Editor's Preface to the Third Edition

In the four years that have elapsed since the highly successful second edition of the *Handbook of Statistical Genetics*, the field has moved on, in some areas dramatically. This is reflected in the present thorough revision and comprehensive updating: 17 chapters are entirely new, 6 providing a fresh approach to topics that had been covered in the second edition, while 11 new chapters cover areas of recent growth, or important topics not previously addressed. These new topics include microarray data analysis (two new chapters to complement the existing one), eQTL analyses and metabonomics. There are also new chapters on graphical models and on pedigrees and genealogies, admixture mapping and genome-wide association studies, cancer genetics, epigenetics, and genetical aspects of insurance. Of the 26 chapters carried over from the second edition, 21 have been revised, among which 5 very substantial revisions are close to being new chapters.

It will be clear from the topics listed above that we continue to define statistical genetics very broadly. Statistics for us goes beyond mathematical models and techniques, and includes the management and presentation of data, as well as its analysis and interpretation. Genetics includes the search for and study of genes implicated in human health and the economic value of plants and animals, the evolution of genes within natural populations, the evolution of genomes and of species, and the analysis of DNA, RNA, gene expression, protein sequence and structure, and now metabonomics. The latter topics probably fall outside even a liberal definition of 'genetics', but we believe they will be of interest to our readers because of their relevance to studies of gene function and because of the statistical methods being used.

We regard more recent terms, such as 'genomics' and 'transcriptomics' as designating new avenues within genetics, rather than as entirely new fields, and we include their statistical aspects as part of statistical genetics. Similarly, we include much of 'bioinformatics', but we do not systematically survey the available genetic databases or computer software, nor methods and protocols for archiving and annotating genetic data. Some pointers to computer software and other Internet resources are given at the end of relevant chapters.

The 43 chapters are intended to be largely independent, so that to benefit from the handbook it is not necessary to read every chapter, nor read chapters sequentially. This structure necessitates some duplication of material, which we have tried to minimise but could not always eliminate. Alternative approaches to the same topic by different authors can convey benefits. The extensive subject and author indexes allow easy reference to topics covered in different chapters.

For those with minimal genetics background, the glossary of genetic terms (newly updated) should be of assistance, while Wiley's *Biostatistical Genetics and Genetic Epidemiology*, edited by Elston, Olson, and Palmer (2002) provides a more substantial

resource of definitions and explanations of key terms from both genetics and statistics. For those seeking a more substantial introduction to the foundations of modern statistical methods applied in genetics, we suggest *Likelihood, Bayesian, and MCMC methods in Quantitative Genetics* by Sorenson and Gianola (2003).

We thank the many commentators of the first two editions who were generous in their praise. We have tried to take on board many of the constructive criticisms and suggestions. No doubt many more improvements will be possible for future editions and we welcome comments e-mailed to any of the editors. We are grateful to all of our outstanding set of authors for taking the time to write and update their chapters with care, and for meeting their deadlines (and sometimes ours as well). Finally, we would like to express our appreciation to the staff of John Wiley & Sons for initially proposing the project to us, and for their friendly professionalism in the preparation of both editions. In particular, we thank Martine Bernardes-Silva, Layla Harden, and Kathryn Sharples.

Glossary of Terms

GLOSSARY OF GENETIC TERMS:

(prepared by Gurdeep Sagoo, University of Sheffield, UK)

N.B. Some of the definitions below assume that the organism of interest is diploid.

Adenine (A): purine base that forms a pair with thymine in DNA and uracil in RNA.

Admixture: arises when two previously isolated populations begin interbreeding.

Allele: one of the possible forms of a gene at a given locus. Depending on the technology used to type the gene, it may be that not all DNA sequence variants are recognised as distinct alleles.

Allele frequency: often used to mean the relative frequency (i.e. proportion) of an allele in a sample or population.

Allelic association: the non-independence, within a given population, of a gamete's alleles at different loci. Also commonly (and misleadingly) referred to as *linkage disequilibrium.*

Alpha helix: a helical (usually right-handed) arrangement that can be adopted by a polypeptide chain; a common type of protein secondary structure.

Amino acid: the basic building block of proteins. There are 20 naturally occurring amino acids in animals which when linked by peptide bonds form polypeptide chains.

Aneuploid cells: do not have the normal number of chromosomes.

Antisense strand: the DNA strand complementary to the coding strand, determined by the covalent bonding of A with T and C with G.

Ascertainment: the strategy by which individuals are identified, selected, and recruited for participation in a study.

Autosome: A chromosome other than the sex chromosomes. Humans have 22 pairs of autosomes plus 2 sex chromosomes.

Backcross: A linkage study design in which the progeny (F1s) of a cross between two inbred lines are crossed back to one of the inbred parental strains.

Bacterial Artificial Chromosome (BAC): a vector used to clone a large segment of DNA (100−200 Kb) in bacteria resulting in many copies.

Base: (abbreviated term for a purine or pyrimidine in the context of nucleic acids), a cyclic chemical compound containing nitrogen that is linked to either a deoxyribose (DNA) or a ribose (RNA).

Base pair (bp): a pair of bases that occur opposite each other (one in each strand) in double stranded DNA/RNA. In DNA adenine base pairs with thymine and cytosine with guanine. RNA is the same except that uracil takes the place of thymine.

Bayesian: A statistical school of thought that, in contrast with the frequentist school, holds that inferences about any unknown parameter or hypothesis should be encapsulated in a probability distribution, given the observed data. Bayes Theorem allows one to compute the posterior distribution for an unknown from the observed data and its assumed prior distribution.

Beta-sheet: is a (hydrogen-bonded) sheet arrangement which can be adopted by a polypeptide chain; a common type of protein secondary structure.

centiMorgan (cM): measure of genetic distance. Two loci separated by 1 cM have an average of 1 recombination between them every 100 meioses. Because of the variability in recombination rates, genetic distance differs from physical distance, measured in base pairs. Genetic distance differs between male and female meioses; an average over the sexes is usually used.

Centromere: the region where the two sister chromatids join, separating the short (p) arm of the chromosome from the long (q) arm.

Chiasma: the visible structure formed between paired homologous chromosomes (non-sister chromatids) in meiosis.

Chromatid: a single strand of the (duplicated) chromosome, containing a double-stranded DNA molecule.

Chromatin: the material composed of DNA and chromosomal proteins that makes up chromosomes. Comes in two types, euchromatin and heterochromatin.

Chromosome: the self-replicating threadlike structure found in cells. Chromosomes, which at certain stages of meiosis and mitosis consist of two identical sister chromatids, joined at the centromere, and carry the genetic information encoded in the DNA sequence.

cis-Acting: regulatory elements and eQTL whose DNA sequence directly influences transcription. The physical location for cis-acting elements will be in or near the gene or genes they regulate.

Clones: genetically engineered identical cells/sequences.

Co-dominance: both alleles contribute to the phenotype, in contrast with recessive or dominant alleles.

Codon: a nucleotide triplet that encodes an amino acid or a termination signal.

Common disease common variant (CDCV) hypothesis: The hypothesis that many genetic variants underlying complex diseases are common, and hence susceptible to detection using current population association study designs. An alternative possibility is that genetic contributions to the causation of complex diseases arise from many variants, all of which are rare.

complementary DNA (cDNA): DNA that is synthesised from a messenger RNA template using the reverse transcriptase enzyme.

Contig: a group of contiguous overlapping cloned DNA sequences.

Cytosine (C): pyrimidine base that forms a pair with guanosine in DNA.

Degrees of freedom (df): This term is used in different senses both within statistics and in other fields. It can often be interpreted as the number of values that can be defined arbitrarily in the specification of a system; for example, the number of coefficients in a regression model. Frequently it suffices to regard df as a parameter used to define certain probability distributions.

Deoxyribonucleic acid (DNA): polymer made up of deoxyribonucleotides linked together by phosphodiester bonds.

Deoxyribose: the sugar compound found in DNA.

Diploid: has two versions of each autosome, one inherited from the father and one from the mother. Compare with haploid.

Dizygotic twins: twins derived from two separate eggs and sperm. These individuals are genetically equivalent to full sibs.

DNA methylation: the addition of a methyl group to DNA. In mammals this occurs at the C-5 position of cytosine, almost exclusively at CpG dinucleotides.

DNA microarray: small slide or 'chip' used to simultaneously measure the quantity of large numbers of different mRNA gene transcripts present in cell or tissue samples.

Depending on the technology used, measurements may either be absolute or relative to the quantities in a second sample.

Dominant allele: results in the same phenotype irrespective of the other allele at the locus.

Effective population size: The size of a theoretical population that best approximates a given natural population under an assumed model. The criterion for assessing the 'best' approximation can vary, but is often some measure of total genetic variation.

Enzyme: a protein that controls the rate of a biochemical reaction.

Epigenetics: the transmission of information on gene expression to daughter cells at cell division.

Epistasis: the physiological interaction between different genes such that one gene alters the effects of other genes.

Epitope: the part of an antigen that the antibody interacts with.

Eukaryote: organism whose cells include a membrane-bound nucleus. Compare with prokaryote.

Exons: parts of a gene that are transcribed into RNA and remain in the mature RNA product after splicing. An exon may code for a specific part of the final protein.

Expression Quantitative Trait Locus (eQTL): a locus influencing the expression of one or more genes.

Fixation: occurs when a locus which was previously polymorphic in a population becomes monomorphic because all but one allele has been lost through genetic drift.

Frequentist: the name for the school of statistical thought in which support for a hypothesis or parameter value is assessed using the probability of the observed data (or more 'extreme' datasets) given the hypothesis or value. Usually contrasted with Bayesian.

Gamete: a sex cell, sperm in males, egg in females. Two haploid gametes fuse to form a diploid zygote.

Gene: a segment (not necessarily contiguous) of DNA that codes for a protein or functional RNA.

Gene expression: the process by which coding DNA sequences are converted into functional elements in a cell.

Genealogy: the ancestral relationships among a sample of homologous genes drawn from different individuals, which can be represented by a tree. Also sometimes used in

place of pedigree, the ancestral relationships among a set of individuals, which can be represented by a graph.

Genetic drift: the changes in allele frequencies that occur over time due to the randomness inherent in reproductive success.

Genome: all the genetic material of an organism.

Genotype: the (unordered) allele pair(s) carried by an individual at one or more loci. A multilocus genotype is equivalent to the individual's two haplotypes without the phase information.

Guanine (G): purine base that forms a pair with cytosine in DNA.

Haemoglobin: is the red oxygen-carrying pigment of the blood, made up of two pairs of polypeptide chains called globins (2α and 2β subunits).

Haploid: has a single version of each chromosome.

Haplotype: the alleles at different loci on a chromosome. An individual's two haplotypes imply the genotype; the converse is not true, but in the presence of strong linkage disequilibrium haplotypes may be inferred from genotype with few errors.

Hardy-Weinberg disequilibrium: the non-independence within a population of an individual's two alleles at a locus; can arise due to inbreeding or selection for example. Compare with linkage disequilibrium.

Heritability: the proportion of the phenotypic variation in the population that can be attributed to underlying genetic variation.

Heterozygosity: the proportion of individuals in a population that are heterozygotes at a locus. Also sometimes used as short for expected heterozygosity under random mating, which equals the probability that two homologous genes drawn at random from a population are not the same allele.

Heterozygote: a single-locus genotype consisting of two different alleles.

HIV (Human Immunodeficiency Virus): a virus that causes acquired immune deficiency syndrome (AIDS) which destroys the body's ability to fight infection.

Homology: similarities between sequences that arise because of shared evolutionary history (descent from a common ancestral sequence). Homology of different genes within a genome is called paralogous while that between the genomes of different species is called orthologous.

Homozygote: a single-locus genotype consisting of two versions of the same allele.

Hybrid: the offspring of a cross between parents of different genetic types or different species.

Hybridization: the base pairing of a single stranded DNA or RNA sequence, usually labelled, to its complementary sequence.

ibd: identity by descent; two genes are ibd if they have descended without mutation from an ancestral gene.

Inbred lines: derived and maintained by repeated selfing or brother–sister mating, these individuals are homozygous at essentially every locus.

Inbreeding: either the mating of related individuals (e.g. cousins) or a system of mate selection in which mates from the same geographic area or social group for example are preferred. Inbreeding results in an increase in homozygosity and hence an increase in the prevalence of recessive traits.

Intercross: A linkage study design in which the progeny (F1s) of a cross between two inbred lines are crossed or selfed. This design is also sometimes referred to as an *F2 design* because the resulting individuals are known as F2s.

Intron: non-coding DNA sequence separating the exons of a gene. Introns are initially transcribed into messenger RNA but are subsequently spliced out.

Karyotype: the number and structure of an individual's chromosomes.

Kilobase (Kb): 1000 base pairs.

Linkage: two genes are said to be linked if they are located close together on the same chromosome. The alleles at linked genes tend to be co-inherited more often than those at unlinked genes because of the reduced opportunity for an intervening recombination.

Linkage disequilibrium (LD): the non-independence within a population of a gamete's alleles at different loci; can arise due to linkage, population stratification, or selection. The term is misleading and 'gametic phase disequilibrium' is sometimes preferred. Various measures of linkage disequilibrium exist.

Locus (pl. Loci): the position of a gene on a chromosome.

LOD score: a likelihood ratio statistic used to infer whether two loci reside close to one another on a chromosome and are therefore inherited together. A LOD score of 3 or more is generally thought to indicate that the two loci are close together and therefore linked.

Marker gene: a polymorphic gene of known location which can be readily typed; used for example in genetic mapping.

Megabase (Mb): 1000 kilobases = 1,000,000 base pairs.

Meiosis: the process by which (haploid) gametes are formed from (diploid) somatic cells.

messenger RNA (mRNA): the RNA sequence that acts as the template for protein synthesis.

Microarray: see DNA microarray above.

Microsatellite DNA: small stretches of DNA (usually 1–4 bp) tandemly repeated. Microsatellite loci are often highly polymorphic, and alleles can be distinguished by length, making them useful as marker loci.

Mitosis: the process by which a somatic cell is replaced by two daughter somatic cells.

Monomorphic: a locus at which only one allele arises in the sample or population.

Monozygotic twins: genetically identical individuals derived from a single fertilized egg.

Morgan: 100 centiMorgans.

mtDNA: the genetic material of the mitochondria which consists of a circular DNA duplex inherited maternally.

Mutation: a process that changes an allele.

Negative selection: removal of deleterious mutations by natural selection. Also known as *purifying selection*.

Neutral: not subject to selection.

Neutral evolution: evolution of alleles with nearly zero selective coefficient. When $|Ns| << 1$, where N is the population size and s is the selective coefficient, the fate of the allele is mainly determined by random genetic drift rather than natural selection.

Non-Coding RNA (ncRNA): RNA segments that are coded for in the genome, but not translated into protein product. Composed of many classes, the complete range of functions of these molecules has yet to be characterised, but they have been shown to affect the rate of transcription and transcript degradation.

Nonsynonymous substitution: Nucleotide substitution in a protein-coding gene that alters the encoded amino acid.

Nucleoside: a base attached to a sugar, either ribose or deoxyribose.

Nucleotide: the structural units with which DNA and RNA are formed. Nucleotides consist of a base attached to a five-carbon sugar and mono-, di-, or tri-phosphate.

Nucleotide substitution: the replacement of one nucleotide by another during evolution. Substitution is generally considered to be the product of both mutation and selection.

Oligonucleotide: a short sequence of single-stranded DNA or RNA, often used as a probe for detecting the complementary DNA or RNA.

Open Reading Frame (ORF): a long sequence of DNA with an initiation codon at the 5′-end and no termination codon except for one at the 3′-end.

PCR (polymerase chain reaction): a laboratory process by which a specific, short, DNA sequence is amplified many times.

Pedigree: a diagram showing the relationship of each family member and the heredity of a particular trait through several generations of a family.

Penetrance: the probability that a particular phenotype is observed in individuals with a given genotype. Penetrance can vary with environment and the alleles at other loci for example.

Peptide bond: linkages between amino acids occur through a covalent peptide bond joining the C terminal of one amino acid to the N terminal of the next (with loss of a water molecule).

Phase (of linked markers): the relationship (either coupling or repulsion) between alleles at two linked loci. The two alleles at the linked loci are said to be in coupling if they are present on the same physical chromosome or in repulsion if they are present on different parental homologs.

Phenotype: the observed characteristic under study, may be quantitative (i.e. continuous) such as height, or binary (e.g. disease/no disease), or ordered categorical (e.g. mild/moderate/severe).

Pleiotropy: is the effect of a gene on several different traits.

Polygenic: influenced by more than one gene.

Polymorphic: a locus that is not monomorphic. Usually a stricter criterion is imposed: a locus is polymorphic only if no allele has frequency over 99 %.

Polynucleotide: a polymer of either DNA or RNA nucleotides.

Polypeptide: is a long chain of amino acids joined together by peptide bonds.

Polypeptide chain: A series of amino acids linked by peptide bonds. Short chains are sometimes referred to as oligopeptides or simply peptides.

Polytene: refers to the giant chromosomes that are generated by the successive replication of chromosome pairs without the nuclear division, thus several chromosome sets are joined together.

Population stratification (or population structure): Refers to a situation in which the population of interest can be divided into strata such that an individual tends to be more closely related to others within the same stratum than to other individuals.

Positive selection: fixation, by natural selection, of an advantageous allele with a positive selective coefficient. Also known as *Darwinian selection*.

Proband: an individual through whom a family is ascertained, typically by their phenotype.

Prokaryote: organism whose cells have no nucleus.

Promoter: located upstream of the gene, the promoter allows the binding of RNA polymerase which initiates transcription of the gene.

Protein: a large, complex, molecule made up of one or more chains of amino acids.

Pseudogene: a DNA sequence that is either an imperfect, non-functioning, copy of a gene, or a former gene which no longer functions due to mutations.

Purine and Pyrimidine: are particular kinds of nitrogen containing heterocyclic rings.

Purine: adenine or guanine.

Pyrimidine: cytosine, thymine, or uracil.

QTL (Quantitative Trait Locus): a locus influencing a continuously varying phenotype.

Radiation hybrid: a cell line, usually rodent, that has incorporated fragments of foreign chromosomes that have been broken by irradiation. They are used in physical mapping.

Recessive allele: has no effect on phenotype except when present in homozygote form.

Recombination: the formation of new haplotypes by physical exchange between two homologous chromosomes during meiosis.

Restriction enzyme: recognises specific nucleotide sequences in double-stranded DNA and cuts at a specified position with respect to the sequence.

Restriction fragment: a DNA fragment produced by a restriction enzyme.

Restriction site: a 4–8 bp DNA sequence (usually palindromic) that is recognised by a restriction enzyme.

Retrovirus: an RNA virus whose replication depends on a reverse transcriptase function, allowing the formation of a cDNA copy that can be stably inserted into the host chromosome.

Ribonucleic acid (RNA): polymer made up of ribonucleotides that are linked together by phosphodiester bonds.

Ribosome: a cytoplasmic organelle, consisting of RNA and protein, that is involved in the translation of messenger RNA into proteins.

Ribosomal RNA (rRNA): the RNA molecules contained in ribosomes.

Selection: a process such that expected allele frequencies do not remain constant, in contrast with genetic drift. Alleles that convey an advantage to the organism in its current environment tend to become more frequent in the population (positive, or adaptive, selection), while deleterious alleles become less frequent. Under stabilising (or balancing) selection, allele frequencies tend towards a stable, intermediate value.

Sense strand: the DNA strand in the direction of coding.

Sex-linked: a trait influenced by a gene located on a sex (X or Y) chromosome.

Single nucleotide polymorphism (SNP): a polymorphism consisting of a single nucleotide.

Sister chromatids: two chromatids that are copies of the same chromosome. Non-sister chromatids are different but homologous.

Somatic cell: a non-sex cell.

Synonymous substitution: Nucleotide substitution in a protein-coding gene that does not alter the encoded amino acid.

TATA box: a conserved sequence (TATAAAA) found about $25-30$ bp upstream from the start of transcription site in most but not all genes.

Thymine (T): pyrimidine base that forms a pair with adenine in DNA.

trans-Acting: eQTL whose DNA sequence influences gene expression through its gene product. These regulatory elements are often coded for at loci far from or unlinked to the genes they regulate.

Transcription: the synthesis of a single-stranded RNA version of a DNA sequence.

Transition: a mutation that changes either one purine base to the other, or one pyrimidine base to the other.

Translation: the process whereby messenger RNA is 'read' by transfer RNA and its corresponding polypeptide chain synthesized.

Transposon: a genetic element that can move over generations from one genomic location to another.

Transversion: a mutation that changes a purine base to a pyrimidine, or vice-versa.

Uracil (U): pyrimidine base in RNA that takes the place of thymine in DNA, also forming a pair with adenine.

Wild-type: the common, or standard, allele/genotype/phenotype in a population.

Yeast artificial chromosome (YAC): a cloning vector able to carry large (e.g. one megabase) inserts of DNA and replicate in yeast cells.

Zygote: an egg cell that has been fertilized by a sperm cell.

Abbreviations and Acronyms

ABC	Approximate Bayesian Calculation
AD	Alzheimer's Disease

Chromosome maps are a natural way of organizing genetic data about chromosomes. Existing
chromosome maps can be broadly divided into four categories: genetic maps, physical maps,
radiation hybrid maps, and gene maps. Although they all make reference to the same biological
entity, namely chromosomes, these maps differ substantially in the types of genetic experiments
conducted and the types of genetic data collected. They further differ in the metrics employed
to define distances and the resolution achievable. Collectively, these maps provide essential tools
to further our understanding of the organization and function of the genome. In this review, we
first describe the biological principles behind each type of chromosome map and then outline the
statistical models and methods that have been developed to construct it. The current state of each
chromosome map is summarized, and links to mapping software are provided for readers interested
in getting hands-on experience with chromosome mapping.

1.1 INTRODUCTION

Chromosome maps are a natural way of organizing genetic data about chromosomes, in
very much the same way that ordinary (cartographic) maps organize geographic data about
continents, countries or cities. Geneticists have long constructed different types of maps
to order genes or markers, breakpoints, deletions, and other features in relation to one
another and to landmarks along chromosomes such as centromeres and telomeres. *Genetic
maps* were the first type of map constructed to position genes along chromosomes, with

the distances between pairs of genes being defined in terms of recombination fractions. Thus genetic maps were unusual for at least two reasons. First, the objects being mapped – genes, later polymorphic markers, collectively described as loci – were frequently abstract, in the sense that data concerning them was only indirectly observed; the genes themselves were never seen. And secondly, the distance was only relative, and defined statistically. Since the rate of recombination varies along chromosomes, genetic map distance is not proportional to actual physical distance, although there are useful average relationships for different organisms.

Physical maps take a number of forms, but common to all is the fact that the objects being mapped are concrete, usually assayable, and the distances are physical, most recently thousands (kb) or millions (Mb) of base pairs, reflecting the fact that chromosomes are long DNA molecules. However, the first physical maps were not exactly of this type. Early examples of physical maps are those based on the salivary gland polytene chromosomes of insects belonging to the order Diptera, such as *Drosophila melanogaster*. In these maps, the positioning is provided by the visible bands. The familiar cytogenetic maps of human (see Figure 1.1) and other mammalian chromosomes created by staining metaphase chromosomes all have a similar character, again with bands providing positioning information.

A slightly confusing aspect is that physical maps refer not only to maps of loci along chromosomes, but also to organized collections of chromosomal segments, such as restriction fragments and more general ordered sets of cloned fragments of a chromosome.

When recombination is used to define distances, the genes or markers must be polymorphic in order to be mappable. By contrast, the physical mapping of loci only requires probes for recognizing specific chromosomal sites or for detecting fragment

overlap. The most useful probe in this context is the sequence-tagged site (STS), which is defined by a pair of 20–30 base pairs polymerase chain reaction (PCR) primers that reliably amplify a unique segment in a genome.

Maps of human (and other) chromosomes intermediate in resolution between the genetic and physical maps are the radiation hybrid (RH) maps. These are based on assay data from human–rodent somatic cell hybrids containing small fragments of human chromosomes. They have their own metric, namely the average number of breaks per unit physical distance, reflecting the radiation dose used to fragment the chromosomes.

Next in resolution, although different in character, are *gene maps*. These maps are currently constructed by clustering expressed sequence tags (ESTs), more specifically short DNA sequences in the $3'$-untranslated regions of complementary DNAs (cDNAs), and then locating the clusters on chromosomes using STSs in these regions. Ideally, each point on such a map corresponds to a unique gene, and so gene maps should locate genes on physical maps. Until a genome is completely sequenced, these maps provide the best usable description of the locations of the genes of an organism.

With the exception of the polytene chromosome and cytological maps, all of the kinds of maps we have mentioned make use of statistical methods in their definition, in their construction, or in the assignment of the corresponding map distance. In this chapter, we give a review of some of the statistical models and methods used in chromosome mapping. It will be partial in the sense that we discuss genetic mapping much more fully, in part because it is the most thoroughly developed mapping method, going back nearly a century.

1.2 GENETIC MAPS

1.2.1 Mendel's Two Laws

Modern genetics began with the work of Mendel on garden peas in the 1860s (Mendel, 1866). In his experiments, Mendel studied a number of heritable traits in peas, including seed color. He interpreted his experiments with this trait by postulating the existence of things that we now call genes. He said that two gene variants controlled color in his two lines, *y* (for yellow) and *g* (for green), and that the color gene-pair in the seed determines what color the seed will be. His experiments led him to believe that all cells in the mature plant contain the seed's color gene-pair, with the exception of sex cells, which contain only one of the pair. If the seed's gene-pair is y/g, then half the pollen cells get *y* and half get *g*; similar observations hold for egg cells. Mendel was able to explain his observations with this theory, and it is largely what we believe today. It is often called *Mendel's first law*, the law of segregation. Mendel's first law says that each adult pea plant has a *gene-pair* (say, *y* and *g*) for each character studied, and that the pair *y* and *g* segregate from each other into gametes, so half the gametes will carry *y*, and the other half will carry *g*.

Mendel also considered two or more heritable traits together, for example, seed color and seed shape. Denoting the two variants of seed shape by *s* (for smooth) and *w* (for wrinkled), he first established that, when considered on its own, seed shape inheritance was also explained by supposing that each cell had one gene-pair, in this case one of the pairs s/s, s/w or w/w, and that sex cells had just one of *s* or *w*, effectively chosen at

random from the pair generally present. Mendel then carried out experiments to determine how the two traits, seed shape and seed color, were inherited together. He concluded that each sex cell received one gene from each gene-pair, chosen at random from the available pair, independently for the two gene-pairs. For example, if the mature organism's cells generally possessed gene-pairs y/g and s/w, then its sex cells received ys, yw, gs, or gw with equal frequency $\frac{1}{4}$. Let us see the sense in which this last statement is true. Consider an organism P whose gene-pairs for two traits are y/g and s/w, that is descended from a parent GF that was y/y and s/s, and a parent GM that was g/g and w/w. Then P is ys/gw, getting y and s from GF, and g and w from GM. In a natural sense, y and s were combined together in GF, as were g and w in GM, while y and g (and s and w) were separated at that generation, being present in different individuals. With peas, when y, g, s, and w corresponded to seed color and shape as above, Mendel saw that this togetherness or separateness in the G-generation had no impact on the choice of genes that P passed on to its offspring C: ys, yw, gs, and gw were found to be passed on with equal frequency. Mendel's second law says that during gamete formation, the segregation of one gene-pair is independent of other gene-pairs. When two gene-pairs, say (y, g) and (s, w), segregate, each (haploid) gamete will be equally likely to have genotypes (y, s), (y, w), (g, s), and (g, w).

The above observation, sometimes known as *Mendel's law of independent segregation*, turns out to hold for some, but not all, pairs of genes. The exceptions are the biological basis for genetic mapping. In the early 1900s, deviations from Mendel's second law were observed by Bateson *et al.* (1905) in the sweet pea, and by Morgan (1911) in Drosophila: some genotypes appeared more often than other genotypes, indicating that the gene-pairs were not segregating independently. There are many pairs of traits whose genes do not recombine freely, but tend to stay together, in the sense that the parent P above with composition ys/gw would be more likely to pass on the pairs ys and gw to its offspring C, than the pairs yw and gs. This phenomenon is known as *linkage*: genes that came to P together from the G-generation are preferentially passed on together to offspring in the C-generation. In the most extreme case, C would receive each of P's parental combinations ys and gw with frequency $\frac{1}{2}$, and never receive yw or gs. We would then say that the genes are *completely linked*; no recombining takes place. For a given pair of traits such as seed color and seed shape, with heritable variants (*alleles*) such as y, g, and s, w, we define their recombination fraction to be the frequency with which P's nonparental combinations yw and gs are passed on; with Mendel's examples this fraction was always $\frac{1}{2}$. In the early part of the twentieth century, examples were found where this fraction was noticeably smaller than $\frac{1}{2}$, and to this day, pairs of genes for traits separate into those that freely recombine, and those for which the recombination fraction is less than $\frac{1}{2}$. Using the then much-debated chromosome theory of Mendelian heredity, Morgan explained this nonindependent segregation by supposing the two pairs of genes lie on the same chromosome. A chromosomal exchange between these two genes will result in a recombination between them. Morgan inferred that genes on the same chromosome tend to remain together much more often than if they are on different chromosomes, and called this principle *the third law of heredity*. He also hypothesized that the cross-shaped structure (called *chiasma*) seen during the diplotene phase of meiosis is a manifestation of *crossing-over*. It is now known that crossovers are precise breakage-and-reunion events that are essential for proper segregation, and can promote genetic variation.

1.2.2 Basic Principles in Genetic Mapping

In the following discussion, we make no distinction between *gene*, *marker*, and *locus*, all of which refer to some region on the chromosome. Consider two genes $\mathcal{A}$ (with alleles A and a) and $\mathcal{B}$ (with alleles B and b) and a diploid cell with AB and ab on homologous chromosomes. There are four possible meiotic products, namely, AB, ab, Ab, and aB. The first two are called *parental* types or *nonrecombinants*, because both AB and ab retain the configuration of one of the homologous chromosomes. The other two types, Ab and aB, are called *recombinants*. If two markers are recombined in a meiotic product, then during meiosis an odd number of crossovers must have occurred between the two markers on the strand carrying them. The recombination fraction, r_{AB}, is defined as the proportion of recombinants. It was Sturtevant (1913) who first used the variations in the strength of linkage to determine the sequence in the linear dimension of the chromosome. He argued that if the arrangement of the genes in the chromosome is linear and the recombination frequencies depend on the physical distance between them, then genes can be arranged like dots in a straight line at distances apart proportional to the recombination fraction. For example, for three genes, y (yellow gene), w (white gene), and mi (miniature gene) on the sex chromosome of Drosophila, the observed recombination fraction between y and w was $r_{y,w} = 1.3\,\%$, that between w and mi was $r_{w,mi} = 32.6\,\%$, and that between y and mi was $r_{y,mi} = 33.8\,\%$. Because $r_{y,mi} \approx r_{y,w} + r_{w,mi}$, the white gene can be inferred to lie between the yellow and miniature genes.

For three genes $\mathcal{A}$, $\mathcal{B}$, and $\mathcal{C}$ on the same chromosome in the order $\mathcal{A}$–$\mathcal{B}$–$\mathcal{C}$, the additivity among the three recombination fractions, i.e. $r_{AC} = r_{AB} + r_{BC}$, generally holds when the recombination fractions are small (less than $10\,\%$). However, as noted by Sturtevant (1913), the additivity in general does not hold when larger recombination fraction values are involved, and usually $r_{AC} < r_{AB} + r_{BC}$. Deviations from additivity are due to the existence of double crossovers. The next major development in genetic mapping was Haldane's definition Haldane (1919) of the genetic distance between two loci as the average number of crossovers between the loci per meiosis. This gave geneticists an additive distance along chromosomes, albeit one that was rapidly found not to correlate precisely with any apparent physical distance. The unit of genetic distance is the centimorgan (cM). Two markers are 1 cM apart if on average there is one crossover occurring between these two markers on a single strand for every 100 meioses.

Therefore, we have two basic concepts in genetic mapping: the recombination fraction, which can be estimated from data on the offspring of suitable parents; and map distance, which will be based upon the same data, but can only be estimated using a probabilistic model for recombination. With experimental organisms such as the fruit fly, maize, mice, fungi and yeast, establishing linkage and estimating recombination fractions was generally straightforward, because crosses could be planned, and large numbers of offspring examined. With humans, even establishing linkage between a pair of genes was a major achievement in the classical era, and estimating recombination fractions was a challenging statistical problem. Part of the reason for this lies in the longer generation times, and hence the difficulty in obtaining large sets of data, and part lies in the fact that matings are not subject to experimental control, forcing the human geneticist to make use of nonrandomly sampled family or pedigree data. One further complication with human data was the existence of genes with only an indirect relationship between genotype and phenotype, the issue of penetrance. Dominant and recessive traits are instances of what

are termed *incompletely penetrant traits*, and there are many human genetic diseases with quite complex patterns of penetrance, including age and sex dependence.

1.2.3 Meiosis, Chromatid Interference, Chiasma Interference, and Crossover Interference

Before describing statistical methods for genetic mapping in detail, we briefly review the process of meiosis and the genetic concepts relevant to genetic mapping. At the start of meiosis two chromosome sets are present, one coming from each parent in the previous generation. Each chromosome thus has a partner called a *homolog*. During the pachytene and diplotene phases of meiosis, homologous chromosomes pair and each of the paired chromosomes duplicates, resulting in a bundle of four homologous *chromatids*. Chromatids that are copies of the same chromosome are called *sister chromatids*, and those originating from homologous chromosomes are called *nonsister chromatids*. Crossovers take place after the formation of this four-strand structure, with each crossover involving two nonsister chromatids. The number and locations of crossovers vary from chromosome to chromosome for the same meiosis, and from meiosis to meiosis for the same chromosome.

Most genetic mapping efforts have focused on the case where data from only one of the four products of any given meiosis can be observed. Extending terminology from fungal genetics, we call this *single-spore data* in recognition of the fact that in organisms such as *Saccharomyces cerevisiae* (baker's yeast) and *Neurospora crassa* (red bread mold) all four products of a single meiosis can be recovered together in what are known as *tetrads* or *octads*. Genetic studies on these organisms have contributed greatly to our knowledge of many biological mechanisms. Some interesting statistical models that have been developed using tetrad and octad data will be discussed in later sections.

Mather (1933) distinguished two aspects of crossing-over that are relevant to the observed recombination outcome: the distribution of crossover events along the bundle of four chromatids; and the pairs of nonsister chromatids to be involved in crossovers. To distinguish crossover events occurring on the four-strand bundle and crossover events on single strands in the following, we describe crossover events on the four-strand bundle as chiasmata, and those on single strands as crossovers. Chiasma interference refers to nonrandom distribution of chiasmata on the four-strand bundle, whereas crossover interference refers to nonrandom distribution of crossover locations along single strands. Muller (1916) first noted that simultaneous recombinations are not independent, e.g. double recombinations take place at a frequency below that expected under the independence assumption. For example, for the three genes discussed above – yellow, white, and miniature – the expected double recombination frequency is $1.3\% \times 32.6\% = 0.43\%$. However, the observed frequency was only 0.045%. This suggests that the occurrence of one recombination reduces the chance of other recombinations in the nearby region. Crossover interference is seen in almost all organisms, including humans, and the presence of one crossover usually inhibits the formation of crossovers in a nearby region. The biological nature of crossover interference is still not well understood.

With respect to the pairs of nonsister chromatids involved in crossovers, we say there is no chromatid interference (NCI) if any pair of nonsister chromatids are equally likely to be involved in any chiasma, independent of which pairs were involved in other chiasmata.

The observation of crossover interference on the meiotic products (single strands) can be the result of chiasma interference alone, of chromatid interference alone, or of both types of interference. Zhao and Speed (1996) noted that the operation of two types of

interference can lead to no apparent crossover interference, and therefore these two types of interference cannot be separated on the basis of single-strand recombination data. In contrast, tetrad data carries information to distinguish these two types of interference.

1.2.4 Genetic Map Functions

Until the mid-1980s, most linkage mapping was two-point, that is, involved the estimation or testing of a single recombination fraction. For two-point data, we can infer the unobservable genetic distance between two markers from the observable recombination fraction through genetic map functions. Under the assumption of NCI, Mather (1935) showed that, given k (≥ 1) chiasmata between two markers on the four-strand bundle, the probability of observing recombination between these two markers is $\frac{1}{2}$. Therefore, the overall recombination fraction between two markers is $\frac{1}{2}(1 - p_0)$, where p_0 is the probability of having zero chiasmata between these two markers. This is called *Mather's formula*. Assuming chiasmata occurring independently of each other, Haldane derived the now well-known Haldane map function relating recombination fraction and map distance: $r = \frac{1}{2}(1 - e^{-2d})$ with inverse $d = -\frac{1}{2}\log(1 - 2r)$. Nearly 90 years later, this approach has proved to be very satisfactory for a wide variety of organisms. Note that Haldane derived his map function under the two-strand model, i.e. assuming only two strands (the two homologous chromosomes) are involved in the crossover process. Although this assumption is incorrect, we would arrive at the same map function under the four-strand model with no chromatid interference.

In addition to deriving the Haldane map function in his seminal 1919 paper, Haldane also proposed the empirical inverse map function $d = 0.7r + 0.3(-\frac{1}{2}\log(1 - 2r))$ to account for crossover interference in the data then available, and introduced a differential equation method that permitted the construction of a variety of map functions. A variety of other genetic map functions embodying different degrees of crossover interference have been proposed, including by Ludwig (1934); Kosambi (1944); Carter and Falconer (1951); Sturt (1976); Rao *et al.* (1977); Felsenstein (1979); and Karlin and Liberman (1978).

For all these map functions, genetic distance is very close to recombination fraction when the latter is small, and map distances can be (and in the fly group were) estimated without a model – provided the pair of genes were connected by a sequence of closely linked genes – by adding small recombination fractions.

1.2.5 Genetic Mapping for Three Markers

Historically, the first formal linkage analysis involving more than two loci was given by Fisher (1922). He showed how to combine data from a number of two-point analyses in order to obtain efficient estimates of a set of recombination fractions. For three markers $\mathcal{A}$, $\mathcal{B}$, and $\mathcal{C}$ in an arbitrary but fixed order, the joint recombination probabilities may be denoted by $\mathbf{p} = (p_{i_1 i_2})$, where the subscript $i_k = 1$ corresponds to recombination across the kth interval, and $i_k = 0$ corresponds to no recombination across the same interval. Therefore, we have four probabilities $\mathbf{p} = (p_{00}, p_{01}, p_{10}, p_{11})$ for three markers, corresponding to the four patterns of recombination or no recombination across $\mathcal{A}$–$\mathcal{B}$ and $\mathcal{B}$–$\mathcal{C}$. Although the data were all two-point, Fisher needed to express the recombination fraction across the union $\mathcal{A}$–$\mathcal{C}$ of two adjacent intervals $\mathcal{A}$–$\mathcal{B}$ and $\mathcal{B}$–$\mathcal{C}$ in terms of their individual recombination fractions. He did so by making the assumption of *complete interference*, that is, by assuming that at most one recombination could occur across any

pair of adjacent intervals. This is equivalent to the following joint distribution:

$$p_{00} = 1 - r_1 - r_2; \quad p_{01} = r_2; \quad p_{10} = r_1; \quad p_{11} = 0,$$

where r_1 and r_2 are the recombination fractions across $\mathcal{A}$–$\mathcal{B}$ and $\mathcal{B}$–$\mathcal{C}$, respectively. This model would not be appropriate for the analysis of three-point data in which double recombinants are observed, but it has been used in modern times with very short intervals. In human linkage analysis one finds almost exclusive use of the extremely tractable Poisson or *no-interference* model, whose joint probabilities for three loci take the form

$$p_{i_1 i_2} = r_1^{i_1}(1 - r_1)^{1 - i_1} r_2^{i_2}(1 - r_2)^{1 - i_2},$$

where, for $i = 1, 2$, the recombination fractions r_i may be expressed in terms of genetic distances d_i by

$$r_i = \tfrac{1}{2}(1 - \mathrm{e}^{-2d_i}).$$

It seems that although this model and its extension to more than three loci fail to fit most data sets of any size, the recombination fractions and locus orderings obtained are generally satisfactory; see Speed *et al.* (1992). Any map function, $r = M(d)$, can be used to analyze three-point data. This is because $r_1 = p_{10} + p_{11} = M(d_1)$, $r_2 = p_{01} + p_{11} = M(d_2)$, and $p_{11} = \tfrac{1}{2}[M(d_1) + M(d_2) - M(d_1 + d_2)]$, and we can derive all the $p_{i_1 i_2}$ from a given map function. Therefore, likelihood functions for the observed data can be constructed and maximum likelihood estimates of genetic distances can be obtained.

For an arbitrary crossover process model, under the assumption of NCI, Speed *et al.* (1992) derived a set of inequality constraints and showed the robustness of the ordering. The order with respect to which these probabilities are defined does not need to be the true one, and if we change it, the probabilities need only be relabeled. For example, if we go from the order $O : \mathcal{A}$–$\mathcal{B}$–$\mathcal{C}$ with probabilities $\mathbf{p}$, to $O' : \mathcal{A}$–$\mathcal{C}$–$\mathcal{B}$ with probabilities $\mathbf{p}'$, then $\mathbf{p}'$ is related to $\mathbf{p}$ as follows:

$$p'_{00} = p_{00}, \quad p'_{10} = p_{10}, \quad p'_{01} = p_{11}, \quad p'_{11} = p_{01}.$$

Three-point phase known crosses (in which allelic combinations across loci are present together on the same chromosome) have been used for decades to order loci in experimental organisms, without any explicit model assumptions. This works because, under very general conditions, the smallest of the four probabilities ($p_{i_1 i_2}$) corresponds to the event of double recombination across two consecutive intervals when the loci are correctly ordered. For example, if the correct order is $O : \mathcal{A}$–$\mathcal{B}$–$\mathcal{C}$, then (assuming no chromatid interference)

$$p_{11} \leq p_{10}, p_{01} \leq p_{00}.$$

If, on the other hand, $O' : \mathcal{A}$–$\mathcal{C}$–$\mathcal{B}$ is the correct order, but we have written our probabilities relative to O, then $p'_{11} = p_{01}$ will be the smallest probability. It follows that, with sufficiently large samples of data, any set of loci can be ordered by inspection, with only a small chance of error. Naturally this is also possible using only the pairwise recombination fractions, but that would take more data to achieve the same level of confidence in the ordering. More generally, it is possible to show that, under the assumption of NCI, a multipoint recombination probability decreases, or at least does not increase, when any nonrecombinant interval is changed to recombinant status; see Speed *et al.* (1992).

1.2.6   Genetic Mapping for Multiple Markers

Although inefficient from the statistical viewpoint, three or more loci can be mapped using only two-point data, since linear maps are determined by pairwise distances. When there are plenty of data, such as with Drosophila, multipoint analyses may be unnecessary. However, in most contexts, data are scarce. In such cases, multipoint linkage analysis can be viewed as an attempt to make more efficient use of recombination data to further the aims of linkage analysis; see Lathrop *et al.* (1984) and Thompson (1984).

Multipoint linkage analyses make fuller use of available data, and can achieve greater precision or power. They are more complex than two-point analyses in several important ways. First, they require the specification of an order for the loci. Second, they require the specification of a joint distribution for all possible recombination patterns: for n loci, there are 2^{n-1} such patterns (including the parental one). Third, from the perspective of parametric statistical inference, joint distributions over recombination patterns corresponding to distinct orderings of the loci define noncomparable statistical models. Most of the difficulties of multipoint linkage analysis stem from these facts, particularly the rate of increase of the number of orders or patterns with the number of loci. When linkage analysis is being done using pedigree data, the size (number of individuals) and complexity (presence of one or more loops) of the pedigrees are additional limiting factors.

At the initial stage of genetic mapping, linkage groups have to be defined. Two markers are in linkage if the recombination fraction between them is less than $\frac{1}{2}$. A linkage group is defined as a set of markers where each marker is linked to at least one other marker in the same set. With enough markers covering the genome, each linkage group will correspond to a chromosome. However, for three markers $\mathcal{A}$, $\mathcal{B}$, and $\mathcal{C}$, it is possible that $\mathcal{A}$ and $\mathcal{B}$ are genetically linked, $\mathcal{B}$ and $\mathcal{C}$ are genetically linked, and yet the recombination fraction between $\mathcal{A}$ and $\mathcal{C}$ may be approaching $\frac{1}{2}$ if they are sufficiently far apart from each other on a chromosome. Although linkage groups have been well defined for humans and some experimental organisms, linkage group construction remains the critical first step for many organisms at the early stage of genetic mapping.

To define whether two markers are in linkage is to test whether the recombination fraction between these two markers is less than $\frac{1}{2}$. This hypothesis testing problem can be carried out using the likelihood ratio test; see Ott (1999). The LOD (log-odds) score is often used to assess the evidence for linkage. It differs from the usual likelihood ratio statistic by a constant factor and is defined as

$$\text{LOD} = \log_{10} \frac{L(data|r)}{L\left(data|r = \frac{1}{2}\right)}.$$

A LOD score of 3 has been used as the threshold for linkage testing. The justification of this threshold is discussed by Ott (1999) and Risch (1991).

After linkage groups are defined, the next task is to order genetic markers within each group. The locus ordering problem resembles the traveling salesman problem (TSP) widely discussed in the field of combinatorial optimization, (see Johnson, 1990), in which there are a large number of discrete states, each of which can be assigned a numerical value by a cost or objective function. The calculation of the objective function can depend either on information from pairwise data (e.g. pairwise LOD scores) or on joint genetic information (e.g. multipoint LOD scores, discussed later). For example, Speed *et al.* (1992) showed that, under the assumption of NCI, a given order imposes linear constraints among

multilocus recombination probabilities. Maximum likelihood under these constraints for each order can be used as the objective function.

With n markers, the ideal ordering approach would be to compute the objective function for each of the $\frac{1}{2}n!$ orders, and then to rank the orders, choosing the one with the largest objective function as the best order. With a few markers, all possible orderings can be considered. However, this quickly becomes impossible with many genetic markers. There is no evidence to suggest that a method exists that is generally better than choosing that order which maximizes the likelihood of the data using a suitable recombination model, at least not when the calculation of the likelihoods corresponding to each of the $\frac{1}{2}n!$ distinct orders is possible. The Poisson or no-interference model is the one typically used in this context. Although there does not appear to be a systematic study of this issue, the available evidence suggests that only small gains in the efficiency of ordering loci are to be found by using a more suitable model when interference exists; see Lathrop *et al.* (1984); Bishop and Thompson (1988); Goldgar and Fain (1988); Speed *et al.* (1992); and Goldstein *et al.* (1995) for related results. Different heuristic ordering strategies were reviewed in Weeks (1991), and more recent development can be found in Mester *et al.* (2003); York *et al.* (2005); and Tan and Fu (2006), among others.

In our previous discussion on genetic distance estimation from two-point or three-point genetic data, we described how map functions can be used to estimate genetic distances. However, when there are more than three markers, the multilocus recombination probabilities cannot be uniquely determined from the map function. A crossover process model is needed to derive joint multilocus recombination probabilities. Several point process models (Fisher *et al.*, 1947; Karlin and Liberman, 1979; Risch and Lange, 1979; King and Mortimer, 1990; Fujitani *et al.*, 2002) have been proposed to incorporate crossover interference in modeling the crossover process. The first satisfactory class of recombination models were the chi-square renewal process models discussed by Fisher and his students and colleagues (Fisher *et al.*, 1947). Bailey (1961) gave a good overview of this research. The simplest of these joint probabilities is too complex to be given here, and this is probably the reason why this class of models has not been used with human data until recently (Lin and Speed, 1996; Broman and Weber 2000; Browning, 2003). The chi-square model has been extended to the Poisson-skip model, which has the chi-square model as its special cases and can also incorporate negative crossover interference; see Lange *et al.* (1997). More recently, Stahl and colleagues have proposed that there exist two separate recombinational pathways, one with independent crossovers and one imposing crossover interference. Empirical data seem to be in favor of this two-pathway model for Arabidopsis (Copenhaver *et al.*, 2002) and humans (Housworth and Stahl, 2003). The major alternatives to the chi-square renewal models are due (independently) to Karlin and Liberman (1979) and Risch and Lange (1979), called *count-location* or *generalized no-interference* models, and the model of Goldgar and Fain (1988). For a review and comparison of different stochastic models for recombination, see McPeek and Speed (1995). One approach that does not depend on specific models for recombination was developed by Weinstein (1936) and was recently used to study human meiosis by Lamb *et al.* (1997); Zhao *et al.* (2000); and Li *et al.* (2001). The only assumption employed by this approach is that there is at most one chiasma in each marker interval, which is likely to be satisfied when many markers are studied on a chromosome. Although substantial number of additional parameters are involved, the results from Weinstein's approach can be used to assess the goodness of fit of different crossover process models and to

identify anomalous features of these models. Despite great efforts made to understand the molecular mechanisms leading to crossover interference, surprisingly little are known to date (e.g. Jones and Franklin, 2006).

Liberman and Karlin (1984) proposed to extend genetic map functions to four or more marker cases by embodying the assumption that, for a pair of noncontiguous intervals, the probabilities for joint recombination patterns across these intervals do not depend on the distance between the intervals, something which is not consistent with observations. Those map functions that can be extended to multilocus data through this approach have been (inappropriately) called *multilocus feasible* by Liberman and Karlin (1984). This criterion excludes many functions that were found to fit well to recombination data, such as the Kosambi map function proposed by Kosambi (1944). However, Zhao and Speed (1996) showed that there exist stationary renewal processes that give rise to most map functions in the literature (including the Kosambi map function). Therefore, these map functions are compatible with the analysis of multilocus data via this approach. Moreover, the interevent distributions of the stationary renewal processes corresponding to most map functions can be closely approximated by γ distributions.

We have discussed the cases where recombination or nonrecombination can be unambiguously scored. For human pedigrees, matters are more complicated at many levels. As with two-point linkage analyses, a major complication in multipoint linkage analyses can be the incompleteness of data. For example, there may be missing data due to some individuals not being typed. All data may be available, but phenotype may not determine genotype, as with dominant traits and other types of incomplete penetrance. Genotypes may be known, but haplotypes may not, that is, phase may be unknown. With known genotypes at n loci, there are 2^{n-1} possible haplotypes. While these incompleteness problems can slow down two-point analyses, they can quickly make exact multipoint analyses impossible. On the other hand, multipoint analyses can make use of data that cannot be used in two-point analyses, for example, when only uninformative data are available at a locus intermediate between two fully informative loci; see Lathrop *et al.* (1985) and Ott (1999). In multipoint linkage analysis using pedigree data, the feasibility of an exact analysis will depend on the number of loci, the size and complexity of the pedigrees involved, and the nature and extent of incompleteness in the data.

For pedigrees with simple structures or with a few genetic markers, the likelihood for a pedigree can be calculated exactly. The exact calculations can be divided into two types of algorithms: the Elston–Stewart algorithm (Elston and Stewart, 1971) and the Lander–Green algorithm (Lander and Green, 1987). Consider a pedigree with m individuals, where $\mathbf{x} = (x_1, x_2, \ldots, x_m)$ is the set of observed phenotypes for the pedigree. If G_i is the set of genotypes g_i compatible with the phenotype of person i, then the likelihood of the pedigree can be written as a sum of products:

$$\sum_{g_1 \in G_1} \cdots \sum_{g_m \in G_m} \prod_i P(x_i | g_i) \prod_{k \text{ founders}} P(g_k) \prod_{\{i_1, i_2, i_3\}} P(g_{i_1} | g_{i_2}, g_{i_3}),$$

where $\{i_1, i_2, i_3\}$ is an offspring–parent triad and i refers to the individuals with observed phenotypes. The probability $P(x_i | g_i)$ is the probability of an individual with genotype g_i having phenotype x_i. For codominant genetic markers, the probability is either 1 or 0. The founder probability $P(g_k)$ is a function of population gene allele frequencies. The Elston–Stewart algorithm can be viewed as a method for choosing an order to perform the iterated sum to minimize the total number of additions and multiplications. The number of

calculations in the Elston–Stewart algorithm scales linearly with the number of individuals in the pedigrees but exponentially with the number of markers.

The Lander–Green algorithm works as follows. Let $\mathbf{x}_L = (\mathbf{x}_{L_1}, \mathbf{x}_{L_2}, \ldots, \mathbf{x}_{L_N})$ denote the collection of phenotypes at locus i, and $\mathbf{g}_L = (\mathbf{g}_{L_1}, \mathbf{g}_{L_2}, \ldots, \mathbf{g}_{L_N})$ denote the collection of ordered genotypes at these loci for the individuals. Then the likelihood for the pedigree can be written as

$$\sum_{g_{L_1} \in L_1} \cdots \sum_{g_{L_N} \in L_N} \left[\prod_i P(x_{L_i}|g_{L_i}) \right] P(g_{L_N}|g_{L_{N-1}}, g_{L_{N-2}}, \ldots, g_{L_1}) \ldots P(g_{L_2}|g_{L_1}) P(g_{L_1}).$$

Assuming no crossover interference, then the likelihood is

$$\sum_{g_{L_1} \in L_1} \cdots \sum_{g_{L_N} \in L_N} \left[\prod_i P(x_{L_i}|g_{L_i}) \right] P(g_{L_N}|g_{L_{N-1}}) \ldots P(g_{L_2}|g_{L_1}) P(g_{L_1}).$$

The Lander–Green algorithm can be extended to incorporate the chi-square model in linkage analysis. The Elston–Stewart algorithm is mostly useful for large pedigrees but only a limited number of markers, whereas the Lander–Green algorithm is useful for multiple markers but is limited in the number individuals in each pedigree. This likelihood can be efficiently evaluated using the forward–backward algorithm of the hidden Markov model methodology. In addition, parameter estimates can be obtained using the expectation maximization (EM) algorithm. The number of operations scales linearly with the number of markers but exponentially with the number of individuals in the pedigree.

Both algorithms will fail if we have large pedigrees with many markers typed, and simulation methods to approximate the likelihood have been proposed by Thompson (1994) and Sobel and Lange (1996). In a recent review, Lin (1996) discussed both the sequential imputation approach of Irwin *et al.* (1994) and Markov chain Monte Carlo methods of Lin and Wijsman (1994).

1.2.7   Tetrads

Recall that tetrads and octads refer to the case where all four products of a single meiosis can be recovered together, such as in yeast and bread mold. Octads are generated from tetrads following one mitosis, and octads can usually be represented by tetrads, except when gene conversions occur. If we ignore the possibility of gene conversions, we need make no distinction between tetrads and octads in the following discussion, and refer to both as tetrads. Genetic studies using tetrad data are very valuable in studying the crossovers during meiosis. Compared to single-spore data, tetrad data have several advantages. First, with tetrad data chromatid interference and chiasma interference can be distinguished. Second, when chromatid interference is absent, chiasma interference can be detected with only two markers, whereas at least three markers are needed for single-spore data. Chiasma interference can even be detected with one marker in some studies. Third, the position of the centromere can be inferred. In some organisms, such as *Neurospora crassa*, the tetrads are produced in a linear order corresponding to the meiotic divisions; these are called *ordered tetrads*. In others, such as *Saccharomyces cerevisiae*, the tetrads are produced as a group without order, and are called *unordered tetrads*.

If a cross involves two strains differing with respect to two genes, geneticists distinguish three possible tetrad types: parental ditype with two representatives of each of the two parental types; nonparental ditype, where all four strands show recombined types; and tetratype, where two of the four strands show parental types and the other two strands show recombined types. For tetrad data involving two genetic markers, let P, T, and N denote the proportion of tetrads having parental ditype, tetratype, and nonparental ditype, respectively. The recombination fraction between the two markers can then be estimated by $N + \frac{1}{2}T$. Although the genetic distance can be estimated from this recombination fraction through a genetic map function, there is more information in the raw tetrad data. Under the assumption of NCI, given two chiasmata between two markers, the probabilities of observing parental ditype, tetratype, and nonparental ditype are $\frac{1}{4}$, $\frac{1}{2}$, and $\frac{1}{4}$, respectively. If there is a single chiasma between two markers, the resulting tetrads always have tetratype. Therefore, we can estimate the probability of having two chiasmata by $4N$, and the probability of having one chiasma by $T - 2N$. This leads to an estimated distance of $\frac{1}{2}(T + 6N)$ if we assume there are no more than two chiasmata between the two markers. This formula was first proposed by Perkins (1949).

Under the assumption of NCI, Mather (1935) showed that if $k \geq 1$ chiasmata occur between a pair of markers, then the conditional probabilities p_0^k, p_1^k, and p_2^k of observing a tetrad with parental ditype, tetratype, and nonparental ditype, respectively, are

$$p_0^k = \tfrac{1}{3} \left(\tfrac{1}{2} + (-\tfrac{1}{2})^k \right),$$

$$p_1^k = \tfrac{2}{3} \left(1 - (-\tfrac{1}{2})^k \right),$$

$$p_2^k = \tfrac{1}{3} \left(\tfrac{1}{2} + (-\tfrac{1}{2})^k \right).$$

For a given crossover process model, the above relations can be used to relate the probabilities of three tetrad patterns to the genetic distance between two markers. For example, under the Poisson model, $p_0 = \frac{1}{6}(1 + 2e^{-3d} + 3e^{-2d})$, $p_1 = \frac{2}{3}(1 - e^{-3d})$, and $p_2 = \frac{1}{6}(1 + 2e^{-3d} - 3e^{-2d})$, where p_0, p_1, and p_2 are the probabilities of parental ditype, tetratype, and nonparental ditype between two markers, respectively, and d is the genetic distance; see Haldane (1931).

One unique feature of ordered tetrad analysis is that there is information on centromeres. The distance between a single marker and its centromere can be estimated using data from a single marker. For marker $\mathcal{A}$ with alleles A and a inherited from two parents, there are six distinguishable configurations, as illustrated in Table 1.1. Because spindle–centromere attachment during meiosis is random (see Griffiths *et al.*, 1996), types 1 and 6 have equal

Table 1.1 Six distinguishable patterns for marker $\mathcal{A}$. Strands 1 and 2 are attached to one centromere and strands 3 and 4 are attached to the other.

Strand	S_1	S_2	S_3	S_4	S_5	S_6
1	A	A	A	a	a	a
2	A	a	a	A	A	a
3	a	A	a	A	a	A
4	a	a	A	a	A	A

probability because of random spindle–centromere attachment at the first meiotic division, whereas types 2–5 have the same probability because of random spindle–centromere attachment at the second meiotic division. Types 1 and 6 are called first-division segregation (FDS) pattern and types 2–5 are called second-division segregation (SDS) pattern (Griffiths *et al.*, 1996).

The probabilities of FDS and SDS can be related to the genetic distance between $\mathcal{A}$ and its centromere if a chiasma process model is specified. Let $S_{\mathcal{A}} = P(\text{SDS})$; then $S_{\mathcal{A}} = c_1 = 2d$ under the complete interference model, where c_1 denotes the probability of having one chiasma. For the Poisson model, $S_{\mathcal{A}}(d) = 1 - F_{\mathcal{A}}(d) = \frac{2}{3}(1 - e^{-3d})$. Several chiasma models and various map functions derived from these models were studied by Zhao and Speed (1998a). It was found that most map functions proposed in the literature can be well approximated by the map functions under the chi-square model. Centromeres can also be mapped with three markers on three different chromosomes using unordered tetrads, as shown by Whitehouse (1957). For three markers $\mathcal{A}$, $\mathcal{B}$, and $\mathcal{C}$, denote the frequencies of SDS for these three loci by x, y, and z. Then the probability of tetratype between $\mathcal{A}$ and $\mathcal{B}$ is $T_{\mathcal{AB}} = x + y - \frac{3}{2}xy$ when $\mathcal{A}$ and $\mathcal{B}$ are on different chromosomes. Similarly, $T_{\mathcal{AC}} = x + z - \frac{3}{2}xz$ and $T_{\mathcal{BC}} = y + z - \frac{3}{2}yz$. These three equations can be used to solve for three unknown parameters. For example,

$$x = \frac{2}{3}\left\{1 \pm \sqrt{\frac{4 - 6T_{\mathcal{AB}} - 6T_{\mathcal{AC}} + 9T_{\mathcal{AB}}T_{\mathcal{AC}}}{4 - 6T_{\mathcal{BC}}}}\right\}.$$

However, this method only has reasonable precision when at least two of the three loci are fairly close to their respective centromeres.

For a cross involving three markers $\mathcal{A}$, $\mathcal{B}$, and $\mathcal{C}$ on the same chromosome, if both marker intervals ($\mathcal{A}$–$\mathcal{B}$ and $\mathcal{B}$–$\mathcal{C}$) show tetratypes, there are three types that can be distinguished according to the pattern between $\mathcal{A}$ and $\mathcal{C}$: parental ditype, tetratype, and nonparental ditype (often called two-strand, three-strand, and four-strand doubles). Under the assumption of NCI, the ratio of these three types is $1:2:1$. A significant deviation from the expected ratio can be attributed to the presence of chromatid interference. Geneticists have examined this ratio in different organisms and, overall, found no consistent evidence against the NCI assumption; see Fincham *et al.* (1979). Although most studies on ordered tetrads and unordered tetrads used only three loci for the detection of chromatid interference, some information is lost when only the $1:2:1$ ratio is examined for each pair of marker intervals. Zhao *et al.* (1995b) derived a set of linear equality and inequality constraints on the probabilities of unordered tetrad patterns with an arbitrary number of loci under the assumption of NCI. For example, for two markers, NCI imposes that $p_0 \geq p_2$ and $p_1 \geq 2p_2$. Similar constraints were derived for ordered tetrads by Zhao and Speed (1998a). These constraints can be used to test the presence of chromatid interference without assuming any model for the chiasma process.

To perform genetic mapping using multiple markers simultaneously, we need to be able to evaluate the probability for any multilocus tetrad pattern under a given model for the chiasma process. Both the count-location model (Risch and Lange, 1983) and the chi-square model (Zhao *et al.*, 1995a; Zhao and Speed, 1998a) have been applied to analyze tetrad data. Detailed procedures can be found in these papers.

1.2.8   Half-tetrads

Half-tetrads can arise either from meiosis I or meiosis II nondisjunctions. The first well-studied half-tetrad data were attached-X chromosomes in Drosophila (Beadle and Emerson, 1935). Half-tetrads were also constructed using autosomes in Drosophila (Baldmin and Chovnick, 1967), and have been used in the study of many other organisms, including maize, potatoes, leopard frog, rainbow trout, salmonid fish, catfish, and zebrafish. In mammals, half-tetrads can be studied in the form of uniparental disomy (Robinson *et al.*, 1993), autosomal trisomies (Morton *et al.*, 1990), nondisjunction in ovarian teratomas (Eppig and Eicher, 1983), and PCR analysis of meiosis I products in individual secondary oocytes (Cui *et al.*, 1992).

Genetic mapping using genetic marker data from human nondisjunction data was discussed by Shahar and Morton (1986); Chakravarti and Slaugenhaupt (1987); Chakravarti *et al.* (1989); and Feingold *et al.* (2000). Map distances, as well as LOD scores for these distances, can be calculated from the observed patterns of nonreduction (heterozygous genotype) and reduction (homozygous genotype) of markers along the nondisjoined chromosome pair. Zhao and Speed (1998b) derived the general relationship between multilocus half-tetrad probabilities and multilocus ordered tetrad probabilities. These relationships can be used for likelihood analysis of half-tetrads, and the same methods have been extended to study uniparental disomy and trisomy.

1.2.9   Other Types of Data

Genetic maps can also be constructed using other types of data, including organisms with more than two copies of chromosomes (Bailey, 1961; Wu *et al.*, 2001; Wu and Ma, 2005; Luo *et al.*, 2006), bacterial and bacteriophage (Stahl, 1979), and recombinant inbred strains (Green, 1981). Genetic background and statistical methods for these types of data can be found in these references.

1.2.10   Current State of Genetic Maps

Statistical methods for establishing linkage and estimating recombination fractions in humans were pioneered by Bernstein (1931), and developed intensively by the British school centered around Fisher and Haldane during the 1930s and 1940s. The first human linkage to be established was between the X-linked genes for hemophilia and red-green color blindness by Bell and Haldane (1937); two decades later, Mohr (1954) found linkage between two blood groups on an autosome. Early ways of establishing linkage were based upon what are now known as *score tests*, and a method using sib-pairs, while likelihood methods quickly came into use for estimation. Several methods of correcting for sampling biases were also developed. All of these ideas continue to be important today.

A major limitation in human genetic mapping before the 1980s was the shortage of genetic markers. Markers are Mendelian factors, often but not necessarily genes in the modern sense, which segregate in human populations. For many years, human genetic markers were mainly blood cell antigens and proteins. They provided the basis of human genetic maps, and were a framework within which new genes could be mapped. Despite there being a fair number of known genetic diseases and Mendelian markers such as those just mentioned, the human genetic map was still very sparse in the 1970s. However, it was during this period that the first good algorithms for calculating probabilities over pedigrees were developed, motivated initially by problems in genetic counseling, and

later by the desire to carry out segregation analyses on large pedigrees. Programs based upon these algorithms continue to play a very important role in modern genetic mapping.

Around 1980, the idea of treating DNA sequence differences as genetic markers arose. It was quickly developed, and the present wide availability of what are collectively known as *molecular markers* has revolutionized human genetic mapping, and that of many other organisms. Development of the centre-d'Étude-du-polymorphisme-humain (CEPH) reference families (Dausset *et al.*, 1990) was a critical step in genetic map construction. The first fairly complete human map was published in 1987, and consisted of about 400 restriction fragment length polymorphisms (RFLPs), mapped using DNA from a panel of 21 three-generation families from the CEPH consortium (Donis-Keller *et al.*, 1987). In order to build this map, new multilocus methods for mapping were developed. The mapping of many loci simultaneously was first carried out by Fisher (1922), but it was only following the availability of cheap, fast computers and suitable algorithms that this idea became widely adopted.

At the time the 1987 map was being developed, the PCR was beginning to revolutionize molecular genetics. Several new types of genetic markers have been developed using PCR, with acronyms such as RAPD (random amplified polymorphic DNAs), STRP (short tandem repeat polymorphism), and SSCP (single-strand conformation polymorphism), and the latest genetic maps include several thousand readily assayed markers. It is now possible to carry out genome-wide scans, effectively searching the entire genome for linkage between a trait and markers. Searches of this kind have been remarkably successful in locating genes contributing to a wide range of disease and other phenotypes. They also raise many new statistical questions, especially as interest now focuses on complex and quantitative traits. Such traits are believed to be influenced by a number of genes, as well as the environment, and mapping these genes with available data remains a challenging task.

In recent genetic maps constructed from CEPH pedigrees, more than 8000 STRPs were mapped to the human genome by Broman *et al.* (1998). This map not only provides guidelines for disease gene mapping, but also allows a very detailed comparison between male and female genetic maps (Broman *et al.*, 1998) and the study of crossover interference (Broman and Weber, 2000). More recently, Kong *et al.* (2002) estimated recombination rates across the human genome through 5136 microsatellite markers typed for 146 Icelandic families, with a total of 1257 meiotic events. They detected 'systematic differences in recombination rates between mothers and between gametes from the same mother, suggesting that there is some underlying component determined by both genetic and environmental factors that affects maternal recombination rates'. In Figure 1.2 we show some features of portions of several genetic maps for human chromosome 21. Most recently, there have been extensive studies of single nucleotide polymorphisms (SNPs) in the human genome. The current map contains more than 10 million SNPs (`www.ncbi.nlm.nih.gov/SNP`) and maps for other types of polymorphisms are also being developed, e.g. the INDEL map (Mills *et al.*, 2006).

Genetic maps for pigs, cows, tomatoes, rice, pine trees and many other species of commercial or scientific interest have followed quickly behind the human maps.

1.2.11 Programs for Genetic Mapping

All the programs described here can be found in the website maintained by the Ott group at Rockefeller University, at `http://linkage.rockefeller.edu/soft/list`.
Figure 1.2 Portion of human chromosome 21 genetic map. [Source: `www.gdb.org/hugo/chr21/geneticMaps.html.`]

`html`. As discussed above, algorithms for carrying out multipoint linkage analysis with human (and other) pedigree data are of two kinds: those based upon the Elston and Stewart (1971) approach, using what is known as *peeling*; and those based upon the Lander and Green (1987) hidden Markov model formulation. Each of these classes of algorithms has its strengths and weaknesses, and there are problems that cannot be solved exactly with either of them. The Elston–Stewart approach underlies most of the algorithms discussed in Terwilliger and Ott (1994). For a recent improvement of the implementation of these algorithms, see O'Connell and Weeks (1995). A suite of genetic mapping programs that have gained much popularity uses the basic Lander–Green algorithm in a number of different human linkage problems. These include MAPMAKER for crosses among inbred strains (Lander *et al.*, 1987), analyses with sib-pairs (Kruglyak and Lander, 1995), the analysis of recessive traits with nuclear families (Kruglyak *et al.*, 1995), and multipoint linkage with many markers for general pedigrees of moderate size (Kruglyak *et al.*, 1996). Similar statistical methods underlie the program CRI-MAP, which is most suitable for CEPH-type pedigrees (Green, 1988). MultiMap is another program that assists with map construction (Matise *et al.*, 1994). It consists of framework construction and comprehensive map construction. MultiMap recently incorporated the Gene Mapping System algorithm (Lathrop *et al.*, 1988; Marinov *et al.*, 1999), which is based on identifying and permuting linkage groups within an initial order of all loci. Other programs include Map/Map+ for map integration (Morton *et al.*, 1992), JoinMap for plants (Stam, 1993), and OUTMAP for outbred populations (Ling, 2000).

When exact linkage analysis methods fail because of time or space constraints, Monte Carlo methods may be used. At present these are more research tools than approaches suitable for routine use, but they are developing rapidly, and should become more widely used in the near future. Some of these simulation methods have been implemented in SIMWALK (Sobel and Lange, 1996) and Morgan (Thompson, 1994).

1.3   PHYSICAL MAPS

Physical mapping is the process of determining the locations of 'sites' such as restriction sites (4–8 bp), STSs (20–30 bp), and cloned fragments (kilobase to megabase) on a larger DNA molecule or a chromosome. Among other things, maps of such sites are helpful, if not essential, for cloning genes and for sequencing large stretches of DNA, and have been very widely used in recent years. To quote from an early successful paper in the area, Olson *et al.* (1986, p. 7830):

> a strong case can be made for the value of constructing physical maps of the genomes of intensively studied organisms. We expect the main value of these maps to lie in facilitating the organization of molecular genetic information. Just as conventional cartography provides an indispensable framework for organizing data in fields as disparate as demography and geophysics, it is reasonable to suppose that 'DNA cartography' will prove equally useful in organizing the vast quantities of molecular genetic data that may be expected to accumulate in the coming decades. Furthermore, the principal by-product of these projects – global clone collections that are cross-indexed to the physical maps – could be expected to improve the efficiency of subsequent structural and functional studies of local regions.

The two most common approaches to physical mapping are termed top-down, producing a macrorestriction map, and bottom-up, resulting in a contig map. With either strategy, the maps represent ordered sets of DNA fragments that are generated by cutting genomic DNA.

However, the first physical maps were made from microscope images, and although their construction and interpretation involve no statistics, we discuss them briefly for completeness.

1.3.1 Polytene Chromosomes

Polytene chromosomes are many-stranded chromosomes resulting from repeated chromosomal replication, without the subsequent separation of sister chromatids. Up to 1024 chromatids can be present, giving giant chromosomes visible under a microscope in nondividing cells. Most widely known are those of the salivary glands of insects of the order Diptera, and a classic reference to the polytene chromosomes in the salivary glands of *Drosophila melanogaster* is Bridges (1935).

After appropriate staining, the Drosophila polytene chromosomes have distinctive banding patterns, which have been cataloged, and have proved invaluable for localizing structural alterations such as deletions, and for use with more recent *in situ* hybridization techniques. For further details, please refer to Saura *et al.* (1997) and FlyBase (`http://flybase.bio.indiana.edu`).

1.3.2 Cytogenetic Maps

A closely related class of physical maps are the familiar cytological maps whose human versions are frequently represented in ideogrammatic form (see Figure 1.1). Such maps were originally derived in a variety of organisms by associating mutant phenotypes with chromosomal defects visible by direct microscopic examination. In this way, genes can be physically located on chromosomes, at least to a low level of resolution.

In the late 1960s, staining techniques were discovered, which led quickly to the adoption of banding patterns of human chromosomes now widely used; see, for example, Vogel and Motulsky (1997). This field has evolved greatly in recent years with the advent of fluorescent in situ hybridization (FISH) and multiple coloring of chromosomes; see Trask (1998).

1.3.3 Restriction Maps

A *restriction site* is the location of a sequence, typically 4–6 bp long, where a particular restriction enzyme will cut DNA. Isolated from various bacteria, restriction enzymes recognize short DNA sequences and cut DNA molecules at specific sites in the sequence. Ignoring, for the moment, variations from uniform base composition, restriction enzymes with 4 bp recognition sites will yield pieces – termed *restriction fragments* – on average about 256 bp long, while those with 6 or 8 bp recognition sites will yield pieces of average length 4 or 64 kb, respectively. Since hundreds of different restriction enzymes have been characterized, and they can be used together, DNA can now be cut with them into fragments of many different sizes in many different ways. A restriction map describes the order and distance between restriction sites.

In *top-down mapping*, a chromosome is cut into large DNA fragments using restriction enzymes having rare restriction sites. The fragments are separated by size and assigned to regions by hybridization with genetically or cytogenetically mapped DNA probes. Then

the fragments are assembled into contiguous blocks, resulting in a macrorestriction map. Such fragments may average 1 Mb in size. For a finer map, the ordered fragments may be taken one at a time and dissected with more frequently cutting restriction enzymes.

The simplest way to construct a restriction map is to compare the fragment sizes produced when a DNA molecule is digested with two different restriction enzymes; see Waterman (1995, Chapters 2–4) for a discussion of some of the computational issues here. Restriction maps are easy to generate if there are relatively few cut sites with the enzymes being used, but most enzymes cut frequently, generating a large number of small fragments (from less than 100 bp to 1 kb). Therefore, such mapping is more applicable to small molecules, such as viral and organelle genomes, or to genomic DNA that has already been cloned.

A major advantage of a restriction map (like that in Figure 1.3) is that accurate lengths are known between sets of reference points. We can preserve an overview of the target and we can reach a nearly complete map relatively quickly. The disadvantage of most restriction mapping efforts is that they do not produce the DNA in a convenient form. This approach yields maps with more continuity and fewer gaps between fragments than contig maps, but map resolution is lower and may not be useful in finding particular genes. Currently, this approach allows DNA pieces to be located in regions measuring from about 0.1 Mb to 1 Mb.

1.3.4   Restriction Mapping via Optical Mapping

Optical mapping is a single-molecule approach for the construction of ordered restriction maps developed by Schwartz *et al.* (1993). It uses light microscopy to directly image individual DNA molecules, which are bound to specially derivatized surfaces and then cleaved by restriction enzymes. Cleaved fragments retain their original order, and restriction sites are flagged by small, visible gaps. Optical mapping solves the problem of determining fragment order.

The statistical analysis of optical mapping data is relatively new and quite complex, so we do not attempt to summarize it here. A first solution to the problem can be found in Anantharaman *et al.* (1997). These authors take a Bayesian approach, constructing a prior model for an ordered restriction map and a probability model for restriction map data from single molecules. They then approximate the mode of the posterior distribution of the parameters. Orientation, false cuts, and sizing errors are among the issues to be dealt with. A second, hierarchical Bayes approach to the same problem using reversible-jump Markov chain Monte Carlo can be found in Lee *et al.* (1998). Most recently, sequence assembly methods have been adapted to optical mapping (Valouev *et al.*, 2006). Finally, there have been several successful applications of the method to a whole genome; for example, see Lai *et al.* (1999) and Reslewic *et al.* (2005).

1.3.5   Ordered Clone Maps

Clones – more fully, cloned DNA fragments – are generated by first breaking a large number of identical chromosomes into fragments, either by physical means such as sonication, compression, or irradiation, or by chemical means, typically complete or partial digestion with one or more restriction enzymes. Individual fragments (inserts) of appropriate sizes are then joined to another DNA molecule (the vector) and the result is incorporated into a (host) organism such as *Escherichia coli* or yeast. The average
Figure 1.3   Restriction map of cosmid clones. [Source: Lawrence Livermore National Laboratory.]

size of the insert varies widely among different hosts and incorporation methods. Yeast artificial chromosomes (YACs) in yeast may have DNA fragments ranging from 100 kb to 1 Mb. Cosmids in *E. coli* may have fragments ranging from 35 to 45 kb, while the now widely used bacterial artificial chromosomes (BACs) have inserts of sizes in

the range 100–200 kb. The hosts are separated from each other and allowed to grow into colonies, with the fragment in each host being replicated along with the host's DNA during cell divisions. After enough divisions, each host colony can be harvested, resulting in a library of cloned DNA fragments, where each fragment is present in large enough quantities to permit isolation and purification for subsequent biochemical analyses.

The bottom-up approach to physical mapping is usually carried out by breaking up the DNA molecule of interest, cloning selected fragments, and subjecting each clone to one more experiments – restriction digestions, hybridizations or PCR assays with unique or repetitive probes, or sequencing – to obtain what is called a *fingerprint* of the clone. These fingerprints are then used to solve the combinatorial puzzle of inferring the arrangement of clones along the molecule with the help of these data. The ordered fragments form contiguous DNA blocks, which are called *contigs*. Clone ordering usually begins by comparing clones to each other, in order to determine the strength of evidence that any pair of clones overlap, and it is here that statistical ideas enter.

Currently, clone libraries ordered in this way have inserts that vary in size from a few thousand base pairs up to 1 Mb. Contig maps thus consist of a linked library of overlapping clones representing a complete chromosomal segment. An advantage of this approach is the accessibility of these clones to other researchers. While useful for finding genes localized to a small region (under 2 Mb), contig maps can be difficult to extend over large stretches of a chromosome because not all regions are clonable.

The statistical analysis of overlap and the estimation of distances will differ somewhat with different fingerprinting techniques. In a hybridization experiment, the fingerprint will be the list of probes that hybridize to the clone; with restriction digestion the fingerprint is a list of observed fragment sizes resulting from the digestion of the clone, while with STS content mapping (see below) the fingerprint consists of an enumeration of the STSs found to be located on that clone. An example of an STS-based clone map is given in Figure 1.4.

1.3.6   Contig Mapping Using Restriction Fragments

One approach, due by Coulson *et al.* (1986), begins with the calculation, for each pair of clones, of the probability of the observed level of matching of fragment sizes, up to a prescribed tolerance, arising by chance, i.e. when the clones do not in fact overlap. This probability – essentially a *p*-value, but called *the probability of coincidence* – is used for selecting possibly overlapping clone pairs. Clones are then assembled into contigs using a variety of *ad hoc* rules based on these probabilities. For details, we refer to Sulston *et al.* (1988). A modified version of this procedure is embodied in the program FPC (Soderlund *et al.*, 1997), which was widely used in preparing physical maps for human genome sequencing.

An alternative approach involving a likelihood ratio or Bayes posterior odds was initiated by Michiels *et al.* (1987), and then more fully developed by Branscomb *et al.* (1990). We sketch it now, referring the reader to Nelson and Speed (1994a) and Nelson *et al.* (1997) and the references cited there for fuller details of the trinomial model.

For each clone in a library of N clones, we create DNA fingerprint data by restriction digestion, electrophoresis, and sizing. This consists of a list of fragment lengths. For a particular length l, there are four patterns when we compare two clones: (1,1) if a fragment of length l is observed in both clones; (1,0) if a fragment of length l is observed in the first clone but not the second one; (0,1) if a fragment of length l is observed in
Figure 1.4 STS map of portion of human chromosome 21. [Source: Mapview at `www.gdb.org/hugo/chr21/`.]

the second clone but not the first one; and (0,0) if a fragment of length l is observed in neither clone. The probability of each outcome under a simple randomness model can be approximated by

$$
\begin{aligned}
p_{00} &= q^{L_1 + L_2 - \theta}, \\
p_{01} &= q^{L_1}(1 - q^{L_2 - \theta}), \\
p_{10} &= q^{L_2}(1 - q^{L_1 - \theta}), \\
p_{11} &= 1 - q^{L_1} - q^{L_2} + q^{L_1 + L_2 - \theta},
\end{aligned}
$$

where L_1 and L_2 are the lengths of the two clones, θ is the overlapping amount, $q = \mathrm{e}^{-\lambda_l}$, and λ_l is the intensity for fragments of size l. When all the clones are of the same size, $p_{01} = p_{10}$ and the data can be reduced to a trinomial variable $(n_{00}, n_{01} + n_{10}, n_{11})$. To decide whether two clones overlap, the likelihood ratio test value $L(\theta)/L(\theta = 0)$ can be calculated. Alternatively, with prior information on the θ, posterior odds can be calculated to decide if two clones overlap. The above simple assumptions can be loosened to allow different intensities and errors in fragment size detections. With pairwise similarity measures such as the log posterior odds for overlap, clustering algorithms can be used to build contigs.

1.3.7   Sequence-tagged Site Maps

An STS is defined by two short sequences, each typically $20-25$ bp in length, that have been designed from a region of sequence that appears as a single copy in the human genome. These sequences can act as primers in a PCR assay to score for presence or absence of the site in any DNA sample. One of the aims of the human genome project was to build a high-resolution RH map using STSs as landmarks throughout the human genome. Geneticists would then be able to use the map to isolate genes through nearby landmarks. Sequencers would be able to decide where to prepare clones for the actual sequencing. In addition, the STSs would become part of a common set of markers that can be screened against maps created using different mapping techniques, helping to integrate the efforts of mapping teams worldwide.

For STS content mapping, the data can be summarized as an incidence matrix with N rows corresponding to N clones and M columns corresponding to M STSs. The (i, j)th entry is 1 if the jth STS hits the ith clone, and is 0 otherwise. If there are no errors, the problem can be solved by testing whether this incidence matrix has the consecutive 1s property. An incidence matrix has the consecutive 1s property for rows if its columns can be permuted so as to make all the 1s in each row appear consecutively. Booth and Lueker (1976) described linear-time algorithms for determining if a matrix has the consecutive 1s property, and they provided a compact description of all possible consistent permutations in the form of a PQ-tree. Therefore, the problem is completely solvable in linear time if the data are error-free.

However, real data sets are never error-free, and the consecutive 1s property no longer holds. Before we discuss various algorithms in the literature, most of which use combinatorial approaches to optimize an objective function of orderings, we consider a likelihood-based approach for STS ordering following Yeh (1999). For a pair of STSs (s_i, s_j), distance D apart, we can count the number of clones retaining both STSs (n_{11}),

the first STS but not the second STS (n_{10}), the second STS but not the first STS (n_{01}), and neither STS (n_{00}). Define the set of coretention probabilities for (s_i, s_j) as $\mathbf{p} = (p_{11}, p_{10}, p_{01}, p_{00})$, where p_{11} is the probability that a clone contains both s_i and s_j, p_{10} is the probability that it retains s_i only, p_{01} is the probability that it retains s_j only, and p_{00} is the probability that is retains neither. Assuming clones are random line segments of length L on the chromosome (genome) of size G, the coretention probabilities are

$$p_{11} = l - d,$$
$$p_{10} = d,$$
$$p_{01} = d,$$
$$p_{00} = 1 - l - d,$$

when $d < l$, and

$$p_{11} = 0,$$
$$p_{10} = l,$$
$$p_{01} = l,$$
$$p_{00} = 1 - 2l,$$

when $d \geq l$, where l is the normalized clone length L/G and d is the normalized STS distance D/G. These probabilities allow us to evaluate the likelihood for each ordering of the STSs. The estimated order is the one that maximizes the overall likelihood. Thus the STS ordering problem is equivalent to a TSP with the STSs as vertices and the pairwise likelihoods as the distances. Using arguments similar to those in marker ordering in genetic mapping (Speed *et al.*, 1992); Yeh (1999) showed that this procedure will recover the true order with probability 1 when the number of clones is large. The objective function here is the same as that discussed by Green and Green (1991), which is the first major paper on this topic, and which describes in outline the widely used program SEGMAP. However, that program goes considerably further, including the solution of a linear programming problem to find bounds on the distance between any pair of points in the map (STSs or clone ends).

In addition to obtaining distance estimates among the STSs, this likelihood approach is robust when the error rates are not too high. Mott *et al.* (1993) used simulated annealing to minimize the total discrepancy among adjacent STSs, where the discrepancy between two STSs a and b is defined as

$$d(a, b) = 1 - \frac{\#(\text{clones positive for } a \text{ and } b)}{\#(\text{clones positive for } a \text{ or } b)}.$$

Alizadeh *et al.* (1995) used the TSP algorithms to minimize the total Hamming distance of the clone-probe incidence matrix, which corresponds to the number of gaps of the probe ordering. They also proposed an alternative objective function based on a weighted sum of the number of chimeric clones, the number of false positives, and the number of negatives. Christof *et al.* (1997) formulated the problem as a weighted betweenness problem, assuming the probes are from both ends of all clones. Alizadeh *et al.* (1995) and Nelson *et al.* (1997) described statistical procedures for evaluating overlapping configurations involving more than two clones.

Once STSs are ordered, clones are ordered with respect to the probes by maximizing a measure of fit between the probe data for that clone and the list of ordered probes. Unlike physical maps constructed from restriction maps, the map constructed using STS content mapping would not be tied to a particular set of clones, and thus could be used to order any subsequently generated library.

In the early 1990s, considerable effort was put into the generation of clone contig maps, using STS screening. The major achievement of this phase of physical mapping was the publication of a clone contig map of the entire genome, consisting of 33 000 YACs containing fragments with an average size of 0.9 Mb (Cohen *et al.*, 1993).

The combined STS maps now include positions for almost 7000 simple sequence length polymorphisms that have already been mapped onto the genome by genetic means. As a result, the physical and genetic maps can be directly compared, and the clone contig maps that include STS data can be anchored on to both maps.

1.4   RADIATION HYBRID MAPPING

A radiation hybrid is a rodent cell that contains fragments of chromosomes from a second organism. The technology was first developed in the 1970s by Goss and Harris (1975; 1977) and reintroduced by Cox *et al.* (1990) based on the observation that exposure of human cells to X-rays causes the chromosomes to break up randomly into fragments, and these chromosome fragments can then be propagated if the irradiated cells are fused with nonirradiated hamster or other rodent cells. A routine selection process is used to screen out hamster cells without human chromosome fragments. In its simplest form, a single human chromosome is exposed to a radiation source. For the whole-genome radiation mapping whole genome radiation hybrid (WG-RH), a normal diploid human cell is used as the donor by Walter *et al.* (1994). The WG-RH mapping has the advantage that pieces of many different human chromosomes may be contained in the same hybrid and so a single panel of WG-RHs can be used to map any region of the human genome. Detailed mapping of the entire human genome can be accomplished with fewer than 100 WG-RHs. The resulting panels can be screened for human-specific markers. Data for RH mapping also can be summarized in an incidence matrix like the one for STS content mapping.

Like STS content mapping, the basic premise of RH mapping is that the closer two loci are on the human chromosome, the less likely it is that they will be broken by irradiation. The retention patterns from the various hybrid clones give clues for determining locus order and for estimating the distance between adjacent loci for a given order.

One criterion that quantifies this heuristic is the minimum obligate breaks criterion. For a given order of the loci, we can count the number of changes from 1 to 0 and from 0 to 1. If we sum these changes over all the clones, we get the total number of obligate breaks. The objective is to find the order that minimizes the total number of obligate breaks across all clones. The advantage of the minimum breaks criterion is that it does not depend on any assumptions about how breaks occur and how fragments are retained. Assuming the same retention rate, one can again use arguments similar to those in marker ordering for genetic mapping and show that this criterion is strongly statistically consistent (Lange, 1997, Chapter 11).

1.4.1 Haploid Data

We now turn to probabilistic models for RH mapping. In RH mapping, the distance between sites can be expressed in units (centirays) representing the percentage probability of separation by breakage with a given irradiation dosage. This gives a better measure of physical distance than genetic distance, because the vulnerability to breakage seems to be fairly constant along the whole length of the chromosome. Therefore, in models for RH mapping, the breakage process along the chromosome can be modeled as a Poisson process (Cox *et al.*, 1990). For any two loci, the probability of at least one break θ and the physical distance δ are related by

$$1 - \theta = e^{-\lambda\delta},$$

where the value of λ depends on the irradiation dose. This function is similar to the Haldane map function used in genetic mapping. Note that the parameters δ and λ cannot be separated from the estimation. For RH mapping, in addition to considering breakage, we also need to take retention into account. It is normally assumed that different segments are retained independently; however, different fragments may be allowed to have different retention probabilities.

For two markers, there are four possibilities for a haploid RH: (1,1) when both markers are present; (1,0) when the first marker is present but not the second marker; (0,1) when the second marker is present but not the first one; and (0,0) when neither marker is present. The probabilities for these four patterns are as follows:

$$p_{11} = \theta P_A P_B + (1 - \theta) P_{AB},$$
$$p_{10} = \theta P_A (1 - P_B),$$
$$p_{01} = \theta P_B (1 - P_A),$$
$$p_{00} = \theta (1 - P_A)(1 - P_B) + (1 - \theta)(1 - P_{AB}),$$

where P_A, P_B, and P_{AB} are the probabilities of a hybrid retaining a fragment with marker A only, with marker B only, and with both markers A and B, respectively (Cox *et al.*, 1990). In the general case of many markers, Boehnke *et al.* (1991) derived the probability for a hybrid with any retention pattern.

Note that when $P_A = P_B = P_{AB} = r$ in the above equations, the probabilities reduce to

$$p_{11} = \theta r^2 + (1 - \theta) r,$$
$$p_{10} = \theta r (1 - r),$$
$$p_{01} = \theta r (1 - r),$$
$$p_{00} = \theta (1 - r)^2 + (1 - \theta)(1 - r).$$

Therefore, the probabilities are simply a reparametrization of those we derived when we discussed ordering STSs: simply put $l = 1 - r$ and $d = \theta r (1 - r)$.

1.4.2 Diploid Data

For the WG-RH mapping, two chromosomes instead of one, are involved. For a pair of markers, we have the same four possibilities for an RH. Assuming the same retention rate
Figure 1.5 RH map of part of human chromosome 21. [Source: Mapview at `www.gdb.org/hugo/chr21/`.]

r for all fragments, the probabilities for the four possibilities are

$$p_{11} = 1 - 2(1 - r)^2 + [(1 - r)(1 - \theta r)]^2,$$

$$p_{10} = (1 - r)^2 - [(1 - r)(1 - \theta r)]^2,$$

$$p_{01} = (1 - r)^2 - [(1 - r)(1 - \theta r)]^2,$$

$$p_{00} = [(1 - r)(1 - \theta r)]^2.$$

For an arbitrary number of markers, hidden Markov models were used by Lange *et al.* (1995) to calculate the probability of any retention pattern.

When the retention probabilities are allowed to vary for different fragments, the number of parameters involved increases quadratically with the number of markers examined. Although a number of computational methods can be used for such problems (see Boehnke *et al.*, 1991; Leach and O'Connell, 1995), this raises a serious optimization problem. If the retention rate is assumed to be constant, the calculation can be simplified. Jones (1997) found that adopting simple models generally does not affect the ability to recover the true locus order, but affects the estimation of distances among the loci.

Bayesian methods have also been developed for RH mapping by Lange and Boehnke (1992) and Guerra *et al.* (1992). Tibshirani *et al.* (1999) proposed to maximize a pseudo-likelihood based on information from all marker pairs and then to use multidimensional scaling to provide starting positions for the markers. Lange (1997) has an excellent chapter on RH mapping, and also recommended is the review by Jones (2000). Other methods include Agarwala *et al.* (2000); Ben-Dor *et al.* (2000); and Ivansson and Lagergren (2004). Hitte *et al.* (2003) compared the performance of two methods for RH map constructions.

There are three human radiation hybrid panels available: Genebridge4 (93 hybrids), Stanford G3 (83 hybrids), and Stanford TNG4 (90 hybrids). These panels differ in radiation dose and retention probabilities. RH panels have also been made for mouse, rat, cow, pig, zebrafish, dog, cat, baboon, and horse. More detailed information can be found at `http://compgen.rutgers.edu/rhmap/`. An example of the RH maps are given in Figure 1.5.

1.5   OTHER PHYSICAL MAPPING APPROACHES

In *directed mapping* (see Palazzolo *et al.*, 1991; Mizukami *et al.*, 1993), random seed clones are selected first, and contigs are extended by anchors generated from contig ends. Then an unmapped clone is selected, and STSs from its ends are constructed and used to find the set of overlapping clones, usually by a PCR assay. The process continues until all clones have been either selected or identified as overlapping some selected clones. Nelson and Speed (1994b) found that a project using a directed strategy makes slower progress in the beginning, but closes the gaps much faster in later stages.

A *double end-sequencing strategy* combines sequencing and mapping by sequencing both ends of subclones and inferring clone overlaps from end-sequence comparisons; see Chen *et al.* (1993) and Roach (1995). A double end-sequencing strategy combined with directed finishing provides an efficient approach to sequencing a large piece of DNA (Yeh, 1999).

High-resolution mapping using FISH uses two or more fluorescent probes to hybridize to chromosomes at a particular stage in the cell cycle. The distance between the fluorescent dots in each cell is measured. The data from FISH experiments consist of a series of distance measurements between two or more probes. Such mapping data are now being linked to more traditional physical mapping data; see Kirsch *et al.* (2000).

1.6   GENE MAPS

Because of the possibilities of having two or more noncontiguous DNA fragments in a single clone, in 1994 the International Radiation Hybrid Mapping Consortium was formed to construct a human gene map in which cDNA-based STS markers from $3'$-untranslated regions of cDNAs were physically mapped and then integrated with the genetic map of polymorphic microsatellite markers. The consortium initially reported a map with about 16 000 genes by Schuler *et al.* (1996); a later map constructed by Deloukas *et al.* (1998) contains 30 181 gene-based markers. The resulting map density approached the target of one marker per 100 kb set as the objective for physical mapping at the outset of the human genome project. The GeneMap '98 or Human Transcript Map STSs are derived from transcribed sequences. Finally, we would like to mention the Integrated Molecular Analysis of Genomes and their Expression (IMAGE) Consortium, 'the world's largest public collection of genes'.

Statistical Significance in Biological Sequence Comparison

W.R. Pearson and T.C. Wood

Department of Biochemistry, University of Virginia, Charlottesville, VA, USA

The chapter reviews the role of statistical significance estimates in biological sequence comparison, focusing on local similarity searches. A brief history of the concept of 'homology' is presented, and the relationship between 'statistical significance' and 'biological significance', is discussed, addressing the question: 'What biological inferences can be drawn from statistically significant sequence similarity?' Algorithms and scoring matrices used to quantify local sequence similarity are summarized, and the statistical basis for the use of the extreme-value distribution to describe local similarity scores, both without and with gaps, is presented in outline. Particular attention is given to λ and K, the two parameters of the extreme-value distribution used by Karlin and Altschul, and to the use of bit-scores, and other scale-independent measures of similarity. Strategies that have been used to estimate the significance of local sequence similarity scores are compared using several distant evolutionary relationships. The reliability of statistical estimates for local sequence similarity scores is discussed in detail; it is shown that, with the exception of highly biased protein sequences and sequences with low-complexity regions, real, unrelated protein sequences behave very similarly to sequences generated randomly, so that the assumptions underlying the statistical models are widely applicable and statistical significance estimates are generally reliable.

2.1 INTRODUCTION

The availability of comprehensive sequence databases, rapid sequence comparison methods, and accurate statistical estimates for sequence similarity has fundamentally changed the practice of biochemistry and molecular biology. With the possible exceptions of *Escherichia coli* and *Saccharomyces*, the vast majority of the genes in newly sequenced genomes are characterized by sequence similarity searching. BLAST, FASTA, and Smith–Waterman similarity searches provide the most informative and reliable method for inferring the biological function of an anonymous gene (or the protein that it encodes). Typically, 60–80 % of eubacterial (and yeast) genes share statistically significant

sequence similarity with sequences from another organism. Significant sequence similarity can be used to infer common ancestors and similar three-dimensional structures, and is routinely used to assign functions in metabolic pathways. Even for the first archebacterial genome sequenced (*Methanococcus jannaschii*; Bult *et al.*, 1996), similarity-based functional gene assignments could be made for about 50 % of the genes (Andrade *et al.*, 1997) and subsequent sequence analyses (Koonin, 1997) suggested functions for another 20 % of the genes.

Unfortunately, some investigators are uncomfortable inferring the relationship between two sequences from a probability or expectation value; they prefer to think in terms of percent identity (sometimes misstated as percent homology). When current versions of the BLAST and FASTA similarity searching programs are used, this concern is rarely justified. It is very unusual for a statistically significant sequence similarity not to reflect common ancestry, and thus common structure, for the two sequences.

This chapter will provide an overview of the role of statistical significance estimates in biological sequence comparison, focusing on local similarity searches. We will begin by discussing the relationship between 'statistical significance' and 'biological significance', addressing the question: 'What biological inferences can be drawn from *statistically significant* sequence similarity?' Next, we will survey strategies that have been used to estimate the significance of local sequence similarity scores. Finally, we will discuss the reliability of statistical estimates for local sequence similarity scores.

2.2   STATISTICAL SIGNIFICANCE AND BIOLOGICAL SIGNIFICANCE

BLAST, FASTA, and other sequence similarity searching programs are designed to identify distantly related – homologous – sequences based on sequence similarity. When we say that two sequences are homologous, we are stating our belief that the two sequences diverged from a common ancestor in the past. A remarkable result of microbial genome sequencing projects has been that a large fraction of proteins, typically 50–80 % of each newly sequenced genome, share statistically significant similarity with proteins in other organisms that diverged hundreds to thousands of millions of years ago. Thus, it is common to observe very strong sequence similarity between prokaryotic and eukaryotic proteins that diverged more than 2 billion years ago.

The inference of homology, at least as the term is commonly used in sequence analysis, implies that the homologous proteins have similar structures. Indeed, structural similarity is the gold standard for homology. Almost without exception, if two sequences share statistically significant sequence similarity, they will share significant structural similarity. However, the converse is not true; there are many examples of similar structures that do not share significant sequence similarity (though perhaps not as many examples as are presented in the literature).

The concept of homology was given wide exposure and common usage by Richard Owen, the first curator of the British Museum. Owen defined a homolog as simply 'the same organ in different animals' (Owen, 1843). He further divided homology into two types: special and serial. Special homology is essentially the definition of homology we use today, 'the same organ in different animals'. In contrast, serial homology specifically refers to similarity between structures in different body segments, such as the legs of a millipede. Darwin's theory of evolution by natural selection conferred upon homology

the specialized meaning of structures or organs that share a common ancestor. Although he regarded Darwin's theory as little more than speculation, Owen did admit that special homology was the result of common ancestry (Owen, 1866).

Implicit in all definitions of anatomical homology is some kind of recognizable similarity, e.g. similarity of form or ontogeny. The classic example of anatomical homology is the similarity of forelimbs in the higher vertebrates. Whether adapted for grasping, running, swimming, or flying, the same basic skeletal pattern can be readily observed. Although forelimbs are detectably similar in their adult forms, some homologous structures are only similar in embryonic stages.

Closely related concepts describe biological similarity that is not the result of a common evolutionary ancestry. Originally, Owen defined *analogy* as similarity of function, without regard to structure (Owen, 1843), and that definition was repeated by Neurath *et al.* (1967). The current definition of analogy adds the qualification that the similarity is not due to homology, that is, the similarity is primarily due to chance and is typically superficial (Kent, 1992). The horns of cows and rhinoceroses, and the limbs of insects and vertebrates are analogous.

Convergence is often invoked as a possible explanation of biological similarity, particularly when discussing protein sequence motifs. Properly understood, convergence refers to the process of evolution: two distantly related species developing a similar trait that was not present in their common ancestor. If convergence is observed over numerous stages of the evolution of two separate groups, it is termed *parallel evolution*. Examples of similarity from convergence include the body plans of sharks, dolphins, and ichthyosaurs. As each organism adapted to existence in the water, they developed a similar body plan by convergent evolution.

2.2.1 'Molecular' Homology

In the 1950s and 1960s, as protein sequences and three-dimensional structures were determined, researchers began to recognize surprising similarity between protein molecules. Though rigorous methods of understanding and detecting protein similarity were years away, the term 'homology' was quickly applied to similarities observed among the trypsin-like proteases and the globins, implying that members of protein families shared their remarkable similarity because of divergence from a common ancestor.

Just as the term *homology* has been misused and misunderstood among anatomists, among biochemists the usage of homology as a synonym for similarity has unfortunately remained common. One often reads of 'low homology' or even a quantified 'percent homology' in papers reporting new sequences. Since homology is qualitative (having a common ancestor), it cannot be quantified as similarity can. Any two sequences have some measurable similarity, but a statement of homology implies that the similarity has some special meaning, specifically common ancestry.

2.2.2 Examples of Similarity in Proteins

Modern biochemical studies have revealed numerous examples of homology and analogy. In general, it is widely accepted that the three-dimensional structures of homologous proteins are more highly conserved than their sequences. Practically speaking, this means that homologous proteins with very low sequence similarity can and do have very similar structures. It is also believed that *orthologous* proteins – sequences that differ as a

result of speciation events, in contrast to *paralogous* sequences, which result from gene duplication – share the same cellular function, and that new biological functions have arisen through the generation of paralogs by gene duplication.

Although mentioned frequently, convergent evolution as an explanation of protein similarity is not well defined. To avoid confusion, Doolittle (1994) proposed three categories of convergent evolution in proteins: mechanistic convergence, structural convergence, and functional convergence. The actual mechanisms that produce convergence are subjects of ongoing research (Sanderson and Hufford, 1996). Here we will qualify convergence as similarity that arises by some kind of common selection. We will reserve the term analogy for similarity by chance, when no common selection is apparent.

Mechanistic convergence refers to similar active sites and residues in otherwise unrelated proteins. The classic example given is the mechanistic similarity between the trypsins and subtilisins. Although these proteins are entirely structurally dissimilar and thus almost certainly unrelated, they have geometrically and chemically equivalent catalytic triads. In mechanistic convergence, one can conclude that the need to accomplish a particular biochemical reaction is the selection producing the convergence. From principles of chemistry, it is reasonable to conclude that there are a limited number of enzymatic mechanisms available to accomplish particular reactions; thus, the occurrence of proteins with similar catalytic sites but distinct evolutionary histories is not surprising.

Structural convergence refers to structural similarity that is not the result of common ancestry. The adaptive selection applied to the structure is not the protein's cellular or biochemical function as in mechanistic convergence, but rather the thermodynamic stability of the particular fold. Doolittle mentions the ubiquitous TIM barrels (named for their well-known example, triosephosphate isomerase) as examples of structural convergence. The structural similarity in convergent TIM barrels is typically both topological and geometric; that is, both the ordering of the secondary structural elements in the peptide chain and the atomic positions in space are similar. A second type of structural convergence is restricted to geometry only, proteins that have a similar three-dimensional arrangement of secondary structural elements but a different ordering of those elements in the peptide. Examples of geometric structural convergence include the pleckstrin homology domain (PHd) and verotoxin (Orengo *et al.*, 1995), and the N-terminal β-barrels of *E. coli* transcription termination factor rho and the F1 ATPase subunits. In each case, the arrangement of atoms in space is very similar, but the tracing of the peptide chain through those atoms is different. In the case of the rho/F1 similarity, the rho barrel is actually traced in reverse order with respect to the F1 barrel (Allison *et al.*, 1998).

A third category of protein convergence defined by Doolittle is *functional convergence*. Multiple examples of independent origins of the same or similar enzymatic activities are known. For example, Rawlings and Barrett (1993) used a sequence analysis and manual structural evaluation to assign peptidases to 64 different 'clans', each with an independent evolutionary origin. Although Doolittle calls this similarity 'functional convergence', no adaptive advantage or selection pressure is known or given for why so many different kinds of peptidases would exist. Analogy, or similarity by chance, seems a better description for this type of gross functional similarity.

2.2.3 Inferences from Protein Homology

The inference of protein homology from similarity is routinely used to assign biochemical and cellular functions of newly sequenced proteins when a protein of known function is

available for comparison. This is of critical importance for initial analysis of genomic sequences. For example, the vast majority of function assignments of the open reading frames (ORFs) of the *M. jannaschii* genome were made based on protein homologs detected by sequence similarity (Bult *et al.*, 1996). By properly using computational tools for sequence comparison, inferring homology from sequence similarity is the single most powerful tool we have today for understanding the function and origin of a protein without actually performing biochemical experiments.

Since protein structure is conserved in divergent evolution, identifying homologous proteins of known structure can give a general insight into the fold of the protein of interest as well as a detailed molecular model if the sequence similarity is high enough. Although a remarkable amount of information about the function of a protein or protein complex can be gained from traditional biochemical and genetic methods, nothing brings these data into such clear focus as an atomic-resolution protein structure. Unfortunately, solving a protein structure by nuclear magnetic resonance or crystallographic methods can be very time-consuming, much more so than determining the sequence. Deriving structural and mechanistic information from closely related proteins of known structure will remain an attractive means of understanding most proteins.

2.3   ESTIMATING STATISTICAL SIGNIFICANCE FOR LOCAL SIMILARITY SEARCHES

The inference of homology from statistically significant sequence similarity is an application of Occam's razor: given two competing hypotheses – first, that a particular sequence ordering arose twice independently by chance; and second, that the similarity reflects divergence from a common ancestor – it seems simpler to conclude that a particular structure arose only once in evolutionary history. Thus, in biological sequence analysis, we infer homology from statistically significant sequence similarity. The inference depends on two parts: our ability to measure sequence similarity; and accurate estimates for the statistical significance of the similarity measure to reduce the likelihood that the similarity could be expected by chance.

2.3.1   Measuring Sequence Similarity

2.3.1.1   *Sequence comparison algorithms*

Effective algorithms for comparing protein and DNA sequences have been available for more than 30 years, since the publication of a global sequence comparison algorithm by Needleman and Wunsch (1970). *Global* sequence comparison algorithms seek to align every residue in one sequence with every residue in a second, in contrast to the more commonly used *local* sequence alignment algorithms, which seek only the strongest region of similarity between two sequences. Global alignment algorithms are used for aligning families of sequences with similar lengths in preparation for phylogenetic analysis; global alignment scores can be transformed to the distance measures used for building evolutionary trees. Global similarity scores are rarely used to infer homology, however, because the distribution of global similarity scores is not well understood and thus it is difficult to assign a statistical significance to a global similarity score. Moreover, many proteins are made up of domains that are homologous only over a portion of the protein sequence.

The most widely used programs for searching protein and DNA sequence databases, including BLAST, FASTA, and implementations of the Smith–Waterman algorithm, measure *local* sequence similarity. First described by Smith and Waterman (1981), local sequence alignment algorithms seek to align the most similar regions of two sequences. Local alignment algorithms have two dramatic advantages over global alignment methods when searching sequence databases for statistically significant matches: first, the statistics of local similarity scores are well understood; and second, local alignments allow one to identify conserved domains in proteins, which may not extend over the entire sequence. BLAST and FASTA use heuristic methods that attempt to approximate the optimal local similarity shared by two sequences. BLAST is particularly efficient in identifying distantly related sequences because it spends very little time calculating similarity scores for sequences that are unlikely to share significant similarity. FASTA is considerably slower than BLAST, because it calculates an approximate similarity score for every sequence in the database. FASTA uses these approximate scores to estimate the parameters of the extreme-value distribution, λ and K, which describes the expected distribution of local similarity scores between random sequences.

2.3.1.2 Similarity scores for sequence comparison

All algorithms that calculate sequence similarity, global or local, optimal or heuristic, seek to maximize a measure of similarity. The earliest (and unfortunately most commonly cited even today) similarity measure was based on percent identical residues (Watson and Kendrew, 1961). Initially, the low percent identity of the myoglobin and hemoglobin sequences (typically less than 30 %) was a surprising feature of two proteins with such similar structures. Later, researchers began to develop means to describe the similarity of different amino acid residues; the first such efforts were based on the redundancy of the genetic code, e.g. the minimal number of nucleotide substitutions required to convert one amino acid in the protein sequence to another (Fitch, 1966). In the 1970s, Margaret Dayhoff developed the notion of an *accepted point mutation* or PAM (Dayhoff *et al.*, 1978). The PAM concept centered around the natural selection against certain amino acid substitutions (thus an *accepted* point mutation) rather than simply the probability of mutations in the underlying DNA sequence. More recently the BLOSUM series of matrices, which tabulate the frequency with which different substitutions occur in conserved blocks of protein sequences, has been shown to be very effective in identifying distant relationships (Henikoff and Henikoff, 1992).

Dayhoff's PAM matrices are based on a well-defined evolutionary model for protein sequences (Dayhoff *et al.*, 1978). Given an estimate for the probability that any amino acid will change to each of the other amino acids, or remain the same, after 1 % change (1 accepted mutation per 100 residues), one can estimate the probability that any amino acid will change into each of the others after 2 %, 10 %,..., 40 %,..., 200 % change by multiplying the transition probability matrix by itself 2, 10,..., 40, 200 times. After incorporating the probability p_i of seeing a particular residue, the resulting matrix gives the probability $q_{i,j}$ of residue i aligning with residue j after a specified amount of evolutionary change. These probabilities are converted to log-odds scores by normalizing the alignment probabilities by the probability of seeing two residues align by chance, $p_i p_j$, yielding a scoring matrix $s_{i,j} = \log(q_{i,j}/p_i p_j)$.

	A	R	N	D	E	I	L		A	R	N	D	E	I	L
A	8							A	2						
R	−9	12						R	−2	6					
N	−4	−7	11					N	0	0	2				
D	−4	−13	3	11				D	0	−1	2	4			
E	−3	−11	−2	4	11			E	0	−1	1	3	4		
I	−6	−7	−7	−10	−7	12		I	−1	−2	−2	−2	−2	5	
L	−8	−11	−9	−16	−12	−1	10	L	−2	−3	−3	−4	−3	2	6
(a)								(b)							

Figure 2.1 Similarity scoring matrices. (a) PAM40 and (b) PAM250 similarity scoring matrices for six amino acid residues. The substitution matrices are symmetric. Diagonal elements are the scores given to amino acid identities; off-diagonal elements are the scores used for amino acid substitutions. Both the PAM40 and PAM250 matrices are scaled to 0.33 bits per unit raw score. Thus, if $\log_2(q_{ij})/(p_i p_j) = 2$, the entry in the matrix would be 6.

Figure 2.1 shows parts of two PAM scoring matrices, PAM40, which incorporates transition probabilities between residues in sequences that have had 40 accepted mutations per 100 residues, and PAM250, which is 'targeted' for sequences that have had 250 accepted mutations per 100 residues.[1] The PAM40 and PAM250 matrices differ dramatically in the relative scores of identities and substitutions; replacements that are considered unlikely at PAM40, e.g. R to N with $s_{N,R} = -7$, are considered neutral, $s_{N,R} = 0$, at PAM250. Likewise, replacements that are expected less frequently than chance ($s_{I,L} = -1$) after 40 % change are more likely than chance substitutions ($s_{I,L} = 2$) after 250 % change. Although the Dayhoff PAM matrices are based on the relatively small number of transitions available in 1978, a modern equivalent is available (Jones *et al.*, 1992), which performs well when appropriate gap penalties are used (Pearson, 1995).

An alternative strategy for calculating scoring matrices was developed by Henikoff and Henikoff (1992). Rather than extrapolate transition probabilities for a very large amount of change from the frequencies obtained after a very small amount of change, they sought to measure transition probabilities directly, by building a very large set of conserved blocks of aligned amino acid residues and then tabulating the amino acid substitution frequencies by examining columns in the aligned blocks with different degrees of identity (Henikoff and Henikoff, 1992). These calculations were used to generate the BLOSUM series of scoring matrices; BLOSUM50, the default scoring matrix used by the FASTA family of sequence comparison programs, reports substitution frequencies for residues in conserved blocks of sequences that show 50 % identity or less; BLOSUM62, which is the default for the BLAST programs, is derived from blocks that are up to 62 % identical, and BLOSUM80 reflects a very high degree of sequence conservation by including sequences up to 80 % identical. The BLOSUM matrices are now more widely used than either the original or modern versions of the PAM matrices because they appear to perform better with many alignment algorithms (Henikoff and Henikoff, 1992) and over a broad range of gap penalties (Pearson, 1995).

---

[1] Because different amino acids have different mutation probabilities, and an amino acid can mutate to a different residue, which can then mutate again back to the original amino acid, sequences that have changed by 250 % are expected to remain about 20 % identical, on average (Dayhoff *et al.*, 1978).

Both the PAM and BLOSUM series of matrices provide similarity scores that are targeted for different levels of sequence identity (Altschul, 1991; Henikoff and Henikoff, 1992); PAM matrices range from low values PAM10–PAM40 for high identity to PAM200–PAM250 for low (25–20 %) identity. BLOSUM matrices range from high (BLOSUM80) values for high identity to low values BLOSUM50–45 for distant relationships. However, despite this apparent similarity, the meaning of a 'shallow' PAM20 matrix is quite different from that of very conservative BLOSUM80 substitution values. The PAM20 provides scores for sequences that have changed by only 20 %; the amount expected for a comparison of mouse and human proteins, for example. In contrast, BLOSUM80 is targeted towards the most highly conserved regions in proteins, blocks that remain up to 80 % identical within two sequences that may share less than 30 % identity overall. Thus, low PAM matrices, but not BLOSUM80, are appropriate for short divergence times.

Although the PAM and BLOSUM matrices were built to target specific models of evolution and conservation, Altschul has shown (Altschul, 1991; States *et al.*, 1991) that any scoring matrix can be written in the form $s_{i,j} = \log(q_{i,j}/p_i p_j)$ reflecting an implied target substitution frequency, which can be calculated using the formula $\lambda s_{i,j} = \log(q_{i,j}/p_i p_j)$. In particular, the BLASTN2.0 program for DNA substitutions, which uses $+1$ for a match and -3 for a mismatch, has $\lambda = 1.374$. Rearranging the equation above, the target frequency for any nucleotide match, assuming $p_{A,C,G,T} = 0.25$, is $q_{A,A} = q_{C,C} = q_{G,G} = q_{T,T} = p_A p_A e^{\lambda(+1)} = 0.2469$ and the overall target identity is $\sum_{b=A,C,G,T} p_{b,b} = 0.988$. Thus, BLASTN2.0 is optimally efficient at identifying homologous sequences that are 98.8 % identical, and considerably less efficient at identifying sequences that share 80 % identity or less. In contrast, the DNA match/mismatch values for BLAST1.4 and FASTA are $+5/-4$, which, with $\lambda = 0.1915$, are targeted for alignments averaging 65 % identity.

2.3.2 Statistical Significance of Local Similarity Scores

A major breakthrough in biological sequence comparison occurred when Karlin and Altschul (1990) published their statistical analysis of local sequence similarity scores without gaps, and the BLAST program incorporated those statistics (Altschul *et al.*, 1990). Although a method for evaluating the statistical significance of sequence similarity scores, the RDF program, was included with the FASTP program (Lipman and Pearson, 1985), along with the advice that sequence similarity scores that were 6 standard deviations above the mean of the distribution of shuffled sequence scores ($z > 6$) were 'probably' significant, there was no statistical basis for this observation. Work by Arratia *et al.* (1986) and by Karlin and Altschul (1990) demonstrated that local similarity scores, at least for alignments without gaps, were accurately described by the extreme-value distribution, which can be written as

$$P(S \geq x) = 1 - \exp(-Kmne^{-\lambda x}) \tag{2.1}$$

where λ and K can be calculated from the similarity scoring matrix $s_{i,j}$ and the amino acid compositions of the aligned sequences p_i, p_j, and m and n are the lengths of the two sequences.

Accurate similarity statistics allow us to discriminate reliably between statistically significant similarities, which reflect *homology*, and similarities that could have arisen by chance, *analogous* sequences. The availability of Karlin–Altschul statistics in the

BLAST program (Altschul *et al.*, 1990) separated 'first-generation' score-only programs from 'second-generation' methods. Without accurate statistics, it is impossible to do large-scale sequence interpretation.

2.3.2.1 Statistics of alignments without gaps

The first statistical models for local and global alignment scores applied to runs of similar amino acid or nucleotide residues, which are equivalent to alignments without gaps. Arratia *et al.* (1986; 1990); Karlin and Altschul (1990); and Karlin *et al.* (1991) demonstrated that local similarity scores are expected to follow the extreme-value distribution. Waterman (1995) presents an intuitive argument when, referring to Erdös and Rényi, he points out that the expected number of runs of heads of length l in n coin tosses is $E(l) \cong np^l$, where p is the probability of heads (Figure 2.2). This relationship follows from the logic that the expected number of heads is the product of the probability of heads at each toss, times the number of tosses. If the longest run R_l is expected once, $1 = np^{R_l}$ and thus $R_l = \log_{1/p}(n)$. The longest run of heads coin-toss example is equivalent to finding the highest scoring region (e.g. a hydrophobic patch) in a single protein sequence using a scoring matrix that assigns a positive value to some of the residues, and $-\infty$ to all of the others. The probability of a positive score, which corresponds to the probability of heads in the coin-toss example, is $\sum p_i$ for each of the residues p_i that obtain a positive score s_i.

The simple example of head runs, or scores with $-\infty$ mismatch penalties, shows that *local* similarity scores for single sequences are expected to increase with the logarithm of the sequence length n. In sequence comparison, we consider possible alignments of

(a)

(b)
Figure 2.2 Sequence comparison as coin tosses. (a) Results from tossing a coin 14 times; black circles indicate heads. The probability of 5 heads in a row is $p(5) = 1/2^5 = 1/32$, but since there were 10 places that one could have obtained 5 heads in a row, the expected number of times that 5 heads occurs by chance is $E(5H) = 10 \times 1/32 = 0.31$. (b) Comparison of two protein sequences, with identities indicated as black circles. Assuming the residues were drawn from a population of 20, each with the same probability, the probability of an identical match is $p = 0.05$. In this example, there are $m = 10 \times n = 8$ boxes, so $E() = mnp = 80 \times 0.05 = 4$ matches are expected by chance. The probability of two successive matches is $p^2 = 1/20^2$ so a run of two matches is expected about $nmp^2 = 8 \times 10 \times 1/20^2 = 0.2$ times by chance.

two sequences, $a_{1..m}$ and $b_{1..n}$, but the probability calculation is quite similar. Rather than calculate the probability of obtaining the k heads, where $p_k = pp_{k-1}$, we consider the case of matching at m positions, or equivalently giving a *head* score if $a_i = b_j$. If the sequences are placed as in Figure 2.2(b), the head-run problem corresponds to the longest run of matches along any of the diagonals. If the letters (residues) in the two sequences have equal probabilities p, then the probability of a match of residue a_i with b_j is p and the probability of a match of length l from a_i, b_j to a_{i+l-1}, b_{j+l-1} is again p^l. In this case, however, there are $m - l + 1 \times n - l + 1$ places where that match could start, so $E(l) \cong mnp^l$. Thus, the expected length of the longest match between two random sequences of length m and n when the match score is positive and the mismatch score is $-\infty$ is $M_{mn} = \log_{1/p}(mn)$ or $2\log_{1/p}(n)$ when $m = n$ (Waterman, 1995). The shift from $\log_{1/p}(n)$ for one sequence to $\log_{1/p}(n^2)$ for two sequences of length n, reflects the larger number of positions where a run of length M_l with probability $P(M_l) = p^{M_l}$ could start. As in the single-sequence case, we can transform the problem from the probability of the longest match run to the probability of score $S_l \geq x$ by considering the probability $P(S \geq x)$ when a pair of residues $a_i b_j$ is matched with positive score $s_{i,j}$ and all negative scores are $-\infty$. For local pairwise alignment scores with a mismatch score of $-\infty$ and no gaps, the expected number of runs of score $S \geq x$ has the general form: $E(S \geq x) \propto mnp^x$, or equivalently $E(S \geq x) \propto mne^{x \ln p}$ or $mne^{-\lambda x}$ where $\lambda = -\ln p$.

Karlin and Altschul provided a natural extension of the problem of head runs, or match runs, or positive similarity scores bounded by $-\infty$ mismatch scores, to the more general case of local sequence patches or local similarity scores for nonintersecting alignments without gaps. To ensure the scores are local, the requirement that $E(s_{i,j}) = \sum_{i,j} p_i p_j s_{i,j} < 0$ must first be met. If so, the expected number of alignments with score S is

$$E(S \geq x) = Kmne^{-\lambda x}. \tag{2.2}$$

Karlin and Altschul (1990) derived analytical expressions for K and λ. $K < 1$ is a proportionality constant that corrects the mn 'space factor' for the fact that there are not really mn independent places that could have produced score $S \geq x$. Compared to λ, K has a modest effect on the statistical significance of a similarity score.

The λ parameter provides the scale factor by which a score must be multiplied to determine its probability. For ungapped alignments, λ is the unique positive solution to the equation

$$\sum_{i,j} p_i p_j e^{\lambda s_{i,j}} = 1. \tag{2.3}$$

λ thus depends both on the scoring matrix ($e^{s_{i,j}}$) and the residue compositions of the two sequences ($p_i p_j$). In some sense, λ can be interpreted as a factor that converts pairwise match scores to probabilities, so that $e^{-\lambda x}$ is similar to p^l in the coin-tossing example. Thus, just as in the coin-tossing case, the expectation of a run of heads (or an alignment run that produces score S) is the product of a space-factor term, Kmn, and a probability term $e^{-\lambda S}$.

The need for a scale factor to convert raw similarity scores into probabilities follows intuitively from the observation that multiplying or dividing every value in a similarity scoring matrix by a constant has no effect on the local alignments that would be produced by that matrix, or on the relative distribution of similarity scores in a library search – the highest scoring sequence will still be the highest, second highest second, etc. Thus it is

impossible, without some previous knowledge of the scoring matrix used and the particular scaling of the scoring matrix, to evaluate the statistical significance of a raw similarity score. However, by using a scaled similarity score λS_{raw}, one can readily compare alignments done with any scoring matrix. BLAST2.0 (Altschul *et al.*, 1997) and the current FASTA3 comparison program (Pearson, 1999) report the scaled score in terms of a *bit*-score that incorporates the space correction factor K: $S_{\text{bit}} = (\lambda S_{\text{raw}} - \ln K)/\ln 2$. Thus, substituting in equation (2.2),

$$E(S_{\text{bit}}) = mn2^{-S_{\text{bit}}} = \frac{mn}{2^{S_{\text{bit}}}} \qquad (2.4)$$

Equations (2.2) and (2.4) describe the number of times a score greater than or equal to S_{bit} would be expected by chance when two random sequences are compared.[2] This expectation can range from a very small value for very high scores (e.g. $S_{\text{bit}} = 1000$), to a value that approaches mn when $S = 0$. In a comparison of two average length protein sequences $n = m = 400$, $S_{\text{bit}} = 10$ would be expected $E(S_{\text{bit}} \geq 10) = mn2^{-S_{\text{bit}}} = 156$ times. To estimate the probability $P(S_{\text{bit}} \geq 10)$, which must range from 0 to 1, of obtaining at least one score $S \geq x$, we use the Poisson approximation.

The Poisson formula describes the probability of an event occuring a specified number of times, based on the average number of times μ it is expected to occur.[3] The Poisson probability of seeing n events when an event is expected μ times on average is $P(n) = e^{-\mu}\mu^n/n!$. In general, we are interested in the probability of seeing the event at least n times, and in the case of sequence comparisons, we ask for the probability of seeing a high score one or more times ($n \geq 1$). In this case, one can calculate the probability of not seeing the event zero times: $P(n \geq 1) = 1 - P(0)$, so $P(S \geq x) = 1 - P(n = 0) = 1 - e^{-\mu}\mu^0/0!$. Since $\mu = E(S \geq x) = Kmne^{-\lambda x}$ and $\mu^0 = 0! = 1$, the probability of seeing a raw similarity score $S \geq x$ is

$$P(S \geq x) = 1 - \exp(-\mu) = 1 - \exp(-Kmne^{-\lambda x}),$$

as seen earlier in equation (2.1).

Equation (2.1) describes the probability of obtaining a similarity score $S \geq x$ in a single pairwise comparison of a query sequence of length m against a library sequence of length n. This equation has the same form as the extreme-value distribution or Gumbel distribution, which is often presented as

$$P(S \geq x) = 1 - \exp(-e^{-(x-a)/b}), \qquad (2.5)$$

with a providing the 'location' of the mode, and b determining the scale, or width, of the distribution. For local similarity scores without gaps, $b = 1/\lambda$ and $a = \ln Kmn/\lambda$. The mean of the extreme-value distribution is $a - b\Gamma'(1)$, where $\Gamma'(1) = -0.577\,216$ is the first derivative of the gamma function $\Gamma(n = 1)$ with respect to n. The variance is $b^2\pi^2/6$ (Evans *et al.*, 1993). Thus, one can express the probability that an alignment

---

[2] More accurately, the statistical model assumes that the two sequences are made up of residues that are independent and identically distributed (i.i.d.). The identical distribution assumption can be violated by low-complexity regions in proteins and DNA or by strongly biased amino acid or nucleotide composition.

[3] λ is generally used to denote the characteristic parameter of a Poisson distribution, but we use μ here to avoid confusion with the λ scaling factor and to reinforce the fact that μ is the mean of the Poisson distribution.

obtains a score z standard deviations above the mean of the distribution of unrelated (or random) sequence scores as

$$P(Z \geq z) = 1 - \exp(-e^{-((\pi/\sqrt{6})z - \Gamma'(1))}). \tag{2.6}$$

These equations describe the probability that two sequences would obtain a similarity score by chance in a single comparison. However, in a sequence database search, the highest-scoring alignments are identified after a query sequence has been compared with each of the tens or hundreds of thousands of sequences in the database. Thus, in the context of a database search after $D = 100\,000 - 500\,000$ or more alignments have been scored, the number of times a score is expected to occur, the *expectation value*, is considerably higher:

$$E(S \geq x) = DP(S \geq x). \tag{2.7}$$

Thus, a similarity score 6 standard deviations above the mean ($z = 6$) has a probability $P(Z \geq 6) < 2.6 \times 10^{-4}$ in a single pairwise comparison. However, in 1985, with 3000 entries in the protein sequence database, $E(Z \geq 6) = 3000 \times 2.6 \times 10^{-4} = 0.77$. Therefore, a score 6 standard deviations above the mean should be seen by chance very frequently, and the advice provided with the description of the FASTP program overestimated statistical significance. Today, with protein sequence databases ranging in size from $100\,000$ to $500\,000$ sequences, a $z = 6$ score would be expected 25 times by chance when searching a $100\,000$ sequence database (equations 2.6 and 2.7), and $z \geq 12.1$ is required to achieve statistical significance of $E(100\,000) \leq 0.01$. (For $E(500\,000) \leq 0.01$, $z \geq 13.4$.)

2.3.2.2　Alignments with Gaps

The statistical analysis of local similarity scores summarized above was derived for alignments without gaps. Although searches that report only the best local alignment without gaps can perform very well, they do not perform as well as a Smith–Waterman search with modern scoring matrices and appropriate gap penalties (Pearson, 1995). Thus, there is considerable interest in the statistical parameters that describe the distribution of local similarity scores with gaps.

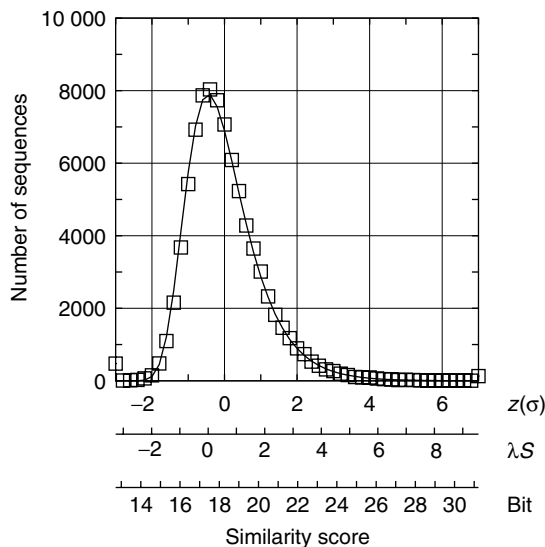
The first implementation of Smith and Waterman's (1981) algorithm that provided statistical estimates for similarity scores was developed by Collins *et al.* (1988). Although they did not use the extreme-value distribution, they recognized that the number of sequences S_x obtaining a score of $x \geq \bar{x}$, where $\bar{x}$ is the mean similarity score, decreases exponentially. A line fit to $\log(S_x)$, the declining number of scores excluding the top 3 %, can be used to extrapolate the expectation of obtaining a high score. This strategy works reasonably well because the number of sequences that obtain a score predicted from the probability density function (PDF) of the extreme-value distribution (Figure 2.3) has the form: $PDF(S = x) = \lambda Kmne^{-\lambda x}e^{-Kmne^{-\lambda x}}$. The second exponential term does not contribute significantly to the PDF when $x > \bar{x}$, so for high scores, the regression becomes $\log(PDF(S = x)) = \log(\lambda Kmn) - \lambda x$. Collins *et al.* (1988) recognized that the highest expected score by chance increased with the length of the query sequence, but they did not incorporate a length correction into their expectation calculation. The lack of a log n_l library sequence length correction significantly reduces the sensitivity of the search, as long unrelated sequences can have higher scores, by chance, than shorter related sequences (Pearson, 1995; 1998).


Figure 2.3 The extreme-value distribution. The observed distribution (squares) of similarity scores from a comparison of the human glucose transporter sequence `gtr1_human` against each of the ~84 000 sequences in SwissProt, and the expected (solid line) distribution of scores, based on the extreme-value distribution, are shown. Similarity scores were calculated with the Smith–Waterman algorithm, with the BLOSUM62 scoring matrix and a penalty of −12 for the first residue in a gap and −1 for each additional residue. The y-axis shows the number of SwissProt sequences obtaining the score shown on the x-axis. Three different scales for the similarity scores are shown: from top to bottom, these are the scores in terms of standard deviations (σ) above the mean (equation 2.6); the scale in terms of $\lambda S - \log(Kmn)$ (equation 2.1); and the *bit* score (equation 2.4).

Mott (1992) provided the first empirical evidence that the distribution of optimal local similarity scores with gaps could be well approximated by an extreme-value distribution. He considered an equation of the form $F(y, m, n, c) = \exp(-\mathrm{e}^{-(y-A)/B})$ where $A = a_0 + ca_1 + ca_2 \log(mn)$, $B = cb_1$ and $c = 1/\lambda_{\mathrm{ungapped}}$, defined as in equation (2.3). In this case, the $c = 1/\lambda$ parameter was calculated for sets of sequence pairs with identical compositions. In addition to correcting for the scaling of the $s_{i,j}$ scoring matrix, c reflects the amino acid composition of the two sequences being compared. Unfortunately, estimating λ or c using equation (2.3) is time-consuming. This approach may improve searches when query sequences have a biased amino acid composition, but it is not generally available in sequence comparison programs.

The most widely used estimates for λ and K for searches with gapped alignments are those provided for in the BLAST2 and PSI-BLAST comparison programs (Altschul *et al.*, 1997). These values are based on maximum likelihood estimates of λ, K, and H from simulations of random protein sequences of average composition (Altschul and Gish, 1996). H describes the relative entropy, or information content, of a scoring matrix and can be thought of as the average score per aligned residue (Altschul and Gish, 1996). In this case, the parameters of the extreme-value distribution are slightly different:

$$P(S \geq x) = 1 - \exp(-Km'n'\mathrm{e}^{-\lambda x}), \tag{2.8}$$

where for m, n, the query and library sequence lengths, $m' = m - \log(Kmn)/H$ and $n' = n - \log(Kmn)/H$. By correcting m and n for the expected length of an alignment between two random sequences $\log(Kmn)/H$, the search space term $Km'n'$ is estimated more accurately (Altschul and Gish, 1996).

The FASTA package of programs estimates the extreme-value parameters from the distribution of similarity scores calculated during the search (Pearson, 1996; 1998). This approach is efficient when scores are available for every sequence in the database, as is the case for a FASTA or Smith–Waterman search; no additional similarity scores must be calculated and the statistical parameters reflect the true distribution of similarity scores produced with the specific query sequence and the specific sequence database. However, a method that estimates statistical parameters from the actual distribution of similarity scores must avoid including scores from 'related' sequences in the estimation sample. This is straightforward in the typical case where a query sequence is compared to 50 000–500 000 sequences in a comprehensive database and fewer than 1000 sequences could be related in the worst case. However, these empirical statistical estimates cannot be used when a search is done against a special-purpose database that may contain only sequences from a single protein family. For this case, the FASTA programs provide an option to calculate a similarity score from a shuffled version of each sequence in the database; the distribution of these shuffled scores is then used for parameter estimation (Pearson, 1999).

By default, the FASTA programs estimate the location and scale parameters of the extreme-value distribution by fitting a line to the relationship between similarity score and $\log(n_l)$, the library sequence length, by calculating the mean and variance of similarity scores in bins of length $\log(n_l)$ of the library sequence (sequences in each bin differ in length by $\sim 10\%$: Figure 2.4). This line provides the location parameter, related to $\log(Kn_l)/\lambda$, and the residual variance $(\widehat{\sigma^2})$ of the $\log(n_l)$-normalized similarity scores, which can be used to calculate $\lambda = \pi/\sqrt{6\widehat{\sigma^2}}$. Binning similarity scores by $\log(n_l)$ provides a simple strategy for excluding related (high-scoring) sequences from the estimation process. $\log(n_l)$ length bins are initially weighted by the inverse variance of their similarity scores; length bins with very high scores have a high variance. After the initial $\log(n_l)$ regression is performed, bins that continue to have very high score variance are excluded and the number of bins and scores excluded is reported. Typically, this process excludes 0–2 of 50 length bins with about 5% of the library sequences. Once the $\log(n_l)$ regression line and $\widehat{\sigma^2}$, the average residual variance, have been determined, the probability of a single pairwise similarity score can be calculated using equation (2.6).

Alternatively, FASTA provides an option to estimate λ and K by maximum likelihood, using equation (2.1). This estimation is similar to that of Mott (1992), but omits the 'composition' data c and estimates the λ parameter directly. To avoid the scores from related sequences, the likelihood model implements a censored estimation strategy that excludes the lowest and highest 2.5% of the scores. This approach has the advantage that both K and λ are estimated directly and that there is no assumption that related sequences have well-defined lengths. (Families that are globally similar, e.g. globins and cytochrome 'c's, have characteristic lengths, but homologous domains, e.g. the EF-hand calcium binding domain, zinc-fingers, or protein kinase domains, may be in proteins with very different lengths.)

The major difference between the FASTA programs and the BLAST programs (aside from speed) is the strategy used for estimating statistical significance of similarity
Figure 2.4 Empirical estimation of extreme-value parameters: sequence similarity scores plotted as a function of library sequence length. All the similarity scores calculated in the comparison of `gtr1_human` with an annotated subset of SwissProt (~24 000 sequences) are summarized. Scores from unrelated sequences are shown as averages (squares) with standard errors indicated; each score from a related sequence is plotted (diamonds). The unrelated sequence scores are plotted linearly against the left ordinate, the related scores are plotted on a logarithmic scale on the right ordinate.

scores. While BLAST pre-calculates λ and K from randomly shuffled sequences, FASTA calculates the extreme-value parameters from the actual distribution of similarity scores obtained in a search. Thus, FASTA must calculate at least an approximate similarity score for every sequence in a database. BLAST is fast because it calculates scores only for sequences that are likely to be homologous. While this strategy works well for protein sequences, it is more problematic for translated-DNA : protein comparisons, where the appropriate statistical model is more difficult to specify.

2.3.2.3 Pairwise Statistical Significance

The strategies outlined above can be used to estimate the statistical significance of a high similarity score obtained during a database search. If the BLAST2.0 (Altschul *et al.*, 1997) λ and K parameters are used as calculated in Altschul and Gish (1996), the statistical significance measurement reports the likelihood that a similarity score as good or better would be obtained by two random sequences with 'average' amino acid composition, and lengths similar to the lengths of the sequences that produced the score. However, if either of the two sequences have amino acid compositions significantly different from 'average', the statistical significance may be an over- or underestimate.

The empirical statistical estimates provided by programs in the FASTA package (Pearson, 1996; 1998) report a slightly different value: the expectation that a sequence with the length and composition of the query sequence would obtain a similarity score against an unrelated sequence drawn at random from the sequence database that was searched.

Again, if the query sequence has a slightly biased amino acid composition, e.g. because it is a membrane-spanning protein with several hydrophobic regions, then while the significance of the similarity with respect to 'average' composition proteins is accurate, the more biologically important question, the significance of the similarity when compared to unrelated membrane-spanning proteins, may be an overestimate. To address this problem one could use Mott's strategy to include the $c = 1/\lambda_{\text{ungapped}}$ composition/scaling parameter in the maximum likelihood fit, with c calculated using equation (2.3) for every pairwise comparison in the database. Although the composition calculation can be time-consuming, this option is available in the FASTA3 package.

The significance of a specific pairwise similarity score, in the context of the residue distributions in each of the two sequences, the query and library sequence, can also be estimated using a Monte Carlo approach. The two sequences are compared, and then one or both of the sequences will be shuffled hundreds of times to generate a sample of random sequences with the same length and residue composition. Similarity scores are calculated for alignments between the query sequence and each of the shuffled sequences. λ and K parameters can then be calculated from this distribution of scores using maximum likelihood, as is done by the PRSS program in the FASTA package (Pearson, 1996). The FASTA programs offer two shuffling options: (a) a *uniform* shuffle, in which each residue is randomly repositioned anywhere in the sequence; and (b) a *window* shuffle, in which the sequence is broken into n/w windows (n is the length of the sequence and w is the length of the window, typically 10–20 residues) and the sequence in each window is randomly shuffled. For 'average' composition query sequences, both uniform and window-shuffle estimates should be similar to those obtained from a database search. However, for scores of alignments between sequences of biased composition, significance estimates derived from the similarity scores of uniformly shuffled sequences should be more conservative than estimates based on the distribution of unrelated sequences from a comprehensive sequence database (Table 2.1). Window-shuffle estimates should be even more conservative, particularly if the similarity reflects a local patch of biased amino acid composition that would be homogenized by the uniform shuffling strategy.

Shuffling strategies rely on the assumption that the similarity scores of real unrelated protein sequences behave like the similarity scores of randomly generated sequences. While this is almost always true, some query sequences may have properties that are present in unrelated sequences but not in shuffled sequences. An alternative strategy for estimating λ and K from a comparison of two sequences has been proposed by Waterman and Vingron (1994),[4] based on a strategy they refer to as 'Poisson de-clumping'. They note that not only are the highest-scoring similarity scores from a sequence similarity search extreme-value distributed, but the highest $H_{(1)}$, second highest $H_{(2)}$, $H_{(3)}, \ldots, H_{(n)}$ alignment scores from a single pairwise comparison can be used to estimate λ and K, as long as the alignments do not overlap or intersect. An algorithm for calculating the n best nonintersecting local alignments between two sequences was described by Waterman and Eggert (1987); a space-efficient version is available as the SIM algorithm (Huang *et al.*, 1990). This approach has the advantage that it does not require the use of shuffled sequences, which may have different statistical properties than 'natural' protein sequences in some cases, and it calculates λ and K for the pair of sequences, with their specific lengths and residue compositions, rather than for an average distribution of library

---

[4] p and γ in Waterman and Vingron (1994) correspond to $e^{-\lambda}$ and K, respectively, in equation (2.1).

Table 2.1 Statistical significance estimates. Expectation values are shown for similarity scores between human glucose transporter type 1 (gtr1_human); three members of the glucose transporter family, quinate permease (qutd_emeni), maltose permease (cit1_ecoli), and α-ketoglutarate permease (kgtp_ecoli); and a probable nonmember, a hypothetical yeast protein (yb8g_yeast). The BLASTP2.0 search was done with the default scoring matrix (BLOSUM62) and gap penalties -12 for the first residue in a gap (-11 gap-open) and -1 for each additional residue (gap-extend). SSEARCH (Smith and Waterman, 1981; Pearson, 1996) searches used either the default matrix (BLOSUM50, BL50) and gap penalties ($-12/-2$) or the same scoring matrix and gap penalties as the BLASTP2.0 search (BL62). SSEARCH statistical estimates were calculated using the default linear regression method (BL50, BL62) or the maximum likelihood method (BL62*). Both BLASTP2.0 and SSEARCH searches examined alignments between sequences with low-complexity regions removed by the SEG program (Wootton, 1994). Expectation values are reported in the context of a search of the SwissProt (Bairoch and Apweiler, 1996) database ($\sim$84 000 entries). The λ scaling/composition-factor for each search is shown in the right column. Statistical significance was also estimated by a Monte Carlo approach (PRSS) in which the second sequence was shuffled 1000 times using either a uniform or 'window' (-w 20) shuffle. Expectations reported by PRSS have been multiplied by 84 to reflect the expectation from a search of the 84 000 entry SwissProt database.

sequences. However, the approach also assumes that, for some i, $H_{(i)}$ reflects the score of an alignment that occurs by chance, rather than because of homology. This is true for single-domain proteins that do not contain internal repeats, but it is not true for proteins containing internal duplications. For example, a comparison of calmodulin with troponin 'C' would produce $H_{(1)}, \ldots, H_{(4)}$ which reflect the homology of the four EF-hand calcium binding domains in each sequence, and $H_{(5)}, \ldots, H_{(n)}$, which could be used to estimate λ and K. A protein with a dozen copies of a duplicated domain would have more than 100 local alignments with scores that reflect homology.

2.3.2.4   Accuracy of λ and K

Reliable statistical estimates for similarity scores can dramatically improve the sensitivity of a similarity search, because they provide an accurate quantitative model for the behavior of scores from unrelated sequences. Thus, it is far more informative to state that a pair of distantly related sequences has a similarity score that is expected by chance only once in 10 000 database searches (E() $< 10^{-4}$) than it is to state that two sequences share 30 % identity. Unfortunately, percent identity remains the most commonly published measure of sequence similarity, despite the fact that identity measures are far less effective than similarity scores that reflect conservative replacements (Schwartz and Dayhoff, 1978; Pearson, 1995; Levitt and Gerstein, 1998). High levels of identity are frequently seen between unrelated sequences over short regions (Kabsch and Sander, 1984) and sequence alignments with less than 25 % identity may either be clearly statistically significant (Table 2.1), (gtr1_human versus cit1_ecoli, BL62, E() $< 10^{-9}$) or not significant (gtr1_human versus yb8g_yeast, BL62, E() < 0.25).

Before accurate statistical estimates for local similarity scores were available, it was routine to consider the tradeoffs between a search strategy's 'sensitivity', the ability to identify distantly related sequences (to avoid false negatives), and its 'selectivity', not assigning high scores to unrelated sequences (false positives). With an accurate model for the distribution of similarity scores from unrelated sequences, the threshold for statistical significance (typically 0.02–0.001) sets the selectivity or false positive rate; a threshold E() < 0.001 predicts a false positive every 1000 searches. Thus, a significance threshold of E() < 0.001 is expected to produce several false positives when characterizing all the proteins in *E. coli* or yeast (4000 and 6000 proteins), and 18 false positives are expected with E() < 0.001 when each of the 18 000 proteins in *Caenorhabditis elegans* is compared to the SwissProt database. However, the conservative strategy of reducing the significance threshold to 0.001/4000 for *E. coli*, or 0.001/18 000 for *C. elegans*, ensures that many homologous proteins will be missed (false negatives).

Of the λ and K parameters for the extreme-value distribution, the scale parameter λ has the largest effect on the statistical significance estimate. In searches using the BLOSUM62 scoring matrix and gap penalties of −12/−2 of a subset of the SwissProt with database 50 unrelated protein sequences with lengths ranging from 98 to 2252 (mean 432 ± 57), maximum likelihood estimates of λ ranged from 0.204 to 0.304 (mean 0.275) while K ranged from 0.0039 to 0.062 (mean 0.012). K and λ are strongly correlated; low values of K are found with low values of λ. Around the average values, however, reducing K by a factor of 2 reduces the E() value only twofold (1 bit), but a similar change in statistical significance would occur by reducing λ from 0.275 to 0.268, or about 2.5 %. Reducing λ by 20 %, which is well within the range of λs seen after shuffling with PRSS in Table 2.1, would reduce the statistical significance of a raw score of 100 by 250-fold, or by 8 bits.

Table 2.1 illustrates the importance of λ on significance estimates for three related and one unrelated sequence. The differences in expectation values reflect differences in estimates for λ and K; for a given scoring matrix (BLOSUM50 or BLOSUM62) the raw similarity scores for each pairwise comparison (e.g. gtr1_human:cit1_ecoli) do not change. The significant differences between the λ values for BLOSUM50 and BLOSUM62 reflect the different scaling of the two matrices. BLOSUM50 is scaled at 0.33 bits per unit raw score, so that a raw score of 148 produces a bit score of ∼148/3

(the actual value for these gap penalties is 0.27 bits/raw-score). BLOSUM62 is scaled at 0.5 bits/raw-score, with a raw score of 75 giving a bit score of 34.[5]

Two trends are apparent: λ estimates from PRSS shuffled comparisons tend to be smaller than λ estimates from database searches; and λ estimates for local (window) shuffles are somewhat lower, reducing the significance even further. These decreases in λ are expected because the query and library sequences used in this example have a somewhat biased amino acid composition; the proteins have multiple transmembrane domains with a bias towards hydrophobic amino acid residues (Kyte and Doolittle, 1982). Thus, the λs from SSEARCH are lower than the BLAST2.0 λ, because the simulations used to assign λ in BLAST2.0 assume an 'average' amino acid composition for both the query and library sequence; the empirical SSEARCH estimates correct for the composition bias of the query sequence, but still reflect the 'average' composition of the library sequences. λs determined by PRSS shuffling are lower still, because PRSS estimates account for the composition bias in both the query and library sequences. Window shuffling in PRSS reduces λ even further, presumably because the highest-scoring regions in each pairwise comparison are restricted to sequence patches with the most biased composition. However, despite these differences in λs, the SSEARCH and PRSS uniform-shuffle significance estimates for the intermediate and distantly related sequence pairs usually agree within a factor of 4. Window-shuffled estimates reduce statistical significance much more dramatically, about 2–4 orders of magnitude for moderately and weakly significant similarities.

The statistical estimates provided by the BLAST2.0 and FASTA sequence comparison programs are generally robust and reliable. To illustrate the factors affecting significance estimates, we have emphasized the modest differences in λ and E() in Table 2.1. However, Table 2.1 illustrates even for sequences with biased amino acid composition that share 20–25 % sequence identity, the significance estimates reported by either BLAST2.0 or programs in the FASTA package are very similar, and consistent with statistical estimates produced by uniform shuffling. Window-based shuffling produces a much more conservative statistical estimate.

2.3.3   Evaluating Statistical Estimates

The inference of homology (common ancestry) from statistically significant similarity rests on two assertions: that similarity scores, calculated with optimal (Smith–Waterman) or heuristic (BLAST or FASTA) algorithms using common scoring matrices (PAM250, BLOSUM62) and gap penalties, follow the extreme-value distribution; and that the behavior of similarity scores for random sequences holds as well for real, unrelated, protein sequences. This second assertion is critical – an accurate statistical theory for similarity scores of random sequences is of little value if real sequences have properties that distinguish their scores from those of random sequences. It seems reasonable that real protein sequences might have statistical properties that distinguish them from random sequences; of the $20^{400} = 2.6 \times 10^{520}$ potential sequences of length 400 that could be generated at random from 20 amino acids, fewer than 10^5–10^8 unrelated sequences are thought to exist in nature, and many structural biologists would argue that there are fewer than 10^3 distinct protein folds (Brenner *et al.*, 1997). Real protein sequences are constrained to fold into a compact three-dimensional structure with a physiological

---

[5] Because of this different scaling, a gap penalty of $-12/-2$ for BLOSUM50, the default with SSEARCH, is equivalent to a gap penalty of $-8/-1$ for BLOSUM62.

function; the fact that such a large fraction (typically $50-80\%$) of the sequences in most organisms can be found in other distantly related organisms suggests that the folding constraint substantially restricts the universe of protein sequences; it is far easier to produce a new protein sequence by duplicating an old one than by producing a sequence *de novo*. Thus, it would not be surprising to learn that the folding/function constraint produced real protein sequences whose similarity scores behave differently from those of random protein sequences.

