis of canine, feline, equine, and porcine cases of myeloblastic leukemia (Fig. 144.2B) and myelomonocytic leukemia (Fig. 144.5).[14,19,23,34–36,49,81]

Sudan Black B

Lipids (including phospholipids, neutral fats, and sterols) within neutrophils/heterophils, eosinophils, and occasional monocytes/azurophils are identified (Fig. 144.3A) by a gray-black reaction using SBB dye.[85] This staining technique is as sensitive as the PER reaction. The mechanism of cellular staining may involve an enzymatic reaction because eosinophils from patients that have eosinophil PER deficiency do not stain after SBB application. The same may be true in cats because their eosinophils also fail to stain. The sudanophilic material within cells is stable with heat or storage.

The blast cells within the bone marrow should stain positively with SBB (Fig. 144.3B) in the following subtypes of acute myeloid leukemia: myeloblastic leukemia (with or without maturation), myelomonocytic leukemia, monocytic leukemia, and erythroleukemia. Lymphoid malignancies traditionally lack positive reactions with SBB. However, one case of canine acute lymphoblastic leukemia displayed slight sudanophilia.[27] One case of canine malignant histiocytosis (now termed disseminated histiocytic sarcoma) had positive SBB reactivity.[27] There are no known reports of SBB reactivity in veterinary cases of acute undifferentiated leukemia, basophilic leukemia, megakaryoblastic leukemia, or mast cell neoplasia. Sudan black B positive expression was helpful in the diagnosis of canine, feline, equine, and bovine cases of myeloblastic leukemia, eosinophilic leukemia, monocytic leukemia, myelomonocytic leukemia, and erythroleukemia.[14,27,28,32,61,70,77,81,100]

Chloroacetate Esterase

Referred to as specific esterase, the CAE reaction is likely produced by a group of enzymes. This reaction is considered more specific for neutrophils (Fig. 144.4B) than PER or SBB reactivity, although the CAE technique is less sensitive. Chloroacetate esterase reactivity is strongest from the promyelocyte to the segmented stage; weaker reactivity is observed in myeloblasts (Fig. 144.4A). The CAE reaction also is specific for mast cells.

[a]PER, peroxidase; SBB, Sudan black B; CAE, chloroacetate esterase; LAP, leukocyte alkaline phosphatase; ANAE, alpha naphthyl acetate esterase; ANBE, alpha naphthyl butyrate esterase; ACP, acid phosphatase; ACP/T, acid phosphatase with tartrate; BG, beta glucuronidase; PAS, periodic acid-Schiff; ET, essential thrombocythemia; neg, no reaction; pos, easily detectable; pos/neg, weak or occasional reactivity.

This enzyme is found within the primary and secondary granules of neutrophils and within the specific granules of basophils. Although CAE is generally specific for neutrophils, other cell types have weak reactions. For example, mild positive reactions may occur within the monocytes of horses and ruminants. In addition, slight reactions within normal megakaryocytes of dogs and cats have been noted.[27,28]

Enzymatic reactivity in the CAE procedure probably involves chymotrypsin and elastase. These enzymes are capable of hydrolyzing esters linked to the substrate naphthol AS-D chloroacetate that when, liberated, complex with a stable diazonium salt to produce an insoluble, colored product at the site of enzyme activity.[69] This esterase group can be distinguished biochemically from NSE on the basis of isoenzyme separation on gel electrophoresis.[26] This esterase group is considered specific related to its resistance to sodium fluoride to inhibit its stain reaction. Chloroacetate esterase staining may be performed together with a nonspecific esterase stain for monocytes to detect both neutrophil and monocyte populations simultaneously (Fig. 144.5).[103] The CAE cytochemical reaction is very stable and may be used in paraffin-embedded tissues.

Positive reactions with CAE occur in the following subtypes of acute and chronic myeloid leukemia: myeloblastic leukemia (with or without maturation), myelomonocytic leukemia (Figs. 144.4C and 144.5), and erythroleukemia. Chloroacetate esterase is less sensitive but more specific than PER in distinguishing granulocytic and monocytic precursors. In addition to its specificity for neutrophils, it regarded as a marker for basophilic leukemia and mast cell tumors. Lymphoid malignancies generally lack positive reactions with CAE. However, one case each of canine and feline acute lymphoblastic leukemia (ALL) displayed a slight reaction.[28] This is similar to human medicine in which rare cases of positive staining have occurred in ALL. In addition CAE staining was noted in several feline lymphoma cases, many of which involved large granular lymphocytes.[82,98] One case of feline eosinophilic leukemia was positive for CAE.[28] Occasional weak to moderate staining was noted in three cases of canine megakaryoblastic leukemia.[21,67] One case of weak CAE staining occurred in a horse with monocytic leukemia.[17] There are no known reports of CAE staining in canine or feline cases of monocytic leukemia. Chloroacetate esterase staining was helpful in the diagnosis of several canine, feline, bovine, equine, porcine, camelid, and saurian cases of myeloblastic leukemia, basophilic leukemia, myelogenous leukemia, myelomonocytic leukemia, malignant histiocytosis, mast cell tumor, and erythroleukemia.[7,12,14,23,27,28,32,66,77,78,81,86,87,91,92,99,100]

Leukocyte Alkaline Phosphatase

Enzymes with LAP activity hydrolyze naphthol AS-BI phosphate at an alkaline pH, releasing naphthol to complex with a diazonium salt, forming an insoluble, colored product near the site of enzyme activity.[1] This group of enzymes is present in granulocytes (Fig. 144.5), osteoblasts, histiocytes, vascular endothelial cells, and a subset of lymphocytes.[26,71] In human neutrophils, LAP activity is present in a subset of granules associated with the plasma membrane. The LAP reactivity of neutrophils varies with the species. In people, metamyelocyte and earlier stages are devoid of reactivity, whereas more mature cells (such as segmenters) stain more intensely. Leukocyte alkaline phosphatase reactivity is normal to increased in leukocytosis or leukemoid reaction, but it is decreased in neoplastic neutrophils (e.g. chronic myelogenous leukemia). Leukocyte alkaline phosphatase reactivity, similar to that in people, occurs in rabbits, rats, guinea pigs, horses, cattle, sheep, goats, and monkeys.[45] In dogs and cats, the late stages of neutrophils are devoid of LAP activity, whereas enzymatic activity is present in myeloblast and promyelocyte stages. Therefore, the LAP technique has been helpful in identifying myelogenous leukemia. Leukocyte alkaline phosphatase activity is absent in human eosinophils. In contrast, LAP activity is strong in the equine eosinophils, moderate in bovine eosinophils, and mild to moderate in canine and feline eosinophils (Fig. 144.5). In each instance, enzymatic activity is observed in the cytoplasm between the specific granules. A subset of B lymphocytes, present in the mantle zone of lymph nodes, exhibits cellular membrane staining with LAP technique in people, dogs, rats, and mice.[71,79] Leukocyte alkaline phosphatase reactivity, though present in a wide variety of cells and tissues, also is helpful for the identification of hemolymphatic cells from mammalian and certain reptilian species.

Because LAP may be found in neutrophil precursors, it has been suggested that the presence of enzyme activity is a specific marker for myelogenous origin of canine and feline leukemia.[35,45] Specific subtypes of acute myeloid leukemia that display LAP (Fig. 144.9) activity include myeloblastic leukemia (with or without maturation), myelomonocytic leukemia, and erythroleukemia. Positive staining has been documented in cases of feline eosinophilic leukemia.[28,89]

One feline case involving basophilic differentiation of an acute myeloid leukemia exhibited cytoplasmic LAP staining.[12] Lymphoid malignancies generally lack positive reactions with LAP. However, positive reactions in lymphoid malignancies have been noted.[27,79,90,97] One case with weak LAP staining was documented in a horse that had monocytic leukemia.[17] Leukocyte alkaline phosphatase staining has been observed in monoblasts from normal dogs and dogs that have monoblastic leukemia. (J. Blue, personal communication, 2005). There are no known reports of LAP staining in feline cases of monocytic leukemia or in canine and feline cases of histiocytic sarcoma (malignant histiocytosis), megakaryoblastic leukemia, and mast cell tumor. Leukocyte alkaline phosphatase staining was helpful in the diagnosis of several canine and feline cases of myeloblastic leukemia, myelomonocytic leukemia (Fig. 144.5), and erythroleukemia.[23,27,28,32,34–36,62]

Periodic Acid-Schiff

In the PAS technique, periodic acid oxidizes carbohydrates to form aldehydes that react with Schiff's reagent to produce a dye product.[58] The bright red or magenta reaction product is focal, diffuse or granular. Depending on the species, PAS may be found within a wide variety of cells, including neutrophils, heterophils, eosinophils, basophils, monocytes, azurophils, lymphocytes, platelets, thrombocytes, and erythrocytes (Fig. 144.11). The materials stained include glycoproteins, mucoproteins, glycolipids, and high-molecular-weight carbohydrates. In blood cells, glycogen usually is the substance demonstrated; however, if the sample is predigested with diastase, glycogen staining is eliminated.

Mature forms of neutrophilic granulocytes and platelets or megakaryocytes stain the most intensely, with monocytes, eosinophils, and basophils producing a weak positive reaction. Myeloblasts and promyelocytes stain negatively and weakly positive with PAS, respectively.[27,28] Lymphocytes usually do not stain positively, or if they do it is a very weak reaction, especially in plasmacytic forms.