The reliability of statistical estimates can be evaluated both by comparing the observed distribution of sequence similarity scores obtained in a search with the expected extreme-value distribution, and by examining the expectation value for the highest-scoring nonhomologous sequence. Figure 2.5 shows the distribution of sequence similarity scores for two query sequences, an 'average' protein sequence, `pyre_colgr`, orotate phosphoribosyltransferase, and a protein sequence with a biased amino acid composition, `prio_atepa`, major prion precursor. Two sets of similarity scores are shown for each sequence. One set shows the scores obtained when all the amino acid residues in the library are examined; the second shows the scores when low-complexity sequences, or regions of sequence with a reduced or biased amino acid composition, are removed (Wootton, 1994). With the 'average' protein, the distributions of the 'complete' database scores and 'high-complexity' scores are indistinguishable. With the prion protein (Figure 2.5b), there is some difference in the central portion of the distribution, but the greatest differences are seen for the highest-scoring sequences, where there are typically $2-3$ times as many 'raw' scores as expected between 4 and 5 standard deviations above the mean, and $5-10$ times as many scores as expected from 5 to 7 standard deviations above the mean. This effect of biased composition is largely removed by searching against a SEGed database that has had low-complexity regions removed.

The effect of biased composition is seen more dramatically by looking at the number of very high-scoring sequences and the expectation value of the highest-scoring unrelated sequence. When `prio_atepa` is used as a query, 198 library 'raw' sequence scores have $z \geq 7.0$;[6] this is reduced to 28, 26 of which are related to the query, when the SEGed database is used. Likewise, when the 'raw' sequences are examined, the highest-scoring unrelated sequence is a glycine-rich cell wall protein that obtains an expectation value of $E() < 10^{-8}$ and there are 90 unrelated sequences with $10^{-8} \leq E() \leq 0.01$. In contrast, with the SEGed database the highest-scoring unrelated sequence has an expectation value of $E() = 0.012$ and the second highest unrelated sequence has $E() = 0.99$.

Reliable statistical estimates – statistics that estimate $E() < 0.02$ about 2% of the time – allow much more sensitive searches. If an investigator can have confidence that an unrelated sequence will obtain a score of $E() < 0.001$ about once in 1000 searches, $E() < 0.001$ can be used to reliably infer homology. However, if unrelated sequences sometimes obtain $E() < 0.001$ by chance, a more conservative threshold may be adopted, e.g. $E() < 10^{-6}$ or even $E() < 10^{-10}$. While using a very stringent threshold for statistical significance ensures that one will rarely infer homology when the proteins are unrelated, it also ensures that moderately distant evolutionary relationships will be missed. Thus, both the FASTA and BLAST developers have given high priority to the accuracy of

---

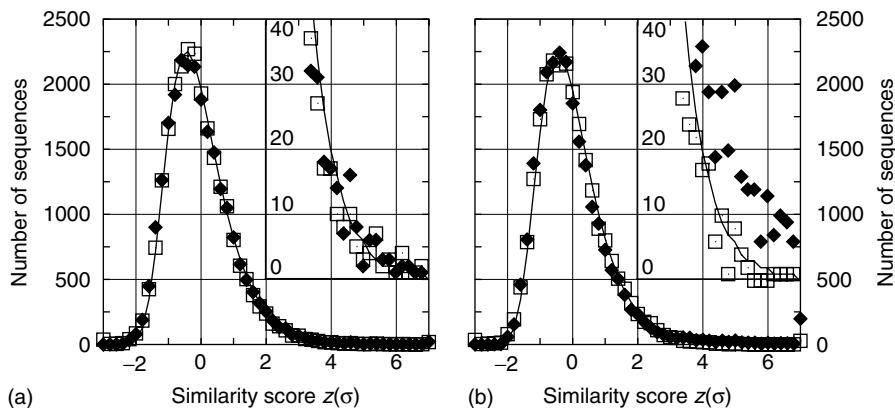
[6] Similarity scores 7 standard deviations above the mean have an expectation value $E() < 1.7$ for this database of 23 981 sequences.


Figure 2.5 Distribution of library sequence similarity scores in searches with (a) an 'average' protein sequence, `pyre_colgr`, and (b) a sequence with biased amino acid composition, `prio_atepa`. Filled diamonds show the distribution of similarity scores that include all the residues in every sequence; open squares show the distribution of scores when low-complexity regions are removed with the PSEG program (Wootton, 1994). The solid line shows the expected distribution of scores predicted from the size of the database and the extreme-value distribution (2.6). The x-axis reports similarity scores scaled in standard deviations above the mean. Searches were done with the SSEARCH33 program (Smith–Waterman) using the BLOSUM62 scoring matrix with gap penalties of -12 for the first residue in a gap and -2 for each additional residue. λ and K were estimated by maximum likelihood ($-z\ 2$) option: (Pearson, 1999).

the statistical estimates, particularly for the highest-scoring unrelated sequences (Brenner *et al.*, 1998).

When evaluating the quality of statistical estimates for high-scoring unrelated sequences, it is important to examine real protein sequences, whose properties may differ from randomly generated sequences. Figure 2.6 summarizes the highest-scoring unrelated sequence similarity scores obtained when query sequences from 50 randomly selected Pfam protein families were used to search a database of sequences with carefully annotated evolutionary relationships. Searches were done with either random sequences generated from the 50 Pfam family queries, or with the queries themselves, against either a 'raw' protein sequence database, or one with low-complexity regions removed. Figure 2.6(a) shows that even when random sequences are used to search the database, similarity scores can be much higher than expected (and E() values much lower than expected) if low-complexity regions are present in the sequence database. Thus, when 50 random sequences were used, the lowest E() value was 0.006 from a match between a randomly shuffled human histone H1 (`h10_human`) and other histone H1 sequences. This may simply reflect the fact that it is difficult to randomly shuffle a sequence that is 30 % lysine. However, when low-complexity regions are removed, the observed and expected distributions of E() values agree extremely well.

When real sequences are used as the query, the statistical estimates are not as accurate, even when low-complexity regions are removed. Most of the time, however, the estimates are not far off. The log/log plot in Figure 2.6 emphasizes the searches that obtained the lowest E() values for unrelated sequences, but 80 % of the real query sequences
Figure 2.6 Quantile–quantile plot of expectation values for searches with (a) 50 random sequences and (b) 50 real protein sequences for which the highest scoring unrelated sequence is known. Searches were performed against a 'raw' annotated protein sequence database (filled diamonds) and the same database with low-complexity regions removed (open squares). For each search, the highest score (a) or highest scoring unrelated (b) sequence was recorded, and converted from an expectation (E()) to a probability of obtaining that E() using the Poisson formula $p(E) = 1 - e^{-E}$. Each set of 50 probabilities was sorted from lowest to highest and plotted. The 50 query sequences were chosen from 50 randomly selected PFAM families (Sonnhammer *et al.*, 1997) with 25 or more members. The random sequences were obtained by shuffling the 50 real PFAM derived sequences. Searches were done using the Smith–Waterman algorithm (SSEARCH33) using the default scoring matrix (BLOSUM50) and gap penalties $(-12/-2)$ with regression-scaled (binned) statistical estimates.

had expectation values E() > 0.1 (low by a factor of 2), and 90 % had E() > 0.02 (low by a factor of 5) when low-complexity sequences were removed from the database. In the search of the SEGed database, again the most 'significant' unrelated similarity score was involved alignments with h1o_human. In the search against the raw database, this alignment had an E() < 0.002 (low by factor of 10); against a SEGed database the score was even lower, E() < 0.0006. Histone H1 has an exceptionally biased amino acid composition, which cannot be completely corrected for by removing low-complexity regions from the database. However, for the vast majority of query sequences (80–90 %), unrelated sequences will have expectation values within a factor of 2–5 of their true frequency in database searches. Thus, thresholds of statistical significance in the range 0.001 < E() < 0.01 against SEGed sequence databases will be reliable with rare exceptions.

The observation that the statistical significance estimates (E() values) from similarity searches with real, unrelated sequences are 2–5 times less conservative than those obtained for genuinely random sequences suggests that to a large extent, real, unrelated protein sequences have many of the same statistical properties as random sequences. The major

difference between real protein sequences and random sequences seems to be the i.i.d. assumption for amino acid residue positions. In real, unrelated sequences, unusual amino acid compositions are distributed in low-complexity clumps. The SEG program, which masks out these regions, removing them from the similarity score calculation, can reduce the effect of clumps with biased composition, but not eliminate it. Fortunately, the deviation from being i.i.d. is modest in 80 % of protein sequences. Other than the biased composition effect, no other property of 'real' protein sequences has been identified that distinguishes them from sequences built from picking amino acids from a probability distribution at random.

2.4   SUMMARY: EXPLOITING STATISTICAL ESTIMATES

The inference of homology from statistically significant sequence similarity is one of the most reliable conclusions a scientist can draw. Indeed, the vast majority of bacterial, *C. elegans*, and *Drosophila* genes are annotated largely on the basis of statistically significant sequence similarity shared by other proteins with known structures or functions. This trend is certain to continue as sequence databases become more comprehensive.

While the inference of homology from significant sequence similarity is reliable – sequences that share much more similarity than expected by chance share a common ancestor – the inference tells us much more about structure than function. Without exception, sequences that share statistically significant similarity share significant structural similarity. However, homologous proteins need not perform the same or even similar functions. Functional inferences are most reliable when based on assignments of *orthology*. *Orthologous* sequences are sequences that differ because of species differences. This contrasts with *paralogous* sequences, which are produced by gene duplication events. While *homology* can be demonstrated by sequence similarity, an inference of *orthology* is best supported by phylogenetic analysis, which is considerably more challenging computationally. In addition, many proteins are built from evolutionarily independent domains with different structures and functions. The inference of homology is transitive – if protein A is homologous to B and B is homologous to C, even if A and C do not share significant similarity – but it is critical that such inferences be limited to the domain to which they apply. There is great concern that incorrect functional assignments are greatly reducing the value of sequence database annotations because functional assignments are inappropriately extended to new family members based on a correct, but functionally uninformative, inference of homology.

Statistical significance estimates, whether as expectation values or bit scores, are far more informative than the most commonly used measure of sequence similarity, percent identity. It has been known for more that 20 years (Dayhoff *et al.*, 1978) that percent identity is much less effective than measures of similarity that distinguish biochemically similar and dissimilar amino acids, and that recognize that some amino acids mutate far more rapidly than others. Moreover, high sequence identity is expected over very short regions by chance in unrelated sequences that share no structural similarity (Kabsch and Sander, 1984). Thus, the inference of homology should always be based on statistically significant sequence similarity using an appropriate scoring matrix (Altschul, 1991).

However, once homology has been established, measures of statistical significance are not good measures of evolutionary distance. Two sequences that have diverged by the same amount, and thus share the same average levels of sequence similarity, can have very different similarity scores, with very different levels of statistical significance, depending on their lengths. For example, two members of the orotate phosphoribosyltransferase family, `pyre_colgr` and `pyre_klula`, that share 48.5% identity over 223 amino acid residues, have similarity scores $S_{bit} = 161$ with $E() < 10^{-39}$, while two members of the twice as long glucose transporter family with slightly lower identity (47.4% over 502 amino acids) obtain a similarity score of 308 bits with $E() < 10^{-82}$. Thus, similarity scores and expectation values must be adjusted when comparing among different length protein sequences if they are used as surrogates for evolutionary divergence.

This review of sequence similarity statistics has focused on protein sequence comparison for two reasons. First, protein sequence comparison is far more sensitive than DNA sequence comparison – the evolutionary lookback time for protein sequences is typically 5–10 times greater than that for DNA sequences (Pearson, 1997). Moreover, protein databases are more compact, so that more rigorous algorithms can be used for similarity searching. Secondly, DNA sequences are well known to have higher-order sequence dependence due to codon bias and simple-sequence repeat regions. Because of the small nucleotide alphabet and the possible translation of normal-complexity DNA sequences into low-complexity protein sequences, it is much more difficult to detect and correct for deviations from i.i.d. in DNA sequences. Thus, in general, statistical estimates from protein sequence comparisons are more reliable than the similar comparisons with DNA.

Our understanding of the statistical properties of biological sequences has improved dramatically over the past decade, so that most sequence similarity searching methods now include reliable statistical estimates. However, there is still room for improvement, as more searches are done with more complex queries, e.g. profiles, position-specific scoring matrices (Altschul *et al.*, 1997), and three-dimensional sequence-structure alignments, whose statistical properties on real sequences are not well understood. Fortunately, there is no shortage of data that can be used to develop and validate new statistical approaches.

Bayesian Methods in Biological Sequence Analysis

Jun S. Liu and T. Logvinenko

Department of Statistics, Harvard University, Cambridge, MA, USA

Hidden Markov models, the expectation-maximization algorithm, and the Gibbs sampler were introduced for biological sequence analysis in early 1990s. Since then the use of formal statistical models and inference procedures has revolutionized the field of computational biology. This chapter reviews the hidden Markov and related models, as well as their Bayesian inference procedures and algorithms, for sequence alignments and gene regulatory binding motif discoveries. We emphasize that the combination of Markov chain Monte Carlo and dynamic-programming techniques often results in effective algorithms for nondeterministic polynomial (NP)-hard problems in sequence analysis. We will also discuss some recent approaches to infer regulatory modules and to combine expression data with sequence data.

3.1 INTRODUCTION

In the past two decades, we have witnessed the development of the likelihood approach to pairwise sequence alignments (Bishop and Thompson, 1986; Thorne *et al.*, 1991); probabilistic models for RNA secondary structure predictions (Zuker, 1989; Lowe and Eddy, 1997; Ding and Lawrence, 2001; Pedersen *et al.*, 2004); the expectation-maximization (EM) algorithm for finding regulatory binding motifs (Lawrence and Reilly, 1990; Cardon and Stormo, 1992), the Gibbs sampling strategies for detecting subtle sequence similarities (Lawrence *et al.*, 1993; Liu, 1994; Neuwald *et al.*, 1997); the hidden Markov models (HMMs) for DNA composition analysis, multiple sequence alignments, gene prediction, and protein secondary structure prediction (Churchill, 1989; Krogh *et al.*, 1994a; Baldi *et al.*, 1994; Burge and Karlin, 1997; Schmidler *et al.*, 2000; **Chapters 4** and **5**); regression and Bayesian network approaches to gene regulation networks (Bussemaker *et al.*, 2001; Segal *et al.*, 2003; Conlon *et al.*, 2003; Beer and Tavazoie, 2004; Zhong *et al.*, 2005); and many statistical-model based approaches to gene expression microarray analyses (Li and Wong, 2001; Lu *et al.*, 2004; Speed, 2003). All these developments show

that algorithms resulting from statistical modeling efforts constitute a significant portion of today's bioinformatics toolbox. This chapter aims at introducing the readers to these modeling techniques and related Bayesian methodologies.

Section 3.2 gives an overview of the Bayesian inference procedure, including model building, prior specification, model selection, and Bayesian computation. Section 3.3 introduces the general HMM framework with an example on DNA compositional heterogeneity. Section 3.4 reviews Bayesian pairwise alignment methods. Section 3.5 demonstrates how HMMs are used in multiple sequence alignment (MSA) and how Bayesian inferences can be made on model parameters. Section 3.6 outlines some Bayesian methods for finding subtle repetitive motifs, which often correspond to transcription factor (TF) binding sites and binding modules, in DNA sequences. Section 3.7 provides a brief overview of recent activities in combining gene expression microarray information with promoter sequence analysis. Section 3.8 concludes the chapter with a brief summary. In this chapter, we emphasize the usefulness of dynamic-programming-like recursive algorithms in Bayesian and likelihood-based inferences and the importance of combining these efficient computational techniques with more flexible Markov chain Monte Carlo MCMC tools for bioinformatics problems.

3.2   OVERVIEW OF THE BAYESIAN METHODOLOGY

In Bayesian analysis, a joint probability distribution $f(\mathbf{y}, \boldsymbol{\theta}, \boldsymbol{\tau})$ is employed to describe relationships among all variables under consideration: those that we observe (data and knowledge, $\mathbf{y}$), those about which we wish to learn (scientific hypotheses, $\boldsymbol{\theta}$), and those that are needed in order to construct the model (missing data or nuisance parameters, $\boldsymbol{\tau}$). The basic probability theory then leads us to an efficient use of the available information and to a precise quantification of uncertainties in estimation and prediction (Gelman *et al.*, 1995). The Bayesian approach has following advantages: (1) its explicit use of probability models to formulate scientific problems (i.e. a quantitative story-telling); (2) its coherent way of incorporating all sources of information and treating nuisance parameters and missing data; and (3) its ability to quantify uncertainties in all estimates. Some other aspects of the Bayesian method are discussed in **Chapters 8**, **15**, **19**, **20**, and **26**.

3.2.1   The Procedure

Bayesian analysis treats parameters $\boldsymbol{\theta}$ and $\boldsymbol{\tau}$ as realized values of random variables that follow a *prior distribution*, $f_0(\boldsymbol{\theta}, \boldsymbol{\tau})$, typically regarded as known to the researcher independently of the data under analysis. The joint probability distribution can then be represented as *Joint = likelihood × prior*, that is,

$$p(\mathbf{y}, \boldsymbol{\theta}, \boldsymbol{\tau}) = f(\mathbf{y} \mid \boldsymbol{\theta}, \boldsymbol{\tau}) f_0(\boldsymbol{\theta}, \boldsymbol{\tau}).$$

The theorem that combines the prior and the data to form the conditional distribution $p(\boldsymbol{\theta}, \boldsymbol{\tau} \mid \mathbf{y})$, also called the *posterior distribution* of $\boldsymbol{\theta}$, is a simple mathematical result first given by Thomas Bayes in his famous article "Essay Towards Solving a Problem in the Doctrine of Chances" (1763), published posthumously in the *Philosophical Transactions of the Royal Society of London*. As per Bayes theorem,

$$p(\boldsymbol{\theta}, \boldsymbol{\tau} \mid \mathbf{y}) = \frac{p(\mathbf{y}, \boldsymbol{\theta}, \boldsymbol{\tau})}{p(\mathbf{y})} = \frac{f(\mathbf{y} \mid \boldsymbol{\theta}, \boldsymbol{\tau}) f_0(\boldsymbol{\theta}, \boldsymbol{\tau})}{\int f(\mathbf{y} \mid \boldsymbol{\theta}, \boldsymbol{\tau}) f_0(\boldsymbol{\theta}, \boldsymbol{\tau}) \mathrm{d}\boldsymbol{\theta} \, \mathrm{d}\boldsymbol{\tau}}. \tag{3.1}$$

The denominator $p(\mathbf{y})$, which is a normalizing constant for the function, is sometimes called the *marginal likelihood* and can be used for model selection. If we are interested in only $\boldsymbol{\theta}$, we can obtain its marginal posterior distribution as

$$p(\boldsymbol{\theta} \mid \mathbf{y}) = \int p(\boldsymbol{\theta}, \boldsymbol{\tau} \mid \mathbf{y})\mathrm{d}\boldsymbol{\tau}. \tag{3.2}$$

Formula (3.2) can give us not only a point estimate of $\boldsymbol{\theta}$ (e.g. posterior mean), but also an explicit measure of uncertainty (e.g. a 95 % probability interval). In contrast, frequentist approaches often face conceptual difficulties in dealing with nuisance parameters and in quantifying uncertainties.

Statistical procedures based on the systematic use of this theorem to manipulate subjective probabilities are often termed *Bayesian*, although they were first developed by Laplace in the early 1800s, after Bayes' death. Despite the deceptively simple-looking form of (3.1) and (3.2), the challenging aspects of Bayesian statistics are (i) the development of a model, $f(\mathbf{y} \mid \boldsymbol{\theta}, \boldsymbol{\tau})f_0(\boldsymbol{\theta}, \boldsymbol{\tau})$, that must effectively capture the key features of the underlying scientific problem; and (ii) the necessary computation for deriving the posterior distribution.

3.2.2 Model Building and Prior

It is often a useful model building strategy to distinguish two kinds of unknowns: population parameters and missing data. Although there is no absolute distinction between the two types, missing data are usually directly related to individual observations. They can be 'imputed' either conceptually or computationally so as to ease the statistical analysis. On the other hand, the parameters usually characterize the entire population under study and are fixed in number. For example, in a multiple alignment problem, alignment variables that must be specified for each observed sequence can be viewed as missing data. Residue frequencies for the aligned positions or the choice of scoring matrices, which apply to all the sequences, are population parameters.

The main controversial aspect of the Bayesian method is the need for *prior* distributions for unknown parameters. Since the choice of priors injects subjective judgments into the analyses, Bayesian methods have long been regarded as less 'objective' than their frequentist counterpart and disfavored. However, the emotive words 'subjective' and 'objective' should not be taken too seriously since there are considerable subjective elements and personal judgments in all phases of scientific investigations. These subjective elements, if made explicit and treated with care, should not undermine the results of the investigation. More importantly, it should be regarded as a good scientific practice for investigators to make their subjective inputs explicit. A truly objective evaluation of any procedure is based on how well it attains the goals of the original scientific problem.

Although it is worthwhile to think of prescribing 'objective' priors (usually with the adjective *'noninformative'*), such choices are usually unattainable in practice. We advocate the use of sensitivity analysis, that is, an analysis of how the inferential statements vary for a reasonable range of prior distributions, to validate the conclusion of a Bayesian analysis.

3.2.3 Model Selection and Bayes Evidence

Classical hypothesis testing can be seen as a model selection procedure in which one chooses between the null and the alternative hypotheses based on the degree of 'surprise' of the observed data. In contrast, Bayesian model selection can be achieved in a coherent

probabilistic framework. First, all the candidate models are embedded into an aggregate model. Second, the posterior probability of each candidate model is computed and used to discriminate or combine the models (Kass and Raftery, 1995).

Consider the situation where there are K competing models. Let $M = m$ indicate the mth model, where $m = 1, \ldots K$. We first write down the full joint distribution with all the models: $P(\mathbf{y}, \boldsymbol{\theta}, M) = P(\mathbf{y} \mid \boldsymbol{\theta}, M) P(\boldsymbol{\theta}, M)$. Since each model may have its own set of parameters, we rewrite the earlier equation as

$$P(\mathbf{y}, \boldsymbol{\theta}, M) = P(\mathbf{y} \mid \boldsymbol{\theta}_m) P(\boldsymbol{\theta}_m \mid M = m) P(M = m),$$

where $P(\boldsymbol{\theta}_m \mid M = m)$ is the prior distribution for the parameters in model m, and $P(M = m)$ is the prior probability of model m. Note that the dimensionality of $\boldsymbol{\theta}_m$ can be different for different m. The posterior probability of model m is simply

$$P(M = m \mid \mathbf{y}) \propto P(\mathbf{y} \mid M = m) P(M = m)$$
$$= \left\{ \int P(\mathbf{y} \mid \boldsymbol{\theta}_m) P(\boldsymbol{\theta}_m \mid M = m) \, \mathrm{d}\boldsymbol{\theta}_m \right\} P(M = m).$$

Sometimes one may not want to select and use a single model. Then the foregoing Bayesian formulation can be used to conduct 'model averaging' (Kass and Raftery, 1995). The model prior $P(M = m)$ is determined independently of the data in study. A frequent choice is $P(M = m) = 1/K$, implying that all models are equally likely *a priori*. In many cases, however, we may want to set smaller prior probabilities for models with higher complexities.

The classic hypothesis testing problem (i.e. null versus alternative models) can be easily fitted into the foregoing framework by letting M take on two possible values. The only caveat is that, in accordance with classical conventions, a small prior probability (e.g. 0.05) for the alternative model is preferable.

3.2.4 Bayesian Computation

In many applications, computation is the main obstacle in applying either the Bayesian or other sophisticated statistical methods. In fact, until recently these computations have often been so difficult that sophisticated statistical modeling and Bayesian methods were largely used by theoreticians and philosophers. The introduction of the bootstrap method (Efron, 1979), the EM algorithm (Dempster *et al.*, 1977), and the (MCMC) methods (Gilks *et al.*, 1998; Liu, 2001) has brought many powerful models into the mainstream of statistical analysis. As illustrated in later sections, by appealing to the rich history of computation in bioinformatics, many required optimizations and integrations can be done exactly, which gives rise to either the exact maximum likelihood estimation (MLE) or the exact posterior distribution, or a better approximation to both.

MCMC refers to a class of algorithms for simulating random variables from a distribution, $\pi(\mathbf{x})$, known up to a normalizing constant. These algorithms are well suited for Bayesian analyses since Bayesian inference can be trivially constructed if we can draw random samples from the posterior distribution (3.1) without computing its denominator. The basic idea behind all MCMC algorithms is the simulation of a Markov chain whose equilibrium distribution is the target distribution $\pi(\mathbf{x})$. Two main strategies for constructing such chains are the Metropolis–Hastings (M-H) algorithm and

the Gibbs sampler (Liu, 2001), both being widely used in diverse fields and reviewed in the Appendix. More discussions on MCMC and its fascinating applications can be found in **Chapters 15** and **26** by Huelsenbeck & Bollback, and Stephens respectively.

3.3 HIDDEN MARKOV MODEL: A GENERAL INTRODUCTION

A sequence of random variables $h_1, h_2, \ldots,$ is said to follow a lth order *Markov chain* if

$$P(h_i \mid h_1, \ldots, h_{i-1}) = P(h_i \mid h_{i-1}, \ldots h_{i-l}).$$

For example, one may assume that an observed sequence of nucleotide bases forms a first-order Markov chain with transition probabilities $P(h_{i+1} \mid h_i) = \theta_{h_i, h_{i+1}}$. With an observed realization of the chain (e.g. a segment of DNA sequence), we can obtain the MLEs of the θ by counting the frequencies of dimer occurrences.

It has long been known that the simple independent model is insufficient to describe genomic sequences. In coding regions, every nonoverlapping triplet of nucleotides codes for one of the 20 amino acid residues or a stop signal. Thus, a second-order Markov chain is perhaps desirable. However, correlation between the neighboring bases is still highly significant in noncoding regions. Some recent studies (Liu *et al.*, 2001; 2002; Huang *et al.*, 2004) show that using a second-order or a third-order Markov chain to model the promoter regions (hundreds to thousands bases upstream of the starting codon of the gene) can significantly improve the accuracy of gene regulatory binding motif discovery. It is clear that the genome is much more complex than a third-order Markov chain. Although it is desirable to model the genome sequences by even higher-order Markov chains, the number of unknown parameters increases so fast that a large amount of sequence data is required. Additionally, even high-order Markov models cannot capture certain local structures, regularities, and inhomogeneities of DNA sequences. Researchers found that it is often more suitable to use HMMs to capture various sequence features.

The HMM was initially introduced in the late 1960s and has been widely used in signal processing, speech recognition, and time series analysis (Rabiner, 1989). The method was first applied to model DNA sequences by Churchill (1989) and has become very popular in early 1990s owing to the pioneering work of Krogh *et al.* (1994a) and Baldi *et al.* (1994) on MSAs. The basic form of an HMM can be written as

$$r_i \sim f_i(r \mid h_i, \theta); \qquad h_i \sim g_i(h \mid h_{i-1}, \tau),$$

where f_i and g_i are probability distributions, θ and τ are parameters, and the r_i are observations. The h_i form a Markov chain and are often unobservable (i.e. hidden). What is of interest is the inference of θ, τ, and perhaps the h_i.

To be specific, let us examine an HMM that can accommodate compositional heterogeneity in DNA sequences. In particular, consider a sequence R consisting of two types of segments, each represented by a nucleotide frequency vector. We can only observe R and are interested in making inference on the locations of the segment change points and the composition parameters for each type of segment. A simple HMM first proposed by Churchill (1989) is shown in Figure 3.1.

In this model, we assume that the hidden layer $\mathbf{h} = (h_0, h_1, \ldots, h_n)$ is a Markov chain. Each h_i takes on only two possible values: $h_i = 0$ implies that residue $r_i \sim \text{Multinom}(\boldsymbol{\theta}_0)$;
Figure 3.1   A graphical illustration of the hidden Markov model.

and $h_i = 1$ indicates that $r_i \sim \text{Multinom}(\boldsymbol{\theta}_1)$. Here $\boldsymbol{\theta}_k = (\theta_{ka}, \theta_{kc}, \theta_{kg}, \theta_{kt})$. A 2×2 transition matrix, $\boldsymbol{\tau} = (\tau_{kl})$, where $\tau_{kl} = P(h_i = k \to h_{i+1} = l)$, dictates the generation of $\mathbf{h}$. A similar model has been developed by Krogh *et al.* (1994b) to predict protein coding regions in the *E. Coli* genome.

Let $\Theta = (\boldsymbol{\theta}_0, \boldsymbol{\theta}_1, \boldsymbol{\tau})$. The likelihood function of Θ can be written as

$$L(\Theta \mid R) = \sum_{\mathbf{h}} P(R \mid \mathbf{h}, \boldsymbol{\theta}_0, \boldsymbol{\theta}_1) P(\mathbf{h} \mid \boldsymbol{\tau}), = \sum_{\mathbf{h}} p_0(h_0) \prod_{i=1}^{n} (\theta_{h_i r_i} \tau_{h_{i-1} h_i}),$$

where h_0 is assumed to follow a known distribution $p_0(h_0)$. This function can be evaluated using a recursive summation method shown later in (3.3). With a prior distribution $f_0(\Theta)$, which may be a product of three independent Dirichlet distributions, we can write down the joint posterior distribution of all unknowns:

$$P(\Theta, \mathbf{h} \mid R) \propto P(R \mid \mathbf{h}, \Theta) P(\mathbf{h} \mid \Theta) f_0(\Theta).$$

In order to sample from this distribution, we can implement a data augmentation method (Tanner and Wong, 1987, a special Gibbs sampler), which iterates the following steps:

- *Path imputation*. Draw $\mathbf{h}^{(t+1)} \sim P(\mathbf{h} \mid R, \Theta^{(t)})$;

- *Posterior sampling*. Draw $\Theta^{(t+1)} \sim P(\Theta \mid R, \mathbf{h}^{(t+1)})$.

The path imputation step samples a hidden chain, or path, $\mathbf{h}$, from its *posterior* distribution with given parameter value, and this task can be achieved by a recursive method. More precisely, we note that

$$P(\mathbf{h} \mid R, \Theta) = c \; P(\mathbf{h}, R \mid \Theta) = c \; P(R \mid \mathbf{h}, \Theta) p(\mathbf{h} \mid \Theta)$$

$$= c \; p_0(h_0) \prod_{i=1}^{n} \left\{ P(r_i|h_i) P(h_i|h_{i-1}) \right\} = c \; p_0(h_0) \prod_{i=1}^{n} \left(\theta_{h_i r_i} \tau_{h_{i-1} h_i} \right),$$

where $c^{-1} = \sum_{\mathbf{h}} \left\{ p_0(h_0) \prod_{i=1}^{n} \left(\theta_{h_i r_i} \tau_{h_{i-1} h_i} \right) \right\}$. Define $F_0(h) = p_0(h)$ and then, recursively, let

$$F_{k+1}(h) = \sum_{h_i=0}^{1} \{ F_k(h_i) \tau_{h_i h} \theta_{h r_{i+1}} \}, \quad \text{for } i = 1, \ldots, n. \tag{3.3}$$

At the end of the recursion, we have $c^{-1} = F_n(0) + F_n(1)$ and

$$P(h_n \mid R, \Theta) = \frac{F_n(h_n)}{F_n(0) + F_n(1)}. \tag{3.4}$$

In order to sample $\mathbf{h}$ from $P(\mathbf{h} \mid R, \Theta)$, we first draw h_n from distribution (3.4) and then draw h_i recursively backward from distribution

$$P(h_i \mid h_{i+1}, R, \Theta) = \frac{F_k(h_i)\tau_{h_i h_{i+1}}}{F_k(0)\tau_{0 h_{k+1}} + F_k(1)\tau_{1 h_{k+1}}}. \qquad (3.5)$$

The posterior sampling step in data augmentation involves only the sampling from appropriate Dirichlet distributions. For example, $\boldsymbol{\theta}_0$ should be drawn from Dirichlet $(n_{0a} + \alpha_a, \ldots, n_{0t} + \alpha_t)$, where, n_{0a}, say, is the counts of the r_i whose type is A and whose hidden state h_i is zero. It is straightforward to extend this model to a k-state HMM so as to analyze a sequence with regions of k different compositional types.

3.4 PAIRWISE ALIGNMENT OF BIOLOGICAL SEQUENCES

Ever since the creation of GenBank, which grew from 680 338 base pairs in 1982 to 22 billion base pairs in 2002 (Benson *et al.*, 2002), and other related databases, sequence comparisons and sequence database search have played a pivotal role in contemporary biological research. By observing sequence similarities between a new target gene (or a segment of it) and some well-studied ones, biologists can gain important insights into its function and structure (see **Chapter 2** for more biological importance). The two most well-known 'rigorous' pairwise alignment methods are the method of Needleman and Wunsch (1970) for global alignment and that of Smith and Waterman (1981) for local alignment. They are based on dynamic programming and are guaranteed to find the global optimum of certain alignment scoring functions. Two most popular 'heuristic' pairwise alignment algorithms are BLAST (Altschul *et al.*, 1990) and FASTA (Pearson and Lipman, 1988), and both are an order of magnitude faster than the rigorous ones. **Chapter 2** provides some detailed discussions on these algorithms and issues related to the statistical significance of the resulting scores. This section discusses a Bayesian version of the Needleman–Wunsch algorithm and a motif-based Bayesian pairwise alignment method. Throughout the section, the observed data consist of two DNA or protein sequences, $R^{(1)} = (r_1^{(1)}, r_2^{(1)}, \ldots, r_{n_1}^{(1)})$ and $R^{(2)} = (r_1^{(2)}, r_2^{(2)}, \ldots, r_{n_2}^{(2)})$.

3.4.1 Bayesian Pairwise Alignment

Since traditional pairwise alignment methods are not based on any statistical models, it is difficult to judge whether they have incorporated all the relevant information, and, more importantly, whether the parameters have been tuned optimally. The use of statistical models and Bayesian methodology can help in these aspects. A Bayesian pairwise alignment method starts with a model, $P(R^{(1)}, R^{(2)} \mid \Theta, \boldsymbol{\tau})$ that describes the relationship between two sequences. To be concrete, we let Θ be a 20×20 joint symmetric probability matrix analogous to a scoring matrix such as the PAM and BLOSUM, describing the joint distribution of a pair of aligned amino acids. For example, according to BLOSUM62, the joint probability $\theta_{r_1 r_2}$ of $r_1 = \text{I}$ (isoleucine) occurring in sequence 1 and $r_2 = \text{L}$ (leucine) in the same position of sequence 2 is about 4 times the product of their respective marginal frequencies, $\theta_{r_1} \times \theta_{r_2}$, where θ_{r_1} is the sum of the entries in the row for r_1 (or the column for r_1, due to symmetry) of Θ. Generally, the (i, j)th entry of a BLOSUMx matrix stores

$2 \log_2 \frac{\theta_{i,j}}{\theta_i \theta_j}$ for amino acid pair (i, j). The number 'x' reflects that these joint frequencies are estimated from the set of protein sequences among which no pair has more than x % alignment positions with identical residues (for more details, see **Chapter 2**).

Conceptually, the alignment of $R^{(1)}$ and $R^{(2)}$ is characterized by an alignment matrix A, where element $a_{i,j}$ are set to 1 if residue i of sequence 1 'aligns' with residue j of sequence 2 and 0 otherwise. A restriction is that the aligned residues have to be 'collinear', that is, if $r_{i_1}^{(1)}$ is aligned with $r_{j_1}^{(2)}$ and $r_{i_2}^{(1)}$ with $r_{j_2}^{(2)}$, then $(i_1 - i_2)(j_1 - j_2) > 0$.

3.4.1.1 *Gap-based Global Alignment*

Let $\Lambda = (\lambda_o, \lambda_e)$ be probabilities of gap opening and gap extension, respectively, which govern the formation of the alignment matrix A. Here we show how the global alignment problem may be treated in a Bayesian way by using the statistical models pioneered by Thorne *et al.* (1991). First, the joint distribution is defined as

$$P(R^{(1)}, R^{(2)}, A, \Theta, \Lambda) = P(R^{(1)}, R^{(2)} \mid A, \Theta)P(\Theta) \ P(A \mid \Lambda)P(\Lambda).$$

Traditional alignment procedures can be seen as optimizing an objective function that is analogous to a log-likelihood (Holmes and Durbin, 1998). More precisely, for a set of fixed values $\Theta = \Theta^0$ and $\Lambda = \Lambda^0$, one finds A^* so that

$$\log P(R^{(1)}, R^{(2)}, A^* \mid \Theta^0, \Lambda^0) = \max_A \{\log P(R^{(1)}, R^{(2)} \mid A, \Theta^0) + \log P(A \mid \Lambda^0)\}.$$
$$(3.6)$$

The need for setting parameter values Θ^0 and Λ^0 has been the subject of much discussion in the field of bioinformatics. A distinctive advantage of the Bayesian procedure is its added modeling flexibility in the specification of parameters.

Let A be the alignment indicator matrix, which can also be seen as a *'path'* in a dynamic-programming setting. With given $\Lambda = (\lambda_o, \lambda_e)$, the probability of any allowable path, prior to seeing the content of the two sequences to be aligned, but conditional on their lengths n_1 and n_2, is

$$P(A \mid \lambda_o, \lambda_e) = \frac{\lambda_o^{k_g(A)} \lambda_e^{l_g(A) - k_g(A)}}{\sum_{A'} \lambda_o^{k_g(A')} \lambda_e^{l_g(A') - k_g(A')}} \tag{3.7}$$

where $k_g(A)$ and $l_g(A)$ are the total number and the total length of the gaps in A, respectively. The summation in the denominator is over all possible alignments of the two sequences. In the derivation given in subsequent text, we condition on the length information, n_1 and n_2.

If we let Θ take values in a series of BLOSUMx matrices (after log-odds transformations), then we can compute the marginal likelihood of Λ as

$$P(R^{(1)}, R^{(2)} \mid \Lambda) = \sum_{\Theta} \sum_A P(R^{(1)}, R^{(2)} \mid A, \Theta)P(A \mid \Lambda)P(\Theta),$$

$$= \frac{\sum_{\Theta} \sum_A P(R^{(1)}, R^{(2)} \mid A, \Theta)P(\Theta)\lambda_o^{k_g(A)} \lambda_e^{l_g(A) - k_g(A)}}{\sum_{A'} \lambda_o^{k_g(A')} \lambda_e^{l_g(A') - k_g(A')}} \tag{3.8}$$

In the numerator, Θ is marginalized out by summing over all the scoring matrices in a given set, each with a prior 'weight' $P(\Theta)$. Both the numerator and the denominator of (3.7) can be computed via a recursive algorithm similar to the Needleman–Wunsch algorithm (Liu and Lawrence, 1999).

As with traditional dynamic-programming alignment algorithms (see Figure 3.3(b), for example), we can describe a path as consecutive moves of three types: $\rightarrow$ (deletion), $\downarrow$ (insertion), and $\searrow$ (match). To ensure uniqueness, one often adds the restriction that an insertion cannot follow a deletion. For example, to obtain the numerator of (3.7), we start with $p(0, 0) = p_\mathrm{m}(0, 0) = 1$, $p_\mathrm{i}(0, 0) = p_\mathrm{d}(0, 0) = 0$, and compute recursively:

$$p_\mathrm{m}(k, l) = p(k - 1, l - 1)\theta_{r_k^{(1)} r_l^{(2)}},$$

$$p_\mathrm{i}(k, l) = \{\lambda_\mathrm{e} p_\mathrm{i}(k - 1, l) + \lambda_\mathrm{o} p_\mathrm{m}(k - 1, l)\}\theta_{r_k^{(1)}},$$

$$p_\mathrm{d}(k, l) = \{\lambda_\mathrm{e} p_\mathrm{d}(k, l - 1) + \lambda_\mathrm{o} p_\mathrm{m}(k, l - 1) + \lambda_\mathrm{o} p_\mathrm{i}(k, l - 1)\}\theta_{r_l^{(2)}},$$

$$p(k, l) = p_\mathrm{m}(k, l) + p_\mathrm{i}(k, l) + p_\mathrm{d}(k, l).$$

In the equations, $p_\mathrm{m}(k, l)$ is the score of entry (k, l) when the last move is a 'match'; $p_\mathrm{i}(k, l)$ is the score when the last move is an 'insertion' for sequence 1; and $p_\mathrm{d}(k, l)$ is the score when the last move is a 'deletion' for sequence 1. Thus, $P(R^{(1)}, R^{(2)} \mid \Lambda, \Theta) = p(n_1, n_2)$, and the posterior distribution of Λ is

$$P(\Lambda \mid R^{(1)}, R^{(2)}) \propto P(R^{(1)}, R^{(2)} \mid \Lambda) f_0(\Lambda).$$

This Bayesian approach provides us with not only the maximum *a posteriori* alignment of the two sequences, but also a *distribution* of the pairwise alignments, which can be represented by a random sample from the posterior alignment distribution and used to measure uncertainty in the alignment result. A Bayesian version of the Smith–Waterman algorithm is given in Webb *et al.* (2002). They showed that the new method outperformed the optimally tuned Smith–Waterman algorithm in detecting distantly related proteins.

3.4.1.2 Motif-based Local Alignment

While the gap-based approaches have dominated alignment methods for many years, Bayesian statistics opens up new directions in dealing with insertions and deletions in alignments. Zhu *et al.* (1998) attacked the Bayesian alignment problem by directly specifying a prior alignment distribution: all alignments with k gaps are equally likely, and all k in the given range are equally likely. This prior penalizes an alignment with many gaps by a factor inversely proportional to the number of that type of alignment. The summation over all alignments is carried out by the dynamic-programming method of Sankoff (1972). Input requirements for the scoring matrices are more flexible in the Bayesian setting than in traditional methods. For example, Zhu *et al.* (1998) examine the use of a series of either the PAM or the BLOSUM matrices as prior input in which all the matrices are assigned equal probability *a priori*. They report that the posterior distribution of the scoring matrices is often flat and sometimes multimodal, indicating that no one matrix is clearly more preferable to others when aligning two sequences.

Consider the expression for the posterior distribution of the scoring matrix:

$$P(\Theta \mid R^{(1)}, R^{(2)}) = \frac{1}{P(R)} \sum_k \sum_A P(R^{(1)}, R^{(2)} \mid A, \Theta) P(\Theta) P(A \mid \Lambda = k) P(\Lambda = k),$$

where Θ indicates one of the series of scoring matrices (PAM or BLOSUM), reflecting to a certain extent the distance between the two sequences, and Λ denotes the number of gaps allowed in the alignment. Since this posterior is obtained by averaging over all alignments, a 'good' alignment is not required for assessing the distance between the two sequences. This feature may be of value in distance-based methods employed in molecular evolutionary studies because the requirement that a pair of sequences must be sufficiently close to permit a good alignment is removed.

3.5   MULTIPLE SEQUENCE ALIGNMENT

Although pairwise alignment methods have been tremendously successful in modern biological researches, these methods treat all the positions of the query sequence as equally important, whereas in biological reality many 'unimportant' regions of a protein can tolerate severe distortions and are not well conserved even for those within a specialized protein family. A more attractive approach for detecting remotely related proteins is to use features common to a set of related proteins to perform the search. These common features can be most effectively represented by a position-specific consensus 'profile' extracted by a comparative study of all the protein sequences in consideration, that is, by the MSA.

Currently, the most widely used MSA method is ClustalW (Thompson *et al.*, 1994a). At first, the algorithm compares all pairs of sequences in the set using a dynamic-programming algorithm (similar to Smith–Waterman). The resulting pairwise comparison scores are transformed into evolutionary distances (Kimura, 1985). Then, a phylogenetic tree is constructed using the neighbor-joining method (Saitou and Nei, 1987). Following the branching order of the built phylogenetic tree, ClustalW progressively performs pairwise alignments of sequences or the consensus profile matrix at each node. To improve the quality of the alignments, ClustalW uses a sequence weighting strategy to avoid overrepresentation of closely related homologs (Thompson *et al.*, 1994b). At the alignment stage, a variety of substitution matrices (chosen depending on the closeness of the relationship between sequences/profiles to be aligned) is used and position-specific gap penalties are incorporated.

Another widely used method for constructing MSA is PSI-BLAST (Altschul *et al.*, 1997). It first uses BLAST (Altschul *et al.*, 1990) to collect all the sequences in the searched database that are significantly related to the query sequence. Then an MSA is created by 'anchoring' selected pairwise alignments to the query sequence (to avoid overrepresentation of closely related proteins, sequences with more than 98 % identity are thrown out). On the basis of the weighted counts of the residues in columns of the MSA (the weighting procedure of Henikoff and Henikoff (1992) is used), a position-specific profile is constructed. Using a modification of BLAST, another iteration of database search is performed using the constructed profile and the next order relatives are collected. They are, in turn, anchored to the current MSA, and used to update the profile. The procedure is repeated until no more relatives can be found from the database.

3.5.1   The Rationale of Using HMM for Sequence Alignment

The heuristics used in both PSI-BLAST and ClustalW incorporate a significant amount of biological knowledge. However, both methods lack principled ways to synthesize more delicate biological information and to tune parameters. In addition, the MSAs resulting from these methods tend to be heavily influenced by either the query sequence or the sequence order. The introduction of the profile HMM for the sequence alignment problem in early 1990s (Krogh *et al.*, 1994a; Baldi *et al.*, 1994) revolutionized the field and provided the scientist fresh ways of looking at many biological problems including MSA.

In the evolution of protein sequences, segment transpositions are rare, so we can safely assume in most cases that the discrepancy between two homologous sequences is caused by insertions/deletions (indels) and point mutations. Thus, although the sequences are misaligned via indels, conserved residues remain in order. By capturing this characteristic, the HMM not only captures an important feature of protein evolution, but also results in an effective algorithm.

As shown in Figure 3.2, in the HMM framework, one treats the sequences to be aligned as iid observations from a probabilistic mechanism (i.e. 'insert', 'delete', and 'match') that perturbs a hypothetical common 'ancestral' model sequence (called *model*), denoted as $M = (\mathbf{m}_1, \ldots, \mathbf{m}_L)$. The 'match' state implies that the current residue at this position has evolved from (i.e. corresponds to) the 'ancestral' residue via mutations, not indels. Note that it does not mean that the residue matches with the ancestral ones. Two major distinctions between this HMM framework and the standard evolutionary model are noteworthy: (a) since the observed sequences are iid given the ancestral model, this HMM does not capture the important tree structure of a realistic evolutionary process, which is often essential to reflect correlations among the observed sequences; (b) the ancestral model is not meant to be an ancestral sequence. In other words, each model position $\mathbf{m}_j$ is not meant to recover what the ancestral residue most likely is, but is used to model this position's residue preference, which results from both the evolutionary force and functional constraints (selection). With principled statistical inference methods, one can estimate optimally all the parameters in this model, and consequently in the ancestral profile model, based on the observed sequences.

The diagram in Figure 3.3(a) describes the generative procedure for the underlying (hidden) Markov chain. In this model, each $\mathbf{m}_l$ is regarded as an abstract residue and is associated with an 'emission' probability vector $\boldsymbol{\theta}_l$ of length p ($p = 4$ for DNA sequences, and $p = 20$ for proteins). For simplicity, we assume that all 'insert' states are associated with a common 'emission' probability $\boldsymbol{\theta}_0$. When generating biological sequences, the
Figure 3.2   Independent generation of protein sequences from an HMM.

types of perturbations allowed are point mutations, insertions, and deletions. A residue in an observed sequence is generated either by a 'match' state, $\mathbf{m}_j$ say, or by an 'insert' state, $\mathbf{i}_k$, say. Another set of transition probabilities, one associated with each arrow in Figure 3.3(a), for example, $\tau_{\mathbf{m}_j\mathbf{m}_{j+1}}$, $\tau_{\mathbf{d}_j\mathbf{m}_{j+1}}$, $\tau_{\mathbf{i}_j\mathbf{i}_j}$, and so on, are needed to describe the underlying Markov chain. Note that probabilities coming out of a node have to sum up to 1, and they can be either given in advance or estimated ('trained') from many unaligned sequences.

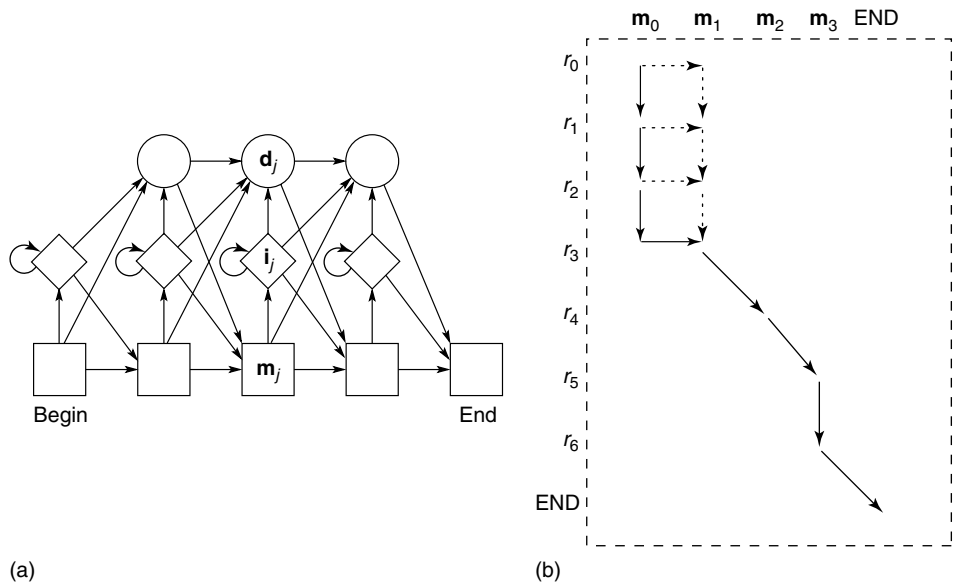
Starting from the 'Begin' state, a protein sequence is 'produced' from the profile HMM as follows. According to the transition probabilities, a series of hidden states is generated until the 'End' state is reached. In turn, each of the 'match' and 'insert' states generates an amino acid based on its state specific 'emission' probability distribution. Figure 3.4 shows how the sequence $R = (r_1, r_2, \ldots, r_6) \equiv \texttt{VLSFFD}$ is generated by a profile HMM with three match states.


Figure 3.3 (a) A profile HMM model for sequence alignment. 'Match', 'insert', and 'delete' states are represented by squares, diamonds, and circles, respectively. (b) A 'Path' representing the alignment of a sequence to a profile HMM.
Figure 3.4 A toy sequence of length 6 generated by a profile HMM with 3 match states. Note that $\mathbf{m}_1$ is replaced by state d_1, implying that first match state is deleted in generating the observed sequence.

One can also think of the process of generating sequence R from the profile HMM as that of choosing a path through an $(n + 1) \times (L + 1)$ table starting from the upper left corner and ending with the lower right corner (Figure 3.3b), very much similar to the diagram used to illustrate the Smith–Waterman and Needleman–Wunsch algorithms. The columns for this table are denoted by $\mathbf{m}_0, \ldots, \mathbf{m}_L$, which correspond to a void start position and L model positions. The rows, $r_0, \ldots, r_n$, correspond to a void starting residue and the n observed sequence residues. At any position (k, j) of this table, the next step allowed is (a) position $(k, j + 1)$, implying that a deletion of model position $\mathbf{m}_{j+1}$ has occurred ($\rightarrow$); (b) position $(k + 1, j)$, implying that r_{k+1} has occurred ($\downarrow$); or, lastly, (c) position $(k + 1, j + 1)$, implying that r_{k+1} is generated by model position $\mathbf{m}_{j+1}$ ($\searrow$). Thus the path depicted by the solid arrows in Figure 3.3(b) corresponds to the following probabilistic transitions:

$$\mathbf{m}_0 \rightarrow \mathbf{i}_0 \rightarrow \mathbf{i}_0 \rightarrow \mathbf{i}_0 \rightarrow \mathbf{d}_1 \rightarrow \mathbf{m}_2 \rightarrow \mathbf{m}_3 \rightarrow \mathbf{i}_3 \rightarrow \text{END},$$

which is exactly the same as in Figure 3.4.

It is worthwhile to note that the hidden states for this HMM are NOT the $\mathbf{m}_l$'s, but the allowable 'paths' that traverse the $(n + 1) \times (L + 1)$ table. Liu *et al.* (1999) provided a slightly different formulation of this model so as to make it conform with the conventional HMM shown in Figure 3.1. In other words, they constructed a hidden chain, $h_0 \rightarrow h_1 \rightarrow \cdots \rightarrow h_n$, that generates the observed sequence R, where each h_i records the number of deletions that have occurred till residue r_i and whether r_i is generated by an insert or a match state.

3.5.2 Bayesian Estimation of HMM Parameters

Let $\mathbf{R} = (R_1, \ldots, R_m)$ be the set of sequences to be aligned, let Θ denote the collection of all parameters including the transition probabilities $\boldsymbol{\tau}$ and the emission probabilities $\boldsymbol{\theta}_j$, and let $\mathcal{A} = (A_1, \ldots, A_m)$ denote the unobserved alignment variable (i.e. for each of the sequences an alignment path as shown in Figure 3.3(b)). For simplicity, we assume that the emission probabilities from the 'insert' state are the same for all positions and denoted as $\boldsymbol{\theta}_0$. It is observed that, once the sequences are aligned (i.e. given $\mathcal{A}$), the transition probabilities, $\tau_{k,l} = P(s_k \rightarrow s_l)$ (from any state s_k to any state s_l), model emission probabilities, $\boldsymbol{\theta}_j(r) = P(\text{residue } r | s_k = \mathbf{m}_j)$, and insertion emission probabilities $\boldsymbol{\theta}_0$ are easy to estimate:

$$\tau_{k,l} = \frac{T_{k,l}}{\sum_{\text{states } l'} T_{k,l'}},$$

$$\boldsymbol{\theta}_j(r) = \frac{E_j(r)}{\sum_{\text{residues } r'} E_j(r')},$$

where $T_{k,l}$ is the number of transitions from state s_k to s_l, and $E_j(r)$ is the number of residues of type r emitted from match state $\mathbf{m}_j$ in the sequence alignment. With Dirichlet priors (or Dirichlet Mixture priors, Sjolander *et al.*, 1996), a Bayesian estimate of these parameters are also easy. On the other hand, once the parameters of the HMM are given, it is also feasible to find either the optimal or the average alignment of each sequence to the model by using a dynamic-programming technique shown earlier (i.e. finding the optimal path in Figure 3.3(b)). On the basis of these insights, Krogh *et al.* (1994a) modified a

Baum–Welch algorithm (an earlier version of the EM algorithm, Baum, 1972) for training the profile HMM. Baldi *et al.* (1994) developed a gradient descent method (Baldi *et al.*, 1994) for finding the MLE of Θ.

The foregoing heuristics that it is 'easy' to estimate Θ given $\mathcal{A}$ and to handle $\mathcal{A}$ given Θ also facilitate a Bayesian MCMC approach (Churchill and Lazareva, 1999). The general procedure is outlined in subsequent text.

- Initialization. Choose model length L (the number of 'match' states) and set initial parameter values. In the absence of prior knowledge, one may let L be the average length of all the sequences.

- Data Augmentation. Starting with $\Theta^{(0)}$, we proceed for $t = 1, \ldots, N$:

  - Alignment imputation. Sample $\mathcal{A}^{(t+1)}$ from $P(\mathcal{A} \mid \mathbf{R}, \Theta^{(t)})$.

  - Parameter simulation. Draw $\Theta^{(t+1)}$ from $P(\Theta \mid \mathbf{R}, \mathcal{A}^{(t+1)})$.

  The number of iterations N may be determined dynamically on the basis of certain convergence criteria (Liu, 2001).

- The final alignment model can be estimated in one of the following ways.

  - Use the average of the $\Theta^{(t)}$ in the last K iterations ($K = 500$, say).

  - Estimate Θ by its posterior mode.

  - One can also find an optimal alignment $\mathcal{A}^*$, and then estimate Θ as $E(\Theta \mid \mathbf{R}, \mathcal{A}^*)$.

Figure 3.5 shows a simple alignment of three sequences, from which the HMM parameters can be estimated.

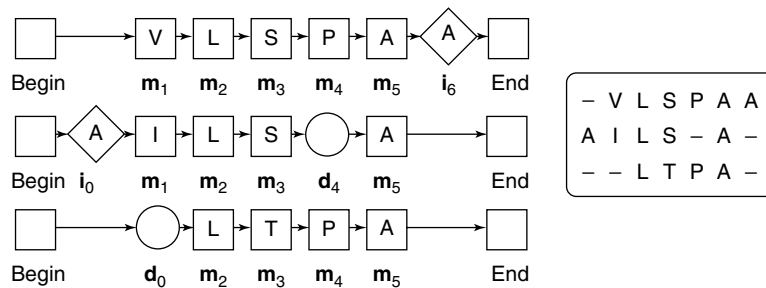
In most applications, the number of match states L is not known and it is desirable to let the data speak for itself. In some available packages for HMM-based MSA, L is updated iteratively using heuristic rules. For example, once an alignment such as the one shown in Figure 3.5 is produced, one can either remove certain 'match' positions if the corresponding column contains more than $x\,\%$ deletions or add a new 'match' position if more than $y\,\%$ of the sequences have insertions of similar types at the same place. It is also possible to treat L as a new parameter and infer the size of HMM in a coherent Bayesian framework. Operationally, one can insert between the alignment imputation and


Figure 3.5   The alignment of three sequences to the profile HMM.

parameter simulation steps of data augmentation a 'match' state updating step to either add or delete a match column using the M-H rule (see the Appendix).

A key step in implementing the data augmentation procedure is the computation of the likelihood:

$$P(\mathbf{R} \mid \mathbf{\Theta}) = \sum_{\mathcal{A}} P(\mathbf{R} \mid \mathbf{\Theta}, \mathcal{A}) P(\mathcal{A} \mid \mathbf{\Theta}),$$

because this is needed in imputing $\mathcal{A}$ from $P(\mathcal{A} \mid \mathbf{R}, \mathbf{\Theta}) = P(\mathcal{A}, \mathbf{R} \mid \mathbf{\Theta})/P(\mathbf{R} \mid \mathbf{\Theta})$. Dynamic-programming recursions can be applied to complete the task with complexity $O(nmL)$, where m is the number of sequences, n is their average length, and L is the number of match states. Since all the sequences in consideration are mutually independent conditional on $\mathbf{\Theta}$, we may focus only on one sequence, that is, the computation of $P(R \mid \mathbf{\Theta})$. The imputation of A for this sequence can be achieved by the following two-stage algorithm, which is analogous to the forward–backward algorithm in Section 3.3.

Forward summation

- Initialization with $f_m(0, 0) = 1$ and $f_i(0, 0) = f_d(0, 0) = 0$.

- Recursion:

$$f_{\mathrm{m}}(j + 1, k + 1) = \boldsymbol{\theta}_{\mathrm{k}}(j + 1)[f_{\mathrm{m}}(j, k)\tau_{\mathbf{m}_k \mathbf{m}_{k+1}} + f_{\mathrm{i}}(j, k)\tau_{\mathbf{i}_k \mathbf{m}_{k+1}} + f_{\mathrm{d}}(j, k)\tau_{\mathbf{d}_k \mathbf{m}_{k+1}}];$$

$$f_{\mathrm{i}}(j + 1, k + 1) = \boldsymbol{\theta}_0(j + 1)[f_{\mathrm{m}}(j, k + 1)\tau_{\mathbf{m}_{k+1} \mathbf{i}_{k+1}} + f_{\mathrm{i}}(j, k + 1)\tau\mathbf{i}_{k+1} \mathbf{i}_{k+1}];$$

$$f_{\mathrm{d}}(j + 1, k + 1) = f_{\mathrm{m}}(j + 1, k)\tau_{\mathbf{m}_k \mathbf{d}_{k+1}} + f_{\mathrm{i}}(j + 1, k)\tau_{\mathbf{i}_k \mathbf{d}_{k+1}} + f_{\mathrm{d}}(i + 1, k)\tau_{\mathbf{d}_k \mathbf{d}_{k+1}}.$$

- The algorithm terminates when the (L, n)th entry is reached.

At the end, we have $P(R \mid \mathbf{\Theta}) = f_{\mathrm{m}}(n, L) + f_{\mathrm{i}}(n, L) + f_{\mathrm{d}}(n, L)$. After the forward summation, one can carry out the backward-sampling step to impute the alignment path A. For a simple description, we let $v()$ be a backward-tracing function of the three types of states: $v(\mathbf{m}) = (-1, -1)$, $v(\mathbf{i}) = (-1, 0)$, and $v(\mathbf{d}) = (0, -1)$.

Backward sampling

- Start from position (n, L) and proceed as follows.

- Suppose we are at a position (x, y). Sample B from one of the three symbols '$\mathbf{m}$', '$\mathbf{i}$' and '$\mathbf{d}$' with probabilities proportional to $f_{\mathrm{m}}(x, y)$, $f_{\mathrm{i}}(x, y)$, and $f_{\mathrm{d}}(x, y)$ respectively; set an arrow from (x, y) to $(x, y) + v(B)$.

- Terminate when the $(0, 0)$th entry is reached. The path indicated by the collection of arrows is a sample of A from distribution $P(A \mid R, \mathbf{\Theta})$.

Several HMM-based software packages for producing multiple protein sequence alignments are available, although none of them are Bayesian. HMMER was developed by Eddy (1998) and is available at `http://hmmer.wustl.edu/`. SAM was developed by the UC Santa Cruz group and is available at `http://www.soe.ucsc.edu/projects/compbio/HMM-apps/HMM-applications.html`. It uses Dirichlet Mixture prior on amino acid emission probabilities.

3.5.3   PROBE and Beyond: Motif-based MSA Methods

Aligning distantly related sequences presents unique algorithmic and statistical challenges because often such proteins only share a minimal structural core with sizable insertions occurring between, and even within, core elements. Classical dynamic programming-based multiple alignment procedures typically have considerable difficulty spanning these insert regions because the log-odds scores associated with weakly conserved core elements are often too low to offset the substantial gap penalties that such insert regions incur. This problem is further exacerbated when core elements contain short insertions or deletions within them.

Although the standard HMM is flexible enough to model multiple related sequences, a large number (over 100) of unaligned sequences is usually required in order to train an HMM with flexible gap penalties due to the large number of parameters present in the model. In order to detect and align more distantly related proteins, one has to further constrain the profile HMM model in a biologically meaningful way. The block-motif propagation model utilized in PROBE (Neuwald *et al.*, 1997; Liu *et al.*, 1999) achieves this type of parameter reduction by focusing on the alignment composed of block motifs.

A block motif is a special HMM that allows no insertions or deletions among the match states. The propagation model consists of a number of block motifs, as shown in Figure 3.6. The gaps between blocks, corresponding to gaps in an HMM, can be modeled by a probability distribution other than the geometric one implied by the standard HMM. PROBE also uses a Bayesian procedure for selecting the sizes of the blocks and the number of blocks.

The propagation model assumes that there are L conserved 'blocks' for each sequence to be aligned, and the lth block of residues is of length w_l. We can imagine that L motif elements propagate along a sequence. Insertions are reflected by gaps between adjacent blocks. No deletions are allowed, but it is possible to relax this constraint by treating each block as a mini-HMM. Again, let Θ be the collection of all parameters needed in the propagation model (e.g. the motif profile matrices, background frequencies, and parameters characterizing the distribution of gaps between motif blocks) and let the alignment variable $\mathcal{A} = (A_1, \ldots, A_L) = (a_{k,l})_{K \times L}$ be a matrix with $a_{k,l}$ indicating the starting position of the lth motif element in sequence k (Figure 3.6). Note that both Θ and $\mathcal{A}$ in this model are of much smaller dimensions compared to their counterparts in the HMM because of the block-motif constraint.

The alignment variable $\mathcal{A}$ as represented by the locations of the motif elements is not observable. But once it is known, we can write down the likelihood $P(\mathbf{R} \mid \mathcal{A}, \Theta)$ (details can be found in Liu *et al.* 1999), from which we can make Bayesian inference on Θ easily. On the other hand, once Θ were given, we could impute $\mathcal{A}$ by a draw from $P(\mathcal{A} \mid \mathbf{R}, \Theta)$, which can be achieved using a forward–backward method similar to that in Section 3.3. Thus, we can again implement a data augmentation strategy to iterate between sampling of $\mathcal{A}$ and Θ. In PROBE, a 'collapsing' technique (Liu, 1994) is employed to further improve the efficiency of the computation.

Figure 3.6   An illustration of the propagation model in Liu *et al.* (1999).

The number of motifs L and the total number of motif columns $W = w_1 + \cdots + w_L$ are treated as random variables and selected according to an approximate Bayesian criterion. PROBE is also one of the earliest algorithms implementing the iterative database search process. Similar to PSI-BLAST, PROBE first uses BLAST to get the first-order relatives of the query sequence and aligns them to produce a block-motif profile. Then, it uses the constructed profile to find more relatives and further refine the alignment. It stops when no new relatives are found. It has been shown that PROBE is a very sensitive method for detecting distantly related proteins and capturing very weak similarities (Hudak and McClure, 1999; Neuwald *et al.*, 1997). The program is available at `ftp://ftp.ncbi.nih.gov/pub/neuwald/probe1.0/`.

A serious limitation of PROBE is that it does not allow gaps within conserved blocks. Neuwald and Liu (2004) recently extended the method to allow indels in conserved blocks–previous ungapped blocks are replaced by local HMMs. They have also described a few MCMC strategies for optimizing the alignment and for adjusting position-specific amino acid frequencies and gap penalties, and implemented them in the software package 'GISMO'. The new alignment method was applied to a statistically based approach called *contrast hierarchical alignment and interaction network* (CHAIN) analysis, which infers the strengths of various categories of selective constraints from co-conserved patterns in a multiple alignment (Neuwald *et al.*, 2003). The power of this approach strongly depends on the quality of the multiple alignments.

The programs MUSCLE (Edgar, 2004a; 2004b) and MAFFT (Katoh *et al.*, 2002) are also designed to avoid alignment of nonhomologous regions, and in other respects they are generally superior to more widely used multiple alignment programs, such as ClustalW and T-coffee (Notredame *et al.*, 2000). Because MUSCLE and MAFFT can handle large data sets, Neuwald explored the use of these programs for CHAIN analysis (personal communication). Somewhat surprisingly, these failed to achieve the degree of accuracy needed to detect subtle, co-conserved patterns, such as those recently identified and structurally confirmed within P loop GTPases (Neuwald *et al.*, 2003). We found that, although these programs align regions globally conserved in the sequences well, for several large test sets they failed to accurately align regions conserved only within more closely related subsets. This is, of course, a major drawback to their general application for CHAIN analysis. By contrast, PSI-BLAST (Altschul *et al.*, 1997), which seems less likely to produce high-quality global alignments given its simple alignment procedure, nevertheless, in many cases, does a better job of aligning database sequences relative to the query.

MUSCLE and MAFFT perform well on small sets of relatively diverse representative sequences, such as the BALIBASE benchmark sets (Bahr *et al.*, 2001), because they incorporate heuristics that unfortunately can also compromise statistical rigor and, as a result, confuse random noise with biologically valid homology. Statistically, the best alignment for random sequences is the 'null alignment', that is, the procedure should leave such sequences unaligned.

3.5.4 Bayesian Progressive Alignment

Owing to its use of MCMC in profile estimation, PROBE (and its later extension) is very slow. Another limitation of PROBE is its inflexibility in introducing gaps within block motifs. As mentioned earlier, the HMM-based model can allow for flexible gaps, but it needs many sequences in order to estimate the excessive number of parameters well. In

contrast, PSI-BLAST produces multiple alignment progressively without having to iterate and can accommodate gaps in motif in a biologically meaningful fashion because of its use of BLAST (a motif-based approach). To combine the attractive features of PSI-BLAST and PROBE, Logvinenko (2002) proposed a Bayesian progressive alignment procedure based on a sequential Monte Carlo principle (Liu, 2001).

The algorithm starts by aligning the query sequence $R^{(1)}$ to each of the other sequences in a set, $R^{(2)}, \cdots, R^{(n)}$, by a gap-based Bayesian local alignment method (similar to the one described in Section 3.4.1.1). The set of sequences can be either given in advance or obtained by an iterative BLAST search as in PSI-BLAST. The sequences are then sorted according to their distances from $R^{(1)}$ derived on the basis of the pairwise alignments. A position-specific profile matrix $\boldsymbol{\Theta} = (\hat{\theta}_{dl})_{20, l_1}$ is constructed on the basis of the alignment of $R^{(1)}$ to its closest relative, $R^{(2)}$, and then to $R^{(3)}$, and so on. Each time a new sequence is introduced, the profile is updated on the basis of the new alignment. As in PSI-BLAST, sequence-weighing strategy of Henikoff and Henikoff (1994) is used in profile computation to avoid overrepresentation of closely related sequences.

In producing the progressive alignment, a Dirichlet Mixture prior distribution (Sjolander *et al.*, 1996) is used for amino acid emission probabilities:

$$P(\boldsymbol{\theta}) \sim \sum_{k=1}^{K} p_k \frac{\Gamma(\alpha_1^{(k)} + \cdots + \alpha_{20}^{(k)})}{\Gamma(\alpha_1^{(k)}) \cdots \Gamma(\alpha_{20}^{(k)})} \theta_1^{\alpha_1^{(k)}-1} \cdots \theta_{20}^{\alpha_{20}^{(k)}-1}$$

For every column l of the alignment, residue counts $\mathbf{m}^{(l)} = (m_1^{(l)}, \cdots, m_{20}^{(l)})$ follow Multinom $(\boldsymbol{\theta}_l)$ distribution. Profile entries are set to be predictive probabilities of the residues:

$$\hat{\theta}_{d,l} = \int_{\boldsymbol{\theta}_l} \theta_{d,l} P(\boldsymbol{\theta}_l \mid \mathbf{m}_l) d\boldsymbol{\theta}_l \propto \int_{\boldsymbol{\theta}_l} \theta_{d,l} P(\mathbf{m} \mid \boldsymbol{\theta}_l) P(\boldsymbol{\theta}_l) d\boldsymbol{\theta}_l.$$

As in Section 3.4.1.1 a dynamic-programming type recursion is used to compute $P(R, \boldsymbol{\Theta} \mid \Lambda) = p(n, L)$:

$$p_{\mathrm{m}}(k, l) = p(k-1, l-1)\hat{\theta}_{r_k l},$$
$$p_{\mathrm{i}}(k, l) = \{\lambda_{\mathrm{e}} p_{\mathrm{i}}(k-1, l) + \lambda_{\mathrm{o}} p_{\mathrm{m}}(k-1, l)\},$$
$$p_{\mathrm{d}}(k, l) = \{\lambda_{\mathrm{e}} p_{\mathrm{d}}(k, l-1) + \lambda_{\mathrm{o}} p_{\mathrm{m}}(k, l-1) + \lambda_{\mathrm{o}} p_{\mathrm{i}}(k, l-1)\},$$
$$p(k, l) = p_{\mathrm{m}}(k, l) + p_{\mathrm{i}}(k, l) + p_{\mathrm{d}}(k, l);$$

where $\Lambda = (\lambda_{\mathrm{o}}, \lambda_{\mathrm{e}})$ are the gap opening and extension probabilities; L is the number of positions in the profile; and $\hat{\theta}_{r_k l}$ is a profile entry corresponding to residue r_k in lth column of the alignment. A backward-tracing procedure analogous to that in **Chapter 2** is used to obtain an alignment.

After all the sequences are incorporated into an alignment, a Gibbs Sampling step is used to improve on its quality. Each sequence $R^{(i)}$ is removed in turn and realigned to the others. The profile is updated accordingly. Although this additional step makes the procedure relatively slow, the resulting alignment is less prone to be only locally optimal.

3.6 FINDING RECURRING PATTERNS IN BIOLOGICAL SEQUENCES

Our focus here is on the discovery of repetitive patterns (often termed as *motif elements*) in a given set of biopolymer sequences. The main motivation for this task is that these motif elements often correspond to the functionally or structurally important part of these molecules. For instance, repetitive patterns in the upstream regions of coregulated genes may correspond to a 'regulatory motif' to which certain regulatory protein binds so as to control gene expressions (Stormo and Hartzell, 1989; Lawrence and Reilly, 1990). Without loss of generality, we concatenate all the sequences in the dataset to form one 'supersequence' R. The multiple occurrences of a motif element in R is thus analogous to the multiple occurrences of a *word* in a long sentence. It is of interest to find out what this motif is and where it has occurred. What makes this problem challenging is that the motif occurrences are not necessarily identical to each other. In other words, there are often some 'typos' in each occurrence of the word. It is therefore rather natural for us to employ probabilistic models to handle this problem.

3.6.1 Block-motif Model with iid Background

A simple model conveying the basic idea of a motif that repeats itself with random variations is the block-motif model as shown in Figure 3.7. It was first developed by Liu *et al.* (1995) and has been employed to find subtle repetitive patterns, such as helix-turn-helix structural motifs (Neuwald *et al.*, 1995) in protein sequences and gene regulation motifs (Roth *et al.*, 1998; Liu *et al.*, 2001; 2002) in DNA sequences.

The model assumes that at unknown locations $A = (a_1, \ldots, a_K)$ there are realized instances of a motif so that the sequence segments at these locations look similar to each other. In other parts of the sequence, the residues (or base pairs) follow a 'background model' represented as iid observations from a multinomial distribution. Since the motif region is a very small fraction of the whole sequence, it is not unreasonable to assume that the background frequency $\boldsymbol{\theta}_0 = (\theta_{0,a}, \ldots, \theta_{0,t})$ is known in advance. For the motif of width w, we let $\Theta = [\boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_w]$, where each $\boldsymbol{\theta}_j$ describes the base frequency at position j of the motif. The matrix Θ is simply the profile matrix for the motif.

To facilitate analysis, we introduce an indicator vector $\mathbf{I} = (I_1, \ldots, I_n)$, where n is the length of R. We let $\mathbf{I}_{[-i]}$ be the vector of I's without I_i. Here, $I_i = 1$ means that position i is the start of a motif pattern, and $I_i = 0$ means otherwise. We assume *a priori* each I_i has a small probability p_0 to be equal to 1. With this setup, we can write down the joint posterior distribution:

$$P(\Theta, \mathbf{I} \mid R) \propto P(R \mid \mathbf{I}, \Theta) P(\mathbf{I} \mid \Theta), f_0(\boldsymbol{\theta}), \qquad (3.9)$$

where $P(\mathbf{I} \mid \Theta) \propto \prod_{i=1}^{n} p_0^{I_i} (1 - p_0)^{1-I_i}$. If we do not allow overlapping motifs, we need to restrict that in $\mathbf{I}$ there is no pair $I_i = 1$ and $I_j = 1$ with $|i - j| < w$.

Figure 3.7 A graphical illustration of the repetitive motif model.

With a prior Dirichlet ($\boldsymbol{\alpha}$) for each $\boldsymbol{\theta}_j$, we can easily obtain the posterior distribution of the $\boldsymbol{\theta}_j$ *if* we know the positions of the motif (Liu *et al.*, 1995). Thus, a simple Gibbs sampling algorithm can be designed to draw Θ and $\mathbf{I}$ from (3.9):

- For a current realization of Θ, we update each I_i, $i = 1, \ldots, n$, by a random draw from its conditional distribution, $P(I_i \mid \mathbf{I}_{[-i]}, R, \Theta)$, where

$$\frac{P(I_i = 1 \mid \mathbf{I}_{[-i]}, R, \Theta)}{P(I_i = 0 \mid \mathbf{I}_{[-i]}, R, \Theta)} = \frac{p_0}{1 - p_0} \prod_{k=1}^{w} \left(\frac{\theta_{k, r_{i+k-1}}}{\theta_{0, r_{i+k-1}}} \right). \tag{3.10}$$

  Intuitively, this odds ratio is simply the 'signal-to-noise' ratio.

- On the basis of the current value of $\mathbf{I}$, we update the profile matrix Θ column by column. In other words, each $\boldsymbol{\theta}_j$, $j = 1, \ldots, w$, is drawn from an appropriate posterior Dirichlet distribution determined by $\mathbf{I}$ and R.

After a burn-in period (until the sampler stabilizes), we continue to run the sampler for m iterations and use the average of the sampled Θ's to estimate the profile matrix. The estimated Θ can then be used to scan the sequence to find the locations of the motif.

3.6.2 Block-motif Model with a Markovian Background

It is well known that the iid multinomial distribution cannot model a DNA or protein sequence (background) well. In particular, Liu *et al.* (2001; 2002) showed that use of a second- or third-order Markov model for the background can significantly improve the motif-finding capability of the method. For simplicity, here we describe only the first-order Markov background model, where a 4×4 transition matrix, $B_0 = (\beta_{jj'})$, needs to be estimated. Since the total number of base pairs occupied by motif sites is a very small fraction of all the base pairs in R, we may estimate B_0 from the raw data directly, assuming that the whole sequence of R is homogeneous. With this approximation, the transition probabilities can be estimated as $\hat{\beta}_{j_1 j_2} = n_{j_1 j_2} / n_{j_1 \cdot}$, similar to that in Section 3.3. We may then treat B_0 as a known parameter.

The joint posterior distribution of $(\Theta, \mathbf{I})$ in this case differs from (3.9) only in the description of the residues in the background. The Gibbs sampler can also be similarly implemented with a slight modification in $P(I_i \mid \mathbf{I}_{[-i]}, R, \Theta)$. In other words, conditional on R, we slide Θ through the whole sequence position by position to update I_i according to a random draw from $P(I_i \mid \mathbf{I}_{[-i]}, R, \Theta)$, which satisfies

$$\frac{P(I_i = 1 \mid \mathbf{I}_{[-i]}, R, \Theta)}{P(I_i = 0 \mid \mathbf{I}_{[-i]}, R, \Theta)} = \frac{p_0}{1 - p_0} \prod_{k=1}^{w} \left(\frac{\theta_{k, r_{i+k-1}}}{\hat{\beta}_{r_{i+k-2} r_{i+k-1}}} \right).$$

For given $\mathbf{I}$, we update the profile matrix Θ in the same way as in Section 3.6.1.

3.6.3 Block-motif Model with Inhomogeneous Background

It has long been noticed that DNA sequences contain regions of distinctive compositions. As discussed in Section 3.3, an HMM can be employed to delineate a sequence with k types of regions. Suppose we decide to use an HMM to model sequence inhomogeneity.

As mentioned earlier, we may estimate the background model parameters using all the sequences by the methods in Section 3.3, assuming that R does not contain any motifs. Then, we can treat these parameters as known at the estimated values and use one of the following two strategies to modify the odds ratio formula (3.10).

In the first strategy, we treat each position in the sequence as a 'probabilistic base pair' (i.e. having probabilities to be one of the four letters) and derive its frequency. In other words, we need to find $\theta_{ij}^* = p(r_i^* = j \mid R)$ for a future r_i^* and then treat residue r_i in the background as an independent observation from Multinom $(\boldsymbol{\theta}_i^*)$, with $\boldsymbol{\theta}_i^* = (\theta_{ia}^*, \ldots, \theta_{it}^*)$. But this computation is nontrivial because

$$\theta_{ij}^* = P(r_i^* = j \mid R) = \theta_{0j} P(h_i = 0 \mid R) + \theta_{1j} P(h_i = 1 \mid R), \qquad (3.11)$$

where $P(h_i)$ can be computed via a recursive procedure similar to (3.3). More precisely, in addition to the series of forward functions F_i, we can define the backward functions B_i. Let $B_n(h) = \sum_{h_n} \tau_{hh_n} \theta_{h_n r_n}$, and let

$$B_k(h) = \sum_{h_i} \left\{ \tau_{hh_i} \theta_{h_i r_i} B_{k+1}(h_i) \right\}, \quad \text{for } k = n - 1, \ldots, 1. \qquad (3.12)$$

Then, we have

$$P(h_i = 1 \mid R) = \frac{F_i(1) B_{i+1}(1)}{F_i(1) B_{i+1}(1) + F_i(0) B_{i+1}(0)}. \qquad (3.13)$$

This is the *marginal* posterior distribution of h_i and can be used to predict whether position i is in state 1 or 0. Thus, in the Gibbs sampling algorithm we only need to modify the denominator of the right-hand side of (3.10) as $\prod_{k=i}^{i+w-1} \theta_{k,r_i}^*$.

In the second strategy, we seek to obtain the joint probability of a whole segment, $R_{[i:i+w-1]} \equiv (r_i, \ldots, r_{i+w-1})$, conditional on the remaining part of the sequence. Then we modify (3.10) accordingly. Clearly, compared with the first strategy, the second one is more faithful to the compositional HMM assumption. The required probability evaluation can be achieved as follows:

$$\begin{aligned} P(R_{[i:i+w-1]} \mid R_{[1:i-1]}, R_{[i+w:n]}) &= \frac{P(R)}{P(R_{[1:i-1]}, R_{[i+w:n]})} = \frac{P(R)}{\sum_{\mathbf{h}} P(R_{[1:i-1]}, R_{[i+w:n]}, \mathbf{h})} \\ &= \frac{F_n(0) + F_n(1)}{\sum_{h_1, \ldots, h_w} F_i(h_1) \tau_{h_1 h_2} \cdots \tau_{h_{w-1} h_w} B_{i+w}(h_w)}, \qquad (3.14) \end{aligned}$$

where the denominator can also be obtained via recursions.

3.6.4 Extension to Multiple Motifs

Earlier, we have assumed that there is only one kind of motif in the sequence and the prior probability for each $I_i = 1$ is known as p_0. Both of these assumptions can be relaxed. Suppose we want to detect and align m different types of motifs of lengths $w_1, \ldots, w_m$, respectively, with each occurring unknown number of times in R. We can similarly introduce the indicator vector $\mathbf{I}$, where $I_i = j$ indicates that an element from motif j starts at position i, and $I_i = 0$ means that no element starts from position i. For simplicity, we consider only the independent background model.

Let $P(I_i = j) = \varepsilon_j$, where $\varepsilon_0 + \cdots + \varepsilon_m = 1$, is an unknown probability vector. Given what is known about the biology of the sequences being analyzed, a crude guess k_j for the number of elements for motif j is usually possible. Let $k_0 = n - k_1 - \cdots - k_m$. We can represent this prior opinion about the number of occurrences of each type of elements by a Dirichlet distribution on $\boldsymbol{\varepsilon} = (\varepsilon_0, \ldots, \varepsilon_m)$, which has the form Dirichlet $(b_0, \ldots, b_m)$ with $b_j = J_0 \frac{k_j}{n}$, where J_0 represents the 'weight' (or 'pseudo-counts') to be put on this prior belief. Then the same predictive updating approach as illustrated in Section 3.6.1 can be applied. Precisely, the update formula (3.10) for $\mathbf{I}$ is changed to

$$\frac{P(I_i = j \mid \mathbf{I}_{[-i]}, R)}{P(I_i = 0 \mid \mathbf{I}_{[-i]}, R)} = \frac{\varepsilon_j}{\varepsilon_0} \prod_{k=1}^{w_j} \left(\frac{\theta_{k,r_{i+k-1}}^{(j)}}{\theta_{0,r_{i+k-1}}} \right),$$

where $\Theta^{(j)} = [\boldsymbol{\theta}_1^{(j)}, \ldots, \boldsymbol{\theta}_{w_j}^{(j)}]$ is the profile matrix for the jth motif. Conditional on $\mathbf{I}$, we can then update $\boldsymbol{\varepsilon}$ by a random sample from Dirichlet$(b_0 + n_0, \ldots, b_m + n_m)$, where n_j $(j > 0)$ is the number of motif type j found in the sequence, that is, the total number of is such that $I_i = j$, and $n_0 = n - \sum n_j$.

3.6.5 HMM for *cis* Regulatory Module Discovery

Motif predictions in high eukaryotes such as human and mouse are more challenging than that for simpler organisms, partly owing to the weak motif signals, larger sizes of promoter regions, and difficulties in identifying transcription start sites. In these higher organisms, regulatory proteins often work in combination to regulate target genes, and their binding sites have often been observed to occur in spatial clusters, or *cis-regulatory modules* (CRMs). One approach to locating CRMs is by predicting novel motifs and looking for co-occurrences (Sinha and Tompa, 2002). However, since individual motifs in the cluster may not be well conserved, such an approach often leads to a large number of false negatives. To cope with these difficulties, one can use HMMs to capture both the spatial and contextual dependencies of the motifs in a CRM and use MCMC sampling to infer the CRM models and locations (Thompson *et al.*, 2004; Zhou and Wong, 2004). Gupta and Liu (2005) introduced a competing strategy, which first uses existing *de novo* motif-finding algorithms and/or TF databases to compose a list of putative binding motifs, $\mathcal{D} = \{\Theta_1, \ldots, \Theta_D\}$, where D is in the range of 50 to 100, and then simultaneously updates these motifs and estimates the posterior probability for each of them for inclusion in the CRM.

Let $\mathbf{S}$ denote the set of n sequences with lengths $L_1, L_2, \ldots, L_n$, respectively, corresponding to the upstream regions of n coregulated genes. We assume that the CRM consists of K ($<D$) different kinds of TFs with distinctive position-specific weight matrices (PWMs, which are just a special sequence HMM that do not allow for any gaps). Both the PWMs and K are unknown and need to be inferred from the data. Let $\mathbf{a} = \{a_{ij}; i = 1, \ldots, n; \ j = 1, \ldots, L_i\}$, where $a_{i,j}$ denotes the location of the jth motif site (irrespective of motif type) in the ith sequence. Associated with each site is its *type* indicator $T_{i,j}$, with $T_{i,j}$ taking one of the K values (Let $\mathbf{T} = (T_{ij})$). We model the dependence between $T_{i,j}$ and $T_{i,j+1}$ by a $K \times K$ transition matrix $\boldsymbol{\tau}$. The distance between neighboring TF binding sites in a CRM, $d_{ij} = a_{i,j+1} - a_{i,j}$, is assumed to follow the distribution $Q(d; \lambda, w) = (1 - \lambda)^{d-w} \lambda$ $(d = w, w + 1, \ldots)$. The *background* sequence follows a multinomial distribution with unknown parameter $\boldsymbol{\rho} = (\rho_A, \ldots, \rho_T)$. Finally,

we let **u** be a binary vector indicating which motifs are included in the module, that is, $\mathbf{u} = (u_1, \ldots u_D)^T$, where $u_j = 1$ if the jth motif type is present in the module, and 0 otherwise. By construction, $|\mathbf{u}| = K$. The set of PWMs for the CRM is then $\boldsymbol{\theta} = \{\Theta_j : u_j = 1\}$.

Since we now restrict our inference of CRM to a subset of $\mathcal{D}$, the probability model for the observed sequence data can be written out explicitly as in Gupta and Liu (2005). To implement the Bayesian analysis, we prescribe a joint prior distribution on the unknown parameters, $\Omega = (\mathcal{D}, \boldsymbol{\tau}, \lambda, \boldsymbol{\rho})$, and a prior probability of π for each $u_i = 1$. A Gibbs sampling approach was developed in Thompson *et al.* (2004) to sample both Ω and **u** from their joint posterior distribution. But given the flexibility of the model and the size of the parameter space for an unknown **u**, it is unlikely that a standard MCMC approach can converge to a good solution in a reasonable amount of time. If we ignore the ordering of sites **T** and assume components of **a** to be independent, this model is reduced to the original motif model, which can be updated through the previous Gibbs or data augmentation (DA) procedure.

The following strategy was developed in Gupta and Liu (2005). With a starting set of putative binding motifs $\mathcal{D}$, we iterate the following Monte Carlo sampling steps: (1) Given the current collection $\mathcal{D}$ of motif PWMs (or sites), sample motifs into the CRM; (2) Given the CRM configuration and the PWMs, update the motif site locations through DA; and (3) Given motif site locations, update the corresponding PWMs and other parameters. Since the construction of a CRM in our formulation is done by using an indicator variable $\mathcal{D}$, it is natural to use a genetic-type algorithm to speed up computation. So we implemented an evolutionary Monte Carlo (Liang and Wong, 2000) strategy for the module inference, and obtained very good results for a range of examples.

3.7 JOINT ANALYSIS OF SEQUENCE MOTIFS AND EXPRESSION MICROARRAYS

A highly successful tactic for TF motif discoveries is to cluster genes based on their expression profiles, and search for motifs in the sequences upstream of tightly clustered genes (Spellman *et al.*, 1998). When noise is introduced into the cluster through spurious correlations, however, such an approach may result in many false positives. A filtering method based on the specificity of motif occurrences has been shown to effectively eliminate false positives (Hughes *et al.*, 2000). An iterative procedure for simultaneous gene clustering and motif finding has been suggested (Holmes and Bruno, 2000), but no effective algorithms were implemented to demonstrate its advantage.

Two methods for discovering TF motifs via the association of gene expression values with k-mer abundance have been proposed by Bussemaker *et al.* (2001) and Keles *et al.* (2002). These approaches operate under the explicit assumption that, in response to a given biological condition, the effect of a TF motif is strongest among genes with the most dramatic increase or decrease in mRNA expression. In Bussemaker *et al.* (2001), all the k-mers (k ranging from 5 to 7, say) are first enumerated. Then, for any k-mer, the number n_g of its occurrence in the promoter region (defined as the 800 base pair segment upstream of the transcription start site for the baker's yeast) of each gene g is counted. A regression model is then fit between the expression level y_g of the gene and n_g, and those k-mers whose occurrences are significantly correlated with the gene expression values are regarded as potential TF motifs.

As an alternative to the *k*-mer approach, Conlon *et al.* (2003) provide a motif regression approach to further utilize gene expression information or experimental data from chromatin immunoprecipitation combined with microarrays (often called *ChIP-chip*) to help motif discovery. They first use a fast and sensitive motif-finding method, such as BioProspector, MEME, or MDscan (Liu *et al.*, 2002) to generate a large set of putative motifs that are enriched in the DNA sequence upstream of genes with the highest fold changes in mRNA level relative to a control condition. Then, they conduct a stepwise linear regression to select candidates that correlate with the microarray expression data. Tadesse *et al.* (2004) later presented a Bayesian version of a similar approach. To alleviate the dependence of the linearity and Gaussian assumptions, Das *et al.* (2004) suggested an approach using MARS, and Zhong *et al.* (2005) designed a modified slice inverse regression approach, which also effectively reduces the dimensionality without assuming linearity.

An interesting and bold approach for combining multiple expression microarrays and TF motif analysis is given by Beer and Tavazoie (2004), where they aspired to 'predict gene expression' using only sequence information. To state briefly, they first collected 255 cDNA microarray datasets and used a tight clustering procedure to produce 49 clusters for ~2600 yeast genes (the remaining 3000+ genes were excluded from this analysis because they cannot be clustered 'tightly' enough). For each cluster, they used AlignACE (Roth *et al.*, 1998) to conduct *de novo* motif search among the promoter regions of the genes in the cluster, retaining 5–15 top motifs. The 49 clusters gave rise to a total of 615 motifs. They further conducted an optimization procedure to make each predicted motif more specific to their corresponding cluster, and added 51 experimentally derived motifs reported by Harbison *et al.* (2004). With the 666 motifs in hand, they then trained 49 Bayes network models to predict each gene's cluster membership based only on its motif occurrence scores, putative motif site positions, and orientations. They showed that their procedure yielded an impressive 71 % accuracy in a fivefold cross-validation experiment (compared to ~20 % under random gene order). However, it is interesting to note that their cross-validation procedure is flawed as they have used the cluster information in their motif-finding and motif optimization step, which could lead to an overly optimistic result. Furthermore, their Bayes network model seems to be too heavy for the data in hand. Indeed, our recent preliminary study showed that perhaps they overestimated their procedure's accuracy by about 15 % and that a simpler Naive Bayes procedure can be as accurate or more accurate than their Bayes network model.

3.8   SUMMARY

This article has reviewed a few statistical models used in biological sequence analysis, the corresponding Bayesian formulations, and related computational strategies. As in classical statistics, optimization has been the primary tool in computational biology, where point estimates of very high-dimensional objects obtained by dynamic programming or other clever computational methods are used. Characterizations of uncertainty in these estimates are mostly limited to simple significance test or completely ignored. The marginalization of nuisance parameters is also problematic, and is most frequently done using the *profile likelihood* method in which the nuisance parameters are fixed at their best estimates. In comparison, the Bayesian method has no difficulties in these important aspects:

the uncertainty in estimation is addressed by posterior calculations and the nuisance parameters are removed by summation and integration. In exchange for these advantages, however, one needs to set prior distributions and overcome computational hurdles, neither of which are trivial in practice. Recursion-based Bayesian algorithms generally have time and space requirements of the same order as their dynamic-programming counterparts. For those problems where there is no polynomial time solution, MCMC methods (and other Monte Carlo methods) provide an effective means to implement Bayesian analysis.

APPENDIX A: MARKOV CHAIN MONTE CARLO METHODS

Metropolis−Hastings Algorithm. Let $\pi(\mathbf{x}) = c \exp\{-h(\mathbf{x})\}$ be the target distribution with unknown constant c. Metropolis *et al.* (1953) introduced the fundamental idea of Markov chain sampling and prescribed the first general construction of such a chain. Hastings (1970) later provided an important generalization. Starting with any configuration $\mathbf{x}^{(0)}$, the M-H algorithm evolves from the current state $\mathbf{x}^{(t)} = \mathbf{x}$ to the next state $\mathbf{x}^{(t+1)}$ as follows:

- Propose a new state $\mathbf{x}'$ that can be viewed as a small and random 'perturbation' of the current state. More precisely, $\mathbf{x}'$ is generated from a *proposal* function $T(\mathbf{x}^{(t)} \to \mathbf{x}')$ (i.e. it is required that $T \geq 0$ and $\sum_{\text{all } \mathbf{y}} T(\mathbf{x} \to \mathbf{y}) = 1$ for all $\mathbf{x}$) determined by the user.

- Compute the Metropolis ratio

$$r(\mathbf{x}, \mathbf{x}') = \frac{\pi(\mathbf{x}')T(\mathbf{x}' \to \mathbf{x})}{\pi(\mathbf{x})T(\mathbf{x} \to \mathbf{x}')}. \tag{3A.1}$$

- Generate a random number $u \sim \text{Unif } [0,1]$.

  - Let $\mathbf{x}^{(t+1)} = \mathbf{x}'$ if $u \leq r(\mathbf{x}, \mathbf{x}')$.
  - Let $\mathbf{x}^{(t+1)} = \mathbf{x}^{(t)}$ otherwise.

A more well-known form of the Metropolis algorithm is obtained by iterating the following steps: (a) a small random perturbation of the current configuration is made; (b) the 'gain' (or loss) in an objective function (i.e. $-h(\mathbf{x})$) resulting from this perturbation is computed; (c) a random number U is generated independently; and (d) the new configuration is accepted if $\log(U)$ is smaller than or equal to the 'gain', and is rejected otherwise. The well-known *simulated annealing* algorithm (Kirkpatrick *et al.*, 1983) is built upon this basic Metropolis iteration with an additional twist of including an adjustable exponential scaling parameter to the objective function (i.e. $\pi(\mathbf{x})$ is scaled to $\pi^{\alpha}(\mathbf{x})$ and

$\alpha \to 0$). Metropolis *et al.* (1953) restricted their choices of the 'perturbation' function to be the symmetric ones, that is, $T(\mathbf{x} \to \mathbf{x}') = T(\mathbf{x}' \to \mathbf{x})$. Hastings (1970) generalized the choice of T to all those that satisfy the property: $T(\mathbf{x} \to \mathbf{x}') > 0$ if and only if $T(\mathbf{x}' \to \mathbf{x}) > 0$.

Heuristically, π can be seen as a 'fixed point' under the M-H operation in the space of all distributions. It follows from the standard Markov chain theory that if the chain is *irreducible* (i.e. it is possible to go from anywhere to anywhere else in a finite number of steps), *aperiodic* (i.e. there is no parity problem), and not drifting away, then in the long run the chain will settle in its invariant distribution (Liu, 2001). The random samples so obtained eventually are like those drawn directly from π.

Gibbs Sampler. Suppose $\mathbf{x} = (x_1, \ldots, x_d)$. In the Gibbs sampler, one randomly or systematically chooses a coordinate, say x_1, and then updates its value with a new sample x_1' drawn from the conditional distribution $\pi(\cdot \mid \mathbf{x}_{[-1]})$, where $\mathbf{x}_{[-A]}$ refers to $\{x_j, \ j \in A^c\}$. Algorithmically, the Gibbs sampler can be implemented as follows:

Random Scan Gibbs sampler. Suppose currently $\mathbf{x}^{(t)} = (x_1^{(t)}, \ldots x_d^{(t)})$.

- Randomly select i from $\{1, \ldots, d\}$ according to a given probability vector $(\alpha_1, \ldots, \alpha_d)$.

- Let $x_i^{(t+1)}$ be drawn from the conditional distribution $\pi(\cdot \mid \mathbf{x}_{[-i]}^{(t)})$, and let $x_{[-i]}^{(t+1)} = \mathbf{x}_{[-i]}^{(t)}$.

Systematic Scan Gibbs sampler. Let the current state be $\mathbf{x}^{(t)} = (x_1^{(t)}, \ldots x_d^{(t)})$.

- For $i = 1, \ldots, d$, we draw $x_i^{(t+1)}$ from the conditional distribution

$$\pi(x_i \mid x_1^{(t+1)}, \ldots, x_{i-1}^{(t+1)}, x_{i+1}^{(t)}, \ldots, x_d^{(t)}).$$

The Gibbs sampler's popularity in statistics community stems from its extensive use of *conditional distributions* in each iteration. Tanner and Wong (1987)'s data augmentation first linked the Gibbs sampling structure with missing data problems and the EM algorithm. Gelfand and Smith (1990) further popularized the method by pointing out that the conditionals needed in Gibbs iterations are commonly available in many Bayesian and likelihood computations.

Other Techniques. A main problem with all MCMC algorithms is that they may, for some problems, move very slowly in the configuration space or may be trapped in the region of a local mode. This phenomena is generally called *slow-mixing* of the chain. When chain is slow-mixing, estimation based on the resulting Monte Carlo samples can be very inaccurate. Some recent techniques suitable for designing more efficient MCMC samplers in bioinformatics applications include simulated tempering, parallel tempering, multicanonical sampling, multiple-try method, and evolutionary Monte Carlo. These and some other techniques are summarized in Liu (2001). Some more discussions and applications of MCMC can also be found in **Chapters 8**, **15**, and **26**.

Statistical Approaches in Eukaryotic Gene Prediction

V. Solovyev

Department of Computer Science, University of London, Surrey, UK

Finding genes in genomic DNA is a foremost problem of molecular biology. With the ongoing genome sequencing projects producing large quantities of sequence data, computational gene prediction is the major instrument for the identification of new genes. Usually, gene-finding programs accurately predict most coding exons in analyzed sequences, while producing a complete set of exact gene structures in any genome is still unsolved and difficult task, complicated by the large amount of gene variants generated by alternative splicing, alternation promoters and alternative polyadenylation sites. Nevertheless using gene prediction, the scientific community is now able to start experimental work with the majority of genes in dozens of sequenced genomes. Therefore, computational methods of gene identification have attracted significant attention of the genomics and bioinformatics communities. This chapter presents a comprehensive description of advanced probabilistic and discriminative gene-prediction approaches such as Hidden-Markov Models and pattern-based algorithms. We have described the structure of functional signals and significant gene features incorporated into the programs to recognize protein-coding genes. We have presented comparative performance data for a variety of gene structure identification programs and discussed some experiences in annotation of sequences from genome sequencing projects. A complex approach for finding promoters and pseudogenes have been considered as well as evaluation of their accuracy in annotation of human genome sequences. Finally, we described structural features and expression of miRNA genes and some computational methods for miRNA gene identification in genomic sequences as well as computational methods of finding miRNA targets.

4.1 STRUCTURAL ORGANIZATION AND EXPRESSION OF EUKARYOTIC GENES

The gene is the unit of inheritance encoded by a segment of nucleic sequence that carries the information representing a particular polypeptide or RNA molecule. A two-stage process comprising transcription and translation makes use of this information.

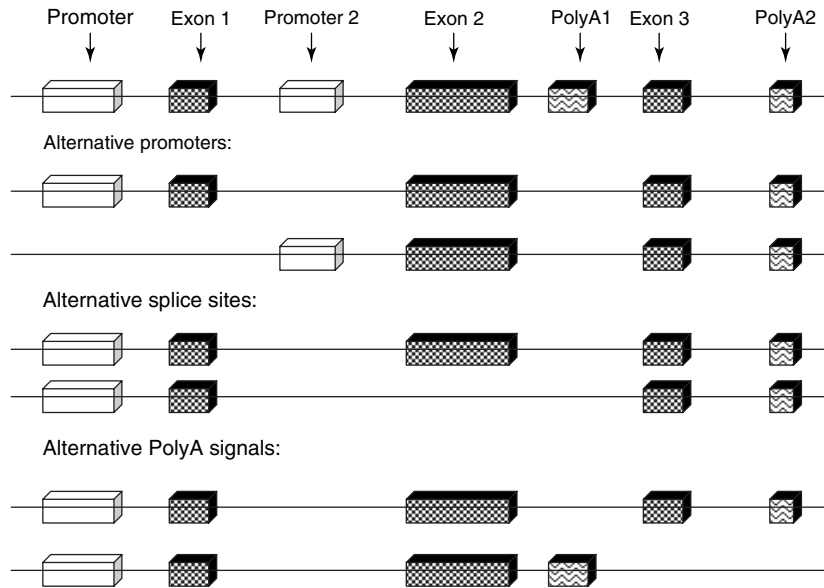
Transcription (or pre-mRNA synthesis on a DNA template) involves initiation, elongation and termination steps. RNA polymerase catalyzing RNA synthesis binds a special region (promoter) at the start of the gene and moves along the template, synthesizing RNA, until it reaches a terminator sequence. Posttranscriptional processing of mRNA precursors includes capping, 3′-polyadenylation and splicing. The processing events of mRNA capping and polyA addition take place before pre-mRNA splicing finally produces the mature mRNA. The mature mRNA includes sequences that correspond exactly to the protein product according to the rules of the genetic codes, called *exons*. The genomic gene sequence often includes noncoding regions called *introns* that are removed from the primary transcript during RNA splicing. Eukaryotic pre-mRNA is processed in the nucleus and then transported to the cytoplasm for translation (protein synthesis). The sequence of mRNA contains a series of triplet codons that interact with the anticodons of aminoacyl-tRNAs (carrying the amino acids) so that the corresponding series of amino acids is incorporated into a polypeptide chain. The small subunit of the ribosome binds to the 5′-end of mRNA and then migrates to the special sequence on mRNA (prior to the start codon) called the *ribosome binding site*, where it is joined by a large ribosome subunit forming a complete ribosome. The ribosome initiates protein synthesis at the start codon (AUG in eukaryotes) and moves along the mRNA, synthesizing the polypeptide chain, until it reaches a stop codon sequence (TAA, TGA or TAG), where release of polypeptide and dissociation of the ribosome from the mRNA take place. Many proteins undergo posttranslational processing (i.e. covalent modifications such as proteolytic cleavage, attachment of carbohydrates and phosphates) before they become functional. The expression stages and the structural organization of a typical eukaryotic protein-coding gene including associated regulatory regions is shown in Figure 4.1. Figure 4.2 illustrates how one DNA sequence may code for multiple proteins due to alternative promoters or terminators and alternative splicing. These processes significantly complicate *ab initio* computational gene finding.
Figure 4.1 Expression stages and structural organization of typical eukaryotic protein-coding gene including its regulatory regions.


Figure 4.2   Alternative gene products coded by the same DNA region.

Information describing structural gene characteristics is accumulated in the GenBank (Benson *et al.*, 1999) and the EMBL (Kanz *et al.*, 2005) nucleotide sequence databases. However, these databases mostly contain annotations of genome fragments. Therefore, one gene can be described in dozens of entries containing partially sequenced gene regions or alternative splicing forms of its mRNA. The value of public availability of predicted genes was recognized during human genome sequencing by creating the InfoGene database (Solovyev and Salamov, 1999), which contained descriptions of known and predicted genes and their basic functional signals. Later, a few big research groups developed powerful specialized WEB accessible recourses, where various annotations of different genomes are stored and can be interactively analyzed: University of California Santa Cruz (USSC) Genome Browser (Kent *et al.*, 2002) and Ensembl genome database (Hubbard *et al.*, 2002). Some big sequencing centers such as The Institute for Genomic Research (TIGR) and Joint Genomic Institute (JGI) produce and present annotation of specific genomes at their Web servers.

Table 4.1 shows the major structural characteristics of human genes deposited to GenBank (Release 116).

41 % of sequenced human DNA consists of different kinds of repeats. Only ∼3 % of the genome sequence contains protein-coding exon sequences. Characteristics of genes in major model organisms such as mouse, *Drosophila melanogaster, Caenorhabditis elegans, S. cerevisiae* and *Arabidopsis thaliana* are presented in Table 4.2.

In general, there is no big difference in the size of protein-coding mRNAs in different types of organisms, but the gene sizes are often higher in vertebrates and especially in primates. Human coding exons are significantly shorter than the sizes of genes. The average size of the exons is about 190 bp that is close to the DNA length associated with the nucleosome particle. There are many exons as short as a few bases. For example, the human pleiotrophin gene (*HUMPLEIOT*) includes a 1-bp exon and one of the alternative

Table 4.1 Structural characteristics of human genes.[*]

Gene features	Numbers from Infogen
CDS/partially sequenced CDS	48 088/26 584
CDS length (minimal, maximal, average)	15, 80 781, 1482
Exons/partially sequenced exons	72 488/19 392
Genes/partially sequenced genes	18 429/14 385
Alternative splicing	12 %
Pseudogenes	8.5 %
Genes without introns	8 %
Number of exons (maximal, average)	117, 5.4
Exon length (range, average)	1–10 088, 195
Intron length (maximal, average)	185 838, 2010
Gene length (maximal, average)	401 910, 7865
Repeats in genome	41 % of total DNA
DNA occupied by coding exons	3 %

[*]The numbers reflect genes described in GenBank, which might deviate from the average parameters for the organism. Gene numbers were calculated for DNA loci only. Many long genes have partially sequenced introns, therefore average sizes of genes and introns are actually bigger. The average numbers of exons and gene lengths were calculated for completely sequenced genes only.
CDS: protein CoDing Sequences.

forms of the human folate receptor (*HSU20391*) gene contains a 3-bp exon. Coding exons can also be very short.

The human myosin-binding protein gene (*HSMYBPC3*) includes 2 exons that are 3-bp long. At the same time we observe a coding region about 90 000 bp for the titin gene (NM_003319) and an exon 8000 bp in human gene encoding microtubule-associated protein 1a (HSU38291). Very often protein-coding exons occupy a small percent of the gene size. The human fragile X mental retardation gene (*HUMFMR1S*) presents a typical example: 17 exons (40–60-bp long) occupy just 3 % of 67 000 bp gene sequence.

The structural characteristics of eukaryotic genes, discussed above, create difficult problems in computational gene identification. Low density of coding regions (3 % in human DNA) will generate a lot of false-positive predictions in fragments of noncoding DNA. The number of these false positives might be even comparable with the true number of exons. Recognition of small exons (1–20 bp) cannot be achieved using any composition-based method that is relatively successful for identification of prokaryote coding regions. It is necessary to develop gene-prediction approaches that rely significantly on the recognition of functional signals encoded in the DNA sequence.

4.2 METHODS OF FUNCTIONAL SIGNAL RECOGNITION

In this paragraph, we will describe several approaches for gene functional signal recognition and some features of these signals used in gene identification. The simplest way to find functional sequences is based on a consensus sequence or weight matrix reflecting conservative bases of the signal. Using a consensus sequence or weight matrix we can scan a given sequence and select high scoring regions as potential functional signals.

Table 4.2 Structural characteristics of genes in eukaryotic model organisms.[*]

	Mus musculus	D. melanogaster	C. elegans	S. cerevisiae	A.thaliana
CDS/partial	20 340/11 192	5095/1057(13 601)	18 146/377	12 629/1040	14 590/1076

[*]Description of features is given in Table 4.1. For Drosophila genes, the numbers in () are taken from computer and manual annotation of Drosophila genome (Adams et al., 2000).

To select only significant matches, a statistical method for estimating the significance of similarity between the consensus of functional signal and a sequence fragment was developed (Shahmuradov *et al.*, 1986; Solovyev and Kolchanov, 1994). Computation of this statistic was implemented in the program NSITE (`http://www.softberry.com/berry.phtml?topic=nsite&group=programs&subgroup=promoter`) (Shahmuradov and Solovyev, 1999) that identifies nonrandom similarity between fragments of a given sequence and consensuses of regulatory motifs from various databases such as Transcription Factor Database (TFD) (Ghosh, 2000), Transfac (Wingender *et al.*, 1996), RegsiteAnimal and RegsitePlant (Solovyev *et al.*, 2003). Here we briefly describe application of weight matrices, which usually contain more information about the structure of functional signal than consensus sequences. Procedures using weight matrices are implemented in many modern gene-prediction approaches that score potential functional signals.

4.2.1 Position-specific Measures

Weight matrices are typically used for functional signal description (Staden, 1984a; Zhang and Marr, 1993; Burge, 1997). We can consider weight matrix as a simple model based on a set of position-specific probability distributions $\{p_s^i\}$, that provide probabilities of observing a particular type of nucleotide in a particular position of functional signal sequence (S). The probability of generating a sequence $X(x_1, \ldots, x_k)$ under this model is

$$P(X/S) = \prod_{i=1}^{k} p_{x_i}^i, \tag{4.1}$$

where each position of the signal is considered to be independent. A corresponding model can also be constructed for a sequence having no functional signal (N): $\{\pi_s^i\}$. An appropriate discriminative score based on these models is the log likelihood ratio:

$$\text{LLR}(X) = \log \frac{P(X/S)}{P(X/N)}. \tag{4.2}$$

To evaluate a given sequence fragment, a score can be computed as an average sum of weights of observed nucleotides using the corresponding weight matrix $w_{(i,s)} = \{log(p_s^i/\pi_s^i)\}$:

$$\text{Score} = \text{LLR}(X) = \frac{1}{k} \sum_{i=1}^{k} w(i, x_i). \tag{4.3}$$

Different weight functions have been used to score the sequence, for example, weights can be obtained by some optimization procedures such as a perceptron or neural network (Stormo *et al.*, 1982). Different position-specific probability distributions $\{p_s^i\}$ can also be considered.

A generalization of the weight matrix uses position-specific probability distributions $\{p_s^i\}$ of oligonucleotides (instead of single nucleotides). Another approach is to exploit Markov chain models, where the probability of generating a particular nucleotide x_i of the signal sequence depends on the $k_0 - 1$ previous bases (i.e. it depends on an oligonucleotide ($k_0 - 1$ base long) ending at the position $i - 1$). Then the probability of generating the

signal sequence X is:

$$P(X/S) = p_0 \prod_{i=k_0}^{k} p_{s_{i-1}, x_i}^{i-1, i} : \qquad (4.4)$$

where $p_{s_{i-1}, x_i}^{i-1, i}$ is the conditional probability of generating nucleotide x_i in position i given oligonucleotide s_{i-1} ended at position $i-1$, p_0 is the probability of generating oligonucleotide $x_{1...}x_{k0-1}$. For example, a simple weight matrix represents independent mononucleotide model (or 0-order Markov chain), where $k_0 = 1$, $p_0 = 1$ and $p_{x_{i-1}, x_i}^{i-1, i} = p_{x_i}^i$. When we use dinucleotides (1st order Markov chain) $k_0 = 2$, $p_0 = p_{x_1}^1$, and $p_{x_{i-1}, x_i}^{i-1, i}$ is the conditional probability of generating nucleotide x_i in position i given nucleotide x_{i-1} at position $i-1$. The conditional probability can be estimated from the ratio of observed frequency of oligonucleotide k_0 bases long ($k_0 > 1$) ending at position i to the frequency of the oligonucleotide $k_0 - 1$ bases long ending at position $i-1$ in a set of aligned sequences of some functional signal.

$$p_{s_{i-1}, x_i}^{i-1, i} = \frac{f(s_{i-1}, x_i)}{f(s_{i-1})}.$$

Using the same procedure we can construct a model for nonsite sequences for computing $P(X/N)$, where often 0-order Markov chain with genomic base frequencies (or even equal frequencies (0.25)) is used.

A log likelihood ratio (3) with Markov chains was applied to select CpG island regions (Durbin *et al.*, 1998). The same approach was used in a description of promoters, splice sites and start and stop of translation in gene-finding programs such as Genscan (Burge and Karlin, 1997), Fgenesh (Find GENES Hmm) (Salamov and Solovyev, 2000) and GeneFinder (Green and Hillier, 1998).

A useful discriminative measure taking into account *a priori* knowledge is based on the computation of Bayesian probabilities as components of position-specific distributions $\{p_s^i\}$:

$$P(S/o_s^i) = \frac{P(o_s^i/S)P(S)}{\left(P(o_s^i/S)P(S) + P(o_s^i/N)P(N)\right)}, \qquad (4.5)$$

where $P(o_s^i/S)$ and $P(o_s^i/N)$ can be estimated as position-specific frequencies of oligonucleotides o_s^i in the set of aligned sites and nonsites; $P(s)$ and $P(N)$ are the *a priori* probabilities of site and nonsite sequences, respectively. S is a type of the oligonucleotide starting (or ending) in ith position (Solovyev and Lawrence, 1993a). The probability that a sequence X belongs to a signal, if one assumes independence of oligonucleotides in different positions, is:

$$P(S/X) = \prod_{i=1}^{k} P(S/o_m^i).$$

Another empirical discriminator called *preference* uses the average positional probability of belonging to a signal:

$$Pr(S/X) = \frac{1}{k} \sum_{i=1}^{k} P(S/o_m^i).$$
(4.6)

This measure was used in constructing discriminant functions for the Fgenes gene-finding program (Solovyev *et al.*, 1995). It can be more stable than the previous measure on short sequences and has simple interpretation: if the $Pr > 0.5$, then our sequence is more likely to belong to a signal than to a nonsignal sequence.

4.2.2 Content-specific Measures

Some functional signal sequences have a distinctive general oligonucleotide composition. For example, many eukaryotic promoters are found in GC-rich chromosome fragments. We can characterize these regions by applying similar methods to the above scoring functions, but using probability distributions and their estimates by oligonucleotide frequencies computed on the whole sequence of the functional signal. For example, the Markov-chain-based probability of generating the signal sequence X will be:

$$P(X/S) = p_0 \prod_{i=k_0}^{k} p_{s_{i-1}}, x_i.$$
(4.7)

4.2.3 Frame-specific Measures

The coding sequence is a sequence of triplets (codons) read continuously from a fixed starting point. Three different reading frames with different codons are possible for any nucleotide sequence (or 6 if the complementary chain is also considered). The nucleotides are distributed unevenly relative to the positions within codons. Therefore the probability of observing a specific oligonucleotide in coding sequence depends on its position relative to the coding frame (three possible variants) as well as on neighboring nucleotides (Shepherd, 1981; Borodovskii *et al.*, 1986; Borodovsky and McIninch, 1993). Asymmetry in base composition between codon positions arises because of uneven usage of amino acids and synonymous codons, as well as the specific nature of the genetic code (Guigo, 1999). Fickett and Tung (1992) did a comprehensive assessment of the various protein-coding measures. They estimated the quality of more than 20 measures and showed that the most powerful is 'in phase hexanucleotide composition'. In Markov chain approaches, the frame-dependent probabilities $p_{s_{i-1},x_i}^f (f = \{1,2,3\})$ are used to model coding regions. The probability of generating a protein-coding sequence X is

$$P(X/C) = p_0 \prod_{i=k_0}^{k} p_{s_{i-1},x_i}^f,$$
(4.8)

where f is equal to 1, 2 or 3 for oligonucleotides ending at codon position 1, 2 or 3, respectively.

4.2.4 Performance Measures

Several measures to estimate the accuracy of a recognition function were introduced in genomic research (Fickett and Tung, 1992; Snyder and Stormo, 1993; Dong and Searls, 1994). Consider that we have S sites (positive examples) and N nonsites (negative

examples). By applying the recognition function, we correctly identify Tp sites (true positives) and T_n nonsites (true negatives). At the same time F_p (false positives) sites are wrongly classified as nonsites and F_n (false negative) nonsites are wrongly classified as sites. $T_p + F_n = S$ and $T_n + F_n = N$. Sensitivity (S_n) measures the fraction of the true positive examples that are correctly predicted: $S_n = T_P/(T_P + F_n)$. Specificity (S_p) measures the fraction of the predicted sites that are correct amongst those predicted: $S_p = T_P/(T_P + F_P)$. Note that the definition of S_p used in gene-prediction research is different from the usual $S_p = T_n/(T_n + F_p)$. Only the simultaneous consideration of both S_n and S_p values makes sense when we provide some accuracy information. Using only one value of accuracy estimation means that the average accuracy of prediction of true sites and nonsites is $AC = 0.5(T_P/S + T_n/N)$. However, this measure does not take into account the possible difference in sizes of site and nonsites sets. A more correct single measure (correlation coefficient) takes the relation between correctly predictive positives and negatives as well as false positives and negatives into account (Matthews, 1975):

$$CC = \frac{(T_p T_n - F_p F_n)}{\sqrt{(T_p + F_p)(T_n + F_n)(T_p + F_n)(T_n + F_p)}}.$$

4.3 LINEAR DISCRIMINANT ANALYSIS

Different features of a functional signal may have different significance for recognition and may not be independent. Classical linear discriminant analysis provides a method to combine such features in a discriminant function. A discriminant function, when applied to a pattern, yields an output that is an estimate of the class membership of this pattern. The discriminative technique provides minimization of the error rate of classification (Afifi and Azen, 1979). Let us assume that each given sequence can be described by vector X of p characteristics $(x_1, x_2, \ldots, x_p)$, that can be measured. The linear discriminant analysis procedure finds a linear combination of the measures (called the *linear discriminant function* or *LDF*), that provides maximum discrimination between site sequences (class 1) and nonsite examples (class 2). The LDF classifies (X) into class 1 if $Z > c$ and into class 2 if $Z > c$. The vector of coefficients $(\alpha_1, \alpha_2, \ldots, \alpha_p)$ and threshold constant c are derived from the training set by maximizing the ratio of the between-class variation of z to within-class variation and are equal to (Afifi and Aizen, 1979):

$$\vec{a} = s^{-1}(\vec{m_1} - \vec{m_2}),$$

and

$$\vec{c} = \vec{a}(\vec{m_1} - \vec{m_2})/2,$$

where $\vec{m_i}$ are the sample mean vectors of characteristics for class 1 and class 2, respectively; s is the pooled covariance matrix of characteristics

$$s = \frac{1}{n_1 + n_2 - 2}(s_1 + s_2)$$

s_i is the covariation matrix, and n_i is the sample size of class i. On the basis of these equations, we can calculate the coefficients of LDF and threshold constant c using the values of characteristics of site and nonsite sequences from the training sets and then test the accuracy of LDF on the test set data. Significance of a given characteristic or a set of characteristics can be estimated by the generalized distance between two classes (called the *Mahalonobis distance* or D^2):

$$\vec{D^2} = (\vec{m_1} - \vec{m_2})s^{-1}(\vec{m_1} - \vec{m_2}),$$

that is computed on the basis of values of the characteristics in the training sequences of classes 1 and 2. To find sequence features a lot of possible characteristics as score of weigh matrices, distances, oligonucleotide preferences at different subregions are generated. Selection of the subset of significant characteristics (among those tested) is performed by a stepwise discriminant procedure including only those characteristics that significantly increase the Mahalonobis distance (Afifi and Aizen, 1979).

4.4   PREDICTION OF DONOR AND ACCEPTOR SPLICE JUNCTIONS

4.4.1   Splice-sites Characteristics

Splice-site patterns are mainly defined by nucleotides at the ends of introns, because deletions of large parts of intron do not affect their selection (Breathnach and Chambon, 1981; Wieringa *et al.*, 1984). A sequence of eight nucleotides is highly conserved at the boundary between an exon and an intron (donor or 5′-splice site). This is AG|GTRAGT and a sequence of 4 nucleotides, preceded by a pyrimidine rich region, is also highly conserved between an exon and an intron (acceptor or 3′-splice site): YYTTYYYYYYNC|AGG (Senapathy *et al.*, 1990). The third less-conserved sequence of about 5−8 nucleotides, and containing an adenosine residue, lies within the intron, usually between 10 and 50 nucleotides upstream of the acceptor splice site (branch site). These sequences provide specific molecular signals by which the RNA splicing machinery can select the splice sites with precision.

Two very conservative dinucleotides are observed in practically all introns. The donor site has GT just after the point where the spliceosomes cut the 5′-end of intron sequences and the acceptor site has AG just before the point where the spliceo-somes cut the 3′-end of intron sequences (Breathnach *et al.*, 1978; Breathnach and Chambon, 1981).

Additionally, a rare type of splice pair AT−AC has been discovered. It is processed by related but different splicing machinery (Jackson, 1991; Hall and Padget, 1994). Introns flanked by the standard GT−AG pairs excised from pre-mRNA by the spliceosome including U1, U2, U4/U6 and U5 snRNPs (Nilsen, 1994). A novel type of spliceosome composed of snRNPs U11, U12, U4atac/U6atac and U5 (Hall and Padgett, 1996, Tarn and Steitz, 1996a; 1996b; 1997) excises AT−AC introns. For AT−AC group a different conserved positions have been noticed: |ATATCCTTT for donor site and YAC| for acceptor site (Dietrich *et al.*, 1997; Sharp and Burge, 1997; Wu and Krainer, 1997).

Burset *et al.* (2000) have done a comprehensive investigation of canonical and noncanonical splice sites. They have extracted 43 427 pairs of exon−intron bound-aries and their sequences from the InfoGene (Solovyev and Salamov, 1999) database

including all the annotated genes in mammalian genomic sequences. Annotation errors present a real problem in getting accurate information about eukaryotic gene functional signals from nucleotide sequence databases, such as GenBank or EMBL (Benson *et al.*, 1999; Kanz *et al.*, 2005). The authors generated a spliced construct for every splice pair combining 40 nt. of the left exon and 40 nt. of the right exon producing the same sequence as the splicing machinery generated by removing intron region (Figure 4.3). To verify the extracted splice sites, the alignments of splice constructs with known mammalian expressed sequence tags (ESTs (Boguski *et al.*, 1993) were used. For 43 427 pairs of donor and acceptor splice sites (splice pairs), 1215 were annotated as nonstandard donor sites (2.80 %) and 1027 were annotated as nonstandard acceptor sites (2.36 %). 41 767 splice pairs (96.18 %) contained the standard splice-site pair GT−AG. As a result of the analysis, from 1660 noncanonical pairs, 441 were supported by ESTs (27.35 %) and just 292 (18 %) were supported by ESTs after removing potential annotation errors and cases with ambiguities in the position of the splice junction (Table 4.3).

It is interesting to note that the EST-supported rate is clearly higher for canonical splice pairs. There were 22 374 out of 42 212 canonical pairs supported by ESTs (53.63 %) and just 27.3 % of noncanonical pairs. About a half (43.15 %) of all noncanonical splice pairs belongs to the GC−AG group (126). The next biggest in size of the noncanonical group GG−AG contains significantly less cases (12). There were many other groups in the same size range, including those processed by the special splicing machinery, the AT−AC group. Weight matrices for GT−AG and GC−AG pairs are presented in Table 4.4 and a consensus sequence for AT−AC pair in Figure 4.4.

Most other noncanonical splice pairs have a canonical conserved dinucleotide shifted by one base from the annotated splice junction. For example, for 12 EST-supported GG−AG pairs, 10 have a shifted canonical donor splice site with the GT dinucleotide, 1 major noncanonical site has the GC dinucleotide, and one GA−AG case (Figure 4.5).

One is prompted to explain the observations with the shifted canonical dinucleotides by an annotation error of inserting/deleting one nucleotide that is actually absent/present in real genomic sequence. This hypothesis was tested by comparing human gene sequences deposited to GenBank earlier with the sequences of the same region obtained in high throughput genome sequencing projects. Several examples of clear annotation and sequencing errors identified by the comparison are presented in Figure 4.6. We found 88
Figure 4.3 Structure of spliced constructs. Two sequence regions of a splice pair (marked as Donor and Acceptor) with the corresponding splice-site dinucleotides surrounded by 40 nt. of gene sequence at each side. Joining exon part of donor (40nt_ exonL) and exon part of acceptor (40nt_exonR) produce a sequence of splice construct to be verified by ESTs.

Table 4.3   Canonical and noncanonical splice sites in mammalian genomes.

examples of independent gene sequencing with sequences overlapping splice junctions. All human EST-supported GC−AG cases having HTS matches were supported by them (39 cases). 31 errors damaging the standard splice pairs were found. 7 cases had one or both intronic GenBank sequences completely unsupported by HTS, 8 cases had intronic GenBank sequences supported, but there was a gap between exonic and intronic parts and finally 16 cases had small errors as some insertions, deletions or substitutions. 5 AT−AC pairs (3 pairs were correctly annotated in original noncanonical set and 2 were recovered from errors) were identified. In additition, 2 cases were annotated as introns, but in HTS the exonic parts were continuous (accession numbers: U70997 and M13300). 7 cases of HTS were themselves GenBank sequences and for this reason they were excluded from the analysis.

Figure 4.5 Shifted splice sites. Example for GG−AG verified splice sites (12 cases). In donor, exactly after the cut point was always found a GG pair. To obtain which splicing pair are characteristic to this donor we should produce a shift of 1 nucleotide downstream. After this we reclassify sites as 10 GT−AG canonical splice sites, 1 GC−AG site and 1 apparently strange GA−AG site.

By generalizing these results we conclude that the overwhelming majority of splice sites contain the conserved dinucleotides GT−AG (99.2 %). The other major group includes GC−AG pairs (0.62 %), the alternative splicing mechanism group AC−AT (about

0.08 %) and a very small number of other noncanonical splice sites (about 0.03 %) (Table 4.3.d). Therefore, gene-finding approaches using only standard GT−AG splice sites can potentially predict 97 % genes correctly (if we assume 4 exons per gene, on average). Including the GC−AG splice pair will increase this level to 99 %. 22 253 verified examples of canonical splice pairs were presented in a database (SpliceDB), which is available for public use through the www (`http://www.softberry.com/berry.phtml?topic=splicedb&group=data&subgroup=spldb`) (Burset *et al.*, 2000). It also includes 1615 annotated and 292 EST-supported and shift-verified noncanonical pairs. This set can be used to investigate the reality of these sites as well as to further understand the splicing machinery.

Analysis of splice-site sequences demonstrated that their consensuses are somewhat specific for different classes of organisms (Senapathy *et al.*, 1990; Mount, 1993) and some important information is encoded by the sequences outside the short conserved regions. Scoring schemes based on consensus sequences or weight matrices which take into account the information about open reading frames, free energy of base pairing of RNA with snRNA and other peculiarities, give an accuracy of about 80 % for the prediction splice-site positions (Nakata *et al.*, 1985; Gelfand, 1989). More accurate prediction is produced by neural network algorithms (Lapedes *et al.*, 1988; Brunak *et al.*, 1991; Farber *et al.*, 1992). The integral view on the difference of triplet composition in splice and pseudosplice sequences is shown in Figure 4.7. This figure demonstrates the various functional parts of splice sites. We can see that the only short regions around splice junctions have a great difference in triplet composition. Their consensus sequences are usually used as determinants of donor or acceptor splice-site positions. However, dissimilarity in many other regions can also be seen. For the donor site – coding region, a G-rich intron region may be distinguished. For acceptor sites – a G-rich intron region, a branch point region, a polyT/C tract and coding sequence. Splice-site prediction methods using a linear function that combines several of such features is described below (Solovyev and Lawrence, 1993a; Solovyev *et al.*, 1994).

4.4.2   Donor Splice-site Characteristics

Seven characteristics were selected for donor splice-site identification. Their values were calculated for 1375 authentic donor site and for 60 532 pseudosite sequences from the learning set. The Mahalonobis distances showing the significance of each characteristic are given in Table 4.5. The strongest characteristic for donor sites is a triplet composition in consensus region ($D^2 = 9.3$) followed by the adjacent intron region ($D^2 = 2.6$) and the
Figure 4.7 Difference of the triplet composition around donor and GT-containing non-donor sequences (a); around acceptor and AG-containing non acceptor sequences (b) in 692 human genes. Each column presents the difference of specific triplet numbers between sites and pseudosites in a specific position. For comparison the numbers were calculated for equal quantities of sites and pseudosites.

Table 4.5   Significance of various characteristics of donor splice sites.

Characteristics	1	2	3	4	5	6	7
Individual D^2	9.3	2.6	2.5	0.01	1.5	0.01	0.4
Combined D^2	9.3	11.8	13.6	14.9	15.5	16.6	16.8

1, 2, 3 are the triplet preferences (13) of consensus (-4 to $+6$), intron G-rich ($+7$ to $+50$) and coding regions (-30 to -5), respectively. 4 is the number of significant triplets in the consensus region. 5 and 6 are the octanucleotide preferences for being coding 54 bp region on the left and for being intron 54 bp region on the right of donor splice-site junction. 7 is the number of G bases, GG doublets and GGG triplets in $+6$ to $+50$ intron G-rich region.

coding region ($D^2 = 2.5$). Other significant characteristics are the number of significant triplets in conserved consensus region; the number of G bases, GG doublets and GGG triplets; and the quality of the coding and intron regions.

Rigorous testing of several splice-site prediction programs on the same sets of new data demonstrated that the linear discriminant function (implemented in SPL program: `http://www.softberry.com/berry.phtml?topic=spl&group=programs&subgroup=gfind`) provides the most accurate local donor site recognizer (Table 4.6) (Milanesi and Rogozin, 1998).

Although a simple weight matrix provides less accurate recognition than more sophisticated approaches, it can be easily recomputed for new organisms and is very convenient to use in probabilistic HMM-gene-prediction methods. An interesting extension of this approach was suggested on the basis of analysis of dependencies between splice-site positions (Burge and Karlin, 1997). Using a maximal dependence decomposition procedure (Burge, 1998), 5 weight matrices corresponding to different subsets of splice-site sequences were generated. The subclassification of donor signals and the matrices constructed based on 22 306 EST-supported splice sites are presented in Figure 4.8. Performance of these matrices compared with other methods was evaluated on the Burset and Guigo (1996) data set (Figure 4.9). We can observe that several weight matrices definitely provide better splice-site discrimination than just one. However, their discriminatory power is similar to that of the matrix of triplets and lower than that of the linear discriminant function described above.

4.4.3 Acceptor Splice-site Recognition

Seven characteristics were selected for acceptor splice-sites recognition. Their values were calculated for 1386 authentic acceptor site and 89 791 pseudosite sequences from the learning set. The Mahalonobis distances showing the individual significance for each characteristic are given in Table 4.7. The strongest characteristics for acceptor sites are the triplet composition in the polyT/C tract region ($D^2 = 5.1$); consensus region ($D^2 = 2.7$); adjacent coding region ($D^2 = 2.3$); and branch point region ($D^2 = 1.0$). Some significance is found using the number of T and C in the adjacent intron region ($D^2 = 2.4$) and the quality of the coding region ($D^2 = 2.6$).

Table 4.8 illustrates the performance of different methods for acceptor site recognition (Milanesi and Rogozin, 1998). The linear discriminant function described above provides the best accuracy. Also, we can observe that acceptor site recognition accuracy is lower than that for donor sites.

It was shown that the first-order Markov chain model (11) based on dinucleotide frequencies of $[-20, +3]$ acceptor site region gives slightly better discrimination than the simple weight matrix model (Burge, 1998). Such a model was incorporated in

Figure 4.8 Classification of donor splice sites by several weight matrices reflecting different splice-site groups (Burge and Karlin, 1997).

Genscan gene-prediction method (Burge and Karlin, 1997). Thanaraj (2000) performed a comprehensive analysis of computational splice-site identification. The HSPL program remains the best local recognizer. Of course, most complex gene-prediction systems use a lot of other information about optimal exon (or splice site) combinations that provides a better level of accuracy. However it cannot be applied to study the possible spectrum of all alternative splice sites for a particular gene. Local recognizers seem useful for such tasks.

4.5　IDENTIFICATION OF PROMOTER REGIONS IN HUMAN DNA

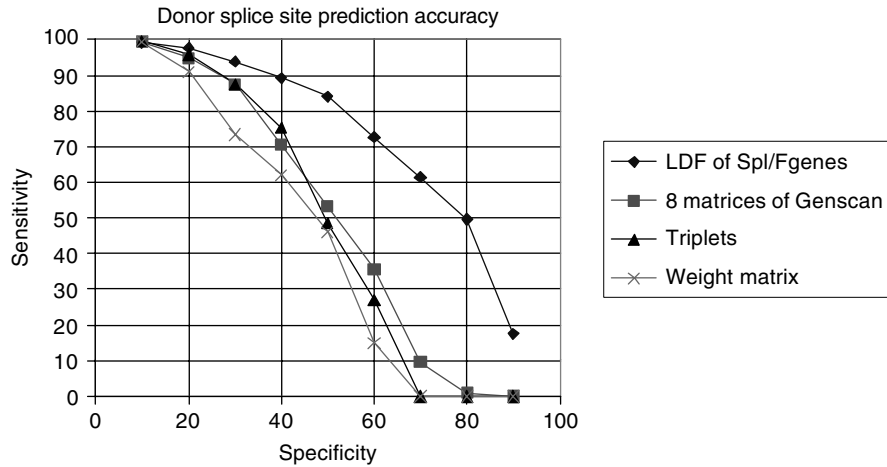
Computational recognition of eukaryotic polymerase II (PolII) promoter sequences in genomic DNA is an extremely difficult problem. Promoter 5′-flanking regions may contain dozens of short motifs (5–10 bases) that serve as recognition sites for proteins providing initiation of transcription as well as specific regulation of gene expression. Each promoter has its own composition and arrangement of these elements providing a unique regime


Figure 4.9 Comparison of the accuracy of donor splice-site recognizers: single weight matrix, five matrices suggested by Burge and Karlin (1997), matrix of triplets, linear discriminant function.

of gene expression. Here we will consider some general features of PolII promoters that can be exploited in promoter prediction programs.

The minimal promoter region that is capable of initiating basal transcription is referred to as the core promoter. It contains a transcription start site (TSS), often located in initiator region (Inr) and typically spans from -60 to $+40$ bp relative to TSS. About 30–50 % of all known promoters also contain a TATA box at a position about 30 bp upstream from TSS. The TATA box is apparently the most conserved functional signal in eukaryotic promoters. In some cases it can direct accurate transcription initiation by PolII, even in the absence of other control elements. Many highly expressed genes contain a

strong TATA box in their core promoter. However for large groups of genes, like most housekeeping genes, some oncogenes and growth factor genes, a TATA box is absent and the corresponding promoters are referred as *TATA-less promoters*. In these promoters, Inr may control the exact position of the transcription start point or the recently found downstream promoter element (DPE), usually located 30 bp downstream of TSS. Many human genes are transcribed from multiple promoters often producing alternative first exons. Moreover, transcription initiation appears to be less precise than initially assumed. In the human genome, it is not uncommon that the 50 ends of mRNAs transcribed from the same promoter region are spread over dozens or hundreds bp (Suzuki *et al.*, 2001; Cooper *et al.*, 2006; Schmid *et al.*, 2006).

The region 200–300 bp immediately upstream of the core promoter constitutes the proximal promoter. The proximal promoter usually contains multiple transcription factor binding sites that are responsible for transcription regulation. Further upstream is the distal part of promoter that may also contain transcription factor binding sites as well as enhancer elements. The typical organization of PolII promoters is shown in Figure 4.10. Because the distal part is usually the most variable region of promoters and generally poorly described, most current promoter recognition tools use the characteristics of only the core and/or proximal regions. Comprehensive reviews of eukaryotic promoters, specifically written from the prediction point of view, have appeared in the literature (Werner, 1999; Pedersen *et al.*, 1999; Cooper *et al.*, 2006).

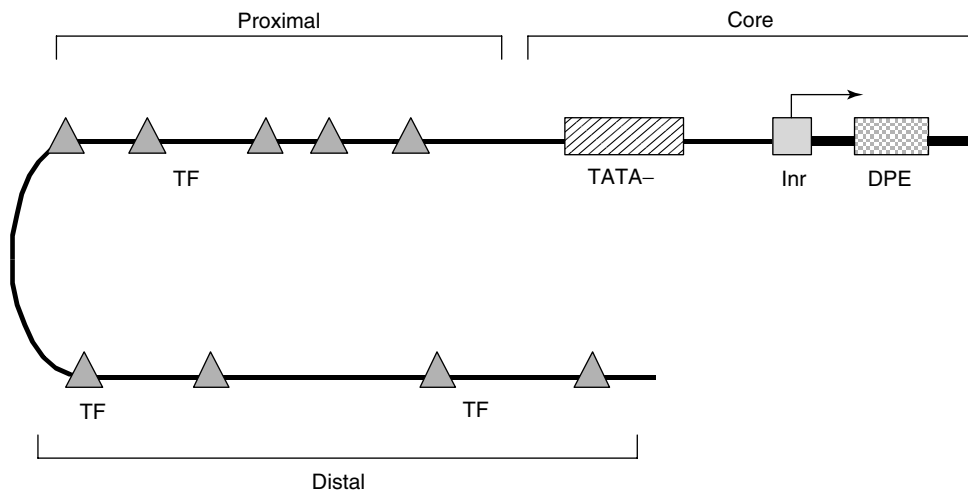
A collection of experimentally mapped TSSs and surrounding sequences called *Eukaryotic Promoter Database* (EPD) was created by Bucher and Trifonov (1986). In 2000, this database comprised about 800 independent promoter sequences including about 150 human promoters. There is no information about specific regulatory features in this database (Perier *et al.*, 2000). Up to release 72 (October 2002) EPD was a manually compiled database, relying exclusively on experimental evidence published in scientific journals. With release 73, they started to exploit 5′-ESTs from full-length cDNA clones


Figure 4.10 Schematic organization of polymerase II promoter. Inr – initiator region, usually containing TSS. DPE – downstream promoter element, often appearing in TATA-less promoters, TF binding sites – transcription factor binding sites.

as a new resource for defining promoters. These data are automatically processed by computer programs and already a year after the introduction of this new method, more than half of the EPD entries (1634) are based on 5′-EST sequences (Schmid *et al.*, 2004). EPD is not the only database providing information about experimentally mapped TSSs. DBTSS (Suzuki *et al.*, 2004) and PromoSer (Halees *et al.*, 2003) are large collections of mammalian promoters based on clustering of EST and full-length cDNA sequences. These databases define the TSS as the furthest 50 position in the genome which can be aligned with the 50 end of a cDNA from the corresponding gene. In contrast, EPD considers the most frequent cDNA 50 end as the TSS and further applies a specialized algorithm to infer multiple promoters for a given gene (Schmid *et al.*, 2006). There is a plant-specific PlantProm (Shahmuradov *et al.*, 2003) database of promoters based on published TSS mapping data.

Regulatory promoter elements are relatively short sequence motifs (typically 5−15 bp in length) (Wingender, 1988; Tjian, 1995; Fickett and Hatzigeorgiou, 1997). A relational TFD including collection of regulatory factors and their binding sites was created by Ghosh (1990; 2000). Over 7900 sequences of transcriptional elements have been described in TRANSFAC database (Wingender *et al.*, 1996; Matys *et al.*, 2006). It gives information about localization and sequence of individual regulatory elements within gene and transcription factors, which bind to them. RegsiteDB (Plant) contains about 1300 various regulatory motifs of plant genes and detail descriptions of their functional properties (http://www.softberry.com/berry.phtml?topic=regsite). Practically it is difficult to use most of these motifs to annotate long genomic sequences, because of their short length and degenerate nature. For example, even using well described the TATA box weight matrix there exists one false positive every 120−130 bp (Prestridge and Burks, 1993). Nevertheless, such resources are invaluable for detail analysis of gene regulation and interpretation of experimental data.

To generate regulatory diversity of gene expression, combinations of simple motifs can be used. Transcription factors and regulatory sequences are composed of modular components to achieve the high level of specificity by a relatively small number of different transcription factors (Tjian and Maniatis, 1994). Therefore, to understand gene function we should concentrate our attention on patterns of regulatory sequences rather than on single elements. Searching for such patterns should be much more effective in annotation of new sequences compared to the poor recognition of single motifs. The simplest examples of regulatory patterns are observed in composite regulatory elements (CE) of vertebrate promoters. Composite elements are modular arrangements of contiguous or overlapping binding sites for various distinct factors, raising the possibility that the bound regulatory factors may interact directly, producing novel patterns of regulation. For example, the composite element of proliferin promoter comprises glucocorticoid receptor (GR) and AP-1 factor binding sites. Both GR and AP-1 are expressed in most cell types, but the composite element demonstrated remarkable cell specificity: the hormone−receptor complex repressed the reporter gene expression in CV-1 cells, but enhanced its expression in HeLa cells and had no effect in the F9 cell (Diamond *et al.*, 1990). The database of composite elements (COMPEL) was set up as a common effort by the groups of Wingender (Germany) and Kolchanov (Russia) (Kel *et al.*, 1995). Currently the compilation contains information about several hundred experimentally identified composite elements, where each element consists of two functionally linked sites.

Development of the Transcription Regulatory Regions Database (TRRD), which describes observed regulatory elements in gene regulatory regions, was started in the Kolchanov group (Russia) in 1994 (Kolchanov *et al.*, 2000). TRRD was created by scanning the literature and covers just a fraction of genes taking into account the rather limited resources and very complex nature of the problem of comprehensive and accurate annotation. We are faced with exponentially growing data on transcriptional control owing to the advancement of experimental technologies. This requires us to unite efforts and expertise in creating knowledge databases in this field.

In one of the first attempts to predict eukaryotic promoters, Prestridge (1995) used the density of specific transcription factor binding sites in combination with the TATA box weight matrix. The program PROMOTERSCAN uses the promoter preferences for each binding site listed in TFD (Ghosh, 1990) previously calculated on the set of promoter and nonpromoter sequences. The other general-purpose promoter recognition tools take into account the oligonucleotide content of promoter sequences (Hutchinson, 1996; Audic and Claverie, 1997; Knudsen, 1999; Ohler *et al.*, 1999). In an earlier version of the linear discriminant recognizer, the signal-specific (TATA box weight matrix, binding site preferences) and content-specific characteristics (hexamer preferences) were combined for recognition of TSS (Solovyev and Salamov, 1997).

Fickett and Hatzigeorgiou (1997) presented a performance review of many general-purpose promoter prediction programs. Among these were oligonucleotide content-based (Hutchinson, 1996; Audic and Claverie, 1997), neural network (Guigo *et al.*, 1992; Reese *et al.*, 1996) and the linear discriminant approaches (Solovyev and Salamov, 1997). Although several problems were identified through the relatively small test set (18 sequences) (Ohler *et al.*, 1999), the results demonstrated that the programs can recognize just 50 % of promoters with false-positive rate about 1 per 700–1000 bp. If the average size of a human gene is more than 7000 bases and many genes occupy hundreds of kilobases, then we will expect significantly more false-positive predictions than the number of real promoters. However, these programs can be used to find promoter position (start of transcription and TATA box) in a given 5′-region or to help selecting the correct 5′-exons in gene-prediction approaches.

We will describe a current version of the promoter recognition program TSSW (Transcription Start Site, W stands for using functional motifs from the Wingender *et al.* (1996) database) (Solovyev and Salamov, 1997) to show sequence features that can be used to identify eukaryotic promoter regions. In this version, it was suggested that TATA+ and TATA− promoters have very different sequence features and these groups were analyzed separately. Potential TATA+ promoter sequences were selected by the value of score computed using the TATA box weight matrix (Bucher, 1990) with the threshold closed to the minimal score value for the TATA+ promoters in the learning set. Such a threshold divides the learning sets of known promoters into approximately equal parts. Significant characteristics of both groups found by discriminant analysis are presented in Table 4.9. This analysis demonstrated that TATA− promoters have much weaker general features compared with TATA+ promoters. Probably TATA− promoters possess more gene-specific structure and they will be extremely difficult to predict by any general-purpose method.

The TSSW program classifies each position of a given sequence as TSS or non-TSS based on two linear discriminant functions (for TATA+ and TATA− promoters) with characteristics calculated in the (−200, +50) region around a given position. If the TATA

Table 4.9 Significance of characteristics of promoter sequences used by TSSW programs for identification of TATA+ and TATA− promoters.

Characteristics	D^2 for TATA+ promoters	D^2 for TATA− promoters
Hexaplets −200 to −45	2.6	1.4 (−100 to −1)
TATA box score	3.4	0.9
Triplets around TSS	4.1	0.7
Hexaplets +1 to +40		0.9
Sp1-motif content		0.9
TATA fixed location	0.7	
CpG content	1.4	0.7
Similarity −200 to −100	0.3	0.7
Motif Density(MD) −200 to +1	4.5	3.2
Direct/Inverted MD −100 to +1	4.0	3.3 (−100 to −1)
Total Mahalonobis distance	11.2	4.3
Number promoters/nonpromoters	203/4000	193/74 000

box weight matrix gives a score higher than some threshold, then the position is classified based on LDF for TATA+ promoters, otherwise the LDF for TATA-less promoters is used. Only one prediction with the highest LDF score is retained within any 300 bp region. If we observe a lower scoring promoter predicted by the TATA-less LDF near a higher scoring promoter predicted by TATA+ LDF, then the first prediction is also retained as a potential enhancer region.

The recognition quality of the program was tested on 200 promoters, which were not included in the learning set. We provide the accuracy values for different levels of true predicted promoters in Table 4.10. The data demonstrate a poor quality of TATA− promoter recognition on long sequences and show that their recognition function can provide relatively unambiguous predictions within regions less than 500 bp. Contrarily, 90 % of TATA+ promoters can be identified within the range 0–2000 bp that makes their incorporation into gene-finding programs valid.

Ohler *et al.* (1999) used interpolated Markov chains in their approach and slightly improved the previous results. They identified 50 % in Fickett and Hatzigeorgiou (1997) promoter set, while having one false-positive prediction every 849 bp. Knudsen (1999), applying a combination of neural networks and genetic algorithms, designed another

Table 4.10 Performance of promoter identification by TSSW program.

Type of promoter	Number of test sites	True predicted (%)	1 false positive per bp
TATA+	101	98	1000
		90	2200
		75	3400
		52	6100
TATA−	96	52	500
		40	1000

program (Promoter2.0). Promoter 2.0 was tested on a complete Adenovirus genome 35 937 bases long. The program predicted all 5 known promoter sites on the plus strand and 30 false-positive promoters. The average distance between a real and the closest predicted promoter is about 115 bp. The TSSW program with the threshold to predict all 5 promoters produced 35 false positives. It gives an average distance between predicted TSS and real promoter of just 4 bp (2 predicted exactly, 1 with 1 bp shift, 1 with 5 bp shift and the weakest promoter was predicted with 15 bp shift).

Figure 4.11 shows an example of the results of the TSSW program for the sequence of human laminin beta 2 chain (GenBank accession number Z68155). The structure of this gene including its promoter region has been extensively studied. The length of gene is 11 986 bp, the first 1724 bp of which constitute a promoter region. TSSW predicts one enhancer at position 931 and one potential TSS at position 1197 with corresponding TATA box at the position 1167. Although both the predicted sites fall inside the designated promoter region, the second prediction is probably a false positive, because the

predicted TATA box is located far upstream (500 bp) from the experimentally determined beginning of the 5′-UTR. TSSW also optionally lists all potential TF binding sites around the predicted promoters or enhancers (Figure 4.11). It outputs the position, the strand (+/−), the TRANSFAC identifier and the consensus sequences of sites found. The information about these sites may be of interest for researchers studying the transcription of a particular gene.

There is a high false-positive rate of promoter prediction in long genomic sequences. It is more useful to remove some false-positive predictions using knowledge of the positions of the coding regions. TSSW was additionally tested on the several GenBank entries that have information about experimentally verified TSS and were not included in the learning set (Table 4.11). The lengths of the sequences varied from 950 to 28 438 bp with a median length of 2938 bp. According to the criteria defined by Fickett and Hatzigeorgiou (1997), all true TSS in these sequences can be considered as correctly predicted, with an average 1.5 false positives per sequence or 1 false positive per 3340 bp. The distances between true TSS and those correctly predicted varied from exact matching to 196 bp, with the median deviation of 9 bp. This can be considered to be quite a good prediction taking into account that experimental mapping of TSS has an estimated precision of +/− 5 bp (Perier *et al.*, 2000).

Accurate prediction of promoters is fundamental to understanding gene expression patterns, where confidence estimation of the produced predictions is one of the main requirements for many applications. Using recently developed transductive confidence machine (TCM) techniques, we developed a new program TSSP-TCM (Shahmuradov *et al.*, 2005) for the prediction of plant promoters that also provides confidence of the prediction. The method presented in the paper identifies ∼85 % of tested promoters with one false positive per ∼5000 bp. It allows us not only to make predictions, but more importantly, it also gives valid measures of confidence in the predictions for each individual example in the test set. Validity in our method means that if we set up a confidence level, say, 95 %, then we can guarantee that we are not going to have more than 5 errors out of 100 examples.

Recently there was an attempt to make a critical assessment of the promoter prediction accuracy in its current state relative to the manual Havana gene annotation (Bajic *et al.*, 2006). There were only 4 programs in this EGASP project: 2 variants of McPromoter

Table 4.11 Results of TSSW predictions on some GenBank entries with experimentally verified TSS.

program (Ohler *et al.*, 1999; 2002), N-scan (Arumugam *et al.*, 2006) and Fprom (Solovyev *et al.*, 2006), which is a modification of TSSW program described above that use TFD transcriptional motif database (Ghosh, 2000). McPromoter and Fprom derived its predictions from a sequence of the genome under analysis; N-scan used corresponding sequences of several genomes (such as human, mouse and chicken). When the maximum allowed mismatch of the prediction from the reference TSS for counting true positive predictions on test sequences was 1000 bp, the N-scan produced ∼3 % higher accuracy than the next most accurate predictor Fprom, but for the distance criterion 250 bp Fprom shows the best performance on most prediction accuracy measures (Bajic *et al.*, 2006). We should note that the sensitivity of computational promoter predictions was only 30–50 % (relatively 5′-gene ends of Havana annotation), but we should take into account that TSS annotation from two experimentally derived databases also produced a sensitivity of only 48–58 %. This leaves the open issue to create a reliable TSS reference dataset. The lesson from this EGASP experiment relative to promoter predictions is that it is beneficial to combine the TSS/promoter predictions with gene-finding programs as was done in generating N-scan or Fprom predictions.

Despite recent improvements in promoter prediction programs, their current accuracy is still not enough for their successful implementation as independent submodules in gene-recognition software tools. The rather small amount of experimentally verified promoters in databases such as EPD and GenBank hindered computational promoter identification progress, while now there is an order more promoter data became available (Seki *et al.*, 2002) generated by CapTrapper technique (Carninci *et al.*, 1996) that provided a relatively reliable method for promoter identification. Many of the above-mentioned promoter prediction algorithms use the propensities of each TF binding site independently and does not take into account their mutual orientation and positioning. It is well known that the transcriptional regulation is a highly cooperative process, involving simultaneous binding of several transcription factors to their corresponding sites. Specific groups of promoters may have specific patterns of regulatory sequences, where mutual orientation and location of individual regulatory elements are necessary requirements for successful transcription initiation or regulation.

4.6   RECOGNITION OF POLYA SITES

Another functionally important signal of eukaryotic transcripts is the 3′-untranslated region (3′UTR), which has a diversity of cytoplasmic functions affecting the localization, stability and translation of mRNAs (Decker and Parker, 1995). Almost all eukaryotic mRNAs undergo 3′-end processing which involves endonucleotide cleavage followed by the polyadenylation of the upstream cleavage product (Wahle, 1995; Manley, 1995). The essential sequences are involved in the formation of several large RNA-protein complexes (Wilusz *et al.*, 1990). RNA sequences directing binding of specific proteins are frequently poorly conserved and often recognized in a cooperative fashion (Wahle, 1995). Therefore we have been forced to use statistical characteristics of the polyA regions that may involve some unknown significant sequence elements.

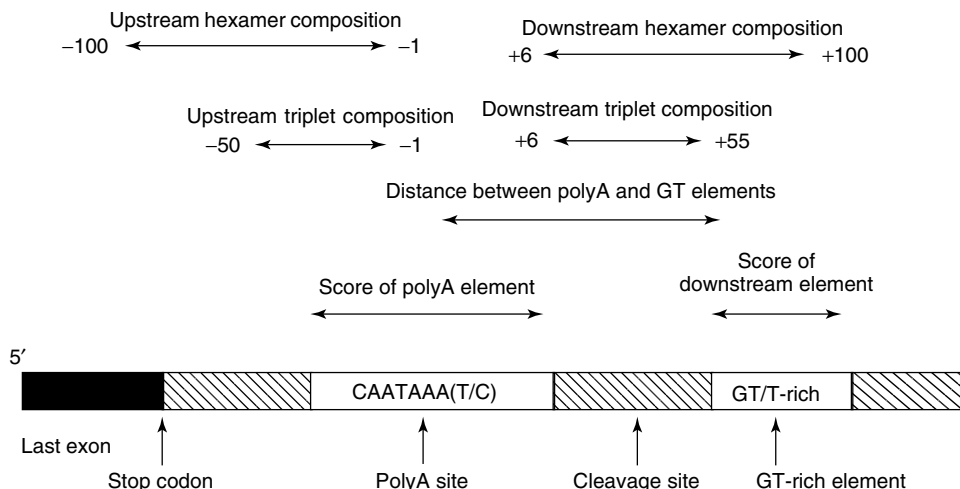
Numerous experiments have revealed three types of RNA sequences defining a 3′-processing site (Wahle, 1995; Proudfoot, 1991) (Figure 4.12). The most conserved


Figure 4.12   Characteristics of polyA signal sequences.

is the hexamer signal AAUAAA (polyA signal), situated 10–30 nucleotides upstream of the 3′-cleavage site. About 90 % of sequenced mRNAs have a perfect copy of this signal. Two other types, the upstream and the downstream elements, are degenerate and have not been properly characterized. Downstream elements are frequently located within approximately 50 nucleotides 3′ of the cleavage site (Wahle and Keller, 1992). These elements are often GU- or U-rich, although they may have various base compositions and locations. On the basis of sequence comparisons McLauchlan *et al.* (1985) have suggested that one of the possible consensuses of the downstream element is YGUGUUYY. The efficiency of polyadenylation in a number of genes can be also increased by sequences upstream of AAUAAA, which are generally U-rich (Wahle, 1995). All these RNA sequences serve as nucleation sites for a multicomponent protein complex catalyzing the polyadenylation reaction.

There have been a few attempts to predict 3′-processing sites by computational methods. Yada *et al.* (1994) conducted a statistical analysis of human DNA sequences in the vicinity of polyA signal in order to distinguish them from AATAAA sequences that are not active in polyadenylation (pseudo polyA signals). They found that a base C frequently appears on the upstream side of the AATAAA signal and a base T or C often appears on the downstream side, implying that CAATAAA(T/C) can be regarded as a consensus of the polyA signal. Kondrakhin *et al.* (1994) constructed a generalized consensus matrix using 63 sequences of cleavage/polyadenylation sites in vertebrate pre-mRNA. The elements of the matrix were absolute frequencies of triplets at each site position. Using this matrix, they have provided a multiplicative measure for recognition of polyadenylation regions. However this method has a very high false-positive rate.

Salamov and Solovyev (1997) developed LDF recognition function for polyA signal. The data sets for 3′-processing sites and 'pseudo' polyA signals were extracted from GenBank (Version 82). 3′-processing sites were taken from the human DNA entries, containing a description of the polyA signal in the feature table. Pseudosites were taken out of human genes as the sequences comprising (−100, +200) around the patterns revealed by polyA weight matrix (see below), but not assigned to polyA sites in the feature table.

4.7 CHARACTERISTICS FOR RECOGNITION OF 3′-PROCESSING SITES

As the hexamer AATAAA is the most conservative element of 3′-processing sites, it was considered as the main block in our complex recognition function. Although the hexamer is highly conserved, other variants of this signal were observed. For example, in the training set, 43 out of 248 polyA sites had hexamer variants of AATAAA with one mismatch. To consider such variants the position weight matrix for recognizing this signal has been used. The other characteristics such as content statistics of hexanucleotides and positional triplets in the upstream and downstream regions were defined relative to the position of the conservative hexamer sequence (Figure 4.12).

1. Position weight matrix for scoring of polyA signal $[-1, +7]$.

2. Position weight matrix [8] for scoring of downstream GT/T-rich element.

3. Distance between polyA signal and predicted downstream GT/T-rich element.

4. Hexanucleotide composition of downstream $(+6, +100)$ region.

5. Hexanucleotide composition of upstream $(-100, -1)$ region.

6. Positional triplet composition of downstream $(+6, +55)$ region.

7. Positional triplet composition of upstream $(-50, -1)$ region.

8. Positional triplet composition of the GT/T-rich downstream element

In Table 4.12, the Mahalonobis distances for each characteristic calculated on the training set are given. The most significant characteristic is the score of AATAAA pattern (estimated by the position weight matrix) that indicates the importance of occurrences almost perfect polyA signal (AATAAA). The second valuable characteristic is the hexanucleotide preferences of the downstream $(+6, +100)$ region. Although the discriminating ability of GT-rich downstream element itself (characteristic 2) is very weak, combining it with the other characteristics significantly increases the total Mahalonobis distance.

Kondrakhin *et al.* (1994) reported the error rates of their method at different thresholds for polyA signal selection. If the threshold is set to predict 8 of 9 real sites, their function also predicts 968 additional false sites. The algorithm-based LDF for 3′-processing site identification is implemented in the POLYAH program (http://genomic.sanger.ac.uk). First, it searches for the pattern similar to AATAAA using the weight matrix and, if the pattern is found, it computes the value of the linear discriminant function defined by the characteristics around this position. A polyA site is predicted if the value of this function is greater than an empirically selected threshold. The method demonstrates $S_n = 0.86$ and $S_p = 0.63$ when applied to a set of 131 positive and 1466 negative examples

Table 4.12 Significance of various characteristics of polyA signal.

Characteristics	1	4	2	5	3	6	8	7
Individual D^2	7.61	3.46	0.01	2.27	0.44	1.61	0.16	0.17
Combined D^2	7.61	10.78	11.67	12.36	12.68	12.97	13.09	13.1

that were not used in the training. The POLYAH program has been tested also on the sequence of the Ad2 genome, where for 8 correctly identified sites it predicts only 4 false sites.

4.8 IDENTIFICATION OF MULTIPLE GENES IN GENOMIC SEQUENCES

Computational gene finding started a long time ago with looking for open reading frames with an organism-specific codon usage (Staden and McLachlan, 1982). The approach worked well for bacterial genes (Staden, 1984b; Borodovskii *et al.*, 1986), but short eukaryotic exons and spliced genes require algorithms combining information about functional signals and the regularities of coding and intron regions. Several internal exon-predicting algorithms have been developed. The program SORFIND (Hutchinson and Hayden, 1992) was designed to predict internal exons based on codon usage plus Berg and von Hippel (1987) suggested discrimination energy for intron–exon boundary recognition. The accuracy of exact internal exon prediction (at both 5′- and 3-′ splice junctions and in the correct reading frame) by the SORFIND program reaches 59 % with a specificity of 20 %. Snyder and Stormo (1993) applied a dynamic programming approach (alternative to the rule-based approach) to internal exon prediction in GeneParser algorithm. It recognized 76 % of internal exons, but the structure of only 46 % exons was exactly predicted when tested on the entire GenBank sequence entries. HEXON (Human EXON) program (Solovyev *et al.*, 1994) based on linear discriminant analysis was the most accurate in exact internal exon prediction at that time.

Later a number of single gene-prediction programs has been developed to assemble potential eukaryotic coding regions into translatable mRNA sequence selecting optimal combinations of compatible exons (Fields and Soderlund, 1990; Gelfand, 1990; Guigo *et al.*, 1992; Dong and Searls, 1994). Dynamic programming was suggested as a fast method of finding an optimal combination of preselected exons (Gelfand and Roytberg, 1993; Solovyev and Lawrence, 1993b; Xu *et al.*, 1994). This is different from the approach suggested by Snyder and Stormo (1993) in the GeneParser algorithm to recursively search for exon–intron boundary positions. FGENEH (Find GENE in Human) algorithm incorporated 5′-, internal and 3′-exon identification linear discriminant functions and a dynamic programming approach (Solovyev *et al.*, 1994; 1995). Burset and Guigo (1996) have made a comprehensive test of gene-finding algorithms. The FGENEH program was one of the best in the tested group having the exact exon prediction accuracy 10 % higher than the other programs and the best level of accuracy at the protein level. A novel step in gene-prediction approaches was application of generalized Hidden Markov Models implemented in Genie algorithm. It was similar in design to GeneParser, but was based on a rigorous probabilistic framework (Kulp *et al.*, 1996). The algorithm demonstrated similar performance to FGENEH.

4.9 DISCRIMINATIVE AND PROBABILISTIC APPROACHES FOR MULTIPLE GENE PREDICTION

Genome sequencing projects require gene-finding approaches able to identify many genes encoded in the transcribed sequences. The value of sequence information for the

biomedical community is strongly dependent on the availability of candidate genes that are computationally predicted. The best multiple gene-prediction programs involve HMM-based probabilistic approaches as implemented in Genscan (Burge and Karlin, 1997) and Fgenesh (Salamov and Solovyev, 2000), Fgenes (discriminative approach) (Solovyev *et al.*, 1995) and Genie (Generalized HMM with neural network splice-site detectors) (Reese *et al.*, 2000). Initially we will describe a general scheme for HMM-based gene prediction (Stormo and Haussler, 1994) (first implemented by the Haussler group (Krogh *et al.*, 1994; Kulp *et al.*, 1996)) as the most general description of the gene model. A pattern-based approach can be considered as a particular case of this approach, where transition probabilities are not taken into account.

4.9.1 HMM-based Multiple Gene Prediction

Different components (states) of gene structure such as exons, introns and 5′-untranslated regions occupy k subsequences of a sequence X: $X = \bigcup_{i=1,k} x_i$. There are 35 states that describe eukaryotic gene model considering direct and reverse strands as possible gene locations (Figure 4.13). However, in the current gene-prediction approaches, noncoding 5′- and 3′-exons (and introns) are not considered because the absence of protein-coding characteristics makes their prediction less accurate. In addition, the major practical goal of gene prediction is to identify the protein-coding sequences. The remaining 27 states include 6 exon states (first, last single and 3 types of internal exons in 3 possible reading frame) and 7 noncoding states (3 intron, noncoding 5′- and 3′-, promoter and polyA) in each strand plus the noncoding intergenic region.

The predicted gene structure can be considered as the ordered set of states/sequence pairs, $\phi = \{(q_1, x_1), (q_2, x_2), \ldots, (q_k, x_k)\}$, called the *parse*, such that the probability $P(X, \phi)$ of generating X according to ϕ is maximal over all possible parses (or a score is optimal in some meaningful sense that best explains the observations (Rabiner, 1989)):

$$P(X,\phi) = P(q_1)\left(\prod_{i=1}^{k-1} P(x_i|l(x_i), q_i)P(l(x_i)|q_i)(P(q_{i+1}, q_i)\right)P(x_i|l(x_k), q_k)P(l(x_k)|q_k),$$

where $P(q_1)$ denotes the initial state probabilities; $P(x_i|l(x_i), q_i)P(l(x_i)|q_i)$ and $P(q_{i+1}, q_i)$ are the independent joint probabilities of generating the subsequence x_i of length l in the state q_i and transitioning to $i+1$ state.

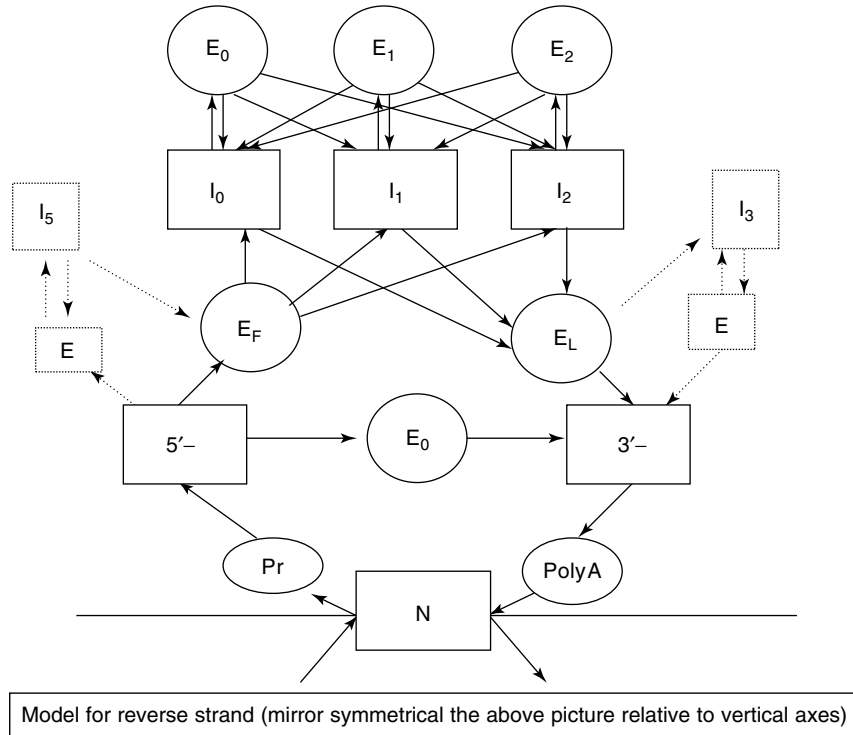
Successive states of this HMM model are generated according to the Markov process with the inclusion of explicit state duration density. A simple technique based on the dynamic programming method for finding the optimal parse (or the single best state sequence) is called the *Viterbi algorithm* (Forney, 1973). The algorithm requires on the order of N^2D^2L calculations, where N is the number of states, D is the longest duration and L is the sequence length (Rabiner and Juang, 1993). A useful technique was introduced by Burge (1997) to reduce the number of states and simplify computations by modeling noncoding state length by a geometrical distribution. The algorithm for gene finding using this technique was initially implemented in the Genscan program (Burge and Karlin, 1997) and used later in Fgenesh program (Salamov and Solovyev, 2000). Since any valid parse will consist only of an alternating series of Noncoding and Coding states: NCNCNC, . . , NCN, we need only 11 variables, corresponding to the different types of N states. At each step corresponding to some sequence position, we select the maximum joint probability to continue the current state or to move to another noncoding


Figure 4.13 Different states and transitions in eukaryotic HMM genes model. E_i and I_i are different exon and intron states, respectively ($i = 0,1,2$ reflect 3 possible different ORF). E marks noncoding exons and I5/I3 are 5′- and 3′-introns adjacent to noncoding exons.

state defined by a coding state (from a precomputed list of possible coding states) that ends in analyzed sequence position.

Define the best score (highest joint probability) $\gamma_i(j)$ of optimal parse of the subsequence $s_{1,j}$, which ends in state q_i at position j. We have a set A_j of coding states $\{c_k\}$ of lengths $\{d_k\}$, starting at positions $\{m_k\}$ and ending at position j, which have the previous states $\{b_k\}$. The length distribution of state c_k is denoted by $f_{c_k}(d)$. The searching procedure can be stated as follows:

Initialization:

$$\gamma_i(1) = \pi_i P_i(S_1) p_i, i = 1, \ldots 11.$$

Recursion:

$$\gamma_i(j+1) = \mathbf{max}\{\gamma_i(j) p_i P_i(S_{j+1}),$$
$$\max_{c_k \in A_j}\{\gamma_i(m_k - 1)(1 - p_{b_k}) t_{b_k,c_k} f_{c_k}(d_k) P(S_{m_k,j}) t_{c_k,i} p_i P_i(S_{j+1})\}\}$$
$$i = 1, \ldots 11, j = 1, \ldots, L - 1.$$

Termination:

$$\gamma_i(L+1) = \max\{\gamma_i(L),$$
$$\max_{c_k \in A_j}\{\gamma_i(m_k-1)(1-p_{b_k})t_{b_k,c_k}f_{c_k}(d_k)P(S_{m_k,j})t_{c_k,i}\}\}$$
$$i = 1, \ldots 11.$$

At each step, we record the location and type of transition maximizing the functional to restore the optimal set of states (gene structure) by a backtracking procedure. Most parameters of these equations can be calculated on the learning set of known gene structures. Instead of scores of coding states $P(S_{m_k,j})$ it is better to use log likelihood ratios, which do not produce scores below the limits of computer precision.

Genscan (Burge and Karlin, 1997) was the first published algorithm to predict multiple eukaryotic genes. Several HMM-based gene-prediction programs were developed later: Veil (Henderson *et al.*, 1997), HMMgene (Krogh, 1997), Fgenesh (Salamov and Solovyev, 2000), a variant of Genie (Kulp *et al.*, 1996) and GeneMark (Lukashin and Borodovsky, 1998). Fgenesh is currently one of the most accurate programs. It is different from Genscan because, in the model of gene structure, a signal term (such as splice site or start site score) has some advantage over a content term (such as coding potential). In log likelihood terms, the splice sites and other exon functional signals have an additional score, depending on the environments of the sites. Also, in computing the coding scores of potential exons, *a priori* probabilities of exons are taken into account according to Bayes theorem. As a result, the coding scores of potential exons are generally lower than in Genscan. Fgenesh works with separately trained parameters for each model organism such as human, drosophila, chicken, nematode, dicot and monocot plants, and dozen yeast/fungi (currently using known genes or predicted protein-supported genes, Fgenesh gene-finding parameters has been computed for about 40 various organisms: `http://sun1.softberry.com/berry.phtml?topic=fgenesh&group=programs&subgroup=gfind`). Coding potentials were calculated separately for 4 isochores (human) and for 2 isochores (other species). The run time of Fgenesh is practically linear and the current version has no practical limit on the length of analyzed sequence. Prediction of about 800 genes in 34 MB of Chromosome 22 sequence takes about 1.5 minutes of Dec-alpha processor EV6 for the latest Fgenesh version.

4.9.2 Pattern-based Multiple Gene-prediction Approach

FGENES (Solovyev, 1997) is the multiple gene-prediction program based on dynamic programming. It uses discriminant classifiers to generate a set of exon candidates. Similar discriminant functions were developed initially in Fexh (Find Exon), Fgeneh (Find GENE) program (h stands for version to analyze human genes) and described in details earlier (Solovyev and Lawrence, 1993a; Solovyev *et al.*, 1995, Solovyev and Salamov, 1997).

The following major steps describe the analysis of genomic sequences by the Fgenes algorithm:

1. Create a list of potential exons, selecting all ORFs: ATG.. GT, AG–GT, AG.. Stop with exons scores higher than the specific thresholds depending on GC content (4 groups);

2. Find the set of compatible exons with maximal total score. Guigo (1998) described an effective algorithm for finding such set. Fgenes uses a simpler variant of a similar algorithm: Order all exon candidates according to their 3′-end positions; Going from the first to the last exon select for each exon the maximal score path (compatible exons combination) terminated by this exon using the dynamic programming approach. Include in the optimal gene structure either this exon or the exon with the same 3′-splicing pattern ending at the same position or earlier (which has the higher maximal score path).

3. Take into account promoter or polyA scores (if predicted) in the terminal exon scores.

The run time of the algorithm grows approximately linearly with the sequence length. Fgenes is based on the linear discriminant functions developed earlier for the identification of splice sites, exons, promoter and polyA sites (Solovyev *et al.*, 1994; Salamov and Solovyev, 1997). We consider these functions in the following sections to see what sequence features are important in exon prediction.

4.10   INTERNAL EXON RECOGNITION

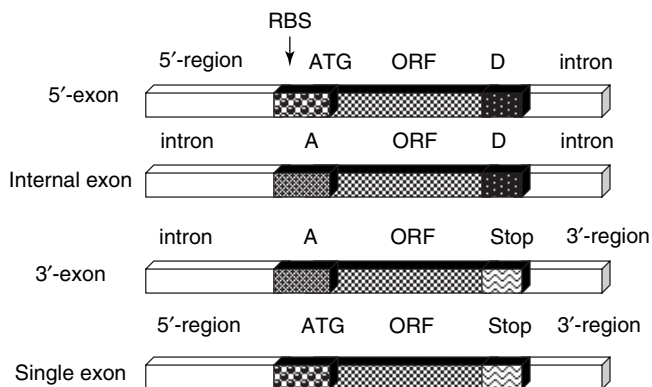
For internal intron prediction, we consider all open reading frames in a given sequence that are flanked by AG (on the left) and by GT (on the right) as potential internal exons. The structure of such exons is presented in Figure 4.14. The values of 5 exon characteristics were calculated for 952 authentic exons and for 690 714 pseudoexon training sequences from the set. The Mahalonobis distances showing significance of each characteristic are given in Table 4.13. We can see that the strongest characteristics for exons are the values of the recognition functions for the flanking donor and acceptor splice sites ($D^2 = 15.04$ and $D^2 = 12.06$, respectively). The preference of an ORF being a coding region has $D^2 = 1.47$ and adjacent left intron region has $D^2 = 0.41$ and right intron region has $D^2 = 0.18$.


Figure 4.14   Different functional regions of the first, internal, last and single exons corresponding to components of recognition functions.

Table 4.13 Significance of internal exon characteristics.

	Characteristics	1	2	3	4	5
a	Individual D^2	15.0	12.1	0.4	0.2	1.5
b	Combined D^2	15.0	25.3	25.8	25.8	25.9

Characteristics 1 and 2 are the values of the donor and acceptor site recognition functions. Characteristic 3 gives the octanucleotide preferences for being coding for each potential exon. Characteristic 4 gives the octanucleotide preferences for being an intron 70-bp region on the left and a 70-bp region on the right of the potential exon region.

The performance of the discriminant function based on these characteristics was estimated using 451 exon and 246 693 pseudoexon sequences from the test set. The general accuracy of the exact internal exon prediction is 77 % with specificity 79 %. At the level of individual nucleotides, the sensitivity of exon prediction is 89 % with specificity 89 %; and the sensitivity of prediction of intron positions is 98 % with specificity 98 %. This accuracy is better than in the most accurate dynamic programming and neural network-based methods (Snyder and Stormo, 1993), which have 75 % accuracy of the exact internal exon prediction with specificity 67 %. The method has 12 % less false exon assignments with a better level of true exon prediction.

4.11   RECOGNITION OF FLANKING EXONS

Figure 4.15 shows the 3-dimensional histograms reflecting the oligonucleotide composition of the gene flanking regions based on a graphical fractal representation of nucleotide sequences (Jeffrey, 1990; Solovyev *et al.*, 1991; Solovyev, 1993). The clear differences in compositions were exploited to develop of recognizers of these regions.

4.11.1   5′-terminal Exon-coding Region Recognition

For 5′-exon prediction, all the open reading frames in a given sequence starting with the ATG codon and ending with the GT dinucleotide were considered as potential first exons. The structure of such exons is presented in Figure 4.14. The exon characteristics and their Mahalonobis distances are given in Table 4.14. The accuracy of the discriminant function based on these characteristics was computed using the recognition of 312 first exons and 246 693 pseudoexon sequences. The gene sequences were scanned and the 5′ exon with the maximal weight was selected for each of them. The accuracy of the prediction of the true first coding exon is 59 %. Competition with the internal exons was not considered in this test.

4.11.2   3′-exon-coding Region Recognition

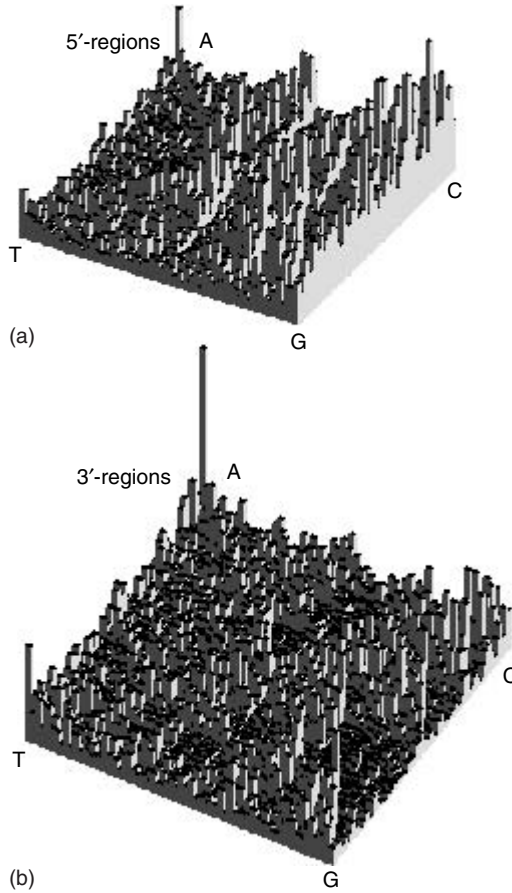
All ORF regions that are flanked by GT (on the left) and finish with a stop codon were considered as potential last exons. The structure of such exons is presented in Figure 4.14. The characteristics of the discriminant functions and their Mahalonobis distances are presented in Table 4.15. The accuracy of the discriminant function was tested on the


Figure 4.15 Graphical representation of the number of different oligonucleotides 6 bp long in 5'
(a) and 3' (b) gene regions. Each colon is the number of a particular oligonucleotide in the set of
sequences.

Table 4.14   Significance of 5'- exon characteristics.

	Characteristics	1	2	3	4	5	6	7
a	Individual D^2	5.1	2.6	2.7	2.3	0.01	1.05	2.4
b	Combined D^2	5.1	8.1	10.0	11.3	12.5	12.8	13.6

Characteristic 1 is the value of donor site recognition function. 2 is the average value of positional triplet
preferences in -15 to $+10$ region around ATG codon. 4 gives the octanucleotide preferences for being intron
in 70 bp region on the right of potential exon. 3, 5 and 7 are the hexanucleotide preferences in -150 to -101
bp, -100 to -51 bp and -50 to -1 bp regions on the left of potential exon, respectively; 6 is the octanucleotide
preferences for being coding in exon region.

recognition of 322 last exons and 2 47 644 pseudoexon sequences. The gene sequences
were scanned and the 3' exon with the maximal weight was selected for each of them.
The function can identify 60 % of annotated last exons.

Table 4.15   Significance of 3′-exon characteristics.

	Characteristics	1	2	3	4	5	6	7
a	Individual D^2	10.0	3.2	0.8	2.2	1.2	0.2	1.6
b	Combined D^2	10.0	11.4	12.0	13.8	14.3	14.5	14.6

Characteristic 1 is the value of acceptor site recognition. Characteristic 2 is the octanucleotide preferences for being coding of ORF region. 3, 5 and 7 are the hexanucleotide preferences in +100 to 150 bp, +50 to +100 bp and +1 to +50 bp regions on the left of coding region, respectively. 4 is the average value of positional triplet preferences in −10 to +30 region around the stop codon. 6 is the octanucleotide preferences for being intron in 70 bp region on the left of exon sequence.

The recognition function for single exons combines the corresponding characteristics of 5′- and 3′-exons.

4.12   PERFORMANCE OF GENE IDENTIFICATION PROGRAMS

Most gene-recognition programs were tested on a specially selected set of 570 single gene sequences (Burset and Guigo, 1996) of mammalian genes (Table 4.16). The best programs predict accurately on average 93 % of the exon nucleotides ($S_n = 0.93$) with just 7 % of false-positive predictions. Because the most difficult task is to predict small exons and exactly identify exon 5′ and 3′ ends, the accuracy at the exon level is usually lower than at the nucleotide level.

The table demonstrates that the modern multiple gene-prediction programs as Fgenesh, Fgenes and Genscan significantly outperform the older approaches. The exon identification rate is actually even higher than the data presented as the overlapped exons were not

Table 4.16   Accuracy of the best gene-prediction programs for single gene sequences from (Burset and Guigo, 1996) data set. S_n (sensitivity) = number of exactly predicted exons/number of true exons (or nucleotide); S_p (specificity) = number of exactly predicted exons/number of all predicted exons. Accuracy data for programs developed before 1996 were estimated by Burset and Guigo (1996). The other data were received by authors of programs.

Algorithm	S_n (exons)	S_p (exons)	S_n nucleotides	S_p nucleotides	Authors/year
Fgenesh	0.84	0.86	0.94	0.95	Solovyev and Salamov (1999)
Fgenes	0.83	0.82	0.93	0.93	Solovyev (1997)
Genscan	0.78	0.81	0.93	0.93	Burge and Karlin (1997)
Fgeneh	0.61	0.64	0.77	0.88	Solovyev *et al.* (1995)
Morgan	0.58	0.51	0.83	0.79	Salsberg *et al.* (1998)
Veil	0.53	0.49	0.83	0.79	Henderson *et al.* (1997)
Genie	0.55	0.48	0.76	0.77	Kulp *et al.* (1996)
GenLang	0.51	0.52	0.72	0.79	Dong and Searls (1994)
Sorfind	0.42	0.47	0.71	0.85	Hutchinson and Hyden (1992)
GeneID	0.44	0.46	0.63	0.81	Guigo *et al.* (1992)
Grail2	0.36	0.43	0.72	0.87	Xu *et al.* (1994)
GeneParser2	0.35	0.40	0.66	0.79	Snyder and Stormo (1995)
Xpound	0.15	0.18	0.61	0.87	Thomas and Skolnick (1994)

counted in exact exon predictions. However, there is a lot of room for future improvement. The accuracy at the level of exact gene prediction is only 59 % for Fgenesh, 56 % for Fgenes and 45 % for the Genscan program even on this relatively simple test set.

The real challenge for *ab initio* gene identification is to find multiple genes in long genomic sequences containing genes on both DNA strands. Often, there is no complete information about the real genes in such sequences. One example studied experimentally at the Sanger Centre (UK) is the human BRACA2 region (1.4 MB) that contains eight genes and 169 experimentally verified exons. This region is one of the worse cases for genome annotation because it has genes with many exons and almost all genes show no similarity of their products with known proteins. Moreover, it contains four pseudogenes and at least two of the genes have alternative splicing variants. The results of gene prediction initially provided by T. Hubbard and R. Bruskiewich (Sanger Centre Genome Annotation Group) are shown in Table 4.17.

Fgenesh predicts 20 % less false-positive exons in this region than the Genscan approach, with the same level of true predicted exons. Even for such difficult region about 80 % of exons were identified exactly by *ab initio* approaches.

The accuracy of the gene-finding programs depends not only on underlying algorithm, but also strongly affected by parameter file computed on the learning set of known genes. While Fgenesh and Genscan demonstrate similar performance for human gene prediction, Fgenesh has shown significantly better accuracy than many other tested gene-finders (including Genscan) in predicting rice genes (Yu *et al.*, 2002).

4.13   USING PROTEIN SIMILARITY INFORMATION TO IMPROVE GENE PREDICTION

The lessons from manual annotations show that it is often advantageous to take into account all the available information to improve gene identification. Automatic gene-prediction approaches can take into account the information about exon similarity with

Table 4.17   Accuracy of gene-prediction programs for BRACA2 1.4 MB human genomic sequence. Masked is prediction when repeats have been defined by RepeatMasker (Smit and Green, 1997) program in the analyzed sequence and excluded from potential exon location during prediction. The region consisted of 20 sequences with 8 verified genes, 4 pseudogenes and 169 exons. Later one sequence was constructed and three additional exons were identified. The results of prediction on this sequence marked bold.

	CC	S_{nb}	S_{pb}	P_e	$C_{e,ov}$	S_{ne}	$S_{n,ov}$	$S_{pe}/S_{pe,ov}$
Genscan	0.68	90	53	271/**271**	109/**131**	65	80/**76**	40/**49**
Fgenesh	0.80	89	73	188/**195**	115/**131**	69	80/**76**	61/**67**
Fgenes	0.69	79	62	298/**281**	110/**136**	66	86/**78**	37/**48**
Genscan masked	0.76	90	66	217	109	65	80	50
Fgenesh masked	0.84	89	82	172/**168**	114/**131**	68	79/**73**	66/**76**
Fgenes masked	0.73	80	68	257/**228**	107/**133**	64	85/**75**	42/**58**

CC is the correlation coefficient reflecting the accuracy of prediction at the nucleotide level. S_{nb}, S_{pb} – sensitivity and specificity at the base level (in %), P_e – number of predicted exons, C_e –number of correctly predicted exons, S_{ne}, S_{pe} – sensitivity and specificity at the exon level, S_{nep} – exon sensitivity, including partially correct predicted exons (in %). Ov is including overlapped exons.

known proteins or ESTs (Gelfand *et al.*, 1996; Krogh, 2000). Fgenesh+ (Salamov and Solovyev, 2000) is a version of Fgenesh which uses additional information from the available protein homologs. When exons initially predicted by Fgenesh show high similarity to a protein from the database, it is often advantageous to use this information to improve the accuracy of prediction. Fgenesh+ requires an additional file with protein homolog, and aligns all predicted potential exons with the protein homolog using own alignment algorithm. To decrease the computational time, all overlapped exons in the same reading frame are combined into one sequence and align only once.

The main additions to the algorithm, relative to Fgenesh, include:

1. Augmentation of the scores of exons with detected similarity by an additional term proportional to the alignment score.

2. An additional penalty included for the adjacent exons in the dynamic programming (Viterbi algorithm), if the corresponding aligned protein segments are not close in the corresponding protein.

Fgenesh+ was tested on the selected set of 61 GenBank human sequences, for which Fgenesh predictions were not accurate (correlation coefficient $0.0 <= CC < 0.90$) and which have protein homologs from another organism. The percentage identity between the encoded proteins and their homologs varied from 99 % to 40 %. The prediction accuracy using this set is presented in Table 4.18. The results show that if the alignment covers the whole length of both proteins, then Fgenesh+ usually increases the accuracy relative to Fgenesh and does not depend significantly on the level of identity (for $ID > 0$ %). This result makes knowledge of proteins from distant organisms valuable for improving the accuracy of gene identification. A similar approach exploiting known EST/cDNA information was implemented in Fgenesh_c program (Salamov and Solovyev, 2000).

4.13.1 Components of Fgenesh++ Gene-prediction Pipeline

Ab initio gene-prediction program such as Fgenesh predicts $\sim$93 % of all coding exon bases and exactly predicts $\sim$80 % of human exons when applied to single gene sequences (Table 4.16). Analysis of multigene, long genomic sequences is a more complicated task. A program can erroneously join neighboring genes or split a gene into two or more. To improve automatic annotation accuracy, we developed a pipeline Fgenesh++, which can take into account available supporting data such as mRNA or homologous protein sequences. Fgenesh++ is a pipeline for automatic, without human modification of results, prediction of genes in eukaryotic genomes. It uses thefollowing sequence analysis software.

Table 4.18 Comparison of accuracy of Fgenesh and Fgenesh+ on the set of 'difficult' human genes with known protein homologs from another organism.

	CG	S_{ne}	S_{pe}	S_{nb}	S_{pb}	*CC*
Fgenesh	0	63	68	86	83	0.74
Fgenesh+	46	82	85	96	98	0.95

The set contains 61 genes and 370 exons. *CG* – percent of correctly predicted genes; S_{ne}, S_{pe} –sensitivity and specificity at the exon level (in %); S_{nb}, S_{pb} – sensitivity and specificity at the base level (in %); *CC* – correlation coefficient.

Fgenesh++ script to execute the pipeline;

Fgenesh: HMM-based *ab initio* gene-prediction program;

Fgenesh+: gene-prediction program that uses homologous protein sequence to improve performance;

Est_map: a program for mapping known mRNAs/ESTs to a genome, producing genome alignment with splice sites identification;

Prot_map: a program for mapping a protein database to genomic sequence.

Est_map can map a set of mRNAs/ESTs to a chromosome sequence. For example, 11 000 full-length mRNA sequences from NCBI reference set were mapped to 52 MB unmasked Y chromosome fragment in ∼20 minutes **Est_map** takes into account statistical features of splice sites for more accurate mapping. **Prot_map** uses a genomic sequence and a set of protein sequences as its input data, and reconstructs gene structure based on protein identity or homology, in contrast to a set of unordered alignment fragments generated by Blast (Altschul *et al.*, 1997). The program is very fast and produces gene structures with similar accuracy to those of relatively slow GeneWise program (Birney and Durbin, 2000), but does not require knowledge of protein genomic location. The accuracy of gene reconstruction can be significantly improved further using Fgenesh+ program on output of Prot_map, that is, using a fragment of genomic sequence (where prot_map found a gene) and the cooreponding protein sequence mapped to it.

Comparison of accuracy of gene prediction by *ab initio* Fgenesh and gene prediction with protein support by Fgenesh+ or GeneWise (Birney and Durbin, 2000) and Prot_ map was performed on a large set of human genes with homologous proteins from mouse or drosophila. We can see that Fgenesh+ shows the best performance with mouse proteins (Table 4.19). With Drosophila proteins, *ab initio* gene prediction by Fgenesh works better than GeneWise for all ranges of similarity and Fgenesh+ is the best predictor if similarity is higher than 60 % (Table 4.20).

Table 4.19   Accuracy of human gene prediction using similar mouse proteins.

(a) Similarity of mouse protein > 90 % in 921 sequences *

	Sn_{ex}	Sp_{ex}	Sn_{nuc}	Sp_{nuc}	CC	$\%CG$

Prot_map	75.1	74.9	91.4	97.5	0.941	10

In addition to the programs listed above, Fgenesh++ package also includes files with gene-finding parameters for specific genome, configuration files for programs and a number of Perl scripts. In addition, Fgenesh++ pipeline uses the following public software and data: BLAST executables blastall and bl2seq (Altschul *et al.*, 1997), NCBI NR database (nonredundant protein database) formatted for BLAST, and NCBI RefSeq database (Pruitt *et al.*, 2005).

Fgenesh++ analyzes genome sequences and, optionally, same sequences with repeats masked by N. Sequences can be either complete chromosomes or their fragments such as scaffolds, contigs, etc. When preparing repeats-masked sequences, it is recommended not to mask low complexity regions and simple repeats, as they can be parts of coding sequences.

There are three main steps in running the pipeline:

1. mapping known mRNAs/cDNAs (e.g. from RefSeq) to genomic sequences;

2. prediction of genes based on homology to known proteins (e.g. from NR);

3. *ab initio* gene prediction in regions having neither mapped mRNAs nor genes predicted on the basis of protein homology.

The output of the pipeline consists of predicted gene structures and corresponding proteins. It also indicates whether particular gene structure was assigned on the basis of mRNA mapping, protein homology, or *ab initio* gene prediction.

4.14 GENOME ANNOTATION ASSESSMENT PROJECT (EGASP)

NHGRI (The National Human Genome Research Institute) has initiated the ENCODE project to discover all human genome functional elements (The ENCODE Project Consortium, 2004). Its pilot phase is focused on performance evaluation of different techniques of genome annotation, including computational analysis, on a specified 30 MB of human genome sequence. The community experiment (EGASP05) was organized (Guigo and Reese, 2005) to evaluate how well automatic annotation methods are able

to reproduce manual annotations. The best performance in most categories has been demonstrated by predictors that used the most sources of available information. Some of them included conservation of corresponding coding regions in several available genomes: Augustus (Stanke *et al.*, 2006), Jigsaw (Allen *et al.*, 2006) and Paragon (Arumugam *et al.*, 2006). The sensitivity of Fgenesh++ pipeline (which uses one genome information) is similar with them, but the above multigenome programs demonstrated better specificity (Guigo *et al.*, 2006). Performance of Fgenesh++ pipeline for mRNA or protein-supported predictions and *ab initio* predictions (in sequence regions where similar mRNA/protein were not found) is presented in Table 4.21 (Solovyev *et al.*, 2006). All the above-mentioned pipelines demonstrate ∼90–95 % sensitivity on the nucleotide level and 75–80 % on the exact exon prediction level. They can exactly predict ∼70 % genes (when we count at least one transcript per locus predicted exactly) and ∼50 % of all annotated transcripts. No annotation strategy produces perfect gene predictions even using a lot of supportive information that is available for human genome. It is worthwhile to note that the human genes are the most difficult to predict (due to regular occurrences ofvery short exons and very long intron sequences), while the accuracy on simpler organisms is usually much better. While human genes present the most difficult case, the other sequenced genomes have much less available experimental information.

4.15   ANNOTATION OF SEQUENCES FROM GENOME SEQUENCING PROJECTS

Knowledge of gene sequences has opened a new way of performing biological studies called *functional genomics* and the major challenge is to find out what all the newly discovered genes do, how they interact and how they are regulated (Wadman, 1998). Comparisons between genes from different genomes can provide additional insights into the details of gene structure and function.

   The successful completion of the Human Genome Project has demonstrated that large-scale sequencing projects can generate high-quality data at a reasonable cost. In addition to human genome, researchers have already sequenced the genomes of a number of important model organisms that are commonly used as test beds in studying human biology. These are the chimpanzee, the mouse, the rat, two puffer fish, two fruit flies, two sea squirts, two roundworms and baker's yeast. Recently, sequencing centers completed working drafts of the chicken, the dog, the honey bee, the sea urchin and a set of four

Table 4.21 Performance data for annotating 44 ENCODE sequences by either mRNA and protein-supported predictions or by *ab initio* predictions.

	91.4	71.71

fungi. A variety of other genomes are currently in the sequencing pipelines. Many new genomes lack such rich experimental information as the human genome, and therefore their initial computational annotation is even more important as a starting point for further research to uncover their biology. The more comprehensive and accurate such computational analysis is performed, the less time consuming and costly experimental work will have to be done to determine all functional elements in new genomes. Using computational predictions, the scientific community can get at least partial knowledge of majority of real genes because usually gene-finding programs correctly predict most exons of each gene. Fgenesh++ gene-prediction software has been used in annotation of dozen new genomes such as human, rice, Medicago, silkworm, many yeast genomes, bee and sea urchin (see for example, Sodergren *et al.*, 2006; The Honeybee Genome Sequencing Consortium, 2006). Annotation of many genomes is quite a complex procedure. For example, five gene lists were combined to produce bee genome master gene set. Three of them present gene predictors from NCBI, Fgenesh++ and ENSEMBL. Two others comprised evolutionary conserved gene set and Drosophila orthologs. These gene sets merged by special procedure (GLEAN), that construct consensus prediction based on combination of evidences provided by the five gene lists. The Glean set of 10 157 genes is considered as based on experimental evidence, the official *ab initio* gene set comprised 15 500 gene models that did not overlap models of the Glean set (The Honeybee Genome Sequencing Consortium, 2006).

4.15.1 Finding Pseudogenes

Pseudogenes prediction can use two types of initial information (Solovyev *et al.*, 2006). One type contains exon–intron structures of annotated genes and their protein sequences for a genome under analysis. To get such information, we can execute a gene-finding pipeline such as Fgenesh++. In this case, we run Prot_ map program with a set of protein sequences to find possible significant genome–protein alignments that do not correspond to a location of a gene for mapped protein. Other type of initial data can be a set of known proteins for a given organism. Having such data, we can restore gene structure of a given protein using Prot_ map program. For each mapped protein, we can select the best scoring mapping and the computed exon/intron structure as the 'parent' gene structure of this protein. If the alignment of a protein with its own parent has obvious internal stop codons or frameshifts, this locus could be included in the list of potential pseudogenes, but we need to keep in mind more trivial explanations like sequencing errors. Such loci cannot be analyzed on their K_a/K_s or checked for intron losses. In any case, for each of two approaches we have a set of protein sequences, their parent gene structures, and protein–genome alignments for further analysis to identify pseudogenes. Most other pseudogene-finding methods do not include gene-finding and rely on the available protein databases (Harrison *et al.*, 2003) or search only for processed pseudogenes (Baren and Brent, 2006). Example of two types of pseudogenes, processed and nonprocessed, and their characteristics are presented in Figures 4.16 and 4.17.

4.15.2 Selecting Potential Pseudogenes

Using genome–protein alignments generated by Prot_ map program, PSF program produces a list of alignments possessing the following properties for each protein.

Alignment vs. protein encoded by the parent gene.

Figure 4.17 An example of not processed pseudogene.

1. Identity in blocks of alignment exceeds certain value

2. Substantial portion of protein sequence is included in the alignment

3. Genomic location of alignment differs from that of parent gene

4. At least one of four events is observed:

    i. *Damage to ORF.* There is one or more frameshifts or internal stop codons;

    ii. *Single exon with close PolyA site.* PolyA site is too close to a 3′-end of an alignment, while C-terminus of protein sequence is aligned to the last amino acid, and a single exon covers 95 % of protein sequence.

    iii. *Loss of introns.* Protein coverage by alignment is at least 95 %, and a number of exons is fewer than in parent gene by a certain number.

    iv. *Protein sequence is not preserved.* The ratio of nonsynonymous to synonymous replacements exceeds certain threshold ($K_a/K_s > 0.5$). K_a/K_s is calculated relative to a parent gene by method presented by Nei and Gojobori (1986).

4.15.3 Selecting a Reliable Part of Alignment

The procedures described above apply to a so-called reliable part of alignment. Necessity of introducing this concept is caused by imperfections in aligning a protein against a chromosome sequence. There are complex cases where accurate alignment cannot be produced, such as very short (1–3 bp) exons separated by a large intron, or some errors in protein or genome draft sequence that prevent perfect alignment. For instance, if a protein as a whole is well aligned to a chromosome, but ∼20 amino acids on its 5′-end cannot be aligned in one continuous block, Prot_ map will most likely try to align these 20 amino acids by scattering them along several short blocks. Most likely, these blocks will not have any relation to a gene or a pseudogene. Therefore, in search for pseudogenes, we remove short insignificant trailer blocks. The rest of alignment is considered as its reliable part. To find a reliable part of alignment, we evaluate the quality of alignment blocks (exons). For each exon found by Prot_map, we calculate the number of aligned amino acid (M), number of nonaligned amino acids (AI) and nucleotides (NI) within an exon, number of aligned amino acids (AO) and nucleotides (NO) located outside of exon region to the left and to the right side of an exon. We also compute the 'correctness' of splice sites conserved dinucleotides (SSC) that flank an exon. If an exon is N- or C-terminal one, we also compute 'correctness' of corresponding start or stop codons. The length of an intron (IL) that separates an exon from nearest exon in the direction of the longest mapped exon is also computed. The empirical 'quality' measure is defined by the following formula:

$$Q = M - P_{AI}(AI) - P_{NI}(NI) - P_{AO}(AO) - P_{NO}(NO) + B_{SSC}(SSC) - P_{IL}(IL).$$

Where P_{AI}, P_{NI}, P_{AO}, P_{NO} are the penalties for the internal and external unaligned amino acids and nucleotides, BSSC is a bonus for correctness of splice sites or start/stop codons, and P_{IL} is a penalty for high intron length. The reliable part of alignment consists of neighboring exons alignments that each have $Q > 5$. After Prot_map mapping, many loci on a chromosome include alignments to more than one protein. In such cases, we choose only one most reliable alignment, based on a sum of included exon's qualities.

The PSF (pseudogene finding) approach described above has been applied to identify pseudogenes in 44 ENCODE sequences (Solovyev *et al.*, 2006). As a result, it was found 181 potential pseudogenes, 118 of which had a significant overlap with annotated 145 HAVANA pseudogenes. 68 (58 %) of these 118 pseudogenes had only one exon and could be classified as processed pseudogenes: 58 had the parent gene with more than one exon and seven others had polyA tail. 106 (90 %) of 118 pseudogenes had one or more defects in their ORFs. Among the remaining 12, there are four pseudogenes with a single exon (while their parents have four or more exons), four contain both polyA signal and polyA tract, four have only a polyA tract, and two have only high K_a/K_s ratios (0.59 and 1.04). The PSF has not found 27 HAVANA annotated pseudogenes. Three of them were not reported because they are located in introns of larger pseudogenes (AC006326.4-001, AC006326.2-001 and AL162151.3-001). The other ten represent fragments of some human proteins and are missing stop codons or frameshifts. We did not include pseudogenes corresponding to fragments of proteins in our pseudogene set. The remaining 14 HAVANA pseudogenes were not found probably due to some limitation of our program and the used datasets of predicted genes and known proteins. Missed pseudogenes might have parent genes that were absent from our initial protein set compiled by Fgenesh++ gene-prediction pipeline. Some of 63 pseudogenes that have been predicted by PSF but were absent from HAVANA set might have appeared because of imperfect predictions by the pipeline, which produced frameshifts when a pseudogene candidate and its parent gene were aligned. However, some of these 'over-predicted' pseudogenes might be actual pseudogenes missed by HAVANA annotators (for example, see Figure 4.18).

To summarize, PSF pseudogene prediction program has found 81 % of annotated pseudogenes. Its quality can further be improved by improving the quality of parent gene/protein sets.

4.16   CHARACTERISTICS AND COMPUTATIONAL IDENTIFICATION OF miRNA GENES

MicroRNA (miRNA) are a class of small (~22 nt), noncoding RNAs that can regulate gene expression by directing mRNA degradation or inhibiting productive translation (Mallory and Vaucheret., 2004). They are sequence-specific regulators of posttranscriptional gene expression in many eukaryotes. Some components of miRNA machinery have been found even in archaea and eubacteria, revealing their very ancient origination. They are believed to control the expression of thousands of target mRNAs, with each mRNA possible targeted by multiple miRNAs (Pillai, 2005). miRNA discovery by molecular cloning has been supplemented by computational approaches that identify evolutionary conserved miRNA genes by searching for patterns of sequence and secondary structure conservation These approaches indicate that miRNA constitute nearly 1–3 % of all identified genes in nematodes, flies and mammalians (Jones-Rhoades and Bartel, 2004). Only in humans the latest miRNA count exceeded 800 genes (Pillai, 2005). The first two miRNA genes (lin-4 and let-7) were discovered in *C. elegans*, where their mutations cause defects in the temporal regulation of larval stage-specific programs of cell divisions. These miRNAs affect by base pairing to partially complementary sites in the 3′ untranslated region (UTR) of their target mRNAs and repressing their translation (Lee *et al.*, 1993; Reinhart *et al.*, 2000).

Figure 4.18 A pseudogene in ENm004 sequence that is absent in the manual HAVANA annotation. The alignment has a stop codon close to position 151636.

The majority of miRNA genes are located in intergenic regions or in antisence orientation to annotated genes, indication that they for independent transcriptional units. Most of the other miRNA genes are found in intronic regions, which may be transcribed as part of the annotated gene. Independent miRNA genes are initially transcribed by RNA PolII (Lee *et al.*, 2004) as part of a long primary transcript, which contain the mature miRNA as part of a predicted RNA hairpin. This transcript is cropped into the hairpin-shaped pre-miRNAs by nuclear RNaseIII Drosha (Lee *et al.*, 2003). The hairpin RNAs of approximately 70 nt bearing the 2-nucleotide 3′ overhang are exported to the cytoplasm by a Ran dependent nuclear transport receptor family. Once in the cytoplasm, pre-miRNAs are subsequently cleaved by cytoplasmic RNase III Dicer into ~22 nt miRNA duplex, one strand of which is degraded by a nuclease, while the other strand remains as a mature miRNA (Lee *et al.*, 2004; Denli *et al.*, 2004). A typical structure of miRNA gene and its processing is presented in Figure 4.19.

Despite the plenty of miRNAs that have identified from cloning, such technique is likely to be far from saturated, as it is biased to abundant miRNA. Therefore, computational approaches have been developed that predict miRNAs encoded in animal and plant genomes (Grad *et al.*, 2003; Jones-Rhoades and Bartel, 2004; Ohler *et al.*, 2004). There are several variations of these methods: one is based on analysis of sequence and secondary structure properties of typical pre-miRNA. However, the short length and high degree of sequence and structure variation limit the accuracy of computational predictions based on such characteristics along. To decrease the number of false-positive predictions, the candidate miRNAs are selected to be conserved across species (the presence in two or more genomes of very similar sequences embedded in the same stems of predicted hairpins). A flowchart of computational selection miRNA candidates for plant miRNA predictions is presented in Figure 4.20 (Jones-Rhoades and Bartel, 2004). Another algorithm is based on the search for possible homologs (including hairpin selection and Smith–Waterman sequence alignment) of a few hundreds of known miRNAs cloned from *C. elegans, D. melanogaster, M. musculus and H. sapiens* (for identification of miRNAs in animal genomes) (Grad *et al.*, 2003). Recently, using similar approaches the FindmiRNA and the TargetmiRNA programs were developed

to search for miRNA and their targets in sequences of a range of model eukaryotic organisms (http://www.softberry.com/berry.phtml?topic=index&group =programs&subgroup=rnastruct).

4.17 PREDICTION OF microRNA TARGETS

While hundreds of miRNAs have been deposited in the databases, their regulatory targets have not been established or predicted for many of them. Finding regulatory targets for plant miRNA is simply performed by looking for near-perfect complementarity to the mRNAs. For example, in a search for the targets of 13 *Arabodopsis* miRNA families, 49 unique targets were found with just a few false predictions (Rhoades *et al.*, 2002). However, animal miRNA targets have complementarity to the miRNAs only in the 'seed' sequence (usually 2–8 nucleotides numbered from the 5′ end) and often have multiple regions of complementarity, therefore more sophisticated search methods considering these features have recently been published (Stark *et al.*, 2003; Enright *et al.*, 2003; Lewis *et al.*, 2003; Rehmsmeier *et al.*, 2004). In general, miRNA, target genes are selected on the basis of three properties: sequence complementarity using a position-weighted local alignment algorithm, free energies of RNA–RNA duplexes, and conservation of target sites in related genomes. Lewis *et al.* (2003) in their TargetScan software took into account multiple miRNA–mRNA UTR complementary regions summing Z-scores (exp(-G/T)) produced by each such region in evaluating a potential target mRNA, where G

is the free energy of miRNA:target site interaction. An example of stem-loop structure and predicted target sites for miR26a in human *SMAD1* gene is presented in Figure 4.21. Using TargetScan ~400 regulatory target genes have been predicted for the conserved vertebrate miRNAs. Eleven predicted targets (out of 15 tested) were supported experimentally (Lee *et al.*, 2003).

4.18   INTERNET RESOURCES FOR GENE FINDING AND FUNCTIONAL SITE PREDICTION

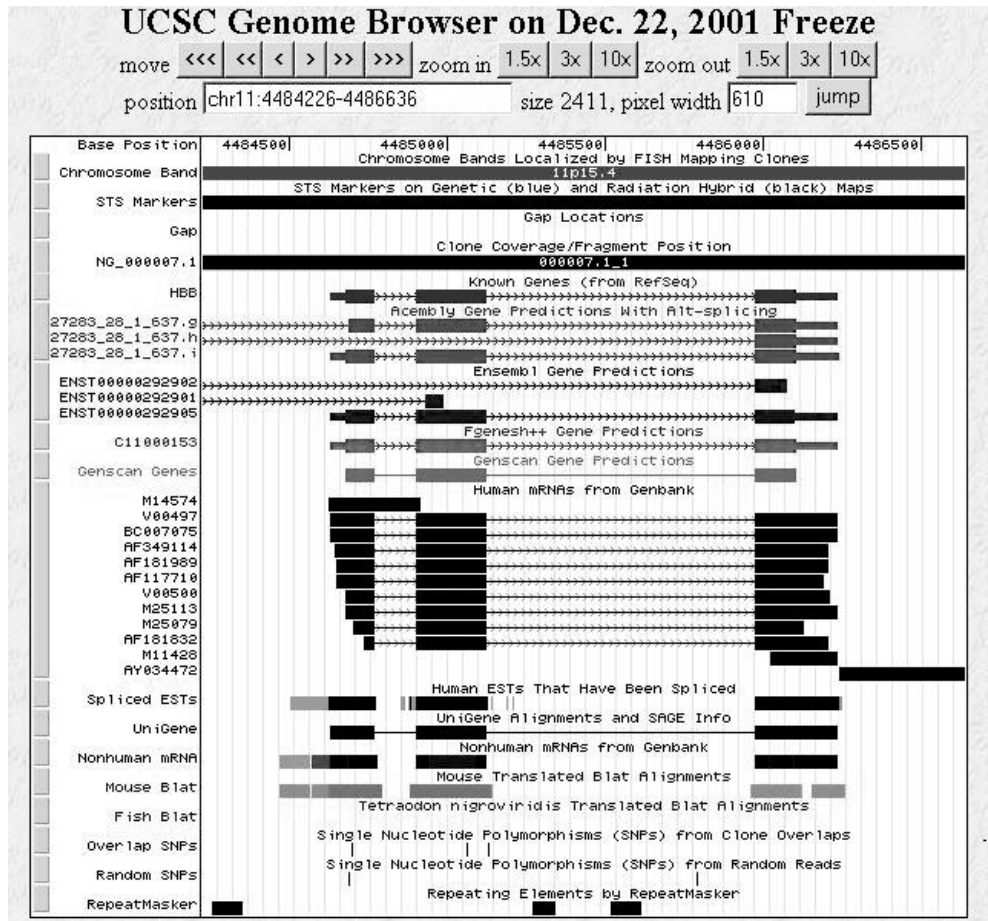
Prediction of genes, ORF, promoter, splice sites finding by the methods described in the preceding text is mostly available via World Wide Web. Table 4.22 presents WEB addresses of some of them. Many of these programs can be used within window-based **Molquest** computer package (www.molquest.com). It is the most comprehensive, easy-to-use desktop application for desktop sequence analysis (see Figure 4.22). The package includes gene-finders family (fgenesh/fgenesh+) programs for many organisms as well as pipelines (fgenesh++ and fgeneshb_annotator) that often used for fully automatic annotation eukaryotic and bacterial genomes (or genome


Figure 4.23 A screenshot of UCSC Genome Browser displaying gene predictions computed by various approaches.

communities) (The Honeybee Genome Sequencing Consortium, 2006; Tyson *et al.*, 2004). The package provides a user-friendly interface for sequence editing, primer design, internet database searches, gene prediction, promoter identification, regulatory elements mapping, patterns discovery protein analysis, multiple sequence alignment, phylogenetic reconstruction, and a wide variety of other functions. A lot of information generated during new genomes annotations (including gene predictions) is available through various genome browsers. A screenshot of popular UCSC Genome Browser (http://genome.ucsc.edu/) is presented in Figure 4.23. Another such interactive tool Genome Explorer (http://sun1.softberry.com/berry.phtml?topic= human&group=genomexp) can show a graph of expression data for selected genes (Figure 4.24). Its version for annotations of bacterial genomes is demonstrated in Figure 4.25. These web browsers provide search of numerous genome elements, visualization and retrieval of gene and protein sequences and fast comparison with auser-provided

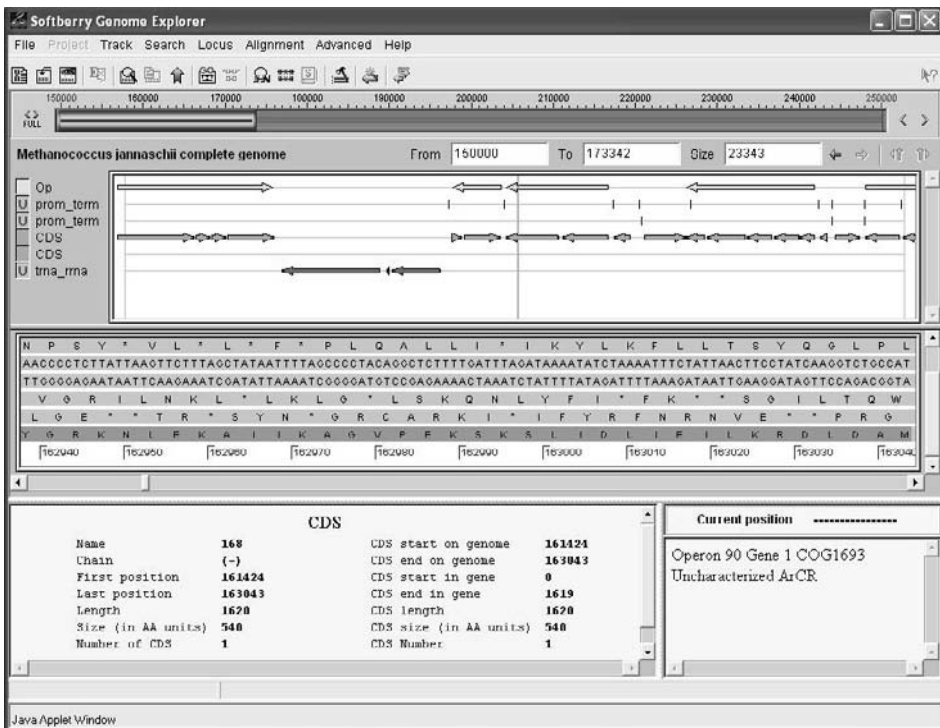

Figure 4.25 The Bacterial genome explorer displaying predicted operons, genes, promoters and terminators.

sequences. They are actively used not only by academic research community but also by many drug discovery and biotechnology companies for identification of drug candidates.

Comparative Genomics

J. Dicks

Department of Computational and Systems Biology, John Innes Centre, Norwich, UK

and

G. Savva

Centre for Environmental and Preventive Medicine, Wolfson Institute of Preventive Medicine, London, UK

Over the last couple of decades, numerous genetic and physical maps have been developed for a wide range of species. These data have led to the development of the field of *comparative genomics*, in which we analyse characteristics of whole genomes, in contrast to the analysis of single genes in comparative genetics. By comparing homologous markers between species, we can get a feel for their relative distributions on the chromosomes of the respective species. Such information also enables us to deduce segments of chromosomes where the gene content, and sometimes also the order of the genes, is similar in two or more species. More recently, DNA sequences of whole genomes have become available, enabling us to compare genomes at both the sequence and the gene levels. Furthermore, these datasets have provided us with more detailed information with which to study the processes involved in genome dynamics. The promise of the post-genome era means that we will see many fully sequenced genomes within the next decade and we should develop analytical methods that are mature when significant quantities of data become available. However, not all species will be sequenced, at least in the near future, and so we should continue to develop methods of analysis that are appropriate for both types of data. In this chapter, we give a flavour of the types of comparative genome analysis that are currently possible. We highlight particular problems such as phylogenetic inference and the use of maps to compare genomes. Finally, we look at problems that should be tackled to enable us to make the most of the emerging genomic data.

5.1   INTRODUCTION

Comparative genomics is pervasive in almost all branches of computational biology. At its broadest, comparative genomics is simply the comparison between two or more

genomic entities from different taxa. These entities can be genomic sequences (either whole sequences or subsets), gene order, gene content, or some other genomic feature such as codon usage or GC content. Furthermore, the way in which we compare these entities across taxa is dependent on the type of data we are analysing.

The growing focus on comparative genomics within computational biology is simple to understand. For example, we would like to be able to look at a particular dataset, say the DNA sequence of a gene, from a single organism and predict the functional characteristics of that dataset. Unfortunately, *ab initio* methods are currently rare or not yet powerful enough to be useful in everyday science. More commonly, we discover information about biological objects that we know little about by comparing them to other objects about which we have been able to gain information, usually by experimental means. Thus, many of the concepts in computational biology with which we are most familiar, such as functional prediction of DNA and protein sequences, have their foundations in comparative biology. Furthermore, we see how methodologies are evolving to take advantage of large quantities of genomic data in related species. For example, in the field of gene prediction, recently developed methods such as Twinscan and N-scan (`http://mblab.wustl.edu/software/`) make use of existing annotated genomes, other than that of the organism on which an analysis is being performed, to improve the results of the analysis. The considerable breadth of computational genomics means that we cannot cover the whole spectrum of methodologies here. Consequently, in this chapter we concentrate on a few areas that most closely embody the spirit of comparative genomics by comparing significant quantities of genomic information from two or more organisms to gain new biological insights. We do not aim to provide an exhaustive bibliography on each of the topics covered, but we introduce many of the key papers that in turn provide the interested reader with a more complete history of the relevant methodology.

In the kinds of analyses we examine in this chapter, we would like to compare the genomes of two or more organisms. But what sort of data do we wish to compare, what is our motivation for comparing them and how do we go about the comparison? To answer these questions, it is simplest to examine in turn each of the datasets. Essentially, different types of dataset have arisen as technological advances have been made. In the early days of comparative genomics, our datasets consisted of mapped genetic markers. Later, as sequencing technologies improved, we began to gain information on the sequences of small genomes, often organellar genomes, leading to the study of gene content and order. More recently, we have seen the sequencing of large eukaryotic organisms and a new series of analytical tools have arisen as a result.

In the next two sections we look at the concepts of homology and genomic mutation, both of which we must understand in order to carry out a comparative genomic analysis. In Section 5.4, we look at comparative mapping and the problems that comparing maps can solve. We refer to the complex nature of chromosomal evolution in Section 5.5 and use the concepts described in Section 5.3 to look at measures of gene order and content difference. We introduce models of chromosomal evolution and show how these models, together with these measures of difference, can be used in evolutionary studies. In Section 5.6, we examine new methodologies emerging for the analysis of genome sequences. These new methods include whole genome alignment, taking the lead from smaller-scale alignment tools, and genomic palaeontology, essentially a combination of sequence and gene order studies that together enable us to understand a genome's evolutionary past through self-comparison. Finally, in Section 5.7, we look at areas of potential future research.

Throughout the chapter we give examples of databases and software tools pertinent to the subject matter covered in the section. References for these items are given in the text, with URLs provided in Table 5.1.

5.2   HOMOLOGY

Comparative genomics is built upon the concept of *homology*. Haldane (1927) laid the foundations of comparative genetics by examining the coat colour of rodents and carnivores. He discussed genetic homology and stated that 'Structures in two species are said to be homologous when they correspond to the same structure in a common ancestor.' Historically, homology was established on the basis of a large array of experimental evidence (see Searle, 1968). Today, we are more used to seeing sequence similarity with, perhaps, the additional evidence of homologous flanking regions (i.e. being within a larger region of homology) as sufficient to state a putative homology.

For much of this chapter, we refer to homology in the context of genes and the similarity of their sequences. However, we should keep in mind that homology is equally relevant to non-genic objects (e.g. markers in comparative mapping studies are not always gene based). There are different categories of homology. For a given gene in one organism we can often, though not always, find a corresponding gene that carries out a similar role in a closely related organism. If the two genes arose from a common ancestor then they are *orthologues*. However, if they evolved from different origins but have similar sequences or functions as a consequence of convergent evolution, then they are analogous to one another and are known as *analogues*. Relationships between genes are further complicated by gene duplication, where we need to consider *paralogous* genes. Fitch (1970) wrote of the difficulties and importance of correctly distinguishing homologous from paralogous proteins. The recent burgeoning popularity of comparative genomic studies has led to this matter being discussed widely, for example by Remm *et al.* (2001). Here, the term *inparalogue* has been created to indicate paralogues that have arisen through a gene duplication event after speciation, such that a group of such genes may together be co-orthologous to a gene in another organism, while *outparalogues* have arisen following a gene duplication preceding speciation. In general, outparalogues should have a more diversified function than inparalogues. Figure 5.1 gives a depiction of the various types of homology, using the representation of O'Brien *et al.* (2005).

Information on homologous structures, particularly genes, is also now available in many public data resources. For example, the original Ensembl database (Hubbard *et al.*, 2002) was developed for dissemination of the annotated human genome sequence. However, it has since been applied to several other genome sequences and this has led to the development of resources for the linking of homologous genes across species and the alignment of pairs of groups of whole genome sequences. In addition, some databases are developed purely on the basis of homology. For example, the Inparanoid program (Remm *et al.*, 2001) was developed to identify orthologous clusters while differentiating between inparalogues, which are included in clusters, and outparalogues, which are not. The Inparanoid database (O'Brien *et al.*, 2005) provides data on eukaryotic orthologues from 17 genomes, examining over 500 000 proteins derived from Ensembl and UniProt. The Clusters of Orthologous Groups (COGs; Tatusov *et al.*, 1997) database compares the protein sequences of genes from complete genomes representing major phylogenetic lineages, grouping together genes that are co-located in multiple organisms. Each COG consists of individual proteins or groups of paralogues from at least three lineages and thus corresponds to an ancient conserved domain. Phylogenetically Inferred Groups (PhIGs; Dehal and Boore, 2006) is a set of databases and web tools that analyse gene
Figure 5.1 Homologous relationships between five contemporary genes in species B and C, all descended from a single gene in the ancestral species A. Black boxes denote gene duplications. Genes C2 and C3 are inparalogues and are co-orthologous to B2. B1 and C1 are orthologues but B1 is an outparalogue of B2 and of C2 and C3.

sets from completely sequenced genomes, building clusters of genes using a graph-based approach, and using maximum likelihood phylogenetic analysis to uncover the evolutionary relationships among all gene families.

5.3   GENOMIC MUTATION

Before we begin to look at some of the main types of comparative genome analysis, we must first understand the ways in which genomes evolve, so that we can understand their relevance to these analyses. It is widely known that DNA sequences evolve via the mutation events substitution, insertion and deletion, which affect single nucleotide sites or perhaps a small number of adjacent sites in the latter two cases. When comparing two relatively small sequences, it is usually sufficient to consider the differences between them in light of these events alone. However, genomes may also change by a series of much larger, but less frequent, mutations known as *chromosomal rearrangements*. When we compare larger genomic datasets such as long DNA sequences or gene orders, we also need to consider these events. Essentially, there are two types of chromosomal rearrangement: those that alter the gene content of the chromosome (the *non-conservative* rearrangements) and those that do not (the *conservative* rearrangements). For ease of understanding, it is simplest to consider chromosomal rearrangements by describing their effect on a series of linear and distinct regions along a genome, such as genes. However, it can be seen easily that these events affect the underlying genomic sequence in a similar way (as we see in later sections of this chapter).

First, let us consider the simple case of a single linear chromosome (this case can be adapted easily to that of a circular chromosome such as the mitochondria or chloroplast). The chromosome contains N genes g_i (for $i = 1$ to N) that are represented as signed integers, such that homologues in other species share the same number. The sign of the number represents the orientation of the gene, denoting the way in which it is *transcribed*,

or read. For example, if we denote a gene as '+1' on our first species then its homologues in all other species must be denoted as '+1' or '−1', depending on their orientations and regardless of their positions on their respective chromosomes. Therefore we can represent the order of genes on the chromosome as a signed permutation:

$$G = \{g_1 g_2, \ldots, g_{N-1} g_N\}.$$

For simplicity, we will define all mutation events as the outcomes of breaks *between genes*, in the intergenic regions. The locations of these breaks are known as *breakpoints*. Although this convention will not always represent biological reality, it is likely to represent the majority of cases.

There are three conservative (*inversion*, *shift* and *inverted shift*) and two non-conservative rearrangements (*tandem duplication* and *deficiency*) that can affect our single chromosome. An inversion (often termed a *reversal* in the computer science literature) is the result of two breaks, with the central segment turning about 180° before rejoining with the two broken ends. Consider e.g.

$$G = \{+1 + 2 + 3 + 4 + 5 + 6 + 7 + 8\} \longrightarrow G' = \{+1 + 2 + 3 - 6 - 5 - 4 + 7 + 8\}.$$

A shift, or *transposition*, is a three-break mutation, where a segment is moved to another part of the same chromosome. Consider e.g.

$$G = \{+1 + 2 + 3 + 4 + 5 + 6 + 7 + 8\} \longrightarrow G' = \{+1 + 2 + 6 + 7 + 3 + 4 + 5 + 8\}.$$

An inverted shift is similar to a shift, but here the segment inverts before it is inserted into its new location. A tandem duplication causes a short chromosomal segment to be duplicated and inserted adjacent to the original copy. Consider e.g.

$$G = \{+1 + 2 + 3 + 4 + 5 + 6 + 7 + 8\} \longrightarrow$$
$$G' = \{+1 + 2 + 3 + 4 + 4 + 5 + 6 + 7 + 8\}.$$

The new segment can remain in its original position or it can be moved to another location by subsequent mutations. For example, the evolution of the haemoglobin locus, from a single gene to a four-gene complex, is thought to be a result of repeated tandem duplication. Finally, a deficiency causes a segment to be removed from a chromosome. Consider e.g.

$$G = \{+1 + 2 + 3 + 4 + 5 + 6 + 7 + 8\} \longrightarrow G' = \{+1 + 2 + 3 + 4 + 5 + 8\}.$$

A genome consisting of two or more chromosomes can be affected by additional mutations (and of course any one of its chromosomes may undergo any of the mutations seen for the single-chromosome case). There are three major additional conservative mutations (*reciprocal translocation*, *centric fusion* and *dissociation*) that alter one or more chromosomes. A reciprocal translocation is a two-break mutation that occurs when parts of two chromosome arms swap with one another. Consider e.g.

$$G = \{+1 + 2 + 3 + 4 + 5\}\{+6 + 7 + 8\} \longrightarrow$$
$$G' = \{+1 + 2 + 3 + 7 + 8\}\{+6 + 4 + 5\}.$$

A centric fusion or *Robertsonian translocation* is a two-break mutation where two distinct chromosomes join at their centromeres (with the very small remaining parts of the chromosomes above the centromeres being lost – these do not usually contain genes). Consider e.g.

$$G = \{+1 + 2 + 3 + 4 + 5\}\{+6 + 7 + 8\} \longrightarrow G' = \{-8 - 7 - 6 + 1 + 2 + 3 + 4 + 5\}.$$

A dissociation (or *fission*) is a one-break mutation, where a single chromosome breaks at its centromere to produce two fully functional chromosomes. Consider e.g.

$$G = \{+1 + 2 + 3 + 4 + 5\} \longrightarrow G' = \{+1 + 2 + 3\}\{+4 + 5\}.$$

Whole genomes may also undergo *polyploidy* events, essentially a genome doubling. There are two kinds of polyploidy: auto-polyploidy and allo-polyploidy. An auto-polyploidy event occurs when a genome gives rise to a new genome with two copies of each of its chromosomes. The organism containing the new genome is an instant species that cannot interbreed with the species from which it derives. An allo-polyploidy event occurs when a new genome receives the genomes of two distinct (but usually closely related) species. Again, the organism containing the new genome belongs to a new instant species that cannot interbreed with either of the species from which it derives.

In addition to the genomic mutations described above, we may wish in future to define other mutations, as we become aware of them. For example, O'Keefe and Eichler (2000) have discussed the possibility of a duplicative transposition event in human evolution, where duplications of large genomic segments are transferred to a new location in the genome. However, the events described above are those most widely considered in comparative genomic analyses at the present time, and so will be sufficient to understand the methodologies introduced in the next sections.

5.4   COMPARATIVE MAPS

Many of the first comparative genome analyses were carried out using comparative maps. Even now, and despite the excitement generated by the human genome mapping program and the genome sequencing projects that preceded and followed it, whole genome sequences are available only for a small minority of organisms. For many species, physical and genetic maps are still highly fruitful resources. Comparative maps focus on the identification of homologous links between markers on two or more maps, where the evidence supporting those links may take a variety of forms, from sequence similarity to experimental evidence (e.g. cross hybridisation of probes). Figure 5.2 shows an example of a comparative map, comparing the locations of homologues between a physical map of *Arabidopsis thaliana* and a genetic map of *Brassica napus*. Note that the comparison appears to indicate an inversion between the two maps.

Comparative maps can be used to extrapolate information from one species, on the location and function of markers and genes, for application in another. For example, imagine that we know about gene A, which is involved in an important function in species 1. We would like to know if there is a 'similar' gene in species 2 that perhaps carries out a similar function. We know that gene A is flanked by genes B and C
Figure 5.2 An example of a comparative map between two plants, *Arabidopsis thaliana* and *Brassica napus*. [Reproduced from Dicks *et al.*, 2000 UK CropNet: a collection of databases and bioinformatics resources for crop plant genomics, *Nucleic Acids Research* **28**(1), 104–107 by permission of Oxford University Press.]

in species 1. If we know the locations of the homologues of genes B and C in species 2 we can predict the location of a potential homologue in species 2. This provides a starting point for further experimentation to confirm or refute the prediction. Of course, this problem is often made more difficult by gene duplication because we cannot always know if two genes are orthologous or paralogous and we may look for a gene in the wrong part of

the genome. Alternatively, we may be interested in gene D in species 3 but we do not know its function. By looking at the functions of its homologues in other species and perhaps the functions of its close neighbours, we may gain more information on a putative function.

A comparative mapping analysis can help us answer questions such as the following:

- Where in species 2 is the homologue of gene A from species 1?

- What is the likely function of gene D in species 3?

- How many conserved chromosomal segments would we see if we knew about every gene within a genome, rather than the subset we see within a map?

When comparing genomes by their maps, we have information about homologous markers, which may or may not be gene based. There are gaps between these markers and we do not know how many genes lie within these gaps or where their homologues lie in other species. Other datasets may hold even less information, where a marker is known to be located on a particular chromosome (a *chromosome assignment*) but its map position is not known. This 'missing' information will undoubtedly bias the results of any analysis carried out on those data. Despite this, it is possible to make inferences about conserved chromosomal segments and evolution. Nadeau and Taylor (1984) used mapping data from the autosomal chromosomes of human and mouse to estimate the number and lengths of conserved chromosomal segments between these two species. They showed that the length of a segment $\hat{m}$, given the assumption that markers and breakpoints were scattered randomly across a genome (the *random breakage model*), could be found as follows:

$$\hat{m} = \frac{r(n+1)}{(n-1)}, \tag{5.1}$$

where n is the number of markers in a segment and r is the distance between the two outermost markers. They reasoned that segments with fewer than two markers would be missed and they used this to derive the expected sample mean of the transformed segment lengths $\hat{m}$:

$$E[x'] \cong \frac{(L^2 D + 3L)}{(LD + 1)}, \tag{5.2}$$

where L is the mean length of conserved segments measured in centimorgans and D is the density of mapped homologous loci in the genome. They further estimated the number of homology disruptions between human and mouse.

Waddington and colleagues generalised the work of Nadeau and Taylor in order to compare maps of chickens with those of human and mouse (Waddington, 2000; Waddington *et al.*, 2000). They no longer assumed that chromosome lengths were large when compared to segment lengths (important as chicken linkage groups vary considerably in length, with some likely to contain just one segment while others may contain several) and they did not assume chromosome breakage occurred at random. They used the beta distribution to model segment lengths and used a scaling parameter l_k, the length of chromosome k, to derive the density function of segment length y on chromosome k:

$$f(y_k) = \frac{\frac{1}{l_k} \left(\frac{y}{l_k}\right)^{a-1} \left(1 - \frac{y}{l_k}\right)^{b-1}}{B(a, b)}, \tag{5.3}$$

where a and b are the beta distribution parameters and $B(a, b)$ the beta function $\int_0^1 x^{a-1}$ $(1 - x)^{b-1}dx$. Consequently, the expected number of segments on chromosome k is $S_k = (a + b)/a$ and the mean segment length on chromosome k is $l_k(a + b)/a$. The special case $a = 1$ corresponds to the random breakage model. They also derived the distribution of the number of genes n in a syntenic group (count data), on the basis of a conserved segment of length y, and the joint distribution of n and the distance between the two outermost markers in the syntenic group (range data) and used these singly and in combination to analyse the chicken dataset. They noted that the flexibility of the new models made them suitable for the analysis of a wide range of datasets, particularly as their formulation enabled testing of the models and data assumptions.

Ehrlich *et al.* (1997) developed methods to estimate *synteny conservation* (i.e. where two or more homologous markers are located on the same chromosome in two or more species). They used their methods to find the percentage of conserved syntenies in human and mouse that had already been observed. They also showed that rates of chromosomal rearrangement varied considerably between mammalian lineages and that inter-chromosomal mutations had occurred four times more often than intra-chromosomal mutations in the lineages leading to human and mouse, despite the strong selective forces against them.

Sankoff *et al.* (2000b) analysed the Nadeau and Taylor approach, in light of the large number of genes mapped in both human and mouse since 1984 (approximately 1500 genes compared to the 83 analysed by Nadeau and Taylor). They concluded that the results of the Nadeau and Taylor analysis, which are consistent with current evolutionary estimates, were accurate due to the formulation of their model and the data used rather than due to luck alone. They also looked at the effect of using chromosomal assignment only on estimating the number of conserved chromosomal segments. They noted that, for example, small intra-chromosomal mutations (e.g. inversions) could result in two chromosomal segments being regarded as one (see Section 5.5 for further analysis of this phenomenon). For this case, they added a correction to their probability function $P(a, m, n)$:

$$P(a, m, n) = \frac{\binom{m-1}{a-1}\binom{n+1}{a}}{\binom{n+m}{m}}, \tag{5.4}$$

the probability of observing a non-empty segments for m genes and n breakpoints so that:

$$Q(b, m, n, c) = \sum_{a=b}^{n+1} P(a, m, n) \binom{a-1}{a-b} \left(\frac{1}{c}\right)^{a-b} \left(\frac{c-1}{c}\right)^{b-1}, \tag{5.5}$$

is the probability that only b of the a non-empty segments are counted on the c chromosomes being examined. They also calculated the number of segments due to inter- rather than intra-chromosomal rearrangements.

Schoen (2000) looked at the effect of marker density on the estimation of the number of chromosomal breakpoints between pairs of species for the random breakage model. He showed that the estimated number of breakpoints was close to the expected value when marker density was high. However, the amount of rearrangement could be underestimated when marker density was low, particularly when the species being analysed were distantly related. He also showed that underestimation could occur when inversions were common

in the divergence of the species and discussed the results of Ehrlich *et al.* (1997) in light of the bias against detecting inversion events.

5.5   GENE ORDER AND CONTENT

Sequencing of small genomes, such as the mitochondria of organisms from many lineages, led to the first datasets where the content and order of all the genes was known. Unlike comparative mapping datasets, these datasets did not contain gaps between the datapoints. These early whole genome datasets led to new methods for genomic comparison, and indeed the field is still highly active today, with the progression from organellar datasets to gene order and gene content of large nuclear genomes.

5.5.1   Gene Order

Gene orders have been studied computationally since the late 1980s, such that current methodologies enable us to:

1.   Estimate the evolutionary distance between two gene orders.

2.   Find the sequence of changes that could have altered the gene order of one genome to that of another.

3.   Estimate an evolutionary tree based on gene order data.

4.   Hypothesise the gene order and content of an ancestral species.

The problems listed above can be tackled with reference to some measure of *genome difference* between a pair of genomes. Genome difference measures can be broadly grouped into two categories: *distance based* and *path decomposition*. The first of these includes several fairly simple measures of the differences between gene orders. The second category involves analysing likely sequences of mutations between gene orders with identical gene contents. However, as we see later, the two categories are not mutually exclusive and some distance measures are based upon the results of a path decomposition analysis. Here we do not present an exhaustive list of distance measures but rather give a flavour of the types of distances that have been proposed.

5.5.1.1   *Distance Measures*

When two DNA sequences are being compared, the *edit distance* is defined as the smallest number of substitutions that transforms one sequence into another. This is fairly simple to calculate and has been used successfully for many years. An analogous distance for gene order was proposed by Sankoff *et al.* (1992). This edit distance d_E is based on the *insertion/deletion distance* d_D, which is just the number of genes found in one genome that are not present in the other, and the *rearrangement distance* d_R, which is the minimum number of chromosomal rearrangements required to convert one gene order into the other (allowing for any differences in gene content) such that $d_E = d_D + d_R$. This distance measure was applied to the gene orders of a variety of plant, animal, and fungal

mitochondrial genomes. A value of d_E was calculated for each pair of gene orders and a distance matrix constructed from the results. A least-squares algorithm was then applied to the distance matrix to obtain a phylogenetic tree. At the time, practical application of the algorithm was very slow, mainly due to the calculation of the rearrangement distance but, as we see below, considerable advances in algorithmic efficiency have been made since then.

In order to compare gene orders more rapidly, Sankoff and Blanchette (1997; 1998) defined the *breakpoint distance* d_{BP}. This is simply the number of adjacent gene pairs in one gene order that are not adjacent (and in a consistent relative orientation) in a second. For example, the breakpoint distance between the two gene orders below (with G_1 being the *identity gene order* for seven genes) is 3, with the vertical bars between genes in G_2 denoting the locations of the breakpoints:

$$G_1 = \{+1+2+3+4+5+6+7\}$$
$$G_2 = \{+1|-6-5|-7|+2+3+4\}.$$

Sankoff *et al.* (2000a) further developed the *normalised induced breakpoint distance* to allow the comparison of very differently sized genomes. First, genes that are not common to both species are removed before calculating the breakpoint distance on the remaining genes, the result being known as the *induced breakpoint distance*. Second, this distance is normalised by dividing it by the number of the remaining shared genes.

Similar to the analysis of breakpoints, gene adjacency conservation was used as a simple measure by Keogh *et al.* (1998) to compare different fungal genomes. The neighbour pair distance d_{NP} is simply the proportion of adjacent gene pairs in one genome that are adjacent in the second. For G_1 and G_2 above, $d_{NP} = 0.5$. Cosner *et al.* (2000) also looked at neighbouring pairs but used them as binary characters – known as a *binary encoding*. Pairs that were adjacent (and of consistent orientation) were scored as '1' and those that were not as '0'. This encoding, which in addition could be weighted, could then be analysed using a maximum parsimony analysis in order to deduce an evolutionary tree.

The distances above are not suitable for application to genomes containing many paralogous genes, as is the case for most eukaryote genomes. Consequently Sankoff (1999) defined the *exemplar distance* for use in this situation. This distance measure involves reducing the size of each gene family to 1, deleting all family members except for the gene that leads to the smallest distance between the reduced genomes. The exemplar distance can be calculated on the basis of any of the above distances (e.g. the exemplar breakpoint distance or the exemplar edit distance). For example, in the simple case below:

$$\{+1+2+3-4+6+7+2-5\},$$

deleting the first instance of the gene '+2' would lead to a breakpoint distance with the identity gene order of 5, whereas deleting the second instance would lead to a distance of 3. Consequently, we would delete the second instance of the gene in order to calculate the exemplar breakpoint distance. Although the breakpoint distance may be calculated rapidly in linear time, calculation of the exemplar breakpoint distance is an NP-hard problem, as there are many combinations in which the gene family members can be deleted in more complex cases. Sankoff chose to calculate the exemplar distance using a

branch-and-bound technique. However, this approach has been surpassed recently by that of Nguyen *et al.* (2005) who used a divide-and-conquer approach.

5.5.1.2 Path Decomposition

The sequence of chromosomal rearrangements that mutates the gene order G_i to gene order G_j is known as an *evolutionary path* $\rho_{i,j}$. Finding such a path or paths between two genomes is known as a path decomposition analysis. For example, one successful path between G_2 and G_1 above, involving just inversion events, is as follows, with underlined segments indicating the location of the mutation at each step along the path:

$$G_2 = \{+1\underline{-6 - 5 - 7} + 2 + 3 + 4\}$$
$$\{+1\underline{+7 + 5 + 6} + 2 + 3 + 4\}$$
$$\{+1\underline{-4 - 3 - 2} - 6 - 5 - 7\}$$
$$\{+1 + 2 + 3 + 4\underline{-6 - 5} - 7\}$$
$$\{+1 + 2 + 3 + 4 + 5 + 6\underline{-7}\}$$
$$\{+1 + 2 + 3 + 4 + 5 + 6 + 7\} = G_1.$$

Note that the number of mutations on this path is different from the number of breakpoints and, indeed, the relationship between these two quantities is not straightforward, with the former generally thought to be a better indicator of true evolutionary distance.

A simple strategy to find an evolutionary path between two fairly short gene orders is to carry out a tree searching technique. In an unrestricted tree search we would mutate one of our genomes in all possible ways, according to our evolutionary model (i.e. our n_E allowed mutations). We are left with n_E new gene orders. We then mutate the n_E gene orders, each according to our n_E mutations to give us n_E^2 new gene orders. We repeat this process, the result being a branching search tree. At each node of the search tree we check to see if we have a genome identical to our target genome. If this is the case, we have achieved a successful path. Thus, the number of nodes in the search tree of depth l is:

$$\sum_{k=1}^{l} n_E^k = \frac{n_E(n_E^l - 1)}{n_E - 1}. \tag{5.6}$$

Obviously, the number of nodes quickly becomes very large, even for a small number of genes. This is greatly pronounced in multi-chromosome genomes and indeed, n_E is not necessarily a constant in this case and so the search tree can become quite complex. In practice, the tree must be pruned according to some heuristic.

The tree searching approach has been used by Blanchette *et al.* (1996) and Dicks (1999). The authors differed slightly in their pruning strategies and more markedly in the goals of their search. Blanchette *et al.* looked for the shortest path(s) separating the query genome from the target genome, pruning the search tree with d_{BP} and using a depth-first search with limited look ahead and branch and bound for a rapid search. Different weights were used for inversions and shifts, comparing the optimal path to the random case. This method was implemented in the DERANGE

II software. Dicks again used d_{BP} to prune the tree with a depth-first search, but here the search did not stop once the shortest path was achieved. Instead, the computation was stopped once the tree had been completely pruned or once a conservative upper bound on tree depth had been achieved, whichever occurred first. The result was a *set of paths R* separating the two genomes, which were then used to calculate a transition likelihood between G_i and G_j, under some probabilistic model M. We can define this likelihood as follows (setting the constant of proportionality to 1):

$$L(M|G_i, G_j) = \sum_R P(\rho_{i,j}|M), \quad (5.7)$$

which is often approximated by:

$$L(M|G_i, G_j) = \max_R P(\rho_{i,j}|M). \quad (5.8)$$

The former approach uses all paths to calculate the transition likelihood. Note that the real set of paths separating two gene orders is of infinite size and that the real transition likelihood is merely approximated by summing over R. A combined likelihood approach was shown by Thorne *et al.* (1992) to be less biased than a single maximum likelihood in the analysis of DNA sequence alignment and, although not formally tested for chromosomal evolution, it is likely to be the case here. The latter definition uses the maximum likelihood path $\hat{\rho}_{i,j}$, which is often used for computational convenience. Under any sensible model of evolution, where $\ell(\rho)$ is the length of a path ρ:

$$\lim_{\ell(\rho) \to \infty} P(\rho) = 0. \quad (5.9)$$

Ideally, we would like to be able to use this fact to choose just those paths that make a significant contribution to the combined transition likelihood and we could even consider using it as a tree-pruning strategy. Indeed Savva (2001) has shown that, for simple cases, just a few short paths make a very large contribution to the combined transition likelihood. Unfortunately, for large gene orders, a tree-based approach is not computationally feasible.

One alternative to finding the maximum likelihood path between two gene orders is to find the most parsimonious path between them. This research area began in earnest in 1995, with the introduction of the Hannenhalli–Pevzner algorithm (Hannenhalli and Pevzner, 1995a) for sorting signed permutations by reversals (i.e. finding the shortest path between two gene orders while permitting only inversion events to occur). This paper has been extremely influential in gene order studies, defining concepts such as the breakpoint graph that have been used both in other parsimony algorithms and in the statistical approaches introduced below. To create a breakpoint graph for a given gene order of size n, the gene order is first transformed so that, (1) a gene i with a positive sign is replaced by elements $2i - 1$ $2i$, (2) a gene j with a negative sign is replaced by elements $2|j|$ $2|j| - 1$ and (3) the gene order is *framed* by elements 0 and $2n + 1$. Thus, the gene order $\{+1 \ -6 \ -5 \ -7 \ +2 \ +3 \ +4\}$ becomes $\{0 \ 1 \ 2 \ 12 \ 11 \ 10 \ 9 \ 14 \ 13 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 15\}$. A graph is then constructed from this transformed gene order by drawing edges between (1) elements on either side of a breakpoint (e.g. between 2 and 12) and (2) even-numbered elements and those with values one larger when the two elements are not adjacent. The result is a graph where all

elements are either isolated or part of a cycle. In our example, it is easy to discover that the number of cycles c is 2. In the subsequent decade, several polynomial-time algorithms have been developed for other mutations or for combinations of mutations, such as for translocations (e.g. Hannenhalli, 1996) and for inversions, translocations, fissions and fusions (e.g. Hannenhalli and Pevzner, 1995b). For other mutations or combinations, such as transpositions, fissions and fusions (e.g. Dias and Meidanis, 2001), heuristic or approximation algorithms have been developed. Many of the major advances are cited in Yancopoulos *et al.* (2005) so we will not list them here. This paper also describes a new algorithm to sort multi-chromosomal gene orders by inversions, reciprocal translocations, fissions, fusions and block interchanges (an event which swaps two segments on a single chromosome, resulting in a transposition event when the segments are contiguous), thereby including all of the major conservative mutations. Interestingly, all mutations are based on a common operation known as a *double-cut-and-join* and the rearrangement distance d is simply the number of breakpoints b minus the number of cycles c in the corresponding breakpoint graph.

The path decomposition problem has also been studied using Markov chain Monte Carlo (MCMC) techniques. York *et al.* (2002) used a simple Poisson process model with a uniform prior for the mean to estimate the posterior distribution of the number of inversions between two gene orders. This method has an advantage over non-statistical approaches in that credible sets of estimates are made. Importantly, simulation studies showed that the method was capable of providing good estimates of the true numbers of inversion events and that these numbers were often underestimated by parsimony approaches. Miklos (2003) also studied this problem, again using a Poisson process model, but examined the broader problem of inversions, shifts and inverted shifts. The method was further implemented in the ParIS genome rearrangement server (Miklos *et al.*, 2005).

The path or paths resulting from a path decomposition analysis can be used directly to answer evolutionary questions about the number and types of mutation separating two gene orders. Furthermore, path decomposition analyses lead naturally to mutation-based distance measures between two genomes. Firstly, we note that the number of events in the shortest path is simply the rearrangement distance d_R as used above by Sankoff *et al.* (1992). Secondly, we can calculate a probabilistic distance measure based on the path decomposition. For example, for each genome pair, where our data are evolving under some stochastic model M, we can find a maximum likelihood estimate for time, $\hat{t}$, as the distance between our two genomes. Durbin *et al.* (2000) showed that maximum likelihood estimates of distance are additive, lending themselves well to a subsequent phylogenetic analysis. Consequently, a few distances based upon maximum likelihood estimates have been developed. Dicks (1999) modelled the number of breakpoints between two gene orders as a function of the mutations lying on an evolutionary path and used it to calculate the probability of a given path for an observed value of d_{BP}. Savva (2006) also investigated the joint conditional probability distribution of d_{BP} and d_R and used it to calculate path likelihoods under a simple evolutionary model. The latter method is implemented in the CHROMTREE software. Caprara and Lancia (2000) also showed some interesting results, such as the expected number of breakpoints in a random permutation of N genes:

$$E[D_{BP}] = N - 1, \tag{5.10}$$

and the expected number of breakpoints in a random permutation of N genes after a random path of k inversions:

$$E[N(k)] = (N-1)\left(1 - \left(\frac{N-3}{N-1}\right)^k\right), \tag{5.11}$$

using the results to calculate the conditional probability of the number of inversions given an observed value of d_{BP}.

5.5.1.3 *Phylogenetic Analysis*

Chromosomal banding patterns gave rise to what was probably the first comparative genome analysis, carried out by Dobzhansky and Sturtevant (1938), where the orders of bands on the chromosomes of the fruit fly *Drosophila* were used to derive an evolutionary tree. This analysis was carried out visually, made possible by the relative simplicity of the dataset. Today, we wish to carry out similar analyses, but for more complex datasets and in a systematic manner.

Markov chains and, more recently hidden Markov models (HMMs), have been used widely to model the evolution of DNA and amino acid sequences, with these models being used successfully for phylogenetic inference in the Felsenstein likelihood framework (Felsenstein, 1981). For DNA sequences, where each nucleotide site is considered independently, the Markov property lends itself well to modelling the transitions between the four possible states A, C, G and T in time t. Even when considering pairs of adjacent sites, as is done for modelling RNA sequences, we need only consider 16 potential states. Amino acid evolution is a little more complicated, with 20 states to consider. We can see that chromosomal mutations also cause gene orders to move between states and it would be natural to consider an analogous model for their evolution. However, a gene order is a signed permutation, where adjacent genes are not independent. Imagine a small chromosome consisting of just 10 genes. If we wished to use a Markov chain model, we would need to consider $10! \times 2^{10}$, or a little over 3.7 billion states. Obviously, this is computationally infeasible, even for such a small dataset. On the basis of the tree search approach discussed above, Dicks (2000) tried to circumvent this problem by suggesting an approximation to the maximum likelihood tree for gene order data, using a small set of states at internal nodes (i.e. those states that lie along successful pairwise search paths), where those states are thought to make a large overall contribution to the tree likelihood. However, such an approach is slow even for small gene orders.

The simplest way to estimate a gene order phylogeny is to carry out a pairwise analysis, perhaps using one of the distance measures described above. A distance matrix is constructed, where each entry in the matrix is the distance between a pair of gene orders. This matrix is then used as input to a tree-building algorithm. The neighbor-joining algorithm (Saitou and Nei, 1987) is perhaps the best known of these algorithms but others such as the FITCH (Fitch and Margoliash, 1967) and KITSCH algorithms within the PHYLIP phylogenetic package (Felsenstein, 1993) are also applicable. Each of these algorithms has its own advantages and disadvantages, as has been described frequently elsewhere. Two software packages developed specifically for gene order analysis are GOTREE and SHOT. GOTREE calculates breakpoint distances for gene orders with both equivalent and differing gene contents and estimates phylogenetic trees

using neighbor-joining. SHOT takes genome sequences as its data rather than gene orders. It first finds homologous genes and subsequently estimates trees using various pairwise distances. It can also perform tree bootstrapping using the jackknife.

A more difficult problem is to find the maximum parsimony tree, searching for a topology and internal node gene order states that minimise the sum of the distances over all edges of the tree. This problem was studied by Sankoff and Blanchette (1998) and Blanchette *et al.* (1999) where the statistic to be minimised was the number of breakpoints on the tree edges. This method was implemented in the BPAnalysis software. The approach was improved by other researchers, as described in Tang and Moret (2003), with later algorithms also facilitating the search for most parsimonious trees that minimised the reversal distance. Tang and Moret's method was implemented in the GRAPPA software. Bourque and Pevzner (2002) also studied the problem of minimising the reversal distance over a tree topology, calling it the Multiple Genome Rearrangement (MGR) problem. They showed how the approach could be extended to the multi-chromosomal case, including not only inversions but also reciprocal translocations, fusions and fissions. This approach is implemented in the MGR software which itself uses algorithms from the GRIMM software (Tesler, 2002) for calculating shortest distances between pairs of gene orders.

The approaches discussed so far illustrate a growing efficiency in the solution of optimal gene order trees, where the main criteria for success are speed, efficiency and parsimony. However, these approaches can tell us little about the accuracy of such methods, except perhaps through simulation studies. In contrast, statistical approaches have the benefit of assessing the uncertainty of parameter estimates. Bayesian MCMC methods have been used successfully to search through tree space for the topology with the maximum posterior probability in the case of DNA sequences. Larget *et al.* (2002) also showed how MCMC methods could be applied to gene order problems, devising a model for inversion events on single chromosomes that could be used in a Bayesian phylogenetic analysis. The model priors defined a uniform distribution for the tree topology τ over the space of all unrooted trees with ℓ leaves and a gamma distribution $\Gamma(\alpha, \lambda)$ for branch lengths β. Counts of inversions were independent Poisson variables with means equal to the relevant branch lengths. Inversion events were chosen uniformly, at random, along a branch from the set M_n, where the size of the set is $\binom{n+1}{2} = n(n+1)/2$ and the position of the event on the branch was a distance u from its start. Given that D is an indicator variable representing whether the observed data were consistent with the parameters and unobservable variables, and which takes the value 1 when this is the case and 0 when it is not, the joint posterior distribution of all of the parameters was shown to be:

$$p(\tau, \beta, x, r, u|D) \propto p(\tau, \beta, x, r, u)p(D|\tau, \beta, x, r, u)$$

$$= \frac{1}{|T_\ell|} \prod_{i=1}^{2\ell-3} g(\beta_i)h(x_i|\beta_i) \left(\frac{1}{\beta_i}\right)^{x_i} \left(\frac{1}{|M_n|}\right)^{x_i} 1_{\{(\tau,x,r) \hookrightarrow D\}}, \quad (5.12)$$

where

$$g(\beta_i) = \frac{\lambda^\alpha}{\Gamma(\alpha)} \beta_i^{\alpha-1} e^{-\lambda\beta_i}$$

and

$$h(x_i|\beta_i) = \frac{e^{-\beta_i} \beta_i^{x_i}}{x_i!},$$

which, after integrating out branch lengths β and inversion locations u analytically and ignoring factors not depending on τ, x or r, becomes

$$p(\tau, x, r | D) \propto 1_{\{(\tau,x,r) \hookrightarrow D\}} \left(\frac{1}{|M_n|(1+\lambda)} \right)^{\sum_{i=1}^{2\ell-3} x_i} \prod_{i=1}^{2\ell-3} \frac{\Gamma(\alpha + x_i)}{x_i!\,\Gamma(\alpha)}. \qquad (5.13)$$

An MCMC technique is used to sample from this distribution, using an update scheme with three moves. The first two moves affect just the histories (i.e. sequences of inversions) in localised areas of the tree, with the third potentially changing the tree topology as well as the histories. This latter move is based on the concept of the breakpoint graph, as described in Hannenhalli and Pevzner (1995a). Notably, York *et al.* (2002) and Miklos (2003) also used the breakpoint graph in their update schemes. Later computational advances in the update scheme enabled the method to be used on larger real datasets (Larget *et al.*, 2005b) and the model and method have been implemented in the BADGER software. Recently, the performance of the method has been contrasted to the maximum parsimony approach on a number of real datasets. For example, Larget *et al.* (2005a) reanalysed the herpesvirus dataset examined in Bourque and Pevzner (2002). This dataset consisted of the gene orders of Herpes simplex virus (HSV), Epstein–Barr virus (EBV) and Cytomegalovirus (CMV). The problem was to construct the state of the ancestral gene order. Figure 5.3 shows the solution found by Bourque and Pevzner, which involved seven inversions. Larget *et al.* showed that there were two most parsimonious solutions and that one of them (shown in Figure 5.3) had a posterior probability three times as great as the other. The Larget *et al.* analyses showed that the method was capable of finding parsimonious solutions as efficiently as parsimony software and also that, for some datasets, parsimonious solutions had a low probability of being correct. The paper also described a strategy for adopting the method within an empirical Bayes framework, which involved estimating values of the hyperparameters α and λ from the datasets undergoing analysis.

5.5.2 Fragile Breakage versus Random Breakage Models

As we saw above, many of the early algorithmic advances in gene order studies were inspired by organellar genomes, particularly mitochondrial genomes. Here, the order and arrangement of a small number of genes was provided, without the need to carry out a complex pre-processing of a raw dataset. However, the advent of sequencing large nuclear genomes has brought new challenges to gene order studies. Firstly, there has been a need to increase the efficiency of the algorithmic approaches. For example, improvements in the computing time of rearrangement distance algorithms (e.g. Bader *et al.*, 2001; Bergeron, 2001; Tesler, 2002) now enable them to be applied to genomes possessing thousands of genes. Secondly, nuclear genomes must be analysed to identify genes and to establish homologous relationships within and between genomes. This latter step is difficult and prone to error, particularly relatively soon after sequencing has been completed. However, these larger genomes also give us larger datasets with which to test hypotheses of evolutionary scenarios and to develop more realistic models of genomic rearrangement.

Pevzner and Tesler (2003a; 2003b) established the concept of the breakpoint reuse statistic r:

$$r = \frac{2d}{b}, \qquad (5.14)$$

Figure 5.3 A gene order phylogeny of three herpesviruses, showing the inferred state A of the ancestral gene order for the most parsimonious tree.

where d is the rearrangement distance between two genomes of size n and b the number of breakpoints separating their gene orders. As it is known that $b/2 \leq d \leq b$ we see that $1 \leq r \leq 2$. A value of $r = 1$ indicates a rearrangement path where each event breaks the genome at two sites unique to that arrangement (i.e. no reuse, thereby supporting random breakage) and $r = 2$ where each event after the first breaks the genome at one new site and one site that is already used. Pevzner and Tesler identified a value of $r = 1.9$ between the human and mouse genomes, suggesting a high level of breakpoint reuse. Indeed, this *fragile breakage* hypothesis, where particular regions are implicated in multiple rearrangement events has been advanced by others (e.g. Kent *et al.*, 2003) and, of course, it had already been hypothesised in the case of comparative maps.

However Sankoff and Trinh (2005), while not rejecting the hypothesis of fragile breakage, argued that the statistic r was not a good estimator of breakpoint reuse and that the high value of r achieved by Pevzner and Tesler may have been due to the method with which they achieved their dataset. Rather than attempting to study large permutations of genes, Pevzner and Tesler analysed almost 600 000 short aligned sequence fragments and used them to build large collinear blocks, ignoring regions of local rearrangement. The result was a set of 281 large blocks. This method was highly useful in that it largely circumvented the problem of establishing gene order from genomic sequence.

Sankoff and Trinh showed through simulation that high values of r could be achieved with no breakpoint reuse, if a proportion of genes θ was deleted at random (essentially attempting to simulate Pevzner and Tesler's smoothing out of small rearrangements). In particular they showed that the greater the rearrangement distance between the two genomes, the more r grew with increasing θ. Furthermore, as θ increased, r initially

increased with a rate depending on d/n and then reached a maximum, before descending sharply. Sankoff and Trinh went on to model the relationship between these statistics, defining d_1 and d_2 as the number of one-breakpoint and two-breakpoint events needed to sort the genome such that $b = 2d_2 + d_1$. Furthermore, they used the model to estimate the rate of change in r:

$$\frac{\mathrm{d}r}{\mathrm{d}\theta} = n\left(\frac{2}{b(t)}\frac{-d_1(t)[d_1(t)-1]^+}{(1-\varepsilon(t))(n-t)(n-t-1)} - \frac{2d(t)}{b(t)2}\frac{-b(t)(b(t)-1)}{(n-t)(n-t-1)}\right), \quad (5.15)$$

where $\varepsilon(t) = d_2(t)/[b(t)(b(t)-1)]$, verifying that $\mathrm{d}r/\mathrm{d}\theta \approx 2d/n$ near to $\theta = 0$. Sankoff and Trinh suggested that, although the reuse statistic r may not be a good estimator of breakpoint reuse, it is a good indicator of a breakdown of genomic structure and therefore could be used to measure the strength of the evolutionary signal in the comparison of genome sequences. Peng *et al.* (2006) countered this argument by showing that the algorithm used by Sankoff and Trinh to calculate collinear blocks was inappropriate and did not mirror the Pevzner and Tesler approach. Peng *et al.* then demonstrated that their method, implemented in the GRIMM-Synteny software, which inferred a greater number of blocks than the Sankoff and Trinh method, did not inflate values of r so significantly in a similar simulation study, and consequently the high value of r from the human/mouse comparison could not be dismissed. They also hypothesised that inhomogeneity of gene distribution and long regulatory regions could in part be responsible for breakpoint reuse. Sankoff and Haque (2006) then went on examine the distribution of cycles in the breakpoint graph for two random genomes. They used their results, together with the relation $d = b - c$ as proved in Yancopoulos *et al.* (2005), to show that r tended to 2 as genomes became randomly ordered with respect to one other, backing up their previous argument. However, whether or not r can be used reliably as an indicator of the fragile breakpoint hypothesis, the model is gaining popularity through the results of empirical studies.

5.5.3 Gene Content

When we compare the *gene contents* of two genomes we are looking to see how many homologues they share and how many genes each contains for which the other does not have a homologue. On average, we would expect closely related species to exhibit roughly the same gene content and more distantly related species to possess species- or group-specific genes, although this does not always hold for individual cases. Data on gene content can be informative in evolutionary studies. For example, the availability of whole genome sequences has enabled many researchers to infer species phylogenies using gene content data (e.g. Herniou *et al.*, 2001; House and Fitz-Gibbon, 2002; Lin and Gerstein, 2000; Montague and Hutchison, 2000; Snel *et al.*, 1999; Tekaia *et al.*, 1999; Whittam and Bumbaugh, 2002; Winzeler *et al.*, 2003). These phylogenetic studies use a variety of approaches, including distance measures derived from fractions of shared genes in genome pairs and parsimony. Gene content data can also be highly useful on a practical level. For example, in a recent analysis of the genomes of three parasites (*Trypanosoma brucei*, *Trypanosoma cruzi* and *Leishmania major*), the authors found a 'core' of 6200 conserved genes (Berriman *et al.*, 2005). It was noted that these common genes provided targets for new drugs that could potentially fight all three parasites. In this section, we will concentrate on recent advances in gene content modelling and analysis for the study of genome evolution.

5.5.3.1   General Approaches

A simple way of analysing gene content data is simply to score gene presence and absence in a number of species, with a '1' representing presence and a '0', absence. The resulting matrix can be further analysed, for example using parsimony algorithms available in many phylogenetic software packages. In addition, a number of distance measures have been developed for gene content datasets. Ferretti *et al.* (1996) proposed the *syntenic distance* for multi-chromosomal genomes. Here, the minimum number of centric fusions, fissions and translocations required to ensure that every chromosome within one genome has the same gene content as a second genome, ignoring gene order, is counted. Snel *et al.* (1999) proposed that the percentage of genes shared by two genomes could be used as a measure of similarity between them:

$$d = 1 - \frac{|G_1 \cap G_2|}{\min\{|G_1|, |G_2|\}}, \qquad (5.16)$$

where $|G_1|$ and $|G_2|$ are the numbers of genes in genomes 1 and 2 respectively and $|G_1 \cap G_2|$ is the number of genes common to both.

Kunin *et al.* (2005) developed a distance measure, which they called *genome conservation*, which takes into account both gene content and sequence similarity within a whole genome context. The authors carried out a BLASTP analysis on the genes of genome pairs, noting hits with an e-value cut-off of e^{-10} and using the 'bit score' as the measure of sequence similarity. The sum of all best hits between genomes A and B was calculated and was denoted by $\sum(A, B)$ (which notably is a non-reciprocal value as reciprocal best hits are not used, so as to filter out paralogous genes) and the conservation between A and B by $S = \min(\sum(A, B), \sum(B, A))$. Two genome conservation measures were then defined as:

$$D_1 = \frac{1 - S}{\min(\sum(A, A), \sum(B, B))}, \qquad (5.17)$$

and

$$D_2 = -\ln\left(S / \frac{\sqrt{2} \times \sum(A, A) \times \sum(B, B)}{\sqrt{(\sum(A, A)^2 + \sum(B, B)^2)}}\right), \qquad (5.18)$$

corresponding to strategies for the transformation and normalisation of self-similarity and adjustment for genome sizes. The new genome conservation distance measure was then used to estimate a phylogeny for 153 sequenced genomes, with a comparison to the results of two other methods. The first of these alternative analyses involved the gene content method as used in Korbel *et al.* (2002) and the second an average orthologue similarity method. In the genome conservation analysis, the pairwise score S was divided by the smallest number of hits between the genomes, with the values being normalised between 0 and 100, for ease of comparison with the other measures. The resulting distance matrices were then analysed using the neighbor-joining tree construction algorithm (Saitou and Nei, 1987). It was noted that all three distance matrices contained a strong phylogenetic signal but that the gene content, and to a lesser extent genome conservation, approaches were affected by significant gene loss in certain lineages. However, genome conservation was found to be capable of producing accurate phylogenetic groupings at a wide range of taxonomic levels and was, in general, superior to both the gene content and average orthologue similarity approaches. Consequently, merging gene content and sequence

information within a single distance measure appears to be a valuable approach for the comparison of whole genome data.

Many gene content analytical methods have been developed with phylogenetic tree inference in mind, but none was developed specifically for more complex scenarios involving genome fusions. In contrast, a recent method known as *conditioned reconstruction* has been developed by Lake and Rivera (2004). The method takes gene presence and absence data conditioned on a reference genome, finds the set of most probable topologies through a bootstrapping technique and tests whether the opposing topologies are consistent with an evolutionary scenario involving genome fusions (i.e. a ring phylogeny). It has been applied by the same authors to a series of bacterial, archaeal and eukaryotic organisms (Rivera and Lake, 2004), which they claim gives evidence for the eukaryotes having evolved through a genome fusion of two diverse prokaryotes.

5.5.3.2 Birth and Death Model–based Approaches

Birth and death processes are proving highly useful in the analysis of gene content, being well-studied mathematical techniques with a natural affinity to this type of dataset. For example Gu (2000) introduced a statistical framework for gene content analysis. The model, which used a death process to describe gene loss, could be adopted to infer a gene content phylogeny using both distance-based and maximum likelihood approaches. Unfortunately, the maximum likelihood approach proved to be very computationally intensive but Zhang and Gu (2004) later introduced a computationally tractable model for gene content evolution. They showed that the transition probabilities between an ancestral genome X_0, possessing r_0 copies of a gene, and a subsequent genomic state X_t, possessing k copies of the same gene, were:

$$P(X_t = k|X_0 = r_0) = \sum_{j=0}^{\min(r_0,k)} \frac{r_0!}{j!(r_0 - j)!}$$

$$\times \frac{(r_0 + k - j - 1)!}{(k - j)!(r_0 - 1)!} \beta^{r_0 - j} \alpha^{k - j} (1 - \alpha - \beta)^j, k \geq 1$$

$$P(X_t = 0|X_0 = r_0) = \beta^{r_0}, \tag{5.19}$$

where

$$\alpha = \lambda \frac{1 - e^{(\lambda - \mu)t}}{\mu - \lambda e^{(\lambda - \mu)t}}$$

$$\beta = \mu \frac{1 - e^{(\lambda - \mu)t}}{\mu - \lambda e^{(\lambda - \mu)t}},$$

simplify to:

$$P(Y = 0|X_0 = r_0) = \beta^{r_0}$$

$$P(Y = 1|X_0 = r_0) = 1 - \beta^{r_0}, \tag{5.20}$$

when gene absence and presence are considered instead of gene family counts. They went on to show that these simplified transition probabilities could be used for maximum likelihood phylogenetic tree estimation on trees with four taxa (using the maximum likelihood phylogenetic framework described by (Felsenstein, 1981) and extensible to

greater numbers of taxa) as the probabilities of all 15 unrooted topologies themselves then greatly simplified to expressions that could be calculated rapidly. Zhang and Gu (2004) went on to evaluate the approach in real and simulated datasets and showed it to possess high accuracy in many simulated situations and to provide a topology consistent with other approaches for the real datasets analysed.

Gu and Zhang (2004) also developed the concept of *extended gene content*. Rather than contrasting the two states of gene presence and gene absence, or a multi-state character denoting the number of members of a gene family, they developed a three-state intermediate character. These three states represented gene families with no members (i.e. gene absence), those with a single member only and those with more than one member. Using this concept, they developed an additive gene content distance measure:

$$G = \sum_{i=1,2} \frac{\alpha_i + \beta_i}{\beta_i - \alpha_i} \ln \frac{1 - \alpha_i}{1 - \beta_i} \tag{5.21}$$

where α_i and β_i represent the gene proliferation and loss parameters within lineage i respectively. Estimates of these parameters may be calculated from an extended gene content matrix using a maximum likelihood-based approach. The authors also introduced a software package, GeneContent (Gu *et al.*, 2004), to implement this and other distance-based methods.

Kunin and Ouzounis (2003) and Karev *et al.* (2003; 2004) also used birth and death processes to model gene content evolution. The latter introduced a series of non-linear stochastic birth, death and innovation models, assessing the suitability of different models to the gene family sizes of several species, but the models have not been used within comparative studies. A recent method developed by Hahn *et al.* (2005) noted that studies of gene presence and absence were not capable of identifying genes involved in adaptive change. They developed a birth–death model of gene family size that could be used to find unusual gene family size change (both expansion and contractions) across a phylogeny of species.

Huson and Steel (2004) developed a maximum likelihood–based distance for gene content. Using a constant-birth, proportional-death model, with gene birth rate λ and gene loss rate μ, they showed that:

$$t_{\mathrm{ML}} = -\frac{1}{\mu} \log \left(\frac{\beta + \sqrt{\beta^2 + 4\alpha_{12}}}{2} \right), \tag{5.22}$$

where $m = \lambda/\mu$, $\alpha_1 = |G_1|/m$, $\alpha_2 = |G_2|/m$, $\alpha_{12} = |G_1 \cap G_2|$ and $\beta = 1 + \alpha_{12} - \alpha_1 - \alpha_2$. The authors then compared the performance of this distance measure to the measure above proposed by Snel *et al.* (1999) and to a Dollo parsimony approach (Le Quesne, 1974), which stipulated that each gene could be gained only once on a phylogeny but could be lost many times. They found that their measure had a similar performance on simulated datasets to the Dollo parsimony approach and that both outperformed the Snel *et al.* measure.

The idea of genome conditioning, as described above, has also been investigated by Savva (2006) modelling gene loss from a reference genome using a death process, while also taking into account rate heterogeneity through a gamma distribution and a 'core' set of genes that cannot be lost. The method, which defines a maximum likelihood–based distance for conditioned gene content, has been applied successfully to datasets arising

from Comparative Genome Hybridisation microarray experiments. A software package, MPP, has been developed to implement the method, along with other steps in the analytical pipeline (Davey, 2005).

5.5.4 Comparison of Gene Order and Gene Content Methods

From the sections above on gene order and gene content, we can see that there are overlaps between the types of analysis that we can perform on each of our datasets. In particular, gene content and gene order have both been used for phylogenetic inference. So how should we decide which type of method is most informative for a particular dataset? This question has been posed by several researchers in the past few years and we are beginning to get a picture of the relative adequacies of each method with regard to different types of dataset.

Herniou *et al.* (2001) examined the phylogeny of nine baculovirus genomes, carrying out three separate analyses. In the first analysis, they applied maximum parsimony algorithms to alignments found for each of the 63 genes common to all 9 genomes and also to the concatenated sequence from these genes. In the second analysis, they calculated the pairwise normalised induced breakpoint distances on their dataset, a method they developed independently of Sankoff *et al.* (2000a) and calculated a phylogeny from the distance matrix using neighbor-joining. Also in this second analysis, they independently developed a binary encoding method, which they applied using maximum parsimony. In the third analysis, they derived the presence/absence gene content matrix from their nine genomes and estimated a phylogeny using maximum parsimony. From their results, Herniou *et al.* concluded that the concatenated sequence phylogeny gave the tree topology most consistent with current knowledge of the evolutionary history of the baculoviruses. Notably, this topology was only identical to 7 of the 63 phylogenies found from analyses of individual genes, highlighting the inadequacy of inferring species trees from genic histories. They also found that the gene content and gene order trees were very similar to the optimal topology, noting that the observed differences could be a consequence of widely different genome sizes and long branch attraction. Interestingly, they mapped gene content gains and losses onto the optimal topology, noting a large number of putative homoplasies (i.e. where two genomes appear erroneously similar because of independent acquisitions of an individual gene, perhaps through horizontal transfer, or because of acquisition and subsequent loss of a gene that was absent from the other genome's lineage). They concluded that gene content and gene order gave useful methods with which to find further supporting evidence for phylogenies derived from concatenated sequences, noting that, 'Gene order and gene content have the advantage of providing independent datasets from the gene sequences, with independent dynamics and rates of evolution.'

Wolf *et al.* (2001) also carried out a comparative analysis of different methods, applying them to bacterial and archaeal genomes. These researchers carried out five different analyses on these genomes. In the first analysis, the presence/absence gene content matrix was derived from the COGs database. A phylogeny was then generated using Dollo parsimony. Crucially, this algorithm reduces the number of homoplasies in the resulting phylogeny and is less sensitive to gene loss (common in prokaryotes) than other parsimony algorithms. In the second analysis, a matrix of conserved pairs of neighbouring genes in genome pairs was constructed. This analysis used a more relaxed definition of a neighbourhood than other algorithms (e.g. the approach used by Herniou *et al.* in which the two genes must be adjacent in both genomes), requiring

adjacency in one genome but allowing a small number of intervening genes in the second. This matrix was again analysed using Dollo parsimony. In the third analysis, pairwise genomic distances were calculated on the basis of the distributions of identity percentages between orthologues (e.g. the mean, median or mode of the percentage values). In the fourth analysis, a maximum likelihood phylogeny was calculated for the concatenated sequence of the ribosomal proteins. In the fifth analysis, maximum likelihood phylogenies were estimated for a subset of carefully selected individual genes. The results indicated that, overall, the sequence-based methods and the third method based on identity percentages of orthologous genes gave trees that were most consistent with the known evolutionary history of the organisms undergoing analysis. While the trees based on local gene order and gene content were partially consistent with these results (and notably included a previously unknown grouping now believed to be correct), the differences were thought to be a consequence of extensive horizontal gene transfer and lineage-specific gene loss.

Looking at these two approaches together, it appears that gene order and gene content methodologies can be valuable in evolutionary studies but that this value varies considerably depending on the type of dataset undergoing analysis. Furthermore, other researchers have noted that gene order and gene content methods may be superior when gene sequences have become saturated for mutations. Of course, if we are looking to find out evolutionary information other than the topology, such as rearrangement histories and ancestral states, then these can only be found using the relevant methodology. However, an alternative strategy would be to map gene content and order changes onto a phylogeny derived from gene sequences, as carried out by Herniou *et al.* above.

We can also compare gene order and gene content methods using the models themselves. In gene order studies, path probabilities tend to a uniform ergodic distribution. This means that, once a particular evolutionary time has passed or a number of events have occurred, the probability of one path is equal to that of any other. Evolutionary analyses under such conditions would be meaningless. Dicks (unpublished) has used a model-based approach to show the time to stationarity under the model in a single chromosome is linear with the number of genes it contains. Savva (2006) has compared simple gene order and gene content models using Fisher's information. Preliminary results show that, for large t, gene content models provide a greater amount of information than gene order models. Consequently, for widely diverged genomes, this would indicate that it is better to compare their gene contents rather than the order of their genes. However, further research is required before we can fully understand the evolutionary boundaries of each method.

5.6   WHOLE GENOME SEQUENCES

Since the first genome, of the bacterium *Haemophilus influenzae*, was sequenced in 1995 we have seen a proliferation of genome sequencing projects. In addition to dozens of bacterial and viral organisms, the genomes of around 50 eukaryotic organisms have now been sequenced. The Institute for Genomic Research (now part of the J. Craig Venter Institute) provides a useful webpage listing the various genome projects underway (`http://www.tigr.org/tdb/`). With the availability of multiple whole genome sequences, we now have a motivation to compare them along their entirety, particularly for relatively close species. How close are two sequences? Do we see good general

correspondence or are there areas that are significantly more closely related than others? In addition, we can delve deeper into problems of their evolutionary histories, looking both within and between organisms. In this section, we examine some of the recently developed methodologies for whole genome alignment of sequences, estimation of conserved chromosomal blocks and dating of large-scale evolutionary events.

5.6.1 Whole Genome Alignment

One simple way to compare two whole genome sequences is to visualise them as a dot plot. Such a plot is based on an underlying matrix derived from a comparison of the two sequences. We 'slide' a window of a certain size (e.g. five bases or residues) along the sequences and, if the sub-sequences within those windows match within a certain range of precision, then the corresponding entry within the matrix is denoted as 1. If there is no such match then an entry 0 is made. By adjusting the window size and tolerance of mismatches, we can change the precision of our matrix. If we then plot the resulting matrix, we can quickly see regions of similarity. If our two sequences align perfectly, then our dot plot will show a perfect diagonal line from the bottom left to the top right corners (or equivalently the top left to the bottom right corners). In a whole genome context, dot plots are useful for spotting large genomic rearrangements such as those described in Section 5.2. For example, Figure 5.4 shows a dot plot in which we see both areas of regional similarity and disjointed regions. Regions that have 'broken away' from the main diagonal are likely to be a consequence of translocations while those that have a differnt orientation become inverted.

In addition to visualising the relationship between two genome sequences, we may wish to align them formally with an alignment algorithm. Over the past couple of decades, it has become commonplace to compare two or more DNA or amino acid sequences by aligning them such that this technique is considered to be part of the biologist's toolkit. If there
Figure 5.4 Visualising a whole genome comparison with a dot plot.

is a good correspondence between two sequences, then this is often seen as an indication of a common evolutionary origin and perhaps also a structural and functional similarity. There are two main types of sequence alignment algorithms: local and global. Local alignments do not try to match two sequences exactly but rather concentrate on local areas of close similarity separated by more divergent regions. This type of algorithm is useful for sequences without a good overall similarity but which are thought to contain conserved regions within them. The well-known alignment algorithms BLAST (Basic Local Alignment Search Tool; Altschul *et al.*, 1990) and Smith–Waterman (Smith and Waterman, 1981) are both local alignment tools. Conversely, global algorithms attempt to align all sites or residues of a sequence, and are most useful when the sequences undergoing comparison are generally similar and are of equal size. The Needleman–Wunsch algorithm (Needleman and Wunsch, 1970), which is based on dynamic programming, is perhaps the best-known algorithm of this type. For a more detailed look at sequence alignment, see Durbin *et al.* (2000). Global alignments can be used to uncover the shared order of biological features within genomic sequences. Furthermore multiple global alignments, which align more than two sequences, can reveal common features between distantly related species, particularly when intermediate sequences are also included in the alignment.

We saw above that global alignment algorithms have been developed to align large sequences along their length. Unfortunately, for large genomes, using a Needleman–Wunsch algorithm is a very slow process as the algorithm requires time proportional to the products of the lengths of the aligned sequences. Consequently, a number of algorithms have been developed specifically for whole genome alignment. Popular pairwise genome alignment algorithms include MUMmer (Delcher *et al.*, 2002), DIALIGN (Brudno and Morgenstern, 2002), WABA (Kent and Zahler, 2000), AVID (Bray *et al.*, 2003) and LAGAN (Brudno *et al.*, 2003a). Furthermore, some of these algorithms have multiple genome alignment versions, such as MLAGAN (Brudno *et al.*, 2003a) and MAVID (Bray and Pachter, 2004). In general, pairwise algorithms reduce the computational burden of alignment by first finding multiple local similarities, or *anchors*. For example, LAGAN finds local similarities using the CHAOS algorithm (Brudno and Morgenstern, 2002), which identifies short inexact sequence matches. Some other algorithms find longer exact matches and therefore are not as appropriate for alignment of distantly related sequences. LAGAN then selects an ordered subset of the local similarities (the anchors) and chains them together into a *rough global map*. Finally, LAGAN searches for an optimal global alignment using Needleman–Wunch in a small, restricted region bounding the rough global map. Figure 5.5 depicts this process, with the thick black lines representing the anchors and the boxes representing the bounded region within which the Needleman–Wunch algorithm is run.

A multiple alignment version of the LAGAN algorithm, MLAGAN, uses LAGAN within a progressive alignment approach (where sequences are added to the alignment one by one) that also uses a known phylogenetic tree to guide the order in which sequences are added. Owing to the computational difficulties of dealing with very long sequences, full statistical approaches to this problem are also not practical. However some programs, such as MAVID (Bray and Pachter, 2004), use a combination of maximum likelihood and heuristic techniques. MAVID aligns sequences travelling upwards (from the leaves) within a guide phylogenetic tree. At internal nodes, two alignments are merged into a single alignment. First, maximum likelihood ancestral sequences are found for each of the two alignments, and the two ancestral sequences are then aligned using AVID.
Figure 5.5   Global pairwise whole genome alignment strategy used by LAGAN.

Second, the alignment of the ancestral sequences is used to create a multiple alignment of all sequences in the two alignments being merged. This efficient strategy is capable of aligning whole genomes rapidly.

Unfortunately, most of the whole genome alignment algorithms listed above can only be used reliably within conserved chromosomal regions that have not undergone rearrangement events. To overcome this, new algorithms have been developed specifically to deal with rearrangements. For example, SLAGAN (Brudno *et al.*, 2003b) builds upon the LAGAN tool, using CHAOS local alignments to build a map of the rearrangements between the genome sequences and LAGAN to align conserved regions. The MULTIZ component of the TBA algorithm (Blanchette *et al.*, 2004) is also able to align genomes containing inversions and duplications. The MAUVE tool (Darling *et al.*, 2004b) was also developed specifically for rearranged genomes. It decomposes genomes into locally collinear blocks (LCBs, which are unaffected by rearrangements), which are ordered sets of multi-MUMs (multiple maximum unique matches; sequences that occurred only once in each genome undergoing analysis, that matched exactly and could not be extended in either direction to develop larger unique matches). LCBs are weighted using breakpoint analysis in order to find the most likely set of LCBs in the final alignment. Following a process to lengthen old LCBs and to uncover new LCBs within large gaps, each LCB in the final set is aligned using the CLUSTALW multiple alignment tool (Thompson *et al.*, 1994).

5.6.2   Finding Conserved Blocks

In Section 5.4, we described work on the estimation of conserved chromosomal segments from mapped markers. With whole genome sequences now available and many more promised for the future, a new generation of algorithms must be developed that can derive such segments from these emerging datasets. Indeed, since 2000 many researchers have developed approaches for conserved block estimation from whole genome sequence. However, until recently, the number of sequenced eukaryotic genomes has been low and

those that have been sequenced have not been closely related. This may have led to the early development of methods for *genomic palaeontology*, essentially searching for blocks of duplicated genes *within* genomes such as human, yeast and *Arabidopsis* (e.g. Abi-Rached *et al.*, 2002; Dehal and Boore, 2005; Lynch and Conery, 2000) to discover more about the nature of gene duplication and perhaps to find evidence of large-scale evolutionary events such as polyploidy.

For example, following the analyses of Vision *et al.* (2000) and Simillion *et al.* (2002), Blanc *et al.* (2003) examined the evolutionary history of *Arobidopsis thaliana*. First, duplicated genes were uncovered by carrying out an all-again-all protein similarity search of the genome. To detect conserved blocks, the authors searched for genomic regions in which duplicated genes were in a consistent order. Notably, pairs of duplicated genes were permitted to be separated by up to a fixed number of unduplicated genes. The resulting blocks are also known as *max-gap clusters*, where the *max gap* is this permitted number of unduplicated genes (typically ranging from around 3 in bacterial genomes to 30 in humans; McLysaght *et al.*, 2002). This analysis led to a set of 108 pairs of blocks sharing 6 or more duplicated genes. The statistical significance of the blocks was determined by a permutation test, where the order of the duplicated genes was randomised many times and the block detection algorithm applied to each randomised dataset. Such analyses have also inspired the development of software for conserved block prediction, such as ADHoRe (Automatic Detection of Homologous Regions; Vandepoele *et al.*, 2002) and its successor i-ADHoRe, DiagHunter (Cannon *et al.*, 2003), FISH (Calabrese *et al.*, 2003), LineUp (Hampson *et al.*, 2003) and CloseUp (Hampson *et al.*, 2005). The methods differ in terms of how conserved blocks are defined, the strategies for estimating them and the ways in which the significance of the blocks is determined, making comparisons between them difficult. Indeed, in an analysis of the rice genome, Wang *et al.* (2005) discussed how different methods of assessment of block significance could change the results of an analysis. Furthermore, Vandepoele *et al.* (2003) showed, in their analysis of rice genome, that many block detection methods were not capable of finding all duplicated regions. Instead, more sophisticated approaches were required to detect *hidden* and *ghost* duplications, with hidden blocks being uncovered by examining a third region in the same species while ghost blocks required the third region to be in another species in order to uncover the evolutionary relationships between them.

Recently, work has begun on the evaluation of cluster significance. We noted earlier the concept of a max-gap cluster in conserved block detection methods. Following Durand and Sankoff (2003) on the testing of gene clustering, Hoberman *et al.* (2005) analysed the statistical properties of max-gap clusters. They show that the probability of observing m marked genes (i.e. those identified as being of interest) in a genome of size n, in a max-gap cluster with a maximum gap of size g, and with w_{mg} the maximum length of a cluster of size m (i.e. $m + (m-1)g$), is:

$$P(n, m, g) = \frac{1}{\binom{n}{m}} \begin{cases} (n - w_{mg} + 1)(g+1)^{m-1} + \dfrac{w_{mg} - m}{2}(g+1)^{m-1}, & \text{if } w_{mg} \leq n+1 \\ d_0(m, g, n) & \text{otherwise,} \end{cases}$$

(5.23)

where

$$d_e(k, g, l) = \sum_{i=0}^{(l-k)/(g+1)} (-1)^i \binom{k-1}{i} \binom{l - i(g+1) - e}{k - e}.$$

Gap of size 4

Cluster of size 4
and length 7

Cluster of size 5
and length 8
Figure 5.6 Two max-gap clusters for a genome of $n = 25$ genes, $m = 10$ marked genes and a max-gap of $g = 3$.

Figure 5.6 shows a simple example of a max-gap cluster for $n = 25$, $m = 10$ and $g = 3$. Hoberman *et al.* then gave a dynamic programming solution to the problem of finding the probability of observing a cluster with a subset, of size h, of the m marked genes and showed that this has an analytic solution when $h > m/2$. Finally, they tackled the problem of finding the probability of a max-gap cluster of size h from m homologues in a whole genome comparison of two genomes of size n. This was not solved exactly, but rather upper and lower bounds for the probability were established. Simulation experiments using these equations provided interesting results. They showed, for example, that the genome comparison upper and lower bounds are tight when the gap size g is small compared to the genome size n and that the probabilities of observing a cluster of size h are not monotonic with increasing cluster size h but may decrease initially before increasing as h tends to m. The authors also noted that *bottom-up* algorithms to find max-gap clusters (i.e. similar to some of those listed above) may not find the maximal clusters in certain cases and that divide-and-conquer solutions such as that used within the Gene Teams software described in Bergeron *et al.* (2002) should be used instead.

Mau *et al.* (2005) also developed a statistical approach to find LCBs using inexact sequence matching. Within the MAUVE alignment tool introduced above, the same research team (Darling *et al.*, 2004b) had described an approach to develop computational monotypic markers using multi-MUMs. However, the use of exact matches gave the approach a limited evolutionary breadth and so the new approach was developed for larger evolutionary distances. Monotypic markers were chosen to be single genes that possessed a reciprocal best BLAST hit in the other genomes undergoing analysis (and which also occurred just once in those genomes). A pseudo-Gibbs sampler was then used to find the posterior probabilities of markers belonging to particular blocks, thereby defining the number, composition and length of the LCB set. Crucially, a scale parameter allowed the user to choose the resolution of the LCBs. If low resolution was chosen, a few long LCBs would be found (essentially filtering out small rearrangements). At higher resolution, some of the LCBs broke up into more, smaller LCBs. Indeed, this is somewhat reminiscent of the gap length choice in the max-gap clustering described above. The authors then described the application of LCB estimation within four Streptococci genomes and showed how the choice of resolution affected the biological plausibility of a subsequent genome rearrangement analysis. The approach was implemented in the GRIL software (Genome Rearrangement and Inversion Locator; Darling *et al.*, 2004a).

5.6.3 Dating Duplicated Genes and Blocks

The ages of duplicated genes and conserved blocks, once determined by methods such as those outlined above, can be estimated by determining the level of synonymous substitution per site, K_S, (sometime also termed ds), in the underlying nucleotide sequence. For a genome with no large-scale duplication events in its past (or at least in the length of time in which such events are still able to be detected), the distribution of K_S values when plotted exhibits a characteristic 'L' shape (see e.g. Lynch and Conery, 2000). However, genomes in which large-scale evolutionary events have occurred tend to exhibit 'spikes' or bursts overlaid on this curve, as shown in Figure 5.7. In the Blanc *et al.* (2003) study discussed above, values of K_S were estimated using the *codeml* method in the PAML software (with large values discarded due to saturation of mutations). See **Chapter 12** for details of the theory underlying the estimation of rates of synonymous substitution. Blanc *et al.* found that the median K_S values within conserved blocks clustered into two groups: recent blocks and old blocks. The values of the 45 recent blocks showed low variance, suggesting a single, recent, whole genome duplication, while the values of the 63 old blocks were more varied though not wholly inconsistent with a second more distant whole genome event. The blocks were then dated by comparing the K_S values of the two groups to K_S values found by comparing *Arabidopsis* genes with their orthologues in other dicotyledon species. In a later study, Blanc and Wolfe (2004) also applied the method to EST contigs from several plant species, showing that large-scale duplications are likely to have occurred in 9 of 14 species analysed.

Phylogenetic approaches for determining evolutionary histories and dating duplication events have been used by Bowers *et al.* (2003). These authors discussed the potential error involved in dating evolutionary events by K_S values, as such values had been shown to vary considerably between genes belonging to different functional categories. Instead, in their analysis of the *Arabidopsis* genome, rooted phylogenies of gene duplicates together with a dicotyledon orthologue and an orthologue in an outgroup species (the latter of which was used to root the tree) were examined. The relative frequencies of trees where the gene duplicates were each other's closest relative and those where the dicotyledon
Figure 5.7 Distribution of ages of pairs of duplicated genes, with two ancient bursts of gene duplication.

orthologue was more closely related to one of the duplicate genes than it was to one another were found for a range of dicotyledons. This information was used to assess whether duplicate events were genome wide and when they were most likely to have occurred relative to speciation events. Furthermore, in their analysis of the rice genome, Wang *et al.* (2005) showed that the negative correlation of GC content with K_S values in rice could affect the characteristic K_S distribution and its interpretation. Instead of relying solely on K_S values to date evolutionary events, the authors decided to use a phylogenetic approach as support for the results.

Recently, the use of K_S values as quantities with which to estimate ages of evolutionary events is being examined in more detail. Maere *et al.* (2005) developed a dynamic population model to describe the shape of the K_S distribution as seen, for example, in Figure 5.7. The model described the number of duplicate genes retained in the genome, performing 50 time steps (at K_S intervals of 0.1) for 4 duplication mode categories (0 being a background process of gene gain and 1, 2 and 3 distinct potential whole genome duplications). It possessed three components:

$$D_0(1, t) = \nu \left[\sum_{x'=1}^{\infty} D_{tot}(x', t-1) + G_0 \right]$$

$$D_i(1, t) = \left[\sum_{x'=1}^{\infty} D_{tot}(x', t-1) + G_0 \right] \delta(t, t_i), \quad i = 1, 2 \text{ or } 3 \text{ and}$$

$$D_i(x, t) = D_i(x-1, t-1)[x/(x-1)]^{-\alpha_i}, \quad x > 1, \ i = 0, 1, 2 \text{ or } 3,$$

which were summed to create the overall distribution:

$$D_{tot}(x, t) = \sum_i D_i(x, t). \tag{5.24}$$

The first component represented the background process of single gene gain, where x was the age of the gene, t the time step, $D_i(x, t)$ the number of genes of age x at time t in duplication mode i, G_0 the number of ancestral genes at $K_S = 5$ and ν the gene birth rate. The second component modelled potential whole genome duplications (three in this case, for analysis of the *Arabidopsis* genome) by means of a parameter δ. Finally, the third component modelled the process of gene loss as a power-law curve with decay rates α_i. The power-law curve was thought to be more appropriate than exponential gene loss as it has been hypothesised that gene loss occurs rapidly immediately following genome duplication, gradually evolving to a process preferentially retaining older duplicates. Together, these components modelled the age distribution of duplicated genes which was then transformed to a K_S distribution through a Poisson smoothing technique. The model could then be fitted to real datasets through, for example, simulated annealing optimisation. The authors used the model to lend support for the three whole genome duplications hypothesised in *Arabidopsis* and to show, for example, differences in gene decay parameters for genes of different functional categories.

A different approach was taken by Cui *et al.* (2006) in their analysis of genome duplications in the history of flowering plants, although the basis of the analysis was again to model the K_S distribution. The authors noted that the null model for this distribution followed a constant rate birth–death process, with gene birth following a Poisson process

with rate β and the number of duplicated genes decreasing exponentially with rate δ. The age distribution of retained duplicates $N(t)$ at time t was then:

$$N(t) \sim P_O\left(\gamma \int_0^t \delta \exp(\delta s)\mathrm{d}s\right) = P_O(\gamma \cdot F(t)), \tag{5.25}$$

where $\gamma = \beta/\delta$ and $F(t) = 1 - \exp(-\delta t)$. This null model was then fitted to each dataset, assessing the fit using a χ^2 test. A quantile–quantile (Q–Q) plot was also used to compare the observed data to a dataset simulated under the null model, using a bootstrapped Kolmogorov–Smirnov test. Following the approach of Schleuter *et al.* (2004), datasets that could not be described adequately by the null model were further analysed by a finite mixture model of genome duplications (i.e. the log-transformed K_S values followed a sum of Gaussian distributions), with each component of the mixture representing a duplication class (e.g. two components, where the first represented the background process of gene gain and the second a whole genome duplication event). The authors went on to show, through simulation, the difficulties of determining both very recent and ancient duplications with K_S-based methods but successfully applied this method to several plant datasets, providing support for several large-scale duplication events in their evolutionary histories.

5.7   CONCLUSIONS AND FUTURE RESEARCH

In this chapter, we chose to focus on a few key problems that are paramount in evolutionary studies of whole genomes, using comparative maps, gene orders and contents, and whole genome sequence data. Of course, there are many other ways in which we can compare genomes (see, e.g. Saccone and Pesole, 2003 for a broader overview). We might wish to discover more about GC signatures within genes and codon usage from the genomic sequence. We might be interested in functional data and compare the protein structures or functions of the proteins encoded by the genes. We might not be interested in genes at all and prefer to look at intergenic entities such as *transposable elements*. As new datasets arise, we see methodologies being developed to analyse all these data types, to compare the results of the different methods and perhaps even to integrate them. We have seen that there are many promising strands of research in comparative genome analysis. How do we see research progressing in these areas?

Much of the early work in gene order studies has been of a computational nature and there is still much work to be done in improving, testing and comparing models of evolution. We have already seen that the fragile breakage model is being tested in newly sequenced genomes and we could also model other phenomena such as rapid rearrangement in sub-telomeric chromosomal regions, as has been seen in several eukaryotes. In addition, we must also consider the possibility that a proportion of genes are not randomly distributed along genomes but that their genomic location has some meaning. It has long been understood that genes are clustered in operons within prokaryotic genomes. However, several recent studies have shown that significant quantities of genes in eukaryotic genomes are clustered according to other criteria (e.g. belonging to a common metabolic pathway). A review of the evolutionary dynamics of eukaryotic gene order (Hurst *et al.*, 2004) discusses these criteria and examines potential mechanisms for cluster formation. In an illuminating study Wong and Wolfe (2005) show how several

genome rearrangement events have driven the formation of a secondary metabolite gene cluster in *sensu stricto* yeast species. See also **Chapter 13**, which discusses the implications of gene location (in addition to gene duplication and genetic redundancy) in a section on genome organisation. These papers show that we may not be able to consider all mutation events equally (i.e. those that separate neighbouring co-regulated genes may be less likely to occur than some others) and perhaps we should not consider gene order data in isolation but should rather analyse it in tandem with gene expression data.

In the analysis of whole genome sequences, it is likely that methods for whole genome alignment will continue to improve, both in terms of speed and accuracy and in dealing with problems such as rearrangement events, perhaps with an increase in model-based methods. There is also a need for a thorough comparison of methods for conserved block estimation. Some current methods search for clusters with a strict ordering of the genes, while others allow it to be entirely random and still others fall somewhere between these two extremes. Furthermore, there are essentially (at least) three types of clusters: blocks between genomes (where we may need to filter out micro-rearrangements), blocks within genomes (where we may need to filter out single-copy genes following large-scale duplications) and functional clusters (e.g. those for secondary metabolites, where a neighbourhood of genes from a number of functional classes may be more important than their actual order). We may find that different stratagies are required for each of these situations. Further modelling of dating methodologies (e.g. K_S signatures) would also be illuminating, formalising the goodness-of-fit of models and hypotheses for model comparison.