In general, PAS staining in veterinary medicine is used to differentiate granulocytic or megakaryocytic precursors from lymphoid precursors. Specific subtypes of acute myeloid leukemia that may display PAS positive activity include myeloblastic leukemia, myelomonocytic leukemia, monocytic leukemia, erythroleukemia or erythroleukemia with erythroid predominance, and megakaryoblastic leukemia.[21,27–29,36,38,77,81,93] Positive staining has been documented in canine histiocytic sarcoma (malignant histiocytosis).[27,38] One case of feline eosinophilic leukemia displayed positive PAS reaction.[28] A weak stain reaction with PAS occurred in a case of basophilic leukemia.[66] Mast cell tumors in the dog, cat, goat, and pig have demonstrated positive PAS reaction.[7,52,78,86] Infrequent or weak PAS staining has occurred with some feline and equine lymphoid malignancies.[28,35,98]

Nonspecific Esterases

Nonspecific esterases compose a group of enzymes capable of hydrolyzing esters to liberate naphthol products that bind with a coupler dye. These esterases demonstrate a wide range of substrate specificity and stain pH environment for various blood cells; therefore, they are termed nonspecific. Many of the esterases, as determined by polyacrylamide gel electrophoresis, are cell specific. Monocytes, granulocytes, and a subset of lymphocytes exhibit unique patterns of reactivity. A red to pinkish brown, diffusely granular pattern is seen in monocytes (Fig. 144.5), macrophages stain more intensely, and a single focal or punctate reaction product is seen in T-lymphocytes. The NSE activity in monocytes is inhibited by the addition of sodium fluoride to the incubation medium, whereas T lymphocytes are resistant. Differentiated histiocytes or macrophages have weakened or abolished reactivity in the presence of sufficient sodium fluoride. Sensitivity to sodium fluoride inhibition also has been observed in megakaryocytes, platelets, and plasma cells.[25,36] The difference in inhibition relates to the location of the enzyme in these cells. For example, two NSE enzymes, alpha naphthyl acetate esterase (ANAE) and alpha naphthyl butyrate esterase (ANBE) have been identified mostly on the plasma membrane of monocytes but only within intracellular organelles of lymphocytes.[13,24,39] The intracellular location of the enzyme appears to be protective. The activity of these enzymes is unstable, being sensitive to heat, fixatives, and storage. Fresh blood smears or tissue imprints are preferred to paraffin-embedded tissues that may not demonstrate the reaction.

Cell specificity for ANAE activity may be demonstrated by altering the pH of the medium, temperature, and length of incubation.[13,57,72] Monocytes are best stained in an acidic medium, whereas both granulocytes and monocytes may show enzymatic activity when the same substrate is used in a neutral medium. Lymphocytes are best demonstrated only with acid conditions and prolonged incubation. Compared with ANBE, ANAE is more sensitive and less specific in identifying monocytes, macrophages, and T-lymphocytes. Therefore, sodium fluoride inhibition is necessary to differentiate the cell types. T lymphocytes have been identified by a focal staining pattern in humans, dogs, and chickens.[6,102,104] The stain reaction may be weak in megakaryocytes, platelets, and plasma cells, all of which are sodium fluoride sensitive.[36]

Similar to the ANAE technique, differential staining of cells for ANBE activity requires changing the pH of the incubation medium. Sodium fluoride inhibition often is not used with ANBE owing to its greater specificity for monocytes compared with ANAE.

Specific subtypes of acute myeloid leukemia that display positive NSE activity include myelomonocytic leukemia, monoblastic leukemia, and megakaryoblastic leukemia. Positive staining has been documented in cases of canine, feline, and equine histiocytic sarcoma (malignant histiocytosis).[22,56,99] Weak stain reactions with ANAE occurred in feline and canine cases involving basophils.[12,66] In addition, occasional positive ANBE reactions have been documented in canine, feline, and porcine mast cell tumors.[7,28,78] One case of feline eosinophilic leukemia reported occasional positive staining with ANBE.[28] A cat with an acute undifferentiated leukemia, formerly termed reticuloendotheliosis, had diffuse ANBE staining in some of the leukemic cells.[30] One case of feline erythroleukemia was positive for ANBE.[28] Lymphoid malignancies may stain with NSE, giving a focal rather than diffuse appearance. Some examples of positive staining of lymphoid neoplasia may be found in dogs, cats, cattle, and sheep.[16,27,28,31,35,75,79,82,90,97,98] There are no known reports of NSE staining in canine, feline, or equine cases of myeloblastic leukemia. In summary, ANAE has been helpful in diagnosing myelomonocytic leukemia, monocytic leukemia (Fig. 144.8), megakaryoblastic leukemia, blast cells of essential thrombocythemia, and histiocytic sarcoma (malignant histiocytosis), whereas ANBE has been helpful in diagnosing myelomonocytic leukemia,

monocytic leukemia, and histiocytic sarcoma (malignant histiocytosis).[14,17–19,21–23,27,28,32,35,36,40,56,67,68,73,77,79,92,99,100]

Acid Phosphatase

Acid phosphatase is a group of enzymes that hydrolyze phosphate esters in an acidic environment. There are erythrocyte and leukocyte isoenzymes that are specific for different cells. Many cell types stain in the ACP cytochemical reaction, including lymphocytes, monocytes, histiocytes, granulocytes (particularly eosinophils), platelets, megakaryocytes, plasma cells, and erythroid precursors.[8,27] The reaction product gives a diffuse pattern in monocytes, with histiocytes staining more intensely. A single focal or punctate reaction product in the Golgi area occurs in T-lymphocytes.[104] Canine lymphocytes with NK-cell activity also react with the ACP technique as focal-staining (Fig. 144.10).[76] Approximately one-third of canine NK cells stained positively, and a small percentage remained positive with tartrate incubation.[54] Tartrate resistance was found in eosinophils and basophils from normal dogs and cats.[27,28] Tartrate resistance is most helpful in human medicine for recognition of hairy-cell leukemia, a condition not recognized in veterinary medicine.[57] All ACP isoenzymes are sensitive to tissue processing and heat. Therefore, the ACP technique is recommended only for fresh cytologic or plastic-embedded materials (Fig. 144.13) and not for paraffin-embedded tissues.

Acid phosphatase may be used to detect many different types of blast cells. Specific subtypes of acute myeloid leukemia that display positive activity include myeloblastic leukemia, myelomonocytic leukemia, erythroleukemia, and megakaryoblastic leukemia.[27,28,67,81] Positive staining has been documented in cases of canine and feline histiocytic sarcoma (malignant histiocytosis).[22,27,98] Eosinophilic and basophilic differentiation of acute and chronic myeloid leukemia in the cat and dog display positive staining.[12,28,66] In addition, occasional positive ACP reactions have been documented in canine, feline, and porcine mast cell tumors.[7,28,78] The amoeboid blast cells in a cat that had an acute undifferentiated leukemia had occasional ACP staining.[30] There are no known reports of ACP staining in feline cases of monocytic leukemia. Acid phosphatase is used in veterinary medicine primarily to detect focal staining in T-lymphocytes. Some examples of positive ACP staining in lymphoid malignancies may be found in dogs, cats, cattle, sheep, and pigs.[16,27,28,75,79,82,90,98,105]

Beta Glucuronidase

A hydrolytic enzyme with a mechanism and pattern of reactivity similar to that of the esterases is βG. β-Glucuronidase hydrolyzes the substrate to produce liberated naphthol compounds which subsequently bind to a colored dye. Enzymatic activity is demonstrable in blood lymphocytes, monocytes, and granulocytes (Fig. 144.14). Both monocytes and neutrophils display weak, diffuse, cytoplasmic reactivity, whereas T-lymphocytes produce a focal or distinct granular reaction.[60] In feline specimens, βG activity appears in monocytes, granulocytes, lymphocytes, and platelets; the strongest reactivity is observed in monocytes.[96] Weakly positive reactivity has been observed in neutrophils of channel catfish.[107] For human blood, the βG staining procedure appears to have little advantage over NSE in detecting T-lymphocytes.[60]

Diffuse positive staining has been documented in a case of feline acute undifferentiated leukemia.[30] β-Glucuronidase is used in veterinary medicine primarily to detect focal staining in T-lymphocytes. Three cats that had large granular lymphocyte lymphoma were noted to have positive staining with βG.[16,98,99]

Miscellaneous Stains

Toluidine Blue

This common histologic stain is helpful for the evaluation of basophil and mast cell populations from many species.[47,103] Toluidine blue (TB) is a basic dye that reacts with the acid mucopolysaccharides to form metachromatic complexes that appear red-purple. Basophils stain readily in acidic TB but not in neutral TB.[44]

Toluidine blue staining was helpful in the diagnosis of two cases of basophilic leukemia in the dog, and for mast cell identification in tumors from the dog, cat, goat, cow, pig, and horse.[7,15,52,63,65,66,78,84,86] Several cases of large granular lymphoma or large granular lymphocyte leukemia in the dog, cat, horse, and ferret were evaluated with TB.[10,16,33,97,98] Of the 13 cases stained in the cat, only one demonstrated a positive reaction.[16]

Omega-Exonuclease

Omega exonuclease is an enzymatic staining technique for basophils or mast cells and their precursors in several species, particularly humans, dogs, cats (Fig. 144.7A), and primates such as the Rhesus monkey and the gibbon. Enzymatic activity is not found in normal basophils of the horse, cow, goat, pig, or alpaca.[47] Positive OEN reactivity produces diffuse, red-brown, granular cytoplasmic deposits. Omega exonuclease is an alkaline phosphodiesterase found within the cytoplasm and not in the specific granules; therefore it is said that OEN activity is more helpful than TB in poorly differentiated or degranulated cells. In addition, it can be helpful to determine the extent of involvement with basophil precursors in cases of acute myeloid leukemia with peripheral basophilia. Omega exonuclease was used for this purpose in one case of basophilia leukemia in the dog.[66] Also, OEN was used to identify mast cells in tumors (Fig. 144.7B) from a dog and cat.[78]

Synacril Black AN

Synacril black AN application results in selective metachromatic staining of acid mucopolysaccharides found in the megakaryocytic cytoplasm.[51] This substance is a textile dye available commercially as Megacolor from Cytocolor, Inc. After fixation with formaldehyde-acetic acid-ethanol solution, specimens are pretreated with ribonuclease to remove ribonucleic acid. The dye stains the cytoplasm of mature and immature megakaryocytes with a red-violet to violet reaction product (Fig. 144.12A). All other cells are pale yellow to yellow-brown except eosinophils whose granules appear pink. In one report, normal equine megakaryocytes along with normal and neoplastic canine megakaryocytes (Fig. 144.12B) from paraffin-embedded samples stained with a magenta reaction with this dye in an attempt to distinguish megakaryocytic precursors from neoplastic histiocytes.[69] Immunohistochemical staining using antibodies against human von Willebrand factor (factor VIII-related antigen) and human platelet glycoprotein (GP IIIa) helped support the characterization of the neoplastic cells in several cases of canine and feline megakaryoblastic leukemia.[21,67,74]

Acetylcholinesterase

Acetylcholinestease (ACH) is another enzymatic marker that specically identifies mature megakaryocytes and platelets from dogs, cats, and rats.[43,48] In addition, ACH is found also within human and murine erythroid precursors.[55] Specimens for cytochemical staining are incubated in a medium containing acetylthiocholine iodide as substrate. The subsequent reaction product is brown.

Acetylcholinestease staining was helpful in the identification of megakaryocytic precursors in canine cases of megakaryoblastic leukemia and essential or primary thrombocythemia.[18,40]

Luna

Luna is a specific stain for eosinophil granules that can be used to identify atypical granulocytes or blast cells with eosinophilic differentiation. It was helpful in confirming the presence of eosinophilic precursor cells in a case of leukemia in a horse in which there was a predominance of positively stained cells.[70]

SUMMARY

Cytochemical staining is relatively inexpensive and provides a convenient manner to identify the chemical constituents of blood cells and characterize poorly differentiated cells in cases of acute nonlymphoid neoplasia. This procedure is particularly useful in a wide variety of animal species including birds, reptiles, amphibians, fish, and invertebrates.

Mammalian granulocytic precursors may be identified by positive staining with peroxidase, Sudan black B, chloroacetate esterase, leukocyte alkaline phosphatase, acid phosphatase, and periodic acid-Schiff. Mammalian monocytic precursors are detected by a positive reaction with nonspecific esterases that are sensitive to fluoride inhibition. Megakaryoblast cells are recognized by positive staining with nonspecific esterases partially sensitive to fluoride inhibition, periodic acid-Schiff, Synacril black AN, and acetylcholinesterase.

Acronyms and Abbreviations

AGE, agarose gel electrophoresis; AGP, alpha-1-acid glycoprotein; APP, acute phase proteins; ASG, acid soluble glycoprotein; CE, capillary electrophoresis; Cp, ceruloplasmin; CRP, C-reactive protein; CZE, capillary zone electrophoresis; EDTA, ethylenediaminetetraacetic acid; ELISA, enzyme linked immunosorbent assay; Hp, haptoglobin; HRE, high resolution electrophoresis; SAA, serum amyloid A; SPE, serum protein electrophoresis.

BASIS OF ELECTROPHORESIS

During the past two decades there has been an increase in the application of serum protein separation as a laboratory test for diagnostic purposes in veterinary patients. The serum protein profiles are mostly defined using routine serum protein electrophoresis (SPE), which allows identification of different fractions or regions, each being composed of one or several proteins, with similar electrophoretic mobility.[1] From a general point of view, electrophoresis is used to separate macromolecules from complex mixtures by application of an electric field. Different macromolecules in the mixture will migrate at different speeds, depending on the nature of the gel and the physical-chemical characteristics of the macromolecules. Electrophoretic techniques can be applied to the separation of any macromolecule, including nucleic acids (DNA and RNA), proteins, lipids, and carbohydrates. However, the principles of separation and matrices used may differ depending on the molecules that need to be separated.[6]

A typical electrophoresis system includes five components:[10,22] (1) buffer solution (with protein electrophoresis barbital buffer having a pH near 8.6 is the most commonly used); (2) two electrodes of either platinum or carbon, the polarity of which is fixed by the mode of connection to the power supply; (3) the electrophoresis support on which separation takes place; (4) a cover to minimize evaporation and protect the system; and (5) a power supply.

Basically, the electrophoresis procedure comprises two steps: separation and detection. To perform an electrophoretic separation, the electrophoretic cell, support media, and voltage meter are prepared following technique specifications. Sample is then added to the media in a narrow band or spot using the method appropriate to the type of media used. Electrophoresis is conducted for a determined length of time under conditions of

either constant voltage or constant current. After completion of electrophoresis the media is treated to allow visualization of the protein. This procedure involves protein fixation and staining. An exception is capillary electrophoresis (CE) in which proteins are eluted and pass through a detector that directly measures the UV absorbance of the peptide bonds. Once electrophoretic separation and staining are complete, direct densitometry is used to quantify the individual zones, either as a percentage of the total or as absolute concentration if the total quantity of protein is known.

In routine clinical chemistry, the main purpose of performing electrophoresis on body fluids such as serum, urine, and cerebrospinal fluid (CSF) is to separate the constituent proteins into major fractions. Electrophoresis generates an electrophoretogram, a display of protein zones, each separated from neighboring zones on the support material. The different electrophoretic patterns could be then interpreted and abnormal findings correlated with disease states.

TYPES OF ELECTROPHORESIS

Zone Electrophoresis

Zone electrophoresis uses a porous medium to support the buffer and allows migration of charged protein molecules on it.

Cellulose Acetate Electrophoresis

Cellulose acetate has the advantage of being inexpensive, and allows fast electrophoretic separation (20 minutes to 1 hour) and long storage time of the transparent membranes. However, several time-consuming procedures are required, including presoaking before use and clearing of membranes before densitometry. Additionally, high-resolution separation is impossible with cellulose acetate electrophoresis. As a result of these limitations, cellulose acetate has been replaced by other types of electrophoresis in most clinical applications.

Agarose Gel Electrophoresis

Agarose gel electrophoresis (AGE) has been one of the most common procedures in veterinary medicine for analysis of serum proteins in clinical situations. It has several advantages over cellulose acetate:[10,22] (1) AGE can be automated. Although standard AGE is a labor-intensive procedure, the introduction of prepackaged gels and integration of computers with electronic instrumentation has resulted in the availability of a number of AGE instruments with semi-automated capabilities. Although this has made the technique less labor-intensive, AGE is not amenable to full automation. (2) Variable pore size makes it possible to use AGE for separation of other molecules such as lipoproteins and nucleic acids. (3) AGE has much better resolution than cellulose acetate. In addition, some laboratories are using an improved method known as high resolution electrophoresis (HRE) that allows the detection of several protein bands that are not well resolved by conventional SPE. High resolution electrophoresis may be particularly useful to detect monoclonal paraproteins but is of limited benefit for analyzing other serum protein patterns, because clinical applications of this information in veterinary medicine are not yet widely understood.[13] (4) The medium is clear after drying and therefore leads to very sensitive densitometry measurements.

There are disadvantages of AGE, including fragility of the media so that the gel must be handled carefully, and the need for expensive equipment.

Polyacrylamide Gel Electrophoresis

Polyacrylamide gel separates more serum protein fractions than the other supporting substances, is less fragile than agarose gel, and is transparent allowing analysis by densitometry. However, the technique is relatively labor-intensive for routine applications and is more used in specialized situations or in research studies where high resolution is desirable.[5,22]

Capillary Electrophoresis

Capillary electrophoresis (CE) allows high-resolution separation of inorganic and organic ions, including nucleic acids, proteins and peptides. In this system, the classic technique of electrophoresis is carried out in a small capillary tube that serves as the electrophoresis chamber that is connected to a detector and, via buffer reservoirs, to a high voltage power supply. There are several CE modes with different separation methods but capillary zone electrophoresis (CZE) is the most frequently used mode for serum protein electrophoresis.[11,21] With CZE, separation of the protein fractions occur in free solution in a narrow-bore fused silica capillary that is exposed to a high voltage. When voltage is applied two forces (i.e. electrical field and electro-osmotic force) act in opposite directions on the proteins. First, proteins are attracted toward the anode because a borate buffer pH 10 is used and at this pH proteins are negatively charged. Second, an electro-osmotic force is involved because the empty capillaries have a negatively-charged surface making the buffer flow in the direction of the cathode.

In CZE the force of the electro-osmotic flow surpasses the force of the electrical field; as a result all proteins are carried toward the cathode.[2] Capillary zone electrophoresis has been proposed as an alternative to conventional AGE in separating human and animal serum proteins[7,19] because it allows fast protein separation (4 minutes compared to 25 minutes) with good efficiency and resolution, and uses only small amounts of sample. Additionally, the method can be fully automated. Commercial systems equipped with automated sample loading and data analysis are available, giving a significant higher sample throughput.

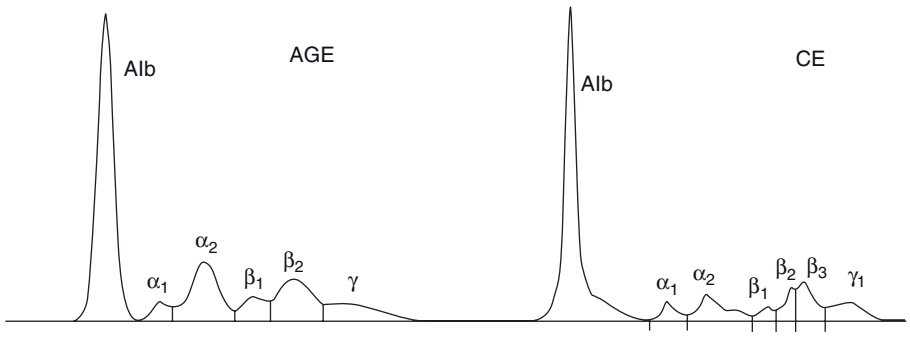

FIGURE 145.1 Agarose gel (AGE) and capillary (CE) electrophoretic patterns of a serum sample from a healthy dog. Notice the larger number of peaks obtained with CE and the better definition of peaks.

Although the initial expense of equipment may be higher than for AGE, the ongoing cost of reagents is relatively small, especially when dealing with a high number of samples.