Overall, it is clear that comparative genomics is an active, flourishing area of computational research and that statistical methods are beginning to make an impact on this field. There is currently a great opportunity for statisticians to become involved in this research and to play an important role in making sense of the enormous quantities of data arising from the genome sequencing projects.

Part 2

Beyond the Genome

Analysis of Microarray Gene Expression Data

W. Huber

Department of Molecular Genome Analysis, German Cancer Research Center, Heidelberg, Germany

A. von Heydebreck and M. Vingron

Department of Computational Molecular Biology, Max-Planck-Institute for Molecular Genetics, Berlin, Germany

This chapter reviews the methods utilized in processing and analysis of gene expression data generated using DNA microarrays. This type of experiment allows relative levels of mRNA abundance in a set of tissue samples or cell populations to be determined for thousands of genes simultaneously. Naturally, such an experiment requires computational and statistical analysis techniques. As processing begins, the computational procedures are largely determined by the technology and experimental setup used. Subsequently, as more reliable intensity values for genes emerge, pattern discovery methods come into play. The most striking peculiarity of this kind of data is that one usually obtains measurements for thousands of genes for a much smaller number of conditions. This is at the root of several of the statistical questions discussed here.

6.1 INTRODUCTION

In the context of the Human Genome Project, new technologies have emerged that facilitate the parallel execution of experiments on a large number of genes simultaneously. The so-called DNA microarrays, or DNA chips, constitute a prominent example. This technology aims to measure mRNA levels in particular cells or tissue samples for many genes at once. To this end, single strands of complementary DNA for the genes of interest – of which there may be many thousands – are immobilized on spots arranged in a grid ('array') on a support which will typically be a glass slide, a quartz wafer, or a nylon

membrane. From a sample of interest, such as a tumor biopsy, the mRNA is extracted, labeled and hybridized to the array. Measuring the quantity of label on each spot then yields an intensity value that should be correlated to the abundance of the corresponding RNA transcript in the sample.

Two schemes of labeling are in common use today. One variant labels a single sample either radioactively or fluorescently. Radioactive labeling is used, for example, in conjunction with hybridization on nylon membranes (Lennon and Lehrach, 1991). The company Affymetrix synthesizes sets of short oligomers on a glass wafer and uses a single fluorescent label (Lipshutz *et al.*, 1999; see also www.affymetrix.com). Alternatively, two samples are labeled with a green and a red fluorescent dye, respectively. The mixture of the two mRNA preparations is then hybridized simultaneously to a common array on a glass slide. This technology is usually referred to as the Stanford technology (Duggan *et al.*, 1999). Quantification utilizes a laser scanner that determines the intensities of each of the two labels over the entire array. Recently, companies like Agilent have immobilized long oligomers 60–70 base pairs in length and used two-color labeling.

The parallelism in this kind of experiment lies in the hybridization of mRNA extracted from a single sample to many genes simultaneously. The measured abundances, though, are not obtained on an absolute scale. This is because they depend on many factors that are hard to control, such as the efficiencies of the various chemical reactions involved in the sample preparation, as well as on the amount of immobilized DNA available for hybridization.

The class of transcripts that is probed by a spot may differ in different applications. Most commonly, each spot is meant to probe a particular gene. The representative sequence of DNA on the spot may be either a carefully selected fragment of cDNA, a more arbitrary polymerase chain reaction (PCR) product amplified from a clone matching the gene, or one of a set of oligonucleotides specific to the gene. Another level of sophistication is reached when a spot represents, for example, a particular transcript of a gene. In this case, or to distinguish mRNA abundances of genes from closely related gene families, careful design and/or selection of the immobilized DNA is required. Likewise, the selection of samples to study and to compare to each other using DNA microarrays requires careful planning, as will become clear upon consideration of the statistical questions arising from this technology (Kerr and Churchill, 2001a; Churchill, 2002; Yang and Speed, 2002).

There are many different ways to plan a microarray experiment. In many cases a development in time is studied, leading to a series of hybridizations following each other. Alternatively, different conditions such as the presence/absence of disease or different disease types may be studied. We generally refer to a time point or a state as a condition, and typically for each condition several replicate hybridizations are performed. The replicates should provide the information necessary to judge the significance of the conclusions one wishes to draw from the comparison of the different conditions. When delving deeper into the subject it soon becomes clear that this simple outline constitutes a rather challenging program.

This chapter is organized along the various steps of analysis of a microarray experiment. Statistical problems arise firstly as a consequence of various technical peculiarities, and their solution is a prerequisite to any meaningful subsequent interpretation of the experiment. Section 6.2 describes some of the issues related to quality control. Visualization methods are introduced because they may greatly help in detecting and

removing obviously failed measurements, as well as in finding more subtle systematic biases associated with variations in experimental conditions.

Microarray measurements are subject to multiple sources of experimental variation, the mathematical treatment of which is discussed in Section 6.3. Some of the variations are *systematic* and may be explicitly corrected for, others are *random* and may be accounted for through an error model. The correction for systematic effects is referred to as calibration or normalization. We will discuss two error models: one involving a constant coefficient of variation, that is, a purely multiplicative noise term; and one allowing for a more general variance-to-mean dependence, with a noise term that has both multiplicative and additive components. From these models we derive *measures of relative abundance* of mRNA.

The goal of many microarray experiments is to identify genes that are differentially transcribed with respect to different biological conditions of cell cultures or tissue samples. Section 6.4 focuses on these issues, paying particular attention to the notoriously low numbers of repeated hybridizations per condition in relation to the high numbers of genes about which one wishes to draw conclusions. Section 6.5 proceeds to highlight some of the issues in pattern discovery in microarray data. Here, again, classical methods of data analysis need to be carefully evaluated with respect to their applicability to the particular type of data at hand. A short summary will be given of the methods that have so far been successfully applied. Emphasis is given to exploratory approaches that allow the subsequent formulation of hypotheses that can be tested through either further analysis or further experiments.

6.2   DATA VISUALIZATION AND QUALITY CONTROL

A microarray experiment consists of the following components: a set of *probes*, an *array* on which these probes are immobilized at specified locations, a *sample* containing a complex mixture of labeled biomolecules that can bind to the probes, and a *detector* that is able to measure the spatially resolved distribution of label after it has bound to the array (see *Nature Genetics* **21**(supplement), 1999). The probes are chosen such that they bind to specific sample molecules; for DNA arrays, this is ensured by the high sequence-specificity of the hybridization reaction between complementary DNA strands. The array is typically a glass slide or a nylon membrane. The sample molecules may be labeled through the incorporation of radioactive markers, such as ^{33}P, or of fluorescent dyes, such as phycoerythrin, Cy3, or Cy5. After exposure of the array to the sample, the abundance of individual species of sample molecules can be quantified through the signal intensity at the matching probe sites. To facilitate direct comparison, the spotted array technology developed in Stanford (Duggan *et al.*, 1999) involves the simultaneous hybridization of two samples labeled with different fluorescent dyes, and detection at the two corresponding wavelengths. Plate 1 shows an example.

6.2.1   Image Quantification

The intensity images are scanned by the detector at a high spatial resolution, such that each probe spot is represented by many pixels. In order to obtain a single overall intensity value for each probe, the corresponding pixels need to be identified (segmentation),

and the intensities need to be summarized (quantification). In addition to the overall probe intensity, further auxiliary quantities may be calculated, such as an estimate of apparent unspecific 'local background' intensity, or a spot quality measure. A variety of segmentation and quantification methods is implemented in available software packages. These differ in their robustness against irregularities and in the amount of human interaction that they require. Different types of irregularities may occur in different types of microarray technology, and a segmentation or quantification algorithm that is good for one platform is not necessarily suitable for another. For instance, the variation of spot shapes and positions that the segmentation has to deal with depends on the properties of the support (e.g. glass or nylon), on the probe delivery mechanism (e.g. quill-pen type, pin and ring systems, ink-jetting), and on the detection method (optical or radioactive). Furthermore, larger variations in the spot positioning from array to array can be expected in home-made arrays than in mass-produced ones. An evaluation of image analysis methods for spotted cDNA arrays was reported by Yang *et al.* (2002).

For a microarray project, the image quantification marks the transition in the work flow from 'wet lab' procedures to computational ones. Hence, this is a convenient time to look at the quality and plausibility of the data. There are several aspects to this: confirmation that positive and negative controls behave as expected; verification that replicates yield measurements close to each other; and checking for the occurrence of artifacts, biases, or errors. In the following we present a number of data exploration and visualization methods that may be useful for these tasks.

6.2.2   Dynamic Range and Spatial Effects

A simple and fundamental property of the data is the dynamic range and the distribution of intensities. Since many experimental problems occur at the level of a whole array or the sample preparation, it is instructive to look at the histogram of intensities from each sample. An example is shown in Figure 6.1. Typically, for arrays that contain quasi-random gene selections, one observes a unimodal distribution with most of its mass at small intensities, corresponding to genes that are not or only weakly transcribed in the sample, and a long tail to the right, corresponding to genes that are transcribed at various levels. In most cases, the occurrence of multiple peaks in the histogram indicates an experimental artifact. To get an overview over multiple arrays, it is instructive to look at the boxplots of the intensities from each sample. Problematic arrays should be excluded from further analysis.

Crude artifacts, such as scratches or spatial inhomogeneities, will usually be observed in the scanner image at the stage of the image quantification. Nevertheless, to get a quick and potentially more sensitive view of spatial effects, a false-color representation of the probe intensities as a function of their spatial coordinates can be useful. There are different options for the intensity scaling, among them the linear, logarithmic, and rank scales. Each will highlight different features of the spatial distribution. Examples are shown in Plate 2.

6.2.3   Scatterplot

Usually, the samples hybridized to a series of arrays are biologically related, such that the transcription levels of a large fraction of genes are approximately the same across the samples. This can be expected, for example, for cell cultures exposed to different conditions or for cells from biopsies of the same tissue type, possibly subject to different
Figure 6.1 Histogram of probe intensities at the green wavelength for a cDNA microarray similar to that depicted in Plate 1. The intensities were determined, in arbitrary units, by an image quantification method, and 'local background' intensities were subtracted. Due to measurement noise, these lead to nonpositive probe intensities for part of the genes with low or zero abundance. The x-axis has been cut off at the 99 % quantile of the distribution. The maximum value is about 4000.
Figure 6.2 Scatterplot of probe intensities in the red and the green color channel from a cDNA array containing 8000 probes.

disease conditions. We call this the *majority of genes unchanged* property. Visually, it can be verified from the scatterplot of the probe intensities for a pair of samples. An example is shown in Figure 6.2.

The scatterplot allows both measurement noise and systematic biases to be assessed. Ideally, the data from the majority of the genes that are unchanged should lie on the bisector of the scatterplot. In reality, there are both systematic and random deviations from this (Schuchhardt *et al.*, 2000). For instance, if the label incorporation rate and photoefficiency of the red dye were systematically lower than that of the green dye by a factor of 0.75, the data would be expected not to lie on the bisector, but rather on the line $y = 0.75x$.

Most of the data in Figure 6.2 is squeezed into a tiny corner in the bottom left of the plot. More informative displays may be obtained from other axis scalings. A frequently used choice is the double-logarithmic scale. An example is shown in Figure 6.3. It is customary to transform to new variables $A = \log R + \log G$, $M = \log R - \log G$ (Dudoit *et al.*, 2002b). Up to a scale factor of $\sqrt{2}$, this corresponds to a clockwise coordinate system rotation by 45°. The horizontal coordinate A is a measure of average transcription
Figure 6.3 (a) The same data as in Figure 6.4, after logarithmic transformation and clockwise rotation by 45°. The dashed line shows a local regression estimate of the systematic effect $M_0(A)$; see text. (b) Similar to (a), but with a constant value $c = 42$ added to the red intensities before log transformation. As a result, the estimated curve for the systematic effect $M_0(A)$ is approximately constant.

level, while the *log ratio M* is a measure of differential transcription. If the majority of genes are not differentially transcribed, the scatter of the data points in the vertical direction may be considered a measure of the random variation. Figure 6.3(a) also shows a systematic deviation of the observed values of M from the line $M = 0$, estimated through a local regression line.[1] There is an apparent dependence $M_0(A)$ of this deviation on the mean intensity A. However, this is most likely an artifact of applying the logarithmic transformation: as shown in Figure 6.3(b), the deviation may be explained sufficiently well through a constant $M_0(A) = M_0$ if an appropriate offset is added to the R values before taking the logarithm. Note that a horizontal line at $M = M_0$ in Figure 6.3(b) corresponds to a straight line with slope 2^{M_0} and intercept c in Figure 6.2.

Figure 6.3 shows the *heteroskedasticity* of log ratios: while the variance of M is relatively small and approximately constant for large average intensities A, it becomes larger as A decreases. Conversely, examination of the differences $R - G$, for example through plots as in Figure 6.2, shows that their variance is smallest for small values of the average intensity $R + G$ and increases with $R + G$. Sometimes one wishes to visualize the data in a manner such that the variance is constant along the whole dynamic range. A data transformation that achieves this goal is called a variance-stabilizing transformation.

---

[1] We used `loess` (Cleveland *et al.*, 1992) with default parameters span $= 0.75$, degree $= 2$.

In fact, *homoskedastic* representations of the data are useful not only for visualization, but also for further statistical analyses. This will be discussed in more detail in Section 6.3.

Two extensions of the scatterplot are shown in Plates 3 and 4. Rather than plotting a symbol for every data point, they use a density representation, which may be useful for larger arrays. For example, Plate 3 shows the scatterplot from the comparison of two tissue samples based on 152 000 probes.[2] The point density in the central region of the plot is estimated by a kernel density estimator. Three-way comparisons may be performed through a projection such as in Plate 4. This uses the fact that the $(1, 1, 1)$ component of a three-way microarray measurement corresponds to average intensity, and hence is not directly informative with respect to differential transcription. Note that if the plotted data were preprocessed through a variance-stabilizing transformation, its variance does not depend on the $(1, 1, 1)$ component.

6.2.4   Batch Effects

Present-day microarray technology measures abundances only in terms of relative probe intensities, and generally provides no calibration to absolute physical units. Hence, the comparison of measurements between different studies is difficult. Moreover, even within a single study, the measurements are highly susceptible to *batch effects* – experimental factors that add systematic biases to the measurements, and may vary between different subsets or stages of an experiment. The following are some examples (Schuchhardt *et al.*, 2000):

1. *Spotting.* To manufacture spotted microarrays, the probe DNA is deposited on the surface through spotting pins. Usually, the robot works with multiple pins in parallel, and the efficiency of their probe delivery may be quite different (see Plate 2d or Dudoit *et al.*, 2002b). Furthermore, the efficiency of a pin may change over time through mechanical wear, and the quality of the spotting process as a whole may be different at different times, due to varying temperature and humidity conditions.

2. *PCR amplification.* For cDNA arrays, the probes are synthesized through PCR, whose yield varies from instance to instance. Typically, the reactions are carried out in parallel in 384-well plates, and probes that have been synthesized in the same plate tend to have highly correlated variations in concentration and quality. An example is shown in Plate 5.

3. *Sample preparation protocols.* The reverse transcription and the labeling are complex biochemical reactions, whose efficiencies are variable and may depend sensitively on a number of circumstances that are hard to control. Furthermore, RNA can quickly degrade, hence the outcome of the experiment can depend sensitively on when and how conditions that prevent RNA degradation are applied to the tissue samples.

4. *Array coating.* Both the efficiency of the probe fixation on the array, and the amount of unspecific background fluorescence strongly depend on the array coating.

5. *Scanner and image analysis.*

These considerations have important consequences for experimental design. First, any variation that can be avoided within an experiment should be avoided. Second, any

---

[2] The arrays used were RZPD Unigene-II arrays (www.rzpd.de).

variation that cannot be avoided should be dealt with so as not to confound the biological question of interest. Clearly, when looking for differences between two tumor types, it would not be wise to have samples of one tumor type processed by one laboratory, and samples of the other type by another laboratory.

Points 1 and 2 are specific to spotted cDNA arrays. For less sensitivity to these variations, the two-color labeling protocol is used, which employs the simultaneous hybridization of two samples to the same array (Duggan *et al.*, 1999). Ideally, if only ratios of intensities between the two-color channels are considered, variations in probe abundance should cancel out. Empirically they do not quite do so, which may, for example, be attributed to the fact that observed intensities are the sum of probe-specific signal and unspecific background (Yue *et al.*, 2001). Furthermore, in the extreme case of total failure of the PCR amplification or the DNA deposition for probes on some, but not all, arrays in an experimental series, artifactual results are hardly avoidable.

If any of the factors 3–5 is changed within an experiment, there is a good chance that this will later show up in the data as one of the most pronounced sources of variation. A simple and instructive visual tool to explore such variations is the correlation plot: given a set of d arrays, each represented by a high-dimensional vector $\vec{Y}_i$ of suitably transformed and filtered probe intensities, calculate the $d \times d$ correlation matrix $\mathrm{corr}(\vec{Y}_i, \vec{Y}_j)$, sort its rows and columns according to different experimental factors, and visualize the resulting false-color images.

6.3 ERROR MODELS, CALIBRATION AND MEASURES OF DIFFERENTIAL EXPRESSION

The relation between a measured intensity y_{ki} of probe k and the true abundance x_{ki} of molecule type k in sample i may be written as

$$y_{ki} = a_{ki} + b_{ki}\, x_{ki}. \tag{6.1}$$

The gain factor b_{ki} represents the net result of the various experimental effects that come between the count of molecules per cell in the sample and the final readout of the probe intensity, such as the number of cells in the sample, the mean number of label molecules attaching to a sample molecule, hybridization efficiency, label efficiency, and detector gain. The additive term a_{ki} accounts for that part of the measured intensity that does not result from x_{ki}, but from effects such as unspecific hybridization, background fluorescence, stray signal from neighboring probes, and detector offset.

The parameters a_{ki} and b_{ki} are different for each probe k and for each hybridization i. It is not practical to determine them exactly, but neither is it necessary. Rather, one is content with obtaining *statistical* statements about *relative* abundances. To this end, one may build stochastic models for the effects a_{ki} and b_{ki}. Different variations on this theme have been proposed, as will be presented below.

First, however, we would like to discuss the functional form of equation (6.1), which says that when the true abundance x_{ki} increases, the measured signal y_{ki} increases proportionally. Might it be necessary to consider more complex nonlinear relationships? Clearly, this cannot be ruled out for all possible experiments or for future technologies. However, a linear operating range over several orders of magnitude has been reported by

a number of authors for current microarray technologies (e.g. Ideker *et al.*, 2000; Ramdas *et al.*, 2001; Irizarry *et al.*, 2003). At the lower end, this range is limited only by the requirement that x_{ki} be nonnegative. At the upper end, the linear range is limited by saturation effects such as quenching, limited probe abundance, and detector saturation. However, for realistic concentrations of sample molecules, the upper limit is not reached in well-conducted experiments.

6.3.1 Multiplicative Calibration and Noise

In a seminal paper, Chen *et al.* (1997) introduced a decomposition of the multiplicative effect (cf. (6.1)),

$$b_{ki} = b_i \beta_k (1 + \varepsilon_{ki}). \tag{6.2}$$

Here, β_k is a probe-specific coefficient, the same for all samples. For each sample i, the normalization factor b_i is applied across all probes. The remaining variation in b_{ki} that cannot be accounted for by β_k and b_i is absorbed by ε_{ki}. Furthermore, since the measured intensities y_{ki} are already 'background-corrected' by the image analysis software's local background estimation, Chen *et al.* assumed the additive effects a_{ki} to be negligibly small. They further simplified the problem in two steps.

First, they noted that one is mainly interested in relative comparisons between the levels of the same gene under different conditions, that is, in the ratios x_{ki}/x_{kj}. Hence the probe-specific effects β_k can be absorbed, $\mu_{ki} = \beta_k x_{ki}$, simply rescaling the units in which molecule abundances are measured, and need not be determined.

Second, they turned to a stochastic description, and modeled ε_{ki} as a normally distributed noise term with mean zero and standard deviation c, independent of i and k. Thus, in the model of Chen *et al.* the measured intensity Y_{ki} is a random variable and depends on the true level μ_{ki} as follows:

$$Y_{ki} = b_i \, \mu_{ki} \, (1 + \varepsilon_{ki}), \qquad \varepsilon_{ki} \sim N(0, c^2). \tag{6.3}$$

Note that Y_{ki} has constant coefficient of variation c.

Chen *et al.* specifically considered two-color cDNA microarrays, where $i = 1, 2$ represents the red and the green color channel, respectively. For a given true ratio μ_{k1}/μ_{k2}, Chen *et al.* derived the distribution of the observed, normalized ratio $M_k = Y_{k2}/Y_{k1} \times b_1/b_2$. This depends only on the values of c and b_1/b_2, and Chen *et al.* gave an algorithm for the estimation of these parameters from the data. Based on this, they were able to formulate a statistical test for differential expression, that is, for the hypothesis $\mu_{k1} = \mu_{k2}$. Hence, the ratios M_k were regarded as a sufficient summary of the results from a single microarray slide, and they, or their logarithms, would then be used as the input for further higher-level analyses of data from multiple slides.

To allow for a more systematic analysis of multiple slide experiments, Kerr *et al.* (2000) proposed an approach based on the ANOVA technique. They modeled the measured intensity Y_{kjlm} of probe k on slide j, in the color channel of dye l, from a sample that received treatment m, as

$$\log Y_{kjlm} = g_k + s_j + d_l + v_m + [gs]_{kj} + [gv]_{km} + \varepsilon_{kjlm}. \tag{6.4}$$

Here g_k, s_j, d_l, v_m are main effects for probe, array, dye, and treatment, respectively. The probe–array interaction $[gs]_{kj}$ accounts for variations of probe quality in the

array manufacture, and the probe–treatment interaction $[gv]_{km}$ for differential levels of transcription of gene g between different treatment groups m. The noise terms ε_{kjlm} account for all other variations and are assumed to be independent and identically distributed. The ANOVA model (6.4) is related to (6.1) by setting

$$a_{ki} = 0, \tag{6.5}$$

$$\log b_{ki} + \log x_{ki} = (s_j + d_l + [gs]_{kj}) + (g_k + v_m + [gv]_{km}) + \varepsilon_{kjlm}, \tag{6.6}$$

where $j \equiv j(i)$, $l \equiv l(i)$ and $m \equiv m(i)$ are slide, dye, and treatment associated with sample i, respectively. The terms in the first set of parentheses on the right-hand side of (6.6) may be attributed to the measurement gain b_{ki}, and the terms in the second set to the actual abundance x_{ki}, but generally such a decomposition is not unique.

Both the models of Chen *et al.* and Kerr *et al.* were formulated with reference to the two-color cDNA array technology. However, (6.4) can be adapted (in fact, simplified) in a straightforward manner to data from one-color array technologies, such as Affymetrix genechips or cDNA membranes with radioactive labeling. Furthermore, to represent more complex experimental designs than simple two-way comparisons, more detailed terms than the single factor v_m can be introduced into (6.4), and the efficiencies of different designs can be compared using standard techniques for linear models (Kerr and Churchill, 2001a).

6.3.2   Limitations

The concepts of Section 6.3.1 have been widely used for microarray data analysis. However, it has also become clear that, for many data sets that are encountered in practice, they are not sufficient. The following points are worth noting:

1. *Robustness.* In order to make model (6.3) identifiable, Chen *et al.* assumed that the transcription levels of all genes were unchanged, and set $\mu_{k1} = \mu_{k2}$ for all k. Thus, their model is misspecified for the part of the data arising from truely differentially transcribed genes, which act as outliers. However, their parameter estimation is based on least-squares criteria, and may be sensitive to the presence of such outliers. In addition, outliers may be caused by technical artifacts.

2. *Heteroskedasticity.* The significance of log ratios depends on the absolute values of the intensities in the numerator and denominator (Beissbarth *et al.*, 2000; Baggerly *et al.*, 2001; Newton *et al.*, 2001; Theilhaber *et al.*, 2001; Kepler *et al.*, 2002). Typically, the variance of log-transformed intensities increases as their mean decreases.

3. *Apparent nonlinearities.* According to the above models, the data from a pair of samples should lie along a straight line in the scatterplot of the log-transformed intensities. However, in real data, several authors have observed data that follows a curved line as in Figure 6.3 (Beissbarth *et al.*, 2000; Dudoit *et al.*, 2002b; Kepler *et al.*, 2002).

4. *Negative values.* While the image quantification's estimates for probe 'foreground' and 'background' intensities are generally positive, this is usually not true for their difference. If a gene is weakly or not expressed, it can happen by chance that the background estimate is larger than the foreground estimate (see Figure 6.1). However, nonpositive values make sense neither for ratios nor for the log-transformation.

To address these problems, various fixes have been proposed. We give a brief and incomplete review.

1. *Robustness.* Robust estimation techniques in the context of microarray data have been described by many authors (Beissbarth *et al.*, 2000; Thomas *et al.*, 2001; Dudoit *et al.*, 2002b; Huber *et al.*, 2002; Kepler *et al.*, 2002). A general overview is given in Rousseuw and Leroy (1987).

2. *Heteroskedasticity.* It is often observed that the variance of the log ratio is a monotonously decreasing function of the mean intensity. One common practice has been to discard the log ratios calculated from intensities below a certain threshold and to treat the rest as if they were homoskedastic.

Newton *et al.* (2001) proposed a *shrinkage estimator*

$$\frac{y'_{k1} + \nu}{y'_{k2} + \nu} \tag{6.7}$$

to replace the naive ratio y'_{k1}/y'_{k2}. Here, $y'_{ki} = y_{ki}/b_i$ are the normalized intensities. Similarly to Chen *et al.* they neglected the additive terms a_{ki} and used a model of the measurement error with a constant coefficient of variation. To arrive at (6.7), they enclosed this in a hierarchical Bayesian model, using a prior distribution for the mRNA abundances, and, in particular, their positivity. The form of this distribution is reflected by the shrinkage parameter ν, which is estimated from the data. To infer differential transcription, they derived 'posterior odds of change', which, however, are not a simple function of the log ratio or of (6.7).

Several authors have addressed the problem of heteroskedasticity by estimating the variance of the log ratios or of log-transformed intensities separately for each gene (e.g. Thomas *et al.*, 2001; Dudoit *et al.*, 2002b). However, in many applications the number of samples available is too small for reliable estimates of gene-specific variance, hence it has been proposed to estimate the variance as a nonparametric smooth function of the mean intensity, through a local regression. The log ratios may then be *studentized* by dividing them by their locally estimated standard deviation (Kepler *et al.*, 2002). Baggerly *et al.* (2001) provided some theoretical foundation for this from models of the measurement error for different levels of replication. According to these, the variance of the log ratio is largest for small intensities and exponentially decreases toward an asymptotic positive value as the intensity increases.

3. *Apparent nonlinearities.* To correct for the curved appearance of the scatterplot of log-transformed data, Dudoit *et al.* (2002b) proposed to replace the normalization factor b_1/b_2 in (6.3) by a smooth function $M_0(A)$ (see Figure 6.3). This is estimated by robust local regression (Cleveland *et al.*, 1992) and, by construction, this correction makes the scatterplot look straight.

A similar correction was proposed by Kepler *et al.* (2002), in the framework of a model similar to (6.4). In their approach, the terms $s_j + d_l$ (slide and dye effects) are replaced by smooth functions of g_k (mean logarithmic abundance of gene k), which are again estimated by robust local regression.

4. *Negative values.* In order to be able to calculate ratios and logarithms from real microarray data, different fixes have been proposed to deal with nonpositive values: marking them as invalid or missing; replacing them by a fixed, small positive value; using an imputation algorithm to replace them by a more acceptable value; adding pseudocounts,

such that the whole set of intensities becomes positive; ignoring the local background estimate (cDNA arrays) or the mismatch probes (Affymetrix genechips) and using only the strictly positive foreground or perfect match intensities.

All of these approaches seem to reflect the common wisdom that molecule abundances are not negative. However, probe intensities are only *measurements* of abundance, and in the presence of an additive component of the measurement noise negative measurements may well be consistent with zero or positive abundance. In any experiment, a certain proportion of genes will have zero or low abundance in some samples but not in others, hence the treatment of the nonpositive intensity measurements may affect a large and potentially informative fraction of the data.

6.3.3 Multiplicative and Additive Calibration and Noise

Interestingly, points 2–4 of Section 6.3.2 can be related to a rather basic assumption of models (6.3) and (6.4), and it appears that in many cases the associated problems can be resolved by using a more general model. Chen *et al.* as well as Kerr *et al.* assumed that the additive terms a_{ki} in (6.1) were negligible, or at least sufficiently accounted for by the image quantification's local background estimation algorithm. One way to arrive at a more realistic model is to set

$$a_{ki} = a_i + b_i \eta_{ki}, \tag{6.8}$$

$$b_{ki} = b_i \beta_k (1 + \varepsilon_{ki}), \tag{6.9}$$

where the decomposition of the multiplicative effect (6.9) is the same as in (6.2), a_i is a sample-specific additive parameter, and η_{ki} are independent and normally distributed random variables with zero mean and common variance. Hence, model (6.3) is replaced by

$$\frac{Y_{ki} - a_i}{b_i} = \mu_{ki}\, e^{\varepsilon_{ki}} + \eta_{ki}, \qquad \varepsilon_{ki} \sim N(0, c^2),\ \eta_{ki} \sim N(0, s^2). \tag{6.10}$$

Model (6.10) was proposed by Rocke and Durbin (2001) and, using different distributional assumptions, by Ideker *et al.* (2000). The latter authors used a more detailed parameterization of the noise terms, allowing for different values of the standard deviations c and s for the red and green color channels $i = 1, 2$ and for correlation between ε_{k1} and ε_{k2}, as well as between η_{k1} and η_{k2}. In both cases, the authors did not try to estimate the calibration parameters a_i, b_i, but rather assumed that a calibration had already been performed by some other means.

6.3.3.1 Consequences

First, the intensities Y_{ki} are no longer supposed to have a constant coefficient of variation. Rather, they obey a variance-to-mean dependence

$$v(u) = c^2(u - a_i)^2 + b_i^2 s^2, \tag{6.11}$$

where, in a slight abuse of notation, $v \equiv \text{var}(Y_{ki})$ and $u \equiv \text{E}(Y_{ki})$, and the equation holds for all probes k for sample i. Recall that a constant coefficient of variation corresponds to

a dependence $v(u) = c^2 u^2$, which is a special case of (6.11) for $a_i = s = 0$. In this case, the logarithm is a variance-stabilizing transformation, that is, the log-transformed data have approximately constant variance. For the more general variance-to-mean dependence (6.11), such a transformation can also be found, as will be explained below.

Second, the ratio of intensities y_{k1}/y_{k2} is no longer the best estimator for the true fold change μ_{k1}/μ_{k2}. This was addressed by Dror *et al* (2002), who estimated $\log(\mu_{k1}/\mu_{k2})$ by the posterior mean of a hierarchical model that consists of (6.10) together with an empirical prior for the distribution of μ_{ki}. Their estimator coincides with the log ratio if both y_{k1} and y_{k2} are large, and remains well behaved for small or nonpositive values of y_{k1} and y_{k2}.

The appropriate variance-stabilizing transformation was described by Huber *et al.* (2002) and Durbin *et al.* (2002). It has the form

$$h_i(y_{ki}) = \operatorname{arcsinh}\left(\frac{c}{s} \cdot \frac{y_{ki} - a_i}{b_i}\right). \tag{6.12}$$

The parameters a_i and b_i may be interpreted as array-specific calibration parameters, while the coefficient of variation c and the background noise level s parameterize the overall error model. The graph of the arcsinh function is depicted in Figure 6.4. The following two relations hold between the arcsinh and the log function:

$$\operatorname{arcsinh}(x) = \log(x + \sqrt{x^2 + 1}), \tag{6.13}$$

$$\lim_{x \to \infty} \{\operatorname{arcsinh}(x) - \log(2x)\} = 0. \tag{6.14}$$

In the framework of Section 6.3.1, log ratios, the differences between the logarithms of normalized intensities, were the appropriate measure of differential transcription to be used in downstream analyses. By analogy, we define (Huber *et al.*, 2002)

$$\Delta h_{k;ij} = h_i(y_{ki}) - h_j(y_{kj}). \tag{6.15}$$
Figure 6.4 Graph of the arcsinh(x) (solid line) and log($2x$) (dashed line). The vertical line marks the singularity of the logarithm function at $x = 0$. The arcsinh function is symmetric, $\operatorname{arcsinh}(x) = -\operatorname{arcsinh}(-x)$; however, most relevant for (6.12) is its behaviour in an x range as depicted here.

For intensities that are much larger than the additive noise level, (6.15) becomes equivalent to the log ratio, as is seen from (6.14). But, in contrast to the log ratio, $\Delta h_{k;ij}$ is well defined and has constant variance c^2 across the whole range of intensities. In fact, $\Delta h_{k;ij}/c$ may be thought of as a 'studentized log ratio'.

To estimate the model and transformation parameters, one could directly fit model (6.10) to the data, using the *majority of genes unchanged* assumption $\mu_{ki} = \mu_k$ for most genes k. A computationally simpler approach is to fit the model

$$h_i(Y_{ki}) = \tilde{\mu}_k + \tilde{\varepsilon}_{ki}, \qquad \tilde{\varepsilon}_{ki} \sim N(0, c^2). \tag{6.16}$$

Up to first and second moments, models (6.10) and (6.16) are equivalent. Parameter estimates can be obtained from a robust variant of the maximum likelihood estimator. A robust estimator with high breakdown point is needed not only because there may be technical outliers, but also because the assumption $\mu_{ki} = \mu_k$ does not hold for a minority of genes that have biologically different transcription levels in different samples (Huber *et al.*, 2002).

The identification of differentially transcribed genes through statistical tests on Δh_k values has been shown to have higher sensitivity and specificity than that through tests on log ratios (Huber *et al.*, 2002). This may be explained by the fact that for nondifferentially transcribed genes the Δh_k values have unimodal distributions with mean zero and variances independent of the genes' mean transcription levels. Hence, within the limits of the error model, all available information with respect to differential transcription of gene k is contained in the values of $\Delta h_{k;ij}$. On the other hand, the distributions of log ratios may have, even for some of the nondifferentially transcribed genes, mean values different from zero due to sensitive dependence on calibration errors, they may have variances that strongly depend on the mean transcription levels, and they may involve missing values, if there are nonpositive net probe intensities. These points are illustrated in Plate 6.

6.3.3.2 Probe Set Summaries

A gene transcript may be represented by multiple probes on an array. To obtain an overall measure of abundance per gene, a straightforward approach is to take the average of the corresponding calibrated and transformed probe intensities (6.12). If additional information on the reliability of the probe measurements is available, a weighted average may be used. This has been investigated most extensively in the context of Affymetrix genechip data (Lipshutz *et al.*, 1999). On these chips, each transcript is represented by 16–20 pairs of oligonucleotide probes referred to as probe sets. Each probe pair consists of an oligonucleotide of 25 bases that exactly matches the target sequence, and of one that has a mismatch in the middle. The mismatch probes are thought to provide estimates of unspecific contributions to the signal measured from the perfect match probes. A good overview, with many further references, was given by Irizarry *et al.* (2003).

6.4   IDENTIFICATION OF DIFFERENTIALLY EXPRESSED GENES

One of the basic goals in the analysis of microarray gene expression data is the identification of differentially expressed genes in the comparison of different types of

cell or tissue samples. In order to control the biological and experimental variability of the measurements, statistical inference has to be based on an adequate number of replicate experiments. Here one may distinguish between cases in which one wishes to make statements on a particular cell population and cases in which one wishes to make statements that hold in the presence of biological variability, such as with biopsy studies of diseased tissues. In the first case independent replications can be obtained at the level of multiple mRNA isolations; in the second they may be provided by samples from different patients.

For the following, we assume that the data are given either as absolute intensities or as relative values with respect to a common reference sample, and have been calibrated (see Section 6.3).

To identify differentially expressed genes with respect to a certain biological question, a suitable statistical test may be performed for each gene (Claverie, 1999). The choice of test statistic depends on the biological question and on the nature of the available experimental data. In the simplest case, one seeks genes that show different transcript abundance between two conditions. In more complex situations, one may look for genes whose abundance is associated with multiple factor levels of one or more sample characteristics. Furthermore, one may consider continuous-valued sample characteristics and test for genes which show nonzero coefficients in a regression model, such as a linear model or a Cox proportional hazards model on patient survival data.

Different test statistics may make more or less strong assumptions on the distributions of replicate measurements. Important questions are whether the distributions are symmetric, how similar or dissimilar they are to normal distributions, what their behavior in the tails is like, and whether or how their variance (or another appropriate measure of scale) varies between different genes or between different conditions. Such differences in the variance may occur for several reasons: in Section 6.3, we discussed the dependence of the variance on the mean, an example of which is given in equation (6.11). There may be other technological effects that can influence the variance of the measurement distributions in a gene- or condition-dependent manner, such as GC content or probe length. Finally, there may be genuine biological differences, such as different tightness of the regulatory control for different genes or for the same gene under different physiological or disease conditions.

Data transformations, such as the logarithmic transformation or a variance-stabilizing transformation like (6.12), may be used to make the distributions more symmetric and possibly close to normal, and to remove the systematic dependence of the variance on the mean (see Section 6.3). In the comparison of two conditions, one might use Student's t-test or the Wilcoxon rank-sum test. Both tests assume that the distributions of the replicate measurements under the two conditions have the same shape and test for differences in the location, with the t-test additionally assuming normal distributions. To account for possibly unequal variances in the two groups, Welch's version of the t-test may be preferred (Welch, 1947; Best and Rayner, 1987). In order to avoid distributional assumptions, Dudoit $et\ al.$ (2002b) proposed to estimate the null distribution of the t-statistic (or, equivalently, of the difference of means) for each gene using permutations of the sample labels. Comparative analyses of different univariate statistical tests in the analysis of gene expression data were presented in Herwig $et\ al.$ (2001), Thomas $et\ al.$ (2001), and Pan (2002), but without a conclusive result.

In addition to standard aspects of hypothesis testing, two specific properties of microarray data have motivated the development of novel strategies:

1. *Variance estimation.* At one extreme, one may try to estimate the variance of the distributions separately for each gene, and possibly for each condition. This requires a large number of repetitions, which are not always available. At the other extreme, one may use a pooled estimate of the variance over all conditions and genes. After the application of a variance-stabilizing transformation such as (6.12), the assumption of constant variance may result in tolerable bias and, due to the large number of genes represented on an array, in very low variance of the estimator. This is the case especially if few repetitions are available. Between the two extremes a number of methods have been proposed that pool the variance estimation over some genes, but also retain some gene dependence.

2. *Multiple testing.* Due to the large number of genes on an array and thus the large number of tests performed, a considerable number of genes may show differential signal intensities simply by chance. Several approaches to assessing the statistical significance of test results obtained from microarray data have been developed.

6.4.1   Regularized t-Statistics

To overcome the instability of the gene-specific variance estimate in the case of few replicate experiments per condition, several authors have proposed methods where a value estimated from a larger set of genes is used to augment the gene-specific standard deviation estimate, thus providing a regularized version of the t-statistic.

Baldi and Long (2001) suggested replacing the within-group empirical variance s_k^2 of gene k in the two-sample t-statistic obtained from d observations by an expression of the form

$$\tilde{\sigma}_k^2 = \frac{v_0\sigma_0^2 + (d-1)s_k^2}{v_0 + d - 2}.$$

This variance estimate results as the posterior mean from a Bayesian hierarchical model for the measurements of each gene under an experimental condition. The measured values are assumed to be normally distributed, and v_0 and σ_0 are hyperparameters of the prior for the parameters of the normal distribution. For practical purposes, the authors recommended choosing σ_0 as the empirical standard deviation obtained from averaging over all genes within a certain intensity range. If a variance-stabilizing transformation has been applied to the data, σ_0 may be obtained from the pooled variance over all genes on the array. The value v_0 is chosen as an integer determining the weight of σ_0 compared to the gene-specific standard deviation. Thus the large number of genes interrogated is exploited to obtain potentially biased but more stable variance estimates for each single gene. The resulting regularized t-statistic, used with a t-distribution with $v_0 + d - 2$ degrees of freedom as null distribution, is shown to perform better than the standard t-test on real and simulated data when there are less than about 5 replications per condition. A similar approach was pursued by Lönnstedt and Speed (2002). Tusher *et al.* (2001), see also Efron *et al.* (2000), also proposed to use a regularized version of the t-statistic, where the empirical standard deviation s_k of gene k is replaced by $\tilde{\sigma}_k = s_k + s_0$, with s_0 determined from the data in a heuristic fashion.

6.4.2 Multiple Testing

Assume that for each gene a statistical test for differential expression has been conducted. If one fixes a genewise significance level of, say, $\alpha = 0.05$, on average one in every 20 genes that are actually not differentially expressed will show a p-value below α just by chance. Due to the large number of genes represented on a microarray, this may lead to a large number of false positive calls. For this reason, Dudoit *et al.* (2002b) suggested choosing a procedure that controls the *familywise error rate* (FWER). The FWER is defined as the probability that the selected set of genes contains at least one false positive. A multiple testing procedure is said to provide *strong control* of the FWER if it controls the FWER for any combination of true and false null hypotheses. If p-values for the test statistics $T_1, \ldots, T_n$ of n genes are available, a simple adjustment that gives strong control of the FWER is the Bonferroni correction, which amounts to multiplying the unadjusted p-values by n. Dudoit *et al.* (2002b) described the use of a stepwise p-value adjustment that is due to Westfall and Young (1993). This procedure is less conservative than the Bonferroni correction and, in contrast to the latter, takes possible dependences between the test statistics into account. The adjusted p-values are estimated by a permutation algorithm.

For many applications, however, control of the FWER is too conservative, with the danger of many interesting genes being missed. As microarrays are often used to screen for candidate genes that may then be validated through further experiments, the researcher may be willing to accept a certain fraction of false positives. This is accommodated by the concept of the *false discovery rate* (FDR; Benjamini and Hochberg, 1995). For a family of hypothesis tests, let R denote the number of rejected null hypotheses, and V the number of falsely rejected null hypotheses. The FDR is defined as

$$FDR = \mathrm{E}\left[\frac{V}{R} \,\middle|\, R > 0\right] \cdot \Pr(R > 0).$$

Benjamini and Hochberg described a procedure to control the FDR under the assumption that the test statistics arising from the true null hypotheses are independent. More precisely, given the set of p-values from all individual hypothesis tests and a desired upper bound q for the FDR, they give a bound p^* such that rejecting all null hypotheses with p-value smaller than p^* guarantees an FDR of at most q for any possible combination of true and false null hypotheses.

Another approach based on the FDR was presented by Storey and Tibshirani (2001); see also Tusher *et al.* (2001). For a given rejection region of the statistical tests, the authors estimated the FDR and the *positive false discovery rate* (pFDR), which is defined as[3]

$$pFDR = \mathrm{E}\left[\frac{V}{R} \,\middle|\, R > 0\right].$$

Rather than computing a rejection region that guarantees an upper bound for the FDR, Storey and Tibshirani assumed that a rejection region was fixed and estimated the FDR on the basis of the distribution of the test statistics. The estimation procedure has been

---

[3] In contrast to the method of Benjamini and Hochberg, where arbitrary but fixed combinations of true and false null hypotheses are allowed, here the null hypotheses are considered as independent and identically distributed Bernoulli random variables that are true with probability π_0.

designed for any kind of dependence between the test statistics and does not require p-values for the single hypothesis tests. The algorithm of Storey and Tibshirani works as follows. They assumed that all null hypotheses were identical and that the same rejection region Γ was used for all test statistics $T_1, \ldots, T_n$, leading to a number $R(\Gamma)$ of rejections. Furthermore, they assumed that the joint null distribution of the test statistics could be simulated by permutations of the sample labels. From this, the authors obtained estimates for the expected number of rejections given that all null hypotheses are true,

$$\widehat{\mathrm{E}}[R^0(\Gamma)],$$

as well as for the probability of at least one rejection,

$$\widehat{\mathrm{Pr}}[R^0(\Gamma) > 0].$$

The pFDR is then estimated by

$$\widehat{\mathrm{pFDR}}(\Gamma) = \frac{\hat{\pi}_0 \cdot \widehat{\mathrm{E}}[R^0(\Gamma)]}{\widehat{\mathrm{Pr}}[R^0(\Gamma) > 0] \cdot \max(R(\Gamma), 1)}, \tag{6.17}$$

and the FDR similarly by

$$\widehat{\mathrm{FDR}}(\Gamma) = \frac{\hat{\pi}_0 \cdot \widehat{\mathrm{E}}[R^0(\Gamma)]}{\max(R(\Gamma), 1)}. \tag{6.18}$$

The expected proportion $\hat{\pi}_0$ of true null hypotheses is estimated as follows. Let Γ' be a rejection region whose complement is likely to be achieved mostly for true null hypotheses. The estimate for π_0 is obtained as

$$\hat{\pi}_0 = \frac{n - R(\Gamma')}{\widehat{\mathrm{E}}[n - R^0(\Gamma')]}.$$

In order to determine how many falsely significant genes may appear with a certain probability, or how likely it is that *all* genes with test statistics in the rejection region are false positives, it is interesting to estimate not only the pFDR, but also quantiles of the distribution of V/R. This is illustrated in Figure 6.5.

Under certain conditions on the dependence structure between the test statistics, it was shown by Storey and Tibshirani (2001) that for all π_0, the estimates are greater than or equal to the true values of the FDR and pFDR in expectation. In Storey (2001) (see also Efron *et al.*, 2001), it is shown that in the case of independent test statistics (and asymptotically also for some forms of dependence) the pFDR can be interpreted in a Bayesian framework as the posterior probability that a gene is not differentially expressed, given its test statistic lies in the rejection region:

$$\mathrm{pFDR}(\Gamma) = \mathrm{Pr}(H = 0 | T \in \Gamma).$$

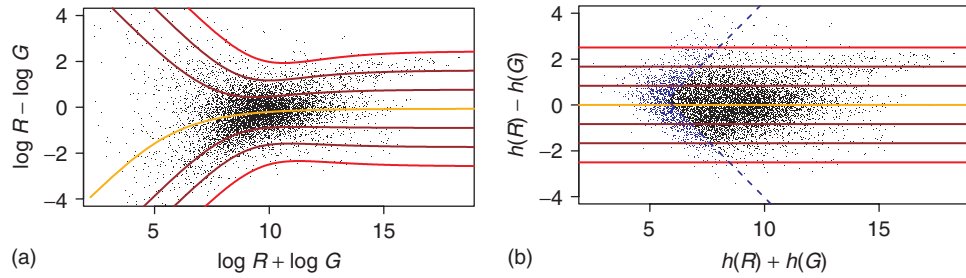
A special property of the approach of Storey and Tibshirani and Tusher *et al.* is how it makes use of the assumption that the null distributions of the test statistics are identical for all genes. The fact that the estimation procedure is based on the test statistics of *all* genes under permutation of the sample labels gives accurate estimates for relatively few replicate experiments, while at the same time it preserves the dependence structure
Plate 1. The detected intensity distributions from a cDNA microarray for a region comprising around 80 probes. The total number of probes on an array may range from a few dozen to tens of thousands. Left: gray-scale representation of the detected label fluorescence at 635 nm (red), corresponding to mRNA sample A. Right: label fluorescence at 532 nm (green), corresponding to mRNA sample B. Spots that light up in only one of the two images correspond to genes that are only transcribed in one of the two samples. Center: false-color overlay image from the two intensity distributions. The spots are red, green, or yellow, depending on whether the gene is transcribed only in sample A, sample B, or both.
Plate 2. False-color representations of the spatial intensity distributions from three different 64×136 spot cDNA microarrays from one experiment series: (a) Probe intensities in the red color channel; (b) local background intensities; (c) background-subtracted probe intensities. In (a) and (b), there is an artifactual intensity gradient, which is mostly removed in (c). For visualization, the color scale was chosen in each image to be proportional to the ranks of the intensities. (d) For a second array, probe intensities in the green color channel. There is a rectangular region of low intensity in the top left-hand corner, corresponding to one print-tip. Apparently, there was a sporadic failure of the tip for this particular array. (e) and (f) show the probe intensities in the green color channel from a third array. The color scale was chosen proportional to the logarithms of intensities in (e) and proportional to the ranks in (f). Here, the latter provides better contrast. Interestingly, the bright blob in the lower right-hand corner appears only in the green color channel, while the crescent-shaped region appears both in green and red (not shown).
Plate 3. Scatterplot of a pairwise comparison of noncancerous colon tissue and a colorectal tumor. Each individual transcripts is represented by a ×. The *x*-coordinate is the average of the appropriately calibrated and transformed intensities (see Section 6.3). The *y*-coordinate is their difference, and is a measure of differential transcription. The array used in this experiment contained 152 000 probes representing around 70 000 different clones. Since plotting all of these would lead to an uninformative solid black blob in the centre of the plot, the point density is visualized by a color scale, and only 1500 data points in sparser regions are individually plotted.
Plate 4. Scatterplot of a triple comparison between noncancerous colon tissue, a lymph-node negative colorectal tumor (N0), and a lymph-node positive tumor (N1). The measurements from each probe correspond to a point in three-dimensional space, and are projected orthogonally on a plane perpendicular to the (1,1,1)-axis. The three coordinate axes of the data space correspond to the vectors from the origin of the plot to the three labels 'normal', 'tumor N0', and 'tumor N1'. The (1,1,1)-axis corresponds to average intensity, while differences between the three tissues are represented by the position of the measurements in the two-dimensional plot plane. For instance, both *c-myc* and *nme1* (nucleoside diphosphate kinase A) are transcribed higher in the N0 and in the N1 tumor, compared to the noncancerous tissue. However, while the increase is approximately balanced for *c-myc* in the two tumors, *nme1* is more upregulated in the N1 tumor than in the N0 tumor, a behavior that is consistent with a gene involved in tumor progression. On the other hand, the apoptosis-inducing receptor *trail-r2* is downregulated specifically in the N1 tumors, while it has about the same intermediate–high transcription level in the noncancerous tissue and the N0 tumor. Similar behavior of these genes was observed over repeated experiments.
Plate 5. (a) Scatterplot of intensities from a pair of single-color cDNA arrays, comparing renal cell carcinoma to matched noncancerous kidney tissue. Similar to Plate 4, the x-coordinate represents average and the y-coordinate differential signal. At the bottom of the plot, there is a cloud of probes that appear to represent a cluster of strongly downregulated genes. However, closer scrutiny reveals that this is an experimental artifact: (b) shows the boxplots of the intensities for the two arrays, separately for each of the 41 PCR plates (see text). Probes from plates 21, 22, 27, and 28 have extraordinarily high intensities on one of the arrays, but not on the other. Since the clone selection was quasi-random, this points to a defect in the probe synthesis that affected one array, but not the other. The discovery of such artifacts may be helped by coloring the dots in the scatterplot by attributes such as PCR plate of origin or spotting pin. While the example presented here is an extreme one, caution toward batch artifacts is warranted whenever arrays from different manufacturing lots are used in a single study.


Plate 6. Scatterplot of differential versus total intensities from a two-color cDNA array, using two different transformations: (a) logarithmic; (b) equation (6.12). The horizontal lines correspond to the z-score $\Delta h/\hat{c} = 0, \pm 1, \pm 2, \pm 3$. The z-score of a pair of red and green probe intensities is their difference divided by its expected standard deviation according to the variance-versus-mean function $v(u)$. The z-score is a statistical measure of how strongly an observed pair of intensities is indicative of true differential abundance. While the contours of the z-score are functions of both log ratio and total intensity (a), they are independent of total intensity in the coordinate system of (b). Due to a local background subtraction, this data set contained small and negative net intensities. (a) shows measurements with $R, G > 0$ and $\log(RG) > 2.5$. All data is shown in (b), with the subset of the upper panel to the right of the dashed line.
Figure 6.5 Estimation of the false discovery rate. Using 24 arrays with 32 000 cDNA probes each, 12 pairs of matched breast cancer tissue samples dissected before and after neoadjuvant chemotherapy were compared. Differentially transcribed genes were selected according to the absolute value of the one-sample t-statistic. The rejection region Γ was fixed such that 50 genes were selected (solid line). The histogram shows the distribution of $R^0(\Gamma)$, estimated from all 924 balanced sign flips. The dashed and dotted lines show median and mean respectively. The mean may be used as an estimate of $E[R^0(\Gamma)]$ in (6.17) and (6.18). Note the skewness of the distribution of $R^0(\Gamma)$.

between genes. On the other hand, this type of procedure is not able to take possibly unequal variances in the two classes into account.

6.5 PATTERN DISCOVERY

Unsupervised as well as supervised learning methods play a central role in the analysis of microarray gene expression data. Supervised methods aim to infer information from the data with respect to a predefined response variable. For instance, in the context of tumor diagnostics one tries to classify mRNA samples obtained from tumor cells with respect to given tumor types. The application of classification methods to microarray data was discussed, for example, in Golub *et al.* (1999), Ben-Dor *et al.* (2000), Dudoit *et al.* (2002a), and Spang *et al.* (2002). In the following, we focus on unsupervised methods, which aim to detect structures in the data without making use of gene or sample annotations. A primary purpose of such methods is to provide a visualization of the data in which conspicuous structures can easily be recognized. These may be relations among genes, among samples, or between genes and samples. The perception of such structures can lead the researcher to develop new hypotheses: for example, the result of a clustering of genes may indicate the putative involvement of uncharacterized genes in a biological process of interest, whereas a separation of the expression profiles of a set of patient tissue samples into clusters may point to a possible refinement of disease taxonomy. On the other hand, unsupervised methods are often used to confirm known differences between genes or samples on the level of gene expression: if a clustering algorithm groups samples from, say, two different tumor types into distinct clusters without using prior knowledge, this provides evidence that the tumor types do indeed show clearly detectable differences in their global gene expression profiles.

For all of the following methods, we assume that we have a gene expression data matrix of suitably calibrated and transformed expression levels with, say, the rows corresponding to genes and the columns corresponding to cell or tissue samples.

6.5.1 Projection Methods

An important class of unsupervised methods works through dimension reduction. The row or column vectors of a gene expression data matrix are projected onto a low-dimensional space such that some measure of similarity between the vectors is optimally preserved. The projected data may be visualized through one or more scatterplots, in the hope that these convey important information contained in the data.

In *principal component analysis*, mutually orthogonal linear combinations of the row or column vectors (the principal components) are computed, such that the ith principal component has maximal variance among all vectors orthogonal to the first $i - 1$ principal components. In applications, one may hope that the first few principal components carry most of the information contained in the data, which can then be displayed in scatterplots. Alter *et al.* (2000) demonstrated the use of principal component analysis for a gene expression study of the cell cycle in yeast. The first principal component was found to reflect experimental artifacts and was consequently filtered out. After that, the authors found that the first two principal components ('eigengenes') are well described by a sine and cosine function of time, respectively. The interpretation is that these 'eigengenes' reflect oscillating gene expression patterns, while the corresponding 'eigenarrays' define a two-dimensional coordinate system for the cell cycle phases.

In *correspondence analysis*, the rows and the columns of a nonnegative data matrix are simultaneously projected onto a low-dimensional space (Greenacre, 1984). The method decomposes the deviations from homogeneity between rows and columns, as we will now explain. For the data matrix $\mathbf{Y}$, let y_{k+} and y_{+i} be the sum of the kth row and the ith column, respectively, y_{++} the grand total, and $r_k = y_{k+}/y_{++}$ and $c_i = y_{+i}/y_{++}$ the mass of the kth row and the ith column. The matrix $\mathbf{S}$, with elements

$$s_{ki} = (y_{ki}/y_{++} - r_k c_i)/\sqrt{r_k c_i},$$

undergoes singular value decomposition, $\mathbf{S} = \mathbf{U}\mathbf{\Lambda}\mathbf{V}^{\mathrm{T}}$. Note that the sum of the squared elements of $\mathbf{S}$ is just the χ^2-statistic of $\mathbf{Y}$. Suitably normalized columns of $\mathbf{U}$ and $\mathbf{V}$ provide the principal coordinates for the rows and the columns of $\mathbf{Y}$, respectively:

$$f_{kj} = \frac{\lambda_j u_{kj}}{\sqrt{r_k}}, \qquad g_{ij} = \frac{\lambda_j v_{ij}}{\sqrt{c_i}}.$$

Usually, only the first two or three principal coordinates are used for a simultaneous display of the rows and columns of the data matrix. The corresponding entries of $\mathbf{\Lambda}$ reflect which proportion of the χ^2-statistic of $\mathbf{Y}$ is represented in the low-dimensional projection. The distances between rows and between columns approximate their χ^2 distances, and moreover, the association between rows and columns is reflected in a biplot: a row and a column that are positively (negatively) associated will approximately lie on the same (opposite) half-ray through the origin, with the distance from the origin reflecting the strength of the association. An example is shown in Plate 7.

6.5.2 Cluster Algorithms

Cluster algorithms generally aim to group objects according to some notion of similarity. An overview of issues and methods in cluster analysis is given in Jain and Dubes (1988). For microarray data, clustering may be applied to the genes whose expression levels are measured, with the expectation that functionally related or coregulated genes will show similar expression patterns. On the other hand, one may use clustering to analyse the expression profiles of a set of cell or tissue samples with the hope that samples with similar biological characteristics will be grouped together. Cluster algorithms are explicitly or implicitly based on a quantitative measure of dissimilarity between the objects of interest. In the case of row and column vectors of a gene expression data matrix, typical examples are the Euclidean distance or 1 minus the correlation coefficient. For the clustering of genes based on their expression patterns, the latter is often used because it is invariant under affine-linear transformations of the input vectors and focuses on the pattern of relative changes.

In *hierarchical* clustering algorithms, a tree structure (dendrogram) is computed that contains the objects as leaves. *Agglomerative* methods build the tree starting with the leaves (Eisen *et al.*, 1998), whereas in *divisive* methods (Alon *et al.*, 1999) the set of objects is iteratively partitioned into subsets. To obtain a partition of the set of objects into clusters, the resulting dendrogram may be cut at a certain height. In the analysis of microarray data, however, hierarchical clustering is often simply used to obtain a linear ordering of both the rows and the columns of a gene expression data matrix such that similar rows or columns are located close to each other. The reordered data matrix is then displayed using a color map, which may be a powerful visualization tool. However, many implementations of hierarchical clustering do not try to find an optimal linear order of the n leaves of the obtained dendrogram out of the 2^{n-1} possible orders that are compatible with the tree structure. Bar-Joseph *et al.* (2001) described an efficient algorithm to compute an optimal linear order of the set of leaves of a cluster tree compatible with the tree structure in the sense that the sum of distances of pairs of neighboring leaves is minimized.

Nonhierarchical clustering algorithms directly yield a partition of the set of objects into clusters, the number of which has to be fixed in advance in most methods. Examples are k-means clustering, partitioning around medoids (Dudoit and Fridlyand, 2002) and self-organizing maps (Tamayo *et al.*, 1999). A graph-theoretical clustering method that was developed especially for gene expression data is described in Ben-Dor *et al.* (1999).

An important but difficult question in cluster analysis is that of the validity of the results. Cluster analysis assumes that the data are organized in distinguishable clusters. However, a cluster algorithm will usually also produce a set of clusters if this assumption is not fulfilled. Furthermore, the results may be affected by random fluctuations of the data. Thus, it is of interest to estimate the number of clusters present in a data set (if any), as well as to assess the variability of various features of the result.

Dudoit and Fridlyand (2002) proposed an approach for estimating the number of clusters in a data set. In the first step, they applied a clustering algorithm to a subset of all observations. Then they analyzed how much an assignment of the remaining observations to the clusters by a class prediction method coincided with the partition obtained from clustering these observations. Through comparing the resulting measure of predictability to that obtained under a null model without cluster structure, they arrived at a quality index that can be computed for different numbers of clusters. If none of the predictability values is significant, there is no evidence for clusters in the data, whereas otherwise the

number of clusters yielding the highest quality index is chosen. The performance of this approach was demonstrated using simulated data and real gene expression data, where clustering is applied to the samples. However, one might imagine that real data sometimes lie between the extreme cases of a common distribution for all objects on the one hand and distinct clusters on the other. Furthermore, if the objects are organized in hierarchically nested clusters, such that there are partitions at different levels of granularity, the question of how many clusters are present is not meaningful without further specifications.

Kerr and Churchill (2001b) used the bootstrap in order to assess the reliability of the results of a cluster analysis. Resampling was performed on the residuals of an analysis of variance model, yielding stability values for the assignment of genes to prespecified clusters. In a more general context, Pollard and van der Laan (2002) analyzed the performance of the bootstrap in assessing the variability of the results of a wide class of clustering methods. Assuming that the expression profiles of the biological samples are generated from a mixture of n-variate probability distributions, where n denotes the number of genes, they gave a general definition of clustering methods (for clustering genes or samples, or the simultaneous clustering of genes and samples) as algorithms to estimate certain parameters of the data-generating distribution. Although an underlying probabilistic model is assumed, the cluster algorithms under consideration do not have to be model-based. This framework allows concepts of statistical inference to be applied to clustering algorithms. In a simulation study, they analyzed both the nonparametric (resampling of sample expression profiles) and the parametric bootstrap (based on normal distributions). The results indicated that both bootstrapping methods are able to assess the variability of various quantities describing the output of a clustering algorithm. In addition, the authors proposed to test the statistical significance of a clustering of samples via the comparison with data generated from an appropriate null model. A similar approach for the evaluation of temporal gene expression patterns was presented in Dougherty *et al.* (2002). Assuming the expression pattern of each gene to be generated from one of several multivariate normal distributions, the authors analyzed the error rate of various clustering algorithms in determining the correct cluster membership of genes.

Probabilistic clustering methods assume that each observation belongs to a cluster k with probability π_k, and the observations within each cluster k are generated according to a probability distribution $\mathcal{L}_k$. After the number of clusters and the family of admissible probability distributions have been specified, the model parameters and the most likely cluster assignment of each observation can be estimated by maximum likelihood. This is usually done via the expectation–maximization algorithm (Dempster *et al.*, 1977), starting with some initial clustering. In such a probabilistic framework, it is possible to assess the adequacy of different models – concerning the number of clusters, as well as the allowed parameter space for the component distributions – through the Bayesian information criterion (Fraley and Raftery, 1998). The application of model-based clustering to microarray data is described in Yeung *et al.* (2001), Ghosh and Chinnaiyan (2002), and McLachlan *et al.* (2002). Concerning the clustering of genes, the application of normal mixture models, possibly with constraints on the covariance matrices in order to reduce the number of free parameters, is more or less straightforward. On the other hand, the application of model-based methods to the clustering of samples poses problems, because in typical microarray data sets the number of genes, and thus the number of parameters to be estimated, exceeds by far the number of samples. Ghosh and Chinnaiyan (2002) suggested clustering the samples via a model-based approach using

the first few components obtained from a principal component analysis. McLachlan *et al.* (2002) proposed clustering the samples into a mixture of factor analysis models.

6.5.3   Local Pattern Discovery Methods

One limitation of clustering methods as described in Section 6.5.2 lies in the fact that they are based on a global measure of similarity between the rows or the columns of the data matrix. However, there may be biologically relevant situations where tissue samples share similar expression levels of one particular set of genes, for example, those belonging to a molecular pathway that is active in this group, whereas they differ with respect to the expression of other genes. Also the similarity of the expression levels of a group of genes may be present only under certain biological conditions. We give a brief overview on methods that were developed with the aim of detecting such structures in an unsupervised fashion.

Getz *et al.* (2000) described an algorithm where hierarchical clustering is alternately applied to the rows and columns of submatrices of the data matrix, the rows and columns of which were obtained as stable clusters in previous iterations.

A number of authors have suggested methods to identify interesting submatrices of a gene expression data matrix (Califano *et al.*, 2000; Chen and Church, 2000; Ben-Dor *et al.*, 2002; Lazzeroni and Owen, 2002). The underlying idea is that a set of genes, perhaps belonging to a common molecular pathway, are coregulated only under certain experimental conditions. This notion is quantified in terms of a score function on submatrices of a gene expression matrix. As the number of submatrices is exponential in the number of genes and the number of samples, efficient heuristics are applied in order to find high-scoring submatrices. The submatrices identified can be evaluated in terms of their statistical significance.

For the identification of conspicuous class distinctions among a set of tissue samples based on microarray data, special approaches have been proposed (Ben-Dor *et al.*, 2001; von Heydebreck *et al.*, 2001). These are based on a score function that quantifies the strength of differential gene expression for any possible bipartition of the set of samples. An optimization algorithm is used in order to find high-scoring bipartitions. As the scoring is not based on global properties of the gene expression profiles, but rather on the presence of subsets of genes that are differentially expressed, several independent bipartitions can be obtained, each based on a specific subset of differentially expressed genes. von Heydebreck *et al.* (2001) show that this approach is able to detect biologically meaningful class distinctions that are not identified with cluster algorithms based on a global dissimilarity measure.

6.6   CONCLUSIONS

We have described different aspects of microarray gene expression data analysis, from quality control of the raw probe intensity data, via calibration, error modeling, and the identification of differentially transcribed genes to explorative methods such as clustering or pattern discovery. Yet, statistical analysis is only one part of a microarray experiment. Frequently, data analysis is expected to correct for technological problems or shortcomings in the design of an experiment. Awareness has grown, though, in recent years; interaction

between experimentalists and data analysts is improving and, very importantly, starting early in the planning of an experiment. This raises the hope that statistical analysis will in future be less and less diverted by troubleshooting, and can increase its focus on generating and validating biological hypotheses from the data.

Unlike with, for example, sequence data, it is still extremely difficult to relate different experiments to each other and to quantitatively compare their results. Much stricter standardization of the measurement process, which will have to include significant improvements of present technologies or development of new ones, will be necessary to obtain measurements that would be comparable across laboratories. As a result, currently each experiment has to be large enough to be analyzable by itself because it is still not feasible to view one's own experiment as an incremental addition to an existing knowledge base on gene expression. While this is both a technical problem and a data integration problem, suggestions regarding the data standardization aspect are given in Brazma *et al.* (2001).

Microarray-based experiments are frequently seen as the stronghold of hypothesis-free genome research. While debatable in itself, this assertion simply shifts the responsibility to the computational scientist analyzing the data. In the absence of a clear hypothesis much of the analysis will be of an exploratory nature. Once this leads to a hypothesis further independent verification is needed. This embeds microarray experiments and statistical analysis into a feedback cycle producing new experiments.

Statistical Inference for Microarray Studies

S.B. Pounds, C. Cheng and A. Onar

Department of Biostatistics, St. Jude Children's Research Hospital, Memphis, TN, USA

Microarrays enable investigators to simultaneously measure the expression levels of thousands of genes in a tissue sample. The technology presents exciting avenues for biological research coupled with interesting statistical challenges. Several methods to address these challenges have been proposed and applied in the literature. We review some methods developed for use in what we term *phenotype-association analyses* that aim to identify a set of genes whose expression is associated with a particular phenotype. A phenotype-association analysis typically consists of initial data processing, tests of the association of expression with phenotype, multiple-testing adjustments, annotation analysis, and validation analysis. We briefly describe some methods used for each of these stages of phenotype-association analysis and describe methods used for performing sample-size calculations in planning a microarray study. We also describe the underlying assumptions of these methods and outline some very basic considerations for choosing which methods are best suited for specific applications.

7.1 INTRODUCTION

Microarrays have opened new and exciting possibilities in biomedical research. The technology allows investigators to measure the messenger-RNA levels of thousands of genes simultaneously. More recently, microarrays have been developed that allow researchers to query genomic DNA at thousands of positions simultaneously as well.

Not surprisingly, the analysis of microarray data presents several statistical challenges including, but certainly not limited to, data reduction, normalization, correlation of variables, and multiple testing. None of these are new to statistics; however, in microarray data, the magnitude of these problems is unprecedented. These challenges provide opportunities for development of new statistical methods.

Statistical researchers have responded to these opportunities by proposing new statistical methods to address these challenges. The number of statistical methods proposed for the

analysis of microarray data has been growing exponentially over the past decade (Mehta *et al.*, 2004). In 2003, roughly 90 articles were published that describe new methods for analysis of microarray data (Mehta *et al.*, 2004). Now, there are several books that address the statistical analysis of microarray data (Draghici, 2003; Allison *et al.*, 2006; Do *et al.*, 2006; Lee, 2004; Simon *et al.*, 2003; Gentleman *et al.*, 2005; Speed, 2003; Parmigiani *et al.*, 2003).

Microarray studies often have one or more of the following objectives: class discovery, class prediction, or phenotype association. In class discovery, the objective is to use the microarray data to partition subjects or samples into biologically meaningful classes that have not been previously defined. Clearly, the idea of 'biologically meaningful' is subjective, and hence the analyses are very exploratory in nature. In class prediction, the objective is to use microarray data to accurately assign subjects or samples into a set of predefined classes. Class-prediction analyses typically rely on a variety of machine and statistical-learning methods to achieve their objective. In phenotype-association analyses, the objective is to identify which genes' (or microarray probe sets') expression is associated with a phenotype of interest. For each probe set, a phenotype-association analysis typically tests the null hypothesis that gene expression is not associated with phenotype and then corrects for multiple testing. Additionally, a phenotype-association analysis often performs a bioinformatics follow-up assessment to determine whether genes with specific annotations, such as ontology (`www.geneontology.org`) or pathway membership (`http://www.genome.jp/kegg/pathway.html`), tend to be more highly represented among the 'significant' genes than expected by chance. This chapter outlines some methods for performing phenotype-association analyses; some useful resources for those interested in class discovery or class-prediction analyses are mentioned briefly below. **Chapters 6** and **8** also review statistical methods for the analysis of microarray data.

Class-discovery analyses use clustering algorithms to assign subjects (or samples) into groups that are similar according to a specified distance metric. Class-discovery analyses are often criticized because they do not test a well-specified hypothesis, many of the clustering algorithms utilized will assign samples of any data set (even complete noise) into classes, and it is unclear how to generalize the results of a class-discovery analysis to a population (Mehta *et al.*, 2004). Despite these shortcomings, class-discovery analyses can lead to biologically important discoveries. For example, the results of a class-discovery analysis led Thompson *et al.* (2006) to identify distinct genomic lesions in pediatric medulloblastoma tumor cells. Nevertheless, it is still important that the statistical analysis attempts to address the concerns of Mehta *et al.* (2004). As mentioned above, a major concern is that many clustering algorithms will assign the subjects into groups even if the data set is completely random noise (McShane *et al.*, 2002). Clearly, in such cases, no 'meaningful' subclasses exist. McShane *et al.* (2002) propose a method to test a null hypothesis of unimodality prior to applying clustering algorithms. Rejection of unimodality indicates that the data set has multiple modes that may be attributed to the existence of two or more distinct subgroups. A class-discovery analysis should also assess the reproducibility, stability, or both, of the resulting cluster assignments (Dudoit and Fridlyand, 2003). Dudoit and Fridlyand (2003), and Smolkin and Ghosh (2003) have proposed methods that use resampling or subsampling to assess cluster reproducibility or stability.

Class-prediction analyses apply statistical-learning (Hastie *et al.*, 2001) or machine-learning (Kecman, 2001) algorithms to a 'training' data set to develop a classifier that

assigns samples into predefined classes and then evaluate the performance of the classifier on a 'test' or 'validation' data set in terms of classification accuracy. The prevalence of class-prediction analyses in the literature may give some investigators (and reviewers) the impression that class prediction is the preferred analysis approach for most microarray studies. However, this is not so. Michiels *et al.* (2005) found that each of the seven largest studies that used class-prediction analyses to examine the association of gene expression with relapse published overly optimistic estimates of prediction accuracy. Additionally, they found that five of the seven studies failed to show that their classifiers were significantly more accurate than random class assignment. Some of these overly optimistic estimates may arise because the validation and training phases of the analysis were not performed totally independent of each other (Allison *et al.*, 2005; Quackenbush, 2006). Moreover, these studies were too small to accommodate training and validation data sets of adequate size to achieve the statistical power needed to develop an accurate classifier and demonstrate that the classifier performs significantly better than chance. Nevertheless, preliminary studies indicate that classifiers based on microarray data may be useful diagnostic tools for some clinical applications. Thus, some studies with the objective of developing and validating classifiers based on microarray gene-expression data are still needed. Simon (2005a; 2005b) provides an excellent overview of how to plan and execute microarray studies with the ultimate objective of developing a useful classifier based on gene expression.

A phenotype-association analysis, the primary focus of this chapter, typically involves at least three basic steps: initial data processing (IDP), tests of the association of phenotype with expression (TAPE), and multiple-testing adjustments (MTA). Validation analysis (VA) and annotation analysis (AA) are two additional steps that are becoming common components of phenotype-association analyses. Figure 7.1 illustrates the steps of a phenotype-association analysis in a flowchart. In IDP, image signals are converted, summarized, and normalized into meaningful probe-set or gene-expression signals. Additionally, IDP may filter out probe sets that are believed to represent genes that are not expressed in any study samples or poorly represent the expression of the targeted gene. The second step, TAPE, applies a statistical procedure to describe and test the association of each probe set's expression signals with the phenotype of interest. The phenotype may be assigned experimentally (e.g. treatment vs. control) or collected in an observational study (e.g. tumor subtype in a human study). The third step, MTA, controls or estimates an appropriate multiple-testing error rate such as the false discovery rate (FDR) (Benjamini and Hochberg, 1995) or the generalized family-wise error rate (gFWER) (van der Laan *et al.*, 2004a). The fourth step, VA, explores the reproducibility of results via cross-validation, bootstrapping, or other data perturbation methods. The fifth step, AA, attempts to determine if the most promising genes found in steps 2 and 3 show a significant tendency to be annotated to specific ontologies or pathways.

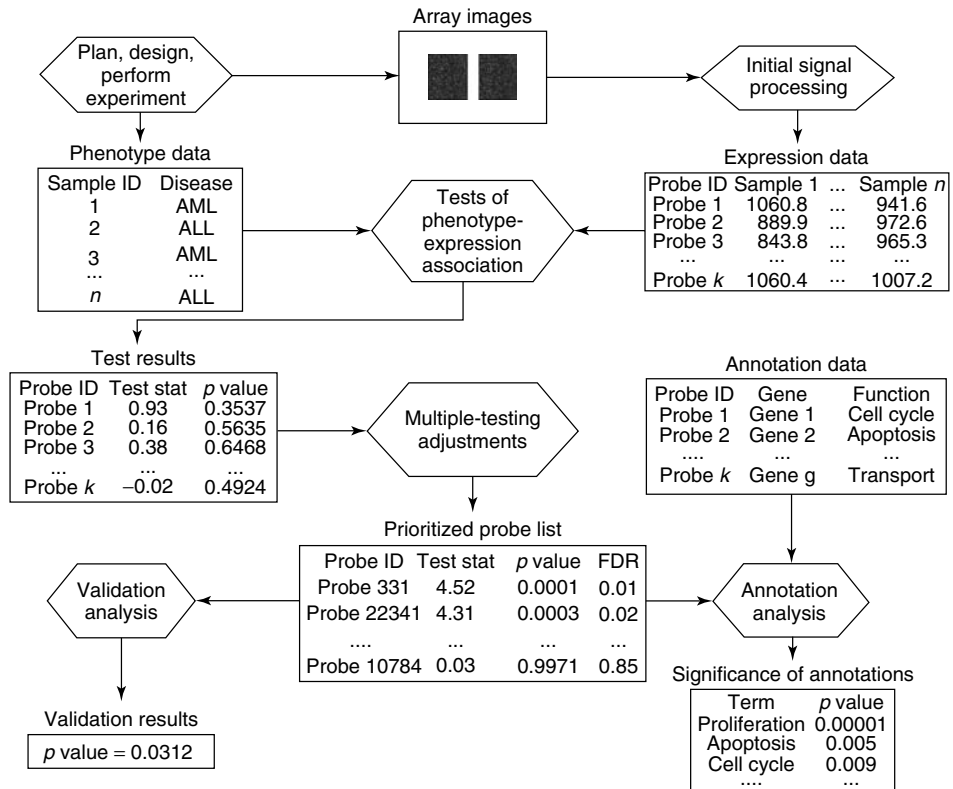
There are several freely available software tools to implement each component of a phenotype-association analysis. Table 7.1 lists websites where some of these software tools can be obtained. The Bioconductor project (www.bioconductor.org; Gentleman *et al.*, 2004; 2005) represents one of the most comprehensive collections of software tools for the analysis of microarray data. Bioconductor is a collection of R software (www.r-project.org) routine libraries to implement various analysis methods. R is a freely available programming language and implementation platform that includes several functions and software libraries that are useful for statistical computations. Thus,


Figure 7.1   Flowchart diagram of a phenotype-association analysis.

effective use of Bioconductor requires some programming (RSP). Other software tools use web-based interfaces (WBI) or are stand-alone packages that offer a graphical user interface (GUI).

The variety of available methods presents the challenge of choosing the best method(s) for a specific application. Several comparisons of methods have been performed via simulation studies, analysis of spike-in data sets, and analysis of case-study applications (Lin and Johnson, 2003; Choe *et al.*, 2005). At present, there is little consensus regarding which methods are best for any of the five components of a phenotype-association analysis and very little work has explored which combination of methods is best for specific applications. Nevertheless, there are some key points to consider when choosing a method. First, the method should be designed to explore the type of phenotype under consideration. For example, it is inappropriate to treat a time-to-event variable, such as duration of remission from cancer or survival time, as a binary outcome without accounting for censoring and follow-up time (Jung *et al.*, 2005a). Additionally, one should consider whether the underlying assumptions of a particular method are reasonable and how robust the method is likely to be against those violations. Many methods have been proposed without explicit or thorough descriptions of their underlying assumptions. The assumptions of a specific method can be ascertained indirectly by envisioning settings that may lead the algorithm to yield misleading results. For example, one might try

to envision how a method would perform if many or few genes were associated with the phenotype, how it might be affected by outliers, how it may perform under various dependency structures, and how it would manage potential heteroskedasticity. Hopefully, as more comparisons of methods are performed, the conditions under which various methods perform reliably will become more thoroughly understood and more specific recommendations will be possible. In this chapter, we review some methods that have been proposed for phenotype-association analyses. We acknowledge that the review is not exhaustive; an exhaustive review is not feasible in this venue given the vast amount of recent research activity in the area.

7.2 INITIAL DATA PROCESSING

At the most fundamental level, microarray data are image files of the florescent signals on the arrays. In their initial state, these image files are not useful for performing statistical analyses to address questions of practical interest. The information in these image files must be summarized into probe-set expression signals that can be used to perform biologically meaningful comparisons across arrays. A data file with information regarding the location of probe sets on the array is used in conjunction with each image file to produce a file that gives a summarized, florescent-intensity signal for each probe set that targets a known or hypothetical gene. Technically speaking, probes are individual features printed on the array, collections of probes are called probe sets, and a probe set is intended to measure the expression of a specific gene. However, in this chapter, we use the terms *probe*, *probe set*, and *gene* interchangeably. A number of purely technical factors can influence these summarized signals. It is often necessary to adjust the signals for these

technical factors before statistical analyses can meaningfully explore the association of these signals with phenotype. The term *normalization* is used to describe data processing that intends to transform the summarized intensity signals into expression signals that are biologically comparable across arrays. Additionally, sometimes probe sets that are deemed as unreliable or believed to represent genes that are unexpressed across all samples are excluded prior to subsequent analysis. The term *filtering* is used to describe data processing that attempts to identify probe sets that should be excluded from statistical analysis.

In this section, we briefly review some normalization and filtering methods. Table 7.2 lists some methods for normalization and filtering. More detailed reviews on normalization are given by **Chapter 6**, Quackenbush (2002), Reimers (2005), Eckel-Passow *et al.* (2005), and Steinhoff and Vingron (2006).

7.2.1   Normalization

A wide variety of methods to normalize microarray signals have been proposed. From a general perspective, the methods fall into one of a few categories: scaling, quantile normalization, local regression (loess) normalization, and model-based normalization. Scaling methods, such as the normalization algorithm of Microarray Analysis Software, version 5.0 (MAS 5.0, `www.affymetrix.com`), assume that each array should have a similar mean or median signal across probe sets. Quantile-normalization methods assume that each array's probe-set signals should have the same distribution. Model-based methods make assumptions typically used in most general linear models. Loess normalization methods assume that the technical biases are intensity dependent, and fit loess curves to identify and remove those biases.

Model-based normalization methods attempt to explicitly account for specific technical sources of variation in the array signals. For example, Wolfinger *et al.* (2001) proposes that the observed initial signals be the dependent variable in a linear model that includes terms for technical factors such as dye, technician, array, spots, pens, and so on, as predictor variables. The residuals from this model are then used as the normalized signals in subsequent analyses. The approach offers essentially the same flexibility as general linear models (Graybill, 1976). Thus, in principle, linear models could be used to normalize data from oligonucleotide arrays or two-color arrays (see **Chapter 6** for more information on the various array platforms). Kerr *et al.* (2000) and Cheng *et al.* (2004, Appendix) also describe normalization methods that utilize linear modeling. Of course, such model-based normalization methods also rely on all the classical assumptions of general linear models, namely that residuals are independent and identically distributed (i.i.d.) normal variables with equal unknown variance. In practice, it may be difficult to determine which specific technical factors should be included in the first model step. Furthermore, the data regarding technical sources of variation may not have been recorded by the laboratory technician or the investigator.

Li and Wong (2001) and Irizarry *et al.* (2003b) propose model-based normalization methods for oligonucleotide arrays. Their models include terms specific to the array platform (e.g. probe effects, etc.), but do not include terms for specific sources of technical variation associated with sample preparation and processing. Thus, the detailed information regarding sample processing and preparation are not required for the algorithms to compute normalized signals. Implicitly, these normalization methods attempt to account for such factors by including an array effect in the model.

Bolstad *et al.* (2003) proposed the quantile-normalization method. Quantile normalization first sorts array signals separately within each array. Next, it computes the average signal for each signal rank. More explicitly, the average of the maximum signal is computed, and then the average of the second largest signal is computed, and so on. Next, for each array, the normalized signals of each probe set are assigned to be the average signals for its rank within the array. For example, the probe set with the highest initial signal is assigned the average of the maximum signals across arrays. Thus, after normalization, a plot of the quantiles of signals from one array against the quantiles of signals from any other array would fall along the line $y = x$.

Yang *et al.* (2002) observed that often the simple scaling methods could not properly normalize two-color cDNA microarray data since the log-transformed signal intensity ratios tended to be intensity dependent. This phenomenon was most prevalent for low intensity spots. Thus they devised an approach based on locally weighted linear regression (lowess) for normalization. This method utilizes what is known as a *ratio-intensity plot* (RI plot) or as a *minus-add plot* (MA-plot), where log ratios of expressions between the two dyes are plotted on the y-axis against log-intensity (average log expression for the two dyes) values on the x-axis. A lowess curve is then fitted to the data which is subsequently used as the basis for normalization by subtracting the best fit from the observed log ratio (see **Chapter 6** for details and examples).

Clearly, normalization methods can have nontrivial effects on the subsequent statistical analyses because the normalized signals are the input data. Thus, any artifacts introduced by the normalization procedure are carried forward into later analyses; as the old adage says, 'garbage in – garbage out'. Hoffmann *et al.* (2002), Irizarry *et al.* (2003b), Choe *et al.* (2005), and Harr and Schlotterer (2006) have explored the impact of normalization

on the inferences of the final statistical analysis. In many cases, the effects are not negligible. At present, there does not appear to be a method that is clearly a good performer across a wide range of data sets. In the analysis of their spike-in experiment, Choe *et al.* (2005) found that lowess renormalization of MAS 5.0-normalized signals gave the most accurate final statistical inferences. In the analysis of the Affymetrix Latin Square spike-in experiment, Irizarry *et al.* (2003b) noted that their normalization methods led to more accurate inferences than did normalization by the Affymetrix algorithm. As mentioned in the introduction, the selection of a normalization method should be guided by considering method with the assumptions that are most reasonable for a specific application.

7.2.2   Filtering

After the microarray signals have been normalized, it is a common practice to remove the data for some probe sets prior to statistical analysis. The term *filtering* is used to refer to this process of excluding selected probe sets from the statistical analysis. A *filter* is a specific filtering method. There are several reasons for which filtering may be useful in practice. The technical aspects of handling and processing samples and arrays may introduce variation or bias so that the probe set does not reliably measure the expression of its intended target gene. Additionally, for some applications, it is expected that many of the probe sets are unexpressed across all experimental conditions. Furthermore, it is difficult to verify differential expression of small magnitudes by polymerase chain reaction (PCR) in follow-up laboratory studies. If these unexpressed, unreliable, or invariant probe sets can be accurately identified, then it seems reasonable to exclude them from the primary analysis so that they do not clutter the final results.

Several filtering methods are available. Some are widely used even though their statistical properties have not been thoroughly explored. A common filter is to remove probe sets with a foreground to background ratio that is lower than a specified threshold. In the analysis of Affymetrix data, it is common to remove probe sets that are called *present* in less than a specified number of samples. Other filters remove probe sets with small mean or variance in expression across all samples. In practice, several filters may be used simultaneously (see e.g. Lampron *et al.*, 2006; Tan *et al.*, 2005).

Ideally, technical replicates will be available to provide useful information to identify unreliable probe sets. Mills *et al.* (2001), Yang *et al.* (2002), and Wang *et al.* (2003) describe methods that use the information in technical replicates for purposes of filtering. The method proposed by Mills *et al.* (2001) utilizes duplicate cRNA generated from a single preparation of sample RNA which is independently hybridized to a pair of chips. These two chips are then compared to each other and genes with expression levels declared as 'increased' or 'decreased' are defined as false positives. A three-dimensional plot is then used to plot the signal intensities of the two chips along with the prevalence of each intensity value combination from the two chips as measured by the fraction of the total number of false positives. For details, see Mills and Gordon (2001). The location of the false positive signals as identified by a grid system is subsequently used to rank the combination of signal intensities based on their likelihood of being false positives. Based on this ranking, lookup tables are constructed, which are used to filter noise from the biologically distinct RNAs. The authors report that their approach eliminated 90 % of false positives in the cases they investigated and that their approach was more reproducible than fold-change based filtering.

For some experiments, technical replication is too expensive or infeasible. Statistical filtering methods have been developed for experiments that do not include technical replication as well. For applications involving Affymetrix arrays, Pounds and Cheng (2005a) proposed two filters that utilize the information in the p-values that are used to make the present/absent calls. The method assumes the present/absent p-values from different samples for an unexpressed or 'absent' probe set are i.i.d. uniform (0,1) observations. Following Fisher (1932), they summarize the present/absent p-values for a probe set across samples into a single, pooled p-value by comparing the negative sum of the log-transformed p-values to a gamma distribution. The *pooled p-value filter* includes all probe sets with a pooled p-value less than a specified α threshold; whereas the *error-minimizing pooled p-value filter* includes all probe sets with a pooled p-value less than the threshold α_{MTE} that minimizes an estimate of the total error risk (Genovese and Wasserman, 2002; Cheng *et al.*, 2004). Additionally, they show that the α-level pooled p-value filter corresponds to the uniformly most powerful test under a β model for the individual present/absent p-values. Furthermore, in simulation studies, they observe that their filters are superior to the widely used filters based on the number of present calls seen across samples.

The rationale for filtering seems reasonable; however, its value in practice is questionable. In their example application, Pounds and Cheng (2005a) observed that the final FDR estimate for the 100 most significant probe sets was greater when their statistically-derived filters were used than when no filter was applied. Similarly, Larsson *et al.* (2005) noted that using a fold-change based filter before running the statistical analysis influences the number of genes that are reported as significant in an unpredictable manner, changes the q values assigned to genes, and affects the results of gene ontology (GO) classifications which may be utilized in an effort to understand the role of the molecular processes in the biological system under study. Therefore, filtering methods should be applied very judiciously.

The intent of filtering is to reduce or eliminate the influence of probe sets that are unexpressed or that measure the expression of their target gene poorly. Recently, several methods have been developed that adhere to this intent without resorting to actually excluding probe sets. Hu *et al.* (2006) introduced hierarchical quality indices that measure the reliability of each probe set, and are used as weights in subsequent test-statistic and p-value calculations. The test statistic for each gene is multiplied by its quality measure and the associated p-value is based on a t-distribution whose degrees of freedom are estimated by Satterthwaite's approximation. The authors consider a variety of approaches for the quality weights which include criteria based on present/absent calls as well as detection p-values. They report that quality weights based on detection p-values generally perform better than weights based on present/absent calls but note that the performance of the various weighting statistics in the presence of MTA appears to be influenced by the magnitude of the treatment effect.

Ritchie *et al.* (2006) proposed a similar approach that uses a heteroskedastic linear model with shared variance terms to assign weights to each microarray based on a residual maximum likelihood (REML) method which requires replicated data at the array level. In addition to the full scale REML, the authors also provide a faster and more computationally efficient method, which updates the weights gene-by-gene in a single pass through the data to estimate the array variances. The array variances are then used as inverse weights in subsequent calculations to detect differential expression. With respect

to detecting differential expression, their results based on both simulations and case studies indicate that their approach is superior to treating all arrays as the same or to removing the worst-quality arrays from further consideration.

7.3   TESTING THE ASSOCIATION OF PHENOTYPE WITH EXPRESSION

The primary objective of a phenotype-association analysis is to identify which probe sets' expressions are associated with the phenotype of interest. A straightforward approach to phenotype-association analysis would be to apply an appropriate classical statistical method to the expression data for each probe set and then adjust for multiple testing. For example, if the phenotype is characterized by membership in one of two groups, then one could apply the two-sample t-test or the rank-sum test to the expression data for each probe set. This approach has a number of advantages. It is conceptually and computationally easy to implement: the data analyst needs only to determine and apply (repeatedly) an appropriate classical method to explore the association of a continuous variable with the phenotype of interest. Most classical methods are implemented in a variety of software packages, including the freely available R software.

Additionally, several methods have been developed specifically for the analysis of microarray data. Many of these more recently developed strategies attempt to borrow information across genes in a way that improves variance estimation or statistical power. As mentioned in the introduction, some of these newer methods have been proposed without a thorough expository on the underlying assumptions. Certainly, information borrowing assumes some form of exchangeability across genes or there are groups of genes that have similar statistical parameters, such as variance of expression that can be identified and pooled to improve estimation of those parameters. The validity of these types of assumptions is difficult to assess for any specific application. However, the inability to assess the validity of assumptions should not necessarily be considered a reason to avoid using a method. It is doubtful that the assumptions of any method hold for all the genes; rather, it is important to consider whether the assumptions hold for most genes and how robust the method is to violations that are likely to occur. In this section, we mention classical methods and briefly review some recently developed methods for some of the most common kinds of analyses, namely two-group comparisons, k-group comparisons, and association with quantitative or time-to-event phenotypes.

7.3.1   Two-group and k-group Comparisons

One of the most common goals for a microarray experiment is to compare expression between two groups. For example, one may wish to assess the effects of a treatment on gene expression by comparing a treated group to an untreated group. Clearly, one approach to the two-group comparison would be to apply a classical method, such as the t-test or the rank-sum test, to the expression of each probe set and then adjust for multiple testing. In recent years, many other methods have been developed specifically for applications involving the analysis of microarray gene-expression data. Most of these newer methods borrow information across genes to modify the t-statistics or their Bayesian analogs. A few of these methods are briefly described below; Pan (2002), and Cui and Churchill (2003b)

Table 7.3 Some methods for phenotype-expression association testing.

Method name and purpose	Reference(s)	Software*	Comments
Local pooled error test Two-group comparison	Jain *et al.* (2003)	2	Assumes genes with similar mean expression have equal variance of expression
CyberT Two-group comparison	Baldi and Long (2001)	7	Uses hierarchical Bayesian model to compute a revised variance estimate for *t*-stat.
Shrinkage estimator K-group comparison	Cui *et al.* (2005)	4	Proposes a shrinkage estimate for error variance and compares it to other existing methods
Rank-based correlation Time-to-event Phenotype	Jung *et al.* (2005a) Jung *et al.* (2005b)	Available from author	Uses a rank-based correlation stat for censored survival times; null dist. derived by permutation
Prop. hazards model Time-to-event phenotype	Cox (1972)	1	Semi-parametric survival time models with/without covariates
Competing risks model Time-to-event phenotype	Fine and Gray (1999)	1

provide more specific reviews of additional procedures. Table 7.3 provides software availability information for some of the methods we review in this section.

Baldi and Long (2001) describe a method that computes Bayesian point estimates of variance for each group and then substitutes those estimates into the usual two-sample *t*-statistic. The Bayesian model used to obtain the variance estimates assumes that the mean and variance of each gene's expression arise from a common joint prior distribution. The method can be implemented in a fully Bayesian manner or in an empirical Bayesian manner by using the data to estimate values for hyperparameters.

Jain *et al.* (2003) proposed a local pooled error test that combines information across genes to compute a variance estimate for a statistic similar to the two-sample *t*-statistic. For each pair of arrays testing the same condition, the mean and difference in log signals are computed for each probe set. Then, the difference in log intensity is plotted against the mean log intensity. A nonparametric regression procedure is used to fit a curve estimating the expected variance in log intensity as a function of the mean log intensity. Then, for each gene, a *z*-statistic is computed as the ratio of the difference of two groups' medians to the square root of the sum of the two groups' standard error estimates. The standard error estimates are obtained from the results of the nonparametric regression. Clearly, genes with similar median signals are assumed to have the same signal variance. Under this assumption, the variance estimate obtained from the nonparametric regression should be more precise than that obtained for each gene separately.

Many times, a microarray study is conducted to compare expression levels across several groups. One objective of such a study would be to identify genes that have unequal mean or median expression across the groups. For example, Pounds and Morris

(2003) compared expressions across four treatment groups. As before, the usual classical methods such as one-way ANOVA or the Kruskal–Wallis test could be applied separately for each gene followed by MTA. As with the two-group comparison, a number of methods have been developed specifically for the analysis of microarray data. We briefly describe one of these methods below.

Cui *et al.* (2005) derived a shrinkage estimator for gene-specific variance that pools across all genes. The purpose of the shrinkage estimator is to avoid having large test statistics due to underestimation of the variance that is likely to occur in applications with small sample sizes. They subsequently use this shrinkage estimator as the denominator of an F-like statistic and assess the significance via permutation. They show that their shrinkage estimator converges to the gene-specific variance estimator as the sample size increases. Thus, in some sense, their procedure uses shrinkage only if the sample size is small enough to warrant it. In several simulation studies, they observe that their method has greater power than several other approaches based on F-statistics.

As with other statistical methods, these analytical methods are based on some underlying assumptions. These assumptions are not always explicitly stated in the literature. Certainly, information-borrowing strategies assume that data can be pooled across genes to improve the variance estimates for t-type statistics for all genes. Thus, there is an implicit assumption of some type of exchangeability across all genes or subsets of genes. Furthermore, any specific method that employs information borrowing implicitly assumes that its particular technique for information borrowing improves the variance estimates for most or all genes. These types of assumptions are sometimes difficult to formulate mathematically. Therefore, it is often impossible to statistically test the validity of such assumptions in a data analysis. Furthermore, it is difficult, if not impossible, to biologically assess the validity of such assumptions. In practice, these assumptions can make a considerable impact on the ordering of genes by significance. It may be useful to explore the data with several methods and assess the consistency across analyses. Furthermore, the conclusions drawn from a microarray study should be confirmed in follow-up laboratory studies.

7.3.2   Association with a Quantitative Phenotype

Another possible objective of a microarray study is to explore the association of gene expression with a quantitative phenotype. For example, the diagnostic white blood count is a measure of disease burden and known to be prognostically relevant among pediatric acute myeloid leukemia patients (Ribeiro *et al.*, 2005). Therefore, it may be interesting to study the association of gene expression in tumor cells with white blood count at diagnosis. As before, phenotype-association analyses can be performed by applying a classical procedure for each gene separately and then adjusting for multiple testing. For instance, Spearman's or Pearson's correlation coefficients and corresponding hypothesis testing procedures may be used to examine the association of each gene's expression with the quantitative phenotype. Regression methods may be used to explore the association of expression after adjustment for other covariates.

7.3.3   Association with a Time-to-event Endpoint

One objective of collecting microarray gene-expression data in a clinical study is to explore the association of gene expression with a measure of outcome. Many times,

outcome is measured in terms of a survival-type endpoint. For example, Ross *et al.* (2004) and Bullinger *et al.* (2004) explored the association of the duration of remission from acute myeloid leukemia with the gene expression of the disease cells at diagnosis. Several methods to examine the association of expression with survival have been described (Shoemaker and Lin, 2005). Unfortunately, many of these methods may be subject to severe biases because they treat an outcome such as relapse as a binary variable (remission vs relapse) rather than as a time-to-event variable that may be censored (Jung *et al.*, 2005b). In other words, it is important that the analyses account for the possibility that some patients may not have been observed for a sufficiently long period for a relapse to occur.

This subsection describes three approaches to explore the association of gene expression with a survival endpoint that accounts for follow up and censoring. The first approach is to fit a separate, proportional, hazards regression model (Cox, 1972) for each gene to describe and test the association of expression with survival and then adjust for multiple testing. The second approach uses a nonparametric method developed by Jung *et al.* (2005a; 2005b). Finally, the third approach accommodates various types of failure for time-to-failure phenotypes (Gray, 1988).

Morris *et al.* (2005) examined the association of gene expression in tumor cells taken at diagnosis with the survival of lung cancer patients. They fit a separate, proportional, hazards model for each microarray probe set to test the association of expression with survival. The fitted models included terms for previously known factors of prognostic relevance so that the analysis would identify genes that may provide prognostic information in addition to that available from the known factors. Thus, they obtained a p-value for each probe set and fit a β-uniform mixture model (Pounds and Morris, 2003) to the p-values to estimate the FDR (Benjamini and Hochberg, 1995). Using this approach, at an estimated FDR of 20 %, they identified 26 genes that provide prognostic information beyond that available from previously known factors.

Jung *et al.* (2005b) used their nonparametric method (Jung *et al.*, 2005a) to explore the association of gene expression in diagnostic tumor samples with the survival time of lung cancer patients. They defined a rank-based correlation coefficient that measures the association of a single continuous variable with a censored time-to-event variable. For each gene, they computed this correlation coefficient to measure the association of expression with survival time. Then, they computed these statistics for 10 000 permuted data sets in which the gene-expression profile was paired at random to a set of follow-up data. Controlling the gFWER at 0.10, they identified two genes associated with survival. Their analysis did not account for the influence of previously known prognostic factors.

In some applications, it may be important to distinguish between various types of failure. For example, treatment for leukemia can fail because of death due to therapy-related complications, failure to achieve remission, relapse of the leukemia, or (rarely) development of additional therapy-related malignancies (Bogni *et al.*, 2006). A particular analysis may want to focus on a specific type of failure, such as the development of a secondary malignancy. Clearly, a therapy-related malignancy cannot be observed in any patient who dies of complications during the early phases of therapy. In this situation, there is no opportunity to observe the time-to-development of a therapy-related malignancy. Thus, death due to complications of remission–induction therapy is a *competing risk* for the development of a secondary therapy-related malignancy. See Gray (1988), Fine and Gray (1999), and Kalbfleisch and Prentice (2002) for more details on the theory and

methods to account for competing risks in the analysis of time-to-event data. See Bogni *et al.* (2006) for an example of how to use the methods of Gray (1988) and Fine and Gray (1999) in exploring the association of gene-expression data with the time-to-development of therapy-related leukemia in the context of competing risks.

Each of the three approaches described above has its strengths and limitations. Proportional hazards models that offer the flexibility to include known prognostic factors are readily implemented in standard statistical packages (e.g. R, S-plus, SAS), and are already familiar to readers in the academic medical community (Peto *et al.*, 1976; 1977). However, the results may be biased because it is quite likely that some genes may violate the model assumptions. Thus, it may be necessary to assess significance via permutation or bootstrap methods. In their application, Morris *et al.* (2005) computed p-values in three different ways (likelihood ratio test, permutation, and bootstrap) and found that the results from the three approaches were qualitatively very similar. Nevertheless, this may not be the case in all applications. The rank-based method of Jung *et al.* (2005a) does not rely on the proportional hazards assumption but does not adjust for other known variables. The rank-based method also offers several practical computational advantages over proportional hazards modeling. The method of Fine and Gray (1999) is likelihood based. In our experience, the model-based approaches can be computationally difficult because the rank ordering of the expression of some genes relative to that of the follow-up times leads to a likelihood that is monotone in one or more parameters. For this monotone likelihood, the maximum likelihood estimates are undefined (Bryson and Johnson, 1981), and software packages terminate calculations after reaching a maximum number of iterations for optimization routines.

7.3.4   Computing p Values

For any given statistical method or test statistic, there are often several ways to compute a p-value. For example, a p-value for the two-sample t-statistic may be computed via permutation, exact methods, or by comparison with the t-distribution having the appropriate degrees of freedom. In the context of microarray data analysis, there are thousands of such t-statistics, one per gene. Considering the possibility of combining information across genes, there are several more ways to compute p-values than the classical methods.

Reiner *et al.* (2003) proposed pooling across genes to compute permutation-based p-values. Briefly, under the assumption that the test statistic for each gene has (approximately) the same null distribution, the p-value for a particular gene is computed by comparing its observed test statistic to all genes' test statistics obtained by permuting the assignments of phenotype to gene-expression profiles. This approach allows one to compute p-values with high resolution using relatively few permutations. The principle can be extended to exact testing when the number of possible assignments is very small.

Many analysts choose permutation methods to compute p-values. Certainly, permutation methods are appealing because they are robust and often do not rely as heavily on distributional assumptions, unlike comparison to a mathematically derived null distribution such as the t-distribution. However, some analysts mistakenly believe that permutation methods do not require *any* assumptions and thus advocate the use of permutation in *all* applications. It is important to recall that permutation methods are based on the assumption of exchangeability under the null hypothesis and this assumption does not hold in all

applications. For example, a permutation approach is an invalid way to compare two groups' means when the variances are unequal (Romano, 1990). Additionally, Huang *et al.* (2006) caution that permutation testing can have inflated Type I error rates in the analysis of microarray data because the assumption of equal variance is often violated.

7.4 MULTIPLE TESTING

After IDP, and testing the association of phenotype with each probe-set's expression, there is a test statistic (and usually a *p*-value) for each probe set. At this stage in the analysis, it is important to adjust for multiple testing in interpreting the results. Although microarray gene-expression studies are exploratory in nature, it is still desirable to control or estimate the prevalence of Type I errors among a set of results considered 'significant'. Follow-up and confirmatory experiments can be costly and time-consuming; therefore, it is advisable to keep the Type I error rate low. Clearly, multiple-testing issues are intrinsic to the analysis of microarray data. Dudoit *et al.* (2003) and Ge *et al.* (2003) provide extensive reviews of several approaches to adjust for multiple testing in the analysis of microarray data. Pounds (2006) reviews some methods that use *p*-values to estimate or control the FDR (Benjamini and Hochberg, 1995) and related error rates. Below, we describe some methods that estimate or control the gFWER, the FDR, and other significance criteria. Table 7.4 lists some of these methods and indicates where the related software can be obtained.

7.4.1 Family-wise Error Rate

Traditional approaches which adjust for multiple-testing attempt to control the gFWER. The gFWER is the probability that one or more Type I errors occur in the analysis. These approaches were originally developed for applications that performed a very small number of tests relative to the number of tests performed in the analysis of microarray data. gFWER methods are typically very conservative for microarray applications. For example, it is essentially impossible to have any rejections when using the well-known Bonferroni correction in the context of thousands of tests.

The (gFWER) has been proposed as a more practical metric of Type I errors for the analysis of microarray data (van der Laan *et al.*, 2004a). The gFWER is defined as the probability that *k* or more Type I errors occur in the analysis, where *k* is determined by the investigator. Clearly, the gFWER is a less stringent measure of the incidence of Type I errors and thus leads to increased statistical power. The theory and methods associated with gFWER have been developed by van der Laan *et al.* (2004a; 2004b) and Dudoit *et al.* (2004). Briefly, they proposed bootstrap-based approaches to control the gFWER. Further details can be found in their articles.

7.4.2 The False Discovery Rate

The FDR (Benjamini and Hochberg, 1995) is a widely used measure of statistical significance that accounts for multiple testing in the analysis of microarray gene-expression data (Storey and Tibshirani, 2003b). Benjamini and Hochberg (1995) defined the FDR as the expected value of the ratio Q of the number V of Type I errors to the

number R of rejections (where $Q \equiv 0$ for $R = 0$). They also developed a simple procedure that operates on a set of m p-values to control the FDR at a prespecified value τ. In the phenotype-association approach to microarray data analysis, m is the number of features included in the analysis after initial processing and filtering. First, the procedure places the m p-values in ascending order, i.e. $p_{(1)} \leq p_{(2)} \leq \ldots \leq p_{(m)}$. Next, the procedure computes

$$r_{(i)} = \frac{p_{(i)}}{i/m}, \qquad (7.1)$$

and

$$q_{(i)} = \min_{j \geq i} r_{(j)}, \qquad (7.2)$$

for $i = 1, 2, \ldots, m$. Each null hypothesis (i) with $q_{(i)} \leq \tau$ is rejected.

Under the assumption that p-values testing true null hypotheses are i.i.d. uniform $(0,1)$ observations, Benjamini and Hochberg (1995) prove that their procedure controls the FDR at $m_0 \tau / m$, where m_0 is the number of tests with a true null hypothesis. In our applications, m_0 would be the number of microarray probe sets that do not exhibit an expression-phenotype association. This observation prompted many groups to develop methods that incorporate an estimate of the null proportion $\pi_0 = m_0/m$ in hopes of improving statistical power while maintaining the actual FDR control at or below the nominal level τ. Pounds (2006) provides a review of some of those methods.

Storey (2002) argued that the positive FDR, the expected value of the ratio Q given that $R > 0$, is a more reasonable error rate than the FDR in exploratory settings such as the analysis of microarray gene-expression data. Subsequently, he developed a procedure that computes a quantity he calls the q value that is useful for controlling the positive false discovery rate (pFDR) at a at a prespecified level in applications with at least one false null hypothesis. Storey's (2002) procedure is identical to the procedure of Benjamini and Hochberg (1995) except that it incorporates an estimate of the null proportion π_0 into the numerator of $r_{(i)}$ for each i and is developed to control the pFDR instead of the FDR.

Several other approaches have been proposed as well. Allison *et al.* (2002), and Pounds and Morris (2003) have proposed methods that model *p*-values as independent observations arising from a mixture of a uniform distribution and one or more β distributions. The fitted model is used to compute values for the numerator and denominator of $r_{(i)}$. Pounds and Morris (2003) observed that the fitted model can be partitioned into four regions, one for each of the four classical hypothesis testing outcomes (Figure 7.2). The partition can be used to estimate several error rates such as the FDR, the empirical Bayes posterior (Efron *et al.*, 2001) that the null hypothesis is true, and the total number of Type I and Type II errors (Genovese and Wasserman, 2002; Cheng *et al.*, 2004). Additionally, (Pounds and Cheng 2004; 2006; Cheng *et al.* 2004) have proposed estimators of these and other error rates by using nonparametric density estimators to describe the distribution of the observed *p*-values. The density estimates are used to compute values
Figure 7.2 Graphical illustration of error-control quantities. Region A corresponds to the occurrence of true positives because it lies above the horizontal line (the alternative component) and to the left of the vertical line (declared significant). Region B corresponds to the occurrence of false negatives because it lies above the horizontal line (the null component) and to the right of the vertical line (not declared significant). Region C corresponds to the occurrence of false positives because it lies below the horizontal line (the null component) and to the left of the vertical line (declared significant). Region D corresponds to the occurrence of true negatives because it lies below the horizontal line (the null component) and to the right of the vertical line (declared significant). (2003) Estimating the occurrence of false positives and false negatives in microarray studies by approximating and partitioning the empirical distribution of p-values. *Bioinformatics* **19**, 1236–1242 by permission of Oxford University Press.]

for the numerator and denominator of the FDR estimate and estimates of various other
error rates.

7.4.3   Significance Criteria for Multiple Hypothesis Tests

When testing a single pair of (null vs alternative) hypotheses, one reports a single p-value.
A decision to reject the null hypothesis is usually made by comparing the p-value to the
customary and subjective levels of Type I error $\alpha = 0.01$, 0.05, or 0.10. It is important
to realize, as seen in the previous section, that in FDR-based multiple hypothesis testing,
5 % FDR does not correspond to the 0.05 significance level (p-value cutoff). In general,
$p = \alpha$ does not correspond to FDR $= \alpha$. Thus, the traditional significance levels are not
necessarily appropriate to use as FDR-control levels. In practice, it is not always clear
how to select an FDR-control level or a p-value threshold α to define the set of results that
will be considered statistically significant, i.e. those having p-value less than or equal to
α. More specifically, it is difficult to know how to balance the trade-off between incurring
too many false positives (Type I errors) against incurring too many false negatives (Type
II errors). Cheng *et al.* (2004) propose two significance criteria to assist in choosing
the p-value significance threshold to balance the number of false positives against the
number of false negatives, namely the profile information criterion (Ip) and the total error
criterion (Er). These significance criteria were developed with microarray applications
in mind; however, they can be used in other applications that involve extensive multiple
testing. Cheng *et al.* (2004) also propose a guide-gene driven criterion for microarray
gene-expression analyses, suitable for applications where a reliable list of differentially
expressed genes is available a priori from existing biological knowledge. This section
briefly reviews Ip and Er.

Let m denote the total number of tests (genes). The Ip criterion is written as follows:

$$Ip(\alpha) = R(\alpha) + \lambda m \pi_0 \alpha. \tag{7.3}$$

The first term, $R(\alpha)$, measures the deviation of the p-values from the uniform (0,1)
distribution in such a way that for each fixed α, $R(\alpha)$ decreases as the p-values distribute
more and more densely around zero than the uniform (0,1) distribution. Furthermore,
when the p-values distribute more heavily around zero than uniform (0,1), $R(\alpha)$ decreases
as α increases. A relatively large number of small p-values indicates the existence of
true alternative hypothesis (discoveries); in this setting, increasing α helps to reduce the
number of false negatives. Thus for the sake of making 'true discoveries' one would
like to reduce $R(\alpha)$ by increasing α. On the other hand, $m\pi_0\alpha$ in the second term is the
expected number of false rejections (false positives/discoveries) and λ is a penalty factor;
this term increases linearly in α. For the sake of avoiding 'false discoveries', one does
not want to make α too large. When the p-values are more heavily distributed around
zero than uniform (0,1), there is a unique α value that minimizes $Ip(\alpha)$. This minimizing
α is the 'optimal' significance threshold (p-value cutoff) according to the Ip criterion.
This α value strikes a balance between the levels of false positives and false negatives,
through the competition of the two terms.

Cheng (2006) formalizes the idea of the profile information criterion Ip and develops
the adaptive profile information (API) criterion: $API(\alpha) = R_\gamma(\alpha) + \lambda m \pi_0 \alpha$. The impor-
tant modification is the inclusion of a parameter γ in the first term. In practice, γ
is estimated from the p-values. This parameter reflects the deviation of the p-value

percentiles from the uniform (0,1) percentiles in a vicinity of zero. The p-value percentiles are directly related to the concentration of small p-values around zero – the higher the concentration, the smaller are the percentiles. If the p-values exactly follow uniform (0,1) then $\gamma = 1$. Also, γ increases as the p-value percentiles become increasingly less than the corresponding uniform (0,1) percentiles. $R_\gamma(\alpha)$ is so constructed that it decreases as the p-values distribute more and more densely around zero than the uniform (0,1) distribution, and decreases in α with the rate of decrement dictated by γ. The larger γ is, the slower is the decrement of $R_\gamma(\alpha)$ in α, in a vicinity of zero. So the γ parameter dictates the emphasis of the deviation from the uniform (0,1) distribution: the higher the concentration of small p-values around zero, the larger γ is, the slower is the decrement of $R_\gamma(\alpha)$ in α; consequently, $API(\alpha)$ tends to minimize at a relatively large α. On the other hand, if the concentration of small p-values around zero is not much higher than that of uniform (0,1), then $\gamma \approx 1$, $R_\gamma(\alpha)$ decreases fast in α, and $API(\alpha)$ tends to minimize at a relatively small α.

A practical issue is the choice of the penalty factor λ. Theoretical investigations and simulation studies in Cheng (2006) and Cheng *et al.* (2004) suggest a few conservative choices. These choices result in 'optimal' α's that guarantee to control the FDR (or equivalently the gFWER) when all null hypotheses are true (i.e. $\pi_0 = 1$, cf. previous section) at the comparable level, as does the Bonferroni procedure. These choices may be too conservative for general microarray applications. For exploratory analyses it may be appropriate to set $\lambda = 1$. This issue remains an open research problem.

Now, we consider the total error criterion, which is written as

$$Er(\alpha) = \pi_0 \alpha + [1 - F_P(\alpha) - \pi_0(1 - \alpha)], \qquad (7.4)$$

where F_P denotes the CDF of the p-values. The Er criterion can be interpreted in terms of the p-value partition (Figure 7.2) recognized by Pounds and Morris (2003). The first term, $\pi_0 \alpha$, is the proportion of all tests resulting in a Type I error when significance is based on comparing p-values to α. In terms of Figure 7.2, $\pi_0 \alpha$ is the area of region A (below $y = \pi_0$ and left of $p = \alpha$). The second term, $[1 - F_P(\alpha) - \pi_0(1 - \alpha)]$, is the proportion of all tests resulting in a Type II error (corresponding to the upper-right region in Figure 7.2). Theoretically, $Er(\alpha)$ is equivalent to the 'total misclassification risk' (Genovese and Wasserman, 2002) in the limiting scenario when the number of tests $m \to \infty$. Thus, choosing α to minimize an estimate $Er(\alpha)$ achieves an optimal balance of Type I and Type II errors in terms of the Er criterion. Cheng *et al.* (2004) develop estimates of π_0, F_P, and $Er(\alpha)$ for each α; the estimate of this optimal α is obtained by minimizing the Er estimate.

7.4.4 Significance Analysis of Microarrays

Tusher *et al.* (2001) proposed the significance analysis of microarrays (SAM) algorithm as a method that incorporates the MTA into the analysis. SAM has become quite popular because it was one of the first statistically developed methods with accompanying user-friendly software made widely available (`www-stat.stanford.edu/~tibs/SAM`). SAM first computes a test statistic of specified form for each of the m probe sets. For a two-group comparison of the expression of probe set i, Tusher *et al.* (2001) proposed a 'relative difference' statistic given by

$$d_i = \frac{\bar{x}_{1i} - \bar{x}_{2i}}{s_i + s_0}, \qquad (7.5)$$

where $\bar{x}_{1i}$ and $\bar{x}_{2i}$ are the mean expression of probe set i in groups 1 and 2, respectively; s_i is a pooled estimate of the standard deviation of expression of probe i; and s_0 is a shrinkage parameter. Tusher *et al.* (2001) provide more details on how the value of the shrinkage parameter is computed. Next, these relative difference statistics are ordered to obtain $d_{(1)} \leq d_{(2)} \leq \cdots \leq d_{(m)}$. SAM then uses permutation to compute values of the ordered statistics under the null hypothesis. More specifically, let $d^{\star}_{(i)j}$ be the value of the i_{th} ordered statistic in the j_{th} permutation. After B permutations,

$$d_{E(i)} = \frac{1}{B} \sum_{j=1}^{B} d_{(i)j}, \tag{7.6}$$

is used as an estimate of the expected value of $d_{(i)}$ under the complete null hypothesis for $i = 1, \ldots, m$. The significance of $d_{(i)}$ is measured by the deviation $\delta_{(i)} = d_{(i)} - d_{E(i)}$. Next, given a user-specified threshold Δ for the δ's, SAM defines $\tilde{j}_+$ as the smallest j such that $\delta_j \geq \Delta$ and $\tilde{j}_-$ as the smallest j such that $\delta_j \leq -\Delta$. Then, the null hypothesis is rejected for all $j \geq \tilde{j}_+$ and all $j \leq \tilde{j}_-$. The algorithm can be generalized by using other test statistics. Given the form of the test statistic T, the algorithm is very easy to program. Thus, it is conceptually straightforward to generalize the algorithm to various types of applications. However, it is not immediately clear how to calibrate the threshold δ to any specific measure of the Type I error rate. Storey and Tibshirani (2003a) describe how to use information from the individual permutation rounds to calibrate the threshold parameter to an estimate of the FDR.

SAM as described by Tusher *et al.* (2001) has been criticized for a variety of reasons. The example application involved a two-group comparison. The relative difference statistic proposed by Tusher *et al.* (2001) is a modified *t*-statistic. They modified the denominator of the *t*-statistic by incorporating a shrinkage parameter into the denominator. This extra term was included with the intention of preventing Type I errors due to underestimation of variance. However, in the analysis of their spike-in experiment, Choe *et al.* (2005) observed that SAM performed more poorly than the usual *t*-statistic with significance assessed by permutation. They attributed the poor performance of SAM in that application to over shrinkage of the *t*-statistic. Additionally, Dudoit *et al.* (2003) caution users that the developers of SAM no longer recommend using some versions of the algorithm.

7.4.5   Selecting an MTA Method for a Specific Application

The number of available methods to perform MTA raises the practical issue of choosing an appropriate method for a specific application. Currently, the literature provides very limited guidance on this issue. Typically, each newly proposed method is shown to be better than some of the previously proposed methods for a certain application. However, later work may show that the newer method is inferior to other methods for a different setting. Recently, Pounds (2006) outlined some recommendations for choosing from among the methods that use *p*-values, a method to estimate or control the FDR and similar error rates. Subsequently, Pounds and Cheng (2006) updated those recommendations in light of the performance of their robust method of estimating the FDR. These recommendations are briefly summarized below and outlined in Table 7.5.

Table 7.5 Recommendations for FDR Methods.

[*]MoL = mild or limited; SaE = Strong and Extensive.
[†]cont. = continuous; disc. = discrete.
[††]Results should be interpreted cautiously in these cases. The FDR-adjusted p-values should not be interpreted as an estimate of the proportion of significant findings that are false discoveries.
[*Source*: Adapted from Pounds (2006), used with permission.]

MTA used in the analysis of microarray data typically have one of two objectives: estimation or control of a multiple-testing error rate. Control is the classical approach to performing MTA. Control methods attempt to select the set of results considered significant in such a way that the error rate of interest is maintained at or below a prespecified threshold of tolerance. Storey (2002) argues that because microarray studies are very exploratory, it may not be necessary or possible to prespecify an appropriate control level. Thus, Storey (2002) suggests estimation of the error rate as a function of the p-value cutoff (possibly chosen after p-values are computed) used to define the set of results to report in a research publication or examine in greater detail through follow-up experiments. Clearly, the theory of error-rate estimation has not been developed as thoroughly as the theory of error-rate control. Nevertheless, one item of special importance is quite clear: interpreting control quantities such as the q value (Storey, 2002) or FDR-adjusted p-values (Reiner *et al.*, 2003) as estimates of the corresponding error rates can grossly underrepresent the actual prevalence of false discoveries (Pounds and Cheng, 2004). More specifically, because the ratios in equation (7.1) can be interpreted as local estimates of the FDR (Benjamini and Hochberg, 2000), applying the minimization operation in equation (7.2) to the ratios prior to smoothing clearly introduces downward bias into the final 'estimates' of the FDR (Pounds and Cheng, 2004). In particular, the q's in equation (7.2) are not conservative estimates of the FDR.

Thus, the first major consideration in choosing an MTA method is determining whether the application's objective is error-rate estimation or error-rate control. As noted above, interpreting control quantities such as the q values or FDR-adjusted p-values may grossly understate the actual prevalence of Type I errors. Subsequently, estimation methods should be used for applications with error-rate estimation as the objective. However, if error-rate control is the objective, then control methods will tend to have greater power than estimation methods (Pounds, 2006). Unless the experimental design is based on statistical sample size and power calculations, Pounds (2006) suggests that estimation methods

be used. When it is unclear whether error-rate control or error-rate estimation is more appropriate, adaptive significance criteria coupled with FDR estimation (Cheng *et al.*, 2004; Cheng, 2006) can be considered.

The properties of the *p*-values should also be considered in choosing an FDR method. Important properties to consider include the sidedness of the *p*-values (i.e. are the *p*-values based on one-sided or two-sided tests?), the discreteness of the *p*-values, and the correlation of *p*-values with one another. Pounds and Cheng (2005a; 2006) have observed that FDR methods that estimate π_0 can be very unstable when applied to *p*-values arising from one-sided tests. Briefly, *p*-values from one-sided tests may be stochastically greater than uniform (0,1) because the 'untested alternative' is true. For example, suppose the tests are of the form $H_0 : \mu \leq 0$ vs $H_A : \mu > 0$. For genes with $\mu < 0$, the test statistic may be stochastically less than the null distribution derived under the assumption $\mu = 0$. Subsequently, the *p*-value from the right-sided test will be stochastically greater than uniform. This violates the assumption that *p*-values testing true null hypothesis are uniformly distributed. The impact of this violation can be unpredictable. Therefore, Pounds and Cheng (2006) developed a method to estimate the FDR in applications that involve one-sided statistical testing.

The discreteness of the *p*-value distribution can affect the performance of the various FDR procedures as well. In proving the control properties of their FDR-control procedure, Benjamini and Hochberg (1995) assumed that the *p*-values testing true null hypotheses were i.i.d. observations from a continuous uniform (0,1) distribution. Pounds (2006) notes that other methods implicitly rely on an assumption of continuity via the use of modeling or smoothing to compute an estimate of the null proportion, i.e. the proportion of tests with a true null hypothesis. In extensive simulation studies, Pounds and Cheng (2006) observed that discreteness of *p*-values introduced substantial instability in the performance of methods that estimate the null proportion. The instability was more pronounced for the nonparametric methods they explored than for the model-based method (Pounds and Morris, 2003) they examined.

The correlation of *p*-values can affect the performance of several FDR methods. The correlation of *p*-values arises from the correlation of genes. Benjamini and Yekutieli (2001) showed that Benjamini and Hochberg's (1995) procedure maintained the prespecified level of control under a specific dependence structure among test statistics. Storey *et al.* (2004) proved a similar result for Storey's (2002) procedure. Storey and Tibshirani (2003b) argue that genome-wide expression studies naturally result in a dependency structure that satisfies the conditions for Storey's (2002) method to maintain its control properties due to the way that genes work together in pathways. Pounds (2006) notes that most FDR methods perform operations similar to Storey's (2002) procedure or Benjamini and Hochberg's (1995) procedure, and thus should have reasonable performance in this setting as well; however rigorous proofs have not been outlined for many of these additional procedures, and data collected in studies which use custom arrays that focus on particular pathways or diseases may not satisfy the positive regressive dependence structure. To our knowledge, there is no readily implemented procedure to test whether a particular data set satisfies these requirements for dependency among *p*-values. Therefore, we currently recommend that biological knowledge be used to suggest whether the data set satisfies the assumption of positive regressive dependency structure. Benjamini and Yekutieli (2001) developed a simple modification of Benjamini and Hochberg's (1995)

method that maintains its control properties for any dependency structure; however this method is extremely conservative.

7.5   ANNOTATION ANALYSIS

There are several databases that summarize the biological knowledge about genes. For example, the GO Consortium (2000) has defined a nomenclature to describe the biological process, molecular function, and cellular component of each gene. Furthermore, the GO consortium maintains and provides free access to databases that describe each gene in terms of this well-defined nomenclature (www.geneontology.org). Additionally, the Kyoto Encyclopedia of Genes and Genomes (KEGG; www.genome.jp/kegg/pathway.html) databases maintain information about known pathways. Incorporating the information from these databases can provide useful hints to understand and further explore the biology driving the associations identified by the statistical analysis. *AA* incorporates these *annotations* of genes available from freely accessible public databases. Table 7.6 provides software availability information for some of the methods we review in this section.

Several approaches to AA have been used in the literature. A very common approach is to construct a two-by-two table for each annotation term of interest. Each microarray probe set is characterized as 'significant' or otherwise, and as having the annotation or not. Then, the hypergeometric distribution is used to assign a *p*-value to the table. This approach has been criticized because it relies heavily on the assumptions of the hypergeometric distribution, which implies that genes are selected as significant in an independent fashion. In reality, genes operate in pathways, and are therefore correlated, thus violating this critical assumption of the hypergeometric-based approach.

Barry *et al.* (2005) propose the significance analysis of function and expression (SAFE) algorithm for performing AA. First, test statistics are computed for each probe set in the usual way and a test statistic is computed for each annotation term. The test statistics of the probe sets characterize the association of expression with the phenotype. The statistic for a particular annotation (such as the term *apoptosis* or participation in a specific pathway) summarizes how strongly the probe sets with the annotation are associated with phenotype. For example, the annotation statistic could be the average of the *p*-values of the probe sets with the annotation. Then, the significance of the test statistics and annotation statistics are assessed via permutation. The permutation is performed by randomly assigning expression vectors to the phenotype data or labels. For instance, in applications involving two-group or k-group comparisons, the permutation is performed by randomly assigning the group

Table 7.6   Some methods for annotation analysis.

labels to the expression vectors. The observed test statistics and annotation statistics are compared to those obtained via permutation to compute p-values and FDR estimates.

A key issue is how the annotation statistics should be defined. For association or differential expression analyses that use linear models (t-test, ANOVA, etc.) at each probe/probe set, Barry *et al.* (2005) propose to define GO annotation statistics by the sum of the F-statistics or squared (or absolute value) t-statistics of the probes/probe sets annotated to the GO category. This is quite a general approach because most of the statistical tests are modified t-statistics or F-statistics. In a similar context, Potter (2006) proposes to use p-values as the basic test statistics and considers several aggregation schemes. Another approach to aggregation can be found in Schaid *et al.* (2005). A complicating issue is how to know whether a particular formula for the annotation statistic actually measures biological significance. For instance, the alteration of one gene may impair an entire pathway, but the overall expression of other genes in the affected pathway may not be substantially altered because of their participation in other pathways. This type of effect may not stand out in an AA that aggregates test statistics across all genes with a particular annotation, but may nevertheless have dramatic biological effects.

7.6   VALIDATION ANALYSIS

Certainly, the results of a microarray study are not definitive if they rely solely on statistical analyses because there are too many possible factors that could cause the statistical analyses to yield misleading results. Even when the 'best' statistical methods are employed, there are too many uncertainties regarding assumption validity and multiple testing for the findings of a microarray study to be considered definitive. Ideally, the findings would be confirmed in a similar, separate, and adequately powered study. Alternatively, auxiliary laboratory experiments may confirm the associations identified in the statistical analysis. However, these studies can be very expensive; hence, it is desirable to avoid committing resources in an attempt to 'validate' a false positive. Thus, computational methods that can provide insights regarding the probability of success for such follow-up studies would prove quite valuable. VA attempts to characterize the 'validity' of the study findings via examination of data sets acquired by resampling, subsampling, permuting, or otherwise perturbing the original study data set.

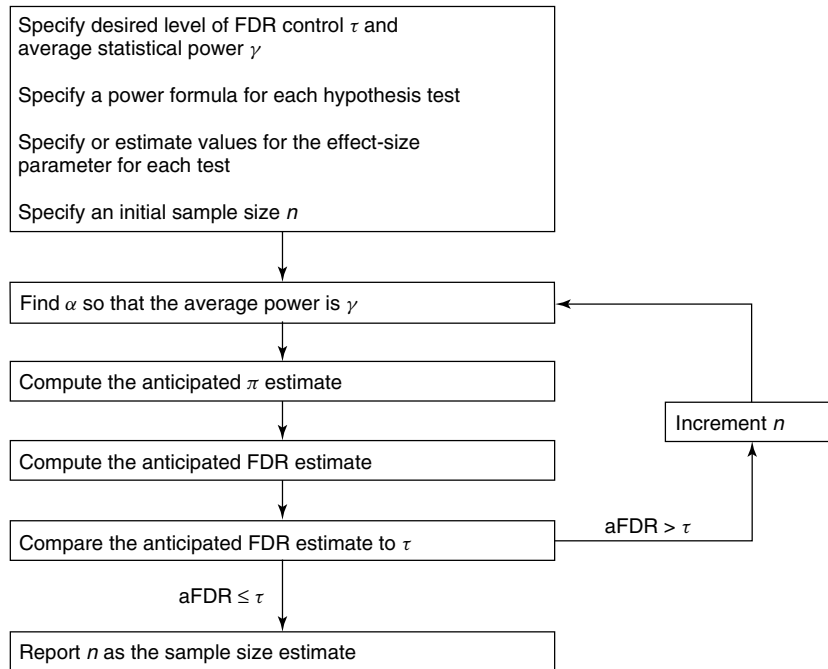
The specific meaning of the validation depends on the type of analysis performed (recall that the introduction outlines three analysis approaches: class discovery, class prediction, and phenotype association). Although our primary focus has been to describe methods used in phenotype-association analyses, we briefly mention some approaches of VA used in class-prediction analysis. Class-prediction analyses attempt to validate their findings by estimating the misclassification error rate on an independent data set. It is important to note that it is the classifiers, not necessarily the probe sets, that are validated in this analysis. Furthermore, prognostic classifiers must be built and validated in a specific therapeutic context in order to be clinically applicable (Simon, 2005a). Thus, class-prediction analysis and the corresponding VA may not be ideal for the objective of identifying genes to study in greater detail in follow-up laboratory experiments. The typical class-prediction analysis splits the study data set into training and validation sets for an internal validation (Simon, 2005b). Figure 7.3 of Bullinger *et al.* (2004) gives a good illustration of this approach. The power to identify genes is diminished by reducing the sample size in this manner.


Figure 7.3 Flow diagram of Pounds and Cheng (2005b) method of sample-size calculation.

It is our perception that many investigators choose class-prediction approaches because they wish to demonstrate that their findings have somehow been validated. However, randomly splitting the study data set into two parts just once is often not adequate either to provide an accurate estimate of the classification accuracy, or to demonstrate association on the validation set, due to reduced statistical power. More importantly, Simon (2005b) notes that 'internal validation' by computational methods is no substitute for the 'external validation' provided by a separate, prospective, and adequately powered study. If the purpose is to accurately identify genes and subsequently understand the biology, then a phenotype association is preferred because it uses all the data and thus has greater power than an analysis using only part of the data to identify interesting probe sets.

   In some studies, the phenotype of interest is simply too infrequent to warrant splitting the study data set. Bogni *et al.* (2006) utilize a combination of cluster analysis, multiple-group failure time comparison, and permutation test to internally validate an expression profile associated with the development of therapy-related myeloid leukemia (tML). First, a hazard regression model (Fine and Gray, 1999; Section 7.3.3) is fitted separately for each probe set to measure the association of expression with the development of tML. An expression profile is formed by choosing the probe sets with *p*-value less than or equal to 0.01 from the fitted Fine–Gray model. Next, hierarchical clustering (Gordon, 1999) is performed to assign subjects into three groups, using probe sets in the expression profile as features. Then, Gray's (1988) test is used to compare the cumulative incidence of tML across the clusters. Finally, the entire process is repeated across 1000 data sets obtained by randomly permuting the assignment of expression to outcome data. The χ-square statistics of Gray's test obtained by permutation are compared to the one computed on

the original data set to yield a *p*-value for the expression profile. A similar permutation-based approach to VA was used by Edick *et al.* (2005) to study the association of gene expression with the development of treatment-related brain tumors.

There are several open questions regarding VA in the context of a phenotype-association analysis. Potentially, one could perform VA using bootstrap, jackknife, cross-validation, or permutation techniques. Another open question is how to represent the association of a particular expression profile with the phenotype. In the examples above, a clustering algorithm was applied to the expression data of the selected profile to separate the subjects into groups and then the groups were compared according to phenotype. This raises the question of choosing the number of clusters and the clustering algorithm. Bair *et al.* (2006) have proposed finding the principal components of the expression of the selected probe sets and then testing the association of the first (few) principal component(s) with the phenotype. Certainly, other methods will be proposed, and some theoretical work and analysis of case studies will help to clarify what methods are best suited for specific applications.

7.7   STUDY DESIGN AND SAMPLE SIZE

Experimental design is the most important phase of a microarray gene-expression study. Decisions regarding sample pooling, replication, batching, and reference samples will strongly impact the complexity and interpretation of the eventual data analyses. Poor designs can lead to uninterpretable results due to inappropriate sample pooling, confounding of batches with phenotypes or treatments, confounding of dyes with phenotypes, comparison to a biologically meaningless reference, or inadequate statistical power. These unfortunate outcomes can be avoided with careful planning and study design.

As with other scientific investigations, the design of a microarray study should be directed by practical and statistical considerations. First, the study should be designed to capture the most relevant biological information. For example, while it may be of interest to compare expression across many groups, it may be more practical and efficient to focus the study on the comparisons that may provide the most important biological insights. More specifically, if resources limit one to study only 12 subjects, it may be preferred to study two groups of size six than to examine four groups of size three. If this is the case, then the investigator should choose which two groups to compare to obtain the biological insights of greatest interest. Also, many times, it is not possible to process all samples and arrays on the same day. Subtle variation in sample preparation and handling can have very noticeable effects on the expression signals obtained (see Section 7.2). Hence, the samples must be processed in batches. Batches should be blocked in the study design to avoid confounding batch effects with phenotype effects. Additionally, studies that use two-color arrays should be designed to avoid confounding dye effects with comparisons of interest (Churchill, 2002). Sometimes, each subject cannot yield enough RNA from the relevant tissues required for one array. Then, it becomes necessary to combine samples from multiple subjects into one RNA pool. The RNA pool is then hybridized to the microarray. Then, it becomes necessary to replicate the RNA pools within each condition or phenotype that is studied (Kerr, 2003). As always, studies should be designed with statistical power kept in mind.

Several methods have been proposed to perform power and sample-size calculations for microarray studies (Table 7.7). Pan *et al.* (2002) describe how to compute the sample size

Table 7.7   Methods for sample size and power calculations.

Sample-size objective	Reference(s)	Software
Control number of Type I errors and achieve desired average power	Lee and Whitmore (2002)	10
Control FDR and achieve desired average power	Pounds and Cheng (2005b)	3
Control FDR and achieve desired average power	Jung (2005)	Available from author
Control FDR and achieve desired average power	Gadbury *et al.* (2004)	NA
Control comparison-wise Type I error and per-comparison power	Pan *et al.* (2002)	11
Sample-size estimation with a variety of objectives	Simon *et al.* (2002)	NA
Balancing tech. and biological replicates via cost constraints	Cui and Churchill (2003a)	NA
Sample size needed for a classifier with given accuracy	Mukherjee *et al.* (2003)	NA
Control FDR to achieve desired average power	Hu *et al.* (2005)	1
Sample-size calculation based on Bayesian loss criteria	Müller *et al.* (2004)	NA

required to control the comparison-wise Type I error rate and achieve a specified level of per-comparison power. Lee and Whitmore (2002) describe how to compute the sample size required to achieve a desired level of power while controlling the expected number of Type I errors. Simon *et al.* (2002) describe how to perform sample-size calculations for a variety of objectives. Cui and Churchill (2003a) describe how to balance the level of technical and biological replication to optimize the power under a cost constraint. Mukherjee *et al.* (2003) describe how to determine the number of replicates needed to develop a classifier with a specified level of accuracy. Gadbury *et al.* (2004) and Hu *et al.* (2005) propose methods to determine the sample size for a two-group comparison to achieve desired levels of power while controlling the FDR or pFDR. Müller *et al.* (2004) describe a computationally demanding approach to determine the sample size needed to achieve desired values for specified Bayesian loss functions. Jung (2005) and Pounds and Cheng (2005b) describe general methods to determine the sample size needed to achieve a desired level of power while controlling the FDR at a specified level; these two approaches are described below briefly.

A key element of statistical sample-size calculations is defining an appropriate analog to statistical power in the multiple-testing setting. The average power (Gadbury *et al.*, 2004) is widely used for this purpose. The average power of a procedure is the expected proportion of true associations that are declared statistically significant. This is clearly equal to the arithmetic average of the powers of the individual tests with true alternative hypotheses. Given the formulae for the powers of the individual tests, the power of each test can be estimated given the values for the effect-size parameters. These formulas can be used either to estimate the average power of an experiment with a specified sample size or to estimate the sample size required to achieve a desired average power while controlling the FDR at a specified level. Of note are the methods proposed by Jung (2005), and Pounds and Cheng (2005b), each of which measure the power of a microarray study by the average power.

Jung (2005) notes that the FDR, incurred by performing all tests at a common level α, can be approximated by

$$f \approx \frac{m_0 \alpha}{m_0 \alpha + r_1}, \tag{7.7}$$

where f is the approximate FDR, m is the total number of tests, m_0 is the number of tests with a true null hypothesis, and r_1 is the expected number of rejections among those tests with a true alternative hypothesis. Solving (7.7) for α yields

$$\alpha \approx \frac{f r_1}{m_0 (1 - f)}. \tag{7.8}$$

Substituting a desired level of FDR control for f and a desired number of true discoveries for r_1 into (7.8) gives a value for α. Then, the sample size is determined such that performing all tests at a common level α has an average power $r_1/(m - m_0)$. Jung (2005) outlines more details on how to perform this calculation when the two-sample t-test is used to perform a two-group comparison.

Equation (7.8) highlights the important factors that affect the sample size required to achieve the desired power while controlling the FDR at a specified level. Clearly, the required sample size increases as α in (7.8) decreases. Thus, the required sample size increases when m_0 increases, f decreases, or r_1 increases. In fact, it is clear that some values of m_0, f, and r_1 give values of α that are less than or equal to 0 or greater than 1. More specifically, for any $m_0 > 0$, Jung's (2005) derivations imply that there are some combinations of f and r_1 which cannot be achieved with *any* sample size.

Jung's (2005) approach overlooks some subtle, yet important, issues regarding sample-size estimation. Most FDR control or estimation procedures compute an estimate of the null proportion. The estimate of the null proportion is typically conservatively biased, i.e. $\mathrm{E}(\widehat{\pi}) \geq \pi$, so as to ensure the conservativeness of the control or estimation procedure (Storey, 2002). Therefore, in practice, the specified average power may not be achieved by the sample size computed using Jung's (2005) approach, because the control procedures will tend to choose a smaller p-value threshold than that determined by (7.8). Additionally, Jung (2005) does not consider how to adjust effect-size estimates obtained from pilot data for multiplicity. Failure to adjust effect-size estimates for multiplicity can lead to inflated estimates of power and eventual underestimation of the sample size required to achieve the desired average power.

Pounds and Cheng (2005b) developed a general iterative procedure to perform sample-size calculations to achieve a specified average power while keeping the reported level of FDR (or related measures) controlled at a desired level. The procedure accounts for the dependence of the π_0-estimator on the sample size and is designed so that the computed sample size achieves the desired average power while being able to report controlling the FDR at a prespecified level. The method relies on a quantity called the *anticipated* false discovery rate (aFDR), which is the expected value of the FDR *estimate* given the sample size, effect-sizes of the tests, power formula for the tests, the FDR procedure to be used to compute FDR estimates, and a common level α for all tests. Thus, the power calculations are performed so that one has the desired average power while *reporting* control of the FDR at a desired level. Given all the necessary background information (effect-sizes, power formula, FDR method for final analysis, desired level of FDR control, and desired average power) and a starting value for the sample size, the procedure finds the level α

that achieves the desired average power and then determines if the anticipated FDR is less than or equal to the desired level of FDR control. If the anticipated FDR does not satisfy the specified level for FDR control, then the sample size is increased and the steps described above are repeated. The process is iterated until a maximum possible sample size is reached or the specified requirements for average power and FDR control are satisfied. Figure 7.3 illustrates the method in a flowchart. Furthermore, Pounds and Cheng (2005b) described a method to adjust effect-size estimates obtained from background data for multiplicity. This adjustment is necessary to prevent the sample-size calculations from being overly optimistic. Pounds and Cheng (2005b) provided details on how to perform the effect-size estimation and sample-size calculations for k-group comparisons based on one-factor ANOVA.

7.8 DISCUSSION

Clearly, there are essentially an infinite number of ways to approach the analysis of any microarray data set. Not surprisingly, numerous methods to explore microarray data have been proposed in the literature. As mentioned in the introduction, most microarray analyses can be characterized in terms of having class discovery, class prediction, or phenotype association as an objective. This chapter has provided a very brief overview of some methods that may be useful in phenotype-association analysis. Certainly, the number of methods will continue to increase dramatically during the coming years. Additionally, practical experience with available methods, simulation studies, and theoretical insights will help to clarify how to select the best methods for specific applications.

Given the plethora of possibilities, choosing methods for a specific application can be a daunting task. Nevertheless, there are some sensible considerations that can help in choosing reasonable methods for specific applications. First, the selected method should be designed to address the particular objective of the analysis. This chapter has described some methods for phenotype-association analyses. Second, the method should be designed to accommodate the data type (e.g. continuous, categorical, censored time-to-event) of the phenotype of interest. For example, the analysis should not treat a censored time-to-event phenotype as a binary outcome (Jung *et al.*, 2005a). Third, the assumptions of the selected method should be reasonable for the specific data set to be analyzed. Many authors do not explicitly describe the assumptions of the methods they propose; therefore, evaluation of assumptions can be difficult. Nevertheless, the validity of underlying implicit assumptions will certainly affect the performance of the method and impact the reliability of the obtained inferences. Finally, one must consider whether the study provides adequate power to apply a specific method. For example, class-prediction analyses typically require very large sample size so that each of the training and validation phases of analysis has adequate statistical power.

There are many open research questions pertaining to the statistical analysis of microarray data. An important question involves how to determine the extent to which two or more studies of the same disease confirm or contradict each other's findings. Simply examining reported lists of most significant probe sets is certainly a flawed approach. It is quite plausible that no genes would appear in two or more of the lists simply because the requirements of being a reportable finding are so stringent that it is virtually impossible for any gene to be reported in two or more studies. Additionally, individual microarray studies

may be underpowered, so combining information across studies may guide investigators to important biological insights. An early attempt at meta-analysis of microarray studies has already been published (Rhodes *et al.*, 2004). Many issues can arise in the meta-analysis of microarray studies, including matching probe sets and genes across multiple platforms and attempting to account for possible study-specific biases. Ghosh *et al.* (2003) elaborate on some of the challenges that arise in the meta-analysis of microarray studies and propose some approaches to address those challenges. This will be an exciting area for future research.

Another opportunity for future research is the development of tests that can help determine when permutation- or resampling-based approaches are necessary or preferred. Some researchers assert that permutation approaches are preferred for microarray studies. However, Huang *et al.* (2006) caution that permutation methods can lead to inflated Type I error rates. Additionally, in their application, Morris *et al.* (2005) observed that computationally demanding methods for *p*-value calculation gave qualitatively similar results as the likelihood ratio test. As microarrays with a very large number of features, such as exon arrays and tiling arrays, are more commonly used, the cost and complexity of implementing computationally intensive methods will increase dramatically. Statistical methods that could quickly assess the value of such methods for a specific data set may prove quite valuable in those applications.

There are several other issues worthy of exploration as well. AA and VA are exciting and relatively new areas to explore. Improvements in pathway analysis may help elucidate biological insights by determining when specific pathways are associated with the phenotype of interest. Additionally, methods to incorporate genotype data collected via SNP arrays into the analysis will need to be developed as investigators perform studies that collect genotype and gene-expression data on a common set of subjects. Furthermore, controversies still exist regarding normalization methods (Choe *et al.*, 2005); so even the seemingly more mature areas within the field still need additional research to clarify fundamental issues.

Bayesian Methods for Microarray Data

A. Lewin and S. Richardson

Division of Epidemiology, Public Health and Primary Care, Imperial College, London, UK

In this article, we review the use of Bayesian methods for analyzing gene expression data. We focus on methods that select groups of genes on the basis of their expression in RNA samples derived under different experimental conditions. First, we describe Bayesian methods for estimating gene expression level from the intensity measurements obtained from the analysis of microarray images. Next, we discuss the issues involved in assessing differential gene expression between two conditions at a time, including models for classifying the genes as differentially expressed or not. In the last two sections, we present models for grouping gene expression profiles over different experimental conditions, in order to find coexpressed genes, and multivariate models for finding gene signatures, i.e. for selecting a parsimonious group of genes that discriminate between entities such as subtypes of disease.

8.1 INTRODUCTION

High-throughput technologies such as DNA microarrays have emerged over the last $5-10$ years as one of the key source of information for functional genomics. Microarrays permit researchers to capture one of the fundamental processes in molecular biology, the transcription process from genes into messenger ribonucleic acid (mRNA) that will be subsequently translated to form proteins. This process is called *gene expression*. By quantifying the amount of transcription, microarrays allow the identification of the genes that are expressed in different types of cells and different tissues and help to understand the cellular processes in which they intervene, thus giving a unique insight into the function of genes. However, transforming the huge quantity of data that is currently produced in experiments that involve microarrays into useful knowledge for system biology is not trivial and research into ways of interpreting this rich body of data has become an active area, involving statisticians, machine learning and computer scientists.

Microarrays generally contain thousands of spots (or probes) at each of which a particular gene or sequence is represented. In effect, a microarray experiment represents data comparable to that obtained by performing tens of thousands of 'experiments' of a similar type in parallel. The 'experiments' on a given array will share certain characteristics related to the manufacturing process of the particular array used and the extraction and handling of the biological sample hybridized to the array. The interest is in comparing expression levels between arrays with samples from different biological conditions of interest (e.g. cancerous against noncancerous cells) and the challenge is identifying differences that are related to the biology of the samples rather than to technical experimental variation.

Many of the characteristic features of experiments involving microarrays render them particularly well suited to a flexible modeling strategy within the Bayesian framework. The aim of this chapter is to focus on the unique contribution that Bayesian methods offer and highlight this by discussing in detail the steps taken for modeling the variability in gene expression data at several levels.

The framework of Bayesian hierarchical modeling refers to a generic model building strategy in which unobserved quantities are organized into a small number of discrete levels with logically distinct and scientifically interpretable functions and probabilistic relationships between them that capture inherent features of the data. It is of course important to perform some basic exploration and visualization of the data before formulating complex models; see **Chapter 6**, for examples. The hierarchy of levels makes it particularly suitable for modeling gene expression data, which arises from a number of processes and is affected by many sources of variability. In the next sections, we look at an approach to modeling these different sources of variability using fixed effects, random effects and distributional assumptions.

One of the most important aspects of Bayesian hierarchical modeling as regards microarray data is the sharing of information across parallel units. For example, gene expression experiments used by biologists to study fundamental processes of activation/suppression frequently involve genetically modified animals or specific cell lines, and such experiments are typically carried out only with a small number of biological samples. It is clear that this amount of replication makes standard estimates of gene variability unstable. By assuming exchangeability across the genes, inference is strengthened by borrowing information from comparable units.

Another strength of the Bayesian framework is the propagation of uncertainty through the model. Owing to the many sources of systematic variation between arrays and samples, gene expression data is often processed through a series of steps, each time estimating and subtracting effects in order to make the arrays comparable. The end result of this process can be overconfident inference, as the uncertainty associated with each step is ignored. In a Bayesian model, it is straightforward to include each of these effects simultaneously, thus retaining the correct level of uncertainty on the final estimates. Further, when including structured priors that are associated with classification, e.g. mixture priors, in the model, estimates of uncertainty of the classification are obtained along with the fit of the model.

The field of microarray data analysis is very large, and it is not possible to cover all aspects in this chapter. In particular, we do not discuss methods for estimating graphical models and Bayesian networks that are aimed at understanding regulatory networks or metabolic pathways. There is a large literature on this subject; see, e.g. a number of

chapters in Do *et al.*, 2006, and references therein. See also **Chapter 9**, **Chapter 6** and **Chapter 7** for non-Bayesian approaches.

We focus on methods that select groups of genes on the basis of their expression in RNA samples derived under different experimental conditions. In the next section, we look at two Bayesian methods for estimating gene expression level from the intensity measurements obtained from analysis of microarray images. This section includes some discussion of the steps involved in a microarray experiment. Section 8.3 discusses the issues involved in assessing differential gene expression between two conditions at a time. There is an extensive literature on this topic. Our presentation is divided into sections on normalization, gene variability and models for classifying the genes as those that are differentially expressed and those that are not. We include a brief explanation of mixture models and some discussion of different decision rules used to choose the lists of genes that are considered to be differentially expressed. In Section 8.4, we present a range of models for grouping gene expression profiles, which are vectors of gene expression over several different experimental conditions, for ordered samples (e.g. time-course data) and for samples with no ordering. Finally, Section 8.5 reviews the current work on multivariate methods for finding subsets of genes that can predict and classify phenotypes. We focus on variable selection methods that have been used to find, e.g. the so-called gene signature of different subtypes of disease, as well as Bayesian shrinkage methods. In both cases, the emphasis is on parsimony of the multivariate model in order to enhance interpretation. In Bayesian models, inference is made in either an empirical or fully Bayesian framework. In the case of fully Bayesian models, Markov Chain Monte Carlo (MCMC) is usually used to estimate the posterior distribution of the model. We do not go into details of these procedures, except in the case of nonstandard algorithms. Table 8.1 gives URLs for software for the models discussed in this chapter.

A note on notation: we use x_g for gene expression measures used as data in Sections 8.3 and onward, rather than the more usual y_g. This is to allow the standard formulation for the variable selection models in Section 8.5, where y stands for the outcome and x stands for the variables (here genes). Throughout the chapter, p stands for the number of genes and n stands for the number of samples or experimental conditions.

8.2   EXTRACTING SIGNAL FROM OBSERVED INTENSITIES

The output from a microarray experiment is an the image of an array (see **Chapter 6**). This image must be gridded and segmented into spots, which are the basis for inference about the sequences present in the sample of interest. There has been some work on Bayesian methods for image analysis (see, e.g. Ceccarelli and Antoniol, 2006; Gottardo *et al.*, 2006a and references therein). This work is beyond the scope of this chapter. The methods we describe in this section first deal with an intensity measurement for each pixel on an array, found from the image analysis, and these are used to construct a summary measure of the amount of RNA present in the sample for each gene of interest.

There are two main types of microarrays in use, spotted or cDNA arrays, which are usually two color, and oligonucleotide arrays, which are one color. Spotted arrays are microscopic slides onto which long strands of cDNA are fixed in a regular grid layout. Each 'spot' on the array will then contain millions of copies of the same (known) sequence

of cDNA (called *probes*). One sequence corresponds to one gene, or expressed sequence tag (EST). In order to find out what sequences are present in a sample of mRNA, a sample of cDNA (the target) is produced from the mRNA by reverse transcription and fluorescently labeled. This sample is introduced onto the array, where hybridization reactions take place between sequences of cDNA that match in the sample and on the array. The array is then washed to remove target cDNA that has not hybridized to the array, and scanned to detect the fluorescent labels of the cDNA strands that have hybridized. For two-color arrays, two samples of cDNA, labeled with dyes of two different frequencies (Cy3 and Cy5), are placed on the array. The two samples are usually from different mRNA samples, enabling the concentrations of particular sequences to be compared between the two samples.

There are two particularly important statistical issues arising from the process of the microarray experiment. First, the Cy3 dye tends to appear brighter than the Cy5, owing to differences in the reaction with the cDNA and different responses to the laser used in the scanning process. This leads to the so-called dye effect. In addition, the known cDNA sequences are printed onto the array using a number of spotting pins. The different pins may deliver slightly different amounts of cDNA to the array, and thus there can be a systematic effect between spots printed with different pins. This is known as the *print-tip effect*.

Oligonucleotide arrays work in a similar way. There are three main differences from spotted arrays (from a data analysis point of view), the first being that just one sample is hybridized to each array, and thus only one dye is used, so there is no dye effect. The second is that the same printing head is used for all spots, and thus there is no print-tip effect. The third difference is that the probe sequences fixed to oligonucleotide arrays are shorter than those used in spotted arrays. For this reason, several probes (of different sequences) are used to detect one gene or EST. Spots on the array come in pairs: one containing the 'perfect match' (PM) probe and an adjacent spot containing the 'mismatch' (MM) probe. The PM probe is a strand of cDNA that has the sequence of interest. The MM probe has the same sequence except for the central nucleotide, which is different.

The reason for this is to provide a measure of cross-hybridization: target cDNA having a similar but not identical sequence to the PM probe may hybridize to the PM, contaminating the signal. The idea behind the MM probe is that these mismatched target cDNAs would also hybridize to the MM probe, but the true matches to the PM would only hybridize to the PM and not to the MM. Thus the amount of cDNA with the exact same sequence as the PM could be estimated by subtracting the MM signal from the PM signal. In reality, target cDNA with exact match to PM also hybridizes partially to the MM, so estimating the correct amount is a complicated process (see Section 8.2.2).

8.2.1   Spotted cDNA Arrays

Most work with data from spotted arrays takes the ratio of the Cy3 and Cy5 intensities as a measure of the *relative* expression of each gene in the two RNA samples. These can be used in a fairly straightforward way to compare gene expression under different experimental conditions. Care must be taken to account for the dye and print-tip effects. These effects are often included as part of the model for differential expression, as seen in Section 8.3.1.

Here we discuss a Bayesian model developed by Frigessi *et al.* (2005) for obtaining estimates of concentrations of RNA from two-color arrays. This model includes the dye and print-tip effects, along with other aspects of the experimental process, usually absorbed into empirical normalization methods. The idea is to follow through the process that the RNA molecules undergo in order to be detected as hybridized to the array. The steps in this process are modeled with a hierarchical model.

The principal data used in the model are the intensity measurements in each pixel j on each array a. These are denoted by $L_{j,s}^{i,a}$, where s labels spots to which the pixel belongs and i labels the particular RNA sample hybridized to the array. The background intensity is assumed to have been subtracted as part of the image analysis. The quantity of interest to estimate is the concentration of RNA (in molecules per unit weight) for gene g in sample i, denoted by K_g^i. The main steps relating this concentration to the observed intensities are hybridization, washing, and scanning.

In order to model the scanning process, consider the number of molecules $J_s^{i,a}$ from sample i left on spot s after hybridization and washing. The observations that contribute directly to $J_s^{i,a}$ are the intensities for the pixels in the spots corresponding to that gene; for a given sample and array, $L_{j,s}^{i,a} \propto J_s^{i,a}/n_s^a$, where n_s^a is the number of pixels in spot s. The constant of proportionality is $2^{f_{\text{dye}} \cdot PMT^{i,a}} \alpha_{\text{dye}}$, where $PMT^{i,a}$ is the voltage used in scanning and f_{dye} is the scanner amplification factor, both of which are known. The factor α_{dye} accounts for the dye effect (this is estimated as part of the model). With this expected relation between intensity and number of molecules on a spot in place, the intensity measurements are modeled as coming from a normal distribution,

$$L_{j,s}^{i,a} \sim N(2^{f_{\text{dye}} \cdot PMT^{i,a}} \alpha_{\text{dye}} J_s^{i,a}/n_s^a, (\sigma_s^{i,a})^2). \tag{8.1}$$

The variance $(\sigma_s^{i,a})^2$ is estimated from the sample variance of the intensities, and treated as fixed in the analysis.

In the second level of the hierarchical model, the prior for $J_s^{i,a}$ depends on the concentrations $K_{g(s)}^i$, where $g(s)$ is the gene corresponding to spot s, and also on other parameters for various effects encountered in the hybridization step. This step is treated as

a selection process where each molecule of gene $g(s)$ has an equal chance of hybridizing to and remaining on spot s. Thus the number of molecules has a binomial distribution:

$$J_s^{i,a} \sim \text{Bin}(cn_s^a q^{i,a} K_{g(s)}^i, p_s^{i,a}), \qquad (8.2)$$

where $q^{i,a}$ is the total weight of sample i and c is a hybridization factor (estimated in a calibration experiment). The probability of hybridization $p_s^{i,a}$ has several contributions:

$$p_s^{i,a} = L^{-1}(\gamma_0 + \gamma_{g(s,a)} + \gamma P^i + \beta X_s^a). \qquad (8.3)$$

P^i is a measure of the purity of sample i, and X_s^a contains the covariates for spot s on array a: probe length, probe quality, print tip and array. Various link functions are used for L. To ensure identifiability, several arrays must be analyzed together. The main object of inference is K_g^i and a purposely designed MCMC algorithm is used to get posterior samples.

8.2.2 Oligonucleotide Arrays

In contrast to cDNA arrays, the intensity measurements for spots on oligonucleotide arrays cannot be combined in a simple manner to form gene expression measurements. The simplest way to use the PM and MM measurements would be to use PM–MM as a measure of expression. However, there is a problem with this, as very often the MM intensity is larger than the PM intensity (see Figure 8.1, top row). There has been much work in the microarray literature on methods to deal with this phenomenon. Here, we present Bayesian models developed to model the PM and MM intensities in order to produce measures of gene expression.

Hein *et al.* (2005) present a fully Bayesian hierarchical model, estimated by MCMC, for obtaining gene expression measures for each gene in each experimental condition. If there are replicate samples for a condition (including biological replicates), the model produces an estimate for that condition, rather than separate estimates for each replicate. On the other hand, by using the variability of the probe sets for each gene, the model can be used with a single array for each condition and meaningful comparison between conditions without any replicates can be obtained (Hein and Richardson, 2006).

The data used for the model in Hein *et al.* (2005) are the PM and MM intensities for probe pair j of gene g in replicate r of condition c, denoted by PM_{gjcr} and MM_{gjcr}. Each c, r pair corresponds to one physical array. The intensity observed at a PM probe is assumed to be the result of hybridization, partly of fragments that perfectly match the probe (specific hybridization, signal: S_{gjcr}) and partly of fragments that do not perfectly match the probe (nonspecific hybridization: H_{gjcr}). A similar pattern is assumed for the MM probe, with only a fraction ϕ of the perfectly matching fragments undergoing binding. Both specific and nonspecific hybridization are estimated separately for each gene and probe. To account for the possibility of the MM being bigger than the PM, the model includes an additive error on the normal scale.

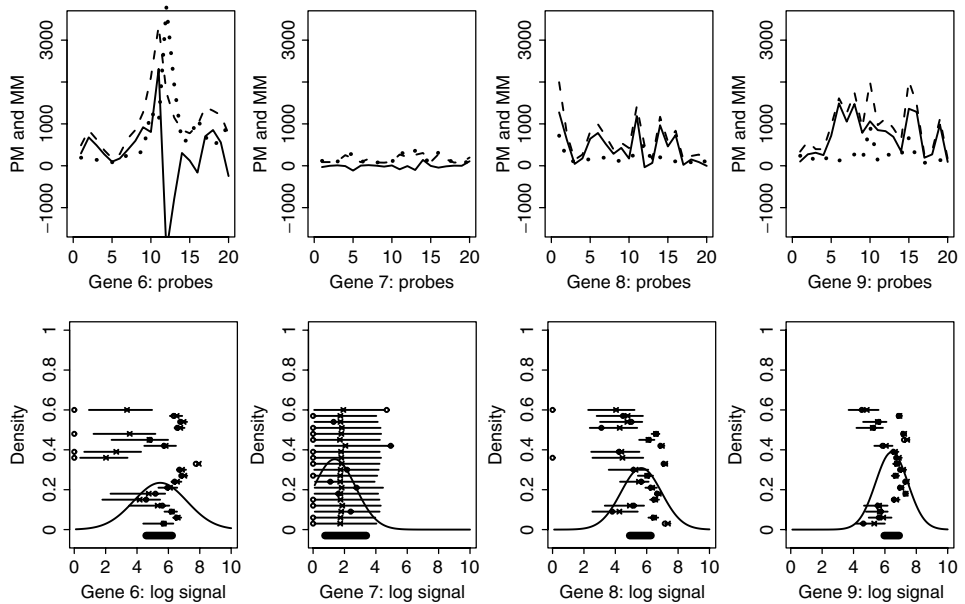
$$PM_{gjcr} \sim N(S_{gjcr} + H_{gjcr}, \tau_{cr}^2),$$
$$MM_{gjcr} \sim N(\phi S_{gjcr} + H_{gjcr}, \tau_{cr}^2). \qquad (8.4)$$


Figure 8.1 Upper panel: probe set response for four genes from an oligonucleotide microarray. Each probe set consists of 20 probe pairs. Solid lines show PM−MM, dashed lines show PM, dotted lines show MM. Lower panel: summaries of posterior distributions related to expression of the four genes, from the model in Hein *et al.* (2005). The 95 % equal-tailed credibility intervals of the S_{gjcr} are shown as horizontal lines (shifted vertically) and should be read off the x axis. The bold line shows the 95 % equal-tailed credibility interval for μ_{gc}. Circles show the observed log(PM−MM) values (plotted at zero when MM > PM). Curves show $TN(\hat{\mu}_{gc}, \hat{\sigma}_{gc}^2)$, with $\hat{\mu}_{gc}$ and $\hat{\sigma}_{gc}^2$ equal to the posterior means. [Reprinted from Hein, A.-M. K., Richardson, S., Causton, H. C., Ambler, G. K., and Green, P. J. (2005). BGX: a fully Bayesian gene expression index for A ymetrix GeneChip data. *Biostatistics* **6**(3), 349–373, by permission of Oxford University Press.]

At the next level of the model, estimates for the specific hybridization for each gene in each condition μ_{gc} are obtained, averaging across probes and replicates. These are the final measures of interest. The nonspecific hybridization is modeled with an arraywide distribution (indexed by c and r).

$$\log(S_{gjcr} + 1) \sim TN(\mu_{gc}, \sigma_{gc}^2),$$
$$\log(H_{gjcr} + 1) \sim TN(\lambda_{cr}, \eta_{cr}^2). \tag{8.5}$$

Here TN stands for the normal distribution truncated at zero on the left. This and the shifted log function allow the hybridization signals to be zero.

Array-specific parameters (those indexed by c, r) are given independent priors. The gene-specific variances σ_{gc}^2 are modeled exchangeably, to share information across the genes and stabilize the variance estimates.

Hein *et al.* (2005) have fit this model to the GeneLogic spike-in data set at `http://www.genelogic.com/media/studies/index.cfm`. This is a widely used data set consisting of gene expression measurements for replicate samples of cRNA

from an acute myeloid leukemia (AML) tumor cell line, with 11 exogenous cRNAs spiked into each sample at a different known concentration in each sample. Each sample was hybridized on one array, thus all measurements for spike-in genes on a particular array correspond to the same cRNA concentration. The top row of Figure 8.1 shows the PM and MM measurements for four of the spiked-in genes (all from the same array). It can be seen that the measurements of different probes within a gene vary widely, owing to the different sequences being detected.

The lower panel shows results for the same four genes when the model is fit to the single array. The plots show the posterior estimates of S_{gjcr} compared with $\log(PM_{gjcr} - MM_{gjcr})$. It can be seen that the posterior estimates get more precise for larger PM–MM, i.e. for probes with high specific hybridization, and consequently that the posterior credibility intervals for the μ_c are reduced. For probes with large MM, the estimates of S_{gjcr} are drawn toward those for the rest of the probes for that gene.

8.3 DIFFERENTIAL EXPRESSION

One of the most widely studied problems in microarray analysis is that of differential gene expression between two experimental conditions, e.g. between knockout and wild-type animals, or between cases and controls. Most work in this area starts with the gene expression measures for each gene on each array, or the log ratios of expression under two conditions. Expression measures have been observed to have increasing variability with increasing value (Schadt *et al.*, 2000), so they are often modeled on the log scale. Sometimes a shifted log transform is used, as, e.g. in Gottardo *et al.* (2006b). **Chapter 6** discusses many transformations used in the literature.

Many models that have been developed for differential expression can be written as a linear model for the log expression level x_{gcr} for gene g, condition $c = 1, 2$ and replicate array r:

$$x_{gcr} = \mu_{gc} + \gamma_{cr} + \varepsilon_{gcr}, \qquad (8.6)$$

where μ_{gc} represents the level of expression of gene g for condition c, γ_{cr} is a normalization term for the array containing the replicate r sample of condition c, and ε_{gcr} is the residual.

Not all models we discuss can be fitted exactly into this format, e.g. Newton *et al.* (2004) and Kendziorski *et al.* (2003) use the gamma distribution to model gene variability and so their models do not quite fit into the linear framework. However, they still involve parameters corresponding to the same biological quantities. In addition, the vast majority of models can be fitted into the linear framework, and thus it is useful to give these equations in an attempt to clarify where models differ or otherwise. We will indicate in the text where models do not use the linear formulation (8.6).

The parameters of interest are the μ_{gc}. Before we discuss how these are modeled, we look at the normalization and error terms.

8.3.1 Normalization

Microarray data show systematic differences between expression levels found on different arrays (e.g. Schadt *et al.*, 2000). Some of these differences are due to dye and print-tip

effects discussed in Section 8.2.1. This may be taken into account when analyzing data at lower levels, but generally empirical differences between arrays are still found for the gene expression values. Often the systematic effect is such that there is nonlinear relationship between the expression levels on different arrays.

Much work has been done in the classical statistical literature on different methods of accounting for these systematic nonlinear differences (normalizing). These usually involve a transformation of the data before it is analyzed with another method. Most work on Bayesian models for gene expression has also assumed that this process has been done beforehand. Bayesian models incorporating normalization include those proposed by Parmigiani *et al.* (2002) and Gottardo *et al.* (2006b). Both of these include a constant term in a linear model, estimated in a fully Bayesian manner.

Bhattacharjee *et al.* (2004) and Lewin *et al.* (2006) model normalization as a nonlinear function of expression level. Bhattacharjee *et al.* (2004) use a normalization term γ_{gcr}, which is modeled as a piecewise linear function of gene expression level. Owing to marginalization over the joint posterior, posterior estimates of γ_{gcr} will be reasonably smooth functions of expression level.

Lewin *et al.* (2006) propose a model starting with that given in (8.6), but for which the normalization term has an additional gene index: $\gamma_{gcr} = f(\mu_{gc})$, where the function f is a quadratic spline. They show that transforming the data first rather than modeling the normalization simultaneously with the other unknown quantities can introduce bias, as the gene expression levels μ_{gc} have to be estimated and thus have variability, as in measurement error problems (Carroll *et al.*, 1995). Figure 8.2 shows the posterior mean array effects γ_{gcr} as a function of expression level for a group of three arrays hybridized to cDNA from wild-type mice, as presented in Lewin *et al.* (2006).

8.3.2 Gene Variability

There are many sources of variation in gene expression data. It is possible to put replicate RNA samples from the same individual on different microarrays, but this is usually considered unnecessary as it has been observed that these so-called technical replicates show very high correlation. More usually different arrays are hybridized with samples taken from different individuals. Thus the variability incorporated in the error term ε_{gcr} in (8.6) represents the biological variability. It is generally accepted that different genes
Figure 8.2 Array effects as a function of expression level for a wild-type mouse expression data set of three arrays as presented in Lewin *et al.* (2006). Each plot shows the array effect from one array (curve) with the data residuals from the mean across arrays (points).

show different levels of biological variability, and thus parameters in the distributions for the errors will depend on the gene index.

Several Bayesian models in the literature assume normal errors (Lönnstedt and Speed, 2003; Baldi and Long, 2001; Bhattacharjee *et al.*, 2004; Lewin *et al.*, 2006). Gottardo *et al.* (2006c) use a *t*-distribution (bivariate for cDNA data) to accommodate more outlying data points. Newton *et al.* (2001; 2004) give the data a gamma likelihood rather than the lognormal implied by (8.6). Simple model-checking techniques suggest that the gamma and lognormal families are equally suitable for gene expression data.

Since the number of individuals for each experimental condition is often small, independent estimates of gene variance parameters would be unstable. Therefore, gene variances σ_{gc}^2 are usually shrunk, by assuming exchangeability across genes (and sometimes conditions). Both empirical Bayes (Lönnstedt and Speed, 2003) and fully Bayesian methods (Lewin *et al.*, 2006; Gottardo *et al.*, 2006c) relying on MCMC algorithms for inference have been used. Rather than allowing a separate variance for each gene, Bhattacharjee *et al.* (2004) allow gene variances to take one of three values, estimated as part of the model, as an alternative way of sharing information across genes. Baldi and Long (2001) allow gene variances to depend on expression level, by making the variances exchangeable among genes with similar expression levels (defined by a window on the expression level) and estimating these using Empirical Bayes methods.

8.3.3 Expression Levels

It is useful to write the expression levels in two experimental conditions as

$$
\begin{aligned}
\mu_{g1} &= \alpha_g - \delta_g/2, \\
\mu_{g2} &= \alpha_g + \delta_g/2,
\end{aligned}
\tag{8.7}
$$

where α_g represents the overall expression level for gene g and δ_g represents the log differential expression. For two-color arrays, the data can be given as log fold changes between the conditions (the data is paired) and in that case there is no α_g parameter. When the data is given separately for the two conditions, α_g must be modeled. It is usually treated as a fixed effect, so no information is shared between genes for this parameter.

The fold change parameter δ_g can also be given an unstructured prior (e.g Baldi and Long, 2001; Bhattacharjee *et al.*, 2004; Lewin *et al.*, 2006); however, many people choose to use mixture models to classify genes as those differentially expressed and those that are not. Usually, this implies putting a mixture prior on some measure of the difference between expression levels in the two experimental conditions. The mixture models can be classified into two groups: those that put a mixture prior on the model parameter δ_g, and those that model the data directly as a mixture. These are not intrinsically different, as the parameters δ_g could be integrated out to give a mixture model on the data, but it is convenient to describe the models separately.

A finite mixture distribution for a quantity Δ_g is a weighted sum of probability distributions,

$$
\Delta_g \sim \sum_{k=0}^{K-1} w_k f_k(\phi_k),
\tag{8.8}
$$

where the weights sum to one ($\sum_{k=0}^{K-1} w_k = 1$). Each mixture component has a certain distribution f_k, with parameters ϕ_k. The weight w_k represents the probability of Δ_g being assigned to mixture component k. In the context of differential expression, most mixture models used consist of two components ($K = 2$), one of which (f_0) can be thought of as representing the 'null hypothesis' that there is no differential expression. The second component corresponds to the alternative hypothesis that there is differential expression. Of course, it is not necessary to see the model in terms of hypothesis testing; in the Bayesian framework, it is a straightforward procedure to classify each gene into one or other of the mixture components. This is usually done using the posterior probability of component membership (see Section 8.3.4 for details).

One of the earliest mixture models used in gene expression analysis was that of Efron *et al.* (2001). In this model, Δ_g in (8.8) is a regularized *t*-statistic t_g, one for each gene.

$$t_g \sim w_0 f_0 + w_1 f_1. \tag{8.9}$$

The densities of the mixture components are estimated nonparametrically using standard kernel density procedures. Regularized *t*-statistics are calculated using expression data from the same experimental condition, to provide an estimate of the null component f_0. An estimate of w_0 (which represents the proportion of genes in the null, or not differentially expressed) is obtained using empirical Bayes methods. The whole mixture distribution ($w_0 f_0 + w_1 f_1$) can be estimated using all the t_g. Thus the second component f_1 can be inferred.

A fully Bayesian version of this model has been discussed by Do *et al.* (2005). In this work, the framework of Dirichlet Process Mixtures (DPMs) is used to formulate a prior probability model for the distributions f_0 and f_1. A DPM model, characterized by a base measure G^*, a scalar parameter α and a mixing kernel to be specified, is one of the most popular nonparametric Bayesian models in view of the simplicity of its representation and MCMC implementation (Escobar and West, 1995; Walker *et al.*, 1999). Do *et al.* (2005) choose base measures $G_0^* \sim N(0, \tau^2)$ and $G_1^* \sim \frac{1}{2}N(-b, \tau^2) + \frac{1}{2}N(b, \tau^2)$ for f_0 and f_1, respectively, and Gaussian mixing kernels with common variance parameter σ^2. The specification of G_1^* reflects the prior belief that DE in either direction is equally likely, in the absence of more specific prior information. Use of the stick-breaking construction of DP (Sethurman, 1994) leads to a useful representation of $f_k, k = 0, 1$ as an infinite mixture of normals:

$$f_k = \sum_{h=1}^{\infty} p_{hk} N(\mu_{hk}, \sigma^2),$$

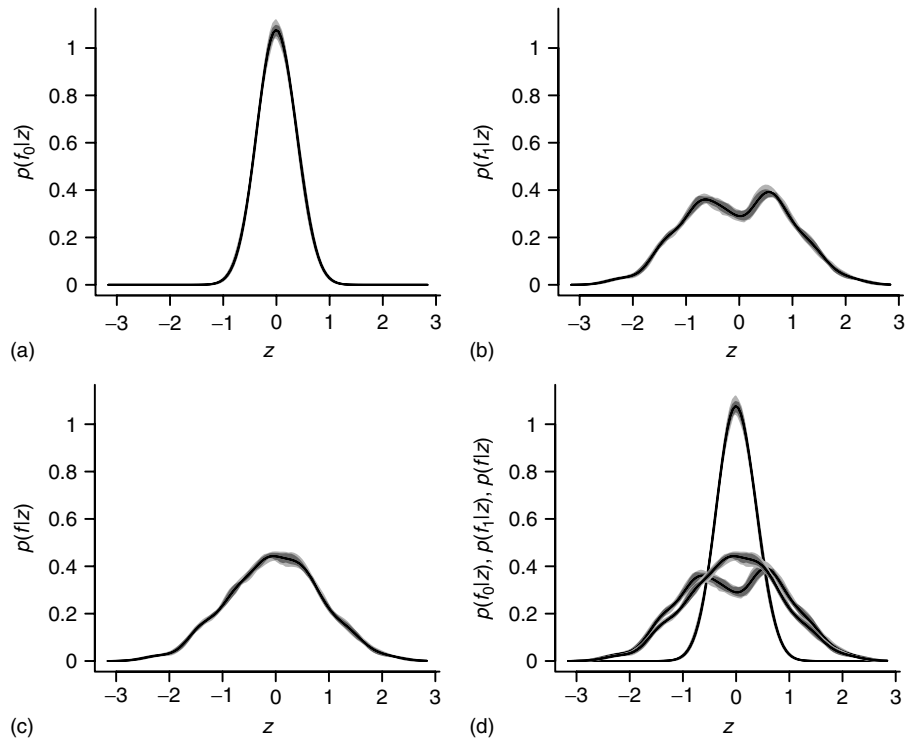
with $\mu_{hk} \stackrel{\text{i.i.d}}{\sim} G_k^*, k = 0, 1$ and the weights following the stick-breaking structure: $p_{hk} = U_h \prod_{j<h}(1 - U_j)$ with $U_h \stackrel{\text{i.i.d}}{\sim} \beta(1, \alpha)$. In Do *et al.* (2005), all the model parameters are given hyperprior distributions, conjugate inverse gamma for τ^2 and σ^2 and conjugate normal for b, α is fixed at 1 and w_0 is given either a beta prior or a uniform prior away from 0. As in Efron *et al.* (2001), within-condition data differences are used to estimate f_0, while between-condition differences are modeled as arising from the mixture defined in (8.9). Figure 8.3 shows posterior estimates of f_0, f_1 and $f \equiv w_0 f_0 + w_1 f_1$ for the Alon colon cancer data set (Alon *et al.*, 1999) as analyzed in Do *et al.* (2005). This is a data set of gene expression measurements for 2000 genes in 62 tissue samples (40 tumors and 22 normal samples). The density f_1 is bimodal, showing that there are genes that


Figure 8.3 Illustration of the posterior distributions for the mixture densities in the Do *et al.* (2005) model, found for the Alon *et al.* (1999) cancer data set. (a–c) show f_0, f_1 and f; (d) shows all three. Each curve is a draw from the posterior distribution of the relevant mixture component. [Figure courtesy of Peter Müller.]

are expressed more in tumors than in normal samples, and genes that are expressed more in normal samples. The estimate of the proportion of differentially expressed genes was around 1 % in this data set. The performance of this model will depend on the number of within-replicate differences that are used to calibrate f_0 and on the information introduced in the hyperprior specification. When there are only a few replicates, the mixture might be close to nonidentifiability.

Broët *et al.* (2002) suggest another model using a mixture at the data level to classify genes. Here the data is first transformed with a linear model to produce normalized log fold changes d_g. The d_g are modeled using a fully Bayesian mixture of normals, which includes estimation of the proportion of differentially expressed genes (the weights in the mixture). The number of components in the mixture K is not restricted to 2. There is still just one component representing the null, but several representing differentially expressed genes. This allows grouping of genes into different levels of differential expression. In fact K is not fixed in this model, but estimated, in a fully Bayesian way, using the split and merge algorithm for mixtures with an unknown number of components introduced in Richardson and Green (1997).

When mixture distributions are put on parameters of the model (prior) rather than on the data (likelihood), care must be taken to ensure identifiability of the parameters

of the mixture components. A common choice is to make the null component a point mass. This corresponds to testing the null hypothesis $\delta_g = 0$ versus the two-sided alternative.

Lönnstedt and Speed (2003), Lin *et al.* (2003) and Smyth (2004) use mixture priors on the parameter δ_g representing difference between conditions. Lönnstedt and Speed (2003) use a mixture of a point mass at zero and a conjugate normal prior on the δ_g. Smyth (2004) uses the same mixture model, but on data that has first been transformed using a linear model similar to that in (8.6) but using a robust estimation method, to obtain log fold changes. These two models are estimated using empirical Bayes methods. The proportion of true nulls is not estimated. Thus these methods produce a ranking of the genes rather than an actual estimate of how many genes are differentially expressed.

Rather than putting the mixture directly on the δ_g, Newton *et al.* (2004) propose a mixture prior on the pair of parameters μ_{g1}, μ_{g2}. Their likelihood is gamma, but the μ_{gc} still represent mean expression in the two conditions. One component of the mixture has $\mu_{g1} = \mu_{g2}$ drawn from one distribution, and the other has μ_{g1}, μ_{g2} drawn from two separate distributions. These distributions are estimated nonparametrically, using an expectation maximization (EM) algorithm. Gottardo *et al.* (2006c) has a similar mixture on the pair μ_{g1}, μ_{g2}, this time using normal priors, and a fully Bayesian estimation method, including estimating the proportion of differentially expressed genes. Reilly *et al.* (2003) has a model with a similar structure, but in addition incorporates prior information about certain genes being controls (and therefore not differentially expressed).

An early model for differential expression, which does not employ a mixture model on the difference between the two conditions, is that of Ibrahim *et al.* (2002). They model the data *in each condition* as that from a mixture of a point mass and a lognormal distribution, the point mass representing the threshold for genes to be unexpressed. A measure for differential expression is formed from the ratio of expectation of expression in the two conditions.

As a final comment, note that finding differentially expressed genes can also be cast in a multivariate framework. This approach was adopted by Ishwaran and Rao (2003) who use multivariate shrinkage effected via a continuous version of the spike and slab variable selection model (see Section 8.5.1 for a discussion of variable selection approaches). They propose to detect differentially expressed genes by formulating the problem as a linear regression. They then use a multivariate shrinkage approach to find posterior means of the differentially expressed parameters and finally they compare these values to percentiles of a standard normal distribution (with a scaling coefficient) in order to select differentially expressed genes.

8.3.4   Classifying Genes as Differentially Expressed

In differential expression problems, the aim is to produce a list of genes that are considered to be differentially expressed between the different experimental conditions. A decision rule is used to classify genes as either differentially expressed (DE) or not differentially expressed (non-DE). In Bayesian models, this will either be based on the value of some model parameter (usually the posterior mean), or on posterior probabilities of some criterion in the model, e.g. of being classified into a certain mixture component or of some parameter being above a certain threshold.

8.3.4.1 Models with Mixture Priors for Fold Changes

In the fully Bayesian mixture models described above, decisions are usually made using the posterior probabilities of a gene being allocated to the different mixture components. The mixture example given in (8.8) can also be written as

$$
\begin{aligned}
\Delta_g | z_g &\sim w_{z_g} f_{z_g}(\phi_{z_g}), \\
\mathbb{P}(z_g = k) &= w_k,
\end{aligned} \tag{8.10}
$$

where the z_g are allocation parameters, which label the mixture component to which gene g is assigned. The posterior probability of gene g being in component k is $\mathbb{P}(z_g = k|\mathbf{x})$.

Defining a loss function enables one to form the decision rule. First, denote the set of genes declared to be DE by S_1 and the set of genes called *non-DE* by S_0. In the two-component mixture models, since there are two possible classifications for each gene, there are two possible penalties for misclassification, one for false positives and one for false negatives. If the ratio of these two penalties is λ, the same for all genes, the loss function is proportional to

$$
L \propto \sum_{g \in S_0} \mathbb{P}(z_g \neq 0|\mathbf{x}) + \lambda \sum_{g \in S_1} \mathbb{P}(z_g = 0|\mathbf{x}). \tag{8.11}
$$

This is minimized by defining S_0 as the set of genes for which $\mathbb{P}(z_g = 0|\mathbf{x}) \geq 1/(1 + \lambda)$, i.e. genes are classified using a threshold on the posterior probabilities of classification in the mixture. Müller *et al.* (2007) discuss different possible loss functions and the decision rules they lead to.

The posterior probabilities can also be used to obtain an estimate of the false discovery rate, which is the ratio of false positives to total declared positives:

$$
FDR = \frac{1}{|S_1|} \sum_{g \in S_1} \mathbb{P}(z_g = 0|\mathbf{x}), \tag{8.12}
$$

(see Newton *et al.*, 2004; Broët *et al.*, 2004; Müller *et al.*, 2007). An estimate of the false nondiscovery rate (ratio of false negatives to total negatives) can be similarly defined. The false discovery rate is widely used in classical statistical analysis of gene expression data (see **Chapter 6** and **Chapter 7**). It is useful to be able to give this estimate when comparing with different analysis methods and it has generally be found in simulation studies that (8.12) gives quite accurate estimates of the true FDR.

For mixtures of more than two components, one may consider different rules. The most obvious would be to assign genes to the component with highest probability, i.e. gene g is assigned to component $k = \max_{k'} \mathbb{P}(z_g = k'|\mathbf{x})$. However, when there are more than two components, this can lead to genes being declared DE (in a particular component) when their posterior probability of being classified into that component is low. For example, with four components, a gene that has almost equal probability of being classified in all components can be declared DE (into the best component for that gene) with posterior probability of 0.26 of being in that component. An alternative, but more conservative, suggestion would be to classify into one of the components representing DE only those

genes for which the corresponding posterior probability of belonging to that component is above a set threshold, e.g. 50 % or higher. Otherwise the genes are classified into the null. Again, evaluating the associated FDR of such rules will guide the choice of appropriate thresholds. Such a rule was used in a related context of modeling DNA copy number changes (gains or losses) in comparative genomic hybridization experiments by a spatially structured mixture model with three components (gain, loss, normal) in Broët and Richardson (2006). For typical noise-to-signal ratio, the authors found that classifying DNA sequences with a posterior probability above 0.8 into the gain or loss components gave good operational characteristics in this context, whereas the Bayes rule had poorer performance.

When mixture models are estimated using empirical Bayes methods, without an estimate of the number of genes in the null, the posterior probability of being allocated to the null can only be estimated up to a constant. In this situation, the posterior odds ratio can be used to rank genes:

$$Odds_g = \frac{\mathbb{P}(z_g = 0|\mathbf{x})}{\mathbb{P}(z_g \neq 0|\mathbf{x})}, \tag{8.13}$$

(Lönnstedt and Speed, 2003; Smyth, 2004).

8.3.4.2 Models with Nonstructured Priors on Fold Change Parameters

In the nonmixture methods of the previous section, a variety of measures of differential expression are used to classify genes. Baldi and Long (2001) and Smyth (2004) propose the so-called regularized or moderated *t*-statistics. These consist of the Bayesian posterior mean estimate of the log fold change parameter, divided by a shrunken estimate of standard deviation. This shrunken estimate is the square root of the posterior mean of the variance parameter, shrinkage being provided by the exchangeable prior on the variances estimated in an expectation maximization (EM) framework.

The model used by Bhattacharjee *et al.* (2004) allows gene variances to take one of three values (a mixture on gene variability). These can be used to classify genes into groups based on their variability within and between tissues.

With a noninformative prior on the δ_g, Lewin *et al.* (2006) proposed a decision rule based on a threshold δ_{cut} set according to a biologically interesting level of differential expression. Differential expression is defined as δ_g being greater than δ_{cut}, corresponding to an interval null hypothesis with the interval fixed *a priori*. The decision rule is that genes are declared to be differentially expressed if the posterior probability $\mathbb{P}(|\delta_g| > \delta_{cut}|\mathbf{x})$ is greater than some threshold probability (e.g. 0.5). This rule combines statistical and biological significance.

When the interval for an interval null hypothesis is required not to be fixed *a priori*, Bochkina and Richardson (2006) suggest two types of decision rule based on tail posterior probabilities. They define a loss function

$$L \propto \sum_{g \in S_0} I[|\delta_g| > \theta(\sigma_g)|\mathbf{x}] + \lambda \sum_{g \in S_1} I[|\delta_g| \leq \theta(\sigma_g)|\mathbf{x}]. \tag{8.14}$$

They consider two possibilities for θ: first, $\theta \propto \sigma_g$, which leads to a decision rule where S_0 is defined as the group of genes with $\mathbb{P}(|\delta_g/\sigma_g| \leq T^{\alpha}|\mathbf{x}) \geq 1/(1 + \lambda)$, which is an analog

of a t-statistic procedure. The second choice is with constant θ, in which case the decision rule defines S_0 as genes with $\mathbb{P}(|\delta_g| \leq \delta_g^\alpha|\mathbf{x}) \geq 1/(1 + \lambda)$. A heuristic argument is used to choose the thresholds T^α and δ_g^α; these are defined as the percentiles of the distribution of δ_g/σ_g or δ_g found by hypothetically conditioning on $\bar{x}_{g2} - \bar{x}_{g1} = 0$ in the model, e.g. $f(\delta_g|\bar{x}_{g2} - \bar{x}_{g1} = 0, s_g^2)$. Bochkina and Richardson (2006) also consider a one-sided rule with threshold zero. This is shown to be equivalent to the moderated t-statistic of Smyth (2004) (when the same variance model is used).

8.3.5 Multiclass Data

A number of models that extend the methods used for differential expression in two conditions to compare expression in several conditions or classes have been proposed. These might be used, e.g. to compare the actions of several drugs and a control sample simultaneously, or to compare different tumor samples. As with the mixture models described previously, it can be useful to describe the classification of genes in terms of null and alternative hypotheses. There are a number of different choices of alternative hypothesis for multiclass data. Here we discuss models that use hypotheses of the type 'the gene is differentially expressed (or not) in at least one condition', without distinguishing what the condition is. Section 8.4 deals with models that classify genes by clustering them according to the pattern of expression across the experimental conditions, thus distinguishing between being differentially expressed in condition 4 only and being differentially expressed in condition 2 only, for example. An intermediate approach is taken by Ishwaran and Rao (2005b) who, similarly to their work on differential expression, formulate the multiclass analysis as a multivariate regression problem, use variable selection and shrinkage to output lists of significant genes between any two conditions and then use these lists to highlight patterns of interest between the conditions.

A common formulation is the classical analysis of variance (ANOVA) model, which tests the null hypothesis 'the gene has the same expression in all conditions' versus the alternative 'the gene has differential expression in at least one condition'. This is used in a Bayesian framework by Broët *et al.* (2004), who start with an F-statistic for each gene. These F-statistics are transformed to the normal scale and modeled with a two-component mixture to classify genes as differentially expressed or not differentially expressed. The null component is a standard normal, while the alternative component is modeled semiparametrically with a mixture of normals. This type of formulation is also suggested by Smyth (2004), who uses moderated F-statistics, using shrunken estimates of variances as with the moderated t-statistics (see Section 8.3.4).

A slightly different formulation is considered by Bochkina and Richardson (2006), who use alternative hypotheses such as 'the gene is DE in a set of pairwise comparisons of interest' versus a compound null, which is the opposite of this, i.e. genes are only selected as being of interest if they show changes in a predefined set of comparisons of interest.

8.4 CLUSTERING GENE EXPRESSION PROFILES

When gene expression is measured in several conditions simultaneously, the data is in the form of a matrix x_{gc} with the index c taking more than two values, $c = 1, \ldots, n$. In

this case, the interest focuses on finding groups of genes that have the same pattern of coexpression across the conditions. These patterns are called *expression profiles*.

8.4.1   Unordered Samples

The models dealt with in this section are designed for experiments in which there is no special ordering of the different conditions, e.g. several tumor samples. Most commonly, this sort of data has no replicate measurements, or at any rate samples from different individuals are not treated as replicates. When replicates under different conditions have been measured, the modeling of the profiles can take this into account to improve the classification (Medvedovic *et al.*, 2004; Dahl, 2006). Even when there are no replicates, the different samples can however be used together to estimate gene variances, even though the samples have different expression levels.

Most of these models are based on a similar linear model to that in (8.6). It is convenient to write the gene profile as a vector:

$$\vec{x}_g = \vec{\mu}_g + \varepsilon_g, \tag{8.15}$$

where the vectors $\vec{x}_g$ and $\vec{\mu}_g$ are of length n. The normalization term is omitted here, as most published Bayesian models do not include this term (instead requiring the data to have been transformed in a suitable way beforehand).

Choices for the distribution used to model gene variability are similar to those discussed in Section 8.3.2. Here our focus is on modeling the mean expression levels in the different groups. As with the differential expression models, a mixture model can be put on the $\vec{\mu}_g$ parameters, or on the data directly. The correspondence with null and alternative hypotheses can also be carried forward to this type of model, though now there may be several alternatives. The null is 'no difference in expression across conditions'. The alternatives are usually all possible patterns showing some difference, though Kendziorski *et al.* (2003) allow the number of alternative patterns to be restricted, which is a useful feature for large numbers of experimental conditions.

The probability of expression (POE) model of Parmigiani *et al.* (2002) and Garrett-Mayer and Scharpf (2006) is a simple three-component mixture model on the data. Its aim is to estimate allocation probabilities for each gene and condition to one of three groups: reference, under-, and overexpressed. In its simplest form, biological information is available to classify some indices c as giving 'normal', i.e. reference values. Reference values are modeled as arising from a normal distribution with additive gene effects plus global condition effects, whereas the under and over components are assumed to be uniformly left or right shifted from the reference mean with a range to be estimated. All unknown parameters are given prior distribution and the mixture is estimated in a fully Bayesian way via MCMC algorithms, (Parmigiani *et al.*, 2002). The output of this mixture model is a simple transformation of the data matrix into a probability scale based on an underlying assumption that the information in the expression values is essentially categorical. In contrast to other work described below, clustering of the probabilities to define interesting subgroups of genes is not attempted within the model, but the authors suggest that data mining tools may be used at a second stage.

Kendziorski *et al.* (2003), Gottardo *et al.* (2006c) and House *et al.* (2006) suggest models for clustering gene expression profiles using a mixture model on the parameters $\vec{\mu}_g$. These models are extensions of those used in differential expression, and are

formulated via combinations of point masses and continuous distributions for the various hypotheses/clusters. Kendziorski *et al.* (2003) extend the model of Newton *et al.* (2004), described in the differential expression section, to a mixture model on gene expression profiles. As an example, when there are three experimental conditions, the gene expression parameters are $\mu_{g1}, \mu_{g2}, \mu_{g3}$. There are five possible patterns for a profile over three conditions: one pattern with $\mu_{g1} = \mu_{g2} = \mu_{g3}$, three patterns with two of the μ_{gc} equal to each other and the third drawn from a separate distribution, and one pattern where all three μ_{gc} are drawn from different distributions. Their implementation allows the restriction to a few interesting patterns, as the number of possible patterns increases rapidly with the number of conditions. One version of the model of Kendziorski *et al.* (2003) is an extension of that used in Newton *et al.* (2004) where the likelihood is a gamma and the mean expression parameters have gamma priors. They also look at a version with lognormal likelihood and normal priors. Gottardo *et al.* (2006c) propose a similar model for profiles, implemented for three experimental conditions. This model is an extension of their differential expression model mentioned in Section 8.3.3, using log normal likelihood and normal priors. They automatically consider all possible patterns. House *et al.* (2006) give another similar model, this time implemented in five conditions.

Vogl *et al.* (2005) gives an example of a mixture model on the data (see Section 8.3.3 for more explanation on mixture models). In this case $\vec{\mu}_g$ is replaced by $\vec{\mu}_k$ in (8.15), where k labels the mixture component and the mixture allocation parameter z_g is equal to k. This model assumes a normal distribution for each mixture component, with variance σ_k^2, i.e. equal variance for all genes in the same component. Note that gene variances integrated over different allocations will not be equal for all genes, as different genes will be allocated to different combinations of mixture components. The prior used in Vogl *et al.* (2005) for the $\vec{\mu}_k$ is a conjugate prior, with independence between different experimental conditions. The number of clusters $k = 1, \ldots, K$ is estimated in the model along the lines of Richardson and Green (1997). This model does not in fact automatically include the null cluster of equal expression in all conditions. Figure 8.4 shows some of the gene profiles found by Vogl *et al.* (2005) for the Spellman cell-cycle data (Spellman *et al.*, 1998). Different clusters of genes peak at different phases of the cell cycle.

Rather than using finite mixture models for clustering profiles, a number of authors (Medvedovic *et al.*, 2004; Dahl, 2006; Lau and Green, 2006a; 2006b) have recently developed fully Bayesian profile clustering, based on DPMs. In this setup, it is assumed that gene profiles characterized by parameters $\vec{\mu}_g$, $g = 1, \ldots, p$ are clustered according to a tractable distribution on partitions corresponding to the Dirichlet process and that, within each cluster, the profiles follow the same distribution. DPM is a popular formulation for implementing clustering and partitions models. Indeed, besides their representation as infinite mixtures (see Section 8.3.3), DP models with baseline distribution G^* and scalar α can be equivalently defined via a prior structure on the space $\mathbf{C}$ of partitions of p items (here the genes) into K clusters, $\{1, \ldots, p\} = \bigcup_{k=1}^{K} C_k$, with p_k items in cluster C_k, a joint distribution on the partition given by:

$$p(C_1, C_2, \ldots, C_K) = \frac{\alpha^K \Gamma(\alpha) \prod_{k=1}^{K} (p_k - 1)!}{\Gamma(\alpha + p)},$$

associated i.i.d. draws of $\vec{\mu}_k^*$ from G^*, $k = 1, \ldots, K$, and setting $\vec{\mu}_g = \vec{\mu}_k^*$ if $g \in C_k$.

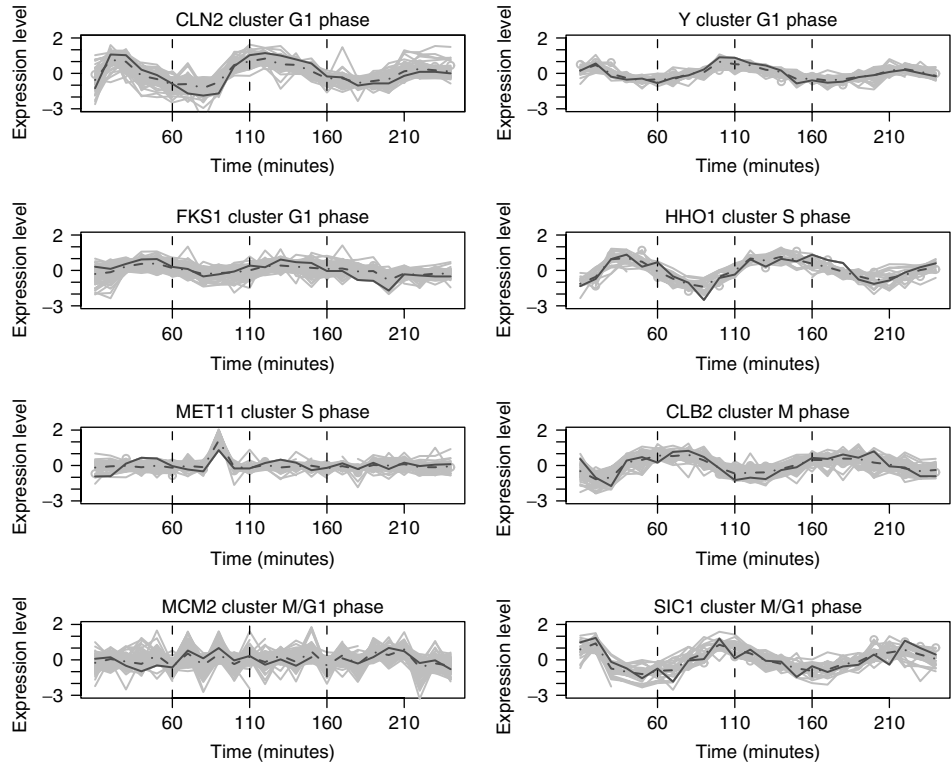
Authors differ in their choice of specification of the base measure distribution, and in whether they choose a fully conjugate specification between the mixture kernels for the


Figure 8.4   Clusters of cell-cycle-regulated genes found in the Spellman *et al.*, 1998 data using the model of Vogl *et al.*, 2005. [Reprinted from Vogl, C., Sanchez-Cabo, F., Stocker, G., Hubbard, S., and Wolkenhauer, O. (2005). A fully Bayesian model to cluster gene-expression pro les. *Bioinformatics* **21**, ii 130–ii 136, by permission of Oxford University Press.]

data part of the model and the base measure. In Lau and Green (2006b), the standard DPM approach is extended by replacing the DP model by a variant in which there is a background cluster not exchangeable with the others and in which there is a different prior distribution of the cluster-specific parameters. Fully conjugate specification (Dahl, 2006; Lau and Green, 2006a; 2006b) is computationally advantageous as all the cluster parameters can be integrated out and efficient MCMC algorithms that update solely the partition can be used. Within cluster, posterior distributions for the parameters are then sampled, conditional on the partition.

In general, drawing inference from the complex posterior clustering distribution is not straightforward and, as the number of partitions grows rapidly with increasing p, recording the partition with the highest posterior probability does not guarantee that it is close to the posterior mode. Medvedovic *et al.* (2004) suggest computing the pairwise posterior probabilities for two genes to be in the same cluster and then postprocessing this output by traditional hierarchical clustering algorithms. Dahl (2006) proposes that, among all the observed clustering, the clustering that minimizes, in the least square sense, the distance between its 0-1 association matrix and the estimated pairwise posterior probabilities be chosen. Lau and Green (2006a) have formulated a Bayesian solution to

define the optimal clustering that optimizes a posterior expected loss function. This loss function penalizes pairs that are clustered together when they should not be and vice versa. They derived an efficient approximation to define the optimal clustering. Heard *et al.* (2006a) propose a hierarchical algorithm that approximates the posterior mode in a Bayesian clustering model without requiring MCMC computations (see next section for details).

It is possible to apply the models presented above to time-course or dose−response data, where there is an ordering of the samples, e.g. in Medvedovic *et al.* (2004) and Vogl *et al.* (2005). In these examples, the unordered sample models work well. However, for data with less pronounced patterns, it is better to use models that take into account the ordering information, such as those presented in the next section.

8.4.2 Ordered Samples

Models for ordered samples also usually start with a linear model,

$$x_{gt} = \mu_{gt} + \varepsilon_{gt}, \qquad (8.16)$$

where again we omit the normalization term, as this is usually assumed to be already taken care of. We use the index t for the ordered data points. For convenience we refer to these as *time points*, though they could be any ordered data. This type of data tends not to have repeated measurements for the same time point. Because of this, it is not possible to estimate separate μ_{gt} for each gene and perform clustering on them. The mixture prior for clustering must be at the data level, i.e. μ_{gt} is replaced by μ_{kt}, where k labels the mixture component to which gene g is allocated.

Two broad classes of models for dependence between time points have been proposed in the literature. One class models the parameter at any given time t in terms of the previous time point or several time points. The other class uses parametric basis functions to give a shape to the parameters across the time points. Note also that the formulation presented in Lau and Green (2006a; 2006b) allows the structuring of $\vec{\mu}_g$ as a linear function of a fixed set of covariates, in particular time (or function thereof), and can thus be used effectively for both ordered and unordered samples.

Ramoni *et al.* (2002) implement the first class of model, using an autoregressive (AR) prior on the μ_{kt} (thus μ_{kt} is regressed on $\mu_{k,t-1}, \ldots, \mu_{k,t-q}$, where q is the order of the AR prior). The AR prior assumes a stationary time series, so it will not be appropriate for many types of microarray data, especially as data is often measured at irregular time points. The clustering used in this method is hierarchical and agglomerative, that is, the posterior space of clusters is not explored fully, but a path is taken through the space in a similar way to classical hierarchical clustering methods. The scoring function used to decide which clusters are to be merged is based on ratios of posterior probabilities of the original and merged partitions.

A more flexible model in this class is given in Wakefield *et al.* (2003) and Zhou and Wakefield (2006), who use a random walk model on the μ_{kt}:

$$\mu_{kt} = \mu_{k,t-1}, +u_t, \qquad (8.17)$$

where $u_t \sim N(0, |X_t - X_{t-1}|\tau^2)$ and X_t is the value of time at the tth time point. Thus the closer adjacent time points are, the more dependent they are. This model is fitted in a fully Bayesian way, with the number of clusters estimated as part of the model. Inference is

made on the basis of posterior probability of cluster membership, with particular attention given to finding pairs of genes with high probability of being allocated to the same cluster. This is to find genes that are coexpressed.

A model in the second class is proposed by Heard *et al.* (2006a). This uses splines (with degree to be chosen) as basis functions for the trajectories of the genes over time,

$$\mu_{kt} = \sum_h X_{th} \beta_{hk}, \tag{8.18}$$

where X_{th} is the (fixed) value of the hth basis function at time t and β_{hk} is the coefficient of the hth basis function for cluster k. By using a fully conjugate specification, the joint distribution of the data conditional on any partition can be computed in closed form. Hence the posterior probability of any partition can also be evaluated. The clustering method exploits this and proceeds by an agglomerative algorithm similar to that used by Ramoni *et al.* (2002), in order to find the partition that approximates the posterior mode. Heard *et al.* (2006b) extend this model to time series taken in a number of different conditions, and estimate covariance between time series in different conditions.

Wakefield *et al.* (2003) also fit a basis function model, for periodic data

$$\mu_{gt} = A_g \sin(wX_t) + B_g \cos(wX_t), \tag{8.19}$$

applied to a cell-cycle data set.

8.5   MULTIVARIATE GENE SELECTION MODELS

In the previous sections, we have discussed *gene expression association studies* where the aim is to find gene expression changes that relate to biological outcomes by comparing, for each gene, their differential expression under different conditions, and *profile clustering* where the interest is to find patterns of coexpressed genes across different experimental conditions, in order to understand pathways. In this section, we are concerned with a different, but related, problem, which is that of using gene expression for phenotype prediction. Our aim here is to build multivariate molecular profiles based on combination of the expression of a subset of genes that can characterize different phenotypes (e.g. clinical outcomes). We are thus in the framework of multivariate regression and classification models. The specific difficulty of genomic applications is that there are typically many more covariates than samples: the so-called large p (thousands of genes), small n (50–100 samples) regression paradigm, and consequently standard regression/discrimination techniques do not apply. Further, the interest is in finding parsimonious regression models that include only small subsets of genes so that biological interpretation and validation can be attempted.

Bayesian approaches to multivariate gene selection have broadly followed two related lines of development: (1) regression methods with covariate selection, (2) multivariate regression with shrinkage priors that favor sparsity. We shall review these in turn. Mostly, we shall discuss so-called supervised classification situations where the characteristic of the samples that one wants to predict are known. Variable selection can also be performed simultaneously with the task of uncovering clustering patterns of the samples in an unsupervised manner.

8.5.1 Variable Selection Approach

Suppose that we have potentially p predictor variables, each measured on a set of n samples: x_{gc} with $g = 1, \ldots, p$ and $c = 1, \ldots, n$. Thus, for each predictor variable g, we have a vector of n measurements $\vec{x}_g$. For the present, the outcome variable, $y_c, c = 1, \ldots, n$, can be continuous (e.g. measuring a biomarker) or categorical (e.g. encoding a cancer subtype) and we denote the vector of regression parameters linking $\mathbf{X}$ and $\mathbf{Y}$ as $\boldsymbol{\beta}$, (these being the matrices for predictors and outcomes, respectively). Thus β_g is the regression parameter corresponding to the covariate $\vec{x}_g$.

Bayesian variable selection (BVS) is usually implemented through a hierarchical model, where all possible 2^p models are represented by a p-dimensional indicator variable $\boldsymbol{\gamma}$:

$$\gamma_g = \begin{cases} 1 & \text{variable (gene) } g \text{ is included} \\ 0 & \text{variable (gene) } g \text{ is excluded} \end{cases}.$$

A prior on the model space can be specified via a prior $p(\boldsymbol{\gamma})$. A common choice is $p(\boldsymbol{\gamma}) = \prod_{g=1}^{p} \pi^{\gamma_g} (1 - \pi)^{1-\gamma_g}$, and by choosing small π, the number of variables selected can be controlled. Alternatively, a beta prior distribution can be assumed for π and the sparsity of the regression only controlled by the choice of prior for the βs.

This generic approach to variable selection, often referred to as the *spike and slab approach*, was taken in Mitchell and Beauchamp (1988), George and McCulloch (1993; 1997) and in many subsequent papers (Clyde, 1999; Brown *et al.*, 1998; 2002). Much of the work on BVS was developed for linear models where y_c is continuous. In this context, authors differ in the choice of the prior distribution for $\boldsymbol{\beta}$, in particular whether the components of $\boldsymbol{\beta}$ are treated as independent, and whether a conjugate formulation is chosen so that the prior on $\boldsymbol{\beta}$ includes the noise parameter of the linear model. Typically, the prior for $\boldsymbol{\beta}$ is formulated via a mixture. Most models define a point mass at zero for β_g when $\gamma_g = 0$, while when $\gamma_g = 1$, large variances are favored with a distribution to be specified. Ishwaran and Rao (2003; 2005a; 2005b) use a modified spike and slab model that assumes a continuous bimodal prior for β_g, a scale mixture of two centered normals, one having a small variance. They show that this prior is useful in gene expression; see Sections 8.3.3 and 8.3.5. In the common case of a prior for β_g with a point mass at zero, for ease of notation, we shall denote all nonzero elements of $\boldsymbol{\beta}$ by β_γ, and correspondingly, we denote the columns of X corresponding to those elements of $\boldsymbol{\gamma}$ equal to 1 by $\mathbf{X}_\gamma$.

A standard choice of prior for β_γ is the so-called g prior, where $\beta_\gamma \sim N(0, c(X_\gamma^T X_\gamma)^{-1})$, where c is a positive scale factor to be chosen. Similarly, if independent normals are specified for the components of $\boldsymbol{\beta}$, again a scalar has to be chosen. These choices influence the sparsity of the final regression model (Chipman *et al.*, 2001) and a full understanding of this aspect is the object of current research.

In the microarray context, because we are in a 'large p, small n' situation, the posterior distribution over the model space of variable dimensions is multimodal. Moreover, full posterior inference for the entire model space of size 2^p is not feasible if p is larger than about 20. Hence, MCMC methods are rather used as stochastic search algorithms with the aim to quickly find many regions of high posterior probability. The Markov chain needs to move quickly around the support of the posterior distribution and, as usual, it is useful to integrate out as many parameters as possible. For this reason, conjugate settings have been favored in the linear model. When proposing changes to $\boldsymbol{\gamma}$, a key question is how to propose sensible changes to the regression vector $\boldsymbol{\beta}$. The current parameter values

may be of little relevance in this case and joint moves that simultaneously update γ and β produce an improvement (Holmes and Held, 2006).

Much of the application of variable selection in microarrays has concerned binary or categorical variables rather than the linear model. Typically, samples are classified as good or poor prognosis or linked to different clinical subentities, like subtypes of cancer. There is no immediate conjugate formulation of Bayesian categorical regression, but following the approach of Albert and Chib (1993), probit regression can be efficiently implemented through the use of latent auxiliary variables, which allows integration of the regression coefficients in the full conditional distribution of the indicator variables γ. This approach was taken by Lee *et al.* (2003) and Sha *et al.* (2004). These authors have implemented different MCMC schemes for updating γ (Gibbs sampling in Lee *et al.* (2003), which will tend to be slow mixing, Metropolis with add/delete/swap moves in Sha *et al.* (2004)). In a recent paper, Holmes and Held (2006) have proposed an auxiliary variable formulation of the logistic model, which allows, in a similar way to the probit model, integration of the regression coefficients when updating the indicator variables, thus improving mixing. For both probit and logistic regression models, the calibration of the prior distribution of the regression coefficients again influences the outcome of the variable selection process. In this respect, the logistic regression, which is more commonly used for binary regression, is easier to calibrate than the probit model as it has heavier tails and so exhibits less sensitivity.

In general, MCMC variable selection algorithms in high dimension are difficult to implement owing to slow convergence. Recent developments in stochastic simulation algorithms, such as population-based reversible jump MCMC and the use of parallel tempered chains seem promising (Jasra *et al.*, 2006). An alternative search algorithm, the *shotgun stochastic search* method, which is close in spirit to MCMC but aims to search rapidly for the most probable models, has been recently proposed by Hans *et al.* (2007). Note that it is a discussion point whether to report models with high posterior probabilities and their associated variables, or to extract marginal information about the selected variables by looking at their marginal posterior probabilities of inclusion (Sha *et al.*, 2004).

We end this section by referring to the recent work of Tadesse *et al.* (2005) and Kim *et al.* (2006) where variable selection and clustering of the samples are performed simultaneously. This joint modeling is motivated by the remark that using a high-dimensional vector of gene expression to uncover clusters among the samples might not be effective and on the contrary can tend to mask existing structure, while a more parsimonious model that selects a only a small subset of covariates to inform the clustering is more easily interpretable. Such joint modeling was discussed in a Bayesian context in two related papers, which differ in their model for the clustering structure. Tadesse *et al.* (2005) formulate their clustering structure using a finite mixture of multivariate normals with a variable number of components and use reversible jump techniques to explore different structures, while Kim *et al.* (2006) exploit the computational benefits of DP mixtures.

8.5.2 Bayesian Shrinkage with Sparsity Priors

An alternative approach to BVS for selecting a small number of regressors is to use a hierarchical formulation of the regression problem with a prior on the regression coefficients that favors sparsity. Effectively, a large number of regression coefficients are essentially set to zero by having very small posterior values. Note that different choices of prior and hierarchical structures can be interpreted as different choice of penalties if one

adopts the point of view of penalized likelihood, framework into which ridge regression and other shrinkage methods can be cast.

A general formulation that encompasses many of the models that have been proposed is that of scale mixture of normals. In this formulation, the regression coefficients β_g are given independent normal priors: $\beta_g \sim N(0, \tau_g)$, and the variances τ_g are themselves given a hyperprior distribution: $\tau_g \sim p(\tau_g)$. Choice of this prior distribution leads to a different kind of sparsity for the βs, but all priors used have in common the desirable feature that the integrated prior for β is a heavy tail distribution with a peak around zero, thus favoring only a small number to be substantially different from zero. Note that a Laplace prior for β_g, which corresponds to a Lasso type penalization, can also be written as a scale mixture of normals with $p(\tau_g)$ being a one-parameter exponential distribution, (Griffin and Brown, 2005).

Bae and Mallick (2004) implement three different choices of prior for τ_g in the context of gene expression studies: an inverse γ with two hyper parameters that are chosen in order to favor large variances, a Laplace prior with one parameter and a Jeffreys improper prior (which implies an improper prior of the form $\frac{1}{\beta_g}$ for β_g). They found that Jeffreys prior induces more sparseness than the Laplace prior and yields good performance. There is currently a lot of interest in using general families of scale mixtures and in calibrating them for efficient inference in high-dimensional setups (Griffin and Brown, 2005).

Sparsity priors can also be used in the context of latent factor models (West, 2003; Lucas *et al.*, 2006). Modeling high-dimensional data via latent factor models is a powerful dimension reduction technique that allows the identification of patterns of covariation among genes. In their application of factor models to the analysis of gene expression data, West (2003) and Lucas *et al.* (2006) further structure the factor loading matrix to encourage sparsity via a mixture prior with point mass at zero. A biological interpretation of the factors as potentially representing biological pathways is then derived by examining the list of genes most weighted on each factor.

Inferring Causal Associations between Genes and Disease via the Mapping of Expression Quantitative Trait Loci

S.K. Sieberts and E.E. Schadt

Rosetta Inpharmatics LLC, Seattle, WA, USA

The ability to monitor transcript levels in a comprehensive fashion allows for a more general characterization of transcriptional networks and their relationship to disease and other complex physiological processes. Information on how variations in DNA impact complex physiological processes flows through the transcriptional networks. Therefore, integrating DNA variation, transcription, and phenotypic data has the potential to enhance identification of the associations between DNA variation and disease, as well as characterize those parts of the molecular networks that drive disease. Toward that end, we discuss mapping expression quantitative trait loci (eQTL) for gene expression traits and then detail a method for integrating eQTL and expression and clinical data to infer causal relationships among gene expression traits and between expression and clinical traits. We further describe methods to integrate these data in a more comprehensive manner by constructing coexpression gene networks, which leverage pair-wise gene interaction data to represent more general relationships. To infer gene networks that capture causal information, we describe a Bayesian algorithm that further integrates eQTL and expression and clinical phenotype data to reconstruct whole gene networks capable of representing causal relationships among genes and traits in the network. These emerging high-dimensional data analysis approaches, that integrate large-scale data from multiple sources, represent the first steps in statistical genetics moving away from considering one trait at a time and toward operating in a network context. Evolving statistical procedures that operate on networks will be critical to extracting information related to complex phenotypes like disease, as research goes beyond the single-gene focus. The early successes achieved with some of the methods described herein suggest that these more integrative genomics approaches to dissecting disease traits will significantly enhance the identification of key drivers of disease beyond what could be achieved by genetics alone.

9.1   INTRODUCTION

DNA microarrays have revolutionized the way we study genes and the role they play in everything from the regulation of normal cellular processes to complex diseases like obesity and cancer. High-throughput DNA microarray technologies are capable of simultaneously providing quantitative measures of RNA present in cells or tissue samples for tens of thousands of protein-coding genes, in addition to other noncoding transcribed sequences. The quantitative measures of transcript abundances in cells are often referred to as *gene expression traits*. In their typical use, microarrays allow researchers to screen thousands of genes for differences in expression or differences in how genes are connected in the network (Schadt and Lum, 2006) between experimental conditions of interest (see **Chapter 6**, Sections 4 and 5, and also **Chapters 7** and **8**). These data are often used to discover genes that differ between normal and diseased tissue, to model and predict continuous or binary measures, to predict patient survival, and to classify disease or tumor subtypes. Because gene expression levels in a given sample are measured simultaneously, researchers are able to identify genes whose expression levels are correlated, implying an association under specific conditions or more generally.

Causal associations among genes or between genes and traits have also been investigated using time series experiments, gene knockouts or transgenics that overexpress a gene of interest, RNAi-based knockdown or viral-mediated overexpression of genes of interest, and chemical activation or inhibition of genes of interest. However, recently a number of studies have demonstrated that naturally occurring DNA polymorphism can be used to help establish causal associations, since gene expression and other molecular phenotypes in a number of species have been shown to be significantly heritable and at least partially under the control of specific genetic loci (Jin *et al.*, 2001; Brem *et al.*, 2002; Klose *et al.*, 2002; Oleksiak *et al.*, 2002; Schadt *et al.*, 2003; Monks *et al.*, 2004; Morley *et al.*, 2004; Hubner *et al.*, 2005; Stranger *et al.*, 2005; DeCook *et al.*, 2006). By examining the effects that naturally occurring variations in DNA have on variations in gene expression traits in human or experimental populations, other phenotypes (including disease) can then be examined with respect to these same DNA variations and ultimately ordered with respect to genes to infer causal control (Figure 9.1) (Mehrabian *et al.*, 2005; Schadt *et al.*, 2005; Kulp and Jagalur, 2006; Lum *et al.*, 2006). The power of this integrative genomics strategy rests in the molecular processes that transcribe DNA into RNA and then RNA into protein, so that information on how variations in DNA impact complex physiological processes often flows directly through transcriptional networks. As a result, integrating DNA variation, transcription, and phenotypic data has the potential to enhance identification of the associations between DNA variation and disease, as well as characterize those parts of the molecular networks that drive disease.

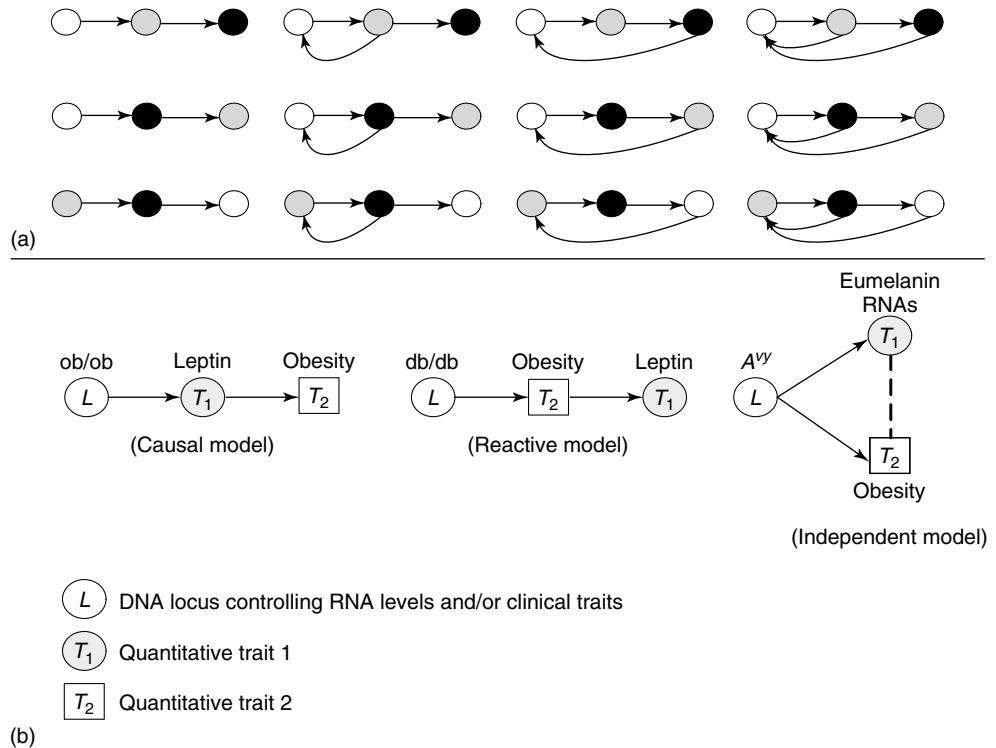
A number of groups have now published on approaches for identifying key drivers of complex traits by examining genes located in regions of the genome genetically linked to a complex phenotype of interest, and then looking for colocalization of cis-acting expression quantitative trait loci (eQTL) for those genes residing in a genomic region linked to the phenotype (Jansen and Nap, 2001; Brem *et al.*, 2002; Schadt *et al.*, 2003; Monks *et al.*, 2004; Morley *et al.*, 2004; Alberts *et al.*, 2005; Chesler *et al.*, 2005; Cheung *et al.*, 2005; Schadt *et al.*, 2005; Petretto *et al.*, 2006a; 2006b). Those genes with (1) expression values that are significantly correlated with the complex phenotype of interest (including disease), (2) transcript abundances controlled by QTL that colocalize with the phenotype QTL, and


Figure 9.1 Possible relationships between phenotypes with and without genetic information. Edges between nodes in each of the graphs represent an association between the nodes. A directed edge indicates a causal association between the nodes. (a) A subset of the number of possible relationships between three variables. (b) The set of possible relationships between two traits and a controlling genetic locus, when feedback mechanisms are ignored.

(3) physical locations supported by the phenotype and expression QTL are natural causal candidates for the complex phenotype of interest. Since DNA variation leads to changes in transcription and other molecular trait activity, it can be used to partition the thousands of gene expression traits that may be correlated with a given phenotype into sets of genes that are supported as causal for, reacting to, or independent of the given phenotype. The key to the success of this approach is the unambiguous flow of information from changes in DNA to changes in RNA and protein function (Figure 9.1). That is, given that two traits are linked to the same DNA locus, and a few simplifying assumptions discussed below, there are a limited number of ways in which such traits can be related with respect to that locus (Schadt, 2005; 2006; Schadt *et al.*, 2005), whereas in the absence of such genetic information, many indistinguishable relationships would be possible, so that additional data would be required to establish the correct relationships.

Here we discuss mapping eQTL for gene expression traits and then detail a method for integrating eQTL and expression and clinical data to infer causal relationships among gene expression traits and between expression and clinical traits. We further describe methods to integrate these data in a more comprehensive manner by constructing coexpression gene networks, which leverage pair-wise gene interaction data to represent more general

relationships. This type of network provides a useful construct for characterizing the topological properties of biological networks and for partitioning such networks into functional units (modules) that underlie complex phenotypes like disease. However, these networks are, by design, undirected and so do not capture causal relationships among genes. To infer gene networks that capture causal information, we describe a Bayesian algorithm that, like the methods operating on only two or three expression traits and/or clinical traits mentioned above, integrates eQTL and expression and clinical phenotype data to reconstruct whole gene networks capable of representing direction along the edges of the network. Here, directionality among the edges corresponds to causal relationships among genes and between genes and clinical phenotypes. These emerging high-dimensional data analysis approaches, which integrate large-scale data from multiple sources, represent the first steps in statistical genetics moving away from considering one trait at a time and toward operating in a network context. Evolving statistical procedures that operate on networks will be critical to extracting information related to complex phenotypes like disease, as research goes beyond the single-gene focus. The early successes achieved with some of the methods described herein suggest that these more integrative genomics approaches to dissecting disease traits will significantly enhance the identification of key drivers of disease beyond what could be achieved by genetics alone.

9.2 AN OVERVIEW OF TRANSCRIPTION AS A COMPLEX PROCESS

Messenger ribonucleic acid (mRNA) is an intermediate product of a process that generates protein starting with DNA, where DNA is transcribed to produce RNA, and then RNA is translated to produce protein. The nucleus is where DNA is transcribed into its RNA analog, and in the case where RNA corresponds to a protein-coding gene, the RNA is processed into a mature mRNA form. The mRNA then migrates to the cytoplasm where it is translated, via tRNA, into a protein, which is often considered the functional product of the gene itself. Thus, gene expression measures corresponding to protein-coding genes are surrogates for either the state of a protein or the amount of protein that is being produced by the corresponding gene. Therefore, the amount of mRNA detected in the cytoplasm of a cell is seen to be the result of a number of different molecular processes, including the transcription process itself, the rate of RNA degradation (which is sequence specific and often sensitive to different functional forms of a protein), transport from the nucleus, and alternative splicing (a microarray probe may target a part of the transcript that is alternatively spliced).

The overall regulation of transcription is a complex process, especially in eukaryotic cells. Transcription in all types of cells begins when RNA polymerase binds to specific DNA sequences known as *promoters*, which are generally located close to the 5′ end of the gene. In order to prevent the binding of the polymerase, and thus regulate the otherwise constant transcription of a given gene sequence, many genes have negative control elements called *operators*, which when bound by specific proteins called *repressor proteins* prevent the binding of the polymerase to the promoter region. Using these simple positive and negative controllers, cells can regulate the transcription of DNA sequences in response to specific conditions or, as appropriate, for a given tissue type.

In eukaryotes, promoters and operators are usually complemented by other regulatory sequences that can operate at much longer distances, often tens of kilobytes or even longer. Some elements, like enhancers, encourage and speed up transcription, while others, like silencers, discourage and slow down transcription. While promoters and operators cause binary, on/off regulation, enhancers and silencers can have much more subtle effects on transcription. Nevertheless, mutations in any of these sequence elements can alter gene expression at the basal level or affect a gene's ability to react under varied cellular conditions. These regulatory elements, which occur in or near the gene transcription region, are referred to as *cis-acting elements* (Figure 9.2).

Complementary to the sequence-based regulatory elements are the protein elements that interact with the sequence elements to regulate transcription. Repressor proteins are one example of regulatory proteins that directly bind to DNA sequences. Other proteins may bind to the promoter region to increase the affinity of RNA polymerase to the region and, thus, are positive controllers of transcription. In eukaryotes, in order for polymerase to bind the DNA and begin transcription, a number of additional molecules must first bind the promoter region. These transcription factor binding–associated proteins (TAFs) form transcription factor complexes that help position the polymerase in the promoter region. This complex alone provides basal regulation of transcription but may also be enhanced by additional ancillary proteins called *activators*, which bind to enhancer sequence elements to speed transcription. Repressor proteins may bind to silencer sequence elements in the DNA as well to slow transcription. Of course, these regulatory proteins may themselves be regulated, where feedback control or other such processes are known to regulate the quantities of these proteins in the cell. Other regulatory proteins may require that allosteric effectors be in their active form or that they become inactivated by effector proteins. Other proteins may inhibit the formation of the transcription factor complexes. These elements,
Figure 9.2 Mapping proximal and distal eQTL for gene expression traits. The white rectangles represent genes that are controlled by transcriptional units. The ellipses represent the transcriptional control units, which could be transcription regulatory sites, other genes that control the expression of the indicated gene, and so on. (a) Cis-acting control unit acting on a gene. DNA variations in this control unit that affected the gene's expression would lead to a cis-acting (proximal) eQTL. (b) cis and trans control units regulating the indicated gene. DNA variations in these control units that affected the gene's expression would lead to proximal and distal eQTL. (c) cis control unit and multiple trans control units regulating the indicated genes. DNA variations in these control units would lead to a complex eQTL signature for the gene. (d) A single control unit regulating multiple genes. DNA variations in this single control unit could lead to a cluster of distal eQTL (an eQTL hot spot).

which are usually coded for far from the genes they regulate, are called *trans-acting elements* (Figure 9.2).

The view of transcription just discussed, although necessarily simplified for this presentation, highlights that it is indeed a complex process, and with the recent discovery of large numbers of noncoding ribonucleic acids (ncRNAs), many of which have already been shown to regulate transcription, the complexity of how cells regulate transcription will no doubt be shown to be more complex than we can appreciate at this time. Variations in transcript abundances can be caused in a number of ways, many of which are ultimately due to variation in genetic sequences, where altering the sequence in the regulatory region or altering the proteins or quantity of the proteins that bind to these regions results in variations in transcript abundances. Additionally, the rate of transcription of degradation of gene transcripts can also be affected by ncRNAs. One class of ncRNAs currently under intense study because of their regulation of transcription is micro-RNAs. These small molecules bind to specific sequences in the mRNA, so that mutations in the DNA encoding either the micro-RNA or the gene transcript can alter the binding affinity and thus the rate of degradation. Whether variations in gene expression are due to changes in the rate of transcription, degradation, transcript transport from the nucleus, alternative splicing, or other such processes, these encoding or micro-RNA variations can be comprised of genetic and environmental components, which when properly identified and integrated with other information can lead to the identification of key drivers of complex phenotypes like disease.

9.3   HUMAN VERSUS EXPERIMENTAL MODELS

eQTL analysis can be done using either designed crosses of experimental organisms or natural segregating populations, like humans, using methods appropriate for the study design (**Chapters 18**, **19**, **20**, **32**, **33**, **34**, **35**, **36**, **37** and **38**). eQTL mapping has been successful both in animal crosses and in humans using both linkage and association. The choice of animal model versus human should depend on many factors that include the goal of the study and the availability of tissue samples in the chosen population.

In humans, there are two primary difficulties that make these studies less common. First is the availability of tissue samples. Preliminary studies in humans were done using lymphoblastoid cell lines, and with the exception of cell types that can be extracted from blood, the procurement of most tissue types of interest is relatively invasive and often prohibitive in most circumstances. Another barrier to performing these types of studies in humans is that of power, which is always an issue when choosing between human and designed animal experiments, due to the lack of full informativeness in human data. In the situation of eQTL mapping, the issue of power is exacerbated by the multiple testing issues that are obtained in examining thousands of expression traits rather than one or few physical phenotypes. Studies must be appropriately powered to distinguish signal from noise given both the dimentionality of the expression data and the size of the genome.

Crosses of inbred lines in animal models are more informative in terms of identifying the grandparental source of alleles; therefore, fewer individuals are required to detect QTL. Additionally, tissue samples of all types are more readily available in animal experiments than they are from human. Still, questions exist about the validity

of extending the results from animal to human. Additional experiments are always required to validate findings in human. Crosses of inbred lines are also limited by the genetic differences between the two parental lines. Because all inbred strains are related in some manner, between any two strains there is always some portion of the genome that is nonvarying (identical by descent) between the two, and, thus, identifiable QTL are limited to those at loci segregating polymorphisms. These are likely to be fewer in number than in a natural population. As a result, no one experiment can fully identify all eQTL and findings from one cross may not replicate in another.

9.4   HERITABILITY OF EXPRESSION TRAITS

As a quantitative measure, gene expression can be treated as any other quantitative trait in a genetic analysis. A variety of linkage methods for the analysis of quantitative traits are described in **Chapters 18**, **19** and **20**, which are just as useful for identifying genetic controllers of gene expression as they are for, say, regulation of plasma LDL cholesterol levels. This premise, of course, is only valid if expression is, indeed, a trait under genetic control. Thus, characterizing the proportion of the trait variance that is attributed to genetics (i.e. the heritability, see **Chapter 32**, Section 3) over a large set of gene expression traits provides important information about the landscape of genetic control, and ultimately determines how useful eQTL mapping strategies are. For instance, if the genetic component of expression control is vastly outweighed by environmental factors and measurement error, then strategies to map genetic contributions and ultimately correlate these contributions with complex disease will fail.

Equally important is identifying the types of expression traits that are heritable. Many studies have identified gene transcripts that (1) are associated with complex disease phenotypes (Karp *et al.*, 2000; Schadt *et al.*, 2003), (2) are alternatively spliced (Johnson *et al.*, 2003), (3) elucidate novel gene structures (Shoemaker *et al.*, 2001; Mural *et al.*, 2002; Schadt *et al.*, 2004), (4) can serve as biomarkers of disease or drug response (DePrimo *et al.*, 2003), (5) lead to the identification of disease subtypes (van 't Veer *et al.*, 2002; Mootha *et al.*, 2003; Schadt *et al.*, 2003), and (6) elucidate mechanisms of drug toxicity (Waring *et al.*, 2001). However, identifying the heritable traits and the extent of their genetic variability provides insight about the evolutionary forces contributing to the changes in expression that associate with biological processes that underlie complex traits like disease, beyond what can be gained by looking at the transcript abundance data alone.

Estimates of genetic heritability can be made with or without the aid of genetic marker data. In the absence of genetic marker data, the correlation between the trait values of related individuals provides information about the heritability of a trait by identifying the extent to which an individual's trait values can be predicted from their relatives. In outbred populations, traditional methods involve regressing an offspring's trait value on those for the parents, comparing the within-family variance for groups of siblings to the among-family variance in an ANOVA, or contrasting the correlation between pairs of monozygotic and dizygotic twins. In general outbred pedigrees, the heritability can be estimated using linear mixed models as in Section 3.2 of **Chapter 19**. In the absence of

genetic marker information, however, specific QTLs are not modeled. Instead, the mixed model contains only the fixed covariate effects and the random polygenic effect

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u} + \mathbf{e}, \tag{9.1}$$

where

$$u \sim N(0, \mathbf{A}\sigma_u^2),$$

Here $\mathbf{A}$ is twice the kinship matrix and σ_u^2 is the additive genetic variance of the trait, so that σ_u^2/σ_y^2 is the narrow-sense heritability. This polygenic model assumes many loci with small effects (i.e. assumes the trait is complex), but these assumptions may be violated in the presence of one or few loci with strong effects.

When a major gene contributes to the trait and genotype data is available, better estimates of the genetic variance can be made by including allelic or genotypic effects at a QTL locus or loci using the models in Sections 3.2 and 3.3 of **Chapter 19**. This is identical to performing linkage analysis through variance components methods. Here, summing over the appropriate variances for the QTL and polygenic components provides an estimate for the genetic variance. Bayesian MCMC (Markov chain Monte Carlo) methods (see Section 4.3 of **Chapter 19**) can provide more accurate estimates of the genetic variance, as well as estimates of the number of major genes, by sampling over the space of genetic models conditional on the data. The drawback to this type of approach, when the number of traits being mapped is high, is that it is computationally intensive, and the interpretations are not as clear-cut as point estimates obtained from frequentist methods. However, even when computation time is a constraint, appropriate filters can be applied to reduce the number of expression traits to consider in such an analysis. For example, one may choose to restrict attention to those genes with at least one eQTL at a relatively loose significance threshold. Brem and Kruglyak (2005) found 132 genes with QTLs significant at the 5×10^{-4} level, which provides a much smaller set of genes to consider, compared to the tens of thousands of genes that were profiled in this study.

Linkage approaches can also be used to estimate the genetic variance contribution in crosses of inbred lines (Brem and Kruglyak, 2005). However, in this case, care should be taken in the extrapolations made. Conclusions in these analyses apply only to populations founded by the same parental strains and are limited by the extent and pattern of identity by descent (IBD) between them. Here, estimates should be made in the presence of genetic marker data. The power of segregation approaches is limited because, in common inbred line designs such as F2 intercrosses or backcrosses, the subjects are genetically equivalent to one large sibship. Because the relationship between each pair of individuals is identical, the kinship coefficient among all pairs is also identical, resulting in no power to estimate the polygenic component. In order to estimate the genetic variance of a trait, each genetic contribution must be modeled explicitly. Further discussion of multilocus models is given in the following section.

9.5 JOINT eQTL MAPPING

Ultimately, expression traits are quantitative measures that can be analyzed like any other quantitative trait. The difficulty in analysis and interpretation comes with the large

number of traits examined. Whatever method is ultimately chosen must be computationally tractable enough to be performed hundreds of thousands of times. In addition, significance thresholds must be adjusted for multiple testing. Multiple testing issues relate not only to the number of transcripts tested but also to the number of markers or proportion of the genome tested. Further, single-trait analyses lose information by ignoring the correlation between associated expression traits. Appropriately chosen joint mapping methods can leverage trait correlation and more elegantly handle multiple testing.

Typical approaches to the joint analysis of genetic traits involve mapping each gene expression trait individually and inferring the genetic correlation between pairs or sets of expression traits based on pair-wise Pearson correlation, eQTL overlaps, and/or tests for pleiotropy. Using a family-based sample, Monks *et al.* (2004) estimated the genetic correlation between pairs of traits using a bivariate variance-component-based segregation analysis, and showed that the genetic correlation was better able to distinguish clusters of genes in pathways than correlations based on the observed expression traits. This method is similar to single-trait variance-component-based segregation analysis as in (9.1). For two trait vectors $\mathbf{v}$ and $\mathbf{y}$, let $\mathbf{t}$ denote the bivariate trait vector

$$\mathbf{t} = \begin{bmatrix} \mathbf{v} \\ \mathbf{y} \end{bmatrix},$$

with piecewise mean vector

$$\mu_t = \begin{bmatrix} \mu_v \\ \mu_y \end{bmatrix}.$$

The partitioned covariance matrix can be written as

$$\mathbf{V}_t = \begin{bmatrix} \mathbf{V}_v & \mathbf{V}_{vy} \\ \mathbf{V}_{vy} & \mathbf{V}_y \end{bmatrix},$$

where $\mathbf{V}_v$ and $\mathbf{V}_y$ are the univariate covariance matrices for traits v and y respectively. More details are available in Section 3.3 of **Chapter 19**. The trait covariance matrix $\mathbf{V}_{vy}$ is modeled as

$$\mathbf{V}_{vy} = \mathbf{A}\sigma_{uvy}^2 + \mathbf{I}\sigma_{evy}^2,$$

where $\mathbf{A}$ is twice the kinship matrix, $\mathbf{I}$ is the identity matrix, σ_{uvy}^2 is the genetic covariance between the two traits, and σ_{evy}^2 is the nongenetic covariance. The genetic and nongenetic covariances can be expressed in terms of the genetic and nongenetic correlation as

$$\sigma_{uvy}^2 = \sigma_{uv}\sigma_{uy}\rho_{uvy},$$

and

$$\sigma_{evy}^2 = \sigma_{ev}\sigma_{ey}\rho_{evy},$$

where σ_{uv} and σ_{uy} are the square root of the genetic variances for traits v and y, σ_{ev} and σ_{ey} are the square root of the environmental variances, and ρ_{uvy} and ρ_{evy} are the genetic and nongenetic correlations respectively.

These methods can be extended to perform bivariate and multivariate linkage analysis, which can be more highly powered to detect linkage when traits are correlated. Clusters of correlated gene expression traits can often contain hundreds or thousands of genes,

which would be computationally prohibitive in a joint analysis. Kendziorski *et al.* (2006) approached this problem in a different way by employing a Bayesian mixture model to exploit the increased information from the joint mapping of correlated gene expression traits, which is computationally tractable for large sets of genes. Instead of doing a linkage scan by computing LOD scores at positions along the genome, Kendziorski *et al.* (2006) compute the posterior probability that a particular gene expression trait maps to marker *m* for each marker, as well as the posterior probability that the trait maps nowhere in the genome. More specifically, for a particular gene expression trait, *k*, from a correlated gene cluster of interest, the marginal distribution of the data, $\mathbf{y}_k$, is

$$p_0 f_0(\mathbf{y}_k) + \sum_m p_m f_m(\mathbf{y}_k),$$

where p_m is the probability that the transcript maps to marker *m* and f_m is the distribution of the data if it does, p_0 is the probability that the transcript does not map to the genome, and f_0 is the data distribution in this case. Given appropriate choices for the distributions, model parameters can be estimated via the EM algorithm, and posterior estimates of $\{p_m\}$ can be obtained. Nonlinkage is declared for a transcript if the posterior probability of nonlinkage exceeds a threshold that bounds the posterior expected false discovery rate (FDR). One benefit to this approach is that it controls false discovery for the number of expression traits being tested, whereas assessing the appropriate significance cutoffs in single-transcript linkage analysis often requires data permutation analyses. The drawback is that this method assumes that linkage occurs at either one or none of the markers tested, and lacks a well-defined method for the case when multiple eQTL control an expression trait.

9.6   MULTILOCUS MODELS AND FDR

In the study of inbred strain crosses, the only valid way of estimating the extent of genetic control of a given trait is to explicitly model each eQTL, including any epistatic interactions if they exist. Brem *et al.* (2005) showed that epistatic interactions were prevalent in the gene expression levels in yeast, and similar suggestions have been made in other species as well (Schadt *et al.*, 2005), but more definitive studies are needed to characterize the extent of epistasis among eQTL in these other species. In the absence of epistasis, the genetic contribution for each transcript can be estimated by summing contributions for each individual eQTL, assuming that little or no allelic association exists between the eQTL loci. In the presence of epistasis, however, this practice does not yield a valid estimate, and multilocus models are required to obtain valid estimates. Additionally, multilocus modeling can identify loci contributing to expression traits that would have been missed in single-locus eQTL scans (Brem and Kruglyak, 2005; Storey *et al.*, 2005).

While forward selection methods for general regression cases, as with any greedy algorithm, do not typically choose the best model, they have been shown to be consistent in the linkage modeling framework (Broman, 1997). For further discussion of model selection techniques, see Section 4.4 of **Chapter 18**. In the eQTL framework, given the large number of tests being performed, particular care needs to be taken to limit the FDR. Storey *et al.* (2005) suggest controlling the FDR at each stage of a forward model selection

procedure, and they employ a Bayesian technique to estimate false positive probabilities. In other words, the posterior probability of linkage at K loci is calculated as

$$Pr(\text{loci } 1, \ldots, K \text{ linked|data}) = Pr(\text{locus 1 linked|data})$$
$$\times Pr(\text{locus 2 linked|locus 1 linked, data}) \times \cdots$$
$$\times Pr(\text{locus } K \text{ linked|loci } 1, \ldots, K-1 \text{ linked, data}).$$

At each stage of selection, the posterior probability of the new locus, conditional on the data and the linkage of the previously selected loci is calculated. All traits with $Pr(\text{loci } 1, \ldots, K \text{ linked|data}) \geq T$, for some threshold T, are called *significant*. If, at any stage, the model for a trait fails to be significant, the last significant model for that trait is chosen and the selection procedure stops.

The posterior probability of linkage is estimated empirically by comparing the distribution of conditional test statistics to the null distribution, which is estimated using permutation methods. Thus, the high dimensionality of the data is exploited to estimate empirically based on the data, instead of assuming a fixed prior. More specifically, let F_{iK} be the test of the model containing all K loci versus the model containing $K-1$ loci at stage K in the model selection procedure. The null distribution for this test statistic can be obtained by permuting the data conditional on the first $K-1$ loci, by permuting the traits within each of the $(K-1)$-locus genotype classes. This maintains the relationship between the trait and the previously selected loci, but randomizes the trait with respect to the remaining loci. For some number of permutations, let F_{iK}^b be the test statistic for the ith trait and the bth permutation. The set of true test statistics $\{F_{iK}\}$ can be assumed to be from a mixture of true tests and false tests, and the set of permuted test statistics $\{F_{iK}^b\}$ provides an estimate of the null distribution of test statistics. For a trait with test statistic equal to some value F at the Kth selection step, the posterior probability of no linkage, conditional on previous linkages, can be estimated as

$$\frac{\left|\{F_{iK} \leq F\}\right|}{\left|\{F_{iK}^b \leq F; b = 1, \ldots, B\}\right|/B},$$

where $|\cdot|$ denotes the cardinality of the set. Note that, since this method relies on empirical estimation of test-statistic distributions over the set of 'active' traits that were significant at the previous step, the number of 'active' traits and the number of permutations must be high enough to give reasonable estimates. When proceeding through the model selection procedure, at the point in which the number of significant traits becomes sufficiently low, this approach to error rate estimation becomes inaccurate, and the model selection should stop.

This Bayesian model selection criteria lends itself well to the FDR concept because the posterior probability of linkage can be used to estimate the number of false models, where a false model is defined to be one in which at least one of the K selected loci is not truly linked. In other words, a false discovery is one in which any of the selected linkages is false. At any stage of the model selection, K, the FDR is defined as the ratio of expected number of false discoveries to the number of significant K-locus selections. The expected number of false discoveries can be estimated as $\sum(1 - Pr(\text{loci } 1, \ldots, K \text{ linked|data}))$, where the summation is over the K-locus models called significant based on the threshold, T.

9.7 eQTL AND CLINICAL TRAIT LINKAGE MAPPING TO INFER CAUSAL ASSOCIATIONS

While understanding the mechanisms of RNA expression is in itself important for understanding biological processes, the ultimate use of this information is identifying the relationship between variation in expression levels and disease phenotypes in an organism of interest. Microarray experiments are commonly used to explore differential expression between disease and normal tissue samples or between samples from different disease subtypes (see **Chapter 6** Sections 4–5, **Chapters 7** and **8**). These studies are designed to detect association between gene expression and disease-associated traits, which in turn can lead to the identification of biomarkers of disease or disease subtypes. However, in the absence of supporting experimental data, these data alone are not able to distinguish genes that drive disease from those that respond. As discussed above, eQTL mapping can aid traditional clinical quantitative trait loci (cQTL) mapping by narrowing the set of candidate genes underlying a given cQTL peak and by identifying expression traits that are causally associated with the clinical traits.

Expression traits detected as significantly correlated with a clinical phenotype may reflect a causal relationship between the traits, either because the expression trait contributes to, or is causal for, the clinical phenotype, or because the expression trait is reactive to, or a marker of, the clinical phenotype. However, correlation may also exist in cases when the two traits are not causally associated. Two traits may appear correlated due to confounding factors such as tight linkage of causal mutations (Schadt *et al.*, 2005) or may arise independently from a common genetic source. The A^y mouse provides an example of correlations between eumelanin RNA levels and obesity phenotypes induced by an allele that acts independently on these different traits, causing both decreased levels of eumelanin RNA and an obesity phenotype. More generally, a clinical and expression trait for a particular gene may depend on the activity of a second gene, in such a manner that, conditional on the second gene, the clinical and expression traits are independent.

Correlation data alone cannot indicate which of the possible relationships between gene expression traits and a clinical trait are true. For example, given two expression traits and a clinical trait detected as correlated in a population of interest, there are 112 ways to order the traits with respect to one another. That is, for each pair of nodes, there are five possible ways the nodes can be connected: (1) connected by an undirected edge, (2) connected by a directed edge moving left to right, (3) connected by a directed edge moving right to left, (4) connected by a directed edge moving right to left and a directed edge moving left to right, (5) not connected by an edge. Since there are three pairs of nodes, there are $5 \times 5 \times 5 = 125$ possible graphs. However, since we start with the assumption that all traits are correlated, we exclude 12 of the 125 graphs in which one node is not connected to either of the other two nodes, and we exclude the graph in which none of the nodes are connected, leaving us with 112 possible graphs, some of which are illustrated in Figure 9.1(a). The joint trait distributions induced by these different graphs are often statistically indistinguishable from one another (i.e. they are Markov equivalent, so that their distributions are identical), making it nearly impossible in most cases to infer the true relationship. On the other hand, when the two traits are at least partially controlled by the same genetic locus and when more complicated methods of control (e.g. feedback loops) are ignored, the

number of relationships between the QTL and the two traits of interest can be reduced to the three models illustrated graphically in Figure 9.1(b). The dramatic reduction in the number of possible graphs to consider (from 112 to 3) is mainly driven by fact that changes in DNA drive changes in phenotypes and not vice versa (it is extremely unlikely that changes in RNA or protein lead to changes in DNA at a high enough frequency to detect associations between germ-line transmitted polymorphisms and phenotype).

It is important to note here that, when we use the term causality, it is perhaps meant in a more nonstandard sense than most researchers in the life sciences may be accustomed to. In the molecular biology or biochemistry setting, claiming a causal relationship between, say, two proteins usually means that one protein has been determined experimentally to physically interact with or to induce processes that directly affect another protein, and that in turn leads to a phenotypic change of interest. In such instances, an understanding of the causal factors relevant to this activity are known, and careful experimental manipulation of these factors subsequently allows for the identification of genuine causal relationships. However, in the present setting, the term 'causal' is used from the standpoint of statistical inference, where statistical associations between changes in DNA, changes in expression (or other molecular phenotypes), and changes in complex phenotypes like disease are examined for patterns of statistical dependency among these variables that allows directionality to be inferred among them, where the directionality then provides the source of causal information (highlighting putative regulatory control as opposed to physical interaction). The graphical models (networks) described here, therefore, are necessarily probabilistic structures that use the available data to infer the correct structure of relationships among genes and between genes and clinical phenotypes. In a single experiment, with one-time point measurement, these methods cannot easily model more complex regulatory structures that are known to exist, like negative feedback control. However, the methods can be useful in providing a broad picture of correlation and causative relationships, and, while the more complex structures may not be explicitly represented in this setting, they are captured nevertheless given they represent observed states that are reached as a result of more complicated processes like feedback control. A mathematical theory of causal inferences from observed dependency patterns from raw data has been established, and Judea Pearl, a pioneer of mathematical and computational methods for this purpose, provides an excellent description and treatment of this underlying theory (Pearl, 1988; 2000).

While in principle the techniques we describe can be applied to any pair of traits, continuous or binary, clinical or molecular (e.g. RNA, protein, or metabolite), we focus on the problem of inferring causality among gene expression traits and between gene expression and a continuous clinical phenotypes. We let T_1 and T_2 denote RNA expression traits or an expression trait and a clinical trait, and L the locus genotype. In the first model, the genetic locus is causal for T_2 only through T_1 (causal model). In the second model, the T_1 is a reaction to T_2 (reactive model). In the final model, the genetic locus affects both T_1 and T_2 independently (independence model). With the inclusion of genetic marker information, the data models are distinguishable due to the conditional independence structure of the variables.

9.7.1 A Simple Model for Inferring Causal Relationships

Assuming the conditional independence structure implied in the graphical models in Figure 9.1(b), the following simplifications can be made for the joint probability distributions for the causal, reactive, and independence models, respectively:

$$
\begin{aligned}
P_1(L, T_1, T_2) &= P_{\theta_L}(L) P_{\theta_{T_1 L}}(T_1|L) P_{\theta_{T_1 T_2}}(T_2|T_1), \\
P_2(L, T_1, T_2) &= P_{\theta_L}(L) P_{\theta_{T_2 L}}(T_2|L) P_{\theta_{T_1 T_2}}(T_1|T_2), \\
P_3(L, T_1, T_2) &= P_{\theta_L}(L) P_{\theta_{T_1 L}}(T_1|L) P_{\theta_{T_2 L}^*}(T_2|L, T_1) \\
&= P_{\theta_L}(L) P_{\theta_{T_2 L}}(T_2|L) P_{\theta_{T_1 L}^*}(T_1|L, T_2).
\end{aligned}
\tag{9.2}
$$

In the causal model depicted in Figure 9.1(b), the clinical trait (T_2) is independent of the genetic locus conditional on the gene expression trait (T_1). In other words, the locus genotype lends no additional information about the clinical phenotype when the gene expression measurement is known. Similarly, in the reactive model, the expression trait is independent of the underlying genetics conditional on the clinical trait. In the independence model, the gene expression and clinical trait are not assumed to be conditionally independent to allow for correlation due to other shared genetic and environmental influences. Failure to account for this correlation, when it is of moderate size, can result in falsely choosing one of the two other models because the two traits contain information, in addition to that provided by the genetic locus, about the other, due to unmeasured common influences.

The modeling framework in (2) is quite general and can accommodate a wide range of genetic and trait dependence models. Genetic models for dichotomous and quantitative traits have been developed for crosses of inbred lines (**Chapter 18**) and for outbred pedigrees (**Chapter 19**). For continuous traits, a variety of trait models have been developed for the purposes of testing for linkage of a QTL to a single locus. These same models can be used to model an expression or clinical trait conditional on the genetic locus. For example, when the data come from an intercross of two inbred lines, it is common to model the trait using a normal distribution with a mean that depends on the genotype at the locus (Section 3.1 of **Chapter 18**).

Given appropriate choices for the conditional distributions in the three models, $P(T_1|L)$, $P(T_2|L)$, $P(T_1|T_2)$, $P(T_2|T_1)$, and $P(T_1|L, T_2)$, likelihoods for the three different models can be maximized with respect to the model parameters and the likelihoods can be subsequently compared. Note that the log-likelihood of each model is the sum of log-likelihoods for each of the three variables with no common parameters. For example,

$$
\begin{aligned}
\log P_1(L, T_1, T_2) &= \log P_{\theta_L}(L) + \log P_{\theta_{T_1 L}}(T_1|L) + \log P_{\theta_{T_1 T_2}}(T_2|T_1) \\
&= \log L(\theta_L|L) + \log L(\theta_{T_1 L}|T_1, L) + \log L(\theta_{T_2 T_1}|T_2, T_1) \\
&= \log L_1(\boldsymbol{\theta}_1|L, T_1, T_2).
\end{aligned}
$$

Thus MLEs (Maximum likelihood estimates) for $\theta_L, \theta_{T_1 L}$, and $\theta_{T_2 T_1}$ can be obtained by separately maximizing each corresponding term. The likelihoods are then compared among the different models in order to find the most likely of the three. When the number of model parameters among the models differs, a penalized function of the likelihood

is used to avoid the bias against parsimony: the model with the smallest value of the penalized statistic

$$-2 \log L_i(\hat{\boldsymbol{\theta}}_i | L, T_1, T_2) + k \times p_i,$$

is chosen. Here, $L_i(\hat{\boldsymbol{\theta}}_i | L, T_1, T_2)$ is the MLE for the ith model, p_i is the number of parameters in the ith model, and k is a constant. Common choices for k include $k = 2$, in which case the statistic is known as the *Akaike information criteria* (AIC), and $k = \log(n)$, where n is the number of observations, which is called the *Bayesian information criteria* (BIC).

An alternate approach, which is often taken in causal inference, is to use a significance tests to identify a model consistent with the data. For example, in the causal model depicted in Figure 9.1(b), the clinical trait is conditionally independent of the genetic locus, L. Thus, a rejected test of conditional independence between T_2 and L implies that the data is not consistent with the causal model. In order to infer among the three models, the steps are as follows:

1. Obtain the p value, $p_{T_2 L | T_1}$, for the test of conditional independence between T_2 and L.

2. Obtain the p value, $p_{T_1 L | T_2}$, for the test of conditional independence between T_1 and L.

3. Infer the model based on the following logic

    i.   If $p_{T_2 L | T_1} \geq \alpha$ and $p_{T_1 L | T_2} < \alpha$, then the data is consistent with the causal model.

    ii. If $p_{T_1 L | T_2} \geq \alpha$ and $p_{T_2 L | T_1} < \alpha$, then the data is consistent with the reactive model.

    iii. If $p_{T_2 L | T_1} < \alpha$ and $p_{T_1 L | T_2} < \alpha$, then the data is consistent with the independence model (neither the causal nor reactive model).

    iv. If $p_{T_2 L | T_1} \geq \alpha$ and $p_{T_1 L | T_2} \geq \alpha$, then the data is consistent with both the causal and reactive models, the test is inconclusive.

In cases in which the clinical and gene expression trait are very highly correlated, this approach may result in an inconclusive test because, conditional on the other trait, the genetic data provides almost no additional information.

The model selection procedure described above does not lend itself very well to a testing paradigm because, when choosing among these three models, there is no standard null distribution that can be used in this context to carry out a test of hypothesis for the 'best' model. As a result, significance cannot be assessed by attaching a p value to a hypothesis test in the usual way. Instead, when the scientific aim is to identify whether a particular gene expression trait is causal, reactive, or independent to a second gene expression trait or clinical trait, with respect to a given locus, a confidence measure for the chosen model can be constructed using resampling methods. In such cases, a large number of bootstrap samples is drawn from the empirical distribution of (L, T_1, T_2), and, for each resample, the model selection procedure is carried out to estimate the proportion of times each model is chosen. This proportion can then be considered as a measure of confidence for the selected model.

A simpler case occurs when only one direction of causality is of interest. For example, in order to identify expression traits that are specifically causal for a clinical trait of

interest, with respect to a particular locus, an appropriate test can be constructed whose alternative hypothesis is

$$P(T_2|T_1, L) = P(T_2|T_1),$$

where, for this case, T_1 denotes an expression trait and T_2 a clinical trait. For example, given the linear model for the clinical trait

$$E[T_{2_i}] = \mu + \gamma f(T_{1_i}) + \beta g(L_i) + \lambda h(T_{1_i}, L_i),$$

where f and g are functions or parameterizations of the RNA expression and the genotype respectively and h is a function of the interaction, we can perform a test with null hypothesis $\beta \neq 0$ and $\lambda \neq 0$. This is a test for the independence of the clinical trait and locus genotype conditional on the gene expression, which would occur when the genetics affects the clinical trait only through the expression trait. In order to test hypotheses of this nature, a bioequivalence paradigm is required, so that hypotheses are actually of the form $|\beta_i| > \varepsilon_i$ and $|\lambda_i| > \delta_i$, which requires the selection of appropriate values for the ε and δ. Dixon and Pechmann (2005) suggest selecting bounds based on biological knowledge and informed judgment. One criterion for the choice of bound might be based on the proportion of variance explained by the genetic component in this model. For example, in the case of an F2 intercross population constructed from inbred lines of mice and where we assume the genetic model contains only additive effects and no genotype-by-gene expression interaction, a common parameterization of the genetic model is $E[T_{2_i}] = \mu + \gamma f(T_{1_i}) + \beta_A g(L_i)$, where

$$g(L) = \begin{cases} -1 & L = BB \\ 0 & L = Bb \\ 1 & L = bb. \end{cases}$$

In this case, the expected additive genetic variance is $\frac{1}{2}\beta_A^2$. Bounding the proportion of variance explained by the genetic component results in a bound of the form $|\beta_A| < \sqrt{2\varphi_A \sigma_{T_2}^2}$ for some value of φ_A, and where $\sigma_{T_2}^2$ is the variance for trait T_2. More complex models can be managed in a similar way, including a bound on each component of the genetic variance, including dominance and interaction terms when appropriate.

Given a single parameter of interest, hypothesis testing in the bioequivalence framework requires testing two one-sided subhypotheses, $H_{01} : \beta < -\varepsilon$ and $H_{02} : \beta > \varepsilon$. Because both null hypotheses cannot simultaneously be true, testing each of these tests at level α results in a test that is also of level α for the composite hypothesis, $H_0 : |\beta| > \varepsilon$. Thus, H_{01} is rejected if the t-statistic $T^{(1)} = (\hat{\beta} + \varepsilon)/\hat{\sigma}_\beta$ is greater than the one-sided t-distribution level-α critical value. Similarly, H_{02} is rejected if the t-statistic $T^{(2)} = (-\hat{\beta} - \varepsilon)/\hat{\sigma}_\beta$ is greater than the same level-α critical value. Confidence intervals can also be used to infer the bioequivalence; however, care needs to be taken to ensure the proper significance level. Specifically, H_0 is rejected at level α if the $(1 - 2\alpha)\,100\,\%$ confidence interval lies entirely within the alternative hypothesis region, $|\beta| \leq \varepsilon$.

Significance under the null hypothesis of the independence model can also be assessed via permutation. In other words, permuting the relationship between the clinical trait and the gene expression trait within each genotype results in a conditionally independent relationship between the two traits.

9.7.2   Distinguishing Proximal eQTL Effects from Distal

As discussed in previous sections, all genes expressed in living systems are cis regulated at some level and so are under the control of various cis-acting elements such as promoters and TATA boxes. In this context, expression as a quantitative trait for eQTL mapping presents a unique situation in quantitative trait genetics because the expression trait corresponds to a physical location in the genome (the structural gene that is transcribed, giving rise to the expression trait). The transcription process operates on the structural gene, and so DNA variations in the structural gene that affect transcription are identified as eQTL in the mapping process. In such cases, we would identify eQTL as cis acting, given that the most reasonable explanation for seeing an eQTL coincident with the physical location of the gene is that variations within the gene region itself give rise to variations in its expression (Doss *et al.*, 2005). However, because we cannot guarantee that the eQTL is truly cis acting (i.e. it could arise from variation in a gene that is closely linked to the gene expression trait in question), it is more accurate to refer to such eQTL as *proximal*, given they are close to the gene corresponding to the expression trait. Because the cis-regulated components of expression traits are among the most proximal traits in a biological system with respect to the DNA (Plate 8), we might expect that true cis-acting genetic variance components of expression traits are among the easiest components to detect via QTL analysis if they exist. This indeed has been observed in a number of studies, where proximal (presumably cis-acting) eQTL have been identified that explain unprecedented proportions of a trait's overall variance (several published studies highlight examples where greater than 90 % of the overall variation was explained by a single cis-acting eQTL) (Brem *et al.*, 2002; Schadt *et al.*, 2003; Monks *et al.*, 2004; Cervino *et al.*, 2005; Cheung *et al.*, 2005; Lum *et al.*, 2006).

Variations in expression levels induced by DNA variations in or near the gene itself may in turn induce changes in the expression levels of other genes. Each of these genes in a population of interest may not harbor any DNA variation in their structural gene, so that they do not give rise to true cis-acting eQTL, but they would give rise to eQTL nevertheless that link to the gene region inducing changes in their expression. Therefore, we see that the individual variation in gene expression can be of two fundamental types. The first, termed *proximal*, often results from DNA variations of a gene that directly influence transcript levels of that gene. The second, termed *trans acting* or *distal*, does not involve DNA variations of the gene in question but rather is secondary to alterations of other true cis-acting genetic variations (Figure 9.2). In reality, variation in expression traits may be due to variation in cis-acting elements and/or one or multiple trans-acting elements. Additionally, master regulators of transcription, which affect the expression of many traits in trans, may exist, though the evidence on this is mixed (Figure 9.2).

Because, in many cases, it is not possible to infer the true regulatory effects (i.e. cis vs trans) of an eQTL without complex bioinformatics study and experimental validation, we instead categorize eQTL into proximal and distal types based on the distance between the eQTL and the location of the structural genes. Obviously, if these are on different chromosomes the eQTL is distal, but if they fall on the same chromosome then we require the distance between the structural gene and the eQTL to not exceed some threshold. The exact threshold is a function of the number of meioses and extent of recombination in a given population dataset. In a completely outbred population, where LD (Linkage Disequilibrium) mapping has been used to finemap the eQTL, it is reasonable to require

the distance between the proximal eQTL and structural gene to be less than 1 MB (Cheung *et al.*, 2005). However, in an F2 intercross population constructed from two inbred lines of mice, the extent of LD will be extreme, given all animals are descended from a single F1 founder, with only two meiotic events separating any two mice in the population. In such cases, the resolution of linkage peaks is quite low, requiring the threshold of peak-to-physical gene distance to be more relaxed, so that eQTL that are within 20 or 30 MB could be considered cis acting (Schadt *et al.*, 2003; Doss *et al.*, 2005). While the proximal eQTL provide an easy path to making causal inference, given the larger effect sizes commonly associated with proximal eQTL make them easier to detect (Brem *et al.*, 2002; Schadt *et al.*, 2003; Monks *et al.*, 2004; Cervino *et al.*, 2005; Cheung *et al.*, 2005; Lum *et al.*, 2006), the methods discussed above work for distal as well as proximal eQTL.

9.8 USING eQTL DATA TO RECONSTRUCT COEXPRESSION NETWORKS

Networks provide a convenient framework for representing high-dimensional data in which relationships among the many variables making up such data are the key to understanding the properties that emerge from the complex systems they represent. Networks are simply graphical models comprised of nodes and edges. For gene networks associated with biological systems, the nodes in the network typically represent genes, and edges (links) between any two nodes indicate a relationship between the two corresponding genes. For example, an edge between two genes may indicate that the corresponding expression traits are correlated in a given population of interest (Zhu *et al.*, 2004), that the corresponding proteins interact (Kim *et al.* 2005), or that changes in the activity of one gene lead to changes in the activity of the other gene (Schadt *et al.*, 2005). Interaction or association networks have recently gained more widespread use in the biological community, where networks are formed by considering only pair-wise relationships between genes, including protein interaction relationships (Han *et al.*, 2004), coexpression relationships (Gargalovic *et al.*, 2006; Ghazalpour *et al.*, 2006), as well as other straightforward measures that may indicate association between two genes.

Forming association networks from expression data based purely on correlations between genes in a set of experiments of interest can give rise to links in the network driven by correlated noise structures between array-based experiments or other such artifacts. The eQTL data can be simply leveraged in this case by filtering out gene–gene correlations in which the expression traits are not at least partially explained by common genetic effects. For example, we may connect two genes with an edge in a coexpression network if (1) the p value for the Pearson correlation coefficient between the two genes was less than some prespecified threshold, and (2) the two genes had at least one eQTL in common. One intuitive way to establish whether two genes share at least one eQTL is to carry out single-trait eQTL mapping for each expression trait and then consider eQTL for each trait overlapping if the corresponding LOD for the eQTLs are above some threshold and if the eQTL are in close proximity to one another.

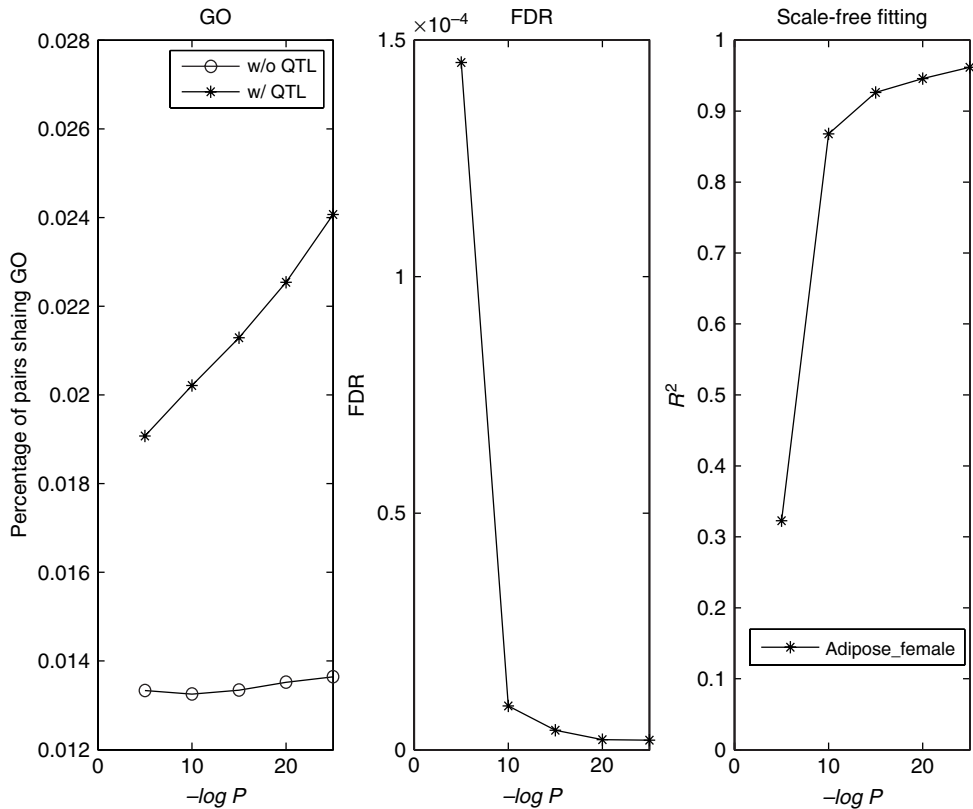
The p-value threshold for considering two genes linked in the coexpression networks is chosen such that the resulting network exhibits the scale-free property (Barabasi and Albert, 1999; Ghazalpour *et al.*, 2006; Lum *et al.*, 2006) and the FDR for the gene–gene


Figure 9.3 Variation in key parameters over different p values provides an objective way to select p-value thresholds for reconstructing coexpression networks. The first box of this figure plots the percent of gene pairs connected in the network that share GO biological process category terms, as a function of $-\log$ of the p-value threshold for the correlation between the gene pairs used to construct the network. The dark gray curve represents genes in the network connected by an edge because the corresponding correlation coefficient is significant at the indicated p-value threshold and the genes share at least one common eQTL (as described in the main text). The light gray curve represents edges based on correlation significance only (no genetics). The second box plots the false discovery rate (FDR) for edges in the coexpression network constructed as a function of p-value threshold. The third box plots the coefficient of determination corresponding to how well the degree distribution for the network nodes fits the inverse power law.

pairs represented in the network is constrained (Figure 9.3). Filtering correlations based on eQTL overlap can be seen to improve the quality of the coexpression networks by examining whether networks reconstructed without the eQTL data are more coherent than networks reconstructed with the eQTL data with respect to the GO (Gene Ontology) database biological process categories (see also 'annotation analysis' in **Chapter 7**). We say one network is more coherent than another with respect to GO biological process categories according to its percentage of gene–gene pairs sharing a common GO biological process category. The pathways represented in GO are independently determined and so provide an independent source of information in testing how much of the known information is captured in the network. As an example, consider a previously described

F2 intercross population constructed from the B6 and C3H inbred lines of mice (referred to throughout as the *BXH cross*) (Lum *et al.*, 2006; Yang *et al.*, 2006). Figure 9.3 plots the percentage of gene–gene pairs sharing common GO biological process categories as a function of minus log of the correlation p value for the coexpression network reconstructed from the BXH adipose data, both with and without the eQTL data. Over a range of p values, the network reconstructed with the eQTL data is seen to be significantly more coherent than the network reconstructed without the eQTL data. This provides direct experimental evidence that incorporating eQTL information into network reconstruction can enhance the accuracy of the network.

9.8.1 More Formally Assessing eQTL Overlaps in Reconstructing Coexpression Networks

While testing whether gene–gene pairs that are significantly correlated are partially controlled by common genetic loci using the overlap method discussed above is intuitively appealing, it fails to make full use of the data to infer whether overlapping eQTLs are really the same eQTL or closely linked eQTL, and such an approach does not lend itself to statistically robust hypothesis testing. One way to test more formally whether two overlapping eQTL represent a single eQTL or closely linked eQTL is to employ a pleiotropy effects test (PET) based on a pleiotropy model initially described by Jiang and Zeng (1995) and Zeng *et al.* (2000). While we discuss this method for considering only two traits simultaneously, the method can be easily extended to consider more traits. The statistical model for PET is an extension of the single-trait model as defined in the following equation:

$$\begin{pmatrix} y_{11} \cdots y_{n1} \\ y_{12} \cdots y_{n2} \end{pmatrix} = \begin{pmatrix} \mu_1 \\ \mu_2 \end{pmatrix} + \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} (x_1 \cdots x_n) + \begin{pmatrix} d_1 \\ d_2 \end{pmatrix} (z_1 \cdots z_n) + \begin{pmatrix} e_1 \\ e_2 \end{pmatrix},$$

where y_i is the vector of trait values for individual $i (i = 1, \ldots, n), a_j$ and d_j are the additive and dominance effects for trait $j (j = 1, 2), x_i$ is as defined above, and e_j is the residual effect for trait j. In this case, we are assuming an F2 intercross population constructed from two inbred lines of mice, but the model is easily generalizable to other experimental cross populations.

From this statistical model, a series of tests of hypotheses can be performed to test whether the two traits are supported as being driven by a single QTL at a given position. The first test involves testing whether a given region is linked to the joint trait vector for the traits under study:

$$H_0 : a_1 = 0, d_1 = 0, a_2 = 0, d_2 = 0,$$

$$H_1 : \text{at least one of the above terms is not 0.}$$

To test the above null hypothesis of no linkage against the alternative linkage hypothesis, likelihoods associated with the null and alternative hypothesis are maximized with respect to the model parameters. From the maximum likelihoods, the log-likelihood ratio statistic is formed and used to test whether the alternative hypothesis (H_1) is supported by the data. With this model, the log-likelihood ratio statistic under the null hypothesis is chi-square distributed with 4 degrees of freedom. If the null hypothesis (H_0) is rejected, the implication is that trait 1 and/or trait 2 have a QTL at the given test locus.

Subsequent to the test just described, resulting in a rejection of the null hypothesis, second and third tests of hypotheses can be performed to establish whether the detected

QTL affects both traits. For a given QTL test position,

$$H_{10} : a_1 = 0, d_1 = 0, a_2 \neq 0, d_2 \neq 0,$$
$$H_{11} : a_1 \neq 0, d_1 \neq 0, a_2 \neq 0, d_2 \neq 0,$$

assesses whether the first trait has a QTL at the test position, and

$$H_{20} : a_1 \neq 0, d_1 \neq 0, a_2 = 0, d_2 = 0,$$
$$H_{21} : a_1 \neq 0, d_1 \neq 0, a_2 \neq 0, d_2 \neq 0,$$

assesses whether the second trait has a QTL at the test position. As above, the log-likelihood ratio statistics are formed for each of these tests, where under the null hypotheses these statistics are chi-square distributed with 2 degrees of freedom. If both null hypotheses H_{10} and H_{20} are rejected, the QTL is supported as having pleiotropic effects on the two traits under study.

At the 2.8 LOD score threshold indicating suggestive linkage in an F2 intercross population, the expected number of QTL detected is 1 for the conditional linkage tests just described (Lander and Kruglyak, 1995). Therefore, an intuitive way to compute the probability that both of these tests for independent traits give rise to a QTL at a given location (so rejection of the null hypothesis for both tests at the same chromosome position) is to consider the probability that the two QTLs expected by chance to be identified for each test happen to be detected at the same chromosome location. This probability can be approximated by the fraction 1/655, where 655 represents the effective number of tests carried out in searching the entire genome at the 2.8 LOD threshold (Lander and Kruglyak, 1995). However, because such an estimate is based on theoretical arguments relying on assumptions that may not hold exactly, and because in practice the traits under consideration will not be independent (especially not in the coexpression network setting where we are interested in highly interconnected sets of genes), permutation testing can also be used to assess the significance of both tests leading to a rejection of the null hypothesis at the 2.8 LOD threshold. In the adipose BXH cross expression data described above, the significance level associated with the 2.8 LOD score threshold was estimated to be 0.004 using permutation methods, only slightly larger than the theoretical estimate of 0.002 given above. Therefore, using the suggestive 2.8 LOD score threshold established for single traits seems reasonable in this situation as it corresponds to a genomewide significance level of 0.004 when considering two traits at a time.

9.8.2 Identifying Modules of Highly Interconnected Genes in Coexpression Networks

Given the scale-free and hierarchical nature of coexpression networks (Barabasi and Oltvai, 2004; Ghazalpour et al., 2006; Lum et al., 2006), one of the problems is to identify the key network modules in the network, representing those hub nodes (nodes that are significantly correlated with many other nodes) that are highly interconnected with one another, but that are not as highly connected with other hub nodes. Plate 9(a) illustrates a topological connectivity map for the most highly connected genes in the adipose tissue of the BXH cross (Chen et al., 2007). After hierarchically clustering both dimensions of this plot, the network is seen to break out into clearly identifiable modules. Gene–gene

coexpression networks are highly connected, and the clustering results shown in Plate 9 illustrate that there are gene modules arranged hierarchically within these networks.

Ravasz *et al.* (2002) used manually selected height cutoff to separate tree branches after hierarchical clustering, in contrast to Lee *et al.* (2004), who formed maximally coherent gene modules with respect to GO functional categories. Another strategy is to employ a measure similar to that used by Lee *et al.* (2004), but without the dependence on the GO functional annotations, given it is of interest to determine independently whether coexpression modules are enriched for GO functional annotations. A gene module in the coexpression network is defined as a maximum set of interconnected genes. A coherence measure for a given gene module can be defined as

$$\text{Coherence} = \frac{GP_{\text{obs}}}{GP_{\text{tot}}},$$

where GP_{obs} is the number of gene pairs that are connected and GP_{tot} is the total number of possible gene pairs in the module. The efficiency of a gene module can then be defined as

$$\text{Efficiency} = \frac{\text{Coherence} \times G_{\text{mod}}}{G_{\text{net}}},$$

where G_{mod} is the number of genes in the module and G_{net} is the number of genes in the network. Given these definitions, we define a process to iteratively construct gene modules by the following steps:

1. Order genes in the gene–gene connectivity matrix according to an agglomerative hierarchical clustering algorithm as previously described (Hughes *et al.*, 2000).

2. Calculate the efficiency $e_{i,j}$ for every possible module, including genes from i to j as given in the ordered connectivity matrix, where $j \geq i + 9$ (i.e. minimum module size is 10), using a dynamic programming algorithm.

3. Determine the maximum $e_{i,j}$.

4. Set $e_{i \ldots j, 1 \ldots G_{\text{net}}} = 0$ and $e_{1 \ldots G_{\text{net}}, i \ldots j} = 0$.

5. Go to step 3 until no additional modules can be found.

The modules identified in this way are informative for identifying the functional components of the network that may underlie complex traits like disease (Lum *et al.*, 2006). It has been demonstrated that the types of modules depicted in Plate 9(a) are enriched for known biological pathways, enriched for genes that are associated with disease traits, and enriched for genes that are linked to common genetic loci (Ghazalpour *et al.*, 2006; Lum *et al.*, 2006).

9.9 USING eQTL DATA TO RECONSTRUCT PROBABILISTIC NETWORKS

Coexpression networks are informative as discussed for gross characterizations of the properties of biological networks, identification of highly connected (hub) nodes, and

identification of functional modules that aid in the characterization of subnetworks associated with disease. Despite these and other advantages, coexpression networks do not provide explicit details on the connectivity structure among genes in the network, including the representation of causal associations among genes and between genes and phenotypes. As detailed in previous sections, naturally occurring variations in DNA can be leveraged as a systematic source of perturbations to infer causal associations among gene expression traits and between gene expression and clinical traits. By examining the effects naturally occurring DNA have on variations in gene expression traits in human or experimental populations, other phenotypes (including disease) can then be examined with respect to these same DNA variations and ultimately ordered with respect to genes to infer causal control (Plate 8) (Mehrabian *et al.*, 2005; Schadt *et al.*, 2005; Kulp and Jagalur, 2006; Lum *et al.*, 2006).

While previous sections highlighted inferring causal associations by integrating eQTL and quantitative trait data for two traits, Zhu *et al.* were among the first to formally incorporate genetic data into the reconstruction of whole gene networks using Bayesian network reconstruction methods (Zhu *et al.*, 2004). Bayesian networks are directed acyclic graphs that, while limited with respect to representing temporal information or feedback loops, allow for the explicit representation of causal associations among nodes in the network. With Bayesian network reconstruction methods taking gene expression data as the only source of input, many relationships between genes in such a setting are Markov equivalent (symmetric), similar to what was discussed for three-node graphs in Figure 9.1(a). This means one cannot statistically distinguish whether a given gene causes another gene to change or vice versa. To break this symmetry, Zhu *et al.* incorporated eQTL data as prior information to establish more reliably the correct direction among expression traits.

Bayesian network methods have been applied previously to reconstruct networks comprised only of expression traits, as well as to networks comprised of both expression and disease traits, where the aim has been to identify those portions of the network that are driving a given disease trait. Forming candidate relationships among genes was carried out using an extension of standard Bayesian network reconstruction methods (Chiellini *et al.*, 2002). In the first approach to extend this method using genetic data, QTL information for the transcript abundances of each gene considered in the network was incorporated into the reconstruction process. It is well known that searching for the best possible network linking a moderately sized set of genes is an NP-hard problem. Exhaustively searching for the optimal network with hundreds of genes is presently a computationally intractable problem. Therefore, various simplifications are typically applied to reduce the size of the search space and to reduce the number of parameters that need to be estimated from the data. Two simplifying assumptions to achieve such reductions are commonly employed. First, while any gene in a biological system can control many other genes, a given gene can be restricted so that it is allowed to be controlled by a reduced set of genes. Second, the set of genes that can be considered as possible causal drivers (parent nodes) for a given gene can be restricted using the type of causality arguments discussed in previous sections, as opposed to allowing for the possibility of any gene in the complete gene set to serve as a parent node.

One method to select potential parents for each gene is to assess the extent of genetic overlap between any two gene expression traits. If RNA levels for two genes are tightly associated, or if such levels are genetically controlled by a similar set of loci, then their

eQTL should overlap. The extent of QTL overlap can be carried out using the PET procedure described in a previous section, or, to consider simultaneously more of the eQTL data for any two traits, the correlation coefficient between vectors of LOD scores associated with eQTL identified over entire chromosomes for each gene can be computed. If we assume no epistasis between eQTL for a given expression trait, then the eQTL can be considered independent between chromosomes, and a measure of genetic relatedness over all chromosomes for any two traits can be subsequently computed as a weighted average of correlations for each individual chromosome:

$$r = \sum_c w(c) \times r(c), \tag{9.3}$$

where $r(c)$ is the correlation coefficient for chromosome c and $w(c)$ is the chromosome-specific weight. The chromosome-specific correlation coefficient is given by

$$r(c) = \frac{\sum_l x_c(l) \times y_c(l) \times I_c(l)}{\sum_l x_c(l) \times x_c(l) + \sum_l y_c(l) \times y_c(l)}. \tag{9.4}$$

In this equation, $x_c(l)$ and $y_c(l)$ are LOD scores at locus l on chromosome c and $I_c(l)$ is an indicator function defined as

$$I_c(l) = \begin{cases} 1, & \text{if } x_c(l) > 1.5, y_c(l) > 1.5 \\ 0, & \text{otherwise} \end{cases}, \tag{9.5}$$

which is incorporated to eliminate low LOD scores that would have likely only contributed noise to the correlation measures. The chromosome-specific weight terms are given by

$$w(c) = \max_l(\min(x_c(l), 10) \times \min(y_c(l), 10)). \tag{9.6}$$

In effect, this equation provides for those chromosomes with high LOD scores to more significantly influence the overall correlation measure. This heuristic weight is intuitively appealing since gene expression traits with common significant eQTL have a larger percentage of their overall variation explained by these common genetic effects. For a particular data set, the weighted correlations can be computed for all gene pairs, and the resulting list rank ordered, so that those genes in the upper percentiles can be chosen as candidate parental nodes (Zhu *et al.* (2004) used the 80th percentile as the threshold).

To differentiate between colocalization of QTL for a pair of traits due to common genetic effects (pleiotropy) versus multiple closely linked QTL, the extent of phenotypic (RNA levels) association can be measured by the mutual information measure

$$mi(A, B) = \sum_{i,j} p(a_i, b_j) \log \frac{p(a_i, b_j)}{p(a_i)p(b_j)}, \tag{9.7}$$

where $p(x)$ is the probability density function for the expression of gene X in the system of interest. For a particular data set, the mutual information measure can be computed for all gene pairs, and the resulting list rank ordered on this measure, so that those genes in the upper percentile can be chosen as candidate parental nodes (Zhu *et al.* (2004) again used the 80th percentile as the threshold).

The selection of the genes in the 80th percentile of the rank-ordered lists generated from the correlation and mutual information measures provides the prior evidence that two genes may be causally related. The QTL data provide the causal anchors that allow this type of inference to be made. That is, by definition, a QTL controlling for the expression of two gene expression traits implies that DNA variations in the QTL lead to variations in the expression of the associated gene traits. Therefore, it must be the case that any gene expression trait pair controlled by a common QTL is either independently driven by the same QTL, or causally associated in that one of the two traits is driven by the QTL, while the other trait responds to the trait driven by the QTL.

In addition to utilizing the QTL information as prior information to restrict the types of relationships that can be established among genes, the QTL information can be more intimately integrated into the network reconstruction process. As indicated in previous sections, correlation measures are symmetric and so can indicate association but not causality. However, QTL mapping information for the gene expression traits can be used to help sort out causal relationships. The different tests described in the section on making causal inferences between pairs of traits provide one way to explicitly sort out such relationships. Zhu *et al.* (2004) leveraged the eQTL data in a different way to make similar types of inferences in their network reconstruction algorithm. Suppose gene expression trait X has two high confidence eQTL at loci L_1 and L_2, while gene expression trait Y has a single eQTL at L_1 that is more significant than the eQTL for X at L_1. In this instance, it is reasonable to infer that Y may control X (or is 'causal' for X), since if X were causal for Y we would expect Y to have an eQTL at L_2 in addition to the eQTL at L_1, given X has an eQTL at L_2. Further, the asymmetry in the significance of the eQTL at L_1 for X and Y also favors Y as being causal for X. Thus, the eQTL overlap information can be used in this more heuristic way to infer causality by defining the prior for a candidate relationship as

$$p(X \to Y) = r(X, Y) \frac{N(Y)}{N(X) + N(Y)}, \qquad (9.8)$$

where N is a gene expression trait's complexity as measured by the number of significant eQTL mapped for the given gene expression trait. If X and Y have coincident QTL, but the overall complexity of Y is greater than the overall complexity of X, then the relationship X causes $Y (X \to Y)$, as opposed to $Y \to X$, is weighted as the more likely scenario in the prior defined above. Implicit in this weighting scheme is the assumption that traits driven by common QTL are causally related (i.e. one trait drives the other), even though it is possible that the traits could be independently driven by the same set of QTL. However, in cases where multiple traits are independently driven by a common set of QTL, the correlation between the traits is smaller than when the traits are causally related, so the prior in this case carries less weight. Further, the conditional mutual information measure discussed below also serves to prevent, in at least some cases, causal links from being made between genes that are independently driven by a common set of QTL.

The causality relationships between gene expression traits can be further assessed by considering whether the QTL for a particular gene expression trait is proximal. As discussed previously, genes that give rise to eQTL that are coincident with the gene's physical location most likely harbor DNA variations that at least partially explain variations in the gene's observed RNA levels (proximal or cis-acting eQTL) (Doss *et al.*,

2005). Therefore, it is reasonable to infer that a gene with a proximal eQTL is at least partially under the control of the gene itself. In this particular situation, where another gene expression trait Y has an eQTL mapping to the physical location of gene X, and $(X \rightarrow Y)$ is inferred as the most likely relationship using a test for causality such as that described in previous sections, we can infer that Y is likely not causal for X and set $p(Y \rightarrow X)$ equal to 0.

With the various constraints and measures defined above, the goal in reconstructing whole gene networks is to find a graphical model M (a gene network) that best represents the relationships between genes, given a gene expression data set, D, of interest. That is, given data D, we seek to find the model M with the highest posterior probability $P(M|D)$. The prior probability $P(M)$ of model M is

$$p(M) = \prod_{X \rightarrow Y} p(X \rightarrow Y), \tag{9.9}$$

where the product is taken over all paths in the network (M) under consideration. The algorithm Zhu *et al.* (2004) employed to search through all possible models to find the network that best fits the data is similar to the local maximum search algorithm implemented by Friedman *et al.* (2000).

The Bayesian network reconstruction algorithm can be employed to elucidate the module connectivity structure depicted in Plate 9(a). Because reconstruction of Bayesian networks is an NP-hard problem (Garey and Johnson, 1979), the number of nodes that can be considered in the network and the extent of connections (edges) among these nodes must be reduced (over what can be considered in reconstructing coexpression networks) in order to make the problem tractable, thereby making such networks more sparse compared to coexpression networks. Toward this end, Plate 9(b) shows the result of the Bayesian network reconstruction algorithm discussed above applied to module 2 depicted in Plate 9(a) for the BXH cross. Further highlighted in Plate 9(c) is a subnetwork containing the gene *Lpl*, a gene recently identified as causal for obesity in the BXH cross (Schadt *et al.*, Submitted). The more detailed structure provided in Plate 9(b) and (c) allows for the examination of the context in which specific genes like *Lpl* operate, providing insights into which parts of the network may impact a given gene's function, as well as what other parts of the network may be impacted by the gene's function.

9.10   CONCLUSIONS

The eQTL mapping methods and network reconstruction methods, including the causality test, discussed here provide a convenient framework for moving beyond examining genes one at a time to understand complex phenotypes like common human diseases. Whether considering the relationship between two traits with respect to common QTL driving each of the traits, interaction networks, Bayesian networks, or other types of networks reconstructed by integrating genetic and molecular profiling data, the advantage the network view affords is the ability to consider more of the raw data informing on complex phenotypes simultaneously, taking into account dependency structures between all of the different fundamental components of the system, and providing a framework to

integrate a diversity of data types (something Bayesian network reconstruction methods are particularly good at). Researchers in the life and biomedical sciences will have few other options available to them in considering the vast amounts of data being generated to elucidate how the hundreds of thousands or even millions of fundamental components within the cell interact to give rise to complex phenotypes. Networks provide one of the only frameworks of which we are aware to systematically and simultaneously take all of the fundamental components into account. Statistical inferences on networks will come to define much of the future research needed in this field to adequately leverage what network models can provide.

Of course, the types of approaches reviewed here represent only the first steps being taken to reconstruct meaningful gene networks, and even in this chapter we have largely restricted attention to genetic, gene expression, and disease phenotype data. Ultimately, it will be necessary to integrate many different lines of experimental data simultaneously. Protein–protein interactions, protein–DNA interactions, protein–RNA interactions, RNA–RNA interactions, protein state, methylation state, and especially differential methylation states that have now been shown to act transgenerationally (Anway *et al.*, 2005), and interactions with metabolites, among other interactions, are all important components that define complex phenotypes that emerge in living systems. What a given protein and RNA does will give way to what a network of protein, RNA, DNA, and metabolite interactions do, where such networks of interaction are defined by the context in which they operate, with environment playing a critical role. A particular network state that drives disease (or other complex phenotypes that define living systems) will not only require knowledge of DNA and environmental variation and the changes these variation components induce in the network but also information on the previous states of the network that led to the current state, where environmental stresses interacting in complex ways with genetic background not only influence the current state of the network but can also lead to longer lasting effects on the network that act transgenerationally.

While this more comprehensive reconstruction of biological networks is still outside the scope of what is presently doable, the types of approaches discussed here represent useful first steps toward this ultimate goal. Even though the number of networks that can be reconstructed from the fundamental components of living systems is truly daunting, as work progresses in this area we will learn the rules that necessarily constrain the possible ranges of molecular interactions, and as a result begin to capture the more conserved network motifs that form the framework upon which all other interactions are based. The complexity revealed by a systems-biology motivated approach to elucidating complex phenotypes like disease should be embraced, given the potential to develop a better understanding of the true diversity of disease and the constellation of genes that need to be targeted to effectively treat disease.

9.11   SOFTWARE

A variety of software is available for the analysis of genetic data. See **Chapters 15**, **29**, **30**, **31**, **32** for details.

Protein Structure Prediction

D.P. Klose and W.R. Taylor

Division of Mathematical Biology, National Institute of Medical Research, London, UK

In this chapter, we assume that most readers know a little about proteins and protein structure prediction, but that their knowledge might now be fuzzy and out of date. In order to refresh their knowledge and get novices up to speed, we concentrate on the most basic principles. We outline the categories of protein structure prediction before examining the underlying methods used in 'successful' prediction tools. Each method will be accompanied by examples of biological applications from recent papers and a section highlighting their advantages and disadvantages.

10.1 HISTORY

While knowledge about protein structure has a long history going back to Astbury's early experiments on hair and silk (and beyond), its current form came into being with the solution, by X-ray crystallography, of the first globular proteins at near atomic resolution. These consisted of two closely related globin structures (by Kendrew and Perutz and co-workers), followed by the first enzyme structure (lysozyme, by Phillips and co-workers). These structures were somewhat unexpected at the time: given the near crystalline regularity of Astbury's hair and silk structures (along with the structure for DNA proposed then), the globular proteins were described by Kendrew as *lacking symmetry* and *visceral*. Even worse, the structure of lysozyme did not immediately provide any clue as to how it, or any enzyme, might work!

   As more structures were solved, some of these early unexpected aspects were partially rectified: symmetry was rediscovered in the structure of triosephosphate isomerase, and plausible catalytic mechanisms for lysozyme and other enzymes were established. However, despite progress, it remains true that proteins do not yield their secrets easily. When a new structure is solved, it is often still difficult to describe its structure in a systematic way and place it in relation to other structures. Similarly, if a structure is solved for a protein of unknown function, it is not necessarily easy or possible to suggest a function from just the structure.

10.2   BASIC STRUCTURAL BIOLOGY

The proteins considered in this chapter are the globular proteins. Fibrous proteins are neglected because they are less interesting – consisting of numerous repeated units forming some trivial helical arrangement. Membrane proteins are neglected because much less is known about them structurally. What is known reveals that they are effectively confined to just two dimensions (in the membrane) and are therefore unable to explore the structural richness available in three dimensions. This leaves globular proteins, which exhibit the greatest variety of structures and functions.

Globular proteins form complex structures consisting of one or more chains of amino acids known as *polypeptides*. For over 30 years it has been generally accepted that the amino acid sequence provides sufficient information to specify the overall structure the protein adopts in three-dimensional (3D) space. This theory is largely accepted owing to work by Anfinsen and co-workers in the 1960s (Anfinsen, 1972; 1973). Since then, several schemes have been devised to exhibit the physico-chemical properties of the amino acids – naturally the authors' favourite was outlined by Taylor (1986) (see Figure 10.1).
Figure 10.1   Amino acid property Venn diagram. Taylor's Venn diagram (Taylor, 1986) shows the relationships of the 20 naturally occurring amino acids and their physico-chemical properties. The two major sets are those that exhibit hydrophobic behaviour (shaded grey) and those that have a polar group (referred to as *hydrophilic*). The third largest category (labelled small) contains nine amino acids, and within this group there are the 'tiny' amino acids that contain, at most, two side-chain atoms. In this representation, cysteine is represented once; however, it is reasonable to represent it twice, in reduced form, where it behaves similarly to serine, or in its oxidised form where it behaves more like valine.

The amino acids can be roughly divided into two groups based solely on their side-chain properties. The first group, termed *hydrophilic* or *polar residues*, are soluble in water (unshaded), and the second group (shaded grey) are less soluble in water and are termed *hydrophobic* or *non-polar residues*. The properties of the amino acids result in the formation of internal structures: a hydrophobic core and secondary structure elements. These features are integral to the overall structure of the protein and from a theoretical perspective it is crucial that they can be predicted with some degree of accuracy.

10.2.1   The Hydrophobic Core

The partitioning of the two types of residues with respect to the solvent (essentially water) is the overall driving force behind protein folding and stability. While hydrogen bonding is important in maintaining specific structural features, it is crucial to remember that for every hydrogen bond formed internally two bonds with water are lost and one water–water bond formed – a simple bond count reveals no net gain. The resulting structure is a core of hydrophobic residues (from which water has been excluded), surrounded by a shell of hydrophilic residues, which interface with the solvent thus making the protein soluble. Experimental biologists should recognise that the white precipitate in their buffers is most likely the result of the collapse of the residue partition. Bearing this in mind, it should be clear how crucial it is to be able to create a properly formed hydrophobic core in predicted structures.

10.2.2   Secondary Structure

Here three broad categories of secondary structure will be introduced. The categories are alpha (α); beta (β), and coil/loop regions. The α and β categories are defined by main chain hydrogen bonding and combined phi (ϕ) and psi (ψ) angle repetitions. Helical structures are formed by local hydrogen bonding while β structures can be formed by distant parts of the backbone. The archetypal α structure is formed by hydrogen bonding between the CO of residue i and residue $i + 4$ with $\phi \approx -60^{\circ}$ and $\psi \approx -40^{\circ}$. Beta sheets have $\phi \approx -120^{\circ}$ and $\psi \approx 140^{\circ}$. Beta structures are less local and modular than helices owing to the fact that the hydrogen bonds occur between strands, and the result is not a single β strand but a pair, which can bond either in parallel or in anti-parallel arrangements. Over 30 years ago, computers were first used to predict secondary structure (Nagano, 1973). Initially, and for some time, the average accuracy of predictions ranged between 50 and 60 %, only 10 % above that of a random prediction – 40 % based on the percentage occurrence of secondary structure elements within the protein data bank (PDB) (Simossis, 2005). Today, using methods that are introduced later in the chapter, it is possible to obtain accuracies of up to 80 % while the average has increased to $\sim$75 % (Montgomerie *et al.*, 2006).

10.3   PROTEIN STRUCTURE PREDICTION

To take a protein sequence and predict the three-dimensional structure into which it folds has been a goal for many years. Yet, despite faster computers and better theories of protein

folding, no one has been able to succeed in this task for anything larger than a peptide of 30–40 residues (Duan and Kollman, 1998) – all of which have simple folding involving only local contacts. An alternative to this direct (*ab initio*) approach is to use what is known from the structures that have been seen to provide constraints on the structures that are to be predicted. These can range from local constraints – such as the preference of secondary structures to connect in a particular way – up to global constraints, which can be inferred if there is some sequence similarity to a protein of known fold. The latter end of this range can obviously lead to good predictions of structure (perfect when there is 100 % identity between the two sequences) but as the sequence similarity diminishes, then the less certain local rules must be relied on more heavily. The key to the success of this approach is to know when a similarity is significant.

10.3.1   Homology Modelling

Where there is clear sequence similarity, the problem of constructing a 3D model is largely how to substitute the existing side chains with the new side chains to which they have been matched (aligned). Since there is clear similarity, many of these will be the same and most will involve only minor substitution of groups (e.g. Asp → Asn). In addition, most of the substitutions will occur on the surface of the protein, leaving much of the tightly packed core intact. This is due to evolutionary constraints, which mean that it is easier to change a side chain when it is not buried. In this situation, the simple axiom, 'if it ain't broke, don't fix it' is the best advice to follow. Indeed, even better advice is to let it all be done automatically as there are now several programs that can construct good models provided the sequences are clearly related. Many of these are commercial but the Swiss-model (Schwede *et al.*, 2003) program can be used freely over the internet for non-commercial purposes.

In situations with less sequence similarity, the problem of indels (relative insertions and deletions) becomes important. These also imply that the protein backbone will need to be remodelled (to close the gaps after deletion, or add new chain for an insertion). Fortunately, again most of these changes will be found on the protein surface where there is usually space to make larger changes. If changes apparently do not occur on the surface, then this is a strong indication that the alignment between sequence and structure is incorrect. While such problems can be attempted to be solved using programs like Swiss model, the limiting factor becomes being able to specify the correct alignment on which to base the model – here the realm of threading must be entered.

10.3.2   Threading

The strategy of aligning the protein sequences using standard alignment methods and then building a model is no longer the standard approach for distantly related sequences. Interaction is needed between the emerging model and the alignment. As mentioned above, if an insertion is found in the core, then the answer is usually to change the alignment – not the structure. Historically, this was carried out in a series of iterations with manual realignment at each stage as, for example, in the construction of the HIV protease model (Pearl and Taylor, 1987). Eventually it became apparent that this progress could become more automated with the alignment and model being calculated simultaneously.