Immunofixation Electrophoresis

Immunofixation electrophoresis is a two-step process involving AGE followed by specific antibody that is layered over the separated proteins. It is considered the gold standard to determine the presence of monoclonal proteins in cases of increases in gamma fractions found with routine electrophoresis systems.[15]

ELECTROPHORETIC PATTERNS IN DIFFERENT SPECIES

Typically proteins are separated into five fractions in humans: albumin, α1-, α2-, β-, and γ-globulins.[3] However, in veterinary medicine more fractions inside β-globulins and even γ-globulins have been described. To identify and separate these fractions in the electrophoretic pattern some rules can be followed: (1) the fractions will appear in the following order: albumin, α-globulins, β-globulins and γ-globulins; (2) albumin is identified as the peak nearest the anode, and usually appears as a high and narrow peak; (3) the midpoint on the horizontal axis of the electrophoretogram is the approximate separation between α-globulins and β-globulins; (4) the separation between α1- and α2-globulins coincides with the more major valley in the α-globulins fractions; (5) the separation between β- and γ-globulins is established as the most marked valley that appears between the β-globulins and γ-globulins (to determine the end of the β-globulin area it is useful to know that the β-globulin area is of similar size to the α-globulin area); and (6) subfractions in β- and γ-globulins can be established if valleys appear inside these fractions.

Once this initial broad separation into five fractions has been completed, the use of highly sensitive methods such as capillary electrophoresis has allowed identification of selected acute phase proteins (APPs) in humans. For example: α-1 antitrypsin and α-1 acid glycoprotein have been identified in the α-1 globulin fractions, haptoglobin and α-2-macroglobulin in the α2-globulin fraction and transferrin and complement in the β-globulin fraction.[2] These APPs could correspond to the subfractions (such as β1- or β2-globulins) identified in veterinary species. Present automated CE equipment is designed and validated for humans and it does not properly identify fractions and peaks in the animal species. Therefore, manual techniques should be used for animals.

Two main sources of variation in the electrophoretic fraction separation have been identified in veterinary medicine. The protein patterns and numbers of peaks obtained are dependent on the sensitivity of the electrophoresis used. For example, more peaks can be obtained with CE than with AGE (Fig. 145.1). In this sense, it is important to define the electrophoretic fractions and subfractions and establish reference intervals for the equipment and assay conditions used in each laboratory. Even changes in the analytical conditions with the same equipment can influence results.[17] There is also considerable species and breed variation in the number, shape, and size of fractions and subfractions. For example, ruminants have undetectable concentrations of haptoglobin, giving lower values of α2-globulin. Variations in serum protein electrophoretic patterns within breeds have been described. For example, Greyhounds have lower serum protein and lower α- and β-globulin concentrations compared with non-Greyhound dogs.[8] These findings could be influenced by low concentrations of haptoglobin in this breed.

COMPARISON BETWEEN ELECTROPHORETIC METHODS

Correlation of Protein Fractions between Methods

When canine protein electrophoresis was performed by CE and AGE, only albumin and α2-globulins had a high degree of correlation.[19] Several reasons could explain the poor correlation of other fractions. In humans, CE gave 2.2 fold higher values for α1-globulin compared with agarose electrophoresis.[16] This could be due to the high concentration in sialic acid in α1-acid glycoprotein that interferes with the stains used in agarose electrophoresis. The poor correlation found for β-globulin could be due to the different migration of β-lipropoteins. It has been reported to be in the β-fraction in agarose and between α2 and β-fraction in CE.[2] In addition, the limits of the fractions were manually defined in both

techniques, producing inaccuracies that could contribute to the poor correlations.

Detecting Monoclonal Peaks

In studies performed in humans, CE seems to have a higher sensitivity for detection of monoclonal peaks than AGE; however, especially at a maximum resolution, the number of false positives is higher in the capillary technique.[15,16]

Detecting Acute Phase Proteins

A high-resolution CE technique has been decribed in human to allow separation of α1-antitrypsin, α1-acid glycoprotein, and haptoglobin in serum samples. This technique had a strong linear correlation with nephelometric determinations for these proteins.[14]

Technical Aspects

Some data are available regarding the influence of several technical aspects in the final electrophoretic results. These data should be viewed with caution, as results may also be dependent on the equipment used and the analytical conditions.

In human studies, inter- and intra-assay precision of less than 5% has been achieved for AGE and less than 4% for CE for all fractions.[16] The manual establishment of the fractions could explain the higher imprecision values in some fractions such as β-globulins when dog samples were analyzed with CZE, although both inter- and intra-assay precisions were less than 14%. In that canine study, the method showed good accuracy when linearity was evaluated by serial dilution of serum samples.[19]

Haemolysis and lipemia produced a change in electrophoretogram morphology in canine samples analyzed by CZE, giving an interference peak located in the β region when hemoglobin was increased and in the α1 region when lipids were increased.[19] Bilirubin produced an increase in albumin and α1 and a decrease in the α2 and β2 fractions. Fibrinogen did not produce any additional peak in CZE, so no differences were found between serum and plasma samples.[19] However, in a recently developed system of CE, fibrinogen was detected in humans.[14]

Regarding anticoagulants, plasma samples obtained with heparin, EDTA, citrate, and fluoride can be used for CE assays. In addition, samples can be stored frozen for long periods of time; however, special care should be taken to avoid sample clotting that could occlude the capillary.

ACUTE PHASE PROTEIN MEASUREMENTS

C-Reactive Protein

Serum C-reactive protein (CRP) is generally measured by immunoassays using species-specific CRP antibodies in several formats such as ELISA, immunoturbidimetric assays adapted for automated biochemical analyzers, slide/capillary latex agglutination tests, or time-resolved fluorometry. Technical improvements are needed to decrease between-run imprecision in some commercial ELISA kits for dogs and pigs.[4] Commercially available automated turbidometric immunoassays, designed for human CRP, have been found to be valid for measuring canine and porcine serum CRP concentration.[12] However, in other investigations very weak or negligible cross-reactivity of canine CRP with different anti-human CRP antibodies was found.[20] Special care should be taken when using non-species-specific assays for CRP measurements and a complete validation of each batch of antibody is recommended before use in these cases.

Serum Amyloid A

A commercially available ELISA for serum amyloid A (SAA) determination in veterinary species using monoclonal antiserum against human SAA has proven to be useful for canine, feline, and porcine SAA quantification;[4,18] however, ideally interassay imprecision should be reduced. An automated commercially available human SAA turbidimetric immunoassay has been validated for feline and equine SAA determination,[9] but does not seem to work in dogs.

Species-specific standards and serum with a high concentration of SAA instead of the purified protein are recommended when the human test is used in animals.

Haptoglobin

Assays for serum haptoglobin (Hp) concentration can be divided into two groups: spectrophotometric and immunoassays. An automated spectrophotometric multispecies assay based on the peroxidase activity of Hp-Hgb complexes, in which interference by serum albumin is eliminated, has been developed into a commercially available kit. This assay was initially developed for Hp measurements in ruminants, so in other species with higher concentrations of Hp, samples should be diluted.[4] Human automated immunoassays have been validated for Hp measurement in animal species. As indicated previously, these assays will depend on the cross-reactivity of the antiserum with the Hp of the species tested and must be properly validated before use.[24]

Alpha-1-Acid Glycoprotein (AGP)

Alpha-1-acid glycoprotein (AGP) can be measured by single radial immunodiffusion on agarose gel or by immunoturbidimetric assays. Both methods use species-specific antibody. Alternatively, AGP can be indirectly estimated as seromucoid or acid soluble glycoproteins (ASGs) by precipitation of the majority of serum proteins by perchloric acid and quantification of the remaining soluble proteins, although in some

species such as pigs it seems that AGP is not a major component of the ASG.[23]

Ceruloplasmin

Automated spectrophotometric assays have been developed for ceruloplasmin (Cp) measurements in pigs and dogs based on oxidation of different compounds such as *p*-phenylenediamine and *o*-dianisine dihydrochloride. The main problem with Cp assays is the lack of available reference materials to standardize Cp concentration (different arbitrary units have been used to report assay results).[4]

APP Measurements in Fluids or Tissues Other than Serum

The use of time-resolved fluorometry has allowed accurate detection of very low concentrations of APP in specimens such as effusions, saliva, or meat juice. Saliva is easy to obtain and sample collection is noninvasive. On the other hand, the possibility of APP measurements in meat juice could be applied to meat inspections.

CHAPTER 146

Measurement of Serum Iron Concentration, TIBC, and Serum Ferritin Concentration

GORDON A. ANDREWS

Measurement of Serum Iron Concentration
Measurement of TIBC
Measurement of Serum Ferritin Concentration

Acronyms and Abbreviations

ELISA, enzyme-linked immunosorbent assay; TIBC, total iron binding capacity; UIBC, unbound iron binding capacity.

MEASUREMENT OF SERUM IRON CONCENTRATION

Iron is transported in plasma by the iron transport protein apotransferrin. Each apotransferrin molecule has two iron binding sites that bind one Fe^{3+} ion. The apotransferrin-Fe^{3+} complex is called transferrin. Under normal conditions approximately one-third of the iron-binding sites of transferrin are occupied by Fe^{3+}. Serum iron concentration refers to the Fe^{3+} bound to transferrin and does not include iron contained in serum as free hemoglobin.

The most common methods employed to measure serum iron are colorimetric procedures based on the formation and quantitation of a colored iron-chromogen complex. Iron is released from transferrin by strong acidification of the serum by addition of hydrochloric, sulfuric, or trichloroacetic acid (that simultaneously precipitates serum proteins). Fe^{3+} is reduced to Fe^{2+} by addition of ascorbic acid, thioglycolic acid, hydrazine, or hydroxylamine,[21] and is then complexed with a chromogen that contains the reactive group –N=C–C=N–.[6] Metal cations are chelated between the two nitrogens forming a colored reaction product. The absorbance of the chromogen at its characteristic wavelength is proportional to the iron concentration. Chromogens commonly used include 4,7-bis(4-phenyl sulfonic acid)-1,10-phenanthroline, sodium salt (bathophenanthroline disfulonate, sodium); 2,4,6-tripyridyl-*s*-triazine (tripyridyl triazine); 3-(2-pyridyl)-5,6-bis(4-phenyl sulfonic acid) 1,2,4 triazine, sodium salt (ferrozine); and 2,6-bis(4-phenyl-2,2-pyridyl)-4-phenyl pyridine (terosite).[6] The assay can be performed manually,[5] by commercial kits, or automated analyzers.