10.3.3 True Threading

To thread a sequence over a structure, two components are necessary: a packing measure for the substituted amino acid and an alignment method that can optimise the sum of packing scores. The former is available in the 'rough' empirical potentials of Sippl (1990) (referred to as *potentials of mean force*). These are 'rough' in that they do not directly consider side-chain interactions (to do so would be impossible until the full model was constructed) but capture the preference of an amino acid to be in a particular environment and (indirectly) secondary structure state. The second component, the alignment method, is readily available from sequence alignment methods, but could not be used directly. One solution is to apply the alignment in a series of iterations, gradually substituting new residues into the existing structure. Another solution is to take the double dynamic programming method (from structure comparison) and modify it (Jones *et al.*, 1992).

10.3.4 3D/1D Alignment

The sequence/structure matching problem was also approached from the sequence alignment side. Beginning with a pure sequence alignment, structural features are predicted (such as secondary structure state and degree of burial), which are then matched to the known corresponding features of a protein structure (along with its sequence) (Bowie *et al.*, 1991; Luthy *et al.*, 1991; Rice and Eisenberg, 1997). Unlike the 'true' threading methods described above, this approach does not take into account the 3D interactions in the final calculation of the alignment, so it can use the dynamic programming algorithm without any complications.

   In theory, the 3D/1D approach is less powerful than the 'true' threading methods. However, when applied to very distant relationships, there is little perceptible difference in the methods. This probably results from the more common incorporation of multiple sequence data into the 3D/1D methods and from accurate prediction of secondary structure. The 'true' threading methods also make the assumption that the basic core structure of the model protein will be the same as the structure on which it was built: for distant relationships this is seldom completely true.

10.3.5 New Fold (NF) Prediction (*Ab initio* and *De novo* Approaches)

The last resort – although arguably the most exciting – is *ab initio* prediction. *Ab initio* (from first principles) prediction relies on the assumption that natively folded proteins exist in a state of low free energy. To obtain the structure of a protein, one simply has to compute all possible interactions between all residues in a sequence until the lowest free energy conformation is found! In reality, this problem is far from trivial – in fact, it has only been done for short (30–40 residue) polypeptides (Duan and Kollman, 1998). Frustrated with a lack of progress, *ab initio* modellers have begun to use existing structural information, often in the form of fragment packing, allowing for proteins up to 100 residues to be predicted – although not from first principles (Rohl and Baker, 2002; Bradley *et al.*, 2005). In order to retain correct nomenclature – as well as to keep physicists happy – the name of the field has been changed to *de novo* or new fold (NF) modelling.

10.4   MODEL EVALUATION

Regardless of the method used to generate the protein structures, many thousands of models can be produced by a single prediction attempt. Some models resemble real proteins, with well-formed secondary structure and a hydrophobic core, while the majority will be poorly formed with little or no ordered secondary structure and 'unnatural' packing in the hydrophobic core (exposed hydrophobics and buried hydrophilics). To build and evaluate models that resemble real proteins, it is crucial to use reliable prediction and evaluation functions, such as YASPIN (Lin *et al.*, 2005) for secondary structure prediction and PHOBIC, an updated version of burial/hydrophobic matching used in Taylor *et al.* (2006), for hydrophobic core evaluation. These functions are constructed using a diverse mixture of methods to numerous to review here (Skolnick, 2006). A number of 'popular' techniques that have been used individually as well as in a combinatorial fashion to predict secondary structure to overall model structure are presented here.

10.4.1   Decision Trees

The classification and regression tree (CART) algorithm was popularised by Breiman *et al.* (1984). Decision trees (DTs) describe a tree structure wherein the leaves represent classifications and branches represent conjunctions of features that lead to associated classifications. DTs are frequently referred to as *classification trees* – used for prediction of class membership (i.e. is residue i buried or exposed) – or *regression trees* – used for assigning a continuous value (i.e. the number of contacts residue i has). As with other methods, the input to a CART should follow the form $(x, y) = (x_1, x_2, x_3, \ldots x_n, y)$, where y corresponds to the label or independent variable and $x_1 \ldots x_n$ correspond to the attributes that define y. The most fundamental concept is splitting the original dataset into subsets based on a particular attribute. This process is recursive and is terminated when a further splitting is either non-feasible or a classification can be made. The result is structurally similar to that shown in Figure 10.2.

There are two primary formulas employed by DTs: the first is called *Gini impurity* – based on squared probability of class membership – and the second is *information gain* – based on entropy as used in information theory (Shannon, 1997). Both deal with the diversity of the data at each node. The application of these formulas allows the current node to be split into further nodes by calculating what is called *impurity loss* or *goodness of split*.

If $y = (x_1, x_2, x_3, \ldots, x_n)$ and $f(i, j)$ is the frequency of value j in node i, then the Gini impurity is defined as shown in (10.1).

$$I_{\mathrm{G}}(i) = 1 - \sum_{j=1}^{n} f(i, j)^2, \tag{10.1}$$

while the information gain is defined as shown in (10.2), which is analogous to Shannon's entropy (10.3).

$$I_{\mathrm{E}}(i) = -\sum_{j=1}^{n} f(i, j) \log_2 f(i, j), \tag{10.2}$$

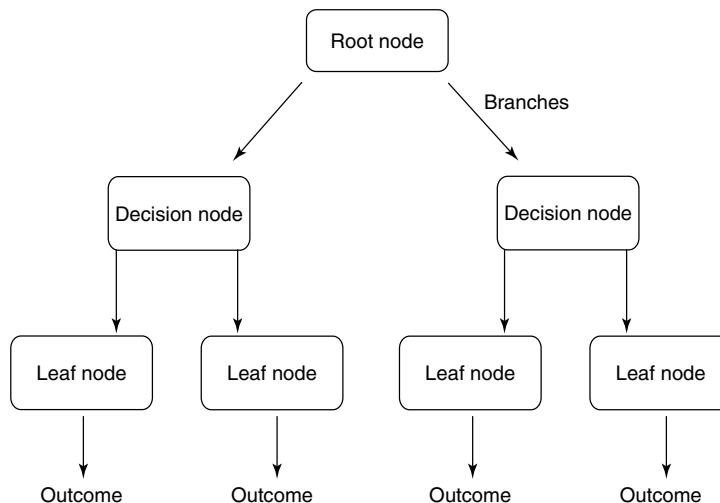
$$H(X) = -\sum_{i=1}^{n} p(x_i) \log_2 p(x_i). \tag{10.3}$$


Figure 10.2 CART general outline. Once constructed, the DT can be viewed as shown here – a set of choices represented by a node that branches out from the root node (starting point). An unknown sample is fed into the system at the root node, and the sample is recursively processed until a classification is made, hopefully correctly. Although this representation shows branches of equal length, this is not a constraint. One of many internal DT methods is a branch-trimming algorithm that attempts to refine the tree during training, reducing complexity and speeding up execution.

Typically DTs are used for data mining, a task that is not directly associated with protein structure prediction. However, Selbig *et al.* (1999) used a DT to derive better consensus secondary structure predictions. Selbig combined predictions from existing programs as input for the DT. The role of the DT was to improve the final consensus prediction – something that is now very popular. At that time (1999) Selbig's program, CoDe, achieved an accuracy of 72.9 %, which outperformed the methods that existed then. Today, more advanced learning machines are used in this role, typically a support vector machine (SVM) or artificial neural network (ANN), which is considered below.

10.4.1.1   Summary of CART Methods

Advantages
- Conceptually simple.
- Data requires very little pre-processing.
- White box – it is possible to look at a DT and see how it works.
- Handle regression and classification problems.
- Handle large datasets – it is possible to complete large tasks using a desktop pc.
- Many existing architectures including Weka (Ian and Witten, 2005) and Yet Another Learning Environment (YALE) (Mierswa *et al.*, 2006).

Disadvantages
- Rubbish in, rubbish out – can be heavily influenced by small amounts of low-quality input.
- Requires qualitative input to give complete picture.

- Probabilities are estimated.
- Real-time data problems.
- Trees become complex – over trained and require trimming.

10.4.2 Genetic Algorithms

Genetic algorithms (GAs) were developed by John Holland and co-workers at the university of Michigan during the 1970s. GAs are based on the idea of natural selection and are designed to approximate solutions to optimisation and search problems. The starting point for a GA is a string, which is also known as a *chromosome*. The first step in a GA is to encode the problem. However, to restrict this chapter only to the basics, this step will be neglected as it often involves complex encoding. Examples applied to 3D structure can be found in Dandekar and Argos (1994; 1996a; 1996b; 1997) and Petersen and Taylor (2003). Each chromosome begins life with a fitness function (f) and it is this feature that the GA aims to maximise via four steps:

1. reproduction

2. 'genetic' Crossover

3. mutation

4. termination.

The reproduction method copies individual strings according to their fitness function. The fitness function determines the probability of selecting a chromosome. Therefore chromosomes with a higher fitness are more likely to be selected from the mating pool for breeding, and thus they are more likely to make the transition to new generations.

The crossover method creates diversity and drives the evolution of the chromosome. There are two steps to crossover: the selection of two parent strings at random from the breeding pool and completion of the crossover itself. Given two strings of length (l), a random position (n) that matches the criterion $1 \leq n \leq l - 1$ is chosen. For example, if two strings (A and Z) are selected at random from a breeding pool:

$$A = 01000001,$$

$$Z = 01011010,$$

and $n = 4$, then the chromosomes are split as shown below.

$$A = 0100|0001,$$

$$Z = 0101|1010.$$

To generate the next generation, the strings are pulled apart at the boundary (|) and recombined, resulting in A' and Z'.

$$A' = 01001010,$$

$$Z' = 01010001.$$

Mutation plays a secondary role in GAs (somewhat unlike biology). The mutation operation exists to compensate for overzealous eradication of useful genetic information,

or simply put, mutation prevents the loss of useful genetic information in the early stages of evolution. Mutation operations generally occur at a low frequency; however it can (and should) be optimised by the user.

All good (and bad) simulations must come to an end and this is taken care of by the termination method. Termination is typically based on the time a method has been running, the number of generations that have passed, or on completion (i.e. f does not increase over a number of generations).

GAs have a long and successful history in computational biology and recent work by Arunachalam *et al.* (2006) and Armano *et al.* (2005) has used GAs to good effect in structure prediction. In Arunachalam *et al.* (2006), the prediction of several all α proteins is described using mutually orthogonal Latin squares and GAs. The method clearly explains the basics of GAs as well as showing how simple it is to extend the simple GA to work on 'real' numbers as opposed to binary strings. Arunachalam's GA is of particular interest as a supplementary method that aims to aid convergence on local minimum is described. Armano *et al.* (2005) introduces a hybrid ANN – GA approach to secondary structure prediction. While the paper does not highlight a ground breaking discovery, it does describe a method that is comparable to MUPRED (Bondugula and Xu, 2007), a method that is discussed in the next section.

10.4.3   k and Fuzzy k-nearest Neighbour

Given a residue (x), the question is, is it part of a helix, sheet, or coil? This 'simple' classification problem lends itself to a k-nearest neighbour (kNN) algorithm (10.4). A kNN is a simple yet powerful method for assigning a class to an unknown sample. Given a number of known samples, the distances between k and these samples is calculated using a distance metric (see below). For the sake of simplicity, consider x to be defined by two coordinates. In this space, the Euclidean (EC) distance (10.5) can be calculated quickly. Initially the class of x will be known, and this allows for the number of neighbours (k) to be optimised – to produce the most accurate prediction. When a new sample x is introduced, the nearest k neighbours will be used to infer the structural class of x. The result is a probability of x belonging to the helix, sheet, or coil classes. The beauty of this method is that only one parameter has to be optimised – the value of k.

$$\mu_c(x) = \frac{\sum_{j=1}^{k} \mu_c(x_j) d_{ij}^{-2}}{\sum_{j=1}^{k} d_{ij}^{-2}}, \quad (10.4)$$

where $1 \ldots k$ are the kNNs, $\mu_c(x_j)$ is the class membership of neighbour j, and d_{ij} is the distance between features i and j. There are two commonly used distance metrics to calculate d_i, the EC distance and the city block (CB) distance (10.6). The formula for calculating the EC distance is shown in (10.5):

$$d_i = \sqrt{\sum_{i=0}^{n} (X_i - Y_i)^2}. \quad (10.5)$$

The EC distance is computationally expensive to calculate, so typically the CB distance is used if the dataset is large. The CB distance (10.5) is less accurate than the EC distance. However, the increase in execution time on large datasets is noticeably reduced.

$$d_i = \sum_{i=0}^{n} |X_i - Y_i|. \tag{10.6}$$

The most crucial and time consuming part of the kNN procedure is the optimisation of k. There are several procedures for optimisation and they come as part of existing kNN packages. The first step is to split the data (typically $60:40$) into two sets – training and hold out test (HOT). The training set is then subjected to either a leave one out or an n-fold validation. The concept of the leave one out validation is simple – remove an example, train the program, establish k, calculate accuracy, and repeat. The n-fold (where n is a number defined by the user) breaks the data into n equal sections, one section is left out and the algorithm is trained on the remaining data, and this is repeated n times. At the end of the validation routes, a plot of k against percentage accuracy should reveal the optimal value for k. When k is defined, each sample in the HOT set should be analysed and an overall accuracy obtained.

A kNN can be improved using another user-definable parameter m. This parameter acts as a 'fuzziness' parameter, weighting the class contribution for each k by its distance. The introduction of this term means that the kNN algorithm is now defined as a *fuzzy k-nearest neighbour* (*fkNN*) *algorithm*. (10.7) shows the fkNN algorithm. Note the difference between this and the previous equation is the inclusion of $-2/(m-1)$.

$$\mu_{\mathrm{c}}(x) = \frac{\sum_{j=1}^{k} \mu_{\mathrm{c}}(x_j) d_{ij}^{-2/(m-1)}}{\sum_{j=1}^{k} d_{ij}^{-2/(m-1)}}. \tag{10.7}$$

The kNN and fkNN approaches have been applied to both secondary structure (Bondugula and Xu, 2007) and solvent accessibility (Sim *et al.*, 2005), both individually and in combination with more sophisticated methods such as ANNs.

10.4.3.1   Summary of kNN/fkNN

   Advantages
- Simple to implement
- Powerful
- Existing architectures for moderate-sized datasets.

   Disadvantages
- Computationally expensive
- Time consuming – have to run over full dataset for each prediction
- Classification problems only.

10.4.4   Bayesian Approaches

Bayesian theory, like the kNN, is a simple approach – indeed it reduces to 'just counting'. In protein structure prediction, this approach has been successfully applied by Thompson and Goldstein for solvent accessibility (Thompson and Goldstein, 1996) and secondary structure (Thompson and Goldstein, 1997) prediction and later by Lathrop for sequence structure alignment (Lathrop *et al.*, 1998).

Bayes' theorem (10.5) provides a method for adjusting the degree of belief in light of new information.

$$P(A|B) = \frac{P(B|A)P(A)}{P(B)}. \qquad (10.8)$$

The term $P(A)$ is the prior probability; it represents the probability of seeing A in a random population. $P(B|A)$, the conditional probability, represents the probability of observing B given knowledge of A. $P(B)$ is referred to as the *marginal probability* and is the probability of observing B in a random population. The left term, $P(A|B)$, is the posterior probability; it represents the probability of A given knowledge of B.

Given a residue (i) and a surrounding window of sequence ($\{A_j\}$), Bayes' theorem can be used to predict protein features (S_k) such as solvent accessibility and secondary structure using a library of known examples (k) (10.9).

$$P(\omega_i|\{A_j\}) = \sum_k \frac{P(\{A_j\}|S_k)}{P(\{A_j\})} P(S_k)\delta(s_j^k \in \omega_i), \qquad (10.9)$$

where s is the structural context (buried β sheet), and s_j^k is a window of known structure (k denotes a particular segment while j is an index in window k). The term $\delta(s_j^k \in \omega_i)$ is essentially a Boolean statement – zero unless the residue in structural context s_j^k has the structural state ω_i (otherwise one). $P(S_k)$ is the probability of witnessing the structural window k at random and is trivially calculated from a library. $P(\{A_j\})$ is the probability of witnessing a window of sequence at random. $P(\{A_j\}|S_k)$ is the probability of observing a sequence with structural context S_k, and again this must be calculated from a library.

When it comes to biological applications, some assumptions have to be made, for example, when considering the probability of seeing a window of 15 residues. The number of possible combinations in a 15 residue window is 15^{20}, which means that it is highly unlikely that all possible combinations of the amino acids will be witnessed in a sequence library – the sequence partner to the structural library. To get around this problem, an assumption is made that the product of the individual amino acid probabilities will be an accurate approximation of the probabilities of the windows (10.10).

$$\frac{P(\{A_j\}|S_k)}{P(\{A_j\})} = \prod_j \frac{P(A_j|s_j^k)}{P(A_j)}. \qquad (10.10)$$

This assumption changes the overall equation (10.9) to (10.11):

$$P(\omega_i|\{A_j\}) = \sum_k \left(\prod_j \frac{P(A_j|s_j^k)}{P(A_j)} \right) P(S_k)\delta(s_i^k \in \omega_i). \qquad (10.11)$$

This approach, despite being 'old', remains one of the most effective tools for predicting solvent accessibility and secondary structure ($\sim$75 % accuracy). For a more general introduction to Bayesian statistics, it is suggested that the reader refers to the chapter by Richard Goldstein in Jorde *et al.* (2005) and to Thompson and Goldstein (1996; 1997) for detailed biological application.

10.4.4.1   Summary of Bayesian Methods

>   *Advantages*
> - Resistant to overtraining.
> - Easy to update given new example data.
> - Several existing architectures, e.g. perl AI::Categorizer::Learner::NaiveBayes, which is fast although it is not the most accurate.
> - Remains one of the most accurate tools for solvent accessibility prediction and solvent accessibility prediction.

>   *Disadvantages*
> - Slow – has to complete a scan against a pattern library for each prediction.
> - Some of the assumptions do not apply to all situations as detailed in Thompson and Goldstein (1997).

10.4.5   Artificial Neural Networks (ANNs)

ANNs mark a significant step forward in complexity and power allowing for modelling of complex non-linear relationships between input and output. The architecture of an ANN is deceptively simple: at its most basic level is the neuron, a simple processing element that is linked to form a complex machine. The ANN is made up of layers of neurons, which are linked together by weighted connections (see Figure 10.3). It is the combination of these weighted connections and transfer functions used in the nodes that defines the overall performance of the machine. There are three categories of transfer functions: linear, where the output is proportional to the total weighted input; threshold, where the output is set to one of two states depending upon whether the input is greater or less than a threshold; sigmoid, where the output varies continually but not linearly with the input.

The first neural networks appeared in 1957 when Rosenblatt created the perceptron, a model that contained a single layer. The perceptron, or single-layer neural net, is the most

Input layer   Hidden layer   Ouput layer
Figure 10.3   A generic ANN layout. The most basic neural networks consist of a single hidden layer that is fully connected to the input and output layers. The connections between each node (black arrows) is given a default value before training, and when training begins the weights are adjusted according to an error function. After training, the weights should be optimised to accurately map input space to output space.

basic of ANNs and is only capable of solving linearly separable problems. The concept behind the network is simple: take the sum of the products of the weights and inputs per node; if the value is above a specific threshold the neuron fires and obtains an 'activated' value or 'higher state'. The simplicity is further reflected in training, which is completed using the 'depth' walk. This function calculates the error between the sample and training set and adjusts the network weights accordingly – this procedure is also referred to as *gradient descent*, a method that is used in more complicated frameworks.

An excellent example of neural network usage in protein structure prediction is YASPIN (Lin *et al.*, 2005). Lin *et al.* presented a feed-forward perceptron network with a single hidden layer to predict seven-state secondary structure, which is then optimised using a hidden Markov model (HMM). YASPIN used a soft-max transition function with a window of 15 residues, with each residue in that window being represented by 20 units. Each unit represents a transition state in a position specific scoring matrix (PSSM) generated by PSI-BLAST. There is an additional element that is used where a terminal is spanned, and the result is a 315 (21×15) dimension input. The hidden layer comprises 15 elements while the output layer contains 7 – one for each structure classification. When the seven-state prediction is made, it is passed to the HMM. The HMM uses the viterbi algorithm (Durbin, 1998) to optimally segment the predictions, the result being transition probabilities between each of the states. The final output to the user is a three-state prediction ($\alpha, \beta, -$) with confidence values.

10.4.5.1 *Summary of ANN Methods*

Advantages
- Very powerful if trained correctly.
- Solve linear and non-linear problems.
- Existing frameworks to build ANNs are available, for example, JOONE.

Disadvantages
- Black box – once they are built and implemented you have no idea how they work.
- Can be slow to train.
- Prone to over training.
- Computationally expensive.

10.4.6   Support Vector Machines

SVMs are supervised learning machines for regression and classification problems; they were introduced by Boser, Guyon, and Vapnik in the 1980s. SVMs are capable of solving linear and non-linear problems by taking an *n*-dimensional input space and mapping it into a higher dimension, often referred to as the *kernel trick*, and once in this space a linear classifier is constructed (see Figure 10.4).

The key part of the SVM is the kernel – a mathematical function that performs the transition from a linear space to a non-linear space, or in the case of a radial basis function (RBF) to a Gaussian infinite space. The majority of existing SVM architectures implement four kernel functions (see Table 10.1), polynomial, radial basis, Gaussian radial basis, and sigmoid. In most cases, the RBF proves to be a suitable starting point as it is able to handle linear and non-linear relationships. Indeed it is the kernel of choice for most biologists.
Figure 10.4 Linear classification of a non-linear problem. The initial step is to determine whether the problem is linearly separable or not. If the problem is linear, then a linear kernel should be applied, skipping the transformation into multidimensional space. If the problem is non-linear (or if checking seems like too much work), the radial basis function (RBF) provides an ideal starting point. This is because it is capable of mapping linear and non-linear problems. Once in the higher dimensional space, a linear separation of the data can be performed.

Table 10.1 Four commonly used kernel methods. Of all the kernels, the best starting point is one of the two RBF functions. This is because they are capable of solving both linear and non-linear problems.

Kernel	Mathematical definition
Polynomial kernel	$k(x, x') = (x \cdot x')^d$
Radial basis function (RBF)	$k(x, x') = \exp(-\gamma \|x - x'\|^2)$ where γ is defined by optimisation routines
Gaussian RBF	$k(x, x') = \exp - \left(\dfrac{\|x - x'\|^2}{2\sigma^2} \right)$
Sigmoid	$k(x, x) = \tanh(kx \cdot x + c)$ for $k > 0$ and $c < 0$

The simplest example of an SVM is a linear classification. Consider a problem where there are two classes. The first class describes residues that are buried, the second those that are exposed. Using a set of features that describe each class, a plot can be constructed as shown in Figure 10.5.

As the problem is clearly linearly separable, a linear kernel can be applied as shown in Figure 10.6.

The central line (dividing hyperplane) splits the two classes, while the parallel hyperplane's function is to maximise the space between the dividing hyperplane and each class. When an unknown sample is passed to the SVM, it should be possible to classify it as buried (-1) or exposed ($+1$). The classification is achieved using (10.12), implying that the problem reduces to defining the support vectors to be able to make a prediction – all other data points can be discarded! To make the machine more robust, error (slack) variables (ξ) can be introduced. Error variables allow for a solution to be found where the data is not so clearly divided.

$$c_i = \{1, \text{ if } \omega \cdot x + b \geq 0; \; -1 \text{ if } \omega \cdot x + b \leq 0\}. \tag{10.12}$$
Figure 10.5 Over simplification of residue burial/exposure. Plotting the state of several residues using a number of features shows a clear separation of the two categories (it should be noted this is not the case in reality). Because of the clear separation in normal space, a simple linear kernel can be applied. However, readers with a creative mind can imagine that they used an RBF and now exist in Gaussian infinite space.
Figure 10.6 Application of a linear kernel on a linearly separable problem. The two classes can be separated by a plane (the dividing plane). To either side of the dividing plane there are parallel hyperplanes, and these define the maximum distance from the dividing hyperplane to each class. The space between the parallel hyperplanes and the dividing hyperplane is void of data points. The name support vector machine is derived from the use of support vectors to establish the position of the parallel hyperplanes. The distance between the hyperplanes is defined by geometrical techniques to be $2/|w|$ (so the aim of the SVM is to minimise $|w|$).

Regression is slightly different from classification in implementation. Generally speaking, existing tools use what is called *epsilon* (ε) support vector regression (SVR). Epsilon defines a threshold under which data is ignored; this is the exact opposite of classification. The detailed workings of this method are beyond the scope of this chapter and readers are strongly advised to read Cristianini and Shawe-Taylor (2000) in order to obtain a full understanding.

SVMs have been used successfully for both classification and for regression in biological scenarios, the easier of the two problems being classification. A good example of a classification problem is Disopred2 (Ward *et al.*, 2004). Disopred2 uses support vector classification and a neural network to predict the ordered or disordered state of a residue. Ward *et al.*, used a linear kernel to solve this problem and achieved a good degree of success as shown by their performance in the critical analysis of structure prediction (CASP) exercise.

An example of the regression problem is Yuan's work (Yuan, 2005) for the prediction of protein contact number. Previous work by Kinjo *et al.* (2005) had shown that contact number prediction was not best solved using a linear method. Yuan implemented an SVM using the RBF kernel to map the data into higher dimensional space before performing a regression to predict absolute contact number. The overall performance of the SVMs showed an improvement over existing techniques, achieving an accuracy 'greater than 77 %' (Yuan, 2005).

10.4.6.1   Summary of SVM Methods

Advantages
- Solve linear and non-linear problems.
- Kernels are hot swappable.
- Kernel addition and weighting allows for colourful combinations of SVMs.
- Simpler to implement compared to ANNs.
- Less prone to over training compared to ANNs.
- Existing frameworks – very simple to set up.

Disadvantages
- Mathematically complex.
- Kernels are hot swappable – many biologists try each kernel until they get the results they want to see. This is not wrong but can be costly.
- Black box – once trained it is not easy to understand the rules that define the system.
- On large datasets, it can be computationally very expensive to optimise all necessary variables.
- Some implementations are more robust than others.

10.5   CONCLUSIONS

Extracting the maximum amount of structural information from sequence data has had a long history of increasing diversity in the methods used and the problems to which

they have been applied. Following secondary structure methods as an example, simple frequency-based methods were used in the early 1970s (Chou and Fasman, 1974; 1978) followed by information-theory-based methods during the late 1970s (Garnier *et al.*, 1978). The 1980s saw the introduction of artificial neural net methods, which have been followed by SVMs in the last decade. Applications have also broadened from a focus on the simple three-state (α, β, other) prediction of local structure to include the solvent exposure of a residue and more recently, the predicted degree of disorder in the chain.

Despite these quantum leaps in methodology, the degree of accuracy in the predictions has improved only slowly in recent years with small, usually single figure, increases in prediction accuracy being reported. Compared to the wide range of variations in the accuracy of the predictions between proteins, these small increases are barely significant. The observed plateau in accuracy is not unexpected as most of the current methods use data derived from a multiple sequence family. Without knowing the structures of the proteins in the families, there will certainly be errors in their alignment that will introduce a base level of noise that cannot be overcome without improved alignment methods. More fundamentally, there is also variation in observed secondary structure definitions between members of the family. Taking all members of the family together means there is no unique definition of secondary structure against which accuracy can be measured. An iterative approach that would overcome this problem might be considered: starting with a wide diverse family to predict a starting state, which is gradually refined using smaller subsets of the family, finishing with one sequence. At this stage, it would then probably be necessary to predict the full three-dimensional structure.

The application of statistical methods to new problems, such as the prediction of chain disorder, is probably where the methods are making their most significant contribution. In this particular area, it is being realised that large parts of the coding sequences in a large fraction of proteins in the genome have no intrinsic structure. They serve as locations for modification, like phosphorylation, or are induced to have structure when they encounter a specific binding partner. Their role is important in dynamic behaviour of cellular systems, such as receptor signalling and gene regulation. With the growing interest in 'systems biology', the identification and understanding of these regions will be of increasing biological importance.

Finally, it is worth considering the direct application of statistical methods to three-dimensional structure prediction. Most of the applications described above involve the prediction of local structure or structural states, which can be used to constrain 3D models. Some attempts have been made to apply ANNs to direct structure prediction but with success only at the local structural level. There may be scope for methods that use a higher level of structural description but the encoding to be used for this is not obvious. A more likely route towards a practical tool is the use of statistical methods in fold-recognition (or threading) methods. As more structures become available, this task, which is essentially a classification problem, will become easier. The only impediment along this route is that large proteins usually need to be broken down into their constituent domains before they can be recognised and these domains are not always contiguous in sequence.

In summary, while structure prediction methods are becoming more powerful and helped by the vast new sources of sequence and structural data, to some extent, their traditional areas of structure prediction are becoming less relevant. The increasing volumes of data also means that there is now a good chance of finding all the necessary structural

information on a protein from another structure related by clear sequence similarity. Interesting application areas appear to lie more in novel directions associated with protein interactions and their relevance to cellular function.

Metabolic profiling (metabonomics or metabolomics) is a field in biomedical investigation that combines the application of nuclear magnetic resonance spectroscopy and other experimental platforms with multivariate statistical analysis in studies of the composition of biofluids, cells and tissues. It is a system-level bioinformatics discipline that involves the quantitative measurement of the multivariable metabolic response of living systems to pathophysiological stimuli or genetic modification. Metabolic profiling therefore represents an important area of biological research that is likely to have an impact on a diverse range of clinical areas. In this chapter, we give a description of some basic metabolic data gathering techniques, and the most commonly used methods of statistical analysis, namely, principal components analyis and partial least squares, cluster analysis, and other modern classification approaches such as neural networks and evolutionary algorithms. Throughout, we illustrate these concepts with specific biological examples.

11.1   INTRODUCTION

Metabolic profiling, also known as *metabonomics* (Nicholson *et al.*, 1999) or *metabolomics* (Raamsdonk *et al.*, 2001), is a rapidly developing field in biomedical science that

combines the application of spectroscopic techniques with multivariate statistical analysis in studies of the molecular composition of biofluids, cells and tissues. The experimental focus is on profiling *metabolites* – the thousands of low-molecular-weight molecules which are the building blocks of the cell. These compounds interact with macromolecules such as proteins and nucleic acids in the fundamental metabolic processes that keep organisms alive. Thus, the metabolic state of an organism, as delineated by its metabolic profile, can reveal information on the genetic, physiological or functional status the system. In addition, in contrast to DNA or RNA, metabolic profiles also reflect the entirety of internal and external influences on an organism or tissue, including environment, behaviours, disease, drugs and interactions with parasitic or symbiotic organisms (Nicholson *et al.*, 2002; Nicholson and Wilson, 2003). This leads to important applications in the molecular diagnosis and prognosis of disease, drug metabolism and toxicity, functional genomics and the investigation of fundamental biological processes. From the statistical point of view, however, metabolic profiles are complex and information rich, presenting unique challenges to data analysis and modelling.

The term *metabolome* refers to the total metabolite complement of a cell, tissue or organism. While there are currently no methods capable of delivering an exhaustive measurement of the metabolome, there are several technologies that can approach this ideal. A gold standard technique would be one that is (1) non-selective, in that, it is not biased towards particular chemical classes of compounds, (2) quantitative and accurate, thus producing data that can be meaningfully modelled by statistical procedures, (3) sensitive to a wide range of metabolite concentrations and (4) able to resolve the complex mixture into separate signals from each metabolite. These requirements are satisfied, though not perfectly, by the techniques of nuclear magnetic resonance (NMR) spectroscopy and mass spectrometry (MS).

11.1.1 Spectroscopic Techniques

The two spectroscopic assay technologies, NMR and MS, are highly complementary and therefore often used in parallel. NMR has the advantage that it is highly non-selective and quantitative; it also requires little sample preparation and is non-destructive, thus permitting multiple measurements on each sample. MS approaches are much more sensitive and generally have higher resolution than NMR; yet they suffer from inaccuracies introduced by differential ionisation efficiencies. These can be partially alleviated by preceding the MS detection with a physical separation step using liquid chromatography (LC) or gas chromatography (GC), leading to LC–MS or GC–MS Wilson *et al.* (2005). Figure 11.1 shows examples of NMR and LC–MS spectroscopic metabolic profiles of urine.

The resulting spectra (or profiles) consist of several thousands of individual measurements at different resonances or masses. The spectra are complex and require dedicated analysis procedures. The inherent high dimensionality immediately precludes many conventional statistical analysis approaches. Similar to other spectroscopic data, the spectral variables are usually highly collinear, a characteristic that arises for both chemical analytic and biological reasons. For example, one metabolite may generate more than one spectral signal (e.g. isotopic patterns in MS) leading to several highly correlated peaks. Alternatively, signals from different metabolites may show high correlations because they are involved in the same biological process. While the above properties are typical of data from many so-called '-omic' techniques such as those from transcriptomics and proteomics, metabolic profiling poses its own challenges. The most important challenge is
Figure 11.1 Typical metabolic profiles of rat urine. (a) a one dimensional ^{1}H NMR spectrum, (b) a two dimensional contour plot of an LC−MS profile. Both the higher number of signals and level of noise are clear in the LC−MS profile.

the problem of unidentified signals; while thousands of signals may be detected, typically only a very small fraction will be identified with a known chemical structure – so such prior chemical information is extremely helpful for correct interpretation and identification. Another difficulty is the sensitivity and resolving power of the analytical technique, as well as the complexity of the analysed mixture. A related problem is that the total number of detected analytes is in general unknown and will vary between different biological conditions. Thus, in metabolic profiling, there is a great emphasis on methods of exploratory data analysis and visualisation, which allow the analyst to probe their data for the presence of poorly detected or resolved signals and help in identifying unknown metabolites.

11.1.2   Data Pre-processing

Metabolic profiles generally undergo some pre-processing prior to more advanced statistical modelling, to account for spectral artefacts and render profiles from different samples more comparable. Pre-processing is necessary to achieve comparability between replicate samples, to achieve some form of measurement noise reduction and to more accurately distinguish the different chemical constituents by means of peak deconvolution and separation. In this chapter, we do not describe these issues in detail, but instead focus on statistical feature extraction and discrimination procedures. However, a brief discussion is given below.

One of the most serious problems affecting NMR profiles is that peak positions can be affected by the pH or ionic strength of the sample. This phenomenon seriously affects a minority of metabolites and means that the spectral intensity at a given NMR chemical shift (or wavelength) may be due to both changes in molecular concentrations as well as shifts in resonance positions, making the interpretation of statistical models difficult. While there exist techniques that account for or correct such shifts automatically (Holmes etal, 1992; Stoyanova *et al.*, 2004), these are most suited to correction of small spectral regions and have not yet been successfully applied to full-width NMR profiles. A similar difficulty occurs in LC, where obtaining highly reproducible separation of metabolites is difficult and peak alignment algorithms are often used to match LC profiles from different samples. In mass spectrometry, various processes can lead to the signal from each metabolite being broken up into multiple peaks. For example, the natural occurrence of multiple isotopes of various nuclei leads to a characteristic isotopic pattern for each primary ion, while the formation of adducts (e.g. the addition of metal ions to the primary ion) ensures each metabolite is characterised by a pattern of different peaks. In MS approaches, differential ionisation efficiency also complicates interpretation of the data. Finally, regardless of the technique employed, the profiles will be affected by gross changes in sample concentration, which can obscure important but subtle treatment-related changes. To alleviate this, profiles are often normalised to unit total intensity, so that subsequent values for any given metabolite relate to its concentration relative to the rest of the mixture, rather than to an absolute measure. In most cases, this does not detract from, and can even improve, the biological interpretation, though when there are large changes between profiles, interpretation of profiles normalised in this way is less clear.

Both NMR and MS spectra are typically data-reduced prior to statistical analysis. This may take the form of discretisation of the continuous spectra by integrating the signal in a grid of bins, or by a form of 'peak picking' and subsequent integration of

individual signals. Thus, depending on the method of preprocessing, each data variable may correspond to either a particular signal or merely an integrated region of the spectrum. The peak picking approach requires complex peak detection algorithms using many tuneable parameters and can be subject to a high degree of bias. The binning approach, on the other hand, may result in a proportion of variables containing little real signal and mainly influenced by noise. This is particularly true in the case of LC-MS, where the grid-based binning approach results in a large number of noisy variables due to the sparse nature of the two-dimensional data (see Figure 11.1b). In either case, there are often many variables whose metabolic identity is difficult to pin down (e.g. because of unidentified signals). It should be noted that, because of the issues described above (peak shifts etc.), optimal preprocessing for both NMR and MS data is an area of active current research.

Several metabolic profile analysis software packages are available. A popular and effective one is the AMDIS software (Davies, 1998; Stein, 1999), which extracts individual component spectra from LC or GC MS data files and then uses them to identify compounds by matching the spectra to a reference library of chemical compounds housed at the US National Institute for Standards and Technology (NIST). The analysis proceeds in four steps (noise analysis, component 'perception' (extraction), spectral deconvolution and compound identification) in an automatic fashions, using a variety of multivariate modelling techniques and heuristic testing procedures. The entire approach has proved very successful for analysing data from these platforms.

The aims of data analysis in metabolic profiling will depend on the scientific objectives of the study. However, the objectives of analysis typically fall into one or more of the following categories. Firstly, we wish to visualise the relationships between groups of both samples and spectral variables. For example, this could include clustering individuals or detecting significant correlations between variables. In addition, we wish to determine whether there is a significant difference between groups related to the effect of interest. The latter is a classic small n, large p inference problem (West, 2002). That is, each individual datum (metabolic profile) consists of a large vector of interrelated (dependent) observations, yet the number of samples in the study is relatively small. Finally, and perhaps most importantly, we are interested in finding out which metabolites are responsible for these changes. This chapter introduces some of the current techniques used in the statistical analysis of metabolic profiles. We give the basic principles and algorithms behind each method and illustrate their use with example datasets. We use X to denote the $n \times p$ matrix of n metabolic profiles, where p is the dimension of the spectrum (usually p is in the order of thousands). Therefore, each row of the X matrix represents a metabolic profile. We define the sample covariance matrix $\mathbf{S} = X'X/n$, assuming that each column of X is standardised to have mean 0, and take $\mathbf{y}$ to be an n-dimensional vector of responses.

11.1.3 Example Data

Several of the methods described in this chapter are illustrated with the help of data from a study profiling the metabolic consequences of hydrazine toxicity (Lindon *et al.*, 2005) (Plates 10 and 11). Thirty Sprague–Dawley rats were randomly and equally assigned to three treatment groups (control, low dose and high dose), and hydrazine was administered orally at doses of 0, 30, and 90 mg kg^{-1}, respectively. Urine samples were collected at 10 time points over 8 days, including 2 pre-treatment samples. All procedures were carried

out in accordance with relevant national legislation and were subject to appropriate local review. ^{1}H NMR spectra were measured at 600 MHz and 300 K using a robotic flow-injection system (Bruker Biospin, Karlsruhe, Germany). After phasing and baseline correction, each NMR spectrum was segmented into $M = 205$ variables by integrating the signal in regions of equal width (0.04 ppm) in the chemical shift ranges δ 0.20–4.50 and δ 5.98–10.0, excluding spectral artefacts in the region δ 4.50–5.98. All segmented spectra were then normalised to a constant integrated intensity of 100 units to take account of large variations in overall urine concentration. The principal component analysis (PCA) and partial least-squares (PLS) analysis shown were performed using SIMCA-P+ version 11 (Umetrics AB, Umea, Sweden). Other analyses were computed using in-house software written in the MATLAB programming environment (version R2006a, The MathWorks, Natick, MA).

11.2 PRINCIPAL COMPONENTS ANALYSIS AND REGRESSION

11.2.1 Principal Components Analysis

PCA is a well-known method of dimension reduction (Massy, 1965; Jolliffe, 1986), which seeks linear combinations of the columns of X with maximal variance, or equivalently, high information. It is routinely applied in chemometrics with the goal of providing the most compact representation of the data. The original p variables $X = [\mathbf{x}_1 \ldots \mathbf{x}_p]$ are transformed in a new predictor set $\mathbf{T} = [\mathbf{t}_1 \ldots \mathbf{t}_k]$, with $k \leq \min(n - 1, p)$. The new variables $\mathbf{t}_j$, called *scores*, are a weighted average of the original X variables. The *principal components* are the eigenvectors, $\mathbf{u}_j$ from the eigendecomposition of $X'X$ (and of the sample covariance matrix $\mathbf{S}$, up to a constant). PCA sequentially maximises the variance of a linear combination of the original predictor variables

$$\mathbf{u}_j = \arg \max_{\|\mathbf{u}\|=1} \mathrm{Var}(X\mathbf{u}),$$

subject to the constraint that $\mathbf{u}_i'\mathbf{S}\mathbf{u}_j = 0$ for all $1 \leq i < j$. This ensures that $\mathbf{t}_j = X\mathbf{u}_j$ is uncorrelated with all the previous linear combinations $\mathbf{t}_i = X\mathbf{u}_i$. The principal components are ordered in terms of the amount of variation of the original data they account for. The first principal component direction has the property that $\mathbf{t}_1 = X\mathbf{u}_1$ has the largest sample variance among all normalised linear combinations of the columns of X. Each subsequent component gives combinations with the largest possible variance which are uncorrelated with those that have been taken earlier.

There are various standard approaches to find the principal components, e.g. taking the singular value decomposition of X. In chemometrics it is common to estimate the principal components using the nonlinear iterative partial least-squares (NIPALS) algorithm (Wold, 1966). This is because the number of required components is usually much less than the total possible number ($k \ll p$). In fact, the NIPALS algorithm does not calculate all the principal components at once, but it first calculates $\mathbf{t}_1$ and $\mathbf{u}_1$ from the X matrix. Then the outer product $\mathbf{t}_1\mathbf{u}_1'$ is subtracted from X and the residual X_2 is calculated. In turn, this residual can be used to calculate $\mathbf{t}_2$ and $\mathbf{u}_2$.

NIPALS algorithm for PCA

---

0. Standardise each $\mathbf{x}_j$ to have mean 0.
1. Initialise $j = 1$, $X_j = X$ and $\mathbf{t}_j$ to any of the columns of X.
2. Project X_j on $\mathbf{t}_j$ to find the corresponding loadings $\mathbf{u}_j : \mathbf{u}_j = X_j'\mathbf{t}_j/\|\mathbf{t}_j\|$.
3. Normalise $\mathbf{u}_j$ to have unit length: $\mathbf{u}_j = \mathbf{u}_j/\|\mathbf{u}_j\|$.
4. Project X_j on $\mathbf{u}_j$ to find the corresponding score vector $\mathbf{t}_j : \mathbf{t}_j = X_j\mathbf{u}_j/\|\mathbf{u}_j\|$.
5. Check convergence: compare $\mathbf{t}_j$ used in step 2 and $\mathbf{t}_j$ calculated in step 4
   (check if the difference is larger than a predefined threshold, e.g. 10^{-6}).
   If they are the same, the iteration has converged; then continue to step 6.
   Otherwise return to step 2.
6. Remove the estimated PCA principal component from $X_j : X_{j+1} = X_j - \mathbf{t}_j\mathbf{u}_j'$.
7. Let $j = j + 1$ and repeat steps 1–7 until $j = k$.

If $k = \min(n - 1, p)$, then we have found all the principal components. We can now form the scores matrix $\mathbf{T}$ and the loadings matrix $\mathbf{U}$ with columns $\mathbf{t}_j$ and $\mathbf{u}_j$, respectively. These matrices are such that

$$X = \mathbf{T}\mathbf{U}',$$

where $\mathbf{U}$ is an orthogonal matrix and the $\mathbf{t}_j$ are orthogonal. Note that $\lambda_j = \|\mathbf{t}_j\|^2$ and $\mathbf{u}_j$ are eigenvalues and eigenvectors of $X'X$, respectively. The NIPALS algorithm can be modified to account for missing data (Christoffersson, 1970).

A key issue is the number of principal components necessary to describe a dataset in a parsimonious way but without loss of important information. After k runs of the NIPALS algorithm, the X matrix is decomposed as

$$X = \mathbf{t}_1\mathbf{u}_1' + \cdots + \mathbf{t}_k\mathbf{u}_k' + X_{k+1}.$$

We want to choose k such that X_{k+1} represents only noise (if $k = \min(n - 1, p)$, $X_{k+1}=\mathbf{0}$) and all the features of X are captured by the $\mathbf{t}_j\mathbf{u}_j'$, $j \leq k$.

The maximum number K of principal components is determined by the number of non-zero eigenvalues, which coincides with the rank of $\mathbf{S}$ and $K \leq \min(n - 1, p)$. However, k is usually chosen through cross-validation (CV) (Stone, 1974; Wold, 1978). The proportion of the total variance explained by a PCA model with k components is quantified by the R^2 parameter defined as

$$R_k^2 = 1 - \sum_{i=1}^{n} \frac{\|\widehat{\underline{x}_i} - \underline{x}_i\|^2}{\text{SS}},$$

where $\underline{x}_i$ denotes a row of X, $\widehat{\underline{x}_i}$ is the estimated $\underline{x}_i$ from the PCA model and SS is the total sum of squares of X, i.e. $\text{SS} = \sum_{i=1}^{n} \|\underline{x}_i\|^2$.

R^2 varies in the range 0–1, taking value one when $k = \min(n - 1, p)$. The CV procedure quantifies how robust the model is to perturbation of data and thus avoids overfitting. In each round of CV, a proportion (usually around 10 %) of the data is held out X_o, the model is computed with the remaining data X_{-o}, and the predicted values of the held out data points are computed using $\hat{X}_o = \sum_{i=1}^{k} \mathbf{t}_i\mathbf{u}_i'$. This is repeated until all data points have been held once. The parameter Q^2 is the CV equivalent of R^2 using the predicted values of the data:

$$Q^2 = 1 - \text{PRESS/SS},$$

where $\text{PRESS} = \sum_{i \in O} \|\widehat{\underline{x}}_i - \underline{x}_i\|^2$, where O is the set of individuals left out. Q^2 is bounded above by the value of R^2, and a high ratio of Q^2/R^2 indicates a robust model which is affected little by perturbations. As more components are computed, both R^2 and Q^2 generally rise as more of the variance is explained. However, a point is reached where the structure represented by the $(m + 1)$'th component is mostly noise. At this point, the predicted data deviates from the true data and Q^2 starts decreasing, indicating that $k = m$ is the correct number of components to use in the model.

Figures 11.2 and 11.3 illustrate the use of PCA on the hydrazine dataset. Figure 11.2 shows the scores plot of the first two principal components. The plot shows the characteristic L-shaped trajectory of hydrazine toxicity; high-dose profiles initially resemble controls but over the time course move to a well-separated region of the plot. Figure 11.3 shows the PCA loadings of the first two principal components. Spectral bins which have a high variance in the X space are indicated by points lying far from the origin and can be used to interpret the distribution of data on the scores plot.

11.2.2 Principal Components Regression

In most applications we are interested in predicting $\mathbf{y}$ from the sets of inputs $\mathbf{x}_j$, e.g. we are interested in studying the relation between the blood pressure and the metabolic profile of an individual. From PCA we derive a representation of the data matrix X as a score matrix $\mathbf{T}$. *Principal component regression* (PCR) uses the score vectors $\mathbf{t}_j$ as explanatory variables and regresses $\mathbf{y}$ on $\mathbf{t}_1, \ldots, \mathbf{t}_k$ for some $k \leq \min(n - 1, p)$:

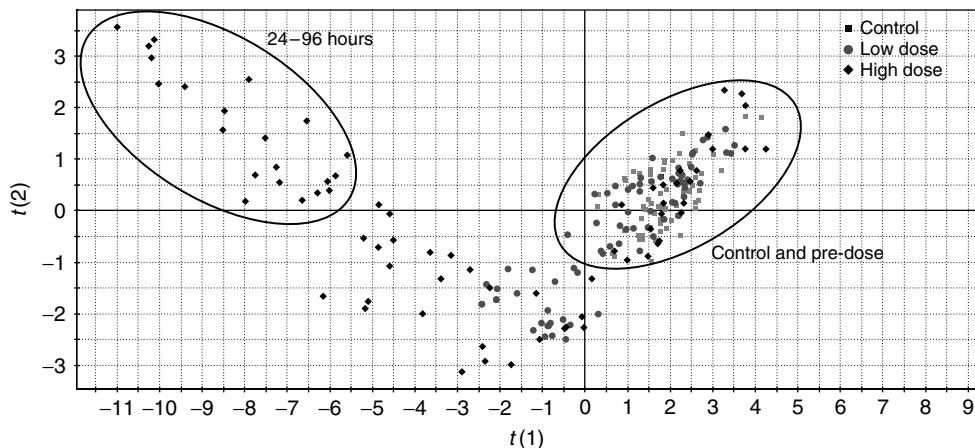
$$\mathbf{y} = \alpha + \sum_{i=1}^{k} \beta_i \mathbf{t}_i + \boldsymbol{\varepsilon},$$


Figure 11.2 Scores plot of the first two principal components for the hydrazine dataset. Each point represents one urine sample (metabolic profile) from one animal at one time point. The different patterns indicate different treatment groups (squares, control; circles, low dose; diamonds, high dose). The plot shows the characteristic L-shaped trajectory of hydrazine toxicity; high-dose profiles initially resemble controls but over the time course move to a well-separated region of the plot. The ellipses identify regions associated with control-like profiles (on the right) and profiles showing maximum toxicity (on the left).
Figure 11.3 PCA loadings plot of the first two principal components for the hydrazine dataset. Each point represents one spectral bin. Points lying far from the origin indicate those bins characterised by a high degree of variation in the data and thus explaining the pattern on the scores plot. Some analytes of interest are labelled on the plot.

where α denotes the intercept, β_i are the regression coefficients and $\boldsymbol{\varepsilon}$ is a normal error term. As the $\mathbf{t}_j$ are orthogonal, PCR reduces to a sum of univariate regressions (Hastie *et al.*, 2001). Usually only the first principal components are used and the $p - k$ smallest eigenvalue components are discarded. PCR has major advantages over standard multivariate regression when X is singular and when $n < p$ due to the dimension reduction. In the latter case, the eigenvalues $\lambda_n = \cdots = \lambda_p = 0$ and so at most $n - 1$ components can be included.

11.3 PARTIAL LEAST SQUARES AND RELATED METHODS

11.3.1 Partial Least Squares

Partial least-squares regression (Wold, 1975) is extensively used in chemometrics as an alternative to ordinary least squares (OLS) in ill-conditioned problems (e.g. $n < p$). It is most often used when the explanatory variables are highly collinear and when they outnumber the observations.

PCA (and therefore PCR) finds, in some way uncritically, those latent variables (scores) that describe as much as possible of the variation in X. In PCR, the latent variables are calculated without consideration of the response and it is possible that useful predictive information for $\mathbf{y}$ is discarded as noise. If there is a lot of variation in X not correlated with the response then the latent variables found by PCR might not be adequate to describe $\mathbf{y}$. PLS tries to solve this problem by constructing latent variables that are *relevant* for describing $\mathbf{y}$. The goal of PLS is to construct linear combinations of the original variables that have simultaneously high variance and high correlation with the response (Frank and

Friedman, 1993; Hastie *et al.*, 2001):

$$\mathbf{u}_j = \arg \max_{\|\mathbf{u}\|=1} \mathrm{Corr}^2(\mathbf{y}, X\mathbf{u})\mathrm{Var}(X\mathbf{u}), \qquad (11.1)$$

subject to the constraint that $\mathbf{u}_i' S \mathbf{u}_j = 0$ for all $1 \le i < j$. Therefore the goal of PLS is to find optimal weights $\mathbf{u}_j$ to form a small number of latent variables that best predict the response $\mathbf{y}$.

PLS was introduced as a modification of the NIPALS algorithm for PCA (Wold, 1966), but it is most often presented as a latent factor regression method and produces a sequence of models $\mathbf{y}_j$. The algorithm to compute the first k latent variables is described below.

PLS algorithm

---

0. Standardise each $\mathbf{x}_j$ to have mean 0 and variance 1.
   Standardise $\mathbf{y}$ to have mean 0.
1. Initialise $j = 1$, $X_j = X$ and $\mathbf{y}_j = \mathbf{y}$.
2. Compute the univariate regression coefficient of $\mathbf{y}$ on each of the $\mathbf{x}$: $\mathbf{w}_j = X_j' \mathbf{y}_j$.
3. Normalise $\mathbf{w}_j$ to have unit length: $\mathbf{w_j} = \mathbf{w}_j / \|\mathbf{w}_j\|$.
4. Project X_j on $\mathbf{w}_j$ to find the corresponding score vector $\mathbf{t}_j : \mathbf{t}_j = X'\mathbf{w}_j$.
5. Regress $\mathbf{y}$ on $\mathbf{t}_j$ to get the ordinary least-square regression coefficient $\widehat{b}_j : \widehat{b}_j = \mathbf{t}_j' \mathbf{y} / \|\mathbf{t}_j\|$.
6. Project X_j on $\mathbf{t}_j$ to find the corresponding loadings $\mathbf{u}_j : \mathbf{u}_j = X_j' \mathbf{t}_j / \|\mathbf{t}_j\|$.
7. Orthogonalise X_j with respect to $\mathbf{t}_j : X_{j+1} = X_j - \mathbf{t}_j \mathbf{u}_j'$.
8. Let $\mathbf{y}_{j+1} = \mathbf{y}_j - \widehat{b}_j \mathbf{t}_j$.
9. Let $j = j + 1$ and repeat steps 2–9 until $j = k$.

Similar to the NIPALS algorithm for PCA, the number of components k is usually determined by CV procedures. The emphasis in PLS is not only on regression but also on uncovering latent structure in X and $\mathbf{y}$. This latent structure is made up of pairs of latent vectors, $\mathbf{t}_j$ and $\mathbf{u}_j$. The latent vectors are determined through the process of estimating the weights $\mathbf{w}_j$ for the linear combination of the X variables. The weights $\mathbf{w}_j$ correspond to directions in the space of X with highest covariance with $\mathbf{y}$ and are such that large variations in X are accompanied by large variations in $\mathbf{y}$. Steps 2 and 3 of the algorithm show that the $\mathbf{w}_j$ are obtained by normalising the covariance matrix between X and $\mathbf{y}$. In step 4 we construct the latent variable $\mathbf{t}_j$ (also called partial least-squares direction) by reweighting the $\mathbf{x}_i$ by the strength of their univariate effect on $\mathbf{y}$ (the weights are given by the covariance between $\mathbf{x}_i$ and $\mathbf{y}$). In step 5 the response $\mathbf{y}$ is regressed on $\mathbf{t}_j$ to obtain the univariate OLS estimate and then in step 6 we obtain the latent variables $\mathbf{u}_j$ by regressing the columns of X on $\mathbf{t}_j$. PLS produces a bilinear representation of the data Martens and Naes (1989):

$$X = \mathbf{t}_1 \mathbf{u}_1' + \cdots + \mathbf{t}_k \mathbf{u}_k' + X_{k+1}$$
$$\mathbf{y} = \widehat{b}_1 \mathbf{t}_1 + \cdots + \widehat{b}_k \mathbf{t}_k + \mathbf{y}_{k+1},$$

where the $\mathbf{t}_j$ are orthogonal and X_{k+1} and $\mathbf{y}_{k+1}$ are the residuals. The $\mathbf{u}_j$ and the $\widehat{b}_j$ are estimated by regression, and PLS fits a sequence of bilinear models by least squares, thus the name *partial least squares*. In steps 7 and 8 the residuals X_{j+1} and $\mathbf{y}_{j+1}$ are calculated and in each iteration only the subspace of X that is orthogonal to the earlier

linear combinations developed in the X space is used and the y space is projected on the space orthogonal to the previous X component. The basic PLS algorithm can be generalised to handle multiple responses.

The maximum number K of components is $\leq \min(n - 1, p)$. The number of components k should be chosen so that X_{k+1} contains no information on y_{k+1} (i.e. they are uncorrelated) and similar to PCA, k is usually chosen through CV. The first few PLS components are retained as they account for most of the covariance between X and y and therefore lead to a more parsimonious representation of the data. We refer to Stone and Brooks (1990), Frank and Friedman (1993), Breiman and Friedman (1997), Burnham *et al.* (1999) and Butler and Denham (2000) for a review of the statistical properties of PLS.

11.3.2   PLS and Discrimination

In many applications it is common that the response variable y is categorical, representing, say, class membership, e.g. control/dosed, affected/unaffected individuals, etc. Partial least-squares discriminant analysis (PLS-DA) consists of a classical PLS regression where the response variable is a categorical one (replaced by the set of dummy variables describing the categories). The goal of PLS-DA is to sharpen the separation between groups of observations, by rotating PCA components such that a maximum separation among classes is obtained, and to understand which variables carry the class separating information. Figure 11.4 shows the application of PLS-DA to a subset of the hydrazine data. To illustrate class discrimination, we have restricted the analysis to samples from control and low-dose animals obtained at 8–72 hours post dose. The separation between the groups is evident on the first latent variable, and metabolites responsible for such separation can be found by examining the corresponding loadings.
Figure 11.4   PLS-DA scores of the first two latent variables for a subset of the hydrazine dataset (control and low dose, 8–72 hours). The plot shows a clear separation between the two subgroups on the first latent variable. The metabolites responsible for the separation can be found from the corresponding loadings (results not shown).

11.3.3   Orthogonal Projections to Latent Structure

Orthogonal projections to latent structure (O-PLS) is a modification of the original PLS algorithm and was proposed with the goal of removing variation from X that is not correlated with $\mathbf{y}$ (Trygg and Wold, 2002). Spectra often contain systematic variations that are unrelated to the response $\mathbf{y}$. This systematic variation may be due to experimental effects (such as a temperature drift in the spectrometer) or systematic biological variation (e.g. differences in diets between human subjects which are not easily controlled) that often constitute the major part of the variation of the sample spectra. It is important to deal with the variation in X that is uncorrelated with $\mathbf{y}$ as it affects the construction and interpretation of statistical models, it may lead to unreliable predictions for new samples and may also affect the robustness of the model over time. In the analytical chemistry literature, differentiation and signal correction are commonly used to remove systematic variation from the sample (see, e.g. Savitsky and Golay, 1964; Geladi *et al.*, 1985).

O-PLS provides a method to remove the variation in X orthogonal to $\mathbf{y}$, therefore improving the interpretation of PLS models and reducing model complexity. It analyses the disturbing variation in each regular PLS component. Also O-PLS produces a bilinear representation of the data:

$$X = \mathbf{t}\mathbf{u}' + \mathbf{t}_{o1}\mathbf{u}'_{o1} + \cdots + \mathbf{t}_{ok}\mathbf{u}'_{ok} + X_{k+1}$$

$$\mathbf{y} = \widehat{b}\mathbf{t} + \mathbf{y}_{k+1}.$$

As in PLS, $\mathbf{t}$ represents the score vector for X and $\mathbf{y}$, $\mathbf{u}$ is the vector of orthonormal loadings, $\widehat{b}$ is a scalar and X_{k+1} and $\mathbf{y}_{k+1}$ are the respective residual matrices for X and $\mathbf{y}$. The $\mathbf{t}_{oj}$ are the scores orthogonal to $\mathbf{y}$ and the $\mathbf{u}_{oj}$ are the corresponding loadings. The O-PLS method requires only a small modification of the PLS algorithm and therefore can be embedded as an integrated part of the regular PLS modelling. It provides predictions that are similar to those provided by PLS (Cloarec *et al.*, 2005), but leads to more parsimonious models. The number of correlated O-PLS components is reduced to one in the case of a single response, thus making interpretation of the model easier. Moreover, the structured noise is modelled separately from the variation common to X and $\mathbf{y}$ and this gives the opportunity to analyse the uncorrelated variation and possibly explain its presence. An extension of the O-PLS algorithm known as *O2-PLS* has been proposed by Trygg and Wold (2003). O2-PLS improves on the original algorithm when dealing with multiple responses by allowing, e.g. the calculation of orthogonal latent vectors in the Y space.

Example. We illustrate the use of the O-PLS method with data from a study on paracetamol (acetaminophen) toxicity (Coen *et al.*, 2003). Twenty-six rats, divided into dose ($n = 17$) and control ($n = 9$) groups were exposed to 150 and $0\,\mathrm{mg\,kg}^{-1}$ paracetamol, respectively. Liver tissue was extracted and ^{1}H NMR spectra acquired to ascertain any metabolic difference due to paracetamol toxicity. Figure 11.5 shows the scores plot from an initial PCA model and shows poor separation between the groups, along with a clear drift over time. This drift was found to be the result of temperature variations in the spectrometer over the course of the experiment, introducing variation in the profiles which was unrelated to the toxicity effect. O-PLS-DA was used to remove the confounding effect of the temperature drift. This is shown in Figure 11.6, where variation orthogonal to the
Figure 11.5 Scores plot of the first two principal components of the paracetamol dataset. The PCA score plot shows no separation and a clear trend due to run order is highlighted by the arrow.
Figure 11.6 Scores plot of the first orthogonal component (y-axis) versus the first correlated component (x-axis) for the paracetamol dataset. The systematic variation visible in Figure 11.5 has been captured by the orthogonal component and it is no longer confounding the interpretation of the correlated component.

class difference has been removed from the first component and a clear separation between the groups is now observed on the scores plot. As mentioned above, a benefit of the O-PLS approach is that one may examine the orthogonal part of the data to ascertain the reasons for the confounding variation. Figure 11.7 plots the scores on the first orthogonal component and a clear trend with run order is seen, indicating that the time-ordered drift has been removed. The orthogonal loadings can also be examined (data not shown) giving an indication of the metabolites that are most affected by the time drift.
Figure 11.7   The plot shows the a strong relationship between the first orthogonal component scores (*y*-axis) and the experimental run order (*x*-axis). The orthogonal filtering captures most of the systematic variation due instrumental drift, visible in Figure 11.5.

11.4   CLUSTERING PROCEDURES

Cluster analysis identifies subgroups or clusters in multivariate data, in such a way that objects belonging to the same cluster resemble each other, whereas objects in different clusters are dissimilar. In two or three dimensions, clusters can often be visualised, but in higher dimensions, we need some kind of analytical assistance.

Datasets for clustering of N observations can have either of the following structures:

- an $N \times p$ *data* matrix, where rows contain the different observations and columns contain the different variables.
- an $N \times N$ *dissimilarity* matrix, whose (i, j) th element is d_{ij}, the *distance* or *dissimilarity* between observations i and j that has the properties

  - $d_{ii} = 0$
  - $d_{ij} \geq 0$
  - $d_{ji} = d_{ij}$.

- The most typical distance measure between two continuously measured data points i and j with measurement vectors $\mathbf{x}_i$ and $\mathbf{x}_j$ is the *Euclidean* distance

$$d_{ij} = \sqrt{\sum_{k=1}^{p} \left(x_{ik} - x_{jk} \right)^2} = \sqrt{\left(\mathbf{x}_i - \mathbf{x}_j \right)^{\mathrm{T}} \left(\mathbf{x}_i - \mathbf{x}_j \right)}.$$

Clustering algorithms fall into two categories:

1. *Partitioning Algorithms.* A partitioning algorithm describes a method that divides the dataset into k clusters, where the integer k needs to be specified. Typically, the algorithm is run for a range of k values. For each k, the algorithm carries out the

clustering and also yields a quality index which allows *selection of* the 'best' value of k.

2. *Hierarchical Algorithms.* A hierarchical algorithm yields an entire hierarchy of clusterings for the given dataset. *Agglomerative methods* start with the situation where each object in the dataset forms its own cluster and then successively merge clusters until only one large cluster (the entire dataset) remains. *Divisive methods* start by considering the whole dataset as one cluster and then split up clusters until each object is separated.

11.4.1 Partitioning Methods

Partitioning methods specify an initial number of groups and iteratively reallocate observations between groups until some equilibrium is attained. Several different algorithms are available

1. *The **k**-means algorithm.* In the k-means algorithm the observations are classified as belonging to 1 of k groups. Group membership is determined by calculating the centroid for each group (the multidimensional version of the mean) and assigning each observation to the group with the closest centroid. The k-means algorithm iterates between calculating the centroids on the basis of the current group memberships and reassigning observations to groups on the basis of the new centroids. When a Euclidean metric is used, cluster centroids are computed (on the basis of a least squares criterion) as the arithmetic means of the observations currently assigned to each cluster, and then observations are re-assigned to the cluster whose centroid is closest. This assignment is performed in an iterative fashion, either from a starting allocation or configuration or from a set of starting centroids. The k-means algorithm is essentially model free (*though it assumes the clusters are compact and spherically symmetric*). It is heavily dependent on initial group assignments and the use of the least-squares penalty.

2. *Partitioning around medoids (PAM).* The PAM method uses medoids rather than centroids, i.e. medians rather than means in each dimension. This approach increases robustness relative to the least-squares approach given above.

11.4.2 Hierarchical Clustering

Hierarchical clustering procedures can be carried out in two ways as listed below:

- *Heuristic criteria.* The basic hierarchical agglomeration algorithm starts with each object in a group of its own. At each iteration, two groups are merged to form a new group; the merger chosen is the one that leads to the smallest increase in the sum of the *within-group sums of squares*. The number of iterations is equal to the number of objects minus 1 and in the end all the objects are together in a single group. This is known as *Ward's method*, the *sum of squares method* or the *trace method*. The hierarchical agglomeration algorithm can be used with criteria other than the sum of squares criterion, such as the *average*, *single* or *complete linkage* methods described below.

- *Model-based criteria.* Model-based clustering is based on the assumption that the data are generated by a mixture of underlying probability distributions. Specifically, it is

assumed that the population of interest consists of k different subpopulations (usually assumed to be multivariate normally distributed) and that the density of an observation from the subpopulation is *specified by* some unknown vector of parameters *which are to be determined*. We study model-based criteria in more detail below.

In conventional hierarchical clustering, the method of agglomeration or combining clusters is determined by the distance between the clusters themselves, and there are several available choices. For merging two clusters C_i and C_j, with N_1 and N_2 elements respectively, the following criteria can be used: (1) *average linkage clustering*, where the two clusters that have the smallest average distance between the points in one cluster and the points in the other are merged, (2) *connected (single linkage, nearest-neighbour) clustering*, where the two clusters that have the smallest distance between *any* point in the first cluster and *any* point in the second cluster are merged, (3) *compact (complete linkage, furthest-neighbour) clustering*, where the two clusters that have the largest distance between *any* point in the first cluster *and any point* in the second cluster are merged. Efficient algorithms to achieve hierarchical clustering exist and are readily available in standard statistical packages such as R.

11.4.3   Model-based Hierarchical Clustering

Another approach to hierarchical clustering is *model-based clustering*, which is based on the assumption that the data are generated by a mixture of K underlying probability distributions. Given that data matrix $\mathbf{X} = \left(\mathbf{x}_1, \ldots, \mathbf{x}_N\right)^{\mathrm{T}}$, let

$$\gamma = \left(\gamma_1, \ldots, \gamma_N\right)$$

denote the cluster labels, where $\gamma_i = k$ if the ith data point comes from the kth subpopulation. In the classification procedure, a maximum likelihood procedure is used to choose the parameters in the model.

Commonly, the assumption is made that the data in the different subpopulations follow multivariate normal distributions, with mean $\boldsymbol{\mu}_k$ and covariance matrix Σ_k for cluster k. If

$$\Sigma_k = \sigma^2 I_p \qquad I_p = \mathrm{diag}\left(1, \ldots, 1\right), \text{ a } p \times p \text{ matrix.}$$

then maximising the likelihood is the same as minimising the sum of the within-group sums of squares.

More general covariance models have been implemented in the statistical package R in the library `mclust`. We give brief details. The key to specifying this is the eigendecomposition of Σ_k, given by eigenvalues $\lambda_1, \ldots, \lambda_p$ and eigenvectors $\mathbf{v}_1, \ldots, \mathbf{v}_p$, as in PCA. The eigenvectors of Σ_k, specify the orientation of the kth cluster, the largest eigenvalue λ_1 specifies its variance or size and the ratios of the other eigenvalues to the largest one specify its shape. Further, if $\Sigma_k = \sigma_k^2 I_p$, the criterion corresponds to hyperspherical clusters of different sizes; this is known as the *spherical* criterion. Another criterion results from constraining only the shape to be the same across clusters. This is achieved by fixing the eigenvalue ratios

$$\alpha_j = \frac{\lambda_j}{\lambda_1} \qquad j = 2, 3, \ldots, p$$

across clusters; different choices for the specification yield ellipsoidal, linear or spherical clusters.

11.4.4 Choosing the Number of Clusters

A hierarchical clustering procedure gives the sequence by which the clusters are merged (in agglomerative clustering) or split (in divisive clustering) according to the model or distance measure used, but does not give an indication for the number of clusters that are present in the data (under the model specification). This is obviously an important consideration. One advantage of the model-based approach to clustering is that it allows the use of statistical model assessment procedures to assist in the choice of the number of clusters. A common method is to use approximate Bayes factors to compare models with different numbers of clusters. This method gives a systematic means of selecting the parameterisation of the model, the clustering method and also the number of clusters. The *Bayes factor* is the posterior odds for one model against the other assuming neither is favoured *a priori*. A common approximation to the Bayes factor is the Bayes information criterion, which for model M is given by

$$BIC_M = -2 \log L_M + \text{const} \approx -2 \log L_M(\widehat{\theta}) + d_M \log N,$$

where L_M is the Bayesian marginal likelihood, $L_M(\widehat{\theta})$ is the maximised log likelihood of the data for the model M, N is the number of data points and d_M is the number of parameters estimated in the model. The number of clusters is not considered a parameter for the purposes of computing the BIC. The first term is a measure of fidelity to the data and the second is a penalty for the number of parameters in the model. The more negative the value of the BIC, the stronger the evidence for the model.

11.4.5 Displaying and Interpreting Clustering Results

The principal display plot for a clustering analysis is the *dendrogram*, which plots all of the individual data linked at successive levels by means of a binary 'tree'. Such a plot is displayed in Plate 10. The distance up the tree, or height, represents overall similarity between the samples and can be useful in determining the number of clusters that are present in the data.

Plate 10 displays the hierarchical clustering results for a subset of the hydrazine dataset (control and low dose, 8–72 hours). The control samples are shown in black while the dosed samples are shown in red. There are two main branches corresponding to control-like samples and dosed samples. The two groups of subjects are almost perfectly delineated by the clustering procedure if a cut is made at similarity level 0.6 units.

Hierarchical clustering has often been used to investigate metabolic profiling data. Some studies have investigated relationships between the metabolic profiles themselves (Beckonert *et al.*, 2003), while others have applied the method to elucidate dependencies between metabolite concentrations (by clustering the transposed data matrix X' (Dumas *et al.*, 2002)). In both cases, dendrograms generated intuitive visualisations of the hierarchy, allowing effects such as outliers, misclassifications and chemical structure correlations to be observed. Clustering approaches do not, of themselves, offer diagnostic information on the reasons for classification of any given object. This can be important if one wishes to know, e.g. the metabolites which are critical to determining cluster

membership. Mean cluster profiles and inter-cluster differences can be inspected; though information can still be lacking on the extent of cluster overlap and the overall relationship between clusters. Finally, note that validation of the results of a clustering exercise is recommended. This can take the form of data perturbation and reclustering to ensure that the removal of a minority of data points is not pivotal to the clustering inferences or the number of clusters selected.

11.5 NEURAL NETWORKS, KERNEL METHODS AND RELATED APPROACHES

An artificial neural network (ANN) is a multilayered statistical model that represents the variation in a potentially highly complex response or output variable to a collection of input variables via varying numbers of unobserved or latent variables linked through simple mathematical functions and a series of probabilistic dependence assumptions. ANNs are a member of a broad class of supervised learning algorithms that attempt to approximate the true data generation mechanism by mathematical models deduced from observation of cases essentially via regression arguments. These models have been perceived as mechanistic approximations to actual biological neural networks, although this interpretation is neither necessary nor uniformly helpful. We summarise the nature of such models below; see, e.g. (Ripley, 1996 Chapter 5) for a comprehensive description of statistical aspects.

11.5.1 Mathematical Formulation

The simplest mathematical formulation of an ANN involves three levels of interlinked variables;

- The *outputs*, Y (a $q \times 1$ vector), interpreted as a single/collection of continuous or categorical random variable(s).
- The *inputs*, X ($p \times 1$), interpreted as a collection of random variables believed to influence the variation in the *response* across an experimental sample of Ys.
- The *hidden variables*, Z ($d \times 1$), interpreted as a collection of unobserved random variables that form the hidden link between X and Ys.

This structure can be generalised to incorporate multiple hidden layers, but we restrict attention to the single *hidden* layer case.

In a classical biological conception of the model, the hidden variables Z have some physical interpretation as nodes in a neuronal network in the brain, but this interpretation is not necessary. Mathematically, perhaps the most useful interpretation of Z is as a *projection* of X onto a lower dimensional space ($p > d$) of *features* that facilitates modelling of the variation in Y. These features may or may not have a physical interpretation. Diagrammatically, such a network (with $q = 2$, $p = 6$ and $d = 3$) is represented in Figure 11.8.

The arrows connecting the nodes in Figure 11.8 represent functional links encompassed through mathematical functions. At the first stage, we represent the components of Z as weighted sums of functions of the input variables, typically

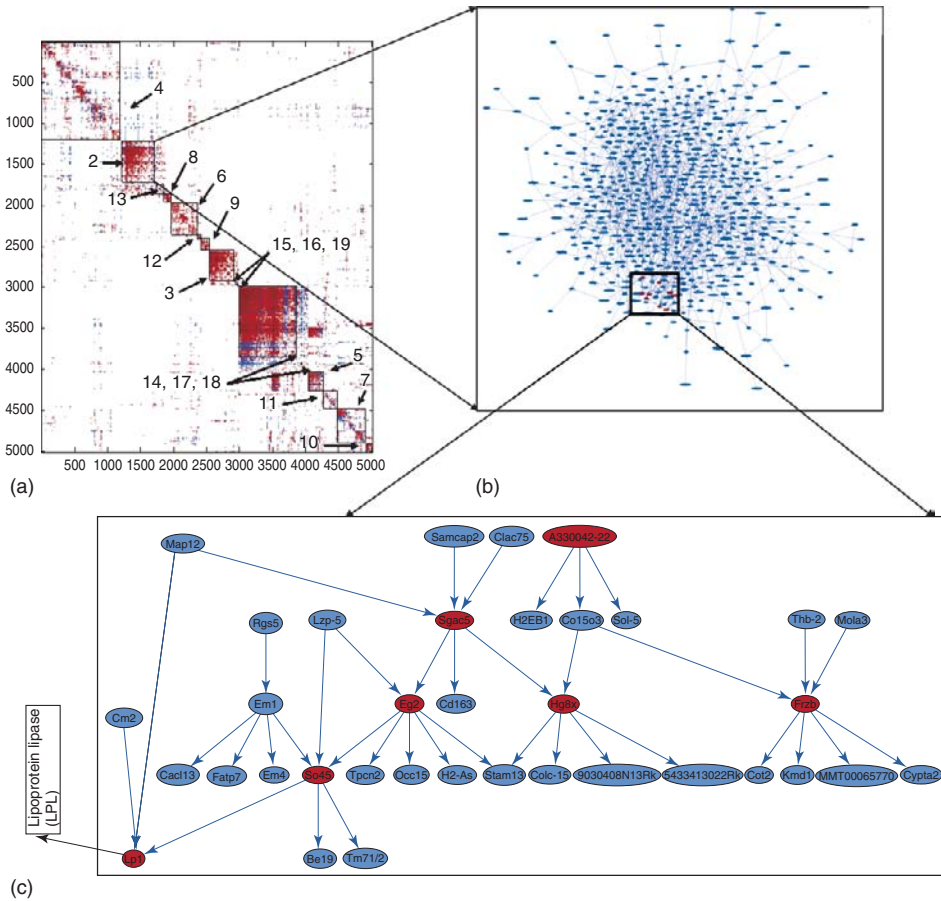
$$z_j = G_j \left(\alpha_j + \sum_{k=1}^{p} w_{jk} g_{jk}(x_k) \right) \qquad j = 1, \ldots, d, \qquad (11.2)$$
Plate 7. Correspondence analysis applied to an experiment that searched for genes expressed as a consequence of induction of the yeast cell cycle gene *CDC14* (Fellenberg *et al.*, 2001). A yeast transgene was constructed with the *CDC14* gene under a galactose-dependent promotor that allows induction of the *CDC14* gene through the addition of galactose. As a consequence, one observes upregulation of genes both due to *CDC14* induction and due to the natural reaction to galactose. Four conditions were studied: wildtype yeast with and without galactose, and the yeast transgene with and without galactose. For each condition several replicates were made. The correspondence analysis biplot shows an embedding of rows and columns of the entire data matrix with genes depicted as black dots and hybridizations depicted as small squares. Replicates for each condition cluster together, and each of the four clusters defines a direction in which the genes that are typical of the condition can be found. The bisection between the two galactose conditions points to two *GAL* genes, known to be involved in the galactose pathway. Genes in the transgene+galactose condition that are turned on in response to the addition of galactose are attracted also by the wildtype+galactose condition. Thus, the lower left direction highlights genes that are exclusively due to the *CDC14* induction. Genes are encircled which show up in a related experiment (Spellman *et al.*, 1998), too, where they are also seen to be linked to *CDC14*. (Adapted with permission from Fellenberg K *et al.* (2001) Correspondence analysis applied to microarray data. *Proc Natl Acad Sci USA*. 98:10781-6. Copyright (1998) National Academy of Sciences, U.S.A.).
Plate 8. Simplified view of strategy for reverse engineering gene networks using genetics in a fixed environment. The top layer represents DNA in the genome, where in any given population we can associate changes in the DNA with changes in the levels of transcription of both protein-coding and ncRNA genes. DNA variations that fall within the region of the structural gene and associate with that gene's expression are referred to as proximal eQTL, as opposed to distal eQTL in which the DNA variation does not fall in the genomic region supporting the corresponding structural gene region (Doss *et al.*, 2005). The proximity of transcribed sequences to the DNA provides for increased power to detect regions of the genome affecting transcript abundance levels. Changes in RNA are then shown to induce changes in proteins, where a complex web of protein interactions can form and give rise to varied cellular functions that in turn lead to disease. The gene network reconstruction methods discussed in the text exploit the ultimate source of perturbations (changes in DNA) in a system under fixed environmental conditions to order nodes in the network.


Plate 9. Coexpression and Bayesian networks from the BXH adipose expression data. (a) Topological overlap map for adipose tissue hub genes in the BXH cross. All pairs of correlations among the 5000 most highly connected genes in the BXH female adipose coexpression network are plotted in the color matrix display (red indicates positive correlation, blue indicates negative correlation, and white indicates correlation was not significant at the $p < 10^{-20}$ level). The genes are ordered along the x and y axes using an agglomerative hierarchical clustering algorithm. Tightly correlated groups of genes (modules) clearly emerge from this plot. Modules are identified as described in the text. (b) Bayesian network corresponding to genes in module 2 from (a). (c) Subnetwork consisting of 36 genes that contain the gene *Lpl*, a gene recently validated as causal for obesity (Schadt *et al.*, Submitted).
Plate 10. Hierarchical clustering for a subset of the hydrazine dataset (control and low dose 8–72 hours). The control samples are shown in black while the dosed samples are shown in red. There are two main branches corresponding to control-like samples and dosed samples. Note some dosed samples appeared to be similar to controls because the relevant animals have either recovered from or not yet responded to the toxin.
Plate 11. Visualisation using CLOUDS. The figure shows the toxicity data of Figure 11.2 (first 3 PCs) superimposed with isosurfaces of constant probability density estimated through CLOUDS. The surface for the high-dose class (blue) has been rendered transparent so as to enable viewing of the control density (green). Red squares denote samples from the low-dose class, while blue triangles denote samples from the high-dose group. One can clearly see how irregular distributions can be modelled in this way.
Plate 12. Summed frequency plot from GP analysis of the number of times each input (wave number) was used for the 10 evolved populations. Also shown are the normalised FT-IR spectra from *E. coli* (blue trace) and *E. coli*+5000 μg ml^{-1} ampicillin (red trace), and the structure of ampicillin. [Reprinted from Goodacre, R. (2005). Making sense of the metabolome using evolutionary computation: seeing the wood with the trees. *Journal of Experimental Botany* **56**, 245–254, with permission from Oxford University Press.].
Figure 11.8 Three-level neural network with $q = 2$, $p = 6$ and $d = 3$. The hidden layer $Z = (Z_1, Z_2, Z_3)'$ links inputs X to outputs Y. Arrows indicate positive weights.

where α_j, $j = 1, \ldots, d$ are unknown constants, w_{jk}, $k = 1, \ldots, p$, $j = 1, \ldots, d$ are weights satisfying

$$0 \leq w_{jk} \leq 1 \qquad \sum_{k=1}^{p} w_{jk} = 1$$

and G_j, $j = 1, \ldots, d$ and g_{jk}, $k = 1, \ldots, p$, $j = 1, \ldots, d$ are known *link* functions, the latter often chosen to be identity functions for convenience. At the second stage we have a similar structure modelling the dependence of Y on Z,

$$y_l = H_l \left(\beta_l + \sum_{j=1}^{d} \omega_{lj} z_j \right) \qquad l = 1, \ldots, p, \tag{11.3}$$

for parameters β_l, $l = 1, \ldots, p$ and weights ω_{lj}, $j = 1, \ldots, d$, $l = 1, \ldots, p$.

In summary, therefore, we have parameters $\boldsymbol{\alpha}$, $\boldsymbol{\beta}$, $\boldsymbol{w}_j$, $j = 1, \ldots, d$ and $\boldsymbol{\omega}_l$, $l = 1, \ldots, p$ to estimate from the data. This is achieved by optimisation of some objective function characterising discrepancy of fit, i.e. for observed cases $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_n$, we choose parameters $\widehat{\boldsymbol{\theta}}$ as

$$\widehat{\boldsymbol{\theta}} = \arg \min_{\boldsymbol{\theta}} \sum_{i=1}^{n} D(\boldsymbol{y}_i, \widehat{\boldsymbol{y}}_i), \tag{11.4}$$

where D measures the discrepancy between the observed $\boldsymbol{y}_i$ and the fitted value $\widehat{\boldsymbol{y}}_i$ given by using parameters $\boldsymbol{\theta}$ in (11.2) and (11.3). D is chosen to represent the continuous or categorical nature of the response variables, and the minimisation in (11.4) is achieved using numerical methods.

As described above, ANNs are flexible non-linear regression models constructed from simple mathematical functions that are learned from the observation of cases. As such, they

are ideal models for classification. However, their flexibility means that model parameters such as those determining the architecture (number of input, hidden and output nodes, etc.) are not predetermined and must be chosen on the basis of the skill and experience of the user. In addition, although good classification performance for metabolic profiles has been obtained (El-Deredy, 1997), interpretation of the rules encoded by an ANN is not straightforward. This has limited their application in the metabolic profiling arena in recent years, since model interpretation is of prime importance in applications such as biomarker screening and chemical structure elucidation. ANNs have found metabolic profiling applications in diverse areas such as classification of tumours (Howells *et al.*, 1992), preclinical toxicity prediction (Anthony *et al.*, 1995) and determination of the mode of action of herbicides in plants (Ott *et al.*, 2003). In all cases, the network weights could not be interpreted directly and other methods had to be used to determine the biochemical reasons for classification.

11.5.2   Kernel Density Estimates, PNNs and CLOUDS

Kernel density estimators (KDEs) are a well-known class of probability density estimators which have been extensively applied in many different areas of science (Parzen, 1962; Duda *et al.*, 2000). In classification problems, KDEs are usually applied to estimation of the class density (the conditional probability of observing an object, given that it is a member of the class). The estimators are especially useful when the class density deviates substantially from standard (e.g. normal) forms and allow us to estimate the density in an essentially non-parametric way. Classification of test objects is then done by calculating the class density at the coordinates of the test object and assigning the object to the class whose density is highest. Use of a Gaussian kernel leads to estimates of the form

$$p\left(\underline{x} \mid \underline{x}_{i \in A}\right) = \frac{1}{N_A (2\pi\sigma^2)^{M/2}} \sum_{i \in A} \exp\left\{-\frac{\|\underline{x} - \underline{x}_i\|^2}{2\sigma^2}\right\}, \qquad (11.5)$$

for the density of class A at point $\underline{x}$, where N_A is the number of training set objects $\underline{x}_i$ in the class, M is the number of dimensions and σ^2 is the width of the kernel. The kernel width regulates the smoothness of the density estimate and requires careful choice. It is often fixed by CV methods at the value that maximises the likelihood of class membership for objects left out of the training set in each CV round.

Probabilistic neural networks (PNNs) are a special kind of ANN whose architecture enables them to compute a kernel density estimate of the above form. Each input node corresponds to a variable in the input space and, when a test object is presented, feeds the corresponding value to each of the nodes in the second layer. Each second-layer node corresponds to one training set vector and computes the exponential of (11.5), feeding its output to a final layer of nodes, which computes the summation. Classification of unknowns by density superposition (CLOUDS) (Ebbels *et al.*, 2003) uses the KDE/PNN framework to both perform pointwise classification and detect similarity between the estimated densities. The latter function uses the overlap integral of the two densities as a measure of similarity and was developed to compare high-dimensional distributions with complex shape and topology.

The potential of PNNs to model complex high-dimensional metabolic data was first recognised by Holmes *et al.* (2001) who developed a model to classify ^{1}H NMR spectra of urine from laboratory rats treated with well-known toxins. When asked to classify

test samples into 1 of 18 toxicity-related classes, the PNN obtained higher classification accuracies than back-propagation neural networks and soft independent modelling of class analogy (SIMCA). In the area of food processing, PNNs were recently applied to classifying ^{1}H NMR spectra of fish tissue extracts according to different processing treatments (Martinez *et al.*, 2005). In order to avoid problems with the high dimensionality of the spectra, the scores from the first 20 principal components were used as inputs to the network, which successfully classified 80 % of the spectra. In metabonomic toxicology, CLOUDS was applied to several thousand ^{1}H NMR urine spectra from laboratory rats subjected to 19 different treatments known to cause toxic or other metabolic effects (Ebbels *et al.*, 2003). The approach was able to classify samples according to liver or kidney toxicity with 77 and 90 % success respectively, while experiencing a low, 2 %, rate of confusion between the classes. The class probabilities were further combined into two parameters, the confidence and uniqueness of the classification, which allowed pre-selection of the best-classified urinary profiles. Recently, the CLOUDS methodology was employed in the construction of an 'expert system' for preclinical toxicity screening using a large database of ^{1}H NMR urinary metabolic profiles from 80 different treatments (Ebbels *et al.*, 2006). A novel measure of similarity between classes was developed on the basis of the overlap integral of the density estimates. Although the system was unable to judge the likely toxicity of some of the treatments, where a decision could be made, over 92 % were classified correctly. In addition, the system correctly determined the site of toxicity for two blinded treatments.

The densities estimated by CLOUDS and similar techniques can be visualised by computing contours or isosurfaces of constant probability density and viewing them with the help of dimension reduction techniques such as PCA. Plate 11 illustrates this with the metabonomic toxicology data of Figure 11.2. The control class has a shape that might be well summarised by a multivariate normal, while the high-dose cloud extends away from the controls in a hairpinlike trajectory. The part of the high-dose density coinciding with controls is due to samples from animals that are either yet to react or have already recovered from the toxic episode.

Overall, use of KDE methods, while versatile and well suited to the characteristics of metabolic profiling data, is subject to some drawbacks. The most important of these is the large amount of data required to accurately estimate the density when the number of dimensions is high. Along with the high storage requirement and the need for the ability to interpret models in terms of spectral features, these are areas that will be the subject of further research in the near future.

11.6 EVOLUTIONARY ALGORITHMS

Evolutionary computations have attracted increasing interest as a method of solving complex problems in medicine, industry and bioinformatics. Evolutionary algorithms (EA) are ideal strategies for mining metabolite data to build useful relationships, rules and predictions. The advantages of this methodology include conceptual simplicity and broad applicability, the ability to optimise complex multimodal objective functions and to outperform standard optimisation procedures in real world applications. The algorithms are typically flexible and easily hybridised with other methods such as neural networks (Fogel and Corne, 2003). EAs are adaptive procedures, motivated by genetic processes

as they evolve a population of *chromosomal structures* (possible solutions), in order to find the *fittest* individual. Candidate solutions to the optimisation problem play the role of individuals in a population that is evolved through generations, undergoing processes inspired by biological evolution: reproduction, mutation, recombination, natural selection and survival of the fittest. In general, the evolutionary optimisation techniques use a population of possible solutions subjected to random *variation* and *selection* until some termination criterion is satisfied. The fitness of each individual in the population reflects the individual's worth in relation to some objective function.

The aim of the EA is to progressively develop better solutions to the problem under study by modifying previous solutions that exhibited good performance. Starting with an initial population of individuals, generated through some randomised process, each individual is then placed in a common environment where it competes and breeds with the other members of the population. In many applications, the environment is usually referred to as the design space and is the set of all possible solutions for a given problem. The individual's fitness shows how well it has adapted to its environment, i.e. larger fitness values correspond to better solutions. The fittest individuals have more chance to survive in the next generation and to be selected to reproduce. New individuals are generated through variation operators, the most common of which are mutation, the introduction of one or more random changes to a single parent individual, and recombination (commonly referred to as crossover), which consists in randomly taking components/characteristics from two or more parent individuals to create children. Variation operators are fundamental as they affect the algorithm's search power: when the search space has many local optima, large-scale mutations might be useful for escaping local optima, but less radical mutations might be important to proceed towards a global optimum. Following the application of variation operators, two sets of solutions exist: the parent population and the child population. Thus a selection for survival stage is required to form the new population. This step requires scoring each solution on its worth with respect to a given goal, i.e. according to its fitness. It is essential that the fitness function reflects the problem characteristics although the specification of a suitable function can, in itself, be a difficult task. Once the solutions have been scored, then the new generation is formed according to various schemes: some schemes require that the new generation is formed only by child solutions, while in other cases the new population is formed by combining individuals from both the parent and the child population. Selection for survival is often a deterministic process, in which the best solutions are selected, however stochastic schemes are also possible. Most EAs work on a generational base, applying variation and selection operators to all members of the population at a given time and iterating this process for a pre-specified number of generations or until convergence to a local or global optimum has been reached.

EAs are becoming increasingly popular in chemometrics as they can provide useful supervised learning techniques that can be utilised in many scenarios, e.g. to identify metabolites associated with a particular phenotype (Goodacre, 2005). These include genetic algorithms, evolution strategies, genetic programming (GP) and genomic computing. Among the evolutionary techniques, GP has been most commonly used in metabolic profiling applications. In the GP framework, the solution is structured as a parse tree. For example, in symbolic regression the parse tree specifies the regression relationship between the response and the predictors. One of the earliest applications of GPs to metabolic data can be found in the work of Gray *et al.* (1998). They proposed

a GP algorithm to classify tumours on the basis of ^{1}H NMR spectra of biopsy extracts. Following successful use of GP algorithms for the analysis of pyrolysis mass spectral data of fruit juice (Gilbert *et al.*, 1997), similar strategies have been developed to analyse metabolic profiling and fingerprinting data from several other spectroscopic and chromatographic techniques including Fourier Transform – Infrared (FT – IR) (Johnson *et al.*, 2000; Goodacre, 2005), high performance liquid chromatography (HPLC) (Kell *et al.*, 2001), non-linear dielectric spectroscopy Woodward *et al.* (1999) and various types of MS (Taylor *et al.*, 1998; Goodacre *et al.*, 2000; 2003). In most applications the authors highlight the ability of the GP to combine small numbers of explanatory metabolites in simple prediction rules to classify the response of interest. For example, as a test of the GP approach to modelling complex mixtures such as metabolic profiles, Goodacre (2005) developed a GP to quantify the levels of the antibiotic ampicillin in cultures of the bacterium *Escherichia coli*. Ampicillin was added to *E. coli* cultures at different concentrations, observed with FT-IR spectroscopy and the GP was used in 'symbolic regression' mode to quantify the ampicillin level using the FT-IR profiles as input. The GP was able to identify the $1767 \, \mathrm{cm}^{-1}$ vibration (corresponding to the β-lactam ring of ampicillin) as the important variable corresponding to ampicillin despite large signals from other *E. coli* metabolites, thus highlighting its promise as a method for data mining complex metabolic profiles. Plate 12 shows the frequency of the number of times each input (wavenumber) was used for 10 evolved populations, i.e. 10 runs of the GP algorithm. The area of the spectra corresponding to vibration $1767 \, \mathrm{cm}^{-1}$ is clearly dominating for *E. coli* treated with ampicillin, but absent from *E. coli* alone.

11.7 CONCLUSIONS

The techniques described here have found a wide variety of applications in metabolic profiling, many of which are mentioned in the preceding paragraphs. Two of the most important applications are biomarker screening and the structural identification of metabolites. In biomarker screening, the goal is to find molecules that differentiate between two biological states, for example, healthy and diseased populations. Almost any of the supervised pattern recognition approaches described above can be employed here. The input data are metabolic profiles (or metabolite levels derived from them) and the task is to fit a model that discriminates between samples from the healthy and diseased groups. If a discrimination is found, then the model can be examined to find out which metabolites are influential in producing the discrimination and thus might be important markers of the disease process itself. We note that some statistical techniques, for example neural networks, are much less amenable to yielding discriminatory markers than others. Additionally, such discriminators are not considered true 'biomarkers' until they have been independently validated across multiple experiments/populations and shown to be mechanistically linked with the disease or condition being studied.

As mentioned in the introduction, a large proportion of the metabolome is currently unknown and therefore the structural identification of molecules is of great importance. For this purpose, statistical analysis is directed at linking multiple signals coming from the same molecule. For example, in NMR, each spin system (group of interacting nuclei) will produce a different set of resonances. In the hands of a spectroscopist, the multiplet

structure and relationship between the resonances can yield valuable information on the likely structure of the molecule. Therefore, methods aimed at linking spectral peaks that exhibit similar statistical properties are useful. For example, signals shown to discriminate between groups in a similar way may originate from the same molecule. Alternatively, specific methods can be designed to identify statistically connected signals, which may originate from a structural relationship (Cloarec *et al.*, 2005; Crockford *et al.*, 2006).

In this chapter we have described the nature of metabolic profiling data and some of the statistical approaches that are typically used to model it. Owing to space considerations we have not undertaken a comprehensive review of all methods used in the field, but have highlighted those that have seen wide application. The reader is referred to Lindon *et al.* (2007) for a more thorough description of both the chemical and data analytic techniques used, along with in-depth reviews of many different application areas of the technology. It is clear that there are many problems still to be solved in the statistical analysis of metabolic profiles, such as peak shifts in NMR and the proper treatment of differential ionisation efficiencies in MS. The lack of structural identification of a large proportion of the signals remains a huge impediment to biological interpretation and, given the diversity of the metabolome throughout the various kingdoms of life, it seems clear that this situation is unlikely to change soon. Therefore statistical approaches which can deal with a mixture of identified and unidentified peaks are likely to have a large impact in this area. Approaches based on mixed-models and wavelet approaches have proved extremely useful (Morris *et al.*, 2006; Brown *et al.*, 2001; Clyde *et al.*, 2006). For example, sparse representation of the NMR spectrum in terms of wavelet coefficients makes wavelets an excellent tool in data compression and hence feature extraction. In addition, the wide range of chemical analytic techniques used in the generation of metabolic profiles will require statistical models that can integrate and combine information across multiple platforms. Overall, the field is a young but rapidly developing one and looks set to reap many benefits from the input of researchers in other fields, including those of machine learning and statistical analysis.

Adaptive Molecular Evolution

Z. Yang

Department of Biology, University College London, London, UK

This chapter reviews statistical methods for detecting adaptive molecular evolution by comparing synonymous and nonsynonymous substitution rates in protein-coding DNA sequences. A Markov process model of codon substitution, which forms the basis for all later discussions in this chapter, is introduced first. The case of comparing two sequences to estimate the numbers of synonymous (d_S) and nonsynonymous (d_N) substitutions per site is then considered. The maximum likelihood (ML) method and a number of *ad hoc* counting methods are evaluated. The rest of the chapter deals with joint analyses of multiple sequences on a phylogeny. Review is provided on Markov models of codon substitution that allow the nonsynonymous/synonymous rate ratio ($\omega = d_N/d_S$) to vary among branches in a phylogeny or among amino acid sites in a protein. Those models can be used to construct likelihood ratio tests (LRTs) to identify evolutionary lineages under episodic Darwinian selection or to infer critical amino acids in a protein under diversifying selection. Real-data examples are used to demonstrate the application of the methods. The chapter finishes with a discussion of the limitations of current methods.

12.1 INTRODUCTION

While biologists accept Darwin's theory of evolution by natural selection for morphological traits, the importance of selection in molecular evolution has been much debated. The neutral theory (Kimura, 1983) maintains that most observed molecular variation (both diversity within species and divergence between species) is due to random fixation of mutations with fitness effects so small that random drift rather than natural selection dominates their fate. Population geneticists have developed a number of tests of neutrality (for reviews, see Kreitman and Akashi, 1995 and **Chapter 22**). Those tests have been applied to identify genes under positive selection from genome-wide analysis of within-species polymorphism (Fay *et al.*, 2001; Smith and Eyre-Walker, 2002). However, they seldom provide unequivocal evidence for positive selection as it is often difficult to distinguish natural selection from demographic processes.

Another class of methods designed to detect adaptive molecular evolution relies on comparison of synonymous (silent) and nonsynonymous (amino acid−changing)

substitution rates in protein-coding genes. The synonymous and nonsynonymous rates (d_S and d_N, or K_s and K_a by some authors) are defined as the numbers of synonymous and nonsynonymous substitutions per site, respectively. The ratio of the two rates, $\omega = d_N/d_S$, then measures selective pressure at the protein level. If selection has no effect on fitness, nonsynonymous mutations will be fixed at the same rate as synonymous mutations, so that $d_N = d_S$ and $\omega = 1$. If nonsynonymous mutations are deleterious, purifying selection will reduce their fixation rate, so that $d_N < d_S$ and $\omega < 1$. If nonsynonymous mutations are favored by Darwinian selection, they will be fixed at a higher rate than synonymous mutations, resulting in $d_N > d_S$ and $\omega > 1$. A significantly higher nonsynonymous rate than the synonymous rate is thus evidence for adaptive evolution at the molecular level. This criterion has been used to identify many cases of positive selection, including the human major histocompatibility complex (MHC, Hughes and Nei, 1988), primate stomach lysozyme (Messier and Stewart, 1997), abalone sperm lysin (Lee *et al.*, 1995), vertebrate visual pigments (Miyamoto and Miyamoto, 1996), and HIV-1 *env* genes (Bonhoeffer *et al.*, 1995; Mindell, 1996; Yamaguchi and Gojobori, 1997). Development of powerful methods, such as those reviewed in this chapter, has led to identification of many more cases of molecular adaptation (Yang and Bielawski, 2000; Yang, 2006: Chapter 8) providing important insights into the mechanisms of molecular evolution.

The ω ratio has most often been calculated as an average over all codons (amino acids) in the gene and over the entire evolutionary time that separates the sequences. The criterion that such an average ω is greater than 1 is a very stringent one for detecting positive selection (e.g. Kreitman and Akashi, 1995). Many amino acids in a protein must be under strong functional constraints, with ω close to 0. Many proteins also appear to be under purifying selection during most of the evolutionary history. Adaptive evolution most likely occurs at a few time points and affects only a few amino acids (Gillespie, 1991). In such a case, the ω ratio averaged over time and over sites will not be greater than 1 even if Darwinian selection has been operating.

A remedy for this problem is to examine the ω ratio over a short evolutionary time period or in a short stretch of the gene such as functionally important domains. For example, Messier and Stewart (1997) (see also Zhang *et al.*, 1997) used inferred ancestral genes to calculate d_N and d_S for each branch in the tree and identified two lineages in the lysozyme phylogeny for primates that went through positive selection. In a similar vein, Hughes and Nei (1988) found that $d_N > d_S$ at 57 amino acids in the MHC that constitute the antigen-recognition site, although $d_N < d_S$ in the whole gene. Those ideas have also been implemented in the likelihood framework. Markov process models of codon substitution have been developed that account for different ω ratios among branches in the tree (Yang, 1998; Yang and Nielsen, 1998). They can be used to construct likelihood ratio tests (LRTs) of adaptive evolution along specific lineages, and have the advantage of not relying on inferred ancestral sequences. Models have also been developed that allow the ω ratio to vary among amino acid sites (Nielsen and Yang, 1998; Yang *et al.*, 2000). They do not require knowledge of functionally important domains and may be used to test for the presence of critical amino acids under positive selection, and, when they exist, to identify them.

This chapter reviews statistical methods for phylogenetic analysis of protein-coding DNA sequences, with a focus on comparing synonymous and nonsynonymous substitution rates to understand the mechanisms of protein sequence evolution. At first, a brief

introduction to the probability theory of Markov process of codon substitution is provided. This theory forms the basis for maximum likelihood (ML) estimation of d_N and d_S between two sequences as well as ML joint analysis of multiple sequences on a phylogeny. Different methods for comparing two sequences to estimate d_N and d_S are discussed. Besides ML (Goldman and Yang, 1994), there are about a dozen so-called counting methods for this estimation (e.g. Miyata and Yasunaga, 1980; Nei and Gojobori, 1986; Li *et al.*, 1985; Li, 1993; Ina, 1995; Yang and Nielsen, 2000). These will be evaluated. Models that account for variable ω ratios among lineages and among sites are then discussed with real-data examples to explain their use in ML analysis. This chapter uses ML as the general framework. ML is known to have nice statistical properties, and indeed offers insights into heuristic methods as well, which may not be based on an explicit probabilistic model. A brief introduction to ML estimation and LRT is provided in the Section 12.3.2. For a detailed and rigorous treatment of likelihood methods, the reader should consult a statistics textbook, such as Edwards (1992), Kalbfleisch (1985), and Stuart *et al.* (1999).

12.2 MARKOV MODEL OF CODON SUBSTITUTION

In molecular phylogenetics, we use a continuous-time Markov process to describe the change between nucleotides, amino acids, or codons over evolutionary time. See Whelan *et al.* (2001) or the chapters by Huelsenbeck and Bollback, and Thorne and Goldman (**Chapter 14** and **Chapter 15**) for use of Markov processes to model nucleotide or amino acid substitution. In this chapter, our focus is analysis of protein-coding DNA sequences, and the unit of evolution is a codon in the gene. We use a Markov process to describe substitutions between the sense codons. We exclude stop codons as they are usually not allowed in a protein. With the 'universal' genetic code, there are 61 sense codons and thus 61 states in the Markov process.

The Markov process is characterized by a rate (generator) matrix $Q = \{q_{ij}\}$, where q_{ij} is the substitution rate from sense codon i to sense codon $j (i \neq j)$. Formally, $q_{ij}\Delta t$ is the probability that the process is in state j after an infinitesimal time Δt, given that it is currently in state i. The basic model we use in this chapter is simpler than the model of Goldman and Yang (1994) but more complex than that of Muse and Gaut (1994). It accounts for the transition–transversion rate difference, unequal synonymous and nonsynonymous substitution rates, and unequal base/codon frequencies. Mutations are assumed to occur independently among the three codon positions, and so only one position is allowed to change instantaneously. Since transitions (changes between T and C, and between A and G) are known to occur more frequently than transversions (all other changes), we multiply the rate by κ if the change is a transition. Parameter κ is the transition–transversion rate ratio. Typical estimates of κ are 1.5–5 for nuclear genes and 3–30 for mitochondrial genes. To account for unequal codon frequencies, we let π_j be the equilibrium frequency of codon j and multiply substitution rates to codon j by π_j. We can either use all π_j's as parameters, with $60 (= 61 - 1)$ free parameters used, or calculate π_j from base frequencies at the three codon positions, with $9 = 3 \times (4 - 1)$ free parameters used.

To account for unequal synonymous and nonsynonymous substitution rates, we multiply the rate by ω if the change is nonsynonymous; ω is thus the nonsynonymous/synonymous

rate ratio, also termed the 'acceptance rate' by Miyata *et al.* (1979). In models considered here, the relationship holds that $\omega = d_N/d_S$. For most genes, estimates of ω are much less than 1. Parameters κ and π_j characterize processes at the DNA level, including natural selection, while selection at the protein level has the effect of modifying parameter ω. If natural selection operates on the DNA as well as on the protein, the synonymous rate will differ from the mutation rate.

Thus, the relative substitution rate from codon i to codon $j (i \neq j)$ is

$$q_{ij} = \begin{cases} 0, & \text{if } i \text{ and } j \text{ differ at two or three codon positions,} \\ \pi_j, & \text{if } i \text{ and } j \text{ differ by a synonymous transversion,} \\ \kappa\pi_j, & \text{if } i \text{ and } j \text{ differ by a synonymous transition,} \\ \omega\pi_j, & \text{if } i \text{ and } j \text{ differ by a nonsynonymous transversion,} \\ \omega\kappa\pi_j, & \text{if } i \text{ and } j \text{ differ by a nonsynonymous transition.} \end{cases} \qquad (12.1)$$

For example, consider substitution rates to codon CTG (which encodes amino acid Leu). We have $q_{\text{CTC,CTG}} = \pi_{\text{CTG}}$ since the CTC (Leu) $\rightarrow$ CTG (Leu) change is a synonymous transversion, $q_{\text{TTG,CTG}} = \kappa\pi_{\text{CTG}}$ since the TTG (Leu) $\rightarrow$ CTG (Leu) change is a synonymous transition, $q_{\text{GTG,CTG}} = \omega\pi_{\text{CTG}}$ since the GTG (Val) $\rightarrow$ CTG (Leu) change is a nonsynonymous transversion, and $q_{\text{CCG,CTG}} = \kappa\omega\pi_{\text{CTG}}$ since the CCG (Pro) $\rightarrow$ CTG (Leu) change is a nonsynonymous transition. Also $q_{\text{TTT,CTG}} = 0$ since codons TTT and CTG differ at two positions.

The diagonal elements of the rate matrix $Q = \{q_{ij}\}$ are determined by the requirement that each row in the matrix sums to 0

$$\sum_j q_{ij} = 0, \text{for any } i, \qquad (12.2)$$

(e.g. Grimmett and Stirzaker, 1992, p. 241). Furthermore, molecular sequence data do not allow separate estimation of rate and time, and only their product can be identified. We thus multiply matrix Q by a constant so that the expected number of nucleotide substitutions per codon is 1:

$$-\sum_i \pi_i q_{ii} = \sum_i \pi_i \sum_{j \neq i} q_{ij} = 1. \qquad (12.3)$$

This scaling means that time t is measured by distance, the expected number of (nucleotide) substitutions per codon. The transition probability matrix over time t is

$$P(t) = \{p_{ij}(t)\} = e^{Qt}, \qquad (12.4)$$

where $p_{ij}(t)$ is the probability that codon i will become codon j after time t. As long as the rate matrix Q can be constructed, $P(t)$ can be calculated for any t using matrix diagonalization. Note that over any time interval, there is a nonzero probability that any codon i will change to any other codon j, even if they are separated by two or three nucleotide differences; that is, for any $t > 0$, $p_{ij}(t) > 0$ for any codons i and j.

Lastly, the model specified by (12.1) is time reversible; that is, $\pi_i q_{ij} = \pi_j q_{ji}$ for any i and j. This means that

$$\pi_i p_{ij}(t) = \pi_j p_{ji}(t), \text{for any } t, i, \text{ and } j. \qquad (12.5)$$

Note that $\pi_i p_{ij}(t)$ measures the amount of change from codons i to j over time t, while $\pi_j p_{ji}(t)$ measures the change in the opposite direction. Equation (12.5), known as the 'detailed balance', means that we expect to see equal numbers of changes from i to j and from j to i. Some implications of reversibility are mentioned in later sections.

12.3 ESTIMATION OF SYNONYMOUS (d_S) AND NONSYNONYMOUS (d_N) SUBSTITUTION RATES BETWEEN TWO SEQUENCES

12.3.1 Counting Methods

We want to estimate the number of synonymous substitutions per synonymous site (d_S) and the number of nonsynonymous substitutions per nonsynonymous site (d_N) between two protein-coding DNA sequences. In the past two decades, about a dozen methods have been proposed for this estimation. They are intuitive and involve treatment of the data that cannot be justified rigorously. Important basic concepts were developed in the early 1980s (Miyata and Yasunaga, 1980; Perler *et al.*, 1980; Gojobori, 1983; Li *et al.*, 1985), which we explain here with a hypothetical example. The critical question is by how much natural selection at the protein level has increased or decreased the nonsynonymous substitution rate. Suppose the gene has 300 codons and we observe five synonymous and five nonsynonymous differences (substitutions) between the two sequences. Can we conclude that synonymous and nonsynonymous substitution rates are equal with $\omega = 1$? The answer is 'No'. An inspection of the genetic code table suggests that all changes at the second codon position and most changes at the first position are nonsynonymous, and only some changes at the third position are synonymous. As a result, we do not expect to see equal proportions of synonymous and nonsynonymous mutations even if there is no selection at the protein level. Indeed, if mutations from any one nucleotide to any other occur at the same rate, we expect 25.5 % of mutations to be synonymous and 74.5 % to be nonsynonymous (Yang and Nielsen, 1998). If we use those proportions, it is clear that selection on the protein has decreased the fixation rate of nonsynonymous mutations by about three times, since $\omega = (5/5)/(74.5/25.5) = 0.34$. There are 900 nucleotide sites in the sequence, so the numbers of synonymous and nonsynonymous sites are $S = 900 \times 25.5\% = 229.5$ and $N = 900 \times 74.5\% = 670.5$, respectively. We then have $d_S = 5/229.5 = 0.0218$ and $d_N = 5/670.5 = 0.0075$.

All counting methods roughly follow the above intuitive procedure (see Ina, 1996; Yang and Nielsen, 2000 for reviews). They involve three steps. The first step is to count the numbers of synonymous (S) and nonsynonymous (N) *sites* in the two sequences; that is, the number of nucleotide sites in the sequence is classified into the synonymous and nonsynonymous categories, measuring substitution opportunities before the operation of selection on the protein. This step is complicated by factors such as transition–transversion rate difference and unequal base/codon frequencies, both of which are ignored in our hypothetical example. The second step is to count the numbers of synonymous and nonsynonymous *differences* between the two sequences; that is, the observed differences between the two sequences are classified into the synonymous and nonsynonymous categories. This is straightforward if the two compared codons differ at one codon position only. When they differ at two or three codon positions, there exist four or

six pathways from one codon to the other. The multiple pathways may involve different numbers of synonymous and nonsynonymous differences and should ideally be weighted appropriately according to their likelihood of occurrence, although most counting methods use equal weighting. The third step is to apply a correction for multiple substitutions at the same site since an observed difference may be the result of two or more substitutions. In our hypothetical example, we ignored the possibility of multiple hits and treated the observed differences as substitutions. All counting methods have used multiple-hit correction formulas based on nucleotide-substitution models, which assume that each nucleotide can change to one of three other nucleotides. When those formulas are applied to synonymous (or nonsynonymous) sites only, this basic assumption of the Markov model is violated (Lewontin, 1989). Nevertheless, such corrections appear usable when the sequence divergence is low.

The method of Miyata and Yasunaga (1980) and its simplified version of Nei and Gojobori (1986) are based on the nucleotide-substitution model of Jukes and Cantor (1969), and ignore transition–transversion rate difference or unequal base/codon frequencies. As transitions are more likely to be synonymous at the third positions than transversions are, ignoring the transition–transversion rate difference leads to underestimation of S and overestimation of N. This effect is well known, and a number of attempts have been made to account for different transition and transversion rates in counting sites and differences (Li *et al.*, 1985; Li, 1993; Pamilo and Bianchi, 1993; Comeron, 1995; Ina, 1995). The effect of unequal base/codon frequencies was not so much appreciated (but see Moriyama and Powell, 1997). However, Yang and Nielsen (1998; 2000) found that extremely biased base/codon frequencies can have devastating effects on the estimation of d_N and d_S, often outweighing the effect of the transition–transversion rate difference. A counting method taking into account both factors was implemented by Yang and Nielsen (2000).

12.3.2 Maximum Likelihood Estimation

Likelihood is a powerful and flexible methodology for estimating parameters and testing hypotheses. Since the data are observed, we view the probability of observing the data as a function (the likelihood function) of the unknown parameters. The likelihood or log-likelihood function is our inference tool and contains all information about the parameters in the model. We estimate the unknown parameters by maximizing the likelihood function. Furthermore, the log-likelihood value under a model measures the fit of the model to data, and we compare two models by comparing their log-likelihood values. This is known as the LRT. When two models are nested, twice the log-likelihood difference between the two models can be compared with the χ^2 distribution, with the difference in the number of parameters between the two models as the degrees of freedom (df). The χ^2 approximation to the likelihood ratio statistic relies on large sample sizes (long sequences). How large the sample should be for the χ^2 approximation to be reliable depends on the specific model being tested as well as other factors such as sequence divergence. In a few cases where LRTs applied to phylogenetics were examined by computer simulation, the χ^2 approximation appears very good with as few as 100 or 200 nucleotides in the sequence (e.g. Nekrutenko *et al.*, 2001). When the sequences are too short or when the two models are not nested, the correct distribution of the test statistic can be derived by Monte Carlo simulation (Goldman, 1993).

The ML method for estimating d_N and d_S (Goldman and Yang, 1994) is described below. The data are two aligned protein-coding DNA sequences. As a numerical example, we will use the human and mouse acetylcholine receptor α genes. The first 15 codons of the gene are shown below.

```
Human GAG CCC TGG CCT CTC CTC CTG CTC TTT AGC CTT TGC TCA GCT GGC ...
Mouse GAG CTC TCG ACT GTT CTC CTG CTG CTA GGC CTC TGC TCC GCT GGC ...
```

We assume that different codons in the sequence are evolving independently according to the same Markov process. As a result, data at different sites are independently and identically distributed. Suppose there are n sites (codons) in the gene, and let the data at site h be $\mathbf{x}_h = \{x_1, x_2\}$, where x_1 and x_2 are the two codons in the two sequences at that site (see Figure 12.1a). In the above example, the data at site $h = 2$ are $x_1 = $ CCC and $x_2 = $ CTC. The probability of observing data $\mathbf{x}_h$ at site h is

$$f(\mathbf{x}_h) = \sum_{k=1}^{61} \pi_k p_{kx_1}(t_1) p_{kx_2}(t_2). \tag{12.6}$$

The term in the sum is the probability that the ancestor has codon k and the two current species have codons x_1 and x_2 at the site. This probability is equal to the prior probability that the ancestor has codon k, given by the equilibrium frequency π_k, multiplied by the two transition probabilities along the two branches of the tree (Figure 12.1a). Since the ancestral codon k is unknown, we sum over all possibilities for k. Time reversibility of the Markov process implies that

$$f(\mathbf{x}_h) = \sum_{k=1}^{61} \pi_{x_1} p_{x_1 k}(t_1) p_{kx_2}(t_2) = \pi_{x_1} \sum_{k=1}^{61} p_{x_1 k}(t_1) p_{kx_2}(t_2) = \pi_{x_1} p_{x_1 x_2}(t_1 + t_2). \tag{12.7}$$

The last step follows from the Chapman–Kolmogorov theorem (e.g. Grimmett and Stirzaker, 1992, pp. 239–246). Thus the data are probabilistically identical whether we consider the two sequences to be descendants of a common ancestor (as in Figure 12.1a) or we consider one sequence to be ancestral to the other (as in Figure 12.1b). In other words, the root of the tree cannot be identified and only $t = t_1 + t_2$ can be estimated, but not t_1 and t_2 individually. Parameters in the model are thus the sequence divergence t, the transition–transversion rate ratio κ, the nonsynonymous/synonymous rate ratio ω, and the codon frequencies π_j's. The log-likelihood function is then given by

Figure 12.1 The tree for two sequences, with the codons x_1, x_2 for one site shown. Codon-substitution models considered in this chapter are all time reversible and do not allow identification of the root. As a result, parameters t_1 and t_2 cannot be estimated separately (a), and only their sum $t = t_1 + t_2$ is estimable (b).
Figure 12.2 The log-likelihood surface contour as a function of parameters t and ω for the comparison of the human and mouse acetylcholine receptor α genes. The maximum likelihood method estimates parameters by maximizing the likelihood function. For these data, the estimates are $t = 0.444$, $\omega = 0.059$, with the optimum log likelihood to be $\ell = -2392.83$.

$$\ell(t, \kappa, \omega) = \sum_{h=1}^{n} \log\{f(\mathbf{x}_h)\}. \tag{12.8}$$

If some sites have the same data $\mathbf{x}$, the probability $f(\mathbf{x})$ need be calculated only once. An equivalent way of deriving the likelihood function is to note that the data follow a multinomial distribution with 61^2 categories corresponding to the 61^2 possible site patterns (configurations).

We usually estimate the codon frequencies (π_j's) by the observed base/codon frequencies. To estimate parameters t, κ, and ω, we use a numerical hill-climbing algorithm to maximize ℓ, since an analytical solution is impossible. Figure 12.2 shows a log-likelihood surface as a function of t and ω for the human and mouse acetylcholine receptor α genes. The model assumes equal transition and transversion rates and equal codon frequencies (with $\kappa = 1$ and $\pi_j = 1/61$ fixed), and involve two parameters only. This is the

model underlying the method of Miyata and Yasunaga (1980) and Nei and Gojobori (1986).

The d_N and d_S rates are defined as functions of parameters t, κ, ω, and π_j, and their ML estimates are simply functions of ML estimates of parameters t, κ, ω, and π_j. The following description thus gives both the definitions of d_N and d_S, and also the ML method for their estimation. The basic idea is the same as explained in our hypothetical example before. Here we count sites and substitutions per codon rather than for the entire sequence. First, note that the sequence divergence t is defined as the number of nucleotide substitutions per codon. We partition this number into the synonymous and nonsynonymous categories. We note that

$$\rho_S^* = \sum_{\substack{i \neq j \\ aa_i = aa_j}} \pi_i q_{ij} \tag{12.9}$$

and

$$\rho_N^* = \sum_{\substack{i \neq j \\ aa_i \neq aa_j}} \pi_i q_{ij} \tag{12.10}$$

are the proportions of synonymous and nonsynonymous substitutions, respectively, as $\rho_S^* + \rho_N^* = 1$ (12.3). The summation in ρ_S^* is taken over all codon pairs i and $j (i \neq j)$ that code for the same amino acid, while the summation in ρ_N^* is taken over all codon pairs i and j $(i \neq j)$ that code for different amino acids; aa_i is the amino acid encoded by codon i. The numbers of synonymous and nonsynonymous substitutions per codon are then $t\rho_S^*$ and $t\rho_N^*$, respectively.

Next, we calculate the proportions of synonymous and nonsynonymous *sites*. Let these be ρ_S^1 and ρ_N^1. As noted before, these measure the substitution opportunities before the operation of selection at the protein level, that is, when $\omega = 1$ (Goldman and Yang, 1994; Ina, 1995). They are calculated similar to (12.9) and (12.10), using the transition–transversion rate ratio κ and codon frequencies (π_j), except that $\omega = 1$ is fixed. We assume there are three nucleotide sites in a codon (see Yang and Nielsen, 1998 for a discussion of the effect of mutations to stop codons). The numbers of synonymous and nonsynonymous sites per codon are then $3\rho_S^1$ and $3\rho_N^1$, respectively. The numbers of synonymous and nonsynonymous substitutions per site are then $d_S = t\rho_S^*/(3\rho_S^1)$ and $d_N = t\rho_N^*/(3\rho_N^1)$, respectively. Note that $\omega = d_N/d_S = (\rho_N^*/\rho_S^*)/(\rho_N^1/\rho_S^1)$, where the numerator ρ_N^*/ρ_S^* is the ratio of the numbers of (observed) substitutions while the denominator ρ_N^1/ρ_S^1 is the ratio of the (expected) numbers of substitutions if $\omega = 1$.

Interpretation of d_N and d_S and definitions of a few other distances between two protein-coding genes were given by Yang (2006, Chapter 2). While the basic concepts discussed in the hypothetical example underlie both the ML and the counting methods for estimating d_N and d_S (and their ratio ω), differences exist between the two classes of methods. In the ML method, the probability theory (i.e. calculation of the transition probabilities by (12.4)) accomplishes several difficult tasks in one step: estimating mutational parameters such as κ, correcting for multiple hits, and weighting evolutionary pathways between codons. The Chapman–Kolmogorov theorem mentioned above ensures that the likelihood calculation accounts for all possible

pathways of change between two codons, weighting them appropriately according to their relative probabilities of occurrence. When we partition the number of substitutions (t) into synonymous and nonsynonymous categories, we only need to do it at the level of instantaneous rates (12.9 and 12.10), where there are no multiple changes.

In the counting methods, each of the three steps offers a challenge. For example, some methods ignore the transition–transversion rate difference. Others take it into account but it has been difficult to estimate κ reliably. Ina (1995) used the third codon positions and Yang and Nielsen (2000) used so-called four-fold degenerate sites and nondegenerate sites to estimate κ, assuming that substitutions at those sites are either not affected or affected equally by selection at the protein level. Both methods use nucleotide-based correction formulas to estimate κ, which seem problematic. Use of a limited class of sites also leads to large sampling errors in the estimates. The steps of counting differences, weighting pathways, and correcting for multiple hits are extremely complicated when we want to incorporate major features of DNA sequence evolution such as the transition–transversion rate difference and unequal base/codon frequencies (Yang and Nielsen, 2000). Notably, the synonymous and nonsynonymous status of a site changes over time and also with the nucleotides at other positions of the codon (Muse, 1996). As a result, nucleotide-substitution models used in counting methods are not capable of dealing with the complexity of the codon-substitution process.

After d_N and d_S are estimated, statistical tests can be used to test whether d_N is significantly higher than d_S. For the counting methods, a normal approximation is applied to the statistic ($d_N - d_S$). For ML, an LRT can be used, which compares the null model with ω fixed at 1 and the alternative model that does not place this constraint. Twice the log-likelihood difference between the two models is compared with a χ^2 distribution with 1 degree of freedom to test whether ω is different from 1. In practice, such tests rarely detect positive selection, as d_N and d_S are calculated as averages over the entire sequence. Indeed, an interesting use of this LRT is to predict protein-coding potentials of genomic regions, making use of the fact that in almost all genes, d_N is significantly lower than d_S (Nekrutenko *et al.*, 2001).

12.3.3   A Numerical Example and Comparison of Methods

To see the differences among methods for estimating d_N and d_S, we compare the human and mouse acetylcholine receptor α genes, using ML as well as several counting methods (Table 12.1). The data set is the first (alphabetically) of the 49 genes analyzed by Ohta (1995). The sequence has 456 codons (1368 nucleotides) after the start and stop codons are removed. With the ML method, we examine the effects of model assumptions. Some models ignore the transition–transversion rate ratio (with $\kappa = 1$ fixed), while others account for it (with κ estimated). Some ignore biased codon frequencies (Fequal), while others account for it to some extent (F1 × 4, F3 × 4, and F61) (see legend to Table 12.1 for definitions of these models).

Most of these models are nested, and the χ^2 approximation can be used to perform LRTs. For example, we can compare models A and B in Table 12.1 to test whether the transition and transversion rates are equal. Model A is the null hypothesis and assumes

Table 12.1 Estimation of d_N and d_S between the human and mouse acetylcholine receptor α genes.

Model	$\hat{\kappa}$	$\hat{S}$	$\hat{d}_N$	$\hat{d}_S$	$\hat{d}_N/\hat{d}_S(\hat{\omega})$	ℓ
Counting Methods						
Nei and Gojobori (1986)	1	321.2	0.030	0.523	0.058	
Li (1993)	N/A	N/A	0.029	0.419	0.069	
Ina (1995)	6.1	408.4	0.033	0.405	0.081	
YN00 (Yang and Nielsen, 2000)	2.1	311.2	0.029	0.643	0.045	
ML methods						
(A) Fequal, $\kappa = 1$	1	348.5	0.029	0.496	0.059	−2392.83
(B) Fequal, κ estimated	2.8	396.7	0.031	0.421	0.073	−2379.60
(C) F1 × 4, $\kappa = 1$, fixed	1	361.0	0.029	0.513	0.057	−2390.35
(D) F1 × 4, κ estimated	2.9	406.5	0.031	0.436	0.071	−2376.12
(E) F3 × 4, $\kappa = 1$, fixed	1	281.4	0.029	0.650	0.044	−2317.72
(F) F3 × 4, κ estimated	3.0	328.1	0.030	0.545	0.055	−2303.33
(G) F61, $\kappa = 1$, fixed	1	261.5	0.028	0.736	0.038	−2251.92
(H) F61, κ estimated	3.0	319.5	0.030	0.613	0.048	−2239.33

Note: Fequal: equal codon frequencies (=1/61) are assumed; F1 × 4: four nucleotide frequencies are used to calculate codon frequencies (three free parameters); F3 × 4: nucleotide frequencies at three codon positions are used to calculate codon frequencies (nine free parameters); F61: all codon frequencies are used as free parameters (60 free parameters). ℓ is the log-likelihood value. [Data are from Ohta (1995) and Yang and Nielsen (1998).]

that transition and transversion rates are equal ($\kappa = 1$). Model B does not impose this constraint and has one more free parameter (κ) than model A. The likelihood ratio statistic, $2\Delta\ell = 2 \times (-2379.60 - (-2392.83)) = 2 \times 13.23 = 26.46$, should be compared with the χ^2 distribution with df = 1, giving a p value of 0.27×10^{-6}. So there is significant difference between the transition and transversion rates.

For these data, both the transition–transversion rate difference and unequal codon frequencies are clearly important. ML results under the most complex model (F61 with κ estimated), which accounts for both factors, are expected to be the most reliable and will be used to evaluate other methods/models. The F3 × 4 model is commonly used as it produces similar results to, and has far fewer parameters than, the F61 model. We note that counting methods give similar results to ML under similar models; for example, Ina's method gives similar estimates to ML accounting for the transition–transversion rate difference and ignoring biased base/codon frequencies (Table 12.1: MLB, Fequal, with κ estimated).

It is well known that ignoring the transition–transversion rate difference leads to underestimation of the number of synonymous sites (S), overestimation of d_S, and underestimation of the ω ratio. This effect is obvious in Table 12.1, when ML estimates with κ estimated are compared with those when κ is fixed at 1, or when the method of Nei and Gojobori (1986) is compared with those of Li (1993) or Ina (1995). Unequal codon frequencies often have opposite effects to the transition–transversion rate difference and lead to a reduced number of synonymous sites. This is the pattern we see in Table 12.1, as estimates of S under the F3 × 4 and F61 models are much smaller than under the Fequal model. The gene is GC-rich at the third codon position, with base frequencies to be 16 % for T, 43 % for C, 14 % for A, and 27 % for G. As a result, most substitutions

at the third codon position are transversions between C and G, and there are more nonsynonymous sites than expected under equal base/codon frequencies. In this data set, the effect of unequal base frequencies is opposite to and outweighs the effect of the transition–transversion rate difference. As a result, the method of Nei and Gojobori (1986), contrary to general belief, *overestimates*, rather than *underestimates*, S and ω. The method of Ina (1995) accounts for the transition–transversion rate difference but ignores the codon frequency bias, and performs more poorly than the method of Nei and Gojobori (1986). The method of Yang and Nielsen (2000) accounts for both biases, and seems to produce estimates close to ML estimates under realistic models.

In general, different methods can produce either very similar or very different estimates of ω. With very little transition–transversion rate difference and little codon usage bias, different methods tend to produce similar results. For other data sets, estimates from different methods can be three to ten times different (Yang and Nielsen, 2000; Dunn *et al.*, 2001). Such large differences can occur even with highly similar sequences, as extreme transition–transversion rate difference or codon usage bias can drastically affect the counting of sites. One feature of the estimation is that when a method overestimates d_S, it tends to underestimate d_N at the same time, resulting in large errors in the ω ratio. This is because the total number of sites (or differences) is fixed, and if the method underestimates the number of synonymous sites (or differences), it will overestimate the number of nonsynonymous sites as well, and vice versa.

Simulation studies performed to compare different methods produced results that are consistent with real-data analysis. For example, Ina (1995) compared several counting methods and concluded that none of them performed well when base frequencies were extreme. Yang and Nielsen (2000) examined the effects of the transition–transversion rate difference and unequal base/codon frequencies, and found that estimation of the ω ratio is very sensitive to both factors. A worrying result is that the method of Nei and Gojobori (1986) can both underestimate and overestimate the ω ratio, often with large biases. In general, counting methods may be used for exploratory data analysis, and the ML method accounting for both the transition–transversion rate difference and the codon usage bias should be preferred.

12.4   LIKELIHOOD CALCULATION ON A PHYLOGENY

Likelihood calculation for multiple sequences on a phylogeny may be viewed as an extension of the calculation for two sequences. The calculation is also similar to that under a nucleotide-substitution model (Felsenstein, 1981), although we now consider a codon rather than a nucleotide as the unit of evolution. We assume in this section that the same rate matrix Q (12.1) applies to all lineages and all amino acid sites. The data are multiple aligned sequences. We assume independent substitutions among sites (codons), so that data at different codon sites are independently and identically distributed. The likelihood is given by the multinomial distribution with 61^s categories (site patterns) for s species. Let n be the number of sites (codons) in the sequence and the data at site h be $\mathbf{x}_h (h = 1, 2, \ldots, n)$; x_h is a vector of observed codons in different sequences at site h. An
Figure 12.3 A tree of four sequences with codons at one site for nodes in the tree. Branch lengths t_0-t_4 are parameters in the model.

example tree of four species is shown in Figure 12.3. As in the case of two sequences, the root cannot be identified, and is arbitrarily fixed at the node ancestral to sequences 1 and 2. The data $\mathbf{x}_h$ can be generated by any codons j and k for the two ancestral nodes in the tree, and thus the probability of observing the data is a sum over all such possibilities.

$$f(\mathbf{x}_h) = \sum_j \sum_k [\pi_j p_{jx_1}(t_1) p_{jx_2}(t_2) p_{jk}(t_0) p_{kx_3}(t_3) p_{kx_4}(t_4)]. \tag{12.11}$$

The quantity in the square bracket is the contribution to $f(\mathbf{x}_h)$ from ancestral codons j and k, and is equal to the prior probability that the codon at the root is j, which is given by the equilibrium frequency π_j, multiplied by the five transition probabilities along the five branches of the phylogeny (Figure 12.3). For a tree of s species with $(s-2)$ ancestral nodes, the data at each site will be a sum over 61^{s-2} possible combinations of ancestral codons. In computer programs, we use the 'pruning' algorithm of Felsenstein (1981) to achieve efficient computation.

The log likelihood is a sum over all sites in the sequence.

$$\ell = \sum_{h=1}^n \log\{f(\mathbf{x}_h)\}. \tag{12.12}$$

Compared with the case of two sequences, we now have the same parameters in the substitution model (κ, ω, and the π_j's), but many more branch length parameters (e.g. $t_0, t_1, \ldots, t_4$ in Figure 12.3 instead of the single t in Figure 12.1b). Again, numerical optimization algorithms have to be used to maximize the likelihood function.

As mentioned above, the quantity in the square bracket in (12.11) is the contribution to the probability of the data $f(\mathbf{x}_h)$ by ancestral codons j and k. This contribution varies greatly depending on j and k, and the codons j and k that make the greatest contribution are the most probable codons for the two ancestral nodes at the site. This gives the empirical Bayes approach (also known as the likelihood approach) to reconstructing ancestral character states (Yang *et al.*, 1995; Koshi and Goldstein, 1996). Compared with the parsimony reconstruction (Fitch, 1971; Hartigan, 1973), the Bayes approach uses branch lengths and relative substitution rates between character states. Intuitive methods that use reconstructed ancestral sequences to detect adaptive molecular evolution will be discussed later in comparison with the ML method.

12.5   DETECTING ADAPTIVE EVOLUTION ALONG LINEAGES

12.5.1   Likelihood Calculation under Models of Variable ω Ratios among Lineages

It is easy to modify the model of the previous section to allow for different ω ratios among branches on a tree. The likelihood calculation under such a model proceeds in a similar way, except that the transition probabilities for different branches need to be calculated from different rate matrices (Qs) generated using different ωs. Suppose we want to fit a model in which the branch for species 1 of Figure 12.4 has a different ω ratio (ω_1), while all other branches have the same 'background' ratio (ω_0). Let $p_{ij}(t; \omega)$ denote the transition probability calculated using the ratio ω. Under this model, the probability of observing data, $\mathbf{x}_h$, is

$$f(\mathbf{x}_h) = \sum_j \sum_k \pi_j p_{jx_1}(t_1; \omega_1) p_{jx_2}(t_2; \omega_0) p_{jk}(t_0; \omega_0) p_{kx_3}(t_3; \omega_0) p_{kx_4}(t_4; \omega_0), \quad (12.13)$$

(compare with (12.11)).

Yang (1998) implemented models that allow for different levels of heterogeneity in the ω ratio among lineages. The simplest model (the 'one-ratio' model) assumes the same ω ratio for all branches in the phylogeny. The most general model (the 'free-ratio' model) assumes an independent ω ratio for each branch in the phylogeny. Intermediate models such as two- or three-ratio models assume two or three different ω ratios for lineages in the tree. These models can be compared using the LRT to examine interesting hypotheses. For example, the likelihood values under the one-ratio and free-ratio models can be compared to test whether the ω ratios are different among lineages. Also, we can let the lineages of interest have a different ω ratio from the background ω ratio for all other lineages in the phylogeny (as in Figure 12.4). Such a two-ratio model can be compared with the one-ratio model to examine whether the lineages of interest have a different ω ratio from other lineages. Furthermore, when the estimated ω ratio for the lineages of interest (say, ω_1 in Figure 12.4) is >1, models with and without the constraint that $\omega_1 = 1$ can be compared to test whether the ratio is different from (i.e. greater than) 1. This test directly examines the possibility of positive selection along specific lineages.
Figure 12.4   A tree of four sequences to explain a model of variable ω ratios among lineages. The ω ratio for the branch leading to species 1 (ω_1) is different from the ratio (ω_0) for all other branches.

It should be pointed out that variation in the ω ratio among lineages is a violation of the strictly neutral model, but is itself not sufficient evidence for adaptive evolution. First, relaxed selective constraints along certain lineages can generate variable ω ratios. Second, if nonsynonymous mutations are slightly deleterious but not lethal, their fixation probabilities will depend on factors such as the population size of the species. In large populations, deleterious mutations will have a smaller chance of getting fixed than in small populations. Under such a model of slightly deleterious mutations (Ohta, 1973), species with large population sizes are expected to have smaller ω ratios than species with small population sizes. At any rate, an ω ratio significantly greater than one provides convincing evidence for Darwinian selection.

12.5.2 Adaptive Evolution in the Primate Lysozyme

In the following, we use the example of the lysozyme c genes of primates (Figure 12.5) to demonstrate the use of codon-substitution models of variable ω ratios among lineages (Yang, 1998). Lysozyme is mainly found in secretions like tears and saliva as well as in white blood cells, where its function is to fight invading bacteria. Leaf-eating colobine monkeys have a complex foregut, where bacteria ferment plant material, followed by a true stomach that expresses high levels of lysozyme, where its new function is to digest these bacteria (Stewart *et al.*, 1987; Messier and Stewart, 1997). It has been suggested that the acquisition of a new function may have led to high selective pressure on the enzyme, resulting in high nonsynonymous substitution rates. In an analysis of lysozyme c genes from 24 primate species, Messier and Stewart (1997) identified two lineages with elevated ω ratios, indicating episodes of adaptive evolution in the lysozyme. One lineage, expected from previous analysis (Stewart *et al.*, 1987), is ancestral to colobine monkeys, and another unsuspected lineage is ancestral to the hominoids. The two lineages are represented by branches h and c in Figure 12.5 for a subset of the data of Messier and Stewart (1997).

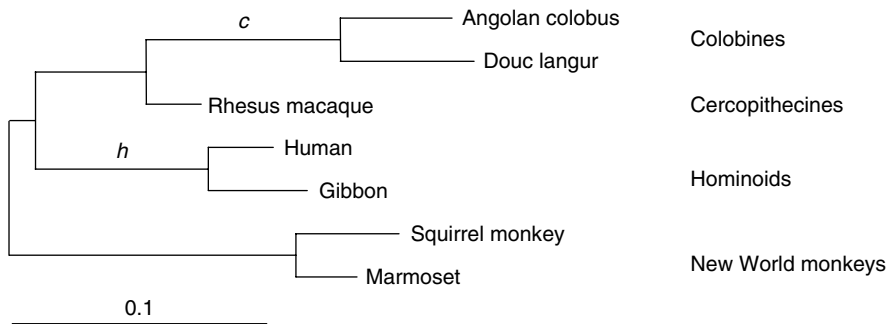
As branches h and c are the lineages of interest, we test assumptions concerning three ω ratio parameters: ω_h for branch h, ω_c for branch c, and ω_0 for all other (background) branches. Table 12.2 lists log-likelihood values and ML parameter estimates under different models. The simplest model assumes one ω ratio (Table 12.2, A) while the most general model assumes three ratios (E, I, and J). The six possible two-ratio models


Figure 12.5 Phylogeny of seven primate species, for a subset of the lysozyme data of Messier and Stewart (1997) used to demonstrate models of variable ω ratios among branches. The analysis uses the unrooted tree, but the root is shown here for clarity. After Yang (1998).

Table 12.2 Log-likelihood values and parameter estimates under different models for the lysozyme c genes.

Model	p	ℓ	$\hat{\kappa}$	$\hat{\omega}_0$	$\hat{\omega}_h$	$\hat{\omega}_c$
A. 1 ratio: $\omega_0 = \omega_h = \omega_c$	22	-906.02	4.5	0.81	$= \hat{\omega}_0$	$= \hat{\omega}_0$
B. 2 ratios: $\omega_0 = \omega_h, \omega_c$	23	-904.64	4.6	0.69	$= \hat{\omega}_0$	3.51
C. 2 ratios: $\omega_0 = \omega_c, \omega_h$	23	-903.08	4.6	0.68	∞	$= \hat{\omega}_0$
D. 2 ratios: $\omega_0, \omega_h = \omega_c$	23	-901.63	4.6	0.54	7.26	$= \hat{\omega}_H$
E. 3 ratios: $\omega_0, \omega_h, \omega_c$	24	-901.10	4.6	0.54	∞	3.65
F. 2 ratios: $\omega_0 = \omega_h, \omega_c = 1$	22	-905.48	4.4	0.69	$= \hat{\omega}_0$	1
G. 2 ratios: $\omega_0 = \omega_c, \omega_h = 1$	22	-905.38	4.4	0.68	1	$= \hat{\omega}_0$
H. 2 ratios: $\omega_0, \omega_h = \omega_c = 1$	22	-904.36	4.3	0.54	1	1
I. 3 ratios: $\omega_0, \omega_h, \omega_c = 1$	23	-902.02	4.5	0.54	∞	1
J. 3 ratios: $\omega_0, \omega_h = 1, \omega_c$	23	-903.48	4.4	0.54	1	3.56

Note: p is the number of parameters. All models include the following 21 common parameters: 11 branch lengths in the tree (Figure 12.5), nine parameters for base frequencies at codon positions used to calculate codon frequencies, and the transition–transversion rate ratio κ.
Source: Yang (1998).

(B−D and F−H) are used as well. In models F-J, the ω ratio for the branch(es) of interest is fixed at 1.

Estimate of the ω ratio under the one-ratio model ($\omega_0 = \omega_h = \omega_c$) is 0.81, indicating that, on average, purifying selection dominates the evolution of the lysozyme. Estimates of ω_c for branch c range from 3.4 to 3.6 when ω_c is allowed free to vary (models B, E, and J in Table 12.2). Estimates of ω_h are always infinite when ω_h is assumed to be a free parameter (models C, E, and I), indicating the absence of synonymous substitutions along branch h. Estimate of the background ratio ω_0 is 0.54, when ω_h and ω_c are not constrained to be equal to ω_0 (models D, E, I, and J).

Results of LRTs are shown in Table 12.3. Tests A−E examine whether the ω ratio for the branch(es) of interest is different from (i.e. greater than) the background ratio, while tests A'−E' examine whether the ratio is greater than 1. For example, test E compares models B and E of Table 12.2 and examines the null hypothesis that $\omega_h = \omega_0$, with ω_c free to vary in both models; ω_h is significantly higher than ω_0 in this comparison. Such tests suggest that ω_h is significantly greater than the background ratio ω_0 ($P < 1\%$; Table 12.3, D and E) and also significantly greater than 1 ($P < 5\%$; Table 12.3, D' and E'). Similar tests suggest that ω_c is significantly greater than ω_0 ($P < 5\%$; Table 12.3, C), but not significantly greater than 1 (P ranges from 17–20 %; Table 12.3, B' and C'). More detailed analyses of the data set can be found in Yang (1998).

12.5.3 Comparison with Methods Based on Reconstructed Ancestral Sequences

Evolutionary biology has had a long tradition of reconstructing characters in extinct ancestral species and using them as observed data in all sorts of analyses. For molecular data, statistical methods (Yang *et al.*, 1995; Koshi and Goldstein, 1996) can be used to obtain more reliable ancestral reconstructions, taking into account branch lengths and relative substitution rates between characters (nucleotides, amino acids, or codons) (see the discussion below (12.12)). Overall, reconstructed molecular sequences appear much

Table 12.3 Likelihood ratio statistics ($2\Delta\ell$) for testing hypotheses concerning lysozyme evolution.

Hypothesis tested	Assumption made	Models compared	$2\Delta\ell$

more reliable than reconstructed morphological characters (Yang *et al.*, 1995; Cunningham *et al.*, 1998).

Messier and Stewart (1997) reconstructed ancestral sequences and used them to perform pairwise comparisons to calculate d_N and d_S along branches in the tree. Their analysis pinpointed two particular lineages in the primate phylogeny that may have gone through adaptive evolution. Crandall and Hillis (1997) took the same approach in an analysis of relaxed selective constraints in the rhodopsin genes of eyeless crayfishes living deep under the ground. Zhang *et al.* (1997) argue that the normal approximation to the statistic $d_N - d_S$ may not be reliable due to small sample sizes. These authors instead applied Fisher's exact test to the counts of differences between the two sequences, ignoring multiple hits at the same site.

A major difference between the ML method discussed in this section and the heuristic approaches using ancestral reconstruction is that ML uses all possible ancestral characters (such as codons j and k for the two ancestral nodes in the tree of Figures 12.3 and 12.4), while the approach of ancestral reconstruction uses only the most likely codons and ignores the others. Ancestral sequences reconstructed by both parsimony and likelihood involve random errors, as indicated by the calculated posterior probabilities (Yang *et al.*, 1995). Using the optimal reconstruction and ignoring the sub-optimal ones may cause a systematic bias. One kind of such bias is obvious if we use reconstructed ancestral sequences to estimate branch lengths, as both parsimony and likelihood tend to minimize the amount of evolution to select the most likely ancestral characters. Biases involved in estimation of d_N and d_S using reconstructed ancestral sequences are more complex. They can be reduced by considering sub-optimal as well as optimal reconstructions, but such modifications have not been attempted. Furthermore, pairwise comparisons along branches of the phylogeny may not be as reliable as a simultaneous comparison of all sequences by ML.

It appears advisable that ancestral reconstruction should be used for exploratory data analysis and ML be used for more rigorous tests. When the LRT suggests adaptive evolution along certain lineages, ancestral reconstruction may be very useful to pinpoint the

responsible amino acid changes. Indeed, an interesting use of ancestral reconstruction is to provide ancestral proteins to be synthesized in the lab to examine its biochemical and physiological properties. Such studies of 'paleobiochemistry' were envisaged by Pauling and Zuckerkandl (1963) several decades ago; see Golding and Dean (1998) and Chang and Donoghue (2000) for reviews.

12.6 INFERRING AMINO ACID SITES UNDER POSITIVE SELECTION

12.6.1 Likelihood Ratio Test under Models of Variable ω Ratios among Sites

Till now, we have assumed that all amino acid sites in a protein are under the same selective pressure, with the same underlying nonsynonymous/synonymous rate ratio (ω). While the synonymous rate may be homogeneous among sites, it is well known that nonsynonymous rates are highly variable. Most proteins have highly conserved amino acid positions at which the underlying ω ratio is close to 0. The requirement that the ω ratio, averaged over all sites in the protein, is greater than 1 is thus a very stringent criterion for detecting adaptive evolution. It would be much more realistic if we allow the ω ratio to vary among sites.

We can envisage two cases, which require different statistical modeling. In the first case, we may know the different structural and functional domains of the protein, and can use such information to classify amino acid sites in the protein into several classes. The different site classes are assumed to have different ω ratios, which are parameters to be estimated by ML. Suppose we have K site classes, with the corresponding ω ratios to be $\omega_1, \omega_2, \ldots, \omega_K$. The likelihood calculation under this model is rather similar to that under the model of one ω ratio for all sites (12.11 and 12.12), except that the corresponding ω ratio will be used to calculate the transition probabilities for data at each site. For example, if site h is from site class $k(k = 1, 2, \ldots, K)$ with the ratio ω_k, then $f(\mathbf{x}_h)$ of (12.11) will be calculated using ω_k. The likelihood is again given by (12.12). A few such models were implemented by Yang and Swanson (2002) and applied to MHC class I alleles in which structural information was used to identify amino acids at the antigen-recognition site. The models were termed 'fixed-sites' models.

In the second case, we assume that there are several heterogeneous site classes with different ω ratios, but we do not know which class each amino acid site belongs to. Such models were termed 'random-sites' models by Yang and Swanson (2002) and will be the focus of discussion here. They use a statistical distribution to account for the random variation of ω among sites (Nielsen and Yang, 1998). We assume that the synonymous rate is constant among sites, and allow only the nonsynonymous rate to be variable, although the same approach can be taken to deal with synonymous rate variation (Kosakovsky Pond and Muse, 2005). Branch length t is defined as the expected number of nucleotide substitutions per codon, averaged over sites. Suppose amino acid sites fall into a fixed number of K classes, with the proportions $p_0, p_1, \ldots, p_{K-1}$, and ω ratios $\omega_0, \omega_1, \ldots, \omega_{K-1}$ treated either as parameters or as functions of parameters in the ω distribution. To calculate the likelihood, we need to calculate the probability of observing data at each site, say data $\mathbf{x}_h$ at site h. The conditional probability of the data, given

ω_κ, $f(\mathbf{x}_h|\omega_k)$, can be calculated as described before (12.11). Since we do not know which class site h belongs to, we sum over all site classes (i.e. over the distribution of ω):

$$f(\mathbf{x}_h) = \sum_{k=1}^{K} p_k f(\mathbf{x}_h|\omega_k). \tag{12.14}$$

The log likelihood is a sum over all n sites in the sequence,

$$\ell = \sum_{h=1}^{n} \log\{f(\mathbf{x}_h)\}. \tag{12.15}$$

Parameters in the model include branch lengths in the tree, κ, π_j's, and parameters in the distribution of ω among sites. As before, we estimate the codon frequency parameters by the observed frequencies, and estimate the other parameters by numerical optimization of the likelihood.

A number of statistical distributions have been implemented by Nielsen and Yang (1998) and Yang *et al.* (2000). Positive selection is tested using an LRT comparing a null model that does not allow $\omega > 1$ with an alternative model that does. Computer simulations have revealed two tests to be particularly effective (Anisimova *et al.*, 2001; 2002; Wong *et al.*, 2004). The first compares the null model M1a (neutral), which assumes two site classes in proportions p_0 and $p_1 = 1 - p_0$ with $0 < \omega_0 < 1$ and $\omega_1 = 1$, and the alternative model M2a (selection), which adds a proportion p_2 of sites with $\omega_2 > 1$. M1a and M2a are slight modifications of models M1 and M2 in Nielsen and Yang (1998), which had $\omega_0 = 0$ fixed and were found to be highly unrealistic for most data sets. As M2a has two more parameters than M1a, the χ_2^2 distribution may be used for the test. However, the regularity conditions for the asymptotic χ^2 approximation are not met, as M1a is equivalent to M2a by fixing $p_2 = 0$, which is at the boundary of the parameter space, and as ω_2 is not identifiable when $p_2 = 0$. The use of χ_2^2 is expected to be conservative. The second test compares the null model M7 (beta), which assumes a beta distribution for ω, and the alternative model M8 (beta & ω), which adds an extra site class of positive selection with $\omega_s > 1$. The beta distribution, beta(p, q), can take a variety of shapes depending on its parameters p and q, such as L-, inverted L-, U-, and inverted U-shapes, but is restricted to the interval (0, 1). It is thus a flexible null model. M8 has two more parameters than M7, so that χ_2^2 may be used to conduct the LRT. As in the comparison between M1a and M2a, use of χ_2^2 is expected to make the test conservative.

Another model, called M3 (discrete), is sometimes useful as well. This assumes a general discrete model, with the frequencies and the ω ratios (p_k and ω_k in (12.14)) for K site classes estimated as free parameters. All models discussed here may be considered special cases of this general mixture model. As is typical in such models, often only a few classes can be fitted to real-data sets. Model M3 may be compared with model M0 (one-ratio) to construct an LRT to test whether the selective pressure varies among sites.

After ML estimates of model parameters are obtained, we can use the empirical Bayes approach to infer the most likely site class (and thus the ω ratio) for any site. The marginal probability of the data $f(\mathbf{x})$ (12.15) is a sum of contributions from each site class k, and the site class that makes the greatest contribution is the most likely class for the site, that

is, the posterior probability that a site with data $\mathbf{x}_h$ is from site class k (with rate ratio ω_k) is

$$f(\omega_k|\mathbf{x}_h) = \frac{p_k f(\mathbf{x}_h|\omega_k)}{f(\mathbf{x}_h)} = \frac{p_k f(\mathbf{x}_h|\omega_k)}{\sum_j p_j f(\mathbf{x}_h|\omega_j)}, \qquad (12.16)$$

(Nielsen and Yang, 1998). When the ω estimates for some site classes are greater than 1, this approach can be used to identify sites from such classes, which are potential targets of positive selection. The posterior probability provides a measure of accuracy. This is known as the *naïve empirical Bayes approach (NEB)* (Nielsen and Yang, 1998). A serious drawback with this approach is that it uses the maximum likelihood estimations (MLEs) of parameters as fixed constants in (12.16), ignoring their sampling errors. This may be a sensible approach in large or medium-sized data sets. However, in small data sets, the information content may be low and the parameter estimates may involve large sampling errors. This deficiency appears to be the major reason for the poor performance of the procedure in small data sets in several simulation studies (e.g. Anisimova *et al.*, 2002; Wong *et al.*, 2004; Massingham and Goldman, 2005; Scheffler and Seoighe, 2005). A more reliable approach, known as the *Bayes empirical Bayes* (*BEB*), was implemented by Yang *et al.* (2005). BEB accommodates uncertainties in the MLEs of parameters in the ω distribution by integrating numerically over a prior for the parameters. Other parameters such as branch lengths are fixed at their MLEs, as these are expected to have much less effect on inference concerning ω. A hierarchical (full) Bayesian approach is implemented by Huelsenbeck and Dyer (2004), using markov chain monte carlo (MCMC) to average over tree topologies, branch lengths, as well as other substitution parameters in the model. This approach involves more computation but may produce more reliable inference in small uninformative data sets, where the MLEs of branch lengths may involve large sampling errors (Scheffler and Seoighe, 2005).

12.6.2 Methods That Test One Site at a Time

An intuitive approach to examining selective pressure indicated by the ω ratio at individual sites is to reconstruct ancestral sequences and then count synonymous and nonsynonymous changes at each site. Comparison of the observed counts with a 'neutral' expectation may then allow us to decide whether the site is evolving under purifying selection or positive selection. On a large phylogeny, some sites may have accumulated many changes at a single site for this approach to be feasible. Fitch *et al.* (1997) performed such an analysis of the hemagglutinin (HA) gene of human influenza virus type A and considered a site to be under positive selection if it has more nonsynonymous substitutions over the gene than the average. Suzuki and Gojobori (1999) compared the counts with the neutral expectation that $d_S = d_N$ at the site, using the method of Nei and Gojobori (1986) to estimate d_S and d_N. A large number of sequences are needed for the test to have any power, as confirmed in computer simulations (Suzuki and Gojobori, 1999; Wong *et al.*, 2004). Both the approaches of Fitch *et al.* (1997) and Suzuki and Gojobori (1999) used the parsimony algorithm to infer ancestral sequences.

The use of reconstructed ancestral sequences may be a source of concern since the reconstructed sequences are not real observed data. In particular, positively selected sites are often the most variable sites in the alignment, at which ancestral reconstruction is the least reliable. This problem may be avoided by taking a likelihood approach, averaging over all possible ancestral states. Indeed Suzuki (2004), Massingham and Goldman (2005),

and Kosakovsky Pond and Frost (2005) implemented methods to estimate one ω parameter for each site using ML. Other parameters in the model such as branch lengths are usually estimated from the whole data set and fixed when the ω ratio is estimated for each site. Then at every site, an LRT is used to test the null hypothesis, $\omega = 1$. This is called the *site-wise likelihood ratio (SLR) test* by Massingham and Goldman (2005). A problem with those methods is that the number of ω ratios estimated in the model increases without bound with the increase of the sequence length. Likelihood methods often perform poorly under such parameter-rich models. However, in computer simulations Massingham and Goldman (2005) found that the SLR test achieved good false-positive rates and reasonably high power.

The methods discussed above test every site for positive selection, and are similar to the BEB procedure for identifying individual amino acid sites under positive selection (Yang *et al.*, 2005). To test whether the gene is under positive selection (i.e. whether the gene has any codon with $\omega > 1$), a correction for multiple testing should be applied (Wong *et al.*, 2004).

12.6.3   Positive Selection in the HIV-1 *vif* Genes

An example data set of HIV-1 *vif* genes from 29 subtype-B isolates is used here to demonstrate the likelihood models of variable ω ratios among sites. The data set was analyzed by Yang *et al.* (2000). The sequence has 192 codons. Several models are used in ML estimation, with the results shown in Table 12.4. Only parameters involved in the ω distribution are listed, as other parameters (branch lengths in the phylogeny, the transition–transversion rate ratio κ, and the base frequencies at the three codon positions) are common to all models. The model codes are those used in Yang *et al.* (2000) and in the CODEML program in the PAML package (Yang, 1997).

Table 12.4   Likelihood values and parameter estimates under models of variable ω ratios among sites for HIV-1 *vif* genes.

Model code	ℓ	d_N/d_S	Estimates of parameters
M0. one-ratio (1)	-3499.60	0.644	$\hat{\omega} = 0.644$
M1a. neutral (2)	-3393.83	0.438	$\hat{p}_0 = 0.611, \hat{\omega}_0 = 0.080,$ $(\hat{p}_1 = 0.389), (\hat{\omega}_1 = 1)$
M2a. selection (4)	-3367.86	0.689	$\hat{p}_0 = 0.573, \hat{\omega}_0 = 0.090,$ $\hat{p}_1 = 0.346, (\hat{\omega}_1 = 1)$ $(\hat{p}_2 = 0.081), \hat{\omega}_2 = 3.585$
M3. discrete (5)	-3367.16	0.742	$\hat{p}_0 = 0.605, \hat{\omega}_0 = 0.108$ $\hat{p}_1 = 0.325, \hat{\omega}_1 = 1.211$ $(\hat{p}_2 = 0.070), \hat{\omega}_2 = 4.024$
M7. beta (2)	-3400.44	0.440	$\hat{p} = 0.176, \hat{q} = 0.223$
M8. beta & ω (4)	-3370.66	0.687	$\hat{p}_0 = 0.909, \hat{p} = 0.222, \hat{q} = 0.312$ $(\hat{p}_1 = 0.091), \hat{\omega}_s = 3.385$

Note: The number of parameters in the ω distribution is given in parentheses after the model code. d_N/d_S is the average ω over all sites in the gene. Parameters in parentheses are given to ease interpretation but are not free parameters. Estimates of the transition–transversion rate ratio κ range from 3.6 to 4.1 among models.
Source: The data are from Yang *et al.* (2000).

The one-ratio model (M0) assumes one ω ratio for all sites and gives an average ω ratio of 0.644, indicating that on average, purifying selection is the dominating force during the evolution of the gene. The selection model (M2a) suggests that about $\hat{p}_1 = 8.1\%$ of sites are under positive selection with $\hat{\omega}_2 = 3.58$, and it has a significantly higher log-likelihood value than model M1a (neutral), which does not allow for sites under positive selection. The LRT statistic for comparing M1a and M2a is $2\Delta\ell = 2 \times 25.97 = 51.94$, much greater than $\chi^2_{2,1\%} = 9.21$. Similarly estimates under model M8 (beta & ω) suggest that about $\hat{p}_1 = 9.1\%$ of sites are under positive selection with $\hat{\omega}_s = 3.385$. M8 fits the data much better than M7 (β), which does not allow for sites with $\omega > 1$. Thus, the two LRTs, which compare M1a with M2a and M7 with M8, provide significant evidence for the presence of sites in the gene under positive selection.

The discrete model (M3) suggests that about $\hat{p}_2 = 7.0\%$ of sites are under strong positive selection with $\hat{\omega}_2 = 4.0$, while a large proportion ($\hat{p}_1 = 33\%$) of sites are under weak positive selection or are nearly neutral with $\hat{\omega}_1 = 1.2$.

Figure 12.6 plots the posterior probabilities for site classes at each site under model M2a (selection), calculated using the NEB approach (12.16). Parameter estimates under M2a suggest that the three site classes have the ω ratios 0.090, 1, and 3.585 and are in proportions 57.3, 34.6, and 8.1% (Table 12.4). These proportions are the prior probabilities for site classes at every site. The observed data at the site alter these prior probabilities considerably, so that the posterior probabilities are very different from the prior. For example, the posterior probabilities for site 1 are 0.986, 0.014, and 0.000, and this site is almost certainly under purifying selection. In contrast, the probabilities at site 31 are 0.000, 0.012, and 0.988, and this site is most likely to be under strong diversifying selection (Figure 12.6).

The above calculation used the NEB procedure (12.16), which treats the estimates of the proportions and ω ratios as true values. NEB is used here as it is simple to explain. In real-data analysis, the BEB procedure should be used instead, which takes into account estimation errors in those parameters. The HIV *vif* data set is relatively large, so that the two procedures produced very similar results. For example, at the 99% cutoff, both methods identified three sites to be under positive selection: 39 F, 127 Y, and 167 K (the amino acids are from the reference sequence B_SF2). At the 95% cutoff, BEB identified five additional sites: 31 I, 33 K, 101 G, 109 L, and 122 N, while the NEB list also included 63 K and 92 K.
Figure 12.6 Posterior probabilities of site classes along the gene for the HIV-1 *vif* genes under the site model M2a (selection).

12.7 TESTING POSITIVE SELECTION AFFECTING PARTICULAR SITES AND LINEAGES

12.7.1 Branch-site Test of Positive Selection

A natural extension to the branch- and site-models discussed above is the *branch-site models*, which allow the ω ratio to vary both among sites and among lineages (Yang and Nielsen, 2002). Such models attempt to detect signals of local episodic natural selection (Gillespie, 1991), which affects only a few sites along particular lineages. In the models of Yang and Nielsen (2002), branches in the tree are divided *a priori* into foreground and background categories, and an LRT is constructed to compare an alternative hypothesis that allows for some sites under positive selection on the foreground branches with a null hypothesis that does not. However, computer simulations conducted by Zhang (2004) suggest that the resulting tests can produce excessive false positives when the model assumptions are violated, and in general, the tests were unable to distinguish positive selection from relaxed selective constraint along the foreground branches. Later, the branch-site models were modified, and the tests constructed using the modified models were found to be much more robust and appeared to produce reliable inference (Yang *et al.*, 2005; Zhang *et al.*, 2005).

The modified model, known as branch-site model A, is summarized in Table 12.5. Along the background lineages, there are two classes of sites: the conserved sites with $0 < \omega_0 < 1$ and the neutral sites with $\omega_1 = 1$. Along the foreground lineages, a proportion $(1 - p_0 - p_1)$ of sites come under positive selection with $\omega_2 \geq 1$. Likelihood calculation under this model is very similar to that under the site models (12.14). As we do not know *a priori* which site class each site is from, the probability of data at a site is an average over the four site classes. Let $I_h = 0, 1, 2a, 2b$ be the site class that site h is from. We have

$$f(\mathbf{x}_h) = \sum_{I_h} p_k f(\mathbf{x}_h | I_h). \tag{12.17}$$

The conditional probability $f(\mathbf{x}_h | I_h)$ of observing data $\mathbf{x}_h$ at site h, given that the site comes from site class I_h, is easy to calculate, because the site evolves under the one-ratio model if $I_h = 0$ or 1, and under the branch model if $I_h = 2a$ or 2b.

To construct an LRT, we use model A as the alternative hypothesis, while the null hypothesis is the same model A but with $\omega_2 = 1$ fixed (Table 12.5). This is known as the *branch-site test of positive selection*. The null hypothesis has one fewer parameter, but since $\omega_2 = 1$ is fixed at the boundary of the parameter space of the alternative hypothesis, the null distribution should be a 50 : 50 mixture of point mass 0 and χ_1^2 (Self and Liang,

Table 12.5 The ω ratios assumed in branch-site model A.

Site class	Proportion	Background ω	Foreground ω
0	p_0	$0 < \omega_0 < 1$	$0 < \omega_0 < 1$
1	p_1	$\omega_1 = 1$	$\omega_1 = 1$
2a	$(1 - p_0 - p_1)p_0/(p_0 + p_1)$	$0 < \omega_0 < 1$	$\omega_2 > 1$
2b	$(1 - p_0 - p_1)p_1/(p_0 + p_1)$	$\omega_1 = 1$	$\omega_2 > 1$

Note: The model involves four parameters: $p_0, p_1, \omega_0, \omega_2$.

1987). The critical values are 2.71 and 5.41 at the 5 and 1 % levels, respectively. One may also use χ_1^2 (with critical values 3.84 at 5 % and 5.99 at 1 %) to guide against violations of model assumptions.

As in the site-based analysis, the BEB approach can be used to calculate the posterior probability that a site is from site classes 2a and 2b, allowing identification of amino acid sites potentially under positive selection along the foreground lineages (Yang *et al.*, 2005).

Similar to the branch test, the branch-site test requires the foreground branches to be specified *a priori*. This may be easy if a well-formulated biological hypothesis exists, for example, if we want to test adaptive evolution driving functional divergences after gene duplication. The test may be difficult to apply if no *a priori* hypothesis is available. To apply the test to several or all branches on the tree, one has to correct for multiple testing. Several correction procedures have been suggested in the statistics literature. The simplest is the Bonferroni correction (Miller, 1981, pp. 67–70), by which one uses α/m as the significance level to test every hypotheses when m hypotheses (branches) are being tested.

12.7.2 Similar Models

Several other models of codon substitution also allow the ω ratio to vary both among lineages and among sites. Forsberg and Christiansen (2003) and Bielawski and Yang (2004) implemented the *clade* models. Branches on the phylogeny are *a priori* divided into two clades, and an LRT is used to test for divergences in selective pressure between the two clades indicated by different ω ratios. There may not be any sites under positive selection with $\omega > 1$. Clade model C, implemented by Bielawski and Yang (2004) is summarized in Table 12.6. This assumes three site classes. Class 0 includes conserved sites with $0 < \omega_0 < 1$, while class 1 includes neutral sites with $\omega_1 = 1$; both apply to all lineages. Class 2 includes sites that are under different selective pressures in the two clades, with ω_2 for clade 1 and ω_3 for clade 2. The model involves five parameters in the ω distribution: $p_0, p_1, \omega_0, \omega_2,$ and ω_3. An LRT can be constructed by comparing model C with the site model M1a (neutral), which assumes two site classes with two free parameters: p_0 and ω_0 (see Section 12.6). The χ_3^2 distribution may be used for the test. The clade models follow on the ideas of Gu (2001) and Knudsen and Miyamoto (2001), who used amino acid substitution rates to indicate functional constraint.

A *switching model* was implemented by Guindon *et al.* (2004), which allows the ω ratio at any site to switch among three different values: $\omega_1 < \omega_2 < \omega_3$. Besides the Markov process that describe substitutions between codons, a hidden Markov chain runs over time and describes the switches of any site between different selective regimes (i.e. the three ω values). The model has the same structure as the covarion model of Tuffley and Steel (1998) (see also Galtier, 2001; Huelsenbeck, 2002), which allows the substitution

Table 12.6   The ω ratios assumed in clade model C.

Site class	Proportion	Clade 1	Clade 2
0	p_0	$0 < \omega_0 < 1$	$0 < \omega_0 < 1$
1	p_1	$\omega_1 = 1$	$\omega_1 = 1$
2	$p_2 = 1 - p_0 - p_1$	ω_2	ω_3

Note: The model involves five parameters: $p_0, p_1, \omega_0, \omega_2, \omega_3$.

rate for any site to switch between high and low values. The switching model is an extension of the site model M3 (discrete) discussed above, under which the ω ratio is fixed at every site. An LRT can thus be used to compare them. Guindon *et al.* (2004) found that the switching model fitted a data set of the HIV-1 *env* genes much better than the site models. An empirical Bayes procedure can be used to identify lineages and sites with high ω ratios, and it appears necessary to apply a correction for multiple testing.

12.8   LIMITATIONS OF CURRENT METHODS

Both the test of positive selection along lineages and the test of positive selection at amino acid sites discussed in this chapter are conservative. When we are testing for lineages under positive selection, we assume that the ω ratio is identical across sites. Positive selection is detected along a lineage only if the ω ratio averaged over all sites is significantly greater than 1. Since many or most sites in a protein are under purifying selection with the underlying ω ratios close to 0, this procedure constitutes a very conservative test of positive selection. Similarly, the LRT for detecting positively selected sites is based on the assumption that the ω ratio is identical among all lineages on the tree. Positive selection is detected for a site only if the underlying ω ratio averaged over all lineages is greater than 1. This assumption appears unrealistic except for genes under recurrent diversifying selection; for most genes, positive selection probably affects only a few lineages.

The branch-site and switching models (Yang and Nielsen, 2002; Guindon *et al.*, 2004; Yang *et al.*, 2005; Zhang *et al.*, 2005) allow the ω ratio to vary both among lineages and among sites and appear to have more power to detect positive selection. Nevertheless, these models are new, and more testing is needed before we know how robust they are. At some stage we will have to compromise. On one hand, we want to focus on a short time period and a few amino acid sites so that the signal of adaptive evolution will not be overwhelmed by purifying selection. On the other hand, a short time period and a few amino acid sites may not offer enough opportunities for evolutionary changes to accumulate to generate a signal that is detectable by statistical tests.

The models discussed here assume the same ω ratio for any amino acid changes; at a positively selected site, changes to any amino acid are assumed to be advantageous. This assumption is unrealistic and appears to make the test conservative. Some authors distinguish between radical and conservative amino acid replacements (i.e. between amino acids with very different and very similar chemical properties, respectively), and suggest that a higher radical than conservative rate is evidence for positive selection (Hughes *et al.*, 1990; Rand *et al.*, 2000; Zhang, 2000). However, this criterion is less convincing than the simple ω ratio and is found to be sensitive to assumptions about transition and transversion rate differences and unequal amino acid compositions (Dagan *et al.*, 2002).

The tests discussed here identify only positive selection that increases the nonsynonymous rates, and may have little power in detecting other types of selection such as balancing selection (Yang *et al.*, 2000). Furthermore, they require a moderate amount of sequence divergence to operate and tend to lack power in population data. They may be useful for species data or fast-evolving viral genes only.

12.9   COMPUTER SOFTWARE

A number of counting methods to estimate d_N and d_S between two sequences, such as those of Nei and Gojobori (1986), Li *et al.* (1985), Li (1993), and Pamilo and Bianchi (1993) have been implemented in MEGA3 (Kumar *et al.*, 2005). These and the likelihood method for estimating d_N and d_S (Goldman and Yang, 1994) have been implemented in the CODEML program in the PAML package (Yang, 1997). The latter program also implements the ML models discussed in this chapter.

Genome Evolution

J.F.Y. Brookfield

Institute of Genetics, School of Biology, University of Nottingham, Nottingham, UK

Our understanding of the forces that have shaped the evolution of genome organisation is still largely rudimentary. The process of genome evolution is, in some ways, different in kind from those more typically studied by population and evolutionary geneticists. Firstly, forces of selection that operate at levels different from the individual may be important, as in the spread of selfish intragenomic parasites and in the impact of changes in genome organisation on the ability of lineages to proliferate and diversify. Secondly, alternative genotypes are often not allelic, such that the process of evolutionary change is not necessarily ended by the spread to fixation of a new genetic type. However, some progress can be made in understanding genome evolution. A number of the most controversial issues in genome evolution, such as the evolution of codon bias, the antiquity of introns and the selfishness of mobile DNAs, are reviewed. In addition, the evolutionary forces affecting gene number, linkage between genes, gene expression and the functional overlap between gene products are considered.

13.1 INTRODUCTION

Evolutionary processes involve mutation, recombination, migration, selection and genetic drift. These forces are typically thought sufficient to explain evolutionary change. Examples of the success of this microevolutionary, population genetics approach to evolutionary explanation include the many cases in which new advantageous alleles have arisen by mutation and spread in populations subjected to new environmental pressures. Indeed, it has become a byword for evolutionary explanation that, in order to explain a feature of an organism, we have to show a way in which, in a polymorphic population, a gene causing the feature would be expected to spread at the expense of its allele. The classic case of the spread of the *carbonaria* form of the peppered moth, *Biston betularia* – notwithstanding doubts about the evidential strength of the story (Majerus, 1998) – provides a case in point. Here the *carbonaria* allele spreads at the expense of the pale allele in conditions of darkened tree trunks, hypothetically as a result of its increased crypsis (Kettlewell, 1955).

This paradigm of evolutionary explanation cannot realistically be applied to some issues of genome structure, which are dealt with in this chapter. There are three reasons. The first is that the levels of comparisons are different. We cannot discuss a situation in which the presence or absence of introns in genes, for example, can be fully explained by a microevolutionary process in which two alternative types of organisms exist, one with introns in all its genes and the ability to process these from the transcripts, and another competing type in which no introns are present. In long-term evolutionary processes such as this, we still need to consider the mechanisms that may cause loss or gain of introns at the mutational level and the microevolutionary forces acting, which allow new variants to spread in the populations in which they first arise. In addition, however, we need to discuss whether the groups of organisms which possess introns will, in the longer term, have a greater ability to evolve to exploit new niches and opportunities. Selection, in other words, is partially operating at the species level, or, indeed, at higher levels. This means that we have to invoke selective forces operating over the longer timescale, involving the ability of species to proliferate in numbers and diversify into successful families, orders, classes and phyla.

The second concept that is different from our paradigm of microevolution, is that in the ordinary explanations of molecular evolutionary change we tend to imagine changes in which a new mutation arises that may then spread, by genetic drift or by selection, to fixation. Fixation signifies the end of the evolutionary process with respect to that particular mutation. Molecular evolutionary change, therefore, only requires a combination of a rate of mutation and probabilities of fixation of individual mutations.

For some aspects of genomic evolution, however, the concept of fixation, which itself follows from the concept of allelism, does not apply. Processes by which the numbers of transposable elements in the genome may be stabilised by a combination of forces involving selection, drift and replicative transposition are discussed later. In these cases, there can be an equilibrium copy number of a transposable element family, even when, as in *Drosophila*, individual transposable element insertions are rarely fixed in populations. So, the spread of a transposable element family may result in an equilibrium state in which few sites are fixed, and in which, indeed, individual transposable element loci are continually being created by transposition, and lost by a combination of deletion, selection and drift.

Similarly, in considering questions such as the determination of the extent of codon usage bias, an equilibrium is envisaged between mutation, selection and drift, in which an equilibrium level of codon bias is maintained despite changes in the nucleotides at individual codons.

This raises a related and more general question, which goes beyond molecular evolution, extending to evolution in general, which is whether organisms can be considered to be at equilibrium with respect to selectively important mutations. In other words, are typical wild populations so well adapted to their environments that virtually no new mutations would improve their fitness and only if the external environment changed would any mutations become selectively advantageous? Alternatively, might wild populations, and their interactions with their environments, typically be such that there are very many adaptive mutations that would be possible, but which have either not arisen or which have, by drift, failed to spread? While the truth must certainly fall somewhere between these two extremes, Li (1997) makes a strong case that the latter situation will be typical in evolution, and that, in this sense, the creation of new advantageous mutations is a limiting factor in evolutionary change. However, in studies of the experimental evolution

of micro-organisms in particular, the rate of morphological evolution in *Escherichia coli* (Mongold and Lenski, 1996), and evolution of patterns of new gene expression in *Saccharomyces cerevisiae* (Farea *et al.*, 1999) when in new environments, implies that very rapid change can arise through advantageous mutations despite the stability of phenotypes in wild populations. Our view on this question influences the way we see many aspects of the interaction between selection and genome variability, such as the likely impacts, through hitch-hiking, of advantageous allelic substitutions.

The third aspect of genome evolution which does not correspond closely to our paradigms of microevolutionary change is particularly relevant to repetitive DNA sequences, and could be summarised as genomic conflicts arising from selfish genetic elements (reviewed in Hurst and Schilthuizen, 1998). These include, e.g. *medea* (maternal effect dominant embryonic arrest) mutations, seen in *Tribolium*, e.g. where heterozygous mothers create eggs, among which only those that contain the *medea* gene itself are viable. Here, if the half of the offspring of a heterozygous mother that inherit the gene benefit from the death of their siblings, from reduced competition or from eating the sibs, a *medea* gene that is initially rare, will spread deterministically (Wade and Beeman, 1994).

More common are selfish transposable elements. Since these typically have a mechanism through which their copy number is increased in the act of transposition, there will be, all else being equal, a rise in the number of elements in the genome from one generation to the next, a rise that appears to be countered by natural selection acting against those individuals who have above-average numbers of copies of the elements. In other words, there is a conflict of interest between the transposable element and the host, and, in this regard, the elements can be regarded as parasites.

This concept of parasitic DNA sequences coexisting with their hosts makes it very unlikely that any stable copy number equilibrium that we see will be stable in the face of mutation. Host mutations which reduce the harmful effects of transposable elements, possibly by reducing copy number, will be favoured, yet transposable element mutations which increase copy number would, in many cases, be expected to spread, even if they reduce host fitness. Thus, any equilibrium that we see will reflect only the genetic properties of the sequences that currently coexist and will be unstable to mutational change. Of course, for parasitic DNAs, as with all parasites, there is strong ascertainment bias, in that we only see selfish DNAs that have succeeded and prevailed despite host efforts to remove them.

13.2   THE STRUCTURE AND FUNCTION OF GENOMES

13.2.1   Genome Sequencing Projects

A feature of the progress in the biological sciences over the last decade has been the availability of whole genome sequences. One very obvious conclusion from genome projects has been that the differences in gene number between organisms are very much less than the differences in DNA content. Thus, among eukaryotes, the largest genomes seen are those of some flowering plants, which exceed 120 000 Mb in size, while the smallest are less than 10 Mb (Brown, 1999). This range in genome size is not matched by gene number, which seems to show little relationship with genome size among eukaryotes. Thus, the estimated gene numbers for *Arabidopsis thaliana* and *Homo sapiens*

are each around 25 000 genes (International Human Genome Sequencing Consortium, 2004; *Arabidopsis* Genome Initiative, 2000), notwithstanding the human genome, at just over 3 Mb (in the haploid) being around 20 times larger than that of *Arabidopsis*. Other animal genome sequencing projects include mouse (*Mus musculus*), rat (*Rattus norvegicus*), chicken (*Gallus gallus*), dog (*Canis familiaris*), zebrafish (*Danio rerio*), two species of pufferfish (*Tetraodon nigroviridis* and *Takifugu rubripes*), chimpanzee (*Pan troglodytes*), rhesus macaque (*Macaca mulatta*), wallaby (*Macropus eugenii*), sea squirt (*Ciona savignyi*), many species of *Drosophila*, the mosquito *Anopheles gambiae*, the beetle *Tribolium castaneum*, the honey bee *Apis mellifera*, the nematode *Caenorhabditis elegans* and the sea urchin *Strongylocentrotus purpuratus* (Gibson and Muse, 2004), while plants also include rice (*Oryza sativa*), maize (*Zea mays*), plus *Populus, Medicago, Sorghum, Lycopersicon, Brassica* and *Solanum* (Paterson, 2006).

More than 300 genomes of unicellular organisms have now been sequenced (TIGR, 2006), and these, in particular, have given rise to the science of comparative genomics. A number of important questions have been addressed by the comparison of prokaryotic genomes, in particular. Firstly, when orthologous genes are found in different sequenced genomes, we can ask what can be said about the relative divergences, and thus rates of evolution, of different genes. Do different types of genes evolve at systematically different rates? Another issue is whether incongruencies in the estimated phylogenetic trees of different genes suggest that horizontal gene transfer has taken place in the evolution of these genomes.

Another very important question is whether the phenotypic and metabolic differences between organisms result from differences in gene contents or differences in the details of the functions of homologous genes. It is tempting to imagine that it is the differences in gene content that underlie phenotypic differences between prokaryotic species, since a catalogue of genes is available as a result of sequencing projects, and genes present in one species but without orthologues in another can easily be identified. If two organisms possess orthologues, the temptation is to assume that these genes are carrying out the same function in the two organisms. By this hypothesis, the changes in amino acid sequence are either neutral or are simply involved in adapting the protein product to the changed physiological and metabolic requirements of a different species, and also perhaps to subtle changes in the amino acid sequences of interacting proteins.

However, often a gene in one species might have two homologues in another, owing to a duplication in the lineage separating the second species from the common ancestor. The two genes in this second species may also have mutant phenotypes that are different from each other. Certainly, as we see later (Section 13.3.5), the maintenance of a gene duplication implies that the two genes have partially non-overlapping functions. One type of explanation is that the function of a gene in the first species is in some way shared between these two genes in the second, a concept referred to as *subfunctionalisation* (Force *et al.*, 1999; Lynch and Force, 2000). The prediction of this model would be that the wild-type allele of the single gene in the first species could simultaneously rescue the mutant phenotypes of both genes in the second. However, another, more radical idea is that the two functions of the genes in the second species are not only different in kind from each other, but also fundamentally different from the role of the gene in the first species. In other words, conservation of sequence should not be regarded as always implying conservation in function (e.g. conserved genes might still clearly encode serine/threonine kinases, yet their targets could differ between species).

13.2.2 The Origins and Functions of Introns

Spliceosomal introns are found in protein-coding genes in the majority of plants, animals and fungi. However, they are absent from the genomes of bacteria, archaea and the most primitive eukaryotes. Intron number is high in vertebrates and plants but lower in the genes of *Drosophila melanogaster* and other invertebrates and introns are almost completely absent from the genes of the yeast *S. cerevisiae*, although *Schizosaccharomyces pombe* has considerably more introns (Jeffares *et al.*, 2006). The debate about the origins and causes of introns is a good illustration of the way in which considerations of the evolution of genome structure depend partly on the advantageous nature of genomic change over the long timescale.

There are two related issues that are important in the study of the evolution of introns. The first is the historical question of when they were introduced into the genomes of organisms (Roy and Gilbert, 2006). The introns-early view (Gilbert, 1987) is that the intron–exon structure seen in the genomes of higher eukaryotes is a relic of the structure of the first genes in the progenote (the first living thing, ancestral to all life today), and what today are exons are the remains of what were shorter ancestral genes in the progenote. The introns-late view suggests that spliceosomal introns are derived from type II bacterial introns and have been being added to eukaryotic genomes, only, throughout their evolution. There is now no doubt that there have been extensive intron gains and losses in eukaryote genes. Rogozin *et al.* (2003), comparing conserved genes from species with fully sequenced genomes, identified many introns conserved between genes from organisms from different kingdoms, while there were very many intron gains and losses also observed. The question, however, remains whether there were any introns present in the progenote – the introns-early view does not require all introns currently seen to be early genomic components, merely that some were. This creates an unsatisfactory situation, in that an introns-early theory in which the proportion of the current introns that are ancient might be very small does not make many very specific predictions about today's intron distribution. One prediction that can be arrived at is that, if ancient introns separate exons that were the original functioning minigenes in the progenote, then ancient exons should correspond to protein domains. In ancient proteins, exons of zero phase, where the intron falls precisely between codons, indeed show the strongest correlation with protein domains (de Souza *et al.*, 1998).

The fundamental problem with the introns-early hypothesis is its requirement that the ancestors of all extant prokaryotic groups would have had to lose all their introns, while the lineage that was to give rise to eukaryotes would have had to retain them. Furthermore, Palmer and Logsdon (1991) noted that, given the then-accepted phylogeny of the early eukaryotes, genomes with introns fall into a rather restricted subgroup of the eukaryotic tree. They suggested that, in order for introns to be present in the progenote, they must have been lost independently in six basal eukaryote taxa, yet maintained in the equally acellular eukaryotes that were our ancestors. However, genome-wide intron loss is a real phenomenon. Parsimony arguments based on intron numbers in other species of fungi indicate that intron losses, in the lineage leading to *S. cerevisiae* in particular, have been extensive. Furthermore, there is evidence that the spliceosomal machinery was ancestrally found in a wider group of eukaryotes than those that now possess introns, and probably in the common ancestor of all extant eukaryotes (Collins and Penny, 2005; Lynch and Richardson, 2002). There is a potential mechanism for intron loss in organisms such as yeast, which contain retrotransposons encoding reverse transcriptase. It is the loss by

gene conversion involving cDNAs as a template. The role of this process as a general mechanism is supported by observations of the simultaneous loss of adjacent introns (Frugoli *et al.*, 1998).

A second issue, conflated with this first, is the mechanistic explanation for the gain and loss of introns, both in terms of the molecular processes creating these changes in the DNA and the population genetics and evolutionary processes determining whether mutated genomes with intron gains or losses proliferate. The mechanism of intron loss by gene conversion by reverse transcribed cDNAs, while elegant in conception, has not been established to be involved in most intron losses. Intron gains, save for the special case of reinsertion of an ancestral intron through gene conversion by a paralogue that has retained it (Hankeln *et al.*, 1997), require an insertion of DNA from a source somewhere else in the genome. The obvious sources are transposable elements and other introns. Coghlan and Wolfe (2004) examined introns gained in *C. elegans* and *C. briggsae* since their split 100 million years ago and showed that the sequences of some of these resembled those of other introns. However, at least one case is known of intron gain by the introduction of a mobile DNA (a short interspersed nuclear element (SINE) element in plants) (Iwamoto *et al.*, 1998). There remains a question whether the rate of DNA sequence evolution of introns is sufficient to explain why introns do not typically have identifiable homologues elsewhere in the genome, notwithstanding the continuing process of intron insertion, which must require a donor element. (Even if this insertion was conservative in the initial creation of the first intron-bearing allele, in that the donor DNA physically moved without replication into the gene to form the intron, recombination during the slow spread of this allele by drift would (unless the intron and its source were tightly physically linked) place it in a genetic background with the donor DNA still present elsewhere in the genome.) The genomic uniqueness of introns means that they cannot typically be derived from currently active families of mobile DNAs. We can thus imagine a model in which, at some time in the past, t million years ago, an intron was inserted into a gene, and the source of that intron and the intron itself have both since evolved in a selectively unconstrained way, with a rate of base substitution of x changes per base per million years. Under this model, the expected base identity between the intron and its source is given (from the simplest Jukes and Cantor (1969) one-parameter model) by Identity $= 0.25 + 0.75e^{-8xt/3}$. Suppose we believe that the identification of the source of a particular intron requires that it shares at least 80 % sequence identity, this predicts, if we use an approximate rate of evolution, x, of 10^{-8} changes per base per million years, that introns inserted in the last 11.65 million years would have their sources identified (provided that the sources themselves had not subsequently been lost from the genome). This would imply that a time-homogeneous process of intron insertion where an intron was inserted somewhere in the genome at least once every 5 million years or so would be likely to result in identifiable sources of recently inserted introns if whole genome sequences are available. In *Caenorhabditis* the rate of intron insertion per genome is estimated to be almost 1–2 per million years (Coghlan and Wolfe, 2002).

What is the mechanism for a new allele with an intron gain or loss to spread through the population? In principle, an allele with a newly inserted intron could be advantageous, neutral or deleterious (possibly weakly so) relative to its progenitor. While arguments for advantageous effects of introns have been suggested (see below) almost none of these have an instantaneously beneficial effect. If so, the implication is that the initial spread of introns must be by genetic drift, which can, in the case of small populations, also

bring about the spread of weakly deleterious alleles. Indeed, Lynch (2006) argues that the smaller effective population sizes of multicellular eukaryotes make introns effectively neutral. He argues that, since genes can be inactivated by mutations in introns, there will be selection against an allele bearing an intron relative to one lacking an intron, but the strength of selection will be dependent on the mutation rate per base, multiplied by the number of bases in the intron where mutational changes create inactivation. The product of these two is likely to be greater than the reciprocal of the large effective population size of unicellular organisms, causing effective selection against intron insertions in these species, while selection of the same strength would be ineffective in the smaller effective population sizes of multicellular organisms, and alleles with inserted additional introns would be able to spread to fixation by genetic drift.

Four types of adaptive functions have been ascribed to introns. The first is that introns play an important role in the process of nonsense-mediated decay. In nonsense-mediated decay, transcripts with premature nonsense (stop) codons are eliminated prior to translation, whether a stop codon is inherited by the organism, is the result of a somatic mutation or represents a transcription error (Maquat, 2004). The effect is a diminution in the amount of truncated and potentially harmful proteins produced. The obvious question is how the cell recognises the difference between these premature stop codons and the codon marking the end of the wild-type polypeptide. Proteins that attach to the junctions between exons being spliced together in the nucleus allow this recognition, with the prediction that introns may play a role in protection against the effects of these premature stop codons (Lynch and Richardson, 2002).

The second advantage for introns is that downstream sequences controlling transcription may evolve in introns, which may be more evolutionary labile than exons, since they will have no constraint arising from a role encoding amino acids, and many examples of intronic enhancers are now known. Thirdly, introns will allow alternative splicing pathways, where functionally different proteins will be produced from the same gene (Xing and Lee, 2006). This has probably been elucidated most clearly in the *D. melanogaster* somatic sex determination pathway, in which a pathway of transcripts from the genes *sex-lethal, transformer, transformer 2* and *doublesex* are alternatively spliced to yield functional female-specific proteins only in a female (XX) cellular environment (Cline, 1993). Finally, introns allow the creation of new genes by exon shuffling. This is where ectopic intronic recombination brings about the creation of hybrid genes combining exons from different sources, which then are spread to fixation by selection or drift. While genes created by exon shuffling were first identified and are most familiar in the vertebrates, they have also been seen in other metazoan groups. They are, however, apparently absent from fungi, plants and protists (Patthy, 1999). Furthermore, many of the genes where exon shuffling may be important are genes that allow animal multicellularity, suggesting that exon shuffling may have played a significant role in its evolution. Note that it is implicit in all these last three adaptive effects of introns that they are long-term advantages, which would require introns to be present in genes long before these advantages could be felt.

A model for the proliferation of introns thus has two components, one of which is the process for the insertion of introns into genes – this insertion process could be seen as a process of selfish spread, with the individual intron insertions being neutral or weakly deleterious (or weakly advantageous as a result of enhancement of nonsense-mediated decay) and with numbers of introns being built up by this mutational pressure. Subsequently, the long-term advantages would give benefit at higher levels of

selection, in which intron-bearing lineages may be able to proliferate and diversify at the expense of intronless competitor lineages. This kind of explanation is, however, still quite unsatisfactory, in that there is no good quantitative theory of selective processes operating at levels higher than the individual.

13.3   THE ORGANISATION OF GENOMES

13.3.1   The Relative Positions of Genes: Are They Adaptive?

Genome projects reveal the relative positions of genes. In prokaryotes, genes are organised into operons, such that non-homologous genes involved in the same metabolic pathway are adjacent and are transcribed into a polycistronic message, as a mechanism for integrating their activities. In eukaryotes, functional clustering of this kind is not seen, and genes involved in a shared metabolic pathway would typically be located on different chromosomes. The overall picture is one in which the positions of genes cannot, by and large, be predicted from their functions (save for a tendency for paralogues to cluster – see Section 13.3.3 below – as a result of the mechanisms for their generation). Are gene positions therefore random? The answer is 'no', and the causes of non-randomness can be seen as a combination of a small contribution from functionality and a larger contribution from the vagaries of evolutionary history.

The most straightforward way to imagine a chromosome is as a segregation device. In this context, linkage between genes is an inevitable consequence of there being more genes than chromosomes. An important issue, therefore, is whether the relative positions of genes on chromosomes have an adaptive significance that follows from the levels of recombination between them.

The fact that patterns of linkage between genes are adaptive has been a major theme in the development of ecological and population genetics. In the Malaysian swallowtail butterfly *Papilio memnon*, the females are mimetic, but are highly polymorphic, and indeed each female morph mimics a different distasteful model butterfly. Clarke and Sheppard (1968; 1969) carried out crosses to find out the pattern of inheritance of the morphs, and found that, at first sight, the complex mimetic patterns were apparently inherited as alleles at a single locus. However, exceptional butterflies were found that combined features of the different mimetic patterns, and seemed to be poor mimics of any of the model species. More detailed crosses revealed that these butterflies showing scrambled mimetic patterns were recombinants. From these experiments, Clarke and Sheppard concluded that at least five tightly linked genes were controlling the variation between mimetic morphs, and that the genes were linked for adaptive reasons, in order to maintain linkage disequilibrium between alleles at the loci, and thereby prevent poor mimics from appearing by segregation. They called such a set of adaptively linked polymorphic loci a *supergene*.

On the basis of these and earlier data, there was considerable discussion of the evolution of supergenes (see, e.g. Ford, 1964). Genes which carried out functionally related tasks, such as the colour and banding loci of *Cepaea nemoralis* (Cain *et al.*, 1960), were hypothesised to physically translocate in the chromosomes, so as to occupy tightly linked chromosomal positions. The results from genome projects, in general, strongly support the maintenance of synteny over evolutionary time periods longer than the duration of

individual functional polymorphisms, and show that genes do not, typically, move between or within chromosomes for reasons connected with the establishment of linkage disequilibrium between polymorphic, functionally distinct alleles. However, there is evidence for some level of clustering on non-homologues in eukaryotic genomes. In *S. cerevisiae*, essential genes show significant evidence of clustering (Pal and Hurst, 2003), as do genes with similar expression patterns (Hurst *et al.*, 2004). Most remarkably, *S. cerevisiae*'s DAL cluster of six genes involved in allantoin degradation has been shown to have been created by the movement of genes from previously unrelated locations (Wong and Wolfe, 2005).

Clustering of coexpressed non-homologues is probably not generated as a mechanism to ensure linkage disequilibrium, as was postulated in the original supergene concept. Rather, the clustering is related to the control of gene expression. The locus control sites of the globin gene clusters are just one example of a mechanism of gene expression control having the result that adjacent genes need to remain so because their joint expression is controlled by cis-acting sequences operating simultaneously on many linked genes. This effect apparently operates through the modulation of chromatin structure (for a review of the case of the β-globin gene cluster, see Li *et al.*, 1999). However, the clustering in the human genome of genes regulated by the aire transcription factor appears not to be the result of an effect of chromatin remodelling (Johnnidis *et al.*, 2005).

13.3.2 Functional Linkage Among Prokaryotes

In bacteria, operons form an example of phylogenetically unrelated genes brought together as a means of coordinating their expression. Genome comparisons have shown that operon structures can be evolutionarily unstable (Itoh *et al.*, 1999). Genes themselves may be added to bacterial genomes by horizontal transfer. Comparisons between the *E. coli* genome and that of *Salmonella enterica* have revealed that between 8 and 18 % of the *E. coli* sequences have been added to the genome by horizontal transfer following the split between the two species (Lawrence and Ochman, 1998). Indeed, it has been suggested that, with such high rates of gene transfer being observed between bacterial cells, the operon itself might be thought of as the unit of function (Lawrence, 1997). The clustering of genes in operons arises not solely from the need for simultaneous expression of all the genes, but also from the ability of a transferred group of functionally related genes to create a complete functional pathway when transformed into a naïve host. One example of collections of functionally related genes are the pathogenicity islands (Hacker *et al.*, 1997). These are groups of genes encoding pathways that allow bacteria to infect specific eukaryotic hosts. Their horizontal transfer is revealed through the sharing of recent ancestry for pathogenicity islands from distantly related bacterial species (Lawrence, 1999). Indeed, such 'genomic islands' of genes of related function are not solely related to pathogenicity, but to a range of ecological adaptations (Dobrindt *et al.*, 2004), and their rapid and promiscuous movement between bacterial lineages has the effect that there can be very major differences in gene content between very closely related genomes (Gogarten and Townsend, 2005).

13.3.3 Gene Clusters

Many vertebrate genes exist as linked clusters of homologous genes. The paradigm for the explanation of this type of organisation is the human globin genes. Here, there are two

clusters. The β-globin genes, consisting of those encoding the adult β and δ globins, the foetal $^G\gamma$ and $^A\gamma$ globins and the embryonic ε globin, along with a $\psi\beta$ pseudogene, are clustered on chromosome 11. The θ globin (the function of which remains unknown (Cooper *et al.*, 2005)), together with the two adult α globins, and the embryonic ζ globin, plus $\psi\alpha$ and $\psi\zeta$ pseudogenes, are in the α-globin cluster on chromosome 16. All genes and pseudogenes are in the same orientation within each cluster. In these α- and β-globin clusters it is clear that the mechanism for the generation of the clusters and thus families is local duplication by unequal crossing over. Unequal crossovers would be expected to create deletions of genes as well as duplications. However, while the deleted chromosome would be expected to have low fitness, at least in the homozygous state, and thus would be eliminated by selection, a haplotype bearing a duplicated gene might be neutral, and thus might (with a probability of $1/2N$, where N is the population size) spread to fixation by genetic drift. Under such a piecemeal process, one would expect that numerous duplications might accumulate, in which case the duplicated gene is, at least initially, truly redundant, in that silencing mutations in it would be neutral. A pair of genes created following duplication have three possible fates. If one is not lost by the reciprocal of the unequal recombination event that created the duplication, then either they could evolve to be functionally different (either through subfunctionalisation or neofunctionalisation, see Section 13.3.5), such that selection maintains each gene, or one copy could be silenced to form a pseudogene. True redundancy of the genes would not be stably maintained (see Section 13.3.6). A cycle of neutral duplication, followed by silencing, followed by decay, would thus be expected, which would lead to an increase in genome size with time. There are abundant examples of such clustered gene families, many containing pseudogenes, in the chromosomes of humans and other vertebrates. However, the extent to which pseudogenes arise and are maintained differs greatly between genomes. Unlike vertebrates, in *Drosophila* pseudogenes are almost unknown. The one case thought to be of a processed *Adh* pseudogene (i.e. a pseudogene generated by the insertion of reverse transcribed mRNA) in the species *D. teissieri* and *D. yakuba* (Jeffs and Ashburner, 1991) turned out to be a new functional gene, *jingwei*, created by the insertion of an Adh cDNA into a coding sequence from another gene (Long and Langley, 1993). The explanation for the absence of pseudogenes seems to be that *Drosophila* shows a high rate of evolutionary loss of DNA for sequences that are not actively maintained by selection (Petrov *et al.*, 1996; Petrov and Hartl, 1998). Indeed, almost the entire non-coding region of the *Drosophila* genome appears to be under selective constraint (Halligan and Keightley, 2006). This purging of the *Drosophila* genome of non-functional sequences may be the result of weak selection, which may be effective in *Drosophila*'s large population size, whereas the same selection strength would be ineffective in the smaller effective population sizes of vertebrates. Alternatively, the selection coefficients associated with DNA loss in *Drosophila* may be larger than their equivalents in other species, possibly reflecting selection for rapid genome division in syncytial early embryonic development, when nuclear division occurs every 9 minutes (Lawrence, 1992).

13.3.4 Integration of Genetic Functions

Systems biology seeks to interpret the effects of genes in terms of the complex networks connecting genes and their products. Thus, there are networks showing causal links between genes whose products influence the expression of other genes, and there are

networks of interactions between protein molecules. Such networks can be described in a Boolean way, concerned only with presence and the signs of interactions of the genes, or in a more quantitative way, in which the strengths of the interactions are also documented. The goal of such integrative approaches is ambitious – by understanding the ways in which genes and their products interact, we should be able to predict the likely phenotypes associated with mutational changes to genes, including gene losses.

Some have noted a scale-free property in a variety of networks in biology and elsewhere (Barabasi and Albert, 1999). The scale-free property is that the probability that a node in the network is connected to i other nodes is given by $P(i) = ci^{-\gamma}$, with c and γ being constants, such that a log–log plot of $P(i)$ against i will give a straight line of slope $-\gamma$. This property has been identified, e.g. in the network of protein–protein interactions in yeast. It implies that networks grow by new nodes preferentially attaching themselves to nodes that already have many connections. It has also been seen approximately in the probability that a gene family has i members in a given genome (although here it has the modified form or a Pareto function, where $P(i) = c(a + i)^{-\gamma}$, where a is a further constant). Karev *et al.* (2003; 2004) have shown that this family size distribution can be the result of a linear model involving gene births by duplication, deaths and innovations (changing the family to which a given gene belongs), although it is not clear whether the timescale of gene family evolution has been sufficient for real families to reach these models' equilibrium states. The scale-free distribution identified in networks of protein interaction also raises the question which modes of gene and thus protein duplication and divergence in protein function would be expected to result in networks with this property (Hughes and Friedman, 2005). Others have also approached gene family evolution from the standpoint of stochastic birth–death models (e.g. Hahn *et al.*, 2005; Csuros and Miklos, 2006, who also include horizontal gene transfer). It should also be said that many argue that the scale-free property is not seen, in detail, in the networks available (Khanin and Wit, 2006), also, it would not be expected to be seen in the sub-networks typically examined, even if it held in networks as a whole (Stumpf *et al.*, 2005).

13.3.5 Gene Duplications as Individual Genes or Whole Genome Duplications?

One of the great recent myths in molecular biology was the very high estimates of gene number in vertebrates, with 80 000 being typical, which were current and in undergraduate textbooks (e.g. Brown, 1999) around the start of this decade, prior to the completion of sequencing projects. These were quoted by, among others, me in the first edition of this book. These inaccurately high estimates arose from measurements of gene density in well-studied regions of the genome, but gene density is itself highly heterogeneous across genomes and well-studied regions were typically chosen because of the genes that they contained, with the result that they constituted a biased sample of genomic material. However, there is still no general agreement about the number of human genes, with recent estimates being as low as 25 000 (International Human Genome Sequencing Consortium, 2004). In fact, the identification of genes in eukaryotes is difficult, mainly as a result of introns: while an open reading frame of the length of a typical polypeptide is statistically highly unlikely, open reading frames the length of exons are not unlikely enough to constitute a strong signal.

We have seen the way in which the globin genes have been created by a series of gene duplications, which have also given rise, ultimately, to pseudogenes. Are gene families therefore typically created by piecemeal gene addition (Lynch and Conery, 2000), or,

rather, do they typically arise from genome-wide duplication events? A clear example of genome doubling is that of the *Xenopus laevis* genome, which is derived from at tetraploidisation event around 30 million years ago. Notwithstanding the presence of effectively four copies of each gene in a diploid *X. laevis*, it appears that both loci of each gene are under selective constraint, in that each shows a reduced rate of amino acid sequence change relative to synonymous changes (Hughes and Hughes, 1993). An earlier duplication has been detected in the budding yeast, *S. cerevisiae* (Wolfe and Shields, 1997) by comparing the *S. cerevisiae* genome to the related *Kluyveromyces*, which does not share the duplication. Genome sequencing of *Kluyveromyces waltii* has confirmed this interpretation (Kellis *et al.*, 2004).

Ohno (1970) suggested that it is through gene duplication that new functions can be developed. He further suggested that there could have been two rounds of tetraploidisation in the origin of the vertebrates (the '2R' hypothesis). While the apparent support for this model that was derived from the apparent fourfold increase in gene number in vertebrates relative to invertebrates proved to be illusory, there remains some evidence to support this hypothesis. One source of support has been the *Hox* genes, clusters of genes encoding transcription factors involved in antero-posterior differentiation, identified initially in *Drosophila*, but since seen in all metazoan animals. These are found as a single cluster in all invertebrates (albeit a broken one in *Drosophila* itself) but exist as four clusters, now called *A*, *B*, *C* and *D*, in tetrapods. The suggestion has been made that the first of the 2R duplications may have occurred initially prior to the divergence of the two clades of agnathans (lampreys and hagfish) from the lineage leading to the jawed vertebrates, followed by a second duplication in the gnathostomes (Holland *et al.*, 1994). The cephalochordate *Branchiostoma,* which is the closest relative to the vertebrates among invertebrates, has a single *Hox* cluster (Garcia-Fernandez and Holland, 1994). However, the situation is not the simple one of there always being four *Hox* clusters in jawed vertebrates. While tetrapods have four *Hox* clusters, the zebrafish (*D. rerio*) has seven clusters (Amores *et al.*, 1998), the result of a teleost-specific genome duplication, with one cluster (a D) having been subsequently lost. Puffer fish *Spheroides nephelus* and *T. rubripes* also have seven clusters, but have lost a C cluster rather than a D (Amores *et al.*, 2004).

The agnathans form an important test of the '2R' hypothesis, since, by this hypothesis, they should either share all four of the gnathostome Hox clusters or have only two clusters. The sea lamprey *Petromyzon marinus* (Force *et al.*, 2002) has at least four Hox clusters, but phylogenetic arguments suggest that the second duplication event was independent of that in the gnathostomes, and it has even been suggested that the common ancestor of lampreys and gnathostomes had a single Hox cluster (Fried *et al.*, 2003). The hagfish *Eptatretus stoutii* has many *Hox* genes in, apparently, at least four clusters, and possibly up to seven, and orthologies with mammalian Hox clusters suggest that at least two Hox clusters were present in the hagfish–gnathostome ancestor (Stadler *et al.*, 2004).

If the 2R hypothesis is correct, there is a strong prediction that, if there is a gene family found as a single gene in invertebrates and as four genes in tetrapods, then the four tetrapod genes should form two clades, each of two genes, in the rooted phylogeny. Bailey *et al.* (1997) looked at the *Hox* gene clusters in mammals and tried to estimate the topology of the phylogeny linking clusters A, B, C and D. While this was impossible with the *Hox* genes themselves, since too many individual genes had been lost from the clusters since their creation, the phylogeny was estimated using collagen genes linked

to each of the four clusters. An unrooted tree showed AD and BC clusters, but rooting with an outgroup placed the root on the branch connecting cluster D to the other three clusters. The implication is that, if the clusters had been derived from whole genome duplications, there would have been three such duplications, not two. The first would create the duplication distinguishing D from the ancestor of the other three clusters; the second would distinguish the ancestor of A from the ancestor of B and C (the duplicate of the D cluster created by this event must subsequently have been lost). Finally, a third genome duplication would be required to create the B and C clusters, after which the duplicates of the A and D clusters would again have to be lost. Alternatively, the clusters could have duplicated individually rather than as parts of whole genome duplications. This failure to find the topology expected from genome-wide duplications has turned out to be typical of developmentally important genes in vertebrates (Hughes, 1999). Clearly if there are multiple genome duplications followed by extensive loss of duplicates, the theory of genome duplications no longer creates any prediction of the number of gene family members expected to be seen or of the phylogeny connecting them (since that will depend on the subsequent pattern of gene loss). Indeed, genome-wide duplications followed by piecemeal and rapid loss of duplicated genes or clusters of genes will be indistinguishable from piecemeal segmental duplications. Only if piecemeal segmental losses affected different genomic regions in different lineages could the extent of the duplicated region at the time the lineages split be reconstructed.

Thus, while the genome duplication in the teleosts is well established, the status of the 2R hypothesis in early vertebrate ancestry is uncertain (Panopoulou and Poustka, 2005). There was undoubtedly a burst of gene duplication at the time suggested for the genome duplications in the 2R hypothesis (Blomme *et al.*, 2006). Furthermore, analysis of chromosomal regions bearing genes duplicated prior to the human−*Tetraodon* split using the ascidian *Ciona*'s genome as an outgroup reveals extensive regions showing fourfold paralogy (Dehal and Boore, 2005).

Whether genes are duplicated singly or as part of the regional or genome duplication, the possible fates, of subsequent loss, formation of a pseudogene or continued functionality are mentioned above (Section 13.3.4). There has been considerable recent debate (Force *et al.*, 1999; Lynch and Force, 2000) as to whether the acquisition of new functions for genes (neofunctionalisation) is preceded by, or indeed replaced by, a process of subfunctionalisation. In the subfunctionalisation model, it is imagined that a gene might have a series of sequences controlling the function of the gene, which can be partitioned into separate subfunctions. The most obvious way that this could come about is for there to be separate enhancer sequences, typically 5′ to the start of transcription, controlling the expression of the coding sequence of a gene at different times or in different tissues. In the simplest case, imagine that there are two enhancer sequences, A and B, which independently bring about the gene's expression in different tissues. Following duplication, which yields two gene copies, I and II, the possibility exists that a mutation arises which inactivates subfunction A in gene copy I. Such a mutation would be effectively neutral and could spread to fixation. A further mutation, causing the inactivation of subfunction B in gene copy I or indeed a mutation inactivating the coding sequence in gene copy I would also be able to spread neutrally. However, another neutral possibility would be a mutation inactivating subfunction B in gene copy II. Spread of such a variant would leave the genes subfunctionalised, with copy I carrying out subfunction B and copy II carrying out subfunction A. Calculations

and simulations (Lynch and Force, 2000; Force *et al.*, 2005) reveal that, provided the effective population size is considerably less than the gene's rate of inactivating mutations (whether they are in the coding sequence or subfunction enhancers), the probability of subfunctionalisation can be reasonably high (particularly when the mutation rate to subfunction loss is large relative to the mutation rate for inactivation of the whole gene). Once the subfunctions of the genes are being carried out by different duplicates, advantageous mutations in the coding sequences of the two genes may spread, adapting the genes for their now subtly different roles. The key element of this model, named *DDC* for 'duplication–degeneration–complementation', is that the molecular events that lead to the sharing of the function of the gene between the two copies are not driven to fixation by natural selection. The prediction is thus that the DDC model's effects should be sensitive to effective population sizes, particularly when these approximate the reciprocal of the rates of inactivating mutations (which might be around $10^{-6} - 10^{-5}$ per generation).

The DDC model has been of considerable interest to those studying the changes to gene functions following gene duplication events. In particular, the events following the genome duplication event in the teleosts have been examined for evidence of subfunctionalisation. Prince and Pickett (2002) showed that the *Hoxb1a* and *Hoxb1b* genes of the zebrafish (*D. rerio*) collectively have an expression pattern that duplicates that of the ancestor – inferred from the expression pattern in mouse – and that, of two sequences controlling the ancestral gene's expression, a autoregulatory sequence 5′ to the gene and a retinoic acid response element 3′ to the coding sequence, the *Hoxb1a* and *Hoxb1b* genes have retained the former and the latter, respectively. The whole genome duplication of the teleosts will supply a rich database for the identification of further cases of subfunctionalisation (Hurley *et al.*, 2005). Is this sharing of functions, expected from the DDC model, typical of the outcomes following this genome duplication? Chiu *et al.* (2002) examined controlling sequences in the HoxA cluster, and identified those conserved between humans and the horn shark (*Heterodontus francisci*). Do these controlling sequences get partitioned between the two zebrafish HoxA clusters? It was found that while there was very high conservation of cluster organisation between shark and human, the duplicated zebrafish clusters were far more diverged in structure. The human–shark-conserved putative cis-acting elements showed no clear pattern of reciprocal partitioning between the zebrafish clusters. Similarly, in duplicated genes of *Arabidopsis*, some pairs show signs of subfunctionalisation and others of neofunctionalisation only (Duarte *et al.*, 2006). Rates of amino acid evolution in gene duplicates are often, and unsurprisingly, very unequal following duplication, a result consistent with either adaptive evolution or reduced constraint in one of the pair (Conant and Wagner, 2003).

The DDC model requires not only that an ancestral gene's function is shared among the duplicates, but that the events that create this functional partitioning are themselves 'degeneration'-neutral events spreading to fixation. However, an outcome in which functions are shared could equally come about through changes that are all individually adaptive. As we have seen above, the DDC functional sharing, itself hypothesised to result in gene duplicate retention, should be more probable in organisms with small population sizes. Yet Shiu *et al.* (2006) demonstrate that the mouse genome has retained more gene duplicates than the human genome. If one makes the fairly strong assumption that the effective size of the lineage leading to the mouse has typically been larger than the effective size of populations leading from the human–mouse common ancestor to humans, then this result is more consistent with selection leading to the retention of

duplicated genes, rather than neutrally spreading degenerative mutations followed by selection. However, an effect of this kind could equally have been created by an enhanced rate of gene duplication in the mouse lineage. However, more genes already duplicated prior to the human–mouse split have been retained in the mouse lineage, an observation which could not be explained in this way.

The teleosts are the most speciose vertebrate group, and as the presence of the extra genes might be seen as creating opportunities for adaptive change, it is tempting to explain the very large number of teleost species as a consequence of their genome duplication. In particular, it has been suggested that the Hox cluster duplications may be correlated with a burst of adaptive radiation in vertebrates (Wagner *et al.*, 2003). Crow and Wagner (2005) suggest that the effect of the teleost genome duplication on the generation of the high species number seen in extant teleosts came through teleosts having a slower rate of extinction than other fish groups. However, the finding that teleosts show this (or any other) property of evolutionary persistence, diversity or adaptability does not demonstrate that the genome duplications in any way caused or facilitated this evolutionary property.

13.3.6 Apparent Genetic Redundancy

One consequence of major gene duplications is that there may be more overlap between functions of genes in duplicated genomes. The results of mouse knockout experiments have often shown that the phenotypes of homozygous null mutations, of genes thought to be important through studies of the biochemical roles of their products, are slight or undetectable (Brookfield, 1997). But is there true redundancy between duplicated genes, in which the selective advantage or disadvantage of loss of a second gene is zero, given that the first gene is present? We have seen that, immediately after a gene duplication event that has spread to fixation by genetic drift, there will be true redundancy, in this sense. We can define partial redundancy as situations in which the fitness loss associated with simultaneous mutations in genes A and B is much greater than the sum of the fitness losses associated with mutations in A and B individually. However, provided the fitness effects of mutation in genes A and B are individually greater than the reciprocal of the effective population size, selection (albeit of a weak and subtle kind) can maintain both genes. In budding yeast, *S. cerevisiae*, the selective impact of gene deletions is less for genes that possess paralogues elsewhere in the genome, but this effect gradually attenuates as the divergence in sequence between the copies increases (Gu *et al.*, 2003).

One method that could be suggested for the creation of a subtle selective advantage required to maintain partial redundancy in genes A and B, deletions in which may not be individually associated with a visible phenotype, is that the possession of two genes may create phenotypic robustness, not just to mutation but to the effects of environmental changes (Kitano, 2004). While having extra gene copies might be expected to buffer an organism against the harmful effects of recessive somatic mutations, it is not clear that somatic mutations are a major force in determining organismal phenotypes. Does a developmental process with multiple genetic pathways being involved in the production of a particular phenotypic trait make the probability of production of the trait (and concomitant Darwinian fitness) higher in an unpredictable environment than would a developmental process involving a single pathway? In my view, a positive and general answer to this question cannot be derived from first principles and is an empirical matter

only. At present, we do not know whether, in general, partial genetic redundancy increases robustness to environmental insults in the way that it does (by definition) to genetic lesions.

One major problem is the identification of the evolutionarily realistic environment in which to carry out tests for the effects of mutants. Deletion strains of *S. cerevisiae* have been created in which, in individual strains, every open reading frame in the genome has been inactivated (Winzeler *et al.*, 1999). Many of these knockouts show no effect on growth rate in a range of laboratory environments, but the conclusion that this represents true genetic redundancy cannot be drawn, since the fitness measurement is imprecise and the appropriate environment might not have been used (Giaever *et al.*, 2002). In fact, systematic characterisation of the visible phenotype of these deletion strains reveals morphological abnormalities even in deletion strains lacking a growth phenotype (Ohya *et al.*, 2005).

13.4   POPULATION GENETICS AND THE GENOME

13.4.1   The Impact of Chromosomal Position on Population Genetic Variability

Does the position of genes have any effect on their evolution? Comparison of the level of genetic polymorphism between *Drosophila* genes has shown that there is a strong correlation between the rate of recombination per unit DNA length and the level of DNA sequence polymorphism, as measured, for example by the gene diversity, π (Begun and Aquadro, 1992; Charlesworth and Wright, 2001). Since there is much smaller apparent effect of the local recombination rate on the divergence between *Drosophila* species, the correlation observed with diversity cannot be completely explained by a directly mutagenic effect of recombination. Rather, it must result from alleles sampled from low-recombination regions having recent shared descent. A number of processes have been suggested to explain how this could have come about.

One of these is a selective sweep. If a new advantageous mutation arises in a non-recombining region, it will arise initially in a particular haplotype and, in spreading, it will take with it this haplotype – extending over a length of chromosome which will be longer the lower is the effective recombination rate (Barton, 2000). This idea has been used to identify the selective sweeps in progress in the human genome, where rapidly spreading, new advantageous alleles generate 'extended haplotype homozygosity' (Sabeti *et al.*, 2002) – the sign of a haplotype which, while at high frequency, shows strong linkage disequilibrium extending into flanking markers – a pattern indicative of the recent rapid spread of the allele from a single progenitor. While sweeps undoubtedly happen, their impact is conditional upon a particular model for adaptive change, in which the rate-limiting step in adaptive allelic substitution is the generation of new mutations. However, another view of adaptive change is of weakly deleterious mutations being generated constantly and being present in an equilibrium population in a mutation–selection balance. An environmental change then changes the sign of the selection coefficient, creating an advantage for some formerly deleterious, phenotypically equivalent mutations. The advantageous alleles spread but, since they exist at the start of the sweep in a variety of different genetic backgrounds, the selective 'sweep' will create less reduction in diversity than would a more classical example of a sweep, starting from a unique mutation. Sweeps

of this kind have been called *soft sweeps* (Hermisson and Pennings, 2005; Pennings and Hermisson, 2006).

While selective sweeps are an effect on diversity resulting from an advantageous mutation, deleterious mutations will also tend to reduce diversity in low-recombination regions, in diverse ways. The first mechanism is 'background' selection (Charlesworth, 1996). Here mutations that are disadvantageous (and with selection coefficients greater than $1/N_e$) will eliminate chromosomes from the population, reducing the effective population size for the chromosomes that remain, and thus reducing neutral variability, and, as with selective sweeps, the size of the reduction generated increases as the local recombination rate drops. Even if the strength of the selection effect is weak, $s < 1/N_e$, if there are very many linked sites subject to selection, the neutral diversity will be reduced (McVean and Charlesworth, 2000) through what has been called the *Hill–Robertson effect* (Hill and Robertson, 1966). Finally, the process of Muller's ratchet (in which, in the absence of recombination, the occasional random irreplaceable loss from the population of the chromosomal class with the smallest number of deleterious mutations will steadily erode fitness) will also cause a reduction in the standing level of variability relative to a neutral population (Gordo *et al.*, 2002).

13.4.2 Codon Usage Bias

The genetic code is degenerate and thus allows different codons to be used to specify the same amino acid. However, not all codons for any given amino acid are used equally frequently, and since the initial finding of such biased codon usage, controversy has existed as to whether the bias is the result of mutation bias or of selection. There are many reasons why selection might be expected to generate a biased set of codons. Those that have been most favoured have suggested that codons are preferred by natural selection if they are complementary to anticodons on abundant tRNA species in the cell. This result was first demonstrated by Ikemura (1981; 1982) for strongly expressed genes in *E. coli* and *S. cerevisiae*. In each species, genes that were weakly expressed were not found to show such strong bias. The bias in strongly expressed genes could potentially arise from selection for increased translation rate or increased accuracy (Akashi, 1994). While the correlation between preferred codons and tRNA abundances has not been directly demonstrated in other species, in *D. melanogaster* strongly expressed genes again appear to show stronger codon bias than do weakly expressed genes (Shields *et al.*, 1988). However, the strong bias in codon usage seen in *E. coli* and yeast is not ubiquitous in bacterial genomes, being seen in only around 70 % of genomes examined (Sharp *et al.*, 2005). These genomes with codon bias seem to be those that have been selected for rapid growth in optimal conditions and are also characterised by high numbers of ribosomal RNA and transfer RNA genes. Biased codon usage also arises from deviations from a 50 % G + C ratio, as in the actinomycete *Streptomyces coelicolor*, for example, with 72 % C–G base pairs (Bentley *et al.*, 2002). Mammalian genomes contain isochores, which are blocks of DNAs of divergent C + G content (Bernardi *et al.*, 1985), the origin of which may be through mutational rather than selective causes.

For weakly expressed genes that fail to show codon bias, the explanation for their lack of bias is not selection to maintain particular non-optimal codons, since the rate of sequence evolution is high at these sites (Sharp and Li, 1989), rather, it appears that any selection operating is too weak to affect the choice of codons. For selection to be effectively neutral, the selection coefficient, *s*, has to be less than the reciprocal of the

effective population size, N_e (Bulmer, 1991). For stronger selection, the degree of codon bias depends on the product sN_e. This product can be estimated from the frequencies of preferred and unpreferred bases at polymorphic silent sites. In *Drosophila simulans*, it is estimated that sN_e is around 1, on average, implying that very weak selection is operating at these sites in this species (Akashi, 1999). If selection in *D. simulans* is only just strong enough to have a detectable effect, one would expect that in *D. melanogaster*, whose lower levels of all types of polymorphism when compared to *D. simulans* imply a smaller historical effective population size, the selection acting on silent sites might not be enough to maintain codon bias. Indeed, the codon bias in *D. melanogaster* is substantially reduced relative to *D. simulans*, and the majority of substitutions in the *D. melanogaster* lineage have been away from preferred codons. It appears that *D. melanogaster* has not reached equilibrium between mutation, selection and drift in its codon usage patterns (Akashi, 1996).

The evidence for selection on codon bias in mammals is less clear cut, but a variety of analyses have pointed to weak selection affecting a minority of synonymous codon variants, even in humans, where the effective population size has recently been particularly small (Chamary *et al.*, 2006; Comeron, 2006).

13.4.3   Effective Population Size

One aspect of population genetics that is of great relevance to the evolution of genome structure is that the impact of purifying selection depends on the strength of selection relative to the effective population size. Specifically, the probability of spread of a mutation with selective advantage s (in the heterozygous state) is given by

$$P = \frac{1 - \exp(-2sN_e/N)}{1 - \exp(-4N_e s)},$$

where N and N_e represent the census population size and the effective population size, respectively (Kimura, 1962). This relationship is important in genome evolution, as we have already seen in the determination of codon usage bias, in the likelihood of subfunctionalisation and in the likelihood that weakly deleterious intron insertions might spread to fixation. Indeed, Lynch (2006) has identified the consequences of the low effective population sizes of multicellular organisms (in particular, the low effective size relative to the reciprocal of mutation rates per generation) as being the cause of the majority of the differences in genome structure between multicellular organisms and micro-organisms. Such a view identifies the fixation process for changes to genome structure as typically being genetic drift acting on effectively neutral variants. Otto and Yong (2002), however, stress that changes to genome structure – in particular, gene duplicates, arise initially in single individuals, and their probability of spread will be greatly enhanced if they bring an instant selective benefit to their bearers (which could occur by a variety of mechanisms).

Effective population sizes may change with time. For humans, e.g. while the current census size is around 7×10^9, the diversity of the human population is more congruent with an effective size of 10 000. Here the appropriate effective size is the harmonic mean effective size over the timescale during which population genetic diversity has been generated (which is of the order of the last $4N_e$ generations). However, in explaining genome structure in terms of effective population sizes, the appropriate time window

over which N_e should be averaged is very much longer, which means that present census sizes of species with contrasting genome structures may be a very poor guide to their evolutionarily realistic $N_e s$ in terms of their genome organisation.

13.5   MOBILE DNAs

13.5.1   Repetitive Sequences

Repetitive sequences can be crudely divided into two broad classes on the basis of their pattern of repetition. Some sequences are found in tandem arrays, while others are found as single copies interspersed with unrelated sequences. The tandemly arrayed sequences can be apparently functionless, such as the microsatellite, minisatellite or longer satellite arrays, or functional, such as the ribosomal RNA genes and the histone genes. Interspersed repeats are shown, by their interspersion pattern itself, to be either currently active mobile DNAs or the descendants of sequences that have been mobile in the past. The mode of transposition is used to distinguish between what are named *Class I elements*, or *retrotransposons*, which move via an RNA intermediate, and Class II elements, which transpose as DNA. Both the RNA and DNA routes give opportunities for transposable elements to increase in the genome as a result of transposition (Brookfield, 1995). This ability to overreplicate has led to the widespread view that these elements are parasitic or selfish DNAs, maintaining their abundance in the genome through a balance between replicative transposition and the combined effects of deletion and of selection against their bearers.

In humans, the interspersed repetitive DNA sequences are dominated by Class I sequences called long interspersed nuclear element (*LINE*) and *SINE* sequences, of which there are very many copies. The long-term existence of these sequences at their current chromosomal locations means that they have almost all been inactivated, either at the moment they were inserted, or subsequently, by what has been called the *pseudogene effect* (McAllister and Werren, 1997). (Selection will not act to maintain sequences required for transposability in a sequence copy at a given genomic location, and individual copies will decay, eliminating their ability to act as donors for new insertions elsewhere in the genome.) Selection for active subfamilies operates through the ability of these families to replicate preferentially through the generation of daughter elements. Once inactivated, sequences independently (save for gene conversion) accumulate copy-specific patterns of base changes, and, from their divergence from the most closely related sequences, it is possible to identify when these sequences were inserted into their current chromosomal locations. This therefore allows the reconstruction of the history of the active elements of a mobile sequence family, as the 'extinct' subfamilies still exist in the genome.

The selfish nature of mobile DNAs does not preclude their evolving to serve roles that are functional for the host, either through 'domestication' or through their abilities as generators of diversity. Very many examples of elements serving adaptive roles are now known, and the number of examples can only increase as our knowledge grows, without threatening the paradigm that it is the capacity for selfish spread of elements through overreplication in transposition that explains the abundance of the majority of elements (Brookfield, 2005).

13.5.2 Selfish Transposable Elements and Sex

The concept of transposable elements as purely selfish DNA sequences faces major problems in the case of bacterial and other clonal populations. In clonally reproducing organisms, any individuals lacking selfish DNA sequences will inexorably outcompete those possessing the sequences, and replicative transposition of selfish elements in lineages possessing them will merely hasten this outcome. It is interesting to note that the purely asexual Bdelloid rotifers lack actively mobile retrotransposing DNAs (Arkhipova and Meselson, 2000). The transition to asexuality in this group may have been successful only because the asexual founders lacked active retroelements at the transition to clonality (Arkhipova and Meselson, 2005).

If selfish spread of mobile DNAs is impossible in clonal populations and if the mobile DNAs lack selectable trans-acting functions (as do bacterial insertion sequences), the obvious way in which these sequences could be maintained is by selection at the level of the host for their role as mutators. In clonal populations evolving adaptively, the frequency of alleles increasing the mutation rate is expected to be higher than in sexual populations, since mutator alleles are spread by hitch-hiking with the advantageous alleles that they generate (Taddei *et al.*, 1997). By a corresponding mechanism involving linkage disequilibrium, Edwards and Brookfield (2003) have produced a model for the selective maintenance of mobile DNAs through their ability to create null mutations which can create an environment-dependent selective advantage but can subsequently revert. Null mutations creating selective advantages were demonstrated in *E. coli* in a companion paper (Edwards *et al.*, 2002). Similarly, in experimental populations of *E. coli*, allowed to adapt to laboratory culture for more than 20 000 generations (Schneider and Lenski, 2004), many of the advantageous mutations were generated by insertion sequences (Schneider *et al.*, 2000).

13.5.3 Copy Number Control

The selfish spread of elements would be expected to continue indefinitely unless the elements themselves evolve a self-limitation in transposition or unless a balance with selection is generated. Examples of self-limitation are known, as in the restriction of the *D. melanogaster I* element's movements by homology-dependent gene silencing (Jensen *et al.*, 1999). However, Charlesworth and Langley (1986) showed that the area of parameter space over which harmful transposable elements would be expected to evolve self-limitation is extremely restricted. However, it has been shown (Brookfield, 1991; 1996) that, if the harmful effects of mobile DNAs arise through the process of transposition itself (rather than through the actions of elements after they have inserted in the genome), the evolution of self-limited transposition is more likely. One way in which copy number could be stabilised is through ectopic recombination between element copies from diverse locations (Langley *et al.*, 1988). Such a process is likely to be most effective in organisms such as *Drosophila*, where there is very high variation between individuals in the positions of their mobile DNAs, such that, in a typical meiosis, an element will find itself without a partner on the homologue.

13.5.4 Phylogenies of Transposable Elements

As there are many copies of a given mobile sequence family in the genome, it is possible to estimate the phylogeny of copies of a repetitive sequence family from the DNA sequence differences between copies. It is also possible to examine members of the same family

from other species and draw a tree including copies from both species. If the time to common ancestry of elements within each of two species is more recent than is the time to common ancestry of sequences from the two species, the elements will be seen to show 'concerted evolution', where species-specific substitutions will distinguish between the collections of elements from the two species (Figure 13.1a). One way in which variation between mobile DNAs from different species has been analysed is through the creation of consensus sequences for the sequences within each host species and comparison between these consensus sequences being used to examine between-species evolution of the family. However, there are problems with such an approach, illustrated in Figure 13.1. Figure 13.1(a) illustrates a tree showing three mobile DNAs sampled from each of two species, A and B, with $t1$, $t2$ and $t3$ representing times in generation between bifurcations in the ancestry of the tree. Here there is a clear split in the tree separating the sequences from species A and those from species B. This is the type of tree expected if the time to common ancestry of sequences in species A and the time to common ancestry of sequences in species B were each more recent than the split between the two species, and thus concerted evolution will be seen. The time to common ancestry of any A sequence with any B sequence is $(t1 + t2 + t3)$. The mean time to common ancestry for any two A sequences (or any two B sequences) is $t1 + 2t2/3$. In the absence of back or recurrent mutation (i.e. assuming an infinite sites model) the consensus sequence for species A would correspond to that ancestral to the most closely related pair of A sequences, and the consensus sequence of species A and the consensus of species B would be separated by $2(t2 + t3)$ generations of evolution. Figure 13.1(b) represents a different situation, where the first split in the tree pre-dated the split of species A and B. However, the representation of the two clades defined by this initial split is different in the two species (or at least in the small samples drawn from the two species). The result is that now, while the difference between the consensus sequence is still created by $2(t2 + t3)$ generations of evolution, A sequences share common ancestry, on average, $t1 + 2(t2 + t3)/3$ generations ago, while A and B sequences share ancestry, on average, $t1 + t2 + 5t3/9$ generations ago. The same difference in sequence between the consensuses masks a much-reduced ratio of the between- to within-species diversity. Figure 13.1(c) shows a case where the mean time to common ancestry within elements within species is $t1 + t2 + 2t3/3$ generations, while that between species is $t1 + (7t2 + 5t3)/9$ generations. Here there is no reason to suspect any difference in transposable element populations between the species, and the mean time to common ancestry within species in this tree is greater (for any $t1$, $t2$ and $t3$ values) than that between species, and yet there is a difference between the species' consensus sequences corresponding to $2t3$ generations of evolution.

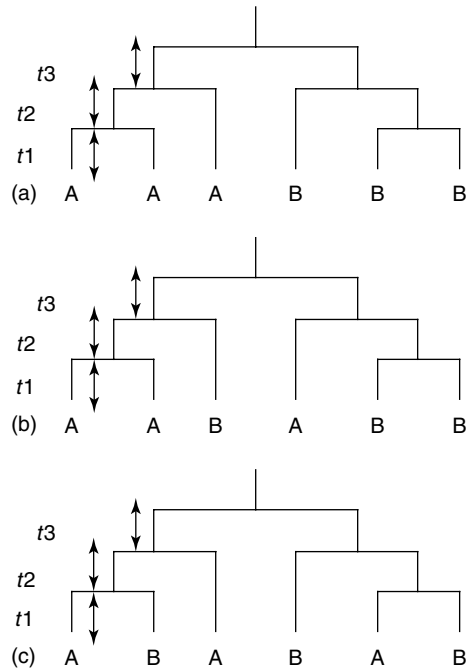
What determines the time to common ancestry of copies of a repetitive sequence family within a given genome? In *D. melanogaster*, many studies have shown that transposable element site frequencies approximately follow the infinite alleles distribution (e.g. see Biemont *et al.*, 1994). A model that would, at least approximately, generate such a distribution would be one in which duplicative transpositions into a very large number of potential target sites could occur, with a process of genetic drift with weak selection generating the infinite alleles distribution at equilibrium. Such a model was initially explored by Langley *et al.* (1983). Suppose that we have an effective population size of N_e and that elements transpose duplicatively at a rate of v per element per generation. It is assumed that v represents the rate of insertion into neutral sites, and that at equilibrium this also represents the rate of deletion of the elements. If the number of available


Figure 13.1   Three possible phylogenetic relationships between six transposable elements sampled from two species, A and B. $t1$, $t2$ and $t3$ represent the times to bifurcations in the tree. The extent of divergence of elements from the two species diminishes in going from (a) to (c). For each of the trees, (a), (b) and (c), it is possible to calculate the mean time to shared ancestry for sequences from A (owing to symmetry the mean time for sequences from B will be the same). It is also possible to calculate the mean time to common ancestry for pairs of sequences, one from A and one from B. The evolutionary time separating the consensus sequences can also be calculated as a function of $t2$ and $t3$ in each case.

sites for transposable element insertion is very high, the equivalence of the rates of element insertion and deletion will have the consequence that the frequency distribution of transposable elements will follow an infinite allele distribution with parameter $4N_e v$.

This model was extended by the author (Brookfield, 1986) to the expected time to common ancestry of randomly chosen transposable elements from different genomic locations, on the basis of an assumption of functional equivalence (as measured by transposition probability) of all elements at all sites. This model showed that the expected time in generations to common ancestry, t, was approximately given by

$$t \approx \frac{(n(1 + 4N_e v))}{2v}, \tag{13.1}$$

where n is the number of element copies per haploid genome. Similar results were found by others (Slatkin, 1985; Ohta, 1985).

This formula gives intuitively reasonable time estimates for the *Drosophila* transposable elements, but is clearly inappropriate for mobile DNAs from, e.g. vertebrates. One reason for this is that there will be very many element insertions which are inactive and the rate

of turnover of the active subset of elements would be greater than that predicted by this formula. Indeed, if only a proportion A of new insertions are active, the corresponding formula to (13.1) is

$$t \approx \frac{(2(1-A) + An(1+4N_e v))}{2v}. \tag{13.2}$$

The pseudogene effect leads to a different kind of model, in which the inactivation process can affect all element copies equally, rather than being restricted to elements inactivated at the moment of their insertion (so-called dead-on-arrival elements). A pseudogene effect further increases the rate of turnover of active elements and relates the rate of turnover of active elements to the proportion of the elements in a gene family that are active. Suppose now that there is a rate of inactivation of κ per element per generation and a rate of deletion of d per element per generation and, thus, a rate of replicative transposition into neutral sites of $(\kappa + d)$ per active element per generation at equilibrium. The expected time to common ancestry of two randomly chosen copies is

$$t \approx \frac{3}{(2\,d)} + \frac{n_a(1+4N_e\kappa)}{2\kappa}, \tag{13.3}$$

where n_a is the number of active elements in the genome (with $n_a >> 1$) and $\kappa >> d$.

However, these considerations of expected times to common ancestry mask another important aspect of transposable element phylogenies, which is the expected phylogeny of transposable element copies sampled from a genome. It had been noted that, for both LINEs and SINEs in mammals, the phylogeny resembles that expected under a 'master gene' model (Deininger $et\ al.$, 1992; Clough $et\ al.$, 1996) in which only a single element serves as the template for all transpositions. The result is a phylogeny in which all the bifurcations occur in a single branch.

Thus, we (Brookfield and Johnson, 2006) considered the expected phylogeny of mobile DNA sequences in an equilibrium model, where we imagine that the sample of copies is taken of members of a mobile sequence family from the genome, and we are interested in the phylogenetic tree connecting these sequences back to their common ancestor. We imagine a mobile sequence family, which was in equilibrium between three processes, replicative transposition of active elements, inactivation of elements (which may occur at the moment of transposition or result from inactivating mutations $in\ situ$ – the pseudogene effect) and deletion of elements. The relative rates of these processes define the expected numbers of copies of active and of inactive elements of this family in the genome, and this population of elements can then be seen as a population from which our sample and their ancestors can be traced following a coalescent approach. In large gene families the majority of elements will be inactive, and so we imagine the coalescent process for a sample of inactive elements. In the ancestry of our sample, tracking backwards in the standard approach of the coalescent, two types of events can occur – activations and coalescences. In the simplest model, where inactivation occurs via a pseudogene effect and never at the moment of transposition itself, coalescence in the ancestry of the sample can only occur between active lineages. Thus, in tracing the sample back to the common ancestor, there will be activation events, and coalescences. The expected shape of the phylogeny thus depends very greatly on the relative size of the two variables determining the probability of activation of a lineage, d (which is, at equilibrium, equal to the rate of deletion), and the probability of coalescence between two active lineages, which we

call T. If $d >> T$, the ancestors rapidly activate and slowly coalesce, which means that at the time of coalescences, there will be very many active lineages and the phylogeny will be complex (with coalescence events affecting many branches). Alternatively, if $T >> d$, coalescence follows rapidly for any pair of ancestral lineages that have activated, with the result that most coalescences involve a single branch. The tree is now as expected if there is a single, active master gene. The relative sizes of T and d are also related to the proportion of elements in the equilibrium population that are active. In the simplest case of pseudogene effect inactivations, having $T > d$ and, thus, a master gene–like tree, is associated with an equilibrium where the number of active elements is less than the square root of the total number.

13.5.5   Functional Variation between Element Copies

In addition to the presence of active and inactive elements and the impact of their presence on the expected element phylogeny, another important issue here is the possibility of advantageous element copies arising in a mobile sequence family. The advantage for such variants would typically be an increased rate of replicative transposition. With a large number of active elements per genome, n, and $2N$ genomes in the host population, one might expect new, advantaged variants to arise frequently in this population of $2Nn$ elements. A new variant of this kind would be expected to sweep through the sequence family in a two-speed process, initially replacing all active elements and subsequently replacing inactive elements much more slowly. However, the probability of spread of a new variant might be low (as a result of a low intrinsic rate of replicative transposition). Imagine that the rate of transposition per active copy is 10^{-3}, e.g. and that there is equilibrium between transposition and the combined effects of inactivation and deletion, such that an active element's probability of loss or inactivation is the same as its probability of copying itself. Now, imagine a more active variant, which has a probability of transposition raised by 10 % of its former value. Such a variant, instead of having, on average, one active descendant after one generation, would have, on average, 1.0001 descendants, and the probability that this variant would spread as a result of its advantage would only be approximately 0.0002. The important point is that the variant will arise initially in a single sequence copy, and its probability of spreading, rather than being lost by drift, may be very small.

13.6   CONCLUSIONS

This necessarily qualitative outline of some of the issues of genome evolution raises some questions concerning the forces that have shaped genome structures. Some of these processes, such as those concerned with mobile genetic elements and biases in codon usage, have long been subject to approaches involving quantitative modelling. Others, such as the effects of gene and genome duplications of gene families and the control of gene expression and its evolution, have mainly been dealt with in a descriptive and qualitative way and are only now being subjected to a quantitative approach. A major problem is whether, if we regard the process of genome duplication, for example, as an example of a Poisson process with an underlying expected rate, we will ever have enough data from the rare events which have actually taken place in evolving lineages to calculate what the underlying rate is likely to be. For many of these issues, the fundamental

problem is whether we can consider the state of the genome as being an equilibrium state in which a balance has been reached between dynamical evolutionary processes acting on the genome or whether the parameters of these underlying processes are themselves changing at such a high rate, relative to the rate of the individual events through which individual genomes change, that attempts to model equilibrium states on the basis of fixed parameters will be futile.

Probabilistic Models for the Study of Protein Evolution

J.L. Thorne

Departments of Genetics and Statistics, North Carolina State University, Raleigh, NC, USA

and

N. Goldman

EMBL-European Bioinformatics Institute, Hinxton, UK

Mathematical models are indispensable tools for characterizing the process of protein evolution, many aspects of which are not easily amenable to direct experimentation. Ideally, a model of protein evolution would provide a good description of the data and would simultaneously be parameterized in a manner that facilitates biological insight. Probabilistic descriptions of protein change are especially valuable because they engender a sound basis for likelihood-based statistical inference, and can provide the foundation for local and global alignment, phylogeny reconstruction, and prediction of protein structure and function. In this chapter, models of protein evolution are reviewed. Their strengths and limitations are emphasized.

14.1   INTRODUCTION

The relationship between genotype and phenotype is central to biology. Proteins are at the heart of this relationship at its fundamental molecular level: the DNA coding for a protein is the genotype whereas a protein's structure and its pattern of expression are phenotype. Evidence that molecular biologists and biochemists have recognized the key role of proteins in this relationship can be found, for example, in the amount of money being spent to deduce all the protein-coding sequences (the proteome) for numerous species, the tremendous enthusiasm surrounding the development of microarray technologies for measuring gene expression, and the copious intellectual capital being invested in the

development of methods for determining protein tertiary structure from protein sequence data.

The relationship between genotype and phenotype is surely as important to the study of evolution as it is to the rest of biology. Largely because of the complexity of the genotype–phenotype relationship, the process of protein evolution remains poorly understood. Many probabilistic models of protein evolution have been proposed and explored, but a model that satisfactorily combines mutation, genetic drift, and natural selection is not yet on the horizon. Nevertheless, existing models provide a statistical foundation for characterizing the process of evolution and for inferring evolutionary history. While these models still have obvious flaws, there have been substantial improvements during the last two decades.

A heightened interest in the ability of probabilistic models to extract biological information has accompanied the improvements. Much recent interest is a result of the emerging field of comparative genomics. In addition to the desire to understand protein evolution on a genomic scale, there are also tasks in comparative genomics for which understanding evolution is not the goal but for which evolution should be carefully treated because common ancestry is responsible for correlations among genomes. The extent and nature of the correlation structure is determined by the phylogeny that relates species and the processes by which genomes have evolved on these phylogenies. Correlation between proteins due to common ancestry is the implicit underlying basis of established techniques of predicting protein function via sequence database searches, global sequence alignment, and homology modeling to predict protein structure. Common ancestry also plays a key role in promising techniques for predicting the phenotypic severity of new mutations and disease contributions of single nucleotide polymorphisms (Ng and Henikoff, 2001; 2002; Stone and Sidow, 2005). All of these techniques have the potential to be improved via better treatments of protein evolution.

In this chapter, we describe some of the important features of existing models of protein evolution. As well as focusing on widely applied models, we also highlight some of the most promising research directions. Molecular evolution and comparative genomics are no longer fields where the ability to collect data is the main obstacle to progress. Instead, we think that progress in these fields is mainly limited by a lack of adequate tools for extracting information from existing data and that improved evolutionary models will inevitably lead to better tools.

14.2   EMPIRICALLY DERIVED MODELS OF AMINO ACID REPLACEMENT

14.2.1   The Dayhoff and Eck Model

Dayhoff and Eck (1968; see also Dayhoff *et al.*, 1972; 1978) introduced the most influential model of protein evolution. It describes the process of amino acid replacement in terms of a continuous-time Markov process on a phylogenetic tree, and is based upon the assumption that all sites in a protein sequence evolve independently and identically. The independence assumption is convenient because it allows the likelihood of an aligned set of protein sequences to be written as a product of likelihoods for individual alignment columns (i.e. site likelihoods).

Site likelihoods can be calculated via the pruning algorithm of (Felsenstein, 1981), mentioned in **Chapter 15** Huelsenbeck and Bollback of this book. We do not repeat the algorithm here, but we emphasize that the pruning algorithm requires the calculation of transition probabilities. In molecular phylogenetics, a transition probability is the probability of a possible state at the end of a branch on a phylogenetic tree conditional upon the state at the beginning of the branch and the amount of evolution represented by the branch (i.e. the branch length), as well as upon values of other model parameters. For the Dayhoff and Eck model there are 20 possible states, each representing one of the 20 amino acids.

The parameters of the Dayhoff and Eck model are the instantaneous rates α_{ij} of replacement of amino acid type i by amino acid type j. Computation of transition probabilities from underlying instantaneous replacement rates of a Markov process is a standard procedure, described for example by Liò and Goldman (1998). The rates in Dayhoff and Eck's formulation are constrained so that the model is time-reversible. In other words,

$$\pi_i \alpha_{ij} = \pi_j \alpha_{ji} \quad \text{for all } i \text{ and } j, \tag{14.1}$$

where the equilibrium frequency of each amino acid type k is denoted π_k and is uniquely determined by the matrix of rates (α_{ij}). Informally, the time-reversibility property means that, without additional information, there is no way to determine which of two sequences is the ancestral protein and which is the descendant protein.

In fact, the Dayhoff and Eck model is the most general 20-state time-reversible homogeneous Markov model. Although four-state models of nucleotide substitution are computationally simpler, it is interesting to note that the most general four-state time-reversible model (see Tavaré, 1986; Yang, 1994a), and even the simplest four-state model (Jukes and Cantor, 1969), were not studied until after the Dayhoff and Eck model was proposed.

For models of nucleotide substitution, all parameters are typically estimated from the aligned data set of interest. The number of parameters defining a 20-state general time-reversible (GTR) rate matrix is 209, greatly exceeding the nine parameters needed to specify a four-state GTR rate matrix. As a consequence, estimates of α_{ij} for a 20-state rate matrix are unlikely to be reliable unless the amount of data being analyzed is large, and estimates of relative rates of replacement for Dayhoff–Eck-type approaches are usually obtained prior to analysis of the aligned data set of interest. These estimates are generally based upon many data sets of aligned protein sequences and are fixed when subsequent data sets of interest are studied.

Dayhoff and Eck estimated the instantaneous rates α_{ij} implicitly, via a clever technique that relied upon comparing closely related protein sequences to derive transition probability matrices. When protein sequences are closely related, they will be identical at the majority of positions. At the few positions where the sequences differ, the cause of the difference will usually be a single amino acid replacement event because the chance that two or more replacement events occurred at a position will be negligible. By comparing closely related sequences and neglecting the possibility of multiple amino acid replacements at positions, Dayhoff and Eck were able to infer implicitly the relative rates of the different kinds of amino acid replacements. Different methods for recovering the instantaneous rates α_{ij} from results such as those presented by Dayhoff and Eck (1968) were subsequently proposed, and are reviewed by Kosiol and Goldman (2005). Goldman

et al.(1998) gave an alternative procedure to estimate rates α_{ij} directly from amino acid replacement counts.

Improved techniques for estimating the α_{ij} parameters are now available (Adachi and Hasegawa, 1996; Yang *et al.*, 1998; Adachi *et al.*, 2000; Müller and Vingron, 2000; Whelan and Goldman, 2001; Holmes and Rubin, 2002; Müller *et al.*, 2002), and we refer the reader to the original Dayhoff and Eck publication (1968; see also Dayhoff *et al.*, 1972; 1978; Kosiol and Goldman, 2005) for other details about their estimation procedure. For an insightful analysis with the original Dayhoff data, see Kishino *et al.* (1990).

Subsequent to the Dayhoff and Eck (1968) publication, Dayhoff and collaborators published updated results as additional protein sequence data became available (Dayhoff *et al.*, 1972; 1978). Conventionally, references to the 'Dayhoff model' do not simply mean the 20-state GTR model of amino acid replacement but instead are usually intended to convey both the Dayhoff and Eck (1968) parameterization of the 20-state GTR model and specific estimates of the α_{ij} parameters obtained from the results of Dayhoff *et al.* (1978).

14.2.2   Descendants of the Dayhoff Model

The widely used 'Jones-Taylor-Thornton' or 'JTT' model of amino acid replacement (Jones *et al.*, 1992b) employs the same parameterization as did (Dayhoff and Eck, 1968) but refers to estimates of α_{ij} that were derived from a much larger data set. Gonnet *et al.*(1992) also published an updated set of α_{ij} estimates. More recently, it has become computationally feasible to obtain maximum likelihood estimates of all parameters in a 20-state general time-reversible model (see Adachi and Hasegawa, 1996; Yang *et al.*, 1998; Adachi *et al.*, 2000; Whelan and Goldman, 2001; Klosterman *et al.*, 2006). Whelan and Goldman (2001) used such a technique to generate the increasingly popular WAG model, based (like the models of Dayhoff and Eck, (1968), Dayhoff *et al.*(1972; 1978) and Jones *et al.*(1992b)) on data sets containing globular proteins encoded by nuclear DNA.

Adachi and Hasegawa (1996) derived amino acid replacement rate estimates from a data set consisting of all the mitochondrial proteins from each of 20 different vertebrate species. They detected some substantial differences between their estimates and those derived from nuclear-encoded proteins. Very similar findings were made by Yang *et al.*(1998), who studied mammalian mitochondrial proteins. A possible source of this variation is that mitochondrially-encoded proteins tend to be integral membrane proteins whereas nuclear-encoded proteins are often not, placing different functional constraints on the proteins and their evolution. It is reasonable to expect that the intracellular environment of a protein and its amino acid replacement process are correlated (see also Jones *et al.*, 1994), and it has been known for some time that mitochondrially encoded proteins exhibit unusual patterns of nucleotide sequence evolution (e.g. Brown *et al.*, 1982). Parameter estimates for protein evolution models derived from chloroplast genes and retroviral polymerase proteins were obtained by Adachi *et al.*(2000) and Dimmic *et al.*(2002), respectively.

14.3   AMINO ACID COMPOSITION

Amino acid replacements tend to involve chemically similar types of amino acids. There have been numerous attempts to classify amino acids on the basis of their physicochemical properties, and physicochemical distances among amino acid types have been proposed

(e.g. Grantham, 1974; Taylor and Jones, 1993). However, these physicochemical distances between amino acid types are unlikely to directly reflect the propensity for amino acid replacements to occur. Studies have been made relating amino acid properties to evolutionary patterns (e.g. Xia and Li, 1998), but these have not led to evolutionary models. The Dayhoff–Eck approach is appealing because estimates of relative amino acid replacement rates are empirically derived.

However, although the Dayhoff–Eck approach reflects the tendency for amino acid replacements to involve similar amino acid types, it describes evolution of the 'average site' in the 'average protein'. In reality, there is variability of amino acid replacement patterns among proteins. Certain proteins might be proline-rich, others might be leucine-rich, and still others might possess their own distinct patterns of amino acid composition. Dayhoff-type models can be modified to allow variation in composition of amino acids among proteins. Let us denote by $\hat{\pi}_i$ and $\hat{\alpha}_{ij}$ the amino acid frequencies and replacement rates estimated with a Dayhoff-type approach (i.e. from a database of aligned protein sequences under the assumption that all families in the database have common composition and replacement rates), and by π'_i and α'_{ij} the corresponding values we will choose to use in the analysis of a particular protein. Then, to allow variation of amino acid composition among proteins, the π'_i can be treated as parameters specific to each protein of interest. This is achieved by forcing the α'_{ij} for $i \neq j$ to obey

$$\alpha'_{ij} = \frac{\pi'_j}{\hat{\pi}_j} \hat{\alpha}_{ij},$$

(Cao *et al.*, 1994). The resulting replacement process defined by the α'_{ij} combines empirical information derived from databases (the $\hat{\alpha}_{ij}/\hat{\pi}_j$, also known as *exchangeabilities* – (Whelan and Goldman, 2001)) with the amino acid frequencies for the particular protein under study (π'_j), now estimated from that data set. Note that this approach maintains time reversibility (14.1). The benefit of this hybrid parameterization can be a sizeable improvement in model fit (Cao *et al.*, 1994). It is also attractive because it maintains the biologically realistic property of allowing amino acid replacements to occur among chemically similar amino acids, and for the pragmatic reason that estimation of the 20 amino acid frequencies π'_j from individual protein alignments is computationally tractable and seems statistically robust. Goldman and Whelan (2002) have obtained even greater improvements in model fit with a more general parameterization that makes the α'_{ij} a function of $\hat{\alpha}_{ij}$, the frequencies of the amino acid being replaced (π'_i and $\hat{\pi}_i$), and the frequencies of the replacement amino acid (π'_j and $\hat{\pi}_j$). The use of these parameterizations has thus been both to increase our understanding of the importance of particular amino acid residues in different proteins and to improve robustness of phylogenetic inferences.

14.4   HETEROGENEITY OF REPLACEMENT RATES AMONG SITES

Not only there is a variability of amino acid replacement among proteins but also there is variability of amino acid replacement rates among sites within a single protein. Yang (1994b) introduced a practical method for incorporating heterogeneity of evolutionary rates among sites into models of nucleotide or amino acid substitution (see **Chapter 15**).

Yang's innovation was to discretize a continuous gamma distribution of rates among sites into a relatively small number C of categories. Evaluation of a likelihood with Yang's discrete gamma treatment of variation of rates among sites requires an amount of computation that is approximately a factor C more than would be needed if all sites were assumed to share identical rates. Yang (1994b) demonstrated that discretization of a gamma distribution into a relatively small number of rate categories (e.g. five or six) often fits data about as well as more general (and more computationally difficult) approaches. It is now convincingly established that, for the majority of proteins, allowing heterogeneity of nucleotide substitution rates over sites is a great improvement over models that assume homogeneity of evolutionary rate, a fact partly attributable to the triplet coding nature of DNA and to the structure of the genetic code. It is also now known that amino acid replacement models often fit data much better when allowance is made for rate variation among sites (e.g. Yang *et al.*, 1998; Goldman and Whelan, 2002). This has confirmed that rate variation over protein sites is a widespread evolutionary phenomenon, that should be considered in all phylogenetic analyses.

14.5   PROTEIN STRUCTURAL ENVIRONMENTS

Although allowing for particular proteins' distinct amino acid compositions and among-site rate variation provides a large improvement in fits of models of protein evolution, the models described so far shed little light on the cause of the variation. It is clear, from considering protein structure and function, that at least some of the variability will be associated with the structural environment of a site. For example, consider the solvent accessibility of a site. A site on the surface of a globular protein will be exposed to solvent, typically water. Sites with high solvent accessibility therefore tend to be occupied by hydrophilic amino acids. In contrast, sites buried in the interior of a protein are less accessible to solvent and are apt to be occupied by hydrophobic amino acids. Further, exposed sites tend to evolve about twice as fast on average as buried sites (Goldman *et al.*, 1998). This is most likely because residues at buried sites interact with many neighboring residues; an amino acid replacement at an exposed surface site is less likely to disrupt the position of other protein residues than is a residue at a buried site.

One of the most striking findings in the study of protein structure has been that proteins' secondary and tertiary structure usually changes very slowly during evolution. In cases where homologous proteins are known to perform the same biological functions, it is often the case that their structures are very similar even when the sequences that code for them are quite diverged. In other words, protein sequence evolution tends in some sense to occur at a higher rate than the evolution of protein structure (e.g. Chothia and Lesk, 1986; Russell *et al.*, 1997). This tendency can be exploited by models of amino acid replacement. Because structure changes more slowly than does sequence, a group of homologous protein sequences is likely to share a common underlying structure. Homologous amino acid residues (i.e. those that are in the same alignment column) are likely to be in a similar structural environment. For example, if a residue from one protein is part of an α helix, then other sequences' residues in the same alignment column are also likely to be in an α helix. If the tertiary structure of one protein sequence in an alignment has been experimentally determined, then each alignment column can be assigned a structural environment and thus a separate 20-state GTR model can be estimated for

each environment (e.g. Overington *et al.*, 1990; Lüthy *et al.*, 1991; Topham *et al.*, 1993; Wako and Blundell, 1994a; 1994b; Koshi and Goldstein, 1995; 1996; Thorne *et al.*, 1996; Goldman *et al.*, 1998).

Further, the structural environment at one site in a protein is not independent of the environment at other sites. For example, if site i is in an α-helix environment, then site $i + 1$ is also probably in the α helix. It is possible to use this knowledge to further improve models of protein evolution. One approach has been the modeling of the organization of structural environments along a protein sequence as a first-order Markov chain. In protein sequence analysis, this approach was first used to predict secondary structure from single protein sequences (Asai *et al.*, 1993; Stultz *et al.*, 1993). The basis for the prediction was the tendency for certain kinds of amino acids to be found in certain secondary structure environments. Such models are referred to as *hidden Markov models* (HMMs) because the secondary structure underlying the sequence is not directly observed. Instead, it is 'hidden' but can be estimated on the basis of the amino acids that encode the protein sequence. A first-order Markov chain for the organization of protein structure along a sequence is not ideal because in reality protein structure is three dimensional rather than linear, and the structural environment of a site may be strongly influenced by other sites that are nearby in the tertiary structure but are far separated along the linear protein sequence. However, a first-order Markov model for structural organization is computationally tractable and is clearly superior to assuming independence of structural environments among sites.

The HMM for organization of structural environment can be combined with the models of amino acid replacement for each structural environment to generate an integrated model of protein sequence evolution. This has been done for the study of globular proteins (Thorne *et al.*, 1996; Goldman *et al.*, 1998), transmembrane proteins (Liò and Goldman, 1999), and mitochondrial proteins (Liò and Goldman, 2002). With this approach, each category k of structural environment has its own equilibrium amino acid frequencies (π_i^k) and its own rates of amino acid replacement (α_{ij}^k).

The algorithms used to calculate the likelihood with a HMM of protein structure were first applied to molecular sequence data by Churchill (1989) and are given in detail by Thorne *et al.*(1996). Felsenstein's (1981) pruning algorithm is used to compute likelihoods conditional on the unobserved states of the HMM, and the HMM's transition probabilities are incorporated to deal with uncertainty about which structure state each site belongs. The likelihood calculations now have a computational burden that is approximately a factor S more than without the HMM, where S is the number of distinct structure states considered, and this remains fast enough to permit maximum likelihood phylogenetic inference.

Algorithms for predicting the underlying protein secondary structure with a HMM also exist (Churchill, 1989; Asai *et al.*, 1993; Stultz *et al.*, 1993; Goldman *et al.*, 1996) but these will not be detailed here. Predictions of secondary structure that are based upon combined explicit treatment of protein structural organization and protein evolution have several potential advantages over methods for protein secondary structure prediction that are not based upon an explicit evolutionary model (Goldman *et al.*, 1996). Although aligned sequences are likely to share a common underlying secondary structure, these sequences are not independent realizations of some process. Instead, aligned sequences are related via an evolutionary tree. It is the phylogeny relating the sequences that is responsible for the correlation structure among sequences (see Felsenstein, 1985; Harvey and Pagel, 1991). Treatment of sequences as independent realizations of some process or

any other *ad hoc* weighting of sequences may be less desirable than explicit treatment of correlation structure.

Studies using these methods have shown the importance of structural environments to protein evolution. Different secondary structure elements do exhibit typical and distinct patterns of evolution, presumably related to different residues' propensities to adopt the local structures and biochemical properties required of protein functions. It is also clear that taking a phylogenetic approach could be of advantage to other sequence analyses aimed at investigating protein function, most obviously the simple goal of protein structure prediction which remains difficult even after many years of intensive research and competition (e.g. Kryshtafovych *et al.*, 2005).

Although they change slowly, secondary structure and solvent accessibility do evolve. Kawabata and Nishikawa (2000) have empirically estimated rates of change among secondary structure categories and solvent accessibility environments. This is a challenging endeavor, particularly because protein alignment becomes difficult when proteins being compared are so diverged as to have moderately different structures. Kawabata and Nishikawa base a procedure for recognizing distantly related protein homologs on their model of secondary structure and solvent accessibility change and they show that this procedure performs well. The future development of these or other ideas (e.g. see Grishin, 1997) into a complete model of protein sequence and structure evolution would be of great value.

14.6   VARIATION OF PREFERRED RESIDUES AMONG SITES

Some, but clearly not all, variation of amino acid composition and replacement rates among sites can be explained by consideration of structural environments among sites. The specific biochemical function of a protein, and even of its individual sites, mean that the evolution of every site of every protein takes place under different constraints, potentially leading to different evolutionary patterns. Bruno (1996) (also see Halpern and Bruno, 1998) made the first progress in this respect, devising a model that allowed each site in a protein to have its own equilibrium frequencies. We denote the frequency of amino acid type i at site s by $\pi_{i,s}$. This highly flexible approach suffers from potential overparameterization problems because the 20 amino acid frequencies per site add 19 degrees of freedom per site to the model. To remedy the overparameterization problems, it is not sufficient to restrict analyses to data sets consisting of a large number of sequences because, if sequences in a data set are closely related, then the sequences will be highly correlated with one another and good estimates of $\pi_{i,s}$ may still not be obtained confidently. Therefore, the approach of Bruno should work best when a data set contains a large number of highly diverged sequences.

Although this approach of allowing variation of 'preferred' residues among sites in a model of protein evolution is not computationally convenient, it is biologically attractive. The Dayhoff-type models allow the tendency of amino acid replacements to involve physicochemically similar amino acid types to be reflected in estimates of the replacement rates α_{ij}. On the other hand, the tendency for amino acid replacements to involve chemically similar amino acids may instead be largely attributable to a tendency for the values of $\pi_{i,s}$ to be positively correlated for physicochemically similar amino acids. These two explanations for the tendency of amino acid replacements to involve

physicochemically similar amino acids are not mutually exclusive, but little is known about their relative importance.

By adopting a Bayesian perspective, Lartillot and Philippe (2004) largely overcome the overparameterization concerns associated with variation of 'preferred' amino acid types among sites. They assume each site belongs to some amino acid replacement process category, but that the category is not directly observed. Different replacement categories share a common set of amino acid exchangeability parameters taken from existing standard models, but have different equilibrium amino acid frequencies. The number of categories and their frequencies are jointly determined by a Dirichlet process prior distribution, and the set of 20 different amino acid frequencies for a given category has a Dirichlet prior. This Bayesian approach, with prior distributions for the number of replacement categories, the frequencies of the categories, and the amino acid composition of each category, enables Lartillot and Philippe to greatly reduce the potential for overparameterization that occurs otherwise. They convincingly demonstrate that their Bayesian scheme is a substantial improvement over models that do not permit variation of preferred residues among sites.

Holmes and Rubin (2002) also investigate models that assume each site of a protein belongs to an amino acid replacement category that is not directly observed. Their innovative expectation-maximization (EM) algorithm yields maximum likelihood estimates of amino acid replacement rates for each replacement category. Although their frequentist procedure may be subject to potential overparameterization problems and requires the number of replacement categories to be prespecified, it has the advantage of not assuming that a particular protein site belongs to the same replacement process call for all of its evolutionary history. Instead, the EM algorithm can simultaneously estimate the rate at which sites switch among the replacement processes being modeled.

This impressive flexibility of the Holmes and Rubin procedure has the potential to assist in identifying biologically interesting cases where the evolutionary behavior of a site changes on a phylogeny. Building upon a practical adaptation by Tuffley and Steel (1998) of ideas first described by Fitch and colleagues (e.g. Fitch and Markowitz, 1970; Fitch, 1971), several groups have shown that evolutionary patterns at sites or codons change over time and that these changes in pattern should not be ignored by evolutionary models (e.g. Galtier, 2001; Huelsenbeck, 2002; Guindon *et al.*, 2004; Philippe *et al.*, 2005; Inagaki *et al.*, 2004). This characteristic of protein evolution, somewhat related to Fitch's (1971) idea of concomitantly variable codons or 'covarions' and also known as *heterotachy* (Lopez *et al.*, 2002), may be attributable to changes in protein structural constraints over long evolutionary times. Absence of heterotachy in evolutionary models has been implicated in failures of phylogenetic inference methods, particularly in cases of long-branch attraction (e.g. Inagaki *et al.*, 2004; Delsuc *et al.*, 2005).

14.7 MODELS WITH A PHYSICOCHEMICAL BASIS

An alternative approach to statistical models that implicitly reflect the tendency for amino acid replacements to involve physicochemically similar amino acid types is for this tendency to be reflected via the explicit inclusion of physicochemical properties into a model. Koshi *et al.*(1999) chose to quantify the physicochemical attributes of amino acid types according to hydrophobicity and bulk–properties that are expected to be of great importance to protein structure. Their approach assumes that each site in a protein belongs

to exactly one of several classes, with each class k occurring with probability γ_k. The probability π_i^k of amino acid i in class k is $\pi_i^k = e^{F_k(i)} / \sum_j e^{F_k(j)}$, where $F_k(i)$ is a measure of the suitability of amino acid type i in structural environment k. Koshi *et al.*(1999) investigated the use of suitability functions $F_k(i)$ that depended on the hydrophobicity H_i and the bulk B_i of the amino acids in both linear ($F_k(i) = \beta_k^H H_i + \beta_k^B B_i$) and quadratic ($F_k(i) = \beta_k^H (H_i - H_0^k)^2 + \beta_k^B (B_i - B_0^k)^2$) forms. Here, β_k^H, β_k^B, H_0^k, and B_0^k represent a relatively small number of additional free parameters (two or four per site class), making this approach statistically attractive in comparison to the 20-state GTR model, which assumes all sites experience identical evolutionary processes and, even so, requires 209 parameters to be estimated. The instantaneous rates of amino acid replacement for the Koshi *et al.*(1999) model are then defined as:

$$\alpha_{ij}^k = \begin{cases} \gamma_k & \text{if } F_k(j) > F_k(i) \\ \gamma_k e^{F_k(j) - F_k(i)} & \text{if } F_k(j) \le F_k(i). \end{cases}$$

This approach has not been widely pursued but it can yield substantially better fits to data than Dayhoff-type models (Koshi *et al.*, 1999). It will be interesting to determine the reason or reasons for these good fits. Aside from the obvious conclusion that the suitability of amino acid types at certain sites in a protein is indeed well described by the hydrophobicity and bulk preferences, another possible reason for the good performance of this model is more mundane. This parameterization scheme is very flexible, e.g. allowing for variation of preferred residue types among sites, and some of the improvement provided by this model may be attributable simply to the parametric forms for α_{ij}^k. This could be addressed by evaluating variants of the model with the formulae for the $F_k(i)$ modified by assigning to each amino acid type i the hydrophobicity and bulk of a randomly selected amino acid type j. If permutation or randomization experiments of this sort tend to result in fits comparable to those found by Koshi *et al.*(1999), then it would be the form of the α_{ij}^k rather than the actual hydrophobicity and bulk attributes themselves that are responsible for the good fit.

14.8   CODON-BASED MODELS

In reality, evolution occurs at the DNA level, with protein change being a consequence of phenomena such as nucleotide sequence mutation, genetic drift, and natural selection. It therefore makes sense to model protein evolution in terms of codons rather than amino acid types (Schöniger *et al.*, 1990; Goldman and Yang, 1994; Muse and Gaut, 1994). Codon-based models are typically framed in terms of the 61 codons that specify amino acids in common genetic codes. The three nucleotide triplets that represent stop codons are not allowed by most codon-based models.

Existing codon-based models follow largely the same approach as the Dayhoff model for amino acids. Codon replacements are modeled as a Markov process, with the instantaneous rate (α_{ij}) of change from codon i to codon j usually being defined as the product $\alpha_{ij} = \pi_j s_{ij}$ where π_j is the frequency of codon j. The exchangeabilities s_{ij} are symmetric ($s_{ij} = s_{ji}$), ensuring reversibility (14.1), and are themselves often products of parameters representing phenomena such as transition–transversion bias and the strength of selection acting on each mutation.

Codon-based models have become quite refined. For instance, Pedersen *et al.*(1998) designed a model to reflect the fact that CpG dinucleotide levels are depressed in lentiviral genes. Codon-based models are also well suited for testing hypotheses regarding natural selection. Through their parameterization of the exchangeabilities s_{ij}, they provide a basis for estimating synonymous and nonsynonymous nucleotide substitution rates (Muse, 1996; Yang and Nielsen, 2000) and have received considerable attention for their potential ability to detect both diversifying natural selection (e.g. Nielsen and Yang, 1998; Yang *et al.*, 2000; Massingham and Goldman, 2005; see **Chapter 12** (Yang), this volume) and purifying natural selection (Massingham and Goldman, 2005).

Halpern and Bruno (1998) have made some progress reconciling codon-based substitution rate matrices with molecular population genetics, explaining variation of preferred amino acid types among sites in terms of selective forces operating at the sites. While their approach may be overly rich in parameters and based upon restrictive assumptions about natural selection, they have taken an important step toward narrowing the gulf between population genetics and the models employed in phylogenetics.

Widely used codon-based models have some limitations. For instance, most assume that all mutational events result in exactly one nucleotide position changing identity. Spontaneous mutations often result in changes that are more complicated than a simple point mutation or than an insertion or deletion (see, e.g. Ripley, 1999). It seems reasonable that some of these more complicated changes are fixed in evolution. There is evidence that a moderate number of evolutionary changes are the result of mutational events that simultaneously affect two consecutive positions in a sequence (Averof *et al.*, 2000). Evolutionary models that allow for these changes now exist (Whelan and Goldman, 2004), and should be the focus of further research in the near future.

14.9 DEPENDENCE AMONG POSITIONS: SIMULATION

A limitation of widely used models of protein evolution is the assumption that the evolution of one position is independent of the sequence at other positions. Proteins are obviously three dimensional, and evolution at one site in a protein is likely to be affected by the amino acids at sites that physically neighbor it in the tertiary structure of the protein. Covariation of residues at different sites may indicate that these sites are nearby in the tertiary structure of the protein, and has been used to make inferences about protein tertiary structure and function (e.g. Pazos *et al.*, 1997; Pollock *et al.*, 1999; Tillier and Lui, 2003).

Parisi and Echave (2001; see also Bastolla *et al.*, 2003) have introduced a noteworthy technique for simulating the evolution of protein-coding genes subject to constraints imposed by protein structure. They begin their simulations with a reference protein that has known tertiary structure, and assume that this structure does not change over time. They then employ a sequence−structure distance scoring function to assess how well protein sequences fold into the known structure. Such scoring functions have been actively developed and are well established for predicting protein folds from protein sequence data. The underlying idea behind the Parisi and Echave technique is that the sequence−structure compatibility function can be employed to help parameterize rates of nonsynonymous substitutions.

As with conventional codon models (e.g. Goldman and Yang, 1994; Muse and Gaut, 1994), Parisi and Echave force the replacement rate between codons i and j to be 0 if i and j differ by more than one nucleotide or if a stop codon is involved. If the difference between i and j represents a single synonymous nucleotide change then the replacement rate is modeled as in conventional codon models, reflecting codon frequencies and different mutational processes that act on DNA. In the Parisi and Echave approach, however, nonsynonymous replacement rates from conventional codon models are multiplied by a factor of either 0 or 1, depending on the sequence–structure distance for the newly arising sequence containing codon j. If the distance is smaller than some prespecified value then the factor has a value of 1, permitting mutations that are considered to perturb the protein structure by not more than a set amount. Otherwise, this factor has a value of 0, disallowing evolutionary changes that lead to biologically implausible sequences.

Through simulations, Parisi and Echave (2001) convincingly demonstrated both that their model captured information that would be missed by other models of protein evolution and that this information capture could occur without requiring large numbers of free parameters to be added to the model. In a specific example, the simulation studies showed tendencies of certain amino acids to preferentially occupy certain sites in the left-handed β-helix domain of UDP-N-acetyl glucosamine acetyltransferases. When a group of actual acetyltransferases with this helix domain was examined, qualitatively similar tendencies were observed. To date, the Parisi and Echave model has been employed for simulation of evolution rather than for inference from a set of observed protein-coding sequences. Phylogenetic inference with models that make allowance for dependence among sites is computationally much more challenging.

14.10   DEPENDENCE AMONG POSITIONS: INFERENCE

Fornasari *et al.*(2002; see also Bastolla *et al.*, 2006) approximated the behavior of the full Parisi and Echave model with a 20-state amino acid replacement model at each position. The resulting model has independent changes among amino acid positions but does not force all of the positions of a protein to experience identical replacement processes. This is accomplished via simulating according to the Parisi and Echave codon-substitution model many times. For each position in a protein, the number of times that simulated changes occur between each pair of amino acid types can be recorded and rates of amino acid replacement for each protein position can be obtained based upon these counts of simulated changes.

A model of change permitting dependence among sequence positions poses enormous challenges for conventional evolutionary inference procedures that use the pruning algorithm of Felsenstein (1981). The difficulty is that Felsenstein's algorithm relies upon converting instantaneous evolutionary rates to transition probabilities. With independently evolving nucleotides or amino acids or codons, the number of rows and columns in the rate and transition probability matrices equals 4 or 20 or 61, respectively. But with a relatively general dependence structure, the number of rows and columns in the rate and transition probability matrices equals the number of possible sequences. Because the number of possible sequences grows exponentially with sequence length, Felsenstein's

pruning algorithm becomes computationally intractable with dependent change among sequence sites unless sequence length is extremely short.

A promising alternative to Felsenstein's inference procedure has been explored by Jensen and Pedersen (2000) and Pedersen and Jensen (2001) as part of their efforts to understand the effects of overlapping reading frames and context-dependent mutation on molecular evolution (see also Siepel and Haussler, 2004; Hwang and Green, 2004; Christensen *et al.*, 2005). Jensen and Pedersen augmented the observed sequence data at the tips of evolutionary trees with 'sequence paths'. The sequence path on a particular branch of a phylogeny specifies all of the changes that occurred on the branch. For each change, the sequence path contains information about the time at which the change occurred, the sequence position at which the change occurred, and the nature of the change. Although the sequence path is not directly observed, Markov chain Monte Carlo techniques can be used to randomly sample possible sequence paths according to the appropriate probability density. The big advantage of the sequence path approach to inference is that it is often computationally tractable in cases where Felsenstein's pruning algorithm is difficult to apply because transition probabilities cannot be calculated or well approximated.

We illustrate the sequence path approach to inference with the technique of Robinson *et al.*(2003), an inference method that combines the innovations of Parisi and Echave (2001), Jensen and Pedersen, (2000) and Pedersen and Jensen (2001). The Robinson *et al.* model of protein-coding evolution is designed for analyzing aligned protein-coding DNA sequences that, when translated, are assumed to share a known protein tertiary structure that does not change during evolution. For simplicity, we discuss evolutionary inference for data sets consisting of only two sequences. This is the case considered by Robinson *et al.*(2003). However, the inference procedure has subsequently been extended to data sets with three (Robinson, 2003) or more (Rodrigue *et al.*, 2005) sequences.

To measure the compatibility between the encoded amino acid sequence of a DNA sequence i and the known tertiary structure, an empirically derived system originally developed for protein fold recognition with globular proteins (Jones *et al.*, 1992a; Jones, 1999) is employed. This system returns two scores for any protein sequence that is folded into a particular structure. One of these scores, $E_s(i)$, is the solvent accessibility score for sequence i when translated and folded into the known structure; the other $E_p(i)$, is the pairwise interaction score for sequence i when translated and folded into the known structure. $E_s(i)$ and $E_p(i)$ loosely resemble free energies: both will be negative when sequence and structure are compatible, and sequence–structure compatibility deteriorates as the two scores rise.

The Robinson *et al.*(2003) model has the parameter κ to differentiate between transitions and transversions and the parameter ω to differentiate between nonsynonymous and synonymous substitutions. It also has parameters π_A, π_C, π_T, and π_G to represent what the frequencies of the nucleotide types would be if all natural selection was absent. Because the model permits a general dependence structure, rates of change are defined at the whole-sequence level rather than at the codon or individual position levels. We now use α_{ij} to denote the rate of change from DNA sequence i to DNA sequence j, with the value of α_{ij} forced to be zero unless sequences i and j differ at exactly one position. If sequence j has nucleotide type $h \in \{A, C, G, T\}$ at the one position where i and j differ,

the rate of change is given by:

$$\alpha_{i,j} = \begin{cases} u\pi_h & \text{for a synonymous transversion} \\ u\pi_h\kappa & \text{for a synonymous transition} \\ u\pi_h\omega e^{s(E_s(i)-E_s(j))+p(E_p(i)-E_p(j))} & \text{for a nonsynonymous transversion} \\ u\pi_h\kappa\omega e^{s(E_s(i)-E_s(j))+p(E_p(i)-E_p(j))} & \text{for a nonsynonymous transition.} \end{cases}$$

(14.2)

The parameters s and p in (14.2) represent the importance of solvent accessibility and pairwise interactions, respectively. When s and p are both zero, protein structure does not influence protein-coding DNA evolution and substitutions occur independently among codons. When these parameters are both positive, the biologically plausible situation of proteins evolving to be compatible with their structure results. While it is formally possible for s and p to be negative, this is biologically unrealistic, representing the situation where proteins evolve to be incompatible with their tertiary structure.

Although Felsenstein's pruning algorithm is not computationally feasible with this model because of the high dimensionality of the rate and transition probability matrices, the inference ideas of Jensen and Pedersen (2000) and Pedersen and Jensen (2001) can be adopted. Using a sequence path approach, what must be calculated instead is the probability of the events described by any given path (ρ). To do this, we need to know the rate of change from each successive sequence in the path, and the probability that when each change occurs, the result is the next sequence in the path. Both of these are readily derived from (14.2). The rate of change away from any sequence i (i.e. to any sequence that differs from i) is:

$$\alpha_{i,\bullet} = \sum_k \alpha_{i,k}.$$

(14.3)

Since rates of change from one sequence to another are 0 unless the two sequences differ at exactly one position, the number of sequences that differ from sequence i at exactly one position cannot exceed the length of sequence i multiplied by 3. The sum in (14.3) is therefore computationally tractable, because most terms being added are 0.

For a particular sequence path ρ from an ancestral sequence i to a descendant sequence j, let q be the total number of nucleotide substitutions on the path and let $t(z)$ be the time of the zth substitution. The time the branch begins will be $t(0) = 0$ and the time the branch ends will be $t(q + 1) = 1$. Because the scaling parameter u can be adjusted, the time at which the branch ends can always be considered to be 1. The sequence that exists immediately after the zth substitution will be represented by $i(z)$, with the initial sequence i now written as $i(0)$ and the final sequence $j = i(q + 1) = i(q)$. The sequence path ρ is then fully specified by $t(0)$, $t(1)$, ..., $t(q)$, $t(q + 1)$ and $i(0)$, $i(1)$, ..., $i(q)$, $i(q + 1)$. Let θ be a vector representing all model parameters, the probability density of the sequence path is then given by:

$$p(\rho|\theta, i) = \left(\prod_{z=1}^{q} \frac{\alpha_{i(z-1),i(z)}}{\alpha_{i(z-1),\bullet}} \alpha_{i(z-1),\bullet} e^{-\alpha_{i(z-1),\bullet}(t(z)-t(z-1))} \right) e^{-\alpha_{i(q),\bullet}(t(q+1)-t(q))}$$

$$= \left(\prod_{z=1}^{q} \alpha_{i(z-1),i(z)} e^{-\alpha_{i(z-1),\bullet}(t(z)-t(z-1))} \right) e^{-\alpha_{i(q),\bullet}(t(q+1)-t(q))}.$$

(14.4)

Here, the product over z gives the probability density for the q sequence changes from $i(z-1)$ to $i(z)$ occurring at times $t(z)$, and the final term is the probability of no further change occurring in the time interval from the final substitution at $t(q)$ until the time $t(q+1) = 1$ at which the path ends. By combining a prior distribution for θ with (14.4) and with the expression for the stationary probability for sequence i, the Metropolis–Hastings algorithm (Metropolis *et al.*, 1953; Hastings, 1970) can be applied to perform Bayesian inference (Robinson *et al.*, 2003).

Initial applications of this model yielded biologically plausible positive estimates of the s and p parameters and indicated that the evolutionary information leading to the estimates of these two parameters was quite distinct from the information contributing to the ω parameter (Robinson, 2003; Robinson *et al.*, 2003). Rodrigue *et al.*(2005; 2006) have carefully evaluated evolutionary models with rate parameterizations similar to that of Robinson *et al.*(2003). Employing a new model comparison procedure (Lartillot and Philippe, 2004; 2006) as well as inference based upon sequence paths, Rodrigue *et al.*(2006) demonstrate that evolutionary models with dependence among sequence positions due to tertiary structure are statistically superior to those without dependence. However, these authors also conclude that available treatments of protein tertiary structure are not sufficient to produce satisfactory evolutionary models. They find that adding rate heterogeneity among sites via the discrete gamma technique of Yang (1994b) generates model fit improvements beyond those realized solely by incorporating tertiary structure.

One reasonable interpretation of these findings is that sequence–structure compatibility measures yield models of protein evolution that are biologically meaningful and statistically valuable, extracting information that is otherwise not utilized, yet which are still incomplete summaries of natural selection. Although the Robinson *et al.*(2003) model was designed to reflect dependence due to protein tertiary structure, the same inference strategy could be applied to add evolutionary dependence due to other aspects of phenotype (e.g. protein expression or protein function). This could be done by incorporating scores for the other phenotypic aspects into the rates of (14.2).

14.11 CONCLUSIONS

After nearly 40 years, progress continues to be made with probabilistic models that give increasingly good statistical descriptions of the patterns of protein evolution. But a useful model is not simply one that fits data well. For a model of protein evolution to help us to understand processes and pressures acting on evolving genomes, it is also important to establish a solid connection between the model parameters and the biological features that they represent. Although the best models of protein evolution are now far more realistic than the earliest models, understanding of protein evolution is still at a primitive stage. Evidence for variation in evolutionary processes and evolutionary rates among sites is strong. Unfortunately, the extent to which this variation can be partitioned into components of interest (e.g. the structural environments of a site, the protein to which the site belongs, mutational tendencies at the site, interactions with other sites, protein function, etc.) remains unclear.

Ideally, protein evolution should be linked to the DNA that codes for the protein, the structure of the protein, the expression patterns of the protein, the function of the protein, and external influences on the protein that act via natural selection. Progress on modeling protein evolution will depend in part on the advances that are made in techniques for *in silico* prediction of phenotype from genotype. Protein-coding DNA that results in deleterious phenotypes is unlikely to be ancestral to extant DNA. Accurate *in silico* prediction of phenotype from genotype would lead to evolutionary models in which substitution rates are high for selectively advantageous changes and low for deleterious changes. Existing systems for *in silico* mapping of genotype to phenotype tend to be crude and this is one reason there is so much room for improvement in models of protein evolution.

Despite the primitive nature of models of protein evolution, software implementing those models for data analysis is in great demand. It must be emphasized that even the existing models of protein evolution, however unrealistic, are better than having no models at all. Explicit evolutionary models provide a basis upon which homologous sequences can be recognized, phylogenetic history can be inferred, evolutionary hypotheses can be evaluated, protein structure can be predicted, and our understanding of evolution can be quantified. For these reasons, the development of model-based approaches to study protein evolution is an attractive, active, and valuable area of research.

Application of the Likelihood Function in Phylogenetic Analysis

J.P. Huelsenbeck and J.P. Bollback

Department of Biology, University of Rochester, Rochester, NY, USA

The likelihood of a phylogenetic tree is proportional to the probability of observing the comparative data (such as aligned DNA sequences) conditional on the tree. The likelihood function is important because it is the vehicle that carries the observations. The likelihood function can be used in two ways to infer phylogeny. First, the tree that maximizes the likelihood can be chosen as the best estimate of phylogeny; this is the method of maximum likelihood. Second, a prior probability distribution on trees can be specified and inferences based upon the posterior probability distribution of trees; this is the approach taken by Bayesians. Although maximum likelihood and Bayesian inference are similar in that the same models of DNA substitution can be used to calculate the likelihood function, they differ in their interpretation of probability. Markov chain Monte Carlo (MCMC) can be used to approximate the posterior probabilities of trees. MCMC also makes it possible to perform comparative analyses that accommodate phylogenetic uncertainty.

15.1 INTRODUCTION

How can the evolutionary history of life be inferred? This problem – called the phylogeny problem – has generated intense interest since publication of *Origin of Species*. The phylogeny problem has by no means been 'solved'; debate continues to center around the merits of competing methods of phylogeny inference, the applicability of concepts such as the accuracy of competing methods, how phylogenies can be used in comparative analyses, and even whether the phylogeny problem is one of statistical inference (Farris, 1983).

Sometimes the choice of phylogenetic method does not appear to matter; the same phylogenetic tree is obtained regardless of the details of the analysis. This type of situation is, of course, an ideal one. Often, however, the details of the phylogenetic analysis do matter; different phylogenies are obtained if different phylogenetic methods are used

or even if the same method of analysis is used under different assumptions. What is the biologist to do when different phylogenetic methods give different trees? Typically, biologists use one or more of the following arguments to choose among competing methods (and by extension, among the competing trees produced by these methods):

Expected accuracy. Sometimes the choice among phylogenetic methods is based upon simulation studies of the expected accuracy of competing methods under specific evolutionary scenarios. Numerous studies have used computer simulation to investigate the ability of different phylogenetic methods to accurately reconstruct phylogeny under idealized models of DNA substitution (Charleston, 1994; Gaut and Lewis, 1995; Huelsenbeck, 1995a; 1995b; Huelsenbeck and Hillis, 1993; Kuhner and Felsenstein, 1994; Nei, 1991). These types of studies have provided useful information on the consistency (ability to correctly estimate phylogeny given an unlimited number of data), efficiency (ability to correctly estimate phylogeny with a limited number of data), and robustness (ability to correctly estimate phylogeny when the assumptions of the analysis are violated) of different phylogenetic methods under a variety of evolutionary scenarios. Specifically, we know that factors such as the overall substitution rate and the relative lengths of the branches of phylogenies are among the main determinants of the performance of methods. Several disturbing properties of phylogenetic methods have also been uncovered in these studies, such as the complete failure of many phylogenetic methods under some combinations of branch length (e.g., the well-known 'Felsenstein zone' in which many phylogenetic methods can converge to the incorrect tree even with an infinite amount of data; see Felsenstein, 1978).

Philosophy. Some methods are considered to be more acceptable than others based upon philosophical concepts. For example, the parsimony method has been justified based upon the ideas of hypothetical deductive reasoning (Gaffney, 1979), falsificationism (Wiley, 1975), and, more recently, on Sir Karl Popper's concept of corroboration (Kluge, 1997; Siddall and Kluge, 1997). Other more explicitly statistical methods have justifications based upon reasoning in the face of uncertainty and use probability models to express the uncertainty of different possible outcomes (see Edwards, 1972).

Flexibility. Some methods of phylogenetic inference can be applied to a wide variety of data types and models of evolution. For example, the maximum parsimony method can easily be used to infer phylogeny from molecular or morphological data or from monomorphic or polymorphic characters. The method of maximum likelihood can be applied to estimate parameters from even complex models of evolution.

Testability. It should be possible, in principle, to test the assumptions made in the course of a phylogenetic analysis (Penny *et al.*, 1992). This is easy to do using explicitly statistical methods, such as likelihood and distance methods (Goldman, 1993; Rzhetsky and Nei, 1995), but very difficult to do using other methods. Moreover, as biologists turn their attention to comparative questions (problems that depend upon phylogeny, but for which the phylogeny is not the central question), the ability of a method to be tailored to address specific evolutionary questions becomes more important.

In this chapter, we concentrate on phylogenetic methods that are based upon the likelihood function – the methods of maximum likelihood and Bayesian inference. We

believe that of the many methods of phylogenetic inference that have been proposed, these methods have the greatest potential to simultaneously satisfy the criteria posed above. Although maximum likelihood and Bayesian inference are very similar in that the likelihood function carries the information about phylogeny contained in the data, these two methods have very different concepts of probability. In a field that has experienced vigorous debate on the relative merits of different methods of phylogenetic inference, it is perhaps safe to predict that the next debate in systematics will focus on the merits of maximum likelihood versus Bayesian inference of phylogeny (mirroring debates in the statistical literature over the past 30 years).

15.2   HISTORY

Most authors (see Edwards, 1974; Berger and Wolpert, 1984) attribute the ideas of likelihood and the method of maximum likelihood estimation to Sir Ronald A. Fisher (1912; 1921; 1922). In Fisher's 1912 work, published while a university undergraduate, he used the Bayesian term 'inverse probability' to describe his method of maximum likelihood by which he was later (Fisher, 1915) able to generate the likelihood surface for two parameters. By 1921 Fisher recognized his inappropriate use of the term 'inverse probability' in his 1912 paper and coined the term 'likelihood' (Fisher, 1921).

15.2.1   A Brief History of Maximum Likelihood in Phylogenetics

Edwards and Cavalli-Sforza made several important contributions to phylogenetics, including the introduction of the least squares, minimum evolution or parsimony, and maximum likelihood methods of phylogenetic inference (Edwards and Cavalli-Sforza, 1964; Cavalli-Sforza and Edwards, 1967). Perhaps their most important contribution, however, was the early realization that the phylogeny problem was one of statistical inference. In fact, a number of authors later emphasized this idea (Felsenstein, 1973; 1988). Both Edwards and Cavalli-Sforza had 'sat at the feet of R.A. Fisher' (Edwards, 1998) and it was natural for them to consider the method of maximum likelihood to infer phylogeny. Indeed, they discussed maximum likelihood estimation of phylogeny at the 1964 meeting of the Systematics Association and at the Cold Spring Harbor Symposium on Quantitative Biology. In 1970 Edwards published a description of a maximum likelihood method for inferring phylogeny using gene frequency data. Neyman (1971) applied the method of maximum likelihood to analyze nucleotide or amino acid sequence data for three species using a simple probabilistic model of symmetric change similar to the Jukes–Cantor formula (Jukes and Cantor, 1969). Soon after, this method was extended to more than three species by considering triplets of species at one time and combining the results in a somewhat arbitrary manner (Kashyap and Subas, 1974). The limitation on the number of species these approaches could address, and possibly why they found little application at the time, centered around the high computational cost of likelihood calculations.

Felsenstein (1973) proposed an algorithm for the application of maximum likelihood to discrete character data, but practical applications of his approach were still hindered by the computational difficulties. Computational limitations were greatly reduced in a seminal paper by Felsenstein (1981) in which he introduced the 'pruning algorithm'. The

pruning algorithm makes possible efficient calculation of the likelihood for a large number of taxa by taking advantage of the form of the tree topology; today, all computer programs for calculating likelihoods on phylogenies use Felsenstein's pruning algorithm. By 1985 maximum likelihood estimation of phylogeny began to be applied more widely. DeBry and Slade (1985) analyzed restriction site data using maximum likelihood. Since then developments in the application of maximum likelihood to phylogenetics have accelerated, centering around construction of increasingly realistic stochastic models of change – e.g. codon models (Muse and Gaut, 1994; Goldman and Yang, 1994) – for a variety of data types, and the application of maximum likelihood estimation to evolutionary questions – e.g. testing the molecular clock (Felsenstein, 1988); testing the monophyly of a group (Huelsenbeck *et al.*, 1996); and reconstructing ancestral states (Yang *et al.*, 1995; Pagel, 1999).

15.2.2 A Brief History of Bayesian Inference in Phylogenetics

Bayesian inference of phylogeny was described in the dissertations of Mau (1996) and Li (1996) and by Rannala and Yang (1996). More recently, Markov chain Monte Carlo has made it possible to efficiently approximate the posterior probability of trees (Yang and Rannala, 1997; Mau *et al.*, 1999; Larget and Simon, 1999). The Bayesian approach has been applied to numerous evolutionary questions, such as host–parasite cospeciation (Huelsenbeck *et al.*, 1997; 2000a; Newton *et al.*, 1999), simultaneous sequence alignment and phylogeny estimation (Mitchison, 1999), inferring the history of a character (Schultz and Churchill, 1999), and estimating species' divergence times under a relaxed molecular clock (Thorne *et al.*, 1998; Huelsenbeck *et al.*, 2000b).

15.3 LIKELIHOOD FUNCTION

The likelihood of a hypothesis is proportional to the probability of observing the data given the hypothesis, or

$$\ell(\text{Hypothesis}) = C \times f(\text{Observations}|\text{Hypothesis}),$$

where $f(\text{Observations}|\text{Hypothesis})$ is the probability of observing the data given a hypothesis. The constant, C, is arbitrary. (Throughout this chapter, we follow the convention of using $f(\cdot|\cdot)$ to denote a conditional probability.) As an example, take the simple case of tossing a coin n times with the object of estimating the probability of observing a head on a single toss of the coin. The number of heads observed in the course of the n tosses is x. The probability of observing the data (x heads) given a particular value for the parameter p can be calculated using the binomial distribution,

$$f(x|p) = \binom{n}{x} p^x (1-p)^{n-x},$$

where $\binom{n}{x} = n!/x!(n-x)!$. The likelihood function, then, is

$$\ell(p) = C \times \binom{n}{x} p^x (1-p)^{n-x}.$$

For the phylogeny problem, the observations are taken to be the aligned character matrix. For DNA sequence data, the aligned matrix will be denoted X. As an example of aligned sequences, consider the first and last 15 aligned sites of the *replicase* gene from nine bacteriophage species of the family Leviviridae:

PP7	GACAGC- - -CGGUUC. . . CGGAUCCCUGACACG
FR	GGCAACGGU- - -GUG. . . GCAGACCCACGCCUC
MS2	GGGAACGGA- - -GUG. . . UCAGAUCCACGCCUC
GA	GGCAACGGU- - -UUG. . . UCAGAUCCGCGACUC
SP	UCA- - -AAUAAAGCA. . . UGGGAUCCUAGAGCA
NL95	UCG- - -AAUAAAGCA. . . UGGGAUCCUAGGGUA
M11	CCUUUCAAUAAAGCA. . .UGGGAUCCUAGGGUA
MX1	CCUUUCAAUAAAGCA. . .UGGGAUCCUAGGGUA
Qβ	CCUUUUAAUAAAGCA. . .UGGGAUCCUAGGGCC

The core region of the replicase gene corresponds to amino acid residue numbers 205 to 443, referenced to Qβ (GenBank accession numbers: FR, X15031; MS2, J02467; GA, X03869; SP, X07489; NL95, AF059243; M11, AF052431; MX1, AF059242; Qβ, X14764; PP7, X80191; Bollback and Huelsenbeck, 2001). The phage PP7 is treated as an outgroup.

The individual observations are the sites. For example, the first observation in the bacteriophage matrix is the site $\mathbf{x}_1 = (G, G, G, G, U, U, C, C, C)'$. The second, third, fourth, and fifth observations are $\mathbf{x}_2 = (A, G, G, G, C, C, C, C, C)'$, $\mathbf{x}_3 = (C, C, G, C, A, G, U, U, U)'$, $\mathbf{x}_4 = (A, A, A, A, -, -, U, U, U)'$, and $\mathbf{x}_5 = (G, A, A, A, -, -, U, U, U)'$, and so on. There are a total of $c = 720$ sites in this example data set.

How can the probability of observing the individual sites $(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_c)$ be calculated? The probability of observing the nucleotides at a site depends upon the topology of the tree relating the species, the lengths of the branches on this tree, and a specific model of how the sequence changes along the tree. Throughout this chapter, the topology of the tree relating the species will be denoted τ and the lengths of the b branches on this tree will be denoted $\mathbf{v} = (v_1, v_2, \ldots, v_b)$, with $b = 2s - 3$ for unrooted trees and $b = 2s - 2$ for rooted trees. The lengths of the branches are in terms of expected number of changes per site.

The model of evolution gives the probability of a change from one state to another over a specified evolutionary distance, v. These transition probabilities are denoted $p_{ij}(v, \theta)$, where i is the starting state, j is the ending state, v is the length of the branch, and θ is a vector of evolutionary parameters (such as the transition/transversion rate ratio). Currently, all stochastic models of evolutionary change on a phylogeny are examples of a continuous-time Markov chain. Figure 15.1 shows an example of a Markov chain in which there are four events of substitution (change in a DNA sequence) at a site. The substitutions occurred at times t_1, t_2, t_3, and t_4. In Figure 15.1, W_i is the waiting time for the ith substitution. The waiting times for a continuous-time Markov chain follow an exponential distribution with parameter λ (the rate may change depending on the state of the chain). The waiting time until the rth substitution ($W_r = W_1 + W_2 + \cdots + W_r$) follows a gamma distribution with shape parameter r and scale parameter λ. The number of substitutions in time interval T_1 is $N(T_1) = 3$ and the number of substitutions in the time interval T_2 is $N(T_2) = 4$. For a Poisson process, the
Figure 15.1 An illustration of a Poisson process. The large dots represent times at which substitutions occur.

number of substitutions in nonoverlapping time intervals are independent, the number of substitutions in a time interval of duration T follows a Poisson distribution with parameter λT, and the number of substitutions at time $T = 0$ (the beginning of the process) is $N(0) = 0$.

For models of character change, different transition types often have different rates. For example, for the simple case of two states ('0' or '1'), the rate of change from $0 \to 1$ and $1 \to 0$ might be different:

$$\mathbf{Q} = \{q_{ij}\} = \begin{pmatrix} -\alpha & \alpha \\ \beta & -\beta \end{pmatrix}.$$

The rows give the rate of change from state 0 or 1 and the columns give the rate of change to state 0 or 1. This means that the rate of change from $0 \to 1$ is α and the rate of change from $1 \to 0$ is β. The diagonal entries of the matrix give the rate of change away from a particular state. The matrix $\mathbf{Q}$ is called the instantaneous rate matrix. The transition probabilities (probability of a change from 0 to 1 or 1 to 0 over a time period t) are calculated by exponentiating the matrix $\mathbf{Q}t$:

$$\mathbf{P}(t, \theta) = \{p_{ij}(t, \theta)\} = \mathrm{e}^{\mathbf{Q}t} = \begin{pmatrix} \dfrac{\beta}{\alpha + \beta} + \dfrac{\alpha \mathrm{e}^{-(\alpha+\beta)t}}{\alpha + \beta} & \dfrac{\alpha}{\alpha + \beta} - \dfrac{\alpha \mathrm{e}^{-(\alpha+\beta)t}}{\alpha + \beta} \\ \dfrac{\beta}{\alpha + \beta} - \dfrac{\alpha \mathrm{e}^{-(\alpha+\beta)t}}{\alpha + \beta} & \dfrac{\alpha}{\alpha + \beta} + \dfrac{\beta \mathrm{e}^{-(\alpha+\beta)t}}{\alpha + \beta} \end{pmatrix},$$

where $\theta = (\alpha, \beta)$ contains the parameters of the substitution model. Note that if the process is run for a very long time, that the probability that the process is in state 0 or in state 1 converges to $\beta/(\alpha + \beta)$ and $\alpha/(\alpha + \beta)$, respectively. These are the stationary or equilibrium frequencies of the process and are usually denoted π_i for the frequency of state i.

The transition probability depends upon two quantities: the rate at which a change occurs between state i and state j (q_{ij}) and the amount of time the process has been running (t). For the phylogeny problem, the observed data can be explained by either a high substitution rate and a small amount of time or by a low substitution rate and a large amount of time. For example, the transition probabilities for the two-state example given above are the same if $\alpha = 1$, $\beta = 1$, and $t = 1$ or if $\alpha = 2$, $\beta = 2$, and $t = 0.25$. For this reason, the branches of a phylogenetic tree are usually in terms of expected number of

substitutions per site, v. To make the branch lengths of a phylogenetic tree in terms of expected number of substitutions per site, the rate matrix $\mathbf{Q}$ is rescaled in such a way that the average rate of change away from some state is 1 (that is, $-\sum_{i=1}^{N} \pi_i q_{ii} = 1$, where N is the number of states).