Thiourea and thioglycolic acid are chelating agents used in some assays to prevent copper from complexing with the chromogen and interfering with iron measurement.[14] Minute amounts of iron can be complexed with other serum proteins. Under normal circumstances this amount is clinically insignificant. Some assays use trichloroacetic acid to precipitate serum proteins or dialysis to remove them. Iron released from serum ferritin in cases of hyperferritinemia can elevate the serum iron concentration when measured by some iron assays.[20]

Serum iron has also been measured by coulometry.[18] The principle of the test is based on development of an electrochemical potential at the interface of a salt solution and an electrode. The amount of current applied to maintain the electrical potential of the electrode at a constant value depends on the electropositivity of the metal being measured and the concentration of the metal. The electropositivity of a metal is a measure of the tendency of a metal to lose one or more electrons. The electropositivity of iron is a known constant value, so the amount of current required is proportional to the iron concentration. The method correlates well with chromogenic methods, has very good accuracy and precision, can be used with microsamples, and can be automated.[14] Unfortunately, the instrument is no longer being manufactured. Other methods are radiometry and atomic absorption spectrophotometry, but these are rarely used in clinical practice.

Iron is ubiquitous in the environment, so care should be taken to ensure blood collection tubes, glassware, water, and reagents are free of environmental contamination with iron. Hemolysis has little effect on serum iron assays because the iron in hemoglobin is not released by acidification of the serum. However, hemoglobin can cause spectral interference in colorimetric assays, so grossly hemolyzed samples should not be analyzed.[8] In human medicine, reference intervals can vary substantially between commercial laboratories so it is recommended that laboratories establish their own reference intervals.[10] The same recommendation applies to veterinary samples.

MEASUREMENT OF TIBC

Total iron binding capacity (TIBC) is the amount of iron that serum transferrin can bind when all iron-binding sites are saturated and is, therefore, an indirect measure of serum transferrin concentration. Two methods can be used to measure TIBC.[14] In one method, excess Fe^{3+} in the form of ferric ammonium citrate is added to the serum adjusted to a pH of 8.0 or above with a buffer solution. At this pH, the iron-transferrin complex is stable and transferrin will bind iron until all binding sites are saturated. The excess unbound Fe^{3+} is removed by an ion exchange resin or by addition of light magnesium carbonate ($MgCO_3$) powder and the iron assay is repeated. The value obtained is the TIBC.

In the second method a known amount of excess iron is added and the pH adjusted to 7.5 or above. At this pH, only the excess free iron can be reduced to Fe^{2+} and react with the chromogen. The iron bound by transferrin remains as Fe^{3+} and gives no color reaction. The unbound iron in the supernatant is measured by the iron method. The concentration of the iron standard minus the unbound iron is called the unbound iron-binding capacity (UIBC), which is used to calculate the TIBC as follows:

$$\text{TIBC} = \text{UIBC} + \text{total serum iron concentration}.$$

Transferrin saturation is the percentage of transferrin iron-binding sites that are occupied. It is calculated as follows:

$$\text{Transferrin saturation (\%)} = 100 \times \text{serum iron concentration}/\text{TIBC}.$$

MEASUREMENT OF SERUM FERRITIN CONCENTRATION

Serum ferritin is measured by immunologic methods. In human medicine, immunoradiometric assay, enzyme-linked immunosorbent assay (ELISA), immunochemiluminescent, and immunofluorometric methods are used.[10] Assays to quantitate human serum ferritin are available in kit form and automated immunoassay instruments.

Immunoassays to quantitate human serum ferritin cannot be used to quantify serum ferritin in other species. Quantitative immunoassays must be calibrated with a standard curve of known concentrations of the purified analyte being measured from the species of interest in order to determine the concentration of the analyte in the unknown sample. Although there is serologic cross-reactivity between serum ferritins of some species,[19] in general, serum ferritins tend to be immunologically species-specific.[13] Therefore, individual assays still must be developed and calibrated for each species.

ELISA tests have been developed for serum ferritin in the dog,[4] cat,[3] horse,[9,12,17] pig,[7,16] cow,[11] northern fur seals *(Callorhinus ursinus)*,[2] black (*Diceros bicornis*) and white (*Ceratotherium simum*) rhinoceroses,[15] and black and white ruffed lemur *(Varecia variegata variegata)*.[1] In all cases, serum ferritin was purified from each species and quantitated by chemical methods. Polyclonal antisera or monoclonal antibodies were raised to the ferritin and used to develop tests for the dog, cat, horse, pig and cattle. In some instances there was sufficient species cross reactivity to allow use of antisera or monoclonal antibodies to serum ferritin of one species to develop an ELISA for another species. Anti-equine ferritin polyclonal antibodies were used for the rhinoceros,[15] mouse monoclonal anti-dog ferritin antibody for the northern fur seal,[2] and anti-human ferritin polyclonal antibodies for the lemur ELISA test.[1] Each ELISA is calibrated with a standard curve of known concentrations of the ferritin purified from the species being measured. Non-human serum ferritin assays are offered by the Comparative Hematology Laboratory at Kansas State University.

CHAPTER 147

Molecular Techniques and Real-Time PCR

CHRISTIAN M. LEUTENEGGER

Sample Submission and Preanalytical Considerations
Nucleic Acid Isolation
Reverse Transcription and Generation of cDNA
RNA Applications
Amplification of DNA and PCR in General Terms
Real-Time Quantitative PCR
Sequencing
Applications of Molecular Techniques

Acronyms and Abbreviations

DNA, deoxyribonucleic acid; EDTA, ethylenediaminetetraacetic acid; FCoV, feline corona virus; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; ^{32}P, radioactive isotope of phosphorus; PCR, polymerase chain reaction; RNA, ribonucleic acid; RT PCR, reverse transcription PCR.

Over the past 20 years, knowledge of infectious diseases including diagnostic approaches and treatment options has advanced significantly. During this period the discoveries of a number of important human and animal agents, antimicrobials, and vaccines as well as a wealth of improved diagnostic tests have been reported. Despite these advances, infectious diseases have remained a leading cause of morbidity and mortality with resurgence of certain infections combined with new resistance patterns.[7] Molecular tools are now being used in addition to conventional culture techniques and antibody based tools for identification and diagnosis of infectious diseases.[13,14] This era of molecular diagnostics for infectious diseases began in 1983 when Dr. Kary Mullis of Cetus Corporation first conceptualized the polymerase chain reaction (PCR).[17,22] He went on to win the Nobel Prize in Chemistry for this technology in 1992. Since the inception of the PCR technology, infectious disease diagnostics have been at the forefront of molecular medicine. Infectious disease testing is expected to increase in value for veterinary molecular diagnostics.

SAMPLE SUBMISSION AND PREANALYTICAL CONSIDERATIONS

In general, molecular diagnostic laboratories provide strict recommendations for sample collection including shipping instructions. These instructions include specimen type, volume, anticoagulant, and specimen transport, storage, and handling. The sample type is largely influenced by the pathogenesis of the disease and plays a key role in performance and interpretation of test results. Veterinarians are advised to adhere to these recommendations, as the quality of the result is directly related to the quality of the sample and its preservation of the nucleic content. Molecular assays often offer the convenience of using a small minimally-invasive specimen. The diagnosis of herpes viruses is a classical example, where culture and neutralization assays have been largely replaced by PCR testing on a small volume of aspirate or swab from mucosal surfaces.[28] Molecular tests can detect the presence of small numbers of organisms; however, the probability of detection increases when a larger volume of specimen is added to the amplification reaction. This reflects, in part, the probability of having any organisms in the tested volume of sample. Because molecular assays do not need viable organisms for testing, more flexibility in specimen transport is possible than for culture methods.

Appropriate specimen collection and transport conditions are important to ensure successful extraction of intact nucleic acid and to prevent pre-analytical cross-contamination.[25] Detailed storage and shipping instructions are crucial if RNA pathogens are part of the diagnostic workup. Large animal practitioners should be aware of these recommendations and consider using appropriate cooling containers when samples are collected in the field. Such samples maintain stability for days if stored appropriately in a cooled environment. Short-term freezing of fresh specimens frequently

affects the quality adversely and should be avoided if not otherwise instructed by the laboratory. Sampling and labeling errors, and contamination of sample containers on their outside are among the many pre-analytical variables to consider; they are not unique to PCR but are general to any laboratory diagnostic test.

NUCLEIC ACID ISOLATION

The purification of nucleic acids (DNA and RNA in case of RNA viruses or viability assessments) is a fundamental step in molecular diagnostics.[2,15,29] The quality and fitness of a molecular diagnostic test is in most part directly dependent on the quality and quantity of nucleic acid. Lysates containing crude total cellular material, including proteins, fats, and nucleic acids, are of limited use for PCR; they contain PCR inhibiting components affecting the limit of detection of the assay.[8] In most cases, the molecular test loses its sensitivity when performed on cell lysates.

In veterinary molecular diagnostics, the variety of sample types make processing a challenge. Automated or semi-automated processing platforms are rapid, accept sufficient specimen sample volume, and provide more consistent and reproducible results than manual methods. In general, these systems are total nucleic acid extraction systems (i.e. deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) are extracted) and support the parallel analysis of DNA and RNA pathogens from the same sample. Commercially available automated systems can reduce hands-on labor requirements as well as the risk of cross-contamination during sample preparation.[15] Most systems can accommodate sample volumes to produce an acceptable limit of detection and can process from 12 to 96 samples in parallel. With automated nucleic extraction systems finding use even in low volume research settings, standardization will become an important factor to increase reliability and acceptability and decrease laboratory artifacts.

REVERSE TRANSCRIPTION AND GENERATION OF cDNA

Reverse transcription (RT) is a process describing the conversion of RNA into complementary DNA or cDNA. This process is necessary for applications where the target (i.e. organism) is RNA. The reverse transcription of RNA into cDNA is a necessary step in PCR because DNA polymerase can not amplify RNA. Depending on the application, a one-tube or a two-tube RT protocol is used. One-tube RT-PCR is the norm for stand-alone RNA virus diagnostics. In such a setup, the RNA is reverse transcribed by an RNA-dependant polymerase into cDNA that subsequently is amplified by a DNA-dependant DNA polymerase present in the same tube. However, if multiple targets (viruses or genes) are analyzed from a single sample, a two-tube RT protocol may be more economical and give more reliable results. In this case, the RNA in a given sample is reverse transcribed in a first reaction tube to generate cDNA; then the cDNA is used in a second tube for the PCR process; hence the acronym one-tube RT-PCR versus two-tube RT-PCR. An additional advantage of two-tube RT-PCR protocols is more uniform generation of cDNA and in many cases increased yield of cDNA compared to one-tube RT-PCR protocols.

RNA APPLICATIONS

RNA-based applications are expanding rapidly in the field of molecular diagnostics. The simplest application is the diagnostic detection of viral genomic RNA. A variation of this application is the detection of splice variants of RNA or DNA viruses, especially if certain splice variants are associated with a particular disease process. For feline corona virus (FCoV) for example, change in the splice variant pattern is indicative of enhanced viral replication in monocytes leading to feline infectious peritonitis (FIP).[26] In feline retrovirus infections (feline leukemia virus [FeLV] and feline immunodeficiency virus [FIV]), both DNA and RNA can be detected simultaneously with molecular methods; while DNA detection confirms infection throughout the entire disease course, quantitative analysis of RNA viral load has implications in early detection of infection and as a prognostic marker.[11] Furthermore, in the case of herpesvirus infections, the detection of RNA indicates virus replication in host tissues.[19] This application, therefore can differentiate between latent (DNA only) and lytic infections (RNA as well as DNA detected for glycoprotein genes), as exemplified by equine herpes virus-4 (EHV-4).[11]

Sets of transcribed genes as indicators of a certain disease or disease states are commonly referred to as biomarkers or gene signatures. In this case, the messenger RNA (mRNA) of genes is targeted, which is a marker for gene activity. These gene signatures are becoming increasingly important in noninfectious and certain infectious human diseases. On a research basis, such gene signatures have also been described in various animals.[3,6,10,16,20,21] Currently, no gene signatures are available in veterinary molecular diagnostic applications but their potential has been recognized.

As a combination of applications described above, the detection of transcribed genes of pathogens at the RNA level has gained importance in recent years for two reasons. First, RNA applications can be of significantly higher sensitivity compared to DNA-based application, especially if multicopy genes such as ribosomal RNA genes are used as targets.[1,4,27] Second, it detects transcribed genes implying that the organisms are viable, as opposed to their DNA that is present in both dead and live organisms. This is because dead organisms carry detectable DNA for a long period of time; conversely, transcribed mRNA is very unstable and normally disintegrates within minutes after loss of infectivity. PCR tests targeting RNA therefore avoid the frequently mentioned disadvantage of regular DNA-based PCR, namely that of detecting 'only' dead organisms.

AMPLIFICATION OF DNA AND PCR IN GENERAL TERMS

The process of chromosomal duplication during cell division or generation of mRNA from a particular gene both contain the features of the PCR laboratory technique. In essence, PCR was developed using mechanisms used by nature since the dawn of the single cell organism. However, it required the ingenuity of a researcher to add a few variations, namely, the use of primer pairs spanning a relatively short stretch of DNA, repetitive cycles of amplification, and a heat stable DNA polymerase. The bidirectional amplification in a repetitive mode (PCR cycles) allows exponential amplification of DNA: with a single DNA molecule as starting material, an excess of one thousand billion copies are accumulated during PCR with ideal amplification conditions.

After about 40 cycles of amplification, PCR products can be stained with a fluorescent dye and separated by size in a process called gel electrophoresis. Once separated, the gel is illuminated on a UV table to make PCR bands visible. This process of PCR product detection is referred to as conventional or traditional PCR.

REAL-TIME QUANTITATIVE PCR

Traditional PCR has been replaced with second-generation PCR protocols in most human and some veterinary molecular diagnostic laboratories. There are good reasons for this: traditional PCR has low throughput, high risk of PCR product carry-over and lack of standardization. In addition, assembling of PCR reagents is inefficient and frequently leads to unstable reagent mixes, making running controls and standards in parallel with diagnostic samples a necessity.

Real-time PCR was introduced in the mid 1990s (Applied Biosystems, Foster City, CA) and has moved the traditional PCR application from the analog age into the digital real-time age.[12] In this technique, PCR products, accumulated during PCR, are detected in real-time in each and every PCR cycle. This is accomplished by adding an additional oligonucleotide called a probe labeled with two fluorescent dyes. As long as the probe is in solution, the 3′ dye (called the quencher) efficiently absorbs the energy of the 5′ dye (called the reporter). Subsequent to the probe's binding to the PCR product, the DNA polymerase recognizes the probe as an obstacle sitting on the strand to be copied and digests the probe with its 5′ nuclease activity (the process is also called the 5′ nuclease assay); this releases the quencher from physical proximity of the reporter whereby the reporter regains its energy.[9] Once excited with a laser, the emitted light from the reporter dye now unbound in solution is captured on a charge coupled sensor device and the results recorded in a computer in digital format. Real-time PCR is more robust and more reliable than traditional PCR, has better reproducibility, shorter cycling times, improved sensitivity, and increased specificity, and offers larger throughput by running PCR reactions on standard 96, 384, and soon 1,536-well microtiter plates. In addition, the problem of PCR product carry-over and the risk for false positive PCR results has been significantly reduced.[18] Pre-mixed reagents with long shelf lives (usually 1 year or longer) at 4 °C have significantly increased reproducibility. All of these factors together make real-time PCR a virtually ideal diagnostic tool. Since the mid 1990s, a large variety of detection chemistries, probe varieties, and equipment platforms have been introduced into the market all based on the next generation real-time PCR principle.

SEQUENCING

In May 1975, Frederick Sanger from the Medical Research Council's Laboratory of Molecular Biology in Cambridge presented the first partial DNA sequence.[24] He went on to deliver the first complete sequence of a viral genome, the 5,375 base pairs in the genetic code of the bacterial phage phi-X174.[23] The Sanger sequencing method used the enzyme DNA polymerase to make numerous copies of the DNA molecules to be sequenced by incorporating a mix of normal and modified (terminator) nucleotides, each radioactively labeled with ^{32}P. The normal nucleotides were incorporated sequentially, whereas each incorporation of a terminator nucleotide causes the extension of the DNA copy to stop with a radioactively labeled terminator nucleotide. Four reactions, one for each of the four nucleotides A, T, C, and G were run in parallel. These reactions were then electrophoresed through a high percentage polyacrlyamide gel to allow the resolution of fragments in single nucleotide increments. The Sanger sequencing method is still in use today; however, technical advancements have brought dramatic changes. While the human genome project was projected to last 10 years with an estimated cost of $2.7 billion, sequencing methods have advanced to a state where a single human genome is analyzed within a week with costs at approximately $50,000.

APPLICATIONS OF MOLECULAR TECHNIQUES

A large number of molecular applications are described to determine genetic (see Chapter 148) and infectious diseases known to be involved in veterinary hematology. Infectious pathogens important in veterinary hematology are summarized in Table 147.1. Hemolytic anemia is the primary manifestation of several rickettsial and protozoal diseases in domestic animals. Red blood cells (RBCs) are directly infected by the hemotropic mycoplasmas, eperythrozoonosis, anaplasmosis, babesiosis, theileriosis, and cytauxzoonosis. In trypanosomiasis and sarcocystosis, hemolytic anemia occurs without direct infection of RBCs by any stage of the organisms. However, infection of RBCs is not necessarily a pathogenic event, as illustrated by several proto-

TABLE 147.1 Infectious Pathogens Causing Red Blood Cell Disturbances In Domestic Animals

Cause	Species	Species	Laboratory Abnormalities
Rickettsial	*Eperythrozoon*	Swine, llama	Hemolytic anemia, icterus
	Anaplasma marginale	Bovine	Hemolytic anemia
	Anaplasma ovis	Goats, sheep	Hemolytic anemia
	Anaplasma platys		Thrombocytopenia
	Anaplasma phagocytophilum	Many	Granulocytic ehrlichiosis, anemia, thrombocytopenia
	Ehrlichia canis	Dog	Monocytic ehrlichiosis; anemia, thrombocytopenia
	Ehrlicha ewingii		Granulocytic ehrlichiosis, anemia, thrombocytopenia
	Ehrlichia chaffeensis		Monocytic ehrlichiosis; anemia,
	Ehrlichia ruminantium		thrombocytopenia

	Babesia bigemina		
	Babesia ovis	Sheep	Intravascular hemolysis
	Theileria parva	Dog	Hemolytic anemia, hemoglobinuria, icterus
	Theileria annulata		Hemolytic anemia
	Theileria lestoquardi	Sheep, goat	Anemia, hemoglobinuria
	Theileria mutans	Cattle	Hemolytic anemia
	Theileria cervi	Deer, elk	Hemolytic anemia
	Cytauxzoon felis	Cat	Nonregenerative anemia, thrombocytopenia, neutropenia with degenerative left shift, icterus
	Trypanosoma sp.	Cattle, horse, swine	Hemolytic anemia
	Hepatozoon canis	Dog	Mild anemia, leukocytosis, neutrophilia
	Hepatozoon americanum		
Bacterial	*Clostridium perfringens* type A	Many	Hemolytic anemia
	Clostridium haemolyticum	Cattle	Acute severe hemolysis
	Leptospira sp.	Many	Anemia, hemoglobinuria, icterus, petechial or ecchymotic hemorrhages
Viral	Equine Infectious Anemia Virus (EIAV)	Horse	Anemia, thrombocytopenia
	Feline Leukemia Virus, FeLV-A	Cat	Anemia
	Feline Leukemia Virus, FeLV-C		Pure red cell aplasia
	Feline Immunodeficiency Virus (FIV)		Anemia, netropenia, lymphopenia
	Feline Panleukopenia Virus		Pancytopenia, mild anemia
	Canine parvovirus 2 (a, b, c)	Dog	Hypercoagulability
	Canine parvovirus 2	Cat	Lymphopenia

zoa, such as *Eperythrozoon*. The diagnostic challenge for hemoparasites occurs because of their variable numbers in circulation and their inconsistent detectability by light microscopy. Parasites exceeding 1,000 parasites/μL (corresponding to 0.1% infected RBCs) can be detected by microscopy. PCR, however can detect 1 parasite/μL.[5] However, many other infectious agents often go undetected in blood smears because of their size (viruses,

bacteria) or low numbers. Serologic assays are not able to differentiate between past exposure, chronic carrier state and active infection, and are further limited by cross-reactivity between species and false-negative results during early phase of infection. The use of molecular tools, particularly quantitative real-time PCR, has proven helpful in the diagnosis of acute anemias for many applications.

Acronyms and Abbreviations

BAC, bacterial artificial chromosome; CGH, comparative genomic hybridization; CLAD, canine leukocyte adhesion deficiency; DNA, deoxyribonucleic acid; FISH, fluorescent in situ hybridization; FXI, coagulation factor XI; GWAA, genome-wide association analysis; HLA, human leukocyte antigen; ITGB2, integrin B2; LD, linkage disequilibrium; MHC, major histocompatibility complex; miRNA, micro RNA; monogenic, pertaining to or influenced by a single gene; mRNA, messenger RNA; MTLs, monogenic trait loci; PCR, polymerase chain reaction; QTL, quantitative trait loci; RFLP, restriction fragment length polymorphism; SINE, short interspersed nucleotide element; SNP, single nucleotide polymorphism.

Domestic animals provide unique opportunities for exploring genotype-phenotype relationships, due to their history of selective breeding in large population sizes. This enables powerful genetic and statistical analysis. No other model organisms have been genetically modified to the same extent as domestic animals. Animal domestication has a long history (10,000 years) compared with the short time of studying experimental organisms. The selective breeding of certain traits has led to dramatic changes in growth patterns, behavior, fertility, metabolism and resistance to various infectious pathogens. This has been accomplished by altering the frequencies of mutations with resultant phenotypic effects, some of which pre-date domestication. During the past century, animal breeding and selection techniques dramatically changed. Increasingly, phenotypic data have been collected from large numbers of progenies from each potential breeding animal. These data, together with information on genetic relationships, allow accurate prediction of the ability to transmit favorable allelic variants. Because of the deep screen of these selection criteria, deleterious mutations are rarer than in model organisms such as the mouse. In fact, domestic animals are rather poor models to study deleterious mutations because of the strong selection against them. The selection screen is enriched for mutations with favorable phenotypic effects on the traits under selection (e.g. milk production), but with no or mild deleterious effects on other traits.

The almost bewildering diversity in size, form, color, and behavior of domesticated animals is most pronounced in the dog. An important explanation as to why the dog exhibits more phenotypic diversity is its role as a pet, rather than as a farm animal bred for fitness and high production efficiency. Because of these differences, deleterious mutations have accumulated in certain breeds more rapidly than in others. In particular

in the dog, there is a considerable amount of genetic drift due to founder effects and small effective population sizes. This leads inherently to large haplotype blocks and homozygosity of recessive disorders in certain breeds.[21] In general, however, it is a common misconception that domesticated animals are highly inbred. Most populations of domestic animals show low levels of inbreeding with the exception of certain breeds of cats and dogs, where strong selection for phenotypic traits (e.g. coat color) in small breeding populations increases homozygosity for certain genetic mutations.

A growing number of monogenic (i.e. pertaining to one gene) disorders in the dog have been characterized at the molecular level (for a comprehensive list, visit the OMIA database at http://omia.angis.org.au). An example of a monogenic dog genetic disease that has developed into a useful model for a human disorder is canine leukocyte adhesion deficiency (CLAD). Initially this disease occurred with high frequency in Irish setters (see Chapter 42).[8,18] The disease, due to defective expression of leukocyte integrins, causes severe recurrent bacterial infections. With a colony of dogs segregated for this mutation, novel hematopoietic therapies for the treatment of this severe immunodeficiency were tested. It was shown that CLAD is treatable by either nonmyeloablative hematopoietic stem cell transplantation from healthy MHC-matched dogs or by ex vivo retroviral-mediated hematopoietic stem cell gene therapy.[1,2]

The progress of genomics in domestic animals has been mainly hampered by lack of financial resources. However, with the release of the first human genome and genomes and single nucleotide polymorphism (SNP) maps from animals, combined with significant technological advancement, this situation is now rapidly improving.[11,20] The first draft genome of the dog was released in 2003 followed by a dense SNP map in 2005.[9,10] The chicken genome sequence was released in 2004.[6,23] The cattle physical genome was published in 2007, as well as a draft genome and SNP map for the horse and cat.[12,13,15] The pig draft genome, initiated at the Welcome Trust Sanger Institute, aims for a 6× coverage with anticipated completion by the end of 2009 (Table 148.1).[14]

PATTERNS OF INHERITANCE FOR GENETIC DISEASES

Knowledge of the definitions for a gene, allele, and haplotype can aid in the understanding of patterns of inheritance and in the understanding of genetic analysis. A gene is defined as follows: a DNA segment that contributes to phenotype/function; a trait, any genetically determined characteristic; also, the condition prevailing in the heterozygous state of a recessive disorder. An allele is defined as one of two or more alternative forms of a gene at corresponding sites (loci) on homologous chromosomes, which determine alternative characters in inheritance. A haplotype is a group of alleles of linked genes (for example, the human leukocyte antigen [HLA] complex) contributed by either parent. There are two rules that are important for understanding the inheritance of genetic disorders: (1) whether the disorder occurs with *one* copy of the mutated gene or *two*, and (2) whether the genetic mutation occurs on one of the *sex* chromosomes (X or Y), or on one of the *autosomes*. These rules combine to make patterns of autosomal dominant, autosomal recessive, and X-chromosomal recessive and rarely dominant inheritance. It is important to recognize that the terms dominant and recessive, according to the Mendelian concept, refer to phenotypic presentations of heterozygous and homozygous animals for a particular trait.

Autosomal Dominant Disorders

In autosomal dominant disorders, the mutated gene occurs on an autosome; one affected copy is deleterious and causes manifestations of the genetic disorder. Males and females are equally likely to inherit the genetic mutation and be affected by it. Offspring of an animal with an autosomal dominant disorder have a 50% chance of inheriting the disorder. Phenotyic expression can be variable and homozygosity may be lethal.

Autosomal Recessive Disorders

In autosomal recessive disorders, the mutant allele also occurs on an autosome; but both alleles of the gene need to be affected for the genetic disorder to become

TABLE 148.1 Genome Resources of Domestic Animals and Human[a]

phenotypically manifest. Carriers are healthy animals with one mutant allele and are important because they can pass on the genetic mutation to offspring. Offspring of parent animals each carrying a mutant allele have a 25% chance of inheriting both mutations and having the disorder, a 50% chance of inheriting only one copy of the mutant gene (thus becoming an asymptomatic carrier), and a 25% chance of not inheriting the mutation (clear).

X-Chromosomal Recessive Disorders

In X-chromosomal recessive disorders, the mutant gene occurs on the X chromosome. As males have only one X chromosome, a mutant allele on the X chromosome is enough to cause a disorder. Females have two X chromosomes; therefore a mutant allele on one X chromosome has minimal effects on a female because of the wild-type copy of the same gene on the other X chromosome (i.e. a female with one gene mutation on one X chromosome would be a carrier). On average, 50% of her male offspring will inherit the mutation and develop the disorder, and 50% of her female offspring will inherit the mutation and become carriers.

GENETIC ANALYSIS

Linkage Studies

Classical linkage analysis is used to determine the arrangement of genes on the chromosomes of an organism. By tracing how often different forms of two variable traits or markers are co-inherited, one can infer whether the genes for the traits are on the same chromosome (called linked genes/markers), and if so, one can calculate the genetic distance between loci of the linked genes. The order of and pairwise distances between the loci of three or more linked genes are displayed as a genetic-linkage map.

The genetic signal in a linkage experiment comes from tracing the inheritance of gametes transmitted from heterozygous parents to their progeny. Monogenic traits with a direct relationship between genotype and phenotype are easy to deduce. A panel of a few hundred highly informative markers is sufficient for the genome-wide scan, which then is followed with fine mapping of the target region. The last step involves traditional sequence analysis of the chromosomal region surrounding the marker for potential candidate genes (positional candidate gene approach). The access to draft genome sequences and high-density SNP maps is of significant importance for linkage analysis and paves the way for genome-wide association analysis (GWAA).

Genome-Wide Association Analysis (GWAA)

Linkage analysis of multifactorial traits controlled by quantitative trait loci (QTL) is much more challenging than linkage mapping of monogenic trait loci (MTLs). This is because the phenotypic effect of each involved locus is small or moderate with no simple one-to-one relationship between genotype and phenotype.

The flow of positional identifications of genes underlying simple and complex genetic traits has been significantly accelerated since the generation of the draft genome sequence and a dense SNP map in the dog in 2005.[10,22] Because of this, the current trend is to replace the linkage approach by genome-wide association analysis in order to circumvent some of the problems associated with classical linkage analysis. First, there is no need to collect pedigrees because the association analysis is based on case versus control material. Ideally the cases should be as unrelated as possible, while the controls need to be well matched. Second, because of the availability of high resolution SNP maps linked to genome sequences, identification of the causal genes is possible in most cases. Association mapping is based on the presence of linkage disequilibrium (LD) between markers and causal polymorphism. The number of markers required for a GWAA is thus dependent on the length of the haplotype blocks (i.e. region of genome with complete LD information). The length of a haplotype block from the HapMap project is estimated to be about 10 kb: as a consequence, genome scans using 100,000 SNPs tested on a few hundred cases and controls are the basis to resolve multifactorial traits.[9] Because of the existence of high density SNP maps and availability of SNP screening tools (for example SNP arrays), this approach to resolve multifactorial traits has become feasible for domestic animals.

For monogenic traits, GWAA will be an extremely powerful approach for gene mapping: for a simple recessive trait, a sample size of 10 affected animals and 10 controls screened using a sufficiently dense set of SNPs (designed in accordance with the LD pattern) may be sufficient for an initial mapping. This method has been demonstrated for the fibroblast growth factor gene mutations that predispose to the developmental disorder of the dermoid sinus in Rhodesians and Thai Ridgeback dogs.[4]

EPIGENETICS

Epigenetics describes heritable phenotypic changes not explainable solely by genetic influences but also by additional non-genetic influences.[19] Phenotypic changes remain throughout the cell's life and may last for multiple generations without a change in the DNA sequence. The field of epigenetics could explain phenotypic variation not found in pure genetic studies. Genetic statisticians can develop tools for analyzing massive amounts of genotypic data in conjunction with environmental factors, thereby allowing for the identification of risk genotypes as well as gene-gene and gene-environment interactions. Thus risk batteries of genetic variation and environmental factors can be developed

for determination of disease risks associated to genetic diseases.

DETECTING MUTATIONS IN INDIVIDUAL PATIENTS

A number of genetic testing methods are available in reference laboratories. Among the most frequently used tests are polymerase chain reaction (PCR), restriction fragment length polymorphism (RFLP), and more recently array-based detection systems.

Single Nucleotide Polymorphisms (SNPs)

Point mutations or single nucleotide polymorphisms cause at least one or more of three outcomes: (1) missense mutation, where a point mutation results in the exchange of one amino acid for another in the final protein product; (2) nonsense mutation where a point mutation results in no or a truncated protein product by creating a premature stop codon; and (3) splice mutation where a point mutation alters the protein product by preventing normal post-transcriptional processing of RNA. An example for a missense mutation is the factor VII deficiency in the Beagle, Scottish Deerhound and Alaskan Klee Kai dog, where a G to A missense mutation in exon 5 results in substitution of glycine 96 (GGA) to glutamic acid (GAA) in the second epidermal growth factor-like domain.[3,7] An example of a nonsense mutation is phosphofructokinase deficiency in English Springer Spaniels. An example of aberrant splicing resulting in a premature termination of transcription is hemophilia A (factor VIII deficiency) in dogs.[5] Beside disease-causing point mutations there are many other SNPs that do not affect the function of a protein and are not within a gene, but may serve as markers for GWAA.

Deletion/Insertion

A deletion or insertion is a loss or gain of DNA sequence information that can range from a single base pair within a gene to a large part of the chromosome. A deletion or insertion may cause a frameshift mutation: a change in the reading frame of the gene (this occurs if the number of base pairs in the deletion or insertion is not a multiple of three). In most cases, the altered reading frame results in a truncated or elongated protein with affected protein function.

An example for an insertion is the coagulation factor XI (FXI) deficiency in Kerry blue terrier dogs. Exon 7 of the FXI gene shows a short interspersed nucleotide element (SINE) insertion, disrupting the reading frame.[17]

Gene Duplication

Gene duplication or gene deletion is the repetition or deletion of an entire gene during meiosis due to unequal crossing over or mispairing of chromosomes/sister chromatids. An example of gene duplication would be fibroblast growth factor genes in Rhodesian and Thai Ridgeback dogs, that cause hair ridges and a disposition to dermoid sinus.[4]

GENOMICS AND PROTEOMICS

Functional genomics bridges over into proteomics. Proteomics studies protein function in the context of the entire organism. The study of small peptides and the receptors with which they interact is called peptidomics.

EXPRESSION PROFILING

A variation of genetic testing that targets identified genetic mutations is the study of the transcriptome of an organism. Gene expression profiling by microarray technologies has been successfully applied to study the transcriptional changes that occur in diseased versus normal tissues, such as heart, vessels and blood cells in different cardiovascular disorders. The aim of these studies is to unravel the complex molecular picture underlying a particular pathophysiology. Gene expression studies may provide a finer molecular classification of patients with diseases (genetic or not) and indicate new markers useful for prognostic and therapeutic strategies. In addition to the study of expressed genes (messenger RNA [mRNA]) themselves, the study of the post-transcriptional regulation of gene expression by micro RNA (miRNA) adds a layer of complexity and opportunity. Relatively few regulatory miRNA molecules have been identified in humans (678 to date) compared to expressed genes (approximately 30,000).[16] (For further information see miRBase, v12.0 at http://microrna.sanger.ac.uk/cgi-bin/sequences/browse.pl.) Many miRNA are highly tissue- and cell-specific and the signal is not confounded by the large pool of "irrelevant" genes.

CYTOGENETICS

Cytogenetics is the study of the structure and function of the cell, especially the chromosomes. It includes routine analysis of G-banded chromosomes, other cytogenetic banding techniques, as well as molecular cytogenetics such as fluorescent in situ hybridization (FISH; Fig. 148.1) and comparative genomic hybridization (CGH). Both techniques are aimed at detection of chromosomal imbalances. FISH can be used to detect and localize the presence or absence of specific DNA sequences on chromosomes. It uses fluorescent probes that bind to only those parts of the chromosome with which they show a high degree of sequence similarity. Fluorescence microscopy is used to find where the fluorescent probe binds to the chromosomes. FISH is often used for finding specific features in DNA for use in

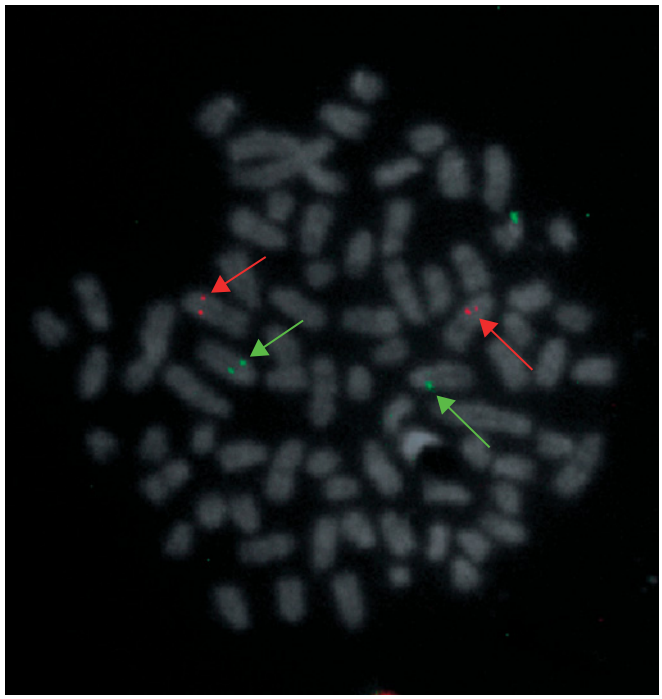

FIGURE 148.1 Results of fluorescence in situ hybridization (FISH) analysis of cultured peripheral-blood lymphocytes using the VIM-biotin (green) and Versican digoxigenin (red) labeling of CFA2 and CFA3 chromosomal pairs, respectively.

TABLE 148.2 Molecular Genetic Tests Available for Hereditary Hematologic Diseases in Dogs and Cats

Genetic Disorders	Affected species and breeds	Laboratory
Erythrocytic disorders		
Pyruvate Kinase (PK) deficiency	Abyssinian, Somali, DSH cats	1,2,11,13
	Basenji	1,4,10,11,13
	Beagle	1
	West Highland white terrier	1,4,5,10,11,13,14
Phosphofructokinase (PFK) deficiency	American Cocker Spaniel	1,3,4,5,10,14,13,14
	English Springer Spaniel	
Feline blood type B	Cats	2,7,9
White blood cell disorders		
Canine leukocyte adhesion deficiency (CLAD)	Irish setter, Red & white setter	3,5,9,11,13
X-linked severe combined immunodeficiency (SCID)	Basset Hound, Welsh Corgi	1,11,13
Mucopolysaccharidosis Type I, II, IIIB, VI, VII	Several canine and feline breeds	1
Cobalamin malabsorption	Australian shepherd, giant schnauzer	1
Cyclic hematopoiesis	Collie	4,10,11
Bleeding disorders (platelets, plasma coagulation proteins)		
Factor VII deficiency	Alaskan Klee Kai, Beagle, Scottish Deerhound	1,4
Factor XI deficiency	Kerry Blue terrier	1
Glanzmann thrombasthenia	Great Pyrenees, Otterhound	6
Hemophelia B	German Wirehaired Pointer	8
Thrombopathia	Basset Hound, Landseer, Spitz	6
Trapped Neutrophil Syndrome	Border Collie	12
Von Willebrand's Disease	Several dog breeds	4,5,11,13

genetic counseling, medicine, and species identification. FISH can also be used to detect and localize specific mRNAs within tissue samples. In this context, it can help define the spatial-temporal patterns of gene expression within cells and tissues.

In CGH, two genomic DNA samples are simultaneously hybridized in situ to normal metaphase spreads, and detected with different fluorophores. The intensity ratio of the two fluorescence signals gives a measure for the copy number ratio between the two genomic DNA samples. Comparative genomic hybridization can be either performed on metaphase chromosomes or using large pieces of cloned genomic DNA (BAC) as an array-CGH.

CURRENT GENETIC TESTING

An ever-expanding number of genetic tests are becoming available for screening of genetic diseases. A partial listing of the molecular genetic tests for hematological diseases available for dogs and cats is provided in Table 148.2.

diurnal effects 930
endotoxin response 930
gender effects 930
leukocytes 927–8, **929**
corticosteroid response 929
normal hematology 927–30
plasma fibrinogen 928
platelets 928
RBCs 927, **928**
sedimentation rate 929
reference intervals 928–30
waterfowl
aging 978
anemia 978
blood collection 979–80
bone marrow 980–1
environmental influences 978–9
leukocytes 978, **979**
normal hematology 977–87
physiological influences 978–9
RBCs 977–8, **979**
reference intervals 978–9
species variations 978
thrombocytes 978
Weibel–Palade bodies 643, 646
whales *see* marine mammals
white blood cell count, total
ADVIA 120/2120® analyzer 1059, *1060,* 1061
avian 346
bison 931, **934**
camelid 914
canine 321, 806
Cell-Dyn® 3500 1061
feline 813–14
hamster 907
laboratory animals
rabbits **864, 866,** 867
rodents 856
manual slide evaluation 1025
psittacine 970–1, **972**
raptors 982, **984**
ratites 988, 989
waterfowl 979
white blood cell impedance count (WIC) 1062
white blood cell optical count (WOC) 1062
whole blood
autoagglutination 228
canine 734–6
collection 732, 734
feline 734, 736
platelet aggregation **1124,** 1125
platelet extraction 752
separation into components 734–6
storage 736
transfusion 738
large animals 757–8