The model of evolution can be tailored to accommodate different types of data. The 2×2 instantaneous rate matrix discussed above, for example, might be most appropriate for morphological data where only two states are typically scored (e.g. the presence or absence of a character state). For DNA or RNA sequence data, each site is assumed to take one of four states (A, C, G, or T/U) and a 4×4 instantaneous rate matrix is typically used. Details of calculating transition probabilities for models of DNA sequence evolution are discussed in Swofford *et al.* (1996). Typical models of DNA substitution include the Jukes and Cantor (1969) model where all substitution types have equal rates and the equilibrium frequencies of the four nucleotides are equal; the Kimura (1980) model, which allows transitions (A $\leftrightarrow$ G or C $\leftrightarrow$ T changes) to occur at a different rate than transversions (A $\leftrightarrow$ C, A $\leftrightarrow$ T, C $\leftrightarrow$ G, and G $\leftrightarrow$ T changes) but assumes that the frequencies of the four nucleotides are equal; and the Hasegawa *et al.* (1984; 1985) model which accommodates a transition/transversion rate bias and potentially different nucleotide frequencies. Even a model that allows there to be 11 different substitution rates has been implemented for DNA sequence evolution (Yang, 1994b). Table 15.1 summarizes the properties of models of DNA substitution commonly used in phylogenetic analysis.

One useful aspect of considering evolution as a stochastic process is that the evolutionary model can be modified to accommodate new biological processes as they are

Table 15.1 Summary of the major features of different models of DNA substitution. All of these models are time reversible.

Rate	JC69	K80	K81	F81	F84	HKY85	TN93	GTR

discovered. For example, models of DNA substitution have been modified to accommodate limited dependence among sites. Schöniger and von Haeseler (1994) accommodate nonindependent substitutions in Watson–Crick bond pairs in stem regions of rRNA genes by expanding the model of DNA substitution around doublets of nucleotides; instead of a 4×4 matrix of rates, there is a 16×16 matrix of rates from one doublet to any other doublet (e.g. from doublet AA $\rightarrow$ AC). Only one substitution in any instant of time is allowed, so many of the elements of the **Q** matrix are 0 (e.g. changes that require a change at both positions simultaneously, such as AA $\rightarrow$ GC). Similarly, models of DNA substitution have been expanded around the codon – a triplet of nucleotides (Goldman and Yang, 1994; Muse and Gaut, 1994). Hence, the instantaneous rate matrix (**Q**) is 64×64 (or, more commonly, 61×61 because stop codons are excluded from consideration). Importantly, codon models allow parameters such as the nonsynonymous/synonymous rate ratio to be directly estimated, and account for all possible histories of synonymous and nonsynonymous change.

The probability of observing the data at a particular site is a sum over all possible nucleotides that can be observed at the internal nodes of the tree. Let **y** be a generic vector of states at the internal nodes of the tree. We will assume that the tree is rooted and that the tips of the tree are labelled $1, 2, \ldots, s$ and the internal nodes of the tree are labeled $s + 1, s + 2, \ldots, 2s - 2$. Moreover, in the following, the ancestor of node k on the tree is denoted $\sigma(k)$ and the length of the kth branch is v_k. The probability of observing the data at site i, then, is

$$f(\mathbf{x}_i|\tau, \mathbf{v}, \theta) = \sum_{\mathbf{y}} \pi_{w_{2s-2}} \left(\prod_{k=1}^{s} p_{w_{\sigma(k)}x_k}(v_k, \theta) \right) \left(\prod_{k=s+1}^{2s-2} p_{w_{\sigma(k)}w_k}(v_k, \theta) \right).$$

The summation is over all 4^{s-1} possible assignments of nucleotides to the internal nodes of the tree. The reason why the probability of observing the data at a site is a sum over all possible assignments of nucleotides at the internal nodes of the tree is that we do not want our inferences to be conditioned on a particular character history; instead, the probability of observing the data is a weighted average over all possible character histories. The number of possible combinations of nucleotides becomes too large to enumerate for even moderately sized problems (e.g. for $s = 20$ species there are 2.75×10^{11} combinations of nucleotides). However, Felsenstein (1981) described a pruning algorithm that takes advantage of the tree topology to evaluate the summation over nucleotide states in a computationally efficient (but mathematically equivalent) manner.

Assuming independence of the substitutions at different sites in the sequence, the probability of observing the entire aligned sequence data set is simply the product of the probabilities of observing the data at each site:

$$f(X|\tau, \mathbf{v}, \theta) = \prod_{i=1}^{c} f(\mathbf{x}_i|\tau, \mathbf{v}, \theta).$$

Typically, this number will be very small (because many numbers between 0 and 1 are multiplied). The log of the probability is used instead so that the number can be accurately stored in computer memory.

The above calculation for the probability of observing the aligned data matrix assumes that the same set of branch lengths (**v**) apply to every site in the sequence. This is another way of saying that the rate across sites is assumed to be equal. This assumption has been

relaxed in two different ways. The first divides the observed sequences into partitions, such as first, second, and third codon positions. The rate of substitution within each partition is assumed to be homogenous but potentially different across partitions. A protein coding gene, for example, might be divided into three partitions according to codon position.

The other method for accommodating rate variation assumes that the rate at a site is unknown but drawn from some distribution. Usually, the rate at a site is assumed to follow the proportion of invariant sites model or a gamma distribution (Yang, 1993). The proportion of invariant sites model states that the rate at a site is $r = 0$ with probability p and $r = 1/(1 - p)$ with probability $1 - p$. The gamma model assumes that the rate at a site is drawn from a gamma distribution with shape and scale parameters equal to α. The gamma distribution, then, is scaled such that the mean rate is 1 and the variation in rates is $1/\alpha$. For the proportion of invariant sites model, the probability of observing the data at the ith site is

$$f(\mathbf{x}_i | \tau, \mathbf{v}, \theta, p) = \left[\sum_{\mathbf{y}} \pi_{w_{2s-2}} \left(\prod_{k=1}^{s} p_{w_{\sigma(k)} x_k}(0, \theta) \right) \left(\prod_{k=s+1}^{2s-2} p_{w_{\sigma(k)} w_k}(0, \theta) \right) \right] p$$

$$+ \left[\sum_{\mathbf{y}} \pi_{w_{2s-2}} \left(\prod_{k=1}^{s} p_{w_{\sigma(k)} x_k}(v_k/(1 - p), \theta) \right) \right.$$

$$\left. \times \left(\prod_{k=s+1}^{2s-2} p_{w_{\sigma(k)} w_k}(v_k/(1 - p), \theta) \right) \right] (1 - p),$$

which is the sum of the probability of observing the data for each category weighted by the prior probability that the site is in each category. Similarly, the probability of observing the data at a site for the gamma-distributed rate variation model is

$$f(\mathbf{x}_i | \tau, \mathbf{v}, \theta, \alpha)$$

$$= \int_0^{\infty} \left[\sum_{\mathbf{y}} \pi_{w_{2s-2}} \left(\prod_{k=1}^{s} p_{w_{\sigma(k)} x_k}(v_k r, \theta) \right) \left(\prod_{k=s+1}^{2s-2} p_{w_{\sigma(k)} w_k}(v_k r, \theta) \right) \right] f(r | \alpha, \alpha) \, \mathrm{d}r$$

where $f(r | \alpha, \alpha)$ is the gamma density with shape and scale parameters equal to α. This function cannot usually be calculated numerically. Instead, an approximation suggested by Yang (1994a) is used. The gamma distribution is divided into K categories of equal weight, with the mean rate for each category representing the rate for the entire category. The probability of observing the data at the ith site then becomes

$$f(\mathbf{x}_i | \tau, \mathbf{v}, \theta, \alpha) = \sum_{j=1}^{K} \left[\sum_{\mathbf{y}} \pi_{w_{2s-2}} \left(\prod_{k=1}^{s} p_{w_{\sigma(k)} x_k}(v_k r_j, \theta) \right) \left(\prod_{k=s+1}^{2s-2} p_{w_{\sigma(k)} w_k}(v_k r_j, \theta) \right) \right] \frac{1}{K}.$$

The logic applied to modelling rate variation across sites has also been applied to the problem of detecting sites that are under the influence of positive selection. The nonsynonymous to synonymous rate of substitution (ω) is assumed to be a random variable drawn from some distribution. The probability of observing the data at a codon position is a sum over all possible values for ω weighted by the prior probability for each ω. Nielsen and Yang (1998) used this type of model to calculate the probability that a particular site is in the positive selection category conditioned on the observed sequences at that site.

As mentioned above, many different types of data can be used in phylogenetic analyses using the likelihood function. Until recently, morphological data were a major exception. Morphological data are difficult to accommodate using stochastic models for two reasons. For one thing, morphological traits are very complex genetically; it is difficult to imagine that many important biological processes are being captured by a simple model of stochastic change. Another impediment to introducing stochastic models of evolution to morphological data has been related to sampling biases in morphological data. Two-state stochastic models have been around for decades that, in principal, could be applied to morphological data; morphological characters are typically scored as presence or absence of a trait, so a simple two-state model seems natural. However, direct application of such a model would not be valid because the calculations assume that all characters have been sampled; most morphologists do not score invariant characters in a phylogenetic analysis. A morphological study of lizards, for instance, never includes a character such as 'presence or absence of vertebral column'. Recently Lewis (1999) proposed a solution to this problem: One simply conditions on the fact that these characters are not sampled in the first place. Practically speaking, the analysis is changed only in that the probability of observing a dummy invariant character must be calculated along with the observed characters.

15.4 DEVELOPING AN INTUITION OF LIKELIHOOD

One of the strengths of likelihood methods is that the assumptions of the analysis are explicit and transparent. What is not so transparent to many is what a likelihood score is and what it means to sum over all possible ancestral states. In this section, we try to develop an understanding of likelihood with reference to the parsimony method.

Consider the simple tree of two sequences shown in Figure 15.2(a). For this tree, the nucleotide 'A' was observed for both species at a particular site. The parsimony method would reconstruct the history of this character as involving no changes. What would likelihood do? The reconstruction provided by maximum likelihood would depend upon the length of the branch separating the two species as well as upon the model of evolution assumed. In this example, we will assume that the sequences evolve under a very simple model of DNA substitution first described by Jukes and Cantor (1969) and consider several different branch lengths (v).

Table 15.2 shows how much weight likelihood and parsimony give to different reconstructions. The numbers in parentheses provide the probability of observing the site
Figure 15.2 A simple phylogenetic tree of two species with two different character patterns (a) AA and (b) AC.

Table 15.2 The percentage probability of different character histories under the Jukes–Cantor model for the tree of Figure 15.2(a). The length of the branch separating the two sequences is denoted v.

Number of changes	Parsimony	$v = 0.01$ (0.2475)	$v = 0.1$ (0.2266)	$v = 0.2$ (0.20611)	$v = 1$ (0.11192)
0	100	99.99	99.83	99.31	82.17
1	0	0.00	0.00	0.00	0.00
2	0	0.0011	0.11	0.44	9.13
3	0	–	–	0.034	3.55
4	0	–	–	–	0.0027

pattern (AA) given the branch length v. The percentages are the percent of the site pattern probability that involves reconstructions of 0, 1, 2, or more changes. Parsimony places all of the weight on the reconstruction that has 0 changes across the simple two-species tree. Likelihood, on the other hand, gives some weight to *all possible reconstructions*. In a sense, likelihood hedges its bets with respect to reconstructing character history. When the branch length is small (e.g. $v = 0.01$), likelihood, like parsimony, places most of the weight on the reconstruction that has no changes. For this particular pattern of nucleotides at the branch tips, likelihood places no weight on the reconstruction that has one change because it is impossible to explain the data with only a single change on the tree. However, likelihood does place some weight on reconstructions that involve two or more changes. Note that as the branch length increases, likelihood places more weight on reconstructions involving multiple changes. In fact, when the branch length is $v = 1.0$, likelihood places 9.13 % of the weight on reconstructions involving two changes and 3.55 % weight on reconstructions involving three changes.

Parsimony and likelihood also behave similarly when there must be a character change. Consider the same tree shown in Figure 15.2(b), now with nucleotide 'A' observed for one species and 'C' for the other species. Table 15.3 gives the weights assigned to various reconstructions for this character pattern. The probability of observing a site pattern with a change increases as the branch length increases. This makes sense because as the branch becomes longer, it becomes more probable that changes will occur along that branch. Also, note that the parsimony and likelihood methods are most similar when the branch length is small; when the branch length is small, parsimony places 100 % weight on the

Table 15.3 The percentage probability of different character histories under the Jukes–Cantor model for the tree of Figure 15.2(b). The length of the branch separating the two sequences is denoted v.

Number of changes	Parsimony	$v = 0.01$ (0.00083)	$v = 0.1$ (0.00786)	$v = 0.2$ (0.01462)	$v = 1$ (0.04602)
0	0	0.00	0.00	0.00	0.00
1	100	99.66	96.64	92.36	66.54
2	0	0.33	3.22	6.22	22.19
3	0		0.12	0.48	8.61
4	0		0.003	0.023	2.05
5	0			0.0037	0.42

reconstruction involving one change whereas likelihood places 99.66 % weight on the same reconstruction.

15.5   METHOD OF MAXIMUM LIKELIHOOD

The likelihood function (probability of observing the data) depends upon several unknown parameters. For the phylogeny problem, these parameters include (minimally) the topology of the phylogenetic tree relating the species and the lengths of the branches on this tree, but may also depend upon parameters of the substitution process, such as the transition/transversion rate ratio, or parameters that describe the degree of rate variation across sites. Up to this point in the chapter, we have assumed that these parameters are fixed. However, we would like to estimate these parameters as they are generally unknown.

The method of maximum likelihood estimates parameters of a stochastic model by finding that combination of parameter values that maximizes the likelihood function. Take, for example, the coin-tossing problem, discussed above. The likelihood function was

$$\ell(p) = C \times \binom{n}{x} p^x (1 - p)^{n-x},$$

which was proportional to the probability of observing the data given a specific value for p (the unknown parameter). The method of maximum likelihood would estimate p by finding that value of p that maximized the likelihood function. This can be done by taking the first derivative of the likelihood function and finding where the first derivative equals 0. Taking the log of the likelihood function does not change where the function is maximized and makes the calculation easier:

$$\log_e \ell(p) = \log_e C + \log_e \binom{n}{x} + x \log_e p + (n - x) \log_e (1 - p).$$

Then, the first derivative is calculated:

$$\frac{d \log_e \ell(p)}{dp} = \frac{x - np}{p(1 - p)}.$$

Solving for $d \log_e \ell(p) / dp = 0$ gives $\hat{p} = x/n$. This means that the maximum likelihood estimate of the parameter p is simply the proportion of the time that heads were observed in the n tosses. This estimate does not depend upon the value of the constant C in the likelihood function.

For the phylogeny problem, the peak of the likelihood surface cannot be found analytically (as it could for the coin-tossing problem). Instead, the peak of the likelihood surface must be found numerically. Most modern computer programs take the following approach: A tree is visited and the parameters for that tree are changed such that the likelihood is maximized. The maximum likelihood value for this tree is then stored and the procedure is repeated for other trees. The tree that has the largest maximum likelihood value is the best estimate of phylogeny. The maximization of the likelihood for the phylogeny problem, then, involves two distinct problems: finding the maximum likelihood combination of parameters for distinct trees and finding the tree that has the greatest likelihood. Lewis (1998) has taken a different approach to finding the maximum likelihood estimate

of phylogeny by using a genetic algorithm. The genetic algorithm takes a population of trees and subjects the trees to mutation (changes of the parameter values on the trees) and recombination (grafting parts of one tree on to another tree). The population is allowed to evolve under the influence of selection, with those trees that have the greatest fitness (highest likelihood scores) contributing the larger number of trees in the next generation.

A practical limitation of maximum likelihood in phylogenetics is that it is very difficult to maximize the likelihood simultaneously for many parameters. Often, the biologist is interested in inferring phylogeny under a more parameter-rich (and presumably more realistic) model of DNA substitution. However, some of the parameters in a substitution model are difficult to maximize. It turns out that it is relatively easy to maximize the likelihood with respect to branch lengths because the algorithm can take advantage of information on the slope and curvature of the likelihood surface; this information tells the algorithm in which direction and by how much to change the length of a branch. Other parameters, such as the transition/transversion rate ratio or parameters specific to the model of DNA substitution, are inherently more difficult to estimate because it is difficult to obtain information on the slope and curvature of the likelihood function for those parameters. This means that it can become very time consuming to maximize the likelihood for parameter-rich models of DNA substitution.

One strategy for maximizing the likelihood under complex models of DNA substitution that can be implemented in PAUP* (Swofford, 1998) is to maximize the likelihood in a stepwise manner (Swofford *et al.*, 1996). First, a reasonable starting tree (e.g. a maximum parsimony tree) is obtained. The parameters of the substitution model are maximized on this tree. Next, the parameters of the substitution model are fixed to their maximum likelihood values and a heuristic search is performed starting from the parsimony tree. This procedure is iterated until one cannot find a better tree than the one on which the parameters were estimated. This strategy relies on the idea that, for trees near the maximum likelihood tree, parameters of the substitution model do not differ by very much. An example of a PAUP block that can implement this search strategy under the GTR $+\ \Gamma$ model of DNA substitution is as follows:

```
begin paup;
set autoclose = yes warnreset = no increase = auto criterion
    = parsimony;
hsearch;
set criterion = likelihood;
lset nst = 6 rmatrix = est basefreq = est rates = gamma shape
    = est ncat = 4 pinvar = 0;
lscores 1;
lset rmatrix = prev basefreq = prev shape = prev;
hsearch start = 1 swap = nni;
savetrees file = like.trees replace = yes;
lset rmatrix = est basefreq = est shape = est;
lscores 1;
lset rmatrix = prev basefreq = prev shape = prev;
hsearch start = 1 swap = spr;
savetrees file = like.trees append = yes;
lset rmatrix = est basefreq = est shape = est;
```

```
lscores 1;
lset rmatrix = prev basefreq = prev shape = prev;
hsearch start = 1 swap = tbr;
savetrees file = like.trees append = yes;
end;
```

This PAUP block performs three iterations of the search strategy using three different heuristic searches.

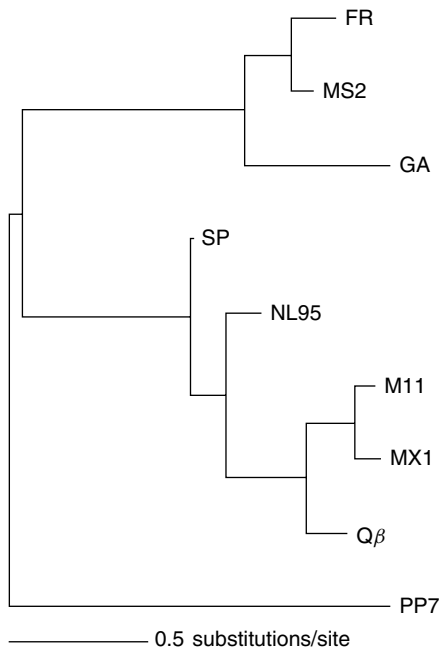
The phylogeny problem involves numerous parameters (e.g. minimally tree topology and branch lengths). Often, however, the biologist is interested in only one or a few of these parameters. The parameters that are not of interest are called nuisance parameters. (For a more extensive discussion of nuisance parameters in phylogenetic analysis, see Goldman, 1990.) Nuisance parameters can be dealt with in one of several ways. First, the likelihood can be maximized with respect to all parameters, including the nuisance parameters. This is the solution taken in most computer programs implementing maximum likelihood. Second, a prior probability distribution can be assigned to these parameters and the likelihood integrated over the range of the parameter. This is how rate variation across sites is often accommodated; a prior such as the gamma distribution is placed on the rate at a site and the overall site likelihood is integrated over all possible rate assignments. Finally, a consistent estimator (but not necessarily a maximum likelihood estimator) can be substituted for the parameter. To our knowledge, this pseudomaximum likelihood method has not been used in phylogenetics.


Figure 15.3 The maximum likelihood estimate of phylogeny under the HKY85 + Γ model of DNA substitution. Parameter estimates for the nuisance parameters were $\kappa = 2.33$, $\alpha = 0.69$, $\pi_A = 0.24$, $\pi_C = 0.26$, $\pi_G = 0.23$, and $\pi_T = 0.27$.

Figure 15.3 shows the maximum likelihood tree for the bacteriophage species. The Hasegawa *et al.* (1985) model of DNA substitution with gamma-distributed rate variation (Yang, 1994a) was assumed in the analysis. Nuisance parameters (e.g. the transition/transversion rate ratio, base frequencies, and branch lengths) were accommodated by maximizing the likelihood with respect to those parameters. The log-likelihood of the tree was -5695.07. The maximum likelihood estimates for the model parameters were $\kappa = 2.33$, $\alpha = 0.69$, $\pi_A = 0.24$, $\pi_C = 0.26$, $\pi_G = 0.23$, and $\pi_T = 0.27$. The analysis was performed using the program PAUP* (Swofford, 1998).

15.6   BAYESIAN INFERENCE

In a Bayesian analysis inferences are based upon what is called the posterior probability of a parameter. The posterior probability of a parameter is the probability of the parameter conditional on the observed data. This is different from maximum likelihood which maximizes the likelihood function (the probability of observing the data given the parameter). The posterior probability of a hypothesis (H_i; $i = 1, 2, \ldots, n$) can be calculated using Bayes formula,

$$f(H_i|D) = \frac{f(D|H_i)f(H_i)}{f(D)},$$

where

$$f(D) = \sum_{j=1}^{n} f(D|H_j)f(H_j)$$

for discrete H. The posterior probability is a function of the likelihood, $f(D|H_i)$, and the scientist's prior beliefs about the hypothesis, $f(H_i)$. Just as with maximum likelihood, the likelihood function is the vehicle that carries the information about the parameter contained in the data.

Figure 15.4 shows the posterior probabilities of the parameter p for the coin-tossing experiment discussed earlier. Here, the proportion of heads observed is always 0.8, for 5, 10, and 100 tosses of a coin. The likelihood function is the first column in this figure. The first (top) row of this figure shows three different priors that express the uncertainty in p before any observations have been made; the first is an uninformative prior, giving equal weight to all values of p in the interval between 0 and 1. The second and third are informative priors, placing more weight on values of p near 0.5. The other plots in Figure 15.4 show the posterior probability of p when the likelihood and prior are combined; the likelihood function for the observations of the row are combined with the prior of the column. Bayes formula is used to combine the scientist's prior beliefs with observation.

How are posterior probabilities of phylogenies calculated? The posterior probability of tree τ_i is obtained using Bayes rule,

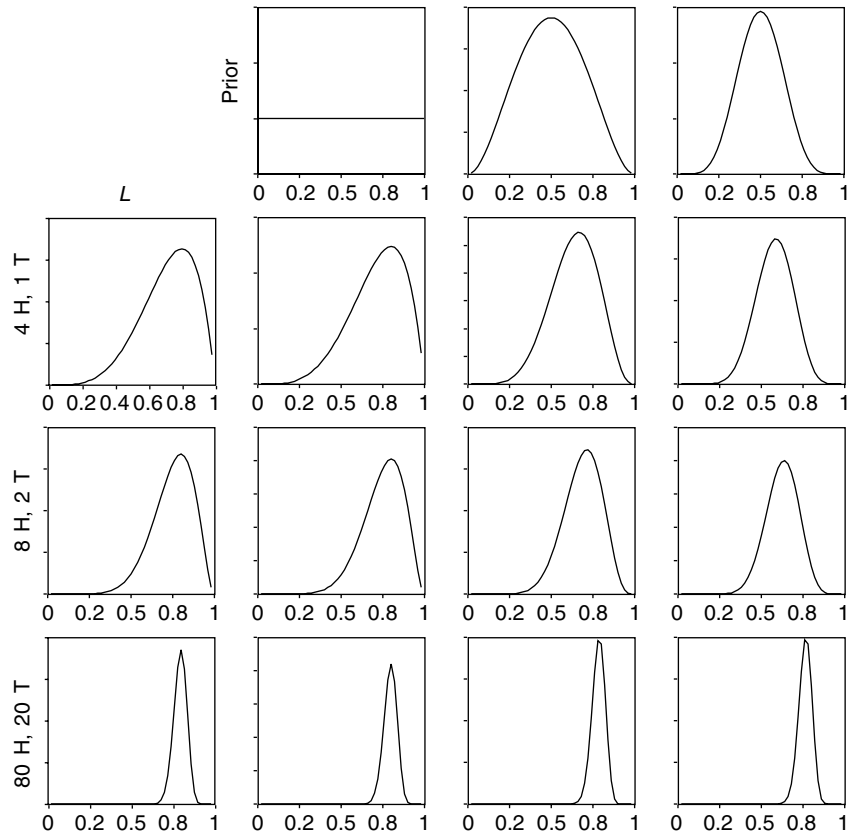
$$f(\tau_i|X, \mathbf{v}, \theta) = \frac{f(X|\tau_i, \mathbf{v}, \theta)f(\tau_i)}{\overset{B(s)}{\underset{j=1}{\sum}} f(X|\tau_j, \mathbf{v}, \theta)f(\tau_j)},$$


Figure 15.4   An example of Bayesian inference for the coin-tossing example with different priors.

where $B(s)$ is the number of possible trees for s species ($B(S) = (2s - 3)!/2^{s-2}(s - 2)!$ for rooted trees and $B(s) = (2s - 5)!/2^{s-3}(s - 3)!$ for unrooted trees). One possible prior for trees is to set $f(\tau_i) = 1/B(s)$, making all trees a priori equally probable.

Note that the posterior probability of a tree was conditioned on the data and several parameters, such as the branch lengths ($\mathbf{v}$) and substitution parameters (θ). One approach to accommodating these parameters is to substitute an estimate (such as the maximum likelihood estimate). This is called an empirical Bayes analysis. An alternative method integrates over uncertainty in these parameters; the inference of phylogeny, then, is not conditioned on unknown parameters taking specific values. Such an analysis is called a hierarchical Bayes analysis. The posterior probability for a hierarchical Bayes analysis is

$$f(\tau_i|X) = \frac{f(X|\tau_i)f(\tau_i)}{\sum\limits_{j=1}^{B(s)} f(X|\tau_j)f(\tau_j)},$$

where

$$f(X|\tau_i) = \int f(X|\tau_i, \mathbf{v}, \theta) \, \mathrm{d}F(\mathbf{v}, \theta)$$

and integration is over all possible combinations of branch lengths on the tree and over all possible values for the substitution parameters. An attractive feature of a hierarchical Bayes analysis is that inferences are conditioned only upon the data.

A Bayesian analysis of phylogeny requires that the scientist specify his or her beliefs about the phylogeny before observing any data. This can be viewed as either a strength or a weakness of Bayesian inference. It is a strength in that the method can potentially take advantage of any prior knowledge the scientist might have about the phylogeny. On the other hand, priors can be difficult to specify. Two different types of priors have been used in the phylogeny problem. The first was specified by Rannala and Yang (1996; also see Yang and Rannala, 1997; Thompson, 1975), who used a birth–death process of cladogenesis to specify the prior probabilities of phylogeny and branch lengths. Under a random branching model of cladogenesis (such as the birth–death process), all labeled histories have equal probability. Labeled histories are distinguished from one another not only by their topology but also by the relative speciation times (Edwards, 1970). The birth–death process has two parameters, the speciation and extinction rates. These can be fixed, or priors (called hyperpriors) can be placed on the rates of speciation and extinction. Mau (1996), Mau and Newton (1997), and Newton *et al.* (1999) place uninformative priors on topology and branch lengths. Equal weight is placed on all trees, and uniform priors (from 0 to a large number) are placed on branch lengths. The posterior probability will be mainly determined by the likelihood function when uninformative priors are used.

15.7   MARKOV CHAIN MONTE CARLO

The posterior probability of a tree involves, minimally, a summation over all possible trees and integration over branch lengths and other parameters of the substitution model. In short, the posterior probability of a tree cannot be evaluated analytically, and must be approximated. Markov chain Monte Carlo (MCMC) can be used to approximate the posterior probability of phylogenies.

MCMC is a method that makes valid, but dependent, draws from the probability distribution of interest. MCMC constructs a Markov chain that has as its state space the parameter(s) of interest. A simple example will illustrate MCMC as applied to the coin–tossing problem (for a good introduction to MCMC, see Gilks *et al.*, 1996). This example is of a variant of MCMC called the Metropolis–Hastings algorithm (Metropolis *et al.*, 1953; Hastings, 1970; Green, 1995). The current state of the chain will be denoted p. If this is the first generation of the chain, then p is initialized to be some value between 0 and 1. A new state, p', is proposed. For this example, the proposal mechanism will be to pick a uniformly distributed random number in the interval $(p - \varepsilon, p + \varepsilon)$; this means that the next state of the chain will be very similar to the current state (ε might be 0.05, for example, meaning that the proposed state of the chain will be within 0.05 of the current state). The proposed state is accepted with probability

$$R = \min\left(1, \frac{\binom{n}{x} p'^x (1 - p')^{n-x} f(p')/f(x)}{\binom{n}{x} p^x (1 - p)^{n-x} f(p)/f(x)} \times \frac{f(p|p')}{f(p'|p)}\right)$$

$$= \min \left(1, \underbrace{\frac{p'^x(1-p')^{n-x}}{p^x(1-p)^{n-x}}}_{\text{likelihood ratio}} \times \underbrace{\frac{f(p')}{f(p)}}_{\text{prior ratio}} \times \underbrace{\frac{f(p|p')}{f(p'|p)}}_{\text{proposal ratio}} \right).$$

Note that the most difficult part of the posterior probability to calculate ($f(x) = \int_0^1 \binom{n}{x} p^x (1-p)^{n-x} f(p) \, dp$) cancels. The proposal probabilities ($f(p'|p)$ and $f(p|p')$) give the probability of proposing a move $p \to p'$ or the reverse move $p' \to p$. Many proposal mechanisms will work as long as the chain is aperiodic and irreducible. Hence, the computer programmer has much latitude in choosing proposal mechanisms, and, in fact, there is an art to constructing a Markov chain that works well. The important point, though, is that any chain will work in that it will converge on the correct distribution if the chain is run long enough.

Once the acceptance probability, R, is calculated, a uniformly distributed random number on the interval [0, 1] is generated. If this random number is less than R, then the proposed state is accepted and $p = p'$. If the new state is not accepted (i.e. the random number is greater than R), then the current state stays the same. This process of proposing a new state and then accepting or rejecting it is repeated a large number of times. The sequence of states (values of p) visited over the course of the analysis forms a Markov chain. The states visited during the analysis (i.e. different values of p) are valid, albeit dependent, draws from the posterior probability; a Markov chain that was run for
Figure 15.5 The posterior probability of p for the coin-tossing problem. The dotted line is the posterior probability calculated analytically. The solid line is the approximation of the posterior probability obtained using Markov chain Monte Carlo. The chain was run for (a) 5000 generations (b) 50 000 generations, and (c) 500 000 generations. *Source*: Huelsenbeck *et al.* (2000a).

100 steps and sampled at every step does not represent 100 independent draws from the posterior probability. However, the proportion of the time that different values of p were visited is a valid approximation of the posterior probability. Figure 15.5 shows an example of an MCMC analysis for the coin-tossing example where the data are $x = 5$ heads in $n = 10$ tosses of a coin. Note that as the length of the chain is increased, that the MCMC approximation converges to the true (analytically calculated) posterior probability.

Although MCMC was illustrated for a Bayesian analysis of coin tossing, the method can be extended to much more complex problems involving many parameters. Moreover, the method has been applied to maximum likelihood analysis where it has been used to integrate over uncertainty in coalescence histories when estimating population parameters (Kuhner *et al.*, 1994; Beerli and Felsenstein, 1999).

A limitation of MCMC is that it is not clear when the chain has been run long enough to produce a reliable approximation of the distribution of interest. The Markov chain law of large numbers guarantees that posterior probabilities can be validly estimated from long-run samples of the chain (Tierney, 1994). However, for any given analysis, it is difficult to determine if the chain has converged to the desired distribution. Several different heuristics are available to determine if the chain has converged (see Gelman, 1996). These involve running several independent chains starting from different (perhaps random) trees.

To illustrate Bayesian inference of phylogeny using MCMC, we analyzed the bacteriophage *replicase* data under the HKY85 + Γ model of DNA substitution. We used MCMC to approximate the posterior probabilities of trees using a program written by one of us (JPH). The Markov chain was run for 500 000 steps. Figure 15.6 shows the log of the likelihood function through time for the chain. Note that at first the log-likelihood was low and that it quickly reached a plateau near the maximum likelihood value (indicated by
Figure 15.6 The log-likelihood function was tracked during the course of the MCMC analysis of the *replicase* sequences. The log-likelihood started at a low value, but quickly reached apparent stationarity. The shaded portion shows the part of the chain that was discarded as the 'burn-in'. The gray horizontal line shows the maximum likelihood value for the data.

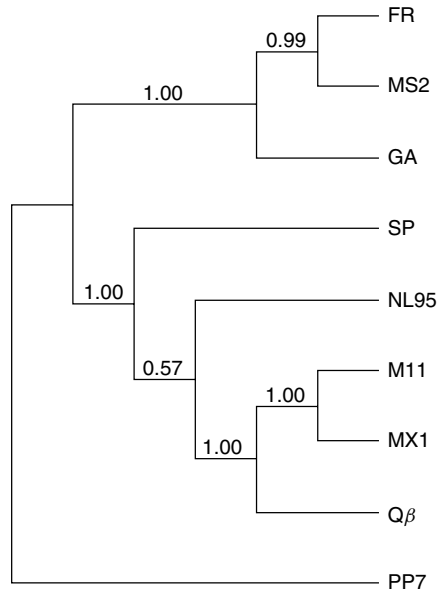
a gray horizontal line). Inferences should be based on the portion of the chain at station-arity. Hence, we discarded the first 50 000 steps in the chain as the 'burn-in'. Figure 15.7 shows the 50 % majority rule tree of the sampled trees. The numbers at the interior nodes of the tree do not represent bootstrap support values but rather the posterior probability that the clade is true. Just as with maximum likelihood, the parameters of the substitution model can be estimated using Bayesian inference. Figure 15.8 shows the posterior probabilities for the transition/transversion rate ratio (κ) and the shape parameter of the gamma distribution (α) for among-site rate variation.


Figure 15.7 The Bayesian estimate of phylogeny. Only clades with greater than 0.5 posterior probability are shown. The numbers at the interior nodes represent the posterior probability that the clade is correct.
Figure 15.8 The posterior probability distribution of the transition/transversion rate ratio (κ) and the gamma shape parameter for among-site rate variation (α).

15.8   ASSESSING UNCERTAINTY OF PHYLOGENIES

The nonparametric bootstrap, introduced to the phylogeny problem by Felsenstein (1985), has become a standard method for assessing the uncertainty in phylogenetic trees. The bootstrap works by constructing many replicate data sets of the same size as the original data matrix by randomly sampling the sites with replacement. Hence, for any single bootstrap data matrix, some sites might be represented several times and others not at all. Each bootstrap data matrix is analyzed in the same manner as the original data. The proportion of the time that a particular clade is found in analysis of the bootstrapped data matrices represents the bootstrap confidence for that clade.

The appeal of the bootstrap is that it can be used to assess the accuracy of estimated phylogenetic trees ($\hat{\tau}$) without making explicit assumptions about the distribution of trees around the true tree (τ^T). However, the application of the bootstrap method to the phylogeny problem has been criticized as providing biased estimates of the accuracy of phylogenetic trees (Hillis and Bull, 1993); Hillis and Bull (1993) performed simulations in which the bootstrap distribution of trees ($\hat{\tau}^B$) was compared to the true tree that generated the simulated data (τ^T). Efron *et al.* (1996) argue that this is not the relevant comparison as the bootstrap method is intended to evaluate the (unobservable) distribution of differences between $\hat{\tau}$ and τ^T by using the (observable) distribution of differences between $\hat{\tau}^B$ and $\hat{\tau}$. The bootstrap is not severely biased in evaluating the difference between the estimated tree and the true tree, though Efron *et al.* (1996) argue that the bootstrap can be improved by performing a more elaborate bootstrap procedure. The bootstrap can also be used to construct confidence intervals for other parameters of evolutionary models. However, use of the bootstrap for this purpose is uncommon in the phylogenetics literature.

Efron *et al.* (1996) also argue that the bootstrap proportions on a tree have a Bayesian interpretation as the assessment of error in the estimated tree when assuming all phylogenetic trees have an equal prior probability. Larget and Simon (1999) point out that, if this is true, it is computationally much more efficient to perform a Bayesian analysis using MCMC than to perform a traditional nonparametric bootstrap using maximum likelihood. MCMC is very efficient in how it uses computational resources. Every calculation of the likelihood for a tree (a task that is computationally difficult) provides some information about the posterior probabilities of trees. If a move to a particular tree is often accepted then, roughly speaking, that tree has a higher posterior probability than a tree that is rarely moved to during the course of the Markov chain.

Figure 15.9 shows the maximum likelihood and Bayesian estimates of phylogeny for the bacteriophage groups with the support for the clades indicated. For the maximum likelihood tree the numbers at the interior branches represent bootstrap support for the clade, whereas for the Bayesian estimate the numbers indicate the posterior probability that the clade is correct. The confidence intervals for the parameters of the substitution model are $\kappa = 2.33$ (1.89, 2.88) for the transition/transversion rate ratio and $\alpha = 0.70$ (0.55, 0.85) for the gamma shape parameter describing the rate variation across sites. In a Bayesian analysis, the uncertainty in the parameters can be evaluated directly from the posterior probability of the parameter (see Figure 15.8). However, a 95 % credibility interval can be constructed by taking the 2.5 and 97.5 % quantiles of the posterior probability distribution. The 95 % credibility intervals for the transition/transversion rate and the gamma shape parameter are $\kappa = 2.28$ (1.93, 2.68) and $\alpha = 0.75$ (0.62, 0.92), respectively.
Figure 15.9   The best estimate of phylogeny for the Leviviridae for the *replicase* gene under the maximum likelihood and Bayesian criteria. The HKY85 + Γ model of DNA substitution was assumed. The numbers above the branches show the posterior probability that the clade is correct, whereas the numbers below the branches show the bootstrap support for the clade.

15.9   HYPOTHESIS TESTING AND MODEL CHOICE

There are a number of ways to construct hypothesis tests. One of the most general and important of these is based on the likelihood ratio. The likelihood ratio is the ratio of the probability of observing the same data under different models. The likelihood ratio in favor of model 1 against model 2 is

$$\Lambda_{12} = \frac{f(\text{Observations}|M_1)}{f(\text{Observations}|M_2)}.$$

When the models are nested (i.e. M_1 is a special case of M_2), twice the negative log of the ratio

$$\Lambda_{12} = \frac{\max[f(\text{Observations}|M_1)]}{\max[f(\text{Observations}|M_2)]},$$

is asymptotically χ^2 distributed, with the degrees of freedom being the difference in the number of free parameters between the two models (Wilks, 1938). Alternatively, if the models are not nested or if the assumptions of the test are otherwise violated, the null distribution of the test statistic can be simulated using the parametric bootstrap. Likelihood

ratio tests have been used extensively in phylogenetic analysis to test the molecular clock, to choose among different models of DNA substitution, and to test hypotheses on trees (see Goldman, 1993; reviewed in Huelsenbeck and Rannala, 1997).

Bayesian model choice is often guided by the Bayes factor (Kass and Raftery, 1995). The Bayes factor in favor of model 1 against model 2 is

$$B_{12} = \frac{\dfrac{f(M_1|\text{Observations})}{f(M_2|\text{Observations})}}{\dfrac{f(M_1)}{f(M_2)}},$$

which is the ratio of the posterior odds ratio to the prior odds ratio. The Bayes factor is on roughly the same scale as the likelihood ratio and should be interpreted as 'the change in the odds in favor of the hypothesis when going from the prior to the posterior' (Lavine and Schervish, 1999). The Bayes factor can be used for nested models, but is also easily extended to nonnested models. To date, Bayes factors have found only a limited application in phylogenetics. For example, Suchard *et al.* (1999) examined nested models of DNA substitution using Bayes factors, with results similar to those found using likelihood ratio tests. Also, Huelsenbeck *et al.* (2000a) examined two models of host switching using Bayes factors.

15.10   COMPARATIVE ANALYSIS

Biologists often test evolutionary hypotheses by comparing some feature of an organism across several different species (broadly referred to as the 'comparative method' here, though the term is usually applied to analyses that examine correlation in two or more characters). The comparative method removes the covariation of characters induced by a common phylogenetic history by performing the analysis in a phylogenetic context. To date, most methods that have been proposed to test specific evolutionary hypotheses assume that the phylogenetic history of a species group is known without error; this assumption is implicitly made when the phylogeny is estimated and then used in the comparative analysis without consideration of the possible errors in the phylogeny. Is it possible to avoid the assumption that the phylogeny of a species group is known without error?

Bayesian inference implemented using MCMC suggests one way of performing comparative analyses without assuming that the tree is known without error: The comparative question is addressed on all possible trees, weighted by the probability that each tree is correct. Suppose, for example, that each possible phylogenetic tree is either consistent with or inconsistent with an evolutionary hypothesis. The overall probability that the hypothesis is correct is simply the sum of the posterior probabilities of trees consistent with the hypothesis. Table 15.4 illustrates how such an analysis might be done. The sum of the posterior probabilities of trees consistent with the evolutionary hypothesis is 0.58. This might be taken as only weak evidence that the hypothesis is true.

A real example better illustrates the concept. The example concerns the evolution of the horned soldier aphids (Stern, 1998). The phylogeny of horned soldier aphids was based

Table 15.4   The posterior probabilities of different trees that are either consistent or inconsistent with some evolutionary hypothesis. The probability that the hypothesis is correct is simply the sum of the posterior probabilities of trees consistent with the hypothesis.

τ_i	$f(\tau_i \mid X)$	Tree consistent or inconsistent with hypothesis
τ_1	0.40	Consistent
τ_2	0.33	Inconsistent
τ_3	0.07	Inconsistent
τ_4	0.07	Consistent
τ_5	0.06	Consistent
τ_6	0.05	Consistent
τ_7	0.01	Inconsistent
τ_8	0.01	Inconsistent

Table 15.5   The posterior probabilities for the number of gains and losses of the horned soldier caste character.

		# Losses					
		0	1	2	3	4	5
#	0	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000
G	1	0.0000	0.0076	0.1759	0.5819	0.0004	0.0000
a	2	0.0000	0.0316	0.1769	0.0006	0.0000	0.0000
i	3	0.0002	0.0131	0.0004	0.0000	0.0000	0.0000
n	4	0.0113	0.0000	0.0000	0.0000	0.0000	0.0000
s	5	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000

on mitochondrial DNA sequences sampled from 34 aphid species. One question concerns the number of times that horned soldiers (a specialized caste for defense only present on the secondary hosts) evolved. Previous analysis suggests that the horned soldiers evolved once and were lost twice. We examined this hypothesis by approximating the posterior probabilities of trees using the program BAMBE (Simon and Larget, 1998; this analysis is from Huelsenbeck *et al.*, 2000c). We ran the Markov chain for 1 000 000 generations, sampling the chain every 200 generations. Inferences on the number of gains and losses of the horned soldiers were made using parsimony mapping on each of the 5000 sampled trees. Table 15.5 summarizes the results. The posterior probability of a reconstruction that has 1 gain and 2 losses is 0.1759. However, the posterior probability is spread out over a number of other reconstructions. For example, the posterior probability of reconstructions involving 1 gain and 3 losses and reconstructions involving 2 gains and 2 losses is also substantial. In fact, these three reconstructions (1 gain, 2 losses; 1 gain, 3 losses; and 2 gains, 2 losses) account for 93 % of the posterior probability. This aphid example illustrates how comparative analyses can be performed in such a way that inferences do not depend critically upon any single phylogeny.

15.11   CONCLUSIONS

The 1990s saw several exciting developments in phylogenetics. First, the models of DNA substitution assumed in statistically based methods were greatly improved to reflect basic biological observations, such as rate variation across sites and nonindependent substitutions. Second, maximum likelihood and Bayesian inference of phylogeny became more practical because of faster computers and improved computer programs implementing the methods (such as PAUP*: Swofford, 1998). Third, Bayesian inference was introduced to the phylogeny problem. Bayesian inference represents the last of the widely used methods of statistical inference to be applied to the phylogeny problem. Finally, MCMC was applied to evolutionary problems with some success. For example, MCMC was applied to maximum likelihood inference of coalescence parameters. Similarly, MCMC has been applied to approximate posterior probabilities of phylogenies in a Bayesian framework.

However, the full potential of statistical methods that are based upon the likelihood function is only beginning to be realized in phylogenetics. For example, coupled with MCMC, it should be possible to examine more complex models of DNA substitution, such as the covarion model, in a Bayesian or maximum likelihood framework. Similarly, many questions that depend upon correlation among several different trees, such as inference of horizontal gene transfer and host-parasite cospeciation, can be usefully addressed using MCMC.

Maximum likelihood and Bayesian inference are very similar in that they both use the likelihood function. However, Bayesian inference uses a subjective concept of probability whereas many of the useful concepts in maximum likelihood (such as confidence intervals and p-values) use a frequentist concept of probability. Much debate in the statistics literature has focussed on the merits of these two definitions of probability and the role that prior information should play in statistical inference (especially when it is difficult to specify the prior information as a part of the statistical model). These problems, as applied to the phylogeny problem, we leave as an exercise for the reader.

Phylogenetics: Parsimony, Networks, and Distance Methods

D. Penny, M.D. Hendy and B.R. Holland

Allan Wilson Center for Molecular Ecology and Evolution, Massey University, Palmerston North, New Zealand

The accurate recovery of evolutionary trees is a major problem in mathematical inference. The relevant theory comes from mathematics (graph theory, combinatorics, and Markov chains), statistics (likelihood, Bayesian methods, resampling, and exploratory data analysis), operations research (optimisation, and search heuristics), and computer science (complexity theory). Different ways of presenting molecular data are described and a consistent terminology is presented. The problem of the combinatorial explosion in the numbers of potential trees leads to a description of the complexity of algorithms. The use of simple Markov models for studying the evolution of DNA sequences is described. Methods for inferring trees are analysed under the three components of, an optimality criterion, searching tree space, and assumptions or knowledge about the mechanism of evolution (which can allow compensation for multiple (unobserved) changes at a site). The analysis of methods in this chapter concentrates on parsimony and distance methods for inferring trees, but also discusses the limited range of cases when maximum parsimony and maximum likelihood are equivalent. A section describes the use of networks to represent the complexities in the data or to summarise the variability of the output trees. An overview of tree-building methods includes several strategies for searching tree space, from complete searches, branch-and-bound searches, to different forms of heuristic approaches.

16.1   INTRODUCTION

The mathematics behind phylogenetic programs is interesting in that it comes from several areas of pure and applied mathematics, both discrete and continuous. These include graph theory, combinatorics, and Markov chains from mathematics, together with statistics (likelihood, Bayesian analysis, resampling), operations research (optimisation, search heuristics), and computer science (complexity theory). Fortunately, the underlying concepts are relatively simple (even if the mathematics is complex) and in this chapter we only consider the concepts. Our description of the mathematics is informal, more formal

discussions are found in the primary literature. Of course, underlying all the algorithms are (or should be) the biological models of the genetic information and biochemical processes. More detailed treatments on tree building are available in Swofford *et al.* (1996), Page and Holmes (1998), Nei and Kumar (2000), and Felsenstein (2003); and the mathematical basis is in Semple and Steel (2003).

We focus on input data that is either aligned sequences representing a set of taxa, or a matrix of differences (genetic distances) between each pair of taxa. The sequence information is usually DNA, RNA, or protein sequences, though increasingly it is information such as gene order or the position of sequence elements (short interspersed nuclear elements (SINEs) and long interspersed nuclear elements (LINEs), respectively, Kriegs *et al.*, 2006), insertions/deletions, presence of exon boundaries, etc). The output is in a graphical form (in the sense of graph theory) and can be either a single phylogenetic tree, a set of trees, or a network (a connected graph with circuits, see later). A consequence of the use of many areas of mathematics is that non-standard terminology has been introduced into phylogeny in an *ad hoc* manner. An unfortunate consequence is that some appropriate areas of mathematics have been overlooked, important problems neglected, or erroneous assumptions made. We will keep our analysis of the problems as broad as possible while keeping to well-defined mathematical terminology that is introduced later in Figure 16.5. Basically, the terminology is both simple and powerful, and it is unclear why phylogenetics does not use a conventional terminology from mathematics.

Another theme of this chapter is the need for careful analysis of concepts in regular use. It is necessary to identify that any 'method' for inferring trees is a combination of at least three components. These are (1) an optimality criterion, (2) a search strategy, and (3) assumptions about the mechanism of evolution (including whether there is sufficient knowledge to correct for multiple changes). Similarly, a concept such as parsimony has two distinct uses: the principle of parsimony (Ockham's razor) is the main use in science generally, and an optimality criterion for inferring an evolutionary tree by minimising the number of mutations on a tree. This second meaning usually uses data without correction for multiple changes at a site, but the same algorithm works (often better) if corrections are made for multiple changes. The two usages (the principle and the optimality criterion) are quite different, and need not agree. For example, the Principle of Parsimony lead to the conclusion that in some cases maximum (average) likelihood is to be preferred over minimising the number of mutations (Steel and Penny, 2000).

It is worth reflecting on the general difficulty of inferring evolutionary trees accurately. Because the events we wish to uncover happened over time periods ranging from hundreds of years to 3000 million years ago, we usually cannot observe them directly (evolution of RNA viruses is a good exception). The subject is therefore both difficult and exciting. Exciting because it is necessary to push the current limits of quantitative science; difficult because it is not possible to check answers directly. This makes the subject ideal for mathematical and statistical reasoning. It also means that controversies will abound, and that is expected when science is stretched to its limits. However, we must never get lost in the mathematical reasoning to the exclusion of the biology.

16.2   DATA

Several ways of presenting data are illustrated in Figure 16.1: character state matrices (such as aligned sequences); distance matrices; splits (partitions, patterns, subsets of taxa);

tensors (3D matrices); gene order; and presence/absence of inserted elements and/or gaps. As used here, tensors are based on three taxa, giving a three-dimensional 'matrix'.

16.2.1 Character State Matrix

Figure 16.1(a) is a multiple alignment for short sequences from four mammals; it is a *character state matrix* or simply the *data matrix, data set*, or *data*. Mathematically a matrix or set is a singular object containing many entries – thus 'data' is singular. Each row in the matrix is a sequence and represents the information about a *taxon* (plural *taxa*). A taxon can be an individual, a group, a population, a species, or some higher taxonomic group. It is a useful general term, and the number of taxa is denoted by t. Each column of the matrix is a *site*, a *column*, a *position* (nucleotide or amino acid), or (as in the case of morphological or behavioral information) a *character*, and their number is denoted as c. An individual entry in a column may be a nucleotide, an amino acid, the presence or absence of a SINE, a code, a *colour*, or a *character state* (hence, *character state matrix*). 'Colour' is a mathematical term for discrete character states and the number of colours is usually given the symbol r. On this terminology DNA has four colours, A, G, C, and T; and proteins have 20. The number of character states is also called the *size* of the alphabet, thus forming a useful analogy with letters in an alphabet. The patterns in the full character state matrix are easily enhanced by a consensus format (see the lower part of Figure 16.1(a)). The preferred method is to make a *consensus* for each site (breaking ties arbitrarily), place it at the top, and show only deviations from the consensus. This is a natural form for introducing another way of describing the data, partitions or splits, but distances will be discussed first.

16.2.2 Genetic Distances (Including Generalised Distances)

Figure 16.1(b) is a distance matrix derived from Figure 16.1(a). In general, values can be derived from any character state matrix, or directly from a range of measurements such as DNA/DNA hybridisation, comparison of shapes of RNA or protein secondary and tertiary structures (Collins *et al.*, 2000), to the number of 'breakpoints' required to equalise gene order in two genomes (Figure 16.1e, Henz *et al.*, 2005). Distances are a subset of difference values that form a 'metric'; to be a metric, the values for any subset of three taxa i, j, and k must have the following properties:

$$d_{i,i} = 0;$$
$$d_{i,j} = d_{j,i} > 0 \text{ for } i \neq j; \text{ and}$$
$$d_{i,j} \leq d_{i,k} + d_{j,k} \text{(this being the triangle inequality).}$$

The first two are straightforward, each thing is identical to itself ($d_{i,i} = 0$); and the difference between A and B must be the same as between B and A (thus $d_{i,j} = d_{j,i}$); and the value must be positive when they differ. The third part of the definition, the triangle inequality is also a simple concept; the direct distance between London and Sydney cannot be greater than the sum of the distances from London to New York plus New York to Sydney. This simple intuitive concept of distances from everyday life is thus extended to a wide range of scientific activities, in this case, the genetic distance between organisms.

When measuring parameters such as DNA/DNA hybridisation, or distances between RNA or protein shapes, it is possible that any the three properties will be violated. There

may be a detectable interaction between, say, the hybridisation of DNA from the same individual ($d_{i,i} \neq 0$), the reciprocal values between two taxa may not be equal ($d_{i,j} \neq d_{j,i}$), and/or the triangle inequality may not hold. Measures based on these properties are *differences* or *dissimilarities* rather than distances; they are still useful though many tree-building algorithms are expected to work better if the data are metric distances.

Hamming distances simply count the relative number of differences between two aligned strings. The strings may be sequences, morphological characters, or even word in copies of an ancient manuscript. Many weightings are possible, e.g. transversions more than transitions. It is important to then divide by c, the length of the sequence, because corrections for multiple changes depend on proportion of sites that vary, not just on the total number of sites that differ. This gives the distance ($d_{i,j}$) as a proportion $0 \leq d_{i,j} \leq 1$. Thus dividing by c leads to more information being included in the distances.

As described, these are *observed distances* and generally, because they do not include multiple changes at a site, underestimate the total number of changes between a pair of taxa. For example the changes A $\rightarrow$ C $\rightarrow$ A between a pair of taxa will not be detected, both sequences have an 'A'. Similarly the series of changes A $\rightarrow$ C $\rightarrow$ G will appear as a single A $\rightarrow$ G change. Later we give the formulae (see Swofford *et al.*, 1996), which estimates the expected number of multiple changes and these *may* allow more accurate estimates of the real distance. Corrections are important for sequences that have diverged for longer times, but they introduce other sources of error. Small differences introduced by sampling can be exaggerated, variances increased, and a bias toward higher values introduced. Corrections become erratic when divergences are large, especially when the underlying processes vary between parts of the evolutionary tree.

These Hamming distances are not the only distances that can be obtained from sequences; the two additional distance matrices in Table 16.1 are also derived from the four sequences in Figure 16.1(a). The entries of the 4×4 matrix on the left is based solely on the nucleotide frequencies of the sequences, in this case the distance between species i and j is $d_{ij} = \sqrt{\Sigma (f_i - f_j)^2}$, where f_i and f_j are the frequencies of the nucleotides. Alternatively, entries in the matrix on the right are derived from divergence matrices, $\mathbf{F}_{ij}$, for each pair of taxa (see the right-hand side of Figure 16.1(b)) with the distance

Figure 16.1 Data for tree building; the same data is used for (a) to (d). (a) Sequence data for 29 nucleotide positions (originally derived from α-crystallin protein sequences). A consensus format is given in the lower part of (a). (b) Distances derived from (a) or (c) by: lower left, counting the number of differences between pairs of taxa; and, upper right, dividing these by the length of the sequences. A divergence matrix, $\mathbf{F}_{ij}$, for monkey and horse is shown on the right. This is used to estimate a genetic distance even when two sequences differ in nucleotide composition. (c) Splits derived from (a) by using the number of times subsets of taxa have a different code to the last taxon (t_4). This form of the data is equivalent to (a) for two-state characters, but omits the order of columns in the sequence, and which of the two codes occurs in (t_1). (d) Tensor (3-D matrix) for (a), recoded as R (purines) and Y (pyrimidines). In this example the entry 3 in front lower left counts the number of sites where monkey and kangaroo have R, while horse is Y – the RYR pattern (sites 8, 22, 24). Similarly, there are two sites (7 and 13) where monkey and horse have Y, and kangaroo R – the YYR pattern. (e) Gene order for five genes, indicating by the arrow the 5′ to 3′ direction of the gene. (f) This is an example of an insertion in one sequence, it is present in one, absent in the other.

Table 16.1 Two distance matrices derived from the data in Figure 16.1(a). The values on the left hand are derived from nucleotide frequencies; those on the right are LogDet distances that compensate for differences in nucleotide composition.

Monkey	$\begin{bmatrix} 0.000 \end{bmatrix}$	0.181	0.181	0.117	Monkey	$\begin{bmatrix} 0.000 \end{bmatrix}$	0.414	0.744	0.834
Horse	0.181	0.000	0.000	0.091	Horse	0.414	0.000	0.578	0.593
Kangaroo	0.181	0.000	0.000	0.091	Kangaroo	0.744	0.578	0.000	0.253
Opossum	0.117	0.091	0.091	0.000	Opossum	0.834	0.593	0.253	0.000
	Monkey	Horse	Kanga	Oposs		Monkey	Horse	Kanga	Oposs

$d_{ij} = \ln(\det \mathbf{F}_{ij})$, the natural logarithm of the determinant of the divergence matrix $\mathbf{F}_{ij}$ for each pair i, j of species. These LogDet (or paralinear) distances compensate partially when the sequences have different nucleotide compositions.

The important point here is that there are many ways of forming pairwise distances–distances do not just appear, they are derived from the data by a calculation that depends on a reasonable knowledge of the organisms, the data, and the mechanisms of evolution.

Three important terms are *additive distances, ultrametric distances*, and the *four-point condition*. Additive distances are values in a distance matrix **D** that can be fitted exactly on a tree. An example is shown in Figure 16.2. Check that the path lengths on the tree add up to the values in the distance matrix. Note also that in this case if the tree were built by selecting the smallest entries in **D**, then taxa 2 and 3 would be selected first – but on this tree these taxa are not joined directly. Additive distances have two interesting features; they describe a unique tree and in addition, the lengths (weights) of the edges of the tree are unique, though it is still be hard to interpret the edge lengths in any particular case. Do not get too excited about additive distances; real data is never additive, even after correcting for multiple changes. The underlying problem is the number of equations and the number of unknowns. In general, there are $(t^2 - t)/2$ distances; 10 for five taxa. Then there are $2t - 3$ edge weights (which are our unknowns, seven for five taxa). It is therefore seldom that distances are additive, although the concept is important for understanding the accuracy and reliability of tree reconstruction.

Ultrametric distances are additive distances with an additional property that can be described both biologically and mathematically. Biologically, the distances fit a rooted tree under a molecular clock so that there are (statistically) equal rates of evolution from the root to all the tips. This is equivalent to the mathematical property that for all triples

Taxon 1	0				
Taxon 2	7	0			
Taxon 3	8	5	0		
Taxon 4	13	10	9	0	
Taxon 5	11	8	7	6	0
	t_1	t_2	t_3	t_4	t_5
Figure 16.2 Additive distances and the corresponding tree.

i, j, and k there is some ordering so that the two largest distances are equal,

$$d_{ik} = d_{jk} \geq d_{ij},$$

('some ordering of i, j, and k' means that the indices of the three taxa can be interchanged to find an order for which this relationship holds). For example, d_{ik} may be 29 nucleotide differences, d_{jk} 31, and d_{ij} 12. In this case you might decide that, statistically speaking, you could not reject the ultrametric relationship. The ultrametric relationship is used in the relative rates test that estimates whether the same rate of change occurs on the two closest taxa. It is necessary to check that taxon k is genuinely more distantly related than the other two taxa, that it is a genuine *outgroup*. However, this test is relatively weak (Bromham *et al.*, 2000).

The third term, the 'four-point condition' is that for any taxa i, j, k, and l, the larger two of the sums

$$d_{ij} + d_{kl}, d_{ik} + d_{jl}, d_{il} + d_{jk},$$

are of equal value i.e. $(d_{ij} + d_{kl}) = (d_{ik} + d_{jl}) \geq (d_{il} + d_{jk})$ for some ordering of i, j, k, and l.

This condition is mathematically equivalent to the distances being additive. As an exercise, test any three distances from the right-hand side of Table 16.1 to see if they are ultrametric. Test also with all four whether the distances satisfy the four-point condition. You will find it helpful to look at the three unrooted trees for four taxa, as follows.
Take a set of distance values, and see how well they fit onto each of the three trees. Most data sets will not fit exactly. Programs, such as SplitsTree (Huson and Bryant, 2006), adds cycles into the graph if the distances carry a signal additional to the tree; an example is shown below on the left. This introduces an additional weight in the graph, shown by the weights, w_{12} and w_{13}, on two internal edges (the parallel edges have the same weights in this graph). This graph will more closely represent the distances in the data by summing the weights on the most direct path between any pair of taxa. This can be extended further to a *Buneman graph*, shown below on the right, where a further weight is included. Again, parallel edges are assigned the same weight.
One additional concept, *generalised distances*, is described now and used later for spectral analysis. Note that the distance values above are for *pairs* of sequences and are therefore 'pairwise distances'. However, for any subset with an even number of taxa

(4, 6, 8 . . .), we can sum the minimum combination of pairwise distances to get a distance value for the subset. For example, in Figure 16.2 the generalised distance value for the subset {1,2,4,5} would be $d_{12} + d_{45} = 7 + 6 = 13$. This broader concept is useful because the total number of subsets with an even number of taxa is the same as the number of splits of the taxa (see next section). In each case there are 2^{t-1} even-order subsets (including zero taxa, which has a distance 0), and 2^{t-1} splits. This equality between the numbers of subsets and of splits is very important because it allows the Hadamard conjugation that is described later. Basically, it is possible to move between splits of the data and generalised distances without any loss of information. However, distance methods traditionally use just the pairwise distances. When distances are derived from sequence data there is loss of information because it is not possible in general to recover the frequency of splits just from the pairwise-distance values (Penny, 1982).

In this section we have shown several ways of forming distance matrices to emphasise the richness and diversity of the concept. Our purpose is to emphasise that the investigator needs to understand the alternatives and choose variants that are appropriate. Science is not a 'passive' process where you put data into a computer program and accept the answer that pops out. Rather it is an active process where the investigator is making hypotheses, testing them, looking for alternatives, challenging dogma, discussing questions with peers – altogether a much more exciting adventure. So review this section quickly with this in mind.

16.2.3   Splits (Bipartitions)

Sequence data can be represented as *splits* (or *bipartitions*), a natural extension of the character state matrix (Figure 16.1). The distribution of characters at a site is a *pattern* and the number of columns in which each pattern occurs is recorded. When only two states are present at a site the pattern can be identified by the subsets of taxa that share a common character. This pair of subsets is called a *split* or *bipartition*.

Examine the lower part of Figure 16.1(a) where the sequences are shown in consensus form. The first and the fifth columns have equivalent character states, the same pattern of taxa sharing the same character. Similarly, in the second and fourth columns the taxa have the same pattern–taxon 1 (monkey) is different from the other three, so the split is {monkey}, {horse, kangaroo, opossum}. Look at columns 2 and 4 again, the patterns are the same but one column is $[GAAA]^t$ and the other is $[AGGG]^t$ (here we *transpose* a column to show it as a row). The pattern of taxa sharing the same character state (code) is also the same as column 22 $[ACCC]^t$–thus the patterns are the same in columns 2, 4, and 22, even though the nucleotides differ. Clearly we will need a simple way of numbering these patterns so that they can be counted easily by computer.

At this point we only describe partitions for two-state characters (two colours) such as for purines and pyrimidines, or the presence or absence of a SINE at a specific site in a sequence. The concept of a *split* (or *bipartition*) comes from the observation that each column in the data set (Figure 16.1a) splits (or partitions) the taxa into two *disjoint* subsets. (Disjoint means that each taxon occurs in just one of the two subsets – no taxon is omitted and no taxon occurs in both.) With four taxa $(t_1 - t_4)$ there are eight possible splits, which we number $0 - 7$ to make it easier to automate calculations. You will find this way of recoding the data very instructive because there is both a direct relationship between splits in the data, and edges in evolutionary trees. It also allows a natural way of introducing estimates of sampling errors.
Figure 16.3   Spectrum for the splits in Figure 16.1(a).

Figure 16.3 gives the frequencies of the splits as a histogram, which is a *spectrum.* When we come to Hadamard transforms we will find that the transforms are examples of Fourier analyses and so they fit into the general framework of spectral analysis (see later).

The indexing system to identify taxa, splits (the information in columns of data), and edges in a tree is simple and beautiful. It is worth mastering because it provides a simple and unambiguous method for describing and relating edges in the tree, the taxa, and patterns in the data. Each taxon has its own *name* or *label* that is fixed for the study, but in addition we give each taxon an *index* that depends on its position in the data set. The taxon *name* (or *label*) may be *Equus caballus*, horse, *Dendroligotrichum dendroides, Drosophila*, kangaroo, Sam, t_5, ..., etc. Its *index* will be selected from successive powers of 2; i.e. 1, 2, 4, 8, 16, ..., etc. depending on whether it is the first, second, third, etc. sequence in the data set (see Figure 16.1). Thus the indices are,

$$2^0, 2^1, 2^2, 2^3, 2^4, 2^5 \cdots$$

$$1, 2, 4, 8, 16, 32 \cdots$$

This is a *binary* indexing system because it uses powers of 2. Indices for taxa are added together to index either splits in the data, or edges of a tree. The indices are shown for the taxa in Table 16.2. Using this indexing system you will find that the sum of the taxon labels of the first t taxa is one less than the label for taxon $t + 1$. For example, with four taxa the sum of the labels is $1 + 2 + 4 + 8 = 15$ and the next label added to make a five-taxon tree is $2^{5-1} = 16$.

Next we need to count all the ways in which t taxa can be *split* into two subsets–these are shown in a natural ordering in Table 16.2. When listing the two subsets, the taxon with the largest index (in this case taxon 4, t_4 with label 8) is always put in subset 2. Consequently subset 1 has all the taxa whose character state differs from the last taxon (t_4 in this case). This indexing is repeated for every site (character).

In the first split in Table 16.2 all taxa have the same code; none differ from t_4. Hence, this split has index 0 (s_0). In the second split, index 1 (s_1), t_1 is the only taxon where the character state differs from t_4, so the split has index 1. With another example, the split in column 19 of Figure 16.1(a) has index $6 = 2 + 4$ because the taxa differing from t_4 are t_2 and t_3, with indices 2 and 4. It is easy to verify that there are 2^{t-1} splits. For two-state characters, each column represents a split and summing over all columns gives the frequencies of each split. The frequencies of the splits in Figure 16.1(a) are 12, 3,

Table 16.2 Splits. A split partitions the taxa into two disjoint subsets, shown on the left as subset 1 and subset 2. All splits of four taxa, $t_1 - t_4$, are shown, together with their indices. (For completeness we also identify the *null* split, where all taxa have the same state, so subset 1 is the empty set ∅.) Check that in every case the sum of the indices is 15 $(1 + 2 + 4 + 8)$; consequently only the index of first subset need be used. The right-hand side of the table has columns representing all eight splits for two-state characters. Under a symmetric model, e.g. $[abbb]^t$ as equivalent to $[baaa]^t$. These pairs of columns are assigned the same indices, 0–7, and are shown above the columns.

					All possible patterns in columns (splits) and their indices. Both symmetric forms are given, e.g. pattern 7 = $[aaab]^t$ and $[bbba]^t$								
Subset 1	Index 1	Subset 2	Index 2	Index 1+ Index 2	Name	0	1	2	3	4	5	6	7
∅	0	$\{t_1, t_2, t_3, t_4\}$	15	15	t_1	$a\|b$	$b\|a$	$a\|b$	$a\|b$	$a\|b$	$a\|b$	$a\|b$	$a\|b$
$\{t_1\}$	1	$\{t_2, t_3, t_4\}$	14	15	t_2	$a\|b$	$a\|b$	$b\|a$	$a\|b$	$a\|b$	$b\|a$	$b\|a$	$a\|b$
$\{t_2\}$	2	$\{t_1, t_3, t_4\}$	13	15	t_3	$a\|b$	$a\|b$	$a\|b$	$b\|a$	$b\|a$	$a\|b$	$b\|a$	$a\|b$
$\{t_1, t_2\}$	3	$\{t_3, t_4\}$	12	15	t_4	$a\|b$	$a\|b$	$a\|b$	$b\|a$	$a\|b$	$b\|a$	$a\|b$	$b\|a$
$\{t_3\}$	4	$\{t_1, t_2, t_4\}$	11	15									
$\{t_1, t_3\}$	5	$\{t_2, t_4\}$	10	15									
$\{t_2, t_3\}$	6	$\{t_1, t_4\}$	9	15									
$\{t_1, t_2, t_3\}$	7	$\{t_4\}$	8	15									

2, 7, 1, 2, 1, and 1, for splits 0–7 respectively. Dividing these values by the number of columns estimates the probability of observing a particular subset in the sequence.

Extending to additional taxa is straightforward and is shown for five taxa. The eight splits in subset 1 are the same as for four taxa – then subset 2 (for four taxa, Table 16.2) is written below subset 1, in reverse order. We now have 16 indices, numbered 0–15. This completes subset 1 for five taxa; subset 2 for these is the complement of subset 1. Calculating their indices, and verifying that for each pair they sum to 31 is a check. This procedure gives a simple recursive method that can be used as t increases. There are other ways for ordering the splits, but it is *essential* to be consistent and this way of indexing is simple for both man and beast (computer). Make sure that you could determine the 32 splits for $t = 6$. There are several ways of indexing four-state characters, but this is outside the scope of this chapter (see Hendy *et al.*, 1994).

16.2.4 Sampling Error

How accurate are our data samples? Biologists are used to the concept of sampling error and any estimate for a distance value or frequency of a split should have an indication of this. For distances, the variance is $d_{i,j} \times (1 - d_{i,j})/c$ where the distances are expressed as differences per site. There is a similar formula for split i (Waddell *et al.*, 1994); its variance is $V_i = s_i(1 - s_i)/c$, where s_i is the frequency of columns with that split. The covariance for the splits i and j is $V_{ij} = s_i(1 - s_j)/c$. The variance on each distance value is expected to be relatively less than that for splits, there are $t(t-1)/2$ distance values compared with 2^{t-1} splits.

There is an additional factor for covariances with distances when a tree-like process generated the data; there is a high correlation between many pairs of distances. Consider the rooted tree in Figure 16.4. The number of differences between any pair of taxa depends on the path between them; most values will be correlated – the extent depends on the proportion of paths they share. In this example chicken–turkey and moa–kiwi distances
Figure 16.4 Correlation of distances. The distance between chicken and kiwi is the path length (dashed line) between them. However the distance from chicken to moa shares much of the same path and consequently its value is highly correlated. The turkey–moa distance is also highly correlated with chicken–kiwi.

Table 16.3 Covariance matrix for the splits from Figure 16.1. Variances are shown on the diagonal, and covariances off the diagonal. Check that, e.g. $V_{01} = V_{10} = -s_0 \times s_1 (-0.4138 \times 0.1034 = -0.0428)$, etc. Fill in the remaining entries.

Index	0	1	2	3	4	5	6	7
s	[0.4138	0.1034	0.0690	0.2413	0.0345	0.0690	0.0345	0.0345]
	0.2426	−0.0428	−0.0286	–	–	–	–	–
	−0.0428	0.0927	−0.0071	–	–	–	–	–
	−0.0286	−0.0071	0.0642	–	–	–	–	–
V[*s*]	−0.0998	−0.0250	−0.0166	0.1831	–	–	–	–
	−0.0143	−0.0036	–	–	0.0333	–	–	–
	−0.0286	−0.0071	–	–	–	0.0642	–	–
	−0.0143	−0.0036	–	–	–	–	0.0333	–
	−0.0143	−0.0036	–	–	–	–	–	0.0333

are not correlated, but this requires knowing the tree. Splits come from a multinomial sampling procedure. For Figure 16.1(a) the covariance matrices are given for both splits (Table 16.3) and distances (Table 16.4). These are calculated using Hadamard transforms and do not require knowledge of the tree (see later).

16.3   THEORETICAL BACKGROUND

This section gives some theoretical background to inferring evolutionary trees and networks. It covers the terminology of trees and graphs, the numbers of trees and its relation to computational complexity and to evolutionary models.

16.3.1   Terminology for Graphs and Trees

The terms we use are given in italics with alternatives given in parentheses. A graph $G = (V, E)$ is a set V of *nodes* (vertices, points) and a set E of *edges* (internodes, links, 'branches') where each edge is represented by a pair of nodes. If edge e is represented by the pair of nodes $\{v_1, v_2\}$, then we can write $e = (v_1, v_2)$, and we say the edge e is *incident*

Table 16.4 Covariance matrices for generalised distances **V[d]**. The vector of distances **d** is shown first. The largest and smallest covariances in **V[d]** are underlined. Entries 1 and 5 in **d** (the distances between taxa 1 and 4, and taxa 1 and 3, respectively) covary the most, while entries 4 and 5 are slightly negatively correlated.

	0	d_{14}	d_{24}	d_{12}	d_{34}	d_{13}	d_{23}	All 4
d	[0.0000	0.4482	0.3793	0.2759	0.1725	0.4137	0.4138	0.4584]
V[d]	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000
	0.0000	0.4947	0.2116	0.0975	0.0524	<u>0.3186</u>	0.2497	0.0594
	0.0000	0.2116	0.4709	−0.0023	0.0072	0.2378	0.3067	0.0239
	0.0000	0.0975	−0.0023	0.3996	0.1118	0.0475	0.0477	0.2116
	0.0000	0.0524	0.0072	0.1118	0.2855	<u>−0.0048</u>	0.0643	0.0547
	0.0000	<u>0.3186</u>	0.2378	0.0475	<u>−0.0048</u>	0.4851	0.2092	0.0761
	0.0000	0.2497	0.3067	0.0477	0.0643	0.2092	0.4852	0.0072

Source: Data from Figure 16.1.

on v_1 and v_2. The graph is often drawn with a dot for each node, and a line connecting two adjacent dots for each edge. Two edges are *adjacent* if they share a common node. A *path* is a sequence of edges $e_1, e_2, \ldots, e_n$, where e_1 is adjacent to e_2, e_2 is adjacent to $e_3, \ldots, e_{n-1}$ is adjacent to e_n. If $e_1 = (v_0, v_1)$ and $e_n = (v_{n-1}, v_n)$, then we say the path connects v_0 to v_n, with v_0 and v_n being the *endpoints* of the path.

A graph is *connected* if for each pair of nodes of G there is a path connecting them. A *circuit* (cycle) is a path with two ends being the same node. Figure 16.5(a) is a graph that is not connected and contains several circuits. The *degree* (valence) of a node v is the number of edges incident on it. A node of degree 1 is a *leaf* (tip, external node, pendant vertex). Figure 16.5(a) contains vertices of degrees 0, 1, 2, 3, and 4. Sometimes we may draw two edges crossing, although the point of crossing does *not* represent a node, as in the centre of Figure 16.5(a).

A *tree* is a graph $T = (V, E)$ which is connected and has no circuits, a '*connected acyclic graph*'; Figure 16.5(b) is a tree. For phylogenetic trees a node may represent a taxon by attaching a *label* (name) to the node; Figure 16.5(c) is a tree where all nodes are labelled. Often the edges have an associated real number, the *weight* (length) of the edge. In phylogenetics this can represent the number of substitutions, time, or a probability of substitution; hence edge weights are non-negative. When the edges are weighted, T is a *weighted* tree (see Figure 16.5d). A graph or tree, or parts of the tree, can be rotated on the page and it is still the same graph or tree. Examples include (t_1, t_2) in Figure 16.5(f) and similarly (t_5, t_6) with t_4. What is essential is the relationship between the edges and vertices, not the way they are represented on the computer screen or on the page.

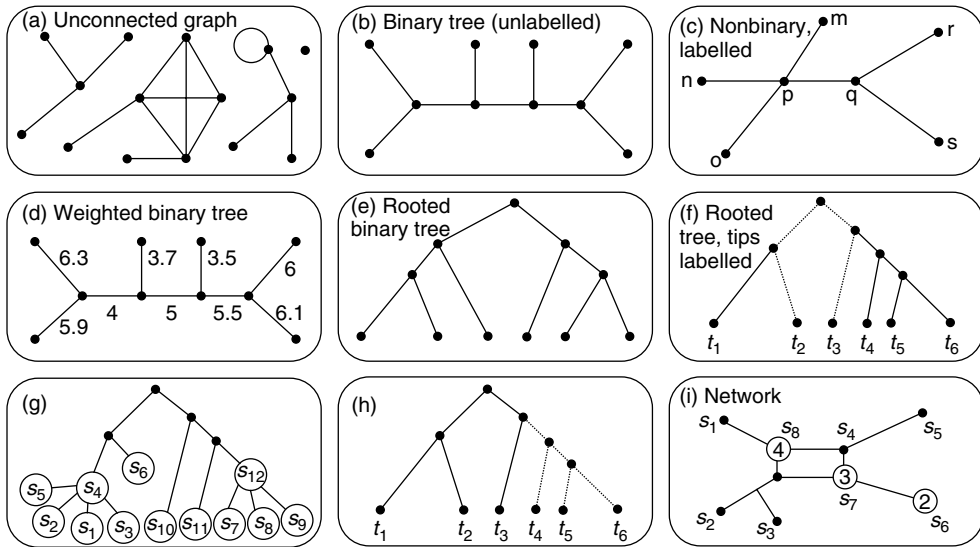
We often wish to identify the *root* of the tree (the most recent common ancestor). Such a tree is a *rooted* (directed) tree; the root is unique and the tree can be drawn at the top, bottom, or to the left, but with all edges directed away from the root. A rooted tree can be derived from an unrooted tree by identifying a root, which may be an existing node, or a new node (of degree 2) can be inserted into an edge. Figure 16.5(e) is a rooted tree obtained from Figure 16.5(b) where the root has been added to the central edge in Figure 16.5(b). Removing the root from Figure 16.5(e) returns to the unrooted tree Figure 16.5(b).


Figure 16.5 Terminology for trees. Examples of graphs (trees and networks), see text for details.

A *phylogenetic tree* (phylogeny, X-tree, cladogram) for a set of taxa S is a tree with labels on all leaves, and possibly on some internal nodes. More than one taxon can label a node. Figure 16.5(f) is a phylogenetic tree on the taxon set $S = \{t_1, t_2, \ldots, t_6\}$. A phylogenetic tree may be rooted or unrooted, weighted or unweighted, binary or nonbinary. A path connecting two labelled vertices (t_2 and t_3), is shown in Figure 16.5(f) as a dotted line. In a rooted tree we can identify a *lineage* as a path from an internal node to a labelled node; the path is directed away from the root. In addition, a *subtree* (branch, in mathematical and botanical terminology) is the set of lineages from a node v with a common first edge e. Figure 16.5(h) shows both a lineage and a subtree. In a *binary* rooted tree, any path from the root has two choices (a bifurcation) at every non-leaf node.

A *phylogenetic network* is a connected graph, again with some of the nodes labelled (Figure 16.5i). In this example the number of times a sequence has been found in a population is indicated by the size of the circle. In a tree the removal of any edge partitions the taxa into disjoint subsets, in a network a set of (parallel) edges may be required to partition the graph into two connected subgraphs (so the graph appears 'box-like' as in Figure 16.5(i) which has two sets of parallel edges).

There are two non-standard usages found in phylogenetics. The first is that a 'branch' refers to an edge (not a subtree; in both mathematical and botanical terminology a branch is a subtree). The second is that 'topology' often refers to an unweighted tree (rather than to an unlabelled tree). It is important to be aware of both alternative usages, only occasionally are they ambiguous. However, we will avoid both non-standard usages.

16.3.2 Computational Complexity, Numbers of Trees

16.3.2.1 Numbers of Trees

A fundamental problem with inferring evolutionary trees is the very large numbers of trees, even in searches limited to unrooted binary trees. The numbers of trees (and either
Figure 16.6 Counting unrooted binary trees. There is a single unrooted binary tree for three taxa. The fourth taxon (t_4) can be connected to any of the three edges a, b, or c. This leads to the three distinct unrooted trees for four taxa (shown as a, b, and c), each with five edges. A fifth taxon can be added to any of these five edges, thus leading to 15 trees (3 trees, times five edges), etc.

the time to calculate them, or the amount of computer storage required) increases faster than exponentially with respect to the number of taxa t, i.e. $\propto t^t$. There are simple formulae for counting tip-labelled binary trees, either unrooted or rooted. The number of unrooted binary trees is $(2t - 5)!!$ and the number of rooted binary trees $= (2t - 3)!!$, where t is the number of taxa. The 'double factorial' notation (!!) is the product of every second number, i.e. $(2t - 5)!! = 1 \times 3 \times 5 \times 7 \times \ldots \times (2t - 5)$ where the '...' indicates repeating the intermediate steps until you reach the last value $(2t - 5)$. For example, for 10 species $2t - 5 = 15$ so there are $1 \times 3 \times 5 \times \ldots \times 15 = 2\,027\,025$ unrooted binary trees. An informal way of finding the above formulae is given in Figure 16.6.

16.3.2.2 Computational Complexity

The fundamental measure of the usefulness of an algorithm (a numerical recipe) is the time and/or computer storage space it requires – its *computational complexity*. This can be the number of computational steps as a function of the size of the input data. It is usually expressed as a function of n; here it is the number of sequences (t) and so we use n and t interchangeably. If this function is bounded (limited) by a polynomial of n (such as n^2, or n^4, etc.), then the algorithm is a polynomial time algorithm and is *efficient*. The classification uses the worst case, and so an order n^2 algorithm guarantees to complete in that number of steps. The number of steps to determine a tree using the neighbor-joining (NJ) algorithm is a polynomial of degree 3 and we write $O(n^3)$ (pronounced as *order n cubed*) for the computational complexity of NJ.

In contrast, any algorithm which requires a separate calculation of each of the $(2n - 5)!!$ tip-labelled binary trees (such as maximum parsimony (MP) or maximum likelihood (ML)) cannot in general be computed in polynomial time. We write $O(n^n)$ for the number of binary trees, because $(2n - 5)!!$ is asymptotic to n^n. We consider complexity under just a single variable, the number of taxa. In practice it is necessary to also consider the complexity of an algorithm under sequence length, c. Most tree-building methods are linear with respect to c, but alignment algorithms may be of order c^2 or c^3. When an algorithm is $O(n.\log n)$ then, because $\log n$ is less than n, $n.\log n$ is less than n^2, so the algorithm is still efficient because its complexity is bounded by a polynomial in n. Some examples of efficient algorithms include:

1. Locating an item in an ordered list of n items is $O(\log n)$. For example, to find the telephone number of a friend in a telephone directory of n names, first compare your friend's name with a name in the middle of the book. Then compare it with the middle of the first, or second half, depending on whether her name is before

or after that central name. Repeating this subdivision process until finding the name requires at most $\log_2 n$ comparisons. The number might be located in fewer steps but the complexity always refers to the *worst* case; we can guarantee the algorithm will terminate in at most $\log_2 n$ steps.

2. If we needed to find the person with a specific number in this telephone directory, then potentially we need to look at each number until it is found. It could be the very first number, but also it could be nth, the very last, so this is an O(n) algorithm.

3. To sort the telephone directory by numbers (rather than by names) requires O($n.\log_2 n$) steps. This is achieved by locating the position of each successive number among those already sorted. The search algorithm of example 1 above orders each of the n numbers in $\log_2 n$ steps.

4. Finding the smallest distance for n taxa is O(n^2). The numbers of entries (distances) is n^2, and because the matrix is symmetric we need only compare the entries above the diagonal. Thus the number of comparisons is bounded by a polynomial in n^2, so the search is O(n^2).

5. In the unweighted pair-group mean average (UPGMA) algorithm (see later), the closest pair of taxa (requiring O(n^2) steps to find them, as in example 4) are amalgamated, giving a new matrix of distances between the $n - 1$ remaining 'taxa'. The closest pair in this matrix is again found, amalgamated, and the process repeated $n - 2$ times. The complete algorithm is thus O(n^3) and so is an efficient algorithm.

6. The tree-building algorithms of MP and ML, if fully implemented, require an evaluation of each of the $(2n - 5)!!$ binary trees. Even if each tree can be evaluated efficiently (as for MP) the number of trees cannot be bounded by a polynomial in n. Consequently, these algorithms are not polynomial and hence *not* efficient. In Table 16.5 we compare the growth of some of these functions for some small values of t.

7. The Hadamard conjugation used in the spectral analysis involves calculating values for each split, and there are 2^{n-1} splits. The fast Hadamard transform involved requires $2n$ steps for each split, and hence Hadamard conjugation is an O($n2^n$) algorithm. Again, this is not an efficient algorithm (even if it is the best possible).

It is easy to demonstrate the general problem resulting from the large numbers of trees. Estimate how long it would take to do all the calculations for algorithms of different efficiencies. Assume that the time for calculating each step is the same for each algorithm. If one million trees could be calculated per second, how long would it take to calculate all trees for 20 species? There are $\approx 2.2 \times 10^{20}$ trees for 20 taxa and $\approx 3.16 \times 10^7$ seconds year^{-1} so we can calculate $\approx 3 \times 10^{13}$ trees per year. Thus we require $2.2 \times 10^{20}/3 \times 10^{13} \approx 7$ million years calculating the trees for 20 taxa!

Thus for $t = 20$, a million-fold increase in computing speed is not going to make the calculation practical. In contrast, at 10^6 calculations per second, the Hadamard conjugation would require almost 21 seconds, and the NJ algorithm would require less than one-hundredth of a second.

This means that for $t > 20$ it is not practical to simply evaluate a function for each tree to find the optimal tree. Finding the optimal tree for t taxa is an example of a

Table 16.5   Values for some polynomial and exponential functions for small values of t.

t	$t \log_2 t$	t^2	t^3	$t2^t$	$(2t-5)!!$	$(2t-3)!!$

non-deterministic polynomial (NP)-complete problem. The travelling salesman problem is another well-known example. That problem is, given the distances between all pairs of n cities, find the shortest path that allows a salesman to visit all cities and return to the start. This general class of NP-complete problems has the following properties: if an efficient solution is found for one, it will work for all; no general solution has been found for any; but there is no proof that an efficient solution cannot exist.

That is the bad news from complexity theory, which deals with the worst case scenarios. There are special cases where algorithms can run in polynomial time for the number of sequences (Fernandez-Baca and Lagergren, 2003). One example is for population data with many similar sequences; there may be only a single nucleotide difference between them. In this case, parsimony is a ML estimator, and a MinMax Squeeze program (Holland *et al.*, 2005a) has been able to guarantee the shortest possible tree for over 50 human mitochondrial genomes. However, having considered some of the theoretical computational questions, it is time to look at the models of evolution used when inferring evolutionary trees from biological data.

16.3.3   Three Parts of an Evolutionary Model

Scientific models are usefully classified into three parts: the structure of the system; the forces (mechanisms) operating on it and; some initial conditions that specify the system at a particular point in time. For an evolutionary model, the equivalencies are as follows,

1. A *tree* (or more generally a graph), is either rooted or unrooted. This is usually a tree, but cycles can arise from endosymbiosis, lateral transfer, gene conversion, allopolyploidy, hybridisation, etc. This part of the model gives the relationships between the sequences and is assumed even if there is insufficient information to specify a common mechanism (see later).

2. A *mechanism* of change (typically, changes to the sequences are stochastic and are independent and identically distributed (i.i.d.) – again, see later).

3. *Probabilities* **q** (weights) of observing a change along each edge of the tree, these are the *initial conditions* including edge lengths, transition/transversion ratios, and nucleotide composition at the starting point.

Given these three features, we calculate or predict the expected frequencies of patterns (splits) in the sequence data (Figure 16.7). For simpler mechanisms this is best done by spectral analysis using Hadamard transforms, a simple discrete-Fourier process. For small numbers of taxa, the calculations can be carried out in spreadsheet programs such as Excel. The transforms convert the vector of the observed frequencies of splits (**s**, the sequence spectrum) to the probabilities of change on each edge of a tree T (in the vector **q**). Each entry in these vectors is indexed by one of the 2^{t-1} possible splits (Section 16.2.3). The intermediate steps are generalised distances (Section 16.2.2), which are equivalent to paths through the tree (or graph). The series of vectors is thus **s** (observed frequencies of splits), **r** (observed generalised distances), **ρ** (rho, predicted (corrected) generalised distances), **γ** (γ, predicted (corrected) frequencies of splits), and finally **q** (γ values fitted onto edges of a tree). For simple models, these transforms are invertible with the use of Hadamard matrices (see later), so that **γ** can be derived from **s**, and vice versa.

The Hadamard transforms are a series of simple invertible steps involving a Hadamard matrix, **H**. This m by m matrix has entries 1 and -1 and satisfies the equation $\mathbf{H^t H} = m\mathbf{I}$, where **I** is the m by m identity matrix and $\mathbf{H^t}$ is the *transpose* of **H** (rows and columns interchanged). The transform allows a simple set of equations that add and subtract the lengths of edges on a tree to give path lengths; or conversely (the inverse) add and subtract path lengths to get lengths of individual edges. Figure 16.7 shows the relationships between data as sequences (i), and the evolutionary model (vi).

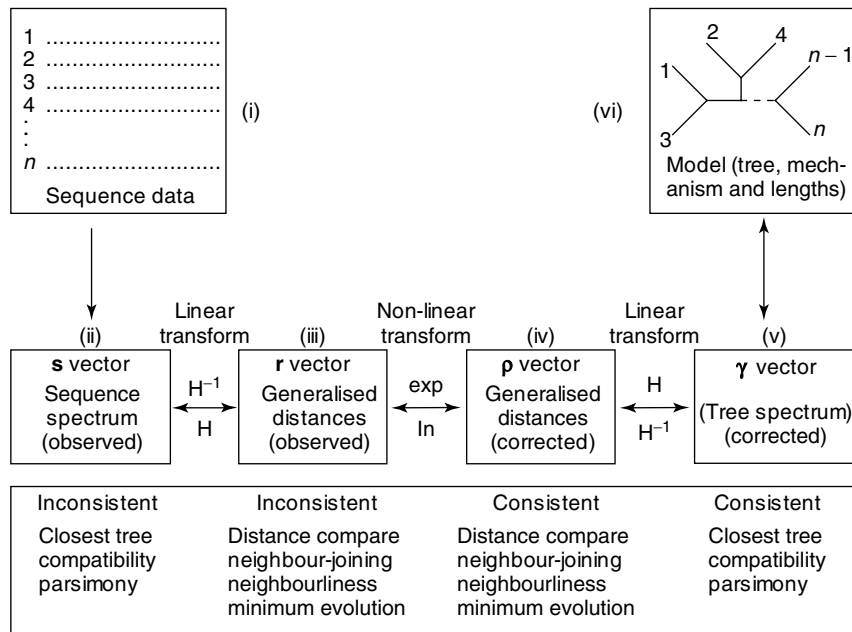
In following Figure 16.7 from (i) to (vi) you will see that the first step is translate the sequence data as a *sequence spectrum* **s**; the observed frequencies of each of the 2^{t-1} possible splits from the sequences for t taxa (see Figure 16.1c and Table 16.2). The Hadamard product $\mathbf{r = Hs}$ (a linear transform) calculates the observed *generalised*


Figure 16.7 Invertible transformations between data (i) and model (vi).

distances **r** (iii). Many methods use just pairwise distances, i.e. distances that are calculated for each pair of taxa. Pairwise distances can be used to infer generalised distances, and they reduce the variance when corrections are made for multiple changes (Waddell *et al.*, 1994).

The step from **r** to **ρ** corrects, depending on the mechanism of evolution, for inferred multiple changes at a site. The values in **ρ** are *predicted generalised distances* (iv). The logarithmic function from (iv) to (iii) corrects for unobserved changes and depends on the distribution of substitution rates in the model. When all sites are evolving at the same rate (the uniform rate model), the natural logarithm is used in going from (iii) to (iv), with its inverse being the exponential function when going from (iv) to (iii). If not all sites evolve at the same rate then a Gamma distribution can be used, though other distributions are possible (Waddell *et al.*, 1997). The inverse Hadamard matrix (a linear transformation) is used to get from the generalised distances to corrected edge lengths $\gamma = \mathbf{H}\rho$, see (v). This inverts path lengths (generalised distances) to individual edges of a tree (observed splits, or splits in the underlying model). The three-step procedure from (ii) to (v) uses a Hadamard transformation, then a logarithmic transformation, and finally the inverse Hadamard transformation. Applying three functions sequentially, with the third being the inverse of the first, is (in mathematics) a conjugation. Thus the three-step procedure is called a *Hadamard conjugation*, and is invertible.

From this spectrum in (v), a tree can be selected by a number of selection criteria (parsimony, closest tree, minimum evolution, etc.) Thus, trees can also be selected anywhere along the transformation from **s** to **p**. Notice that in Figure 16.7 the Hadamard conjugation is NOT a tree selection criterion, it is an invertible method for moving between paths and edges without loss of information. The transformations are invertible, so the method can be used to calculate properties of sequences from simple models of evolution, or recover a model of evolution given observed sequences. Different tree selection procedures can be applied to components within the transformation. Distance based methods are applied to the **r** and the **ρ** vectors, while sequence based methods can be applied to the **s** and the **γ** vectors. The selection procedures are statistically consistent after the correction for multiple changes (iii) to (iv) (provided that the correct mechanism was used), but can be inconsistent otherwise.

For analysis of a set of t taxa, the Hadamard conjugation is a function of a spectrum (a vector of 2^{t-1} components) where each entry is indexed by a split. The simplest substitution process is the symmetric two character state model. The two character states could be purines (R) and pyrimidines (Y) in DNA or RNA. The model has a probability p_e for each edge e of the tree T, where p_e is the probability of a substitution (either R to Y or Y to R) between the vertices of the edge. It can also be applied (Hendy *et al.*, 1994) to the symmetric four-state models of Jukes and Cantor, and Kimura's 2ST and 3ST models (see Swofford *et al.*, 1996).

A Hadamard matrix is a square matrix with entries of 1 and −1 and where all the columns (or rows) are orthogonal. (Two vectors are orthogonal if the result is zero when their corresponding entries are multiplied and summed.) An 8×8 Hadamard matrix in an appropriate form is shown below. The order of rows and columns is critical, it must correspond to the order of the entries in **p**, **q**, **γ**, and the other vectors. That is, changing the order of rows and/or columns still gives a Hadamard matrix, but no other order would be suitable unless we also change the ordering of splits and subsets. Below we show H in two forms, the usual way on the left and on the right-hand matrix + stands for +1

and – for -1. The right-hand matrix is broken by dotted lines into four 4×4 submatrices to illustrate the recursive process for generating the matrix. The two top and the lower left submatrices are identical, the lower right has the sign reversed for every entry.

$$
\begin{bmatrix}
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\
1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \\
1 & 1 & -1 & -1 & 1 & 1 & -1 & -1 \\
1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 \\
1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 \\
1 & -1 & 1 & -1 & -1 & 1 & -1 & 1 \\
1 & 1 & -1 & -1 & -1 & -1 & 1 & 1 \\
1 & -1 & -1 & 1 & -1 & 1 & 1 & -1
\end{bmatrix}
\quad
\begin{bmatrix}
+ & + & + & + & \cdot & + & + & + & + \\
+ & - & + & - & \cdot & + & - & + & - \\
+ & + & - & - & \cdot & + & + & - & - \\
+ & - & - & + & \cdot & + & - & - & + \\
\cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\

+ & - & + & - & \cdot & - & + & - & + \\
+ & + & - & - & \cdot & - & - & + & + \\
+ & - & - & + & \cdot & - & + & + & -
\end{bmatrix}
$$
$$\mathbf{H}^{(3)} \qquad\qquad\qquad\qquad \mathbf{H}$$

For t taxa, $\mathbf{H}$ is generated recursively starting from the matrix with a single entry $\mathbf{H}^{(1)} = [1]$, and then forming the next larger Hadamard matrix as follows.

$$\text{Let } \mathbf{H}^{(1)} = [1], \text{ and } \mathbf{H}^{(m+1)} = \begin{bmatrix} \mathbf{H}^{(m)} & \mathbf{H}^{(m)} \\ \mathbf{H}^{(m)} & -\mathbf{H}^{(m)} \end{bmatrix}, \text{ for } 1 \leq m \leq t - 2, \mathbf{H} = \mathbf{H}^{(t-1)}.$$

Note that the signs of the upper left 2×2 submatrix are of the form,

$$\begin{bmatrix} + & + \\ + & - \end{bmatrix},$$

and the upper left 4×4 submatrix can be derived from this upper left 2×2 submatrix with the same pattern of sign changes. Thus, the four upper left 2×2 submatrices have the same pattern of sign changes. For example, row 6, column 5 will be the negative of row 2, column 1; row 8, column 7 will be the negative of row 4, column 3. Similarly, you can repeat the generating process once more to derive $\mathbf{H}^{(4)}$, the 16×16 matrix for five taxa, and in general $\mathbf{H}^{(t-1)}$, for the $2^{t-1} \times 2^{t-1}$ matrix for t taxa.

Hadamard matrices have several important properties. Firstly, it allows an invertible transform between splits and generalised distances. This requires the same numbers of entries in each vector, here 2^{t-1}. In mathematical terms the transform is one to one and 'onto', therefore it is invertible. A second important property is that multiplication of a vector by $\mathbf{H}^{(t)}$ can be reduced to $t2^t$ additions and subtractions (the fast Hadamard transform). Another particularly useful property is that the inverse of any Hadamard matrix ($\mathbf{H}^{-1}$) is the transpose of the matrix, $\mathbf{H}^{(t)}$ divided by the number of rows (2^{t-1} in our case), i.e. $\mathbf{H}^{-1} = \mathbf{H}^{(t)}/2^{t-1}$. Together these make the method simple but powerful. However, it is now time to consider the final aspect of theoretical background; mechanisms of evolution for sequence data.

16.3.4 Stochastic Mechanisms of Evolution

Markov models (named after a Russian mathematician) are widely used in science, including describing the evolution of sequences through time. They are very general and the simplest versions just require that the probability of substitution depends only on the current state. For sequences, this means that the probability of a substitution depends only on the present nucleotide at a site; it is independent of what the sequence might have been earlier in evolution. This is realistic for molecular evolution where, e.g. no

information is retained in a human sequence as to which nucleotide was present at a given site in early primates.

Fortunately, Markov models are well studied and relatively easy to work with. Consider a sequence that evolves from time A until time B, the total length of time is t. We are interested in both the rate of change at any point x, as well as the total amount of change from A to B. Evolutionary models are effectively reversible, we could equally consider the amount of change from B to A (though a different Markov process might be required).
At any point x, the instantaneous rate matrix, $\mathbf{K}$, describes the rate (per site) that mutations are fixed into the sequence. The transition matrix, $\mathbf{M}$, describes the probability of states at a site being different at A and B, it depends on both $\mathbf{K}$ and the time t. (In Markov models, 'transition' is used in a general sense for any type of substitution, not as a contrast to a transversion.) The 3ST Kimura model (shown below on the left) is frequently used with nucleotides and has three classes of substitution, rates α, β, and γ (identified in the middle graph below). This model can be simplified to the Kimura 2ST model by setting $\beta = \gamma$, giving the model with separate rates for transitions and transversions. Furthermore, setting $\alpha = \beta = \gamma$ gives the simple Poisson model, the Jukes–Cantor model.

3ST rate matrix   graph of rate classes   a specific transition matrix

where $* = -(\alpha + \beta + \gamma)$.

Consider the rate matrix $\mathbf{K}$. At any point x along a lineage from A to B there is a probability (per unit time) that an adenine will be mutated to guanine (α), or to cytosine (β), or to thymine (γ). Consequently, the probability of replacing adenine by another nucleotide is $= (\alpha + \beta + \gamma)$. $\mathbf{K}$ is normalised with diagonal entries $-(\alpha + \beta + \gamma)$ so that each of the rows sums to zero; thus there is conservation of the nucleotides. The same process holds for the other nucleotides; they also have similar probabilities of changing (α, β, and γ). Under this model (which is simplistic, but useful and popular), the nucleotide composition will converge to equal proportions (25 %) of A, G, C, and T, even if the proportions of nucleotides was different when the process started.

The next step is to obtain the transition matrix, the expected probability of a difference between A and B over the time t. The expected number of substitutions of each class is αt, βt, and γt. The transition matrix, $\mathbf{M}$, is calculated from the instantaneous rate matrix $\mathbf{K}$ and t, as, $\mathbf{M} = \exp(\mathbf{K}t)$; with $\exp(\mathbf{K}) = \mathbf{I} + \mathbf{K} + \mathbf{K}^2/2! + \mathbf{K}^3/3! + \mathbf{K}^4/4! + \ldots$, which converges. This transition matrix gives probabilities for each class of substitution during the time interval t, and entries in $\mathbf{M}$ predict the number and classes of nucleotide changes between the times A and B. In the right-hand example above, there is a 3 % chance that any adenine in the sequence will have mutated to G, and 7 % to C and 7 % to thymine.

Consequently, there is an 83 % chance it is still an adenine (even though it may have mutated to another nucleotide and then mutated back again).

These matrices are simple and symmetric (the rate A → G is equal G → A). It is straightforward to compensate for unequal frequencies of nucleotides (or amino acids) if all sequences are similar, say 60 % G + C. This is modelled with a symmetric matrix plus a vector of nucleotide frequencies. However, when sequences have different nucleotide (or amino acid) compositions, an asymmetric rate matrix with its resulting asymmetric transition matrix is required. This asymmetry is not a problem (apart from requiring more parameters) if the transition matrix is being used to predict sequence data, such as in a simulation study, or for ML. However, when compensating for multiple changes it is necessary to make a 4 × 4 divergence matrix for DNA (or 20 × 20 for amino acids) for each pair of sequences (see Figure 16.1b, right). Taking the logarithm of the determinant of this divergence matrix corrects for multiple changes. This is the LogDet (or paralinear) distance correction (Lockhart *et al.*, 1994).

A frequent assumption is that changes occurring in the sequence are 'i.i.d'. Independent means that a change at any site in the sequence, and on any lineage on the tree, is independent of all other changes. Identically distributed is that all sites (nucleotides or amino acids) are selected from the same distribution of rates. Sites may have different rates, but are still drawn from the same distribution. The mathematics requires (Tuffley and Steel, 1997) that sites are always in the same rate class over the whole tree, whether fast, medium, or slower sites. This is problematic, and contradicts the biochemical knowledge that the 3D structure of proteins evolves through time. The covarion model of Walter Fitch is an early attempt to allow, over time, sites to vary in their rates. His model assumed a limited number of sites were free to change, but that this set could slowly drift as the 3D structure evolved. A hidden Markov Model (Tuffley and Steel, 1997) can approximate this covarion process, using just two additional parameters. These are the proportion of nucleotides that are (for functional reasons) free to change, and how quickly variable and fixed sites interchange. A relaxed covarion model would allow this proportion of fixed sites to vary. Future developments will probably incorporate more biochemical realism. Some mechanisms also assume the same rate of change along each edge of the tree – the *molecular clock* – and this imposes additional constraints on edge lengths. The chapter of Swofford *et al.* (1996) has a good discussion of the standard mechanisms, and how they are interrelated.

16.4   METHODS FOR INFERRING EVOLUTIONARY TREES

Most new methods for inferring trees have been developed for sequence data (DNA and protein), but most work equally well on discrete (i.e. not continuous) data from morphology, anatomy, biogeography, behaviour, etc. Methods for inferring tree are considered in three parts:

1.   an *optimality criterion*, to measure how the data 'fits' a particular tree (or graph);

2.   a *search strategy* for finding the optimal tree(s); and

3.   assumptions about the *mechanisms of evolution* for the data.

It is incorrect to speak of a 'method' of inferring trees without specifying the optimality criterion, the search strategy, and how multiple changes are handled (by the mechanism assumed). Examples of these three combinations are given with the optimality criterion identified as (1), search strategy as (2), and the mechanism as (3). A method could be, a parsimony (1) branch-and-bound search (2) on data corrected for multiple changes by the Kimura 2ST model (3). Or, a NJ search (2) for the minimum evolution tree (1) using observed (uncorrected) distances (3). Or, ML with hill climbing to find the optimal parameters on a tree (1), a general reversible model of change (3), and a heuristic search through the tree space (2).

Comparing two methods that differ in all three of above options has generated a great deal of confusion. To take just one example, several studies have compared 'MP' and 'NJ' (details are given later). These 'methods' differ in their optimality criterion, their search strategy, and whether or not they correct for multiple changes. But which of the three differences leads to a particular set of results? Such sloppy work is poor science, and unfortunately many simulation studies are not worth the silicon they are computed on. We will examine some criteria for evaluating the different approaches.

16.4.1   Five Desirable Properties for a Method

There is still no general agreement how to evaluate tree reconstruction methods. We have suggested that being *efficient, consistent, powerful, robust*, and *falsifiable* is a good starting point for analysis (Penny *et al.*, 1992). *Efficiency* is discussed earlier under computational complexity – to have any real chance of finding the global optimum for medium to large data sets, the algorithm must run in polynomial time. The concept is used in multiple alignment, in evaluating an optimality criterion on a single tree, and searching over all trees. Alignment is not discussed here, but there are efficient algorithms available for a weighting scheme of matches, mismatches, and gaps for pairs of sequences. However, in general it is necessary to optimise an alignment on a tree and there are no known efficient solutions for the combined problem. Optimality criteria such as parsimony, minimum evolution, and closest tree can be calculated efficiently for a single tree. For ML it is not yet known whether this is true.

The next two desirable features come from considering the effects of increasing the length of the sequences, c. Biologists accept that, with short sequences, there will be sampling error and are not too surprised if details of the optimal tree changed when longer sequences became available. Eventually, with long sequences, we expect convergence to a single tree. But is it the correct tree, the tree on which the sequences were generated? Two questions that arise are: does the method converge to the correct tree, and how long do sequences need to be to get *convergence*? A method (optimality criterion, search strategy, plus assumed mechanism of evolution) is said to be *consistent* if it guarantees to converge to the correct tree; conversely, it is *inconsistent* if it can converge to an incorrect tree.

There is both good news and bad news here. Any reasonable optimality criterion is consistent if the correct assumptions are made about the mechanism of evolution. But each is also inconsistent if invalid assumptions are made. Parsimony is consistent if the correct assumptions are made (and compensated for), inconsistent otherwise. ML is inconsistent if, e.g. it assumes that all sites are free to vary when most are fixed for functional reasons. Differences in nucleotide composition between sequences lead to similar problems for all optimality criteria. There has been a lot of confusion with statements that optimality

criteria are, or are not, consistent, when the real issue is the consistency of the complete method – optimality criterion, search strategy, and assumed mechanism of evolution.

In an important development J. Felsenstein showed in 1978 (see Swofford *et al.*, 1996) that even with only four taxa, but with unequal rates of evolution, uncorrected parsimony, and some distance methods using observed (uncorrected) data were not consistent even with two-state sequences under a symmetric model of substitution. With five or more taxa, uncorrected parsimony is also inconsistent even with equal rates of evolution, and even with equal edge lengths for larger numbers of taxa. We (Hendy and Penny, 1989) suggested that there was a general problem when there was a juxtaposition of long-short-long edges on a tree – the two long edges (branches) tended to join together. We called this the *long-edges-attract* problem. Although it may appear bad news, it does give biologists the chance to use their biological knowledge to select taxa that intersect long edges in the tree. Uncorrected parsimony can be improved with additional taxa that join into what would otherwise be long edges on the tree, and/or by correcting for multiple changes. A method is inconsistent under a given model if there are any possible cases where it converges to the wrong tree. It is a separate, but important, question as to whether such cases are common. This leads us into the next criterion, how long should the sequences be.

Do we need to analyse sequences of 10^3, 10^5, or 10^7 nucleotides in length? Convergence with relatively short sequences we call *powerful* and is another desirable property. Not surprisingly, considerable effort has gone into measuring the rates of convergence and the techniques available include: computer simulation; repetitive sampling (bootstrap and jackknife); congruence of trees from different sets of data; fit to a model; prior knowledge (occasionally possible); and analytical solutions.

Different rates of convergence can result from methods using different amounts of the information in sequences. As the number t of taxa increases, methods using genetic distances use only a vanishingly small fraction of the information in the data. The number of distance values increases in proportion to t^2 while the number of patterns in the data (bipartitions or splits) increases exponentially (2^{t-1}). Uncorrected parsimony omits sites that are constant or where only one character state occurs more than once (singletons). But both types of position give information about the appropriate model of evolution. In addition, such sites occur frequently, so the estimates of their frequencies are more accurate.

Many optimality criteria, especially non-parsimony methods, ignore information from insertions and/or deletions (which are highly informative), and also from other types of biochemical information (such as SINEs). Using only subsets of taxa (such as quartets) disregards most of the information that can come from incompatibilities. Variability within taxa is again ignored. Information loss is not limited to a particular method. All omit some information and consequently the power of each method is reduced. As yet, we can make only rather weak predictions about the relative power of methods. For large data sets, ML and closest tree methods use more sequence information than uncorrected parsimony, and these together use more than distance methods.

To move onto the fourth desired feature – *robustness*. A method may be consistent under one model, but become inconsistent with only small deviations from it. Everyone would like a method that is efficient, powerful, and consistent, even with sizeable deviations from the model – i.e. a method that is *robust*. Robustness is an area where there is almost a conspiracy of silence from those developing techniques. In general, we only compare data from simulations where the data is generated on a tree, and by a known mechanism.

With simulation, data can be generated under one mechanism of evolution and different assumptions tested when inferring a tree. For example, data may be generated with a γ distribution of rates at different sites, and the effect studied of recovering the tree with very different γ values (including all sites evolving at the same rate). This is an excellent start, but we still have little idea of the consistency of different approaches as real data start deviating from the simplest models.

Computer simulations can study several aspects of the problem of robustness. A method that was consistent with equal nucleotide frequencies can become inconsistent when the frequencies of character states (such as GC (guanine plus cytosine) content) vary between taxa. Simulation studies are only of limited help unless the results are integrated into a theoretical analysis of the methods. The real problem is that, considering all models, there are billions of combinations of parameters to be tested. By itself, testing four or five combinations of parameters is not that useful. Simulations are more powerful when testing predictions from theoretical studies of algorithms.

The final desired feature is the standard scientific requirement that the data, in principle, must be able to *falsify* the model. This is perhaps the least studied, and the most difficult, of our five desirable features. Perhaps the worst methods in this respect are clustering (or local search) methods that do not evaluate an optimality criterion over the whole tree. They output just a single tree, and give no ranking of the other $(2t - 5)!!$ trees. Would a network be better for a given data set? We distinguish cases when the model is very wrong, from those when the model is incomplete – missing some significant aspect. Examples are when recombination, or gene conversion, has occurred and a tree (lacking cycles) is then incomplete. Another case is when the mechanism assumes similar nucleotide compositions, when the sequences differ significantly. In such cases, features of the model such as, the tree, stochastic mechanism, similar rates, may all be reasonable; but the full model requires at least one additional parameter.

In practice it is difficult to test the full model completely. If a tree is assumed, it may be easy to test quantitatively two versions of the mechanism of evolution. Conversely, for a given mechanism, we can test between different trees. This aspect of the falsifiability of models requires more consideration. At present we are left with the status that no method (combination of optimality criterion, search strategy, and initial conditions) can meet all five of our desired features. This is a problem, but has not stopped a lot of progress in understanding the evolution of both macromolecules and organisms. It is perhaps a call for less special pleading about our own favourite method, more caution in interpreting results, and a challenge to keep improving.

16.4.2 Optimality Criteria

It is time to consider the first aspect of a method for recovering trees – the optimality criterion (objective function). Common optimality criteria include parsimony, minimal length, ML, least-squares fit, minimum evolution, etc. An optimality criterion usually estimates how well the data fits a particular tree though the splits-graph criterion is a fit of distance data to a phylogenetic network.

16.4.2.1 *General Comments on Parsimony*

Parsimony is one of the most frequently used optimality criteria, but there are ambiguities in the use of the concept. In everyday life the term is used as an adjective, e.g. when

someone is said to be parsimonious; not sharing, thrifty, or stingy. However, parsimony has a long history in science as looking for the 'simplest' explanation. Thus there are two major usages.

1. The Principle of Parsimony (Ockham's razor). This is its most common usage in science – find the simplest hypothesis that explains the data; do not add complexities to a model that works.

2. Minimising the number of mutations when fitting sequences onto a tree.

The two usages can be in contradiction. In other words, it is not always true that the simplest explanation (the Principle of Parsimony) is to minimise the observed number of mutations on a tree (Steel and Penny, 2000). It is traditional when minimising the number of mutations on a tree not to make any adjustments for multiple changes at a site. This is best called *maximum parsimony* to distinguish it from other variants such as weighted parsimony, or corrected parsimony. Weighted parsimony uses additional knowledge of the mechanism of evolution such as the transition/transversion ratio, or the relative rates of change between nucleotides or between amino acids. Similarly, corrected parsimony (Penny *et al.*, 1996) minimises the number of mutations on a tree after correcting for inferred multiple changes.

MP thus consists of two independent concepts: minimising the number of mutations on a tree (the optimality criterion), and, using the observed data (not correcting for multiple changes). Normally the only part of the model of evolution it assumes is the tree itself. However, parsimony can be modified to minimise the number of mutations of data onto a network (i.e. a connected graph with cycles). The failure to distinguish between the minimal length (number of mutations) criterion, and using observed data (uncorrected for multiple changes) has led to acrimonious debates because the problem was not analysed adequately.

16.4.2.2 Relationship between Parsimony and Maximum Likelihood

Just as with parsimony, there are many usages of the term *maximum likelihood* (Steel and Penny, 2000) and we use their terminology. All usages have the common theme of maximising the likelihood of observing the data, given some background information about the model of evolution (in this case, a tree, a mechanism of change, and initial conditions). J Huelsenbeck discusses ML itself separately. Here we only consider the relationship between parsimony and ML.

The usual form of ML in phylogeny is called *maximum average likelihood* (ML_{av}). This uses a *weighted* tree (weights associated with edges), and then sums the likelihoods of observing the data over all codings at the internal nodes. We illustrate ML_{av} with two character states 'a' and 'b' over an unrooted tree connecting four taxa (Figure 16.8). There are four ways the two internal nodes (ancestors) could be coded, both internal nodes could be 'a' [a, a, Case 1], or one 'a' and one 'b' [a, b, Case 2 or b, a, Case 3] or both 'b' [b, b, Case 4]. For simplicity we assume the same rates (probabilities) of change on each edge of the tree, namely 0.05. It is straightforward to calculate the likelihood of the pattern [a, a, b, b] by:

1. calculating the probability of a specified coding at internal nodes for Cases 1–4; and

2. summing the probabilities over all possible internal codings (four in this example).
Figure 16.8   Calculating maximum average likelihood, given the pattern **a**, **a**, **b**, **b** on the external points, and with the internal points indicated as being either '*a*' or '*b*'. The symbol '×' marks each edge where a change (mutation) is required for a particular coding at internal points. There are two such changes in Case 1, one for Case 2, etc. This simple model gives the same results wherever the root is placed; the model is essentially an unrooted tree.

For 0.05 as the probability of a change, the probability of no change is 0.95 $(1 - 0.05)$. Thus, for the tree in Case 1 of Figure 16.8, the probability (to five decimal digits) is

Case 1[a, a] $0.00214 \ (= 0.95 \times 0.95 \times 0.95 \times 0.05 \times 0.05)$;

Case 2[a, b] $0.04073 \ (= 0.95 \times 0.95 \times 0.05 \times 0.95 \times 0.95)$;

Case 3[b, a] $0.00000 \ (= 0.05 \times 0.05 \times 0.05 \times 0.05 \times 0.05)$; and again

Case 4[b, b] $\underline{0.00214}$ (the same as the first). Summing these values gives

0.04501 as the probability for observing this data under this model.

This is for just a single site in the data, probabilities for each site are multiplied together (in practice, the logarithms are taken and added in order to keep the numbers manageable).

Another form of ML is to find the most-likely codings at the internal nodes of the tree, and this is maximum most-parsimonious likelihood (ML_{mp}, Steel and Penny, 2000). For the example above, Case 2 is the most likely and so the internal codes [a, b] would be selected. (In this example, the same choice would be made by MP, but this is not always true.) This form of ML would be chosen if a researcher wishes, e.g. to synthesise the most-likely ancestral form of a gene and test whether it functions as expected.

However, even more detailed information might be required; perhaps the investigator wishes to know the most-likely coding at every point along the edges of the tree, not just for the internal nodes as for ML_{mp}. This more highly specified form of ML is called *evolutionary pathway likelihood* (ML_{ep}). This form of ML is equivalent to MP (Steel and Penny, 2000), this is the first of the equivalencies between ML and MP.

These three (ML_{av}, ML_{mp}, ML_{ep}) are examples of maximum relative likelihood. In each case they are selecting a weighted tree. Another form of ML in phylogeny is maximum integrated likelihood (Steel and Penny, 2000). This form of likelihood is probably closer to what researchers really want and may, e.g. take into account the *a priori* distribution of trees. However, this is outside the scope of studying the relationship between parsimony and likelihood. To sum up, there are several forms of both parsimony and likelihood. This in itself is not a problem at all, as long as it is made explicit about which version is being used.

Having considered some forms of ML, we turn to a more detailed consideration of parsimony and ML, an area that has been controversial. The relationship between the two concepts appears complex but is being resolved. There are occasions when the MP solution is equivalent to a ML solution.
Figure 16.9 Common mechanism and no common mechanism. (a) Common mechanism – each site evolves on the same tree and proportionally has the same expected rate of change on every edge (branch). (b) No common mechanism – each character or site evolves on the same tree, but each character has different rates of change for every edge.

If there is only a single column of data, then the ML and MP solutions are the same. That is for this particular case, the ML estimator is MP. With only a single site, there is no additional information from combining additional sites. This may sound trivial but it leads to a much more interesting case, when there is no common mechanism of evolution shared by all the characters. For example, each character may have evolved on the same tree, but the potential for a character to change on a particular edge of the tree varies between characters. The concepts of common mechanism, and no common mechanism, are illustrated in Figure 16.9. An example of no common mechanism could occur with morphological data – the chance of an insect evolving eight legs may be zero, but somewhere deep in the invertebrate tree a $6 \leftrightarrow 8$ change (for example) must have been possible. Some major rearrangements in genomes and/or gene structure have similar properties. Although with no common mechanism the MP and ML solutions are the same, it is an area where ML itself does not guarantee consistency. Basically, with a common mechanism each site is an estimate of the same process. This means that additional sites give an improved estimate of the common underlying process. Conversely, with no common mechanism, each site is basically a new and unique process.

Before considering additional examples where parsimony is the ML estimator it is worth noting that with the present example it is a good point to consider whether the 'Principle of Parsimony' supports using observed data (rather than considering multiple changes at a site). Unfortunately, it does not. Advocates of Ockham's razor (the Principle of Parsimony) would, as illustrated by the following example, invoke the principle at this point. They would point out that, for some data sets, assuming a common mechanism for all sites is 'more parsimonious' than assuming 'no common mechanism' (each site evolving differently).

Table 16.6 has a small segment of homologous sequences from a pseudogene (a duplicate copy of a gene that no longer codes for a gene product). The full sequences are over 10 000 nucleotides long, and as a first approximation it is expected that there is little selection at any of the sites – most mutations would be neutral. Therefore, according to the Principle of Parsimony, it is simplest to assume one common mechanism for all sites, not 10 000 different mechanisms, one for each site. Each site is thus an estimate of the same underlying model – the same tree, the same mechanism, and same rates of change on each edge of the tree. In this case the Principle of Parsimony supports the standard (average) ML approach, rather than assuming a separate mechanism for each site (as MP does). Thus it is 'simpler' to correct for multiple changes. In this case, the two uses of parsimony (Ockham's razor, and minimising the number of mutations on observed data) are not in agreement.

Another example of the equivalency between parsimony and likelihood is with an extremely large number of character states, two changes may never occur at same site in

Table 16.6 A small segment of sequences from a pseudogene. If there is little selection at such sites, then it is more parsimonious to assume one common mechanism for all 10 000 sites.

... A C A C T G A G G G A A G G A T G A G A A A T A A A T G T G A A A G C A ...			Human
	G		Chimpanzee
	T		Gorilla
	T	C	Orang-utan
G	T		Rhesus monkey

different lineages. Here again the MP and ML solutions coincide (Steel and Penny, 2004; 2005). Examples include SINEs or LINEs inserting at a new site. Such unique events may be the most reliable evidence for oldest divergences, but this requires large amounts of sequence data to find the relevant examples. For example, each insertion of a transposable element would be at a different location in the genome. Some gene and/or chromosomal rearrangements may also be unique events and MP is then the ML solution.

A major difficulty with ML is that it is computer intensive. There is no efficient algorithm known for calculating the ML for just a single tree, even before considering the large numbers of trees. In Figure 16.8, the calculation was done for just one set of edge weights (rates). It is necessary to repeat the calculation many times, adjusting the rates slightly until the highest likelihood value is found. It has been shown that data sets can have many optima on a single tree (i.e. combinations of edge weights that cannot be improved by slight iterations, see Chor *et al.*, 2000). Again, this is for a single tree and, for large data sets, likelihood methods are limited to heuristic searches of tree space (see later).

To summarise this section, there are interesting relationships between maximum (uncorrected) parsimony and likelihood. They are equivalent on a single column of data and thus when there is no common mechanism shared by the characters. They are also equivalent under ML_{ep}, or there are infinite character states (the same mutation never occurs twice). Another example is when there are many sequences just one mutation apart (i.e. the sequences are 'abundant', as in a population study). However, sequences from different species are usually quite distinct ('sparse') and the two criteria differ, and need not arrive at the same tree. It is now time to look at the parsimony criterion itself.

16.4.2.3   The Fitch Algorithm for Parsimony

Parsimony is both easy and fast to calculate on a single tree, it is $O(t)$ – though the problem of the large number of trees still remains. For a set of t aligned sequences, and a labelled tree T, parsimony counts the minimum number of changes on the edges of T. Consider an example of five species (taxa), where at one site, the first two have A (adenine), and the other three have G (guanine). Find a tree that requires the smallest number of changes (see Figure 16.10). With only five taxa a minimal coding can be found by eye. The trees are unrooted because the parsimony score is independent of the position of the root; other information is required to identify the root.

The data A_1 and A_2, and G_3 to G_5 are the leaves of the tree. In the first tree, only a single A $\leftrightarrow$ G change is required, indicated by the arrow (unrooted trees do not specify which direction the change is going), but two changes are necessary for tree II. On the parsimony criterion, tree I is preferred over tree II for this single column of data. Tree II requires at least two changes, no matter how you code the internal nodes (all three
Figure 16.10 The parsimony criterion. The data is a site with character states $[A,A,G,G,G]^t$, these are shown as A_1, G_3, etc. Two trees (I and II) are shown in (a) and (b) and then minimal coding at the internal points are shown in (c) and (d); the changes (mutations) required are shown as arrows. Parsimony selects the tree with fewest changes, tree I in this example, but this is just for one site in the sequence.

internal nodes are be labelled 'G' in this case). This visual process works only for a few columns on a small number of taxa.

The Fitch algorithm quickly finds the parsimony score. It moves through the internal nodes (starting from neighbouring pairs of taxa) and gives both the minimal number of changes for the tree and a first estimate of the character states at internal nodes. There are many alternatives for moving through the tree, but the result is independent of the choice. For each internal node the algorithm checks two adjacent nodes where the character states are already defined; either because they are external nodes labelled by the sequences, or they are internal nodes for which a first estimate has already been made. The first estimate takes the intersection ($\cap$) of the character states at the two adjacent nodes. If the intersection is not empty, keep the value and move to the next internal node. If the intersection is empty, then take the union ($\cup$) of the character states and add a 'cost' to the total length of the tree. The cost (or weight) is usually equal for each column, but if the same pattern occurs in several columns then the cost is the number of times the pattern appears (or the expected number of times for corrected parsimony). For weighted parsimony the cost varies between character states, transitions are usually weighted less than transversions, and the weights need no longer be integers. The costs are summed over all columns in the data.

The tree (or trees) that requires the smallest number of changes (mutations) over the whole data set is selected. There is a second pass for the Fitch algorithm but it is only used to finalise the alternatives that may occur at an internal node on a minimal coding. The Fitch algorithm is efficient (on a single tree) because it is linear with respect to t, the number of taxa.

Many other things could be said about parsimony. As an optimality criterion it is not consistent on observed sequences, but neither are other criteria. However, we have pointed out that most criteria are consistent if appropriate corrections are made for multiple changes, and this includes parsimony. There is an interesting case under a molecular clock where MP can be inconsistent if applied to the tree as a whole, but is consistent if the tree is built up from quartets of taxa. There is still much to be learned about the properties of optimality criteria!

16.4.2.4 Minimum Evolution and Related Criteria

This section includes several optimality criteria that involve distances directly, or else edge lengths on trees (often calculated from distances). The details are well covered in

Swofford *et al.* (1996) and consequently we only give an overview here. However, the section again illustrates the necessity of distinguishing between optimality criteria and search strategies.

NJ, e.g. is one of the most popular 'methods' for distances but it is basically a tree search strategy that can be implemented with other optimality criteria, including parsimony and ML. In the standard NJ programs a pair of taxa x and y is selected to combine based on their *net divergence* – estimates of the length of the internal edges that results from pairing two taxa. Initially x and y are separate taxa, but later in the search they can belong to a cluster of taxa that has already been combined. To calculate the net divergence for any pair x and y, ($\mathbf{E}_{xy}$), the distances from each taxon in the pair to every other taxon is used, as follows,

$$\mathbf{E}_{xy} = \frac{1}{n'-2} \left(\sum_{i=1}^{n'} \left(d_{xi} + d_{yi} \right) \right) - d_{xy},$$

where n' is the current number of clusters (n' decreases during tree building; i.e. part of the tree searching section). Suppose we choose clusters x and y to amalgamate to form the new cluster, z. A new distance matrix $\mathbf{D}$ is recalculated with z replacing x and y, as follows

$$d_{zj} = \frac{d_{xj} + d_{yj} - d_{xy}}{2} = d_{jz} \text{ (the values are symmetric).}$$

The procedure is consistent if the distances are additive. Essentially, the optimality criterion is maximising the lengths of the internal edges of the tree but the search strategy only finds the maximum value for the next edge. It is relatively easy to evaluate the optimality criterion over the entire tree (not just a single edge at a time). In a general sense then, NJ is a local (greedy) search strategy using a minimum evolution optimality criterion.

Another optimality criterion just selects the smallest entry in the distance matrix, this is UPGMA, or average linkage. After each clustering the distance matrix, $\mathbf{D}$, is modified to

$$(d_{zj}) = \frac{a_x d_{xj} + a_y d_{yj}}{a_x + a_y} = (d_{jz}), \text{ where } a_x \text{ is the size of cluster } x, a_y \text{ that of cluster } y.$$

Additive distances are not sufficient to guarantee that UPGMA is consistent; it also requires that they fit a molecular clock, i.e., the distances between each taxon and the root are the same. On the other hand, when a molecular clock is appropriate UPGMA can out perform NJ (see Holland *et al.*, 2003). There are also a group of Fitch–Margoliash (FM) methods where each possible tree is tested, and edge lengths assigned to minimise

$$\sum_{1 \le i < j \le n} w_{ij} \left| d_{ij} - p_{ij} \right|^{\alpha},$$

where w_{ij} is a weighting factor, d_{ij} is the distance (which may be adjusted for multiple changes), p_{ij} is the sum of the edge lengths on the path on the tree between i and j (the patristic distance). α is a constant, usually 1 or 2 depending on whether absolute or squared deviations are to be minimised. While reasonably fast algorithms exist to find the best-fit edge lengths when $\alpha = 1$ or 2, they are not available for other values of α.

An important criterion, Closest Tree, minimises the Euclidean distance between either the inferred (or observed) bipartition spectrum γ (or s), and that expected for a particular tree T. When the split spectrum is known, as from character sequences, the square of this distance is

$$\sum_{i>0, e_i \notin T} \gamma_i^2 + (2n-2)\gamma_T^2,$$

where

$$\gamma_T = \frac{1}{2n-2}\left(\gamma_0 + \sum_{e_i \in T}\gamma_i\right) \text{ and } \gamma_0 = -\sum_{i=1}^{m-1}\gamma_i.$$

This optimality criterion, because it is implemented over the whole tree, can be implemented with branch-and-bound searches of tree space, as described in Section 16.6.1.1. Thus there is a range of optimality criteria that work either directly on distances, or on how well edge lengths on a tree predict the data. More research is still required with different combinations of optimality criteria and search strategies; there tends to be unnecessary associations of criteria, corrections, and search strategies.

Distances (pairwise or generalised) are readily corrected for multiple changes at a site for a wide range of possible mechanisms. Again the details are well handled in standard texts such as Swofford *et al.* (1996), Page and Holmes (1998), and Nei and Kumar (2000). The simplest is a standard Poisson correction, which is called *Neyman* or *Cavender/Farris* for two character states, Jukes/Cantor for four. In general, the correction is

$$d'_{xy} = -((r-1)/r) \cdot \ln(1 - (r/(r-1) \cdot d_{xy}),$$

where d' is the inferred distances after correcting for multiple changes at a site and r the number of character states ($r = 2$ for two-state characters, 4 for nucleotides and 20 for amino acids).

The main problem with the corrections is that they both increase the variance on the distances, and introduce a bias that overestimates the distances. This bias results from taking the logarithm of the observed distances and is particularly marked for relatively short and/or quite distant sequences. The formulae under-correct slightly if a particular distance is smaller than expected – but even more overcorrect if the distance is larger than expected, even by the same amount ε. This asymmetry in the correction leads to the bias. Formulae are available to reduce the bias, and in our experience should always be used. The Tajima (1993) formula is;

$$d'_{ab} = \Sigma\frac{((k_{ab}^{(i)} \times 2^{i-1})}{(i \times c^{(i)}))}, \text{ where } i \text{ is summed over 1 to } k_{ab}$$

and where

$$z^{(i)} = \frac{z!}{(z-i)!}$$

The parsimony criterion can also be used after correcting for multiple changes (Penny *et al.*, 1996) and although such a method does not use 'distances' in its final step, it does use distances (pairwise or generalised) in intermediate steps during the correction for multiple changes. This emphasises that there are many interrelationships between methods and each 'method' is a combination of an optimality criterion, a search strategy, and an assumed mechanism of evolution (included the option of insufficient knowledge

to be able to correct for multiple changes). The interrelationship of methods is still an active area of research.

16.5 PHYLOGENETIC NETWORKS

Phylogenetic networks can usefully illustrate evolutionary relationships when the evolutionary history of sequences or species may be poorly represented by a tree. They have been used to study viruses and plants species where the underlying assumption of tree-like evolution is inadequate possibly due to recombination, lateral gene transfer, or hybridisation. They display the extent of conflicting signals in the data and thus provide a visual measure of confidence in a model. Across a range of taxonomic groups, species trees and gene trees may differ due to gene duplication and loss, or lineage sorting. This gives rise to the gene tree/species tree reconciliation problem, which prompted Maddison (1997) to describe species phylogeny as *a cloud of gene histories*. In studies within interbreeding populations, networks can represent recombination. In all these cases it is of interest to reconstruct a reticulate evolutionary history and represent it with a *directed acyclic graph* (DAG). Even when the underlying historical signal fits a tree there may be conflicting non-historical signals caused by sampling error, long-branch attraction, nucleotide composition bias, or changes in the substitution rate at individual sites across the tree, as well as alignment or misreading errors. Here we require networks that can visualise conflicting signals in data, but we do not require an explicit representation of evolutionary history.

16.5.1 Reconstructing Reticulate Evolutionary Histories

Each site (character) has a tree-like history, even when sequences have a reticulate history. We expect that contiguous segments of DNA (for instance most genes) evolve along a tree, but that the complete sequence alignment may be a mosaic of different tree-like parts (Maddison, 1997). This means that the problem of representing the evolutionary history of the complete sequences often reduces to finding a DAG that displays a set of trees. There will not generally be a unique solution so we need to find minimal DAGs that minimise the number of reticulation nodes (such as hybridisation events or recombination nodes).

Bordewich and Semple (2007) have shown that in general it is NP hard to find a minimal hybrid phylogeny (a DAG with some restrictions) that displays two gene trees. Baroni *et al.* (2006) gave a non-polynomial time algorithm for computing a minimal hybrid phylogeny for two gene trees, but the problem of combining more than two gene trees is unresolved. Special cases can be solved in polynomial time. For instance, if the hybridisation events are all independent (cycles do not overlap) the minimal hybrid phylogeny can be found efficiently (Nakhleh *et al.*, 2005). Huson *et al.* (2005) have made further progress; their method solves cases where the reticulations are non-independent but overlap in a special way. These approaches all make the assumption that the gene trees are error free. Nakhleh *et al.* (2005) provide a polynomial time algorithm for constructing a hybrid phylogeny from two gene trees where error is allowed but the network can have only a single reticulation. Another special case is when one of the input trees is known to be the species tree for the gene tree/species tree reconciliation problem; the aim is to find a series of events (gene duplication, loss, or lateral transfer) that explain how a gene tree

has arisen in the species tree. Hallett and Lagergren (2001) give an efficient algorithm for this where only lateral gene transfer is considered.

Huber *et al.* (2006) infer DAGs that represent the evolutionary history of polyploids. Unlike a lateral gene transfer event, where a species acquires a novel gene or a current gene is displaced, a polyploidy hybridisation event is additive, all versions of the gene are retained. This scenario gives rise to multilabelled trees that are like standard phylogenetic trees except that the same taxon name may appear at more than one tip. Their algorithm finds a DAG that exhibits a multilabelled tree using a minimal number of recombination nodes.

Recombination is an important process within a sexual population and in this case we need to recover the ancestral recombination graph – a DAG where at recombination nodes a breakpoint indicates which sites inherit their state from the left parent and which inherit from the right parent. Work in this area usually assumes the infinite sites model of sequence evolution, which implies that each site undergoes at most one mutation, so any incompatibilities between sites must be explained by recombination events rather than parallel mutations or reversals (Hein, 1990). The problem of finding the minimal ancestral recombination graph (where minimal refers to the number of recombination events) is NP hard (Wang *et al.*, 2001). Song and Hein (2005) give a non-polynomial time algorithm for it. Gusfield *et al.* (2003) give a polynomial time algorithm for the special case where cycles introduced into the DAG by recombination nodes are all independent.

16.5.2 Displaying Conflicting Phylogenetic Signals

Rather than attempting to explicitly model reticulate evolution it is often of interest to simply display conflicting signals in the input data. This is partly because the problem of estimating reticulate evolution is computationally difficult, and partly because although we think a tree is useful we are nevertheless interested in the signals in the data that do not fit on a tree.

Splits graphs are a versatile tool for displaying conflict in many types of phylogenetic data. A split is a bipartition of the taxa set (see Section 16.2.3), so every edge in a tree corresponds to a split, since its removal separates the labels into disjoint subsets. A split system is any collection of splits, and a splits graph is a network that represents the split system. Trees are the simplest splits graphs; split systems that correspond to trees are called *compatible*, and those that do not are *incompatible*. Incompatible split systems can be represented by splits graphs but each split corresponds to a set of parallel edges (Figure 16.11). Although every splits graph corresponds to a unique split system, the same split system can be displayed by many splits graphs.

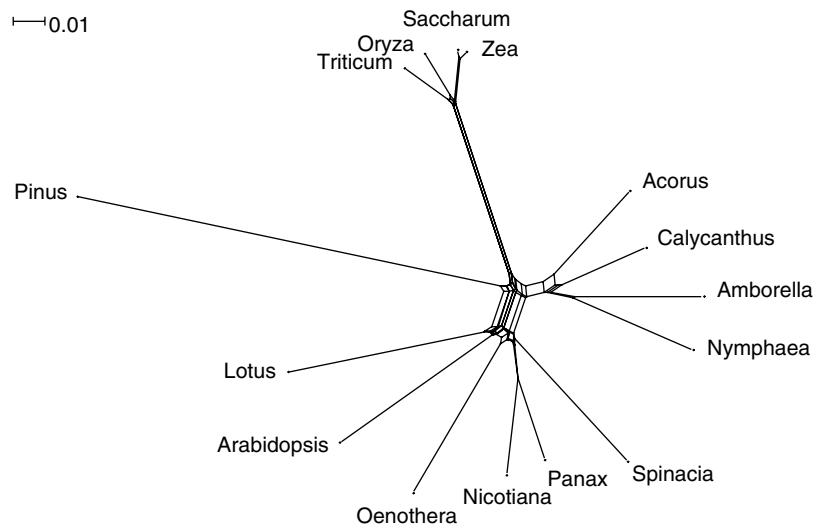
A k-clique in a split system is a collection of k pairwise incompatible splits, a k-*compatible split system* is defined by requiring that there is no $(k + 1)$ clique. Any k-compatible split system can be displayed by a k-dimensional graph. However, it is hard to interpret splits graphs in more than three dimensions, so it has been an active area of research to characterise split systems that are less complex than general split systems. *Circular split systems* arise from defining a circular ordering of the taxa and then only allowing splits that correspond to a contiguous segment of this ordering, or in graphical terms, splits that correspond to cuts though the circle. Circular split systems can be displayed by planar graphs even though they can contain k-cliques for arbitrarily large k (see Figure 16.12). *Weakly compatible split systems* are defined by requiring that there is no set of four taxa a, b, c, d where all three possible quartet trees $ab|cd, ac|bd, ad|bc$
Figure 16.11 Incompatible split systems can be represented by splits graphs. Unlike a tree where each edge corresponds to a split here each set of parallel edges corresponds to a split. The edges in the splits graph that correspond to the split {a,c,e}, {b,d,f} are shown in bold.


Figure 16.12 A NeighborNet of uncorrected distances from an alignment of 89 436 sites of the chloroplast genomes of 14 angiosperms and 1 gymnosperm (Pinus). The split system found by NeighborNet is circular and the resulting splits graph can be drawn in the plane.

are displayed in the split system. In other words, any two quartets can be shown on the graph, but not all three. Weakly compatible split systems can be displayed by 'almost' planar graphs.

We now give a brief description of splits-based methods. All the methods mentioned below (with the exception of quartet imputation supernetworks) are implemented in the freely available software package *SplitsTree4* (Huson and Bryant, 2006). Spectral analysis and median metworks are implemented in spectronet (Huber *et al.*, 2002).

Split decomposition (Bandelt and Dress, 1992) works from a distance matrix and identifies a set of weakly compatible splits. Split weights are assigned by a function (the *isolation index*) which is a minimum of a quantity evaluated over all quartets displayed by the split; this means that split-decomposition networks can be poorly resolved (star-like) especially for large data sets. The split residue or percentage of the distances that is not captured by the split system is summarised by the fit percentage.

NeighborNet (Bryant and Moulton, 2004) works from a distance matrix, it begins by finding a circular ordering on the taxa by an extension of the NJ algorithm. This circular ordering selects the splits and it then uses a least-squares criterion to find non-negative weights for each split. The circular ordering ensures that the splits can be displayed by a planar splits graph. NeighborNets are almost always more resolved than split-decomposition graphs.

Median networks (Bandelt, 1994) are one-connected networks where edges represent a single mutation and nodes represent sequences (extant or inferred). New sequences are inferred using the median hull operation which, given three sequences, can form a potentially new sequence by taking the majority-rule consensus, this is repeated until no new sequences can be derived. These networks are guaranteed to contain all the most-parsimonious trees. Unlike split decomposition or NeighborNet, the resulting split system need not be weakly compatible or circular, and the associated splits graph can be complex. Median networks have proven useful for analysing population data where sequences are densely sampled (Bandelt *et al.*, 1995).

Spectral analysis exploits the relationship between sites patterns and splits (Hendy and Penny, 1993). Any site where only two different states occur corresponds directly to a split of the taxon set. If more than two states are observed at a site then some recoding is required, e.g. RY coding or other projections to two states. The spectral graph displays all splits that correspond to site patterns in the data. Spectral analysis can be used directly on a sequence alignment or combined with Hadamard conjugation and applied to the γ vector (see Figure 16.7), although only with simple models (K3ST and subclasses). As with median networks, the splits graph can be complex, so usually a threshold is specified and splits with fewer than this number of supporting sites are excluded.

Consensus networks and *super-network* methods take trees as input, rather than the initial data (distances or sequences). The trees could arise from bootstrap analysis, Monte Carlo Markov Chain (MCMC) analysis, equally parsimonious trees or trees estimated from different genes. Consensus networks (Holland *et al.*, 2004; 2005b) display all splits that appear in more than some threshold t of the input trees. This threshold controls the complexity of the resulting graph which is k compatible, where k is the first integer less than or equal to $1/t$. A drawback of the consensus network method for gene trees is that all trees must include the same taxa. When the taxa set is overlapping, but not identical, supernetwork methods are required. The first supernetwork method was the Z-closure network of Huson *et al.* (2004), which is based on repeated use of a closure operation that takes two partial splits (i.e. splits on a subset of the complete taxa set) and extends them; the closure rule is applied iteratively until no further splits can be extended, and then all the full splits are displayed in a splits graph. The method is dependent on the order of the partial splits, so typically many orders are used and the union of the full splits found is displayed. A new super-network method was recently presented by Holland *et al.* (2007); it adds all missing taxa into each partial tree according to a scoring function that maximises the number of quartets in agreement with other trees in the input set. If there is enough information to complete the partial trees they are combined in a consensus network.

Other approaches also show conflict within phylogenetic data but are not within the splits-graph framework. Legendre and Makarenkov (2002) developed Reticulograms that use a least-squares criterion with distance data. They begin by constructing a tree and then augment it with additional edges that improve the fit to the data. It adds edges

one at a time by minimising a least-squares fit of the distances on the network to the observed distances. A scoring function that considers both the least-squares fit and the total number of edges decides when to stop adding edges. The method is implemented in the software package *T-Rex*. Statistical parsimony (Templeton *et al.*, 1992) creates a minimum spanning network up to some connection limit. A graph is constructed starting with the taxa as vertices and no edges; edges are added between taxa that differ at only one site, then between taxa that differ at two sites, etc until either the network is connected or the connection limit is reached. The connection limit is set by calculating how likely multiple substitutions are at a site between taxa, a certain distance apart. If the probability of multiple substitutions is greater than 5 % then connections at that distance are disallowed.

Further information on network methods can be found in recent review articles, including Linder and Rieseberg (2004) who discuss the application of network approaches to reconstructing reticulate evolution in plants; Morrison (2005) who discusses the application of networks to problems in population biology; Posada and Crandall (2001) who discuss the gene tree/species tree problem; Huson and Bryant (2006) who describe splits-based methods and their implementation in the software package SplitsTree4; and Huber and Moulton (2005) who give a detailed description of median networks, consensus networks, split decomposition, and NeighborNet.

16.6   SEARCH STRATEGIES

Optimality criterion that are evaluated on a tree have the problem, discussed earlier, of the large number of trees on which the criterion must be evaluated. This is what makes finding the optimal tree NP complete; there is no efficient algorithm for searching all trees. We consider strategies of searching for an optimal tree under three classes, exact methods that (in principle) consider all trees, heuristic searches with limited (or local) searches, and heuristic searches that move through the space of all trees.

16.6.1   Complete or Exact Searches

For small numbers of taxa (for most optimality criteria up to about 10 taxa, 2 027 025 unrooted binary trees) we can search all trees. However, even in this case, it is better to use the first branch-and-bound search strategy outlined below.

16.6.1.1   *Branch-and-bound Methods*

These are standard methods in Operations Research. The 'branch' is a structured search through the space of trees; this is the standard use of 'branch', not the non-standard use in phylogeny for an edge of a tree. The 'bound' is the cost of the optimality criterion on the best tree found (for parsimony, the tree with the fewest changes). If the 'bound' is exceeded, there is no need to search deeper from that point, thus eliminating large numbers of trees from the search.

The two most popular branch-and-bound approaches are adding taxa sequentially (thus forming subtrees with a subset of taxa), and adding sites sequentially ('TurboTree').

The first starts with a subtree of three widely separated taxa; adds a fourth to every position on that subtree, etc. (see Figure 16.6). If a subtree with, say, 10 out of 20 taxa is already longer than the best tree already found then there is no need to add the remaining 10 taxa. For example, if the best tree has 769 changes, and a subtree of 10 taxa has 770, then $17 \times 19 \times 21 \times \ldots \times 35 (> 10^{14})$ trees are excluded because each *must* be worse. It is important to eliminate early unproductive regions of the search space. A second approach, TurboTree, ranks the most frequent patterns first. It then forms a tree by adding these most frequent sites sequentially, but includes the cost of excluding the other sites. Patterns in the data that fit the optimal tree are expected to be more frequent and are added quickly. By having a gain from including an edge in a tree, and the costs of excluding other edges, it finds optimal trees quickly (especially for closest tree).

Branch-and-bound methods are readily implemented with parsimony, minimum evolution, and closest tree optimality criteria. They can be used with either observed data, or data corrected for multiple changes. Branch-and-bound methods are easy to implement, even though optimising them in order to decrease average run time still has scope for improvement. It is unfortunate that branch-and-bound methods have not yet been so useful with maximum (average) likelihood. They can be implemented quite readily but do not give the many orders of magnitude speedup that occurs with the simpler optimality criteria.

If branch-and-bound searches run to completion, they *guarantee* to have found the best trees for that optimality criterion. For MP, the searches should work for up to 20 taxa and improvements will work for up to 30 taxa in some cases, especially for corrected parsimony. But many data sets have 100+ sequences! Approximations are possible to cut running time, but this will sacrifice the certainty of finding the shortest possible tree, and so are really a heuristic searches. By using an artificial bound, a tight limit on the length of the minimal tree can be determined, even if the unrestricted search takes too long to complete. For example, a heuristic search may have found a tree with 679 changes, but the branch-and-bound search does not run to completion. You can repeat the search with a bound of 677 or of 678. The search with bound 677 may run to completion and simply report that there are no trees of that length or shorter. Even if the search trees of length 678 keeps running forever, you now know that the shortest possible tree is of length 678 or 679. Consequently, the known tree of length 679 cannot be more than one mutation longer than the global minimum.

16.6.1.2   *Converging Upper and Lower Bounds (the Minmax Squeeze)*

This approach combines two search methods simultaneously, neither of which can guarantee optimality by itself. They are: a heuristic search for shorter and shorter trees (thus reducing the 'upper bound' – the shortest tree cannot be longer than one you have already found); and partitioning sites into subsets for which a minimal tree can be found (thus increasing the lower bound – the minimum length of the shortest tree). The lower bound comes from partitioning sites into small subsets for which a guaranteed minimal tree can be found. For example, if there are 12 distinct combinations of codes for a subset of sites, and linked with steps no more than a single mutation (see Figure 16.5g), then the minimal length subtree has 11 steps. Every tree on the full data must have at least 11 parsimony steps for this subset of sites. The lower bound is the sum of the lengths of all disjoint subsets of columns. The aim is to find shorter and shorter trees (reducing

the upper bound) and larger and larger lower bounds, until they meet, hence the name MinMax Squeeze.

If (emphasise 'if') the length of the shortest tree (the upper bound) reaches the same value as the lower bound, then no tree with fewer mutations can exist. This combined approach has been used to establish a minimum length tree for 127 complete human mitochondrial genomes (Pierson *et al.*, 2006). In general, this approach is better for population samples because it works most efficiently when the sequences are close together (abundant). However, the general approach will be of growing interest with the increasing use of molecular information such as gene order, presence or absence of inserted elements, major insertions and/or deletions.

16.6.2   Heuristic Searches I, Limited (Local) Searches

Heuristic methods do not guarantee to find a global optimum; but based on previous experience, they will quickly find a 'reasonable' solution. They are sometimes called '*quick and dirty*', and a huge effort has been spent in improving them because they are used in thousands of applications worldwide. We consider them under the two categories, limited or greedy searches, and hill-climbing searches. We discuss the first group under cluster methods, and subtree searches.

16.6.2.1   *Cluster Methods*

There are a many cluster search strategies, including NJ and UPGMA, which build trees sequentially by joining pairs of taxa. They sequentially select internal edges of the tree until the tree is fully resolved. There are several optimality criteria, as well as methods of adjusting the distance values after joining two groups. The searches are essentially 'greedy' in that the programs do not evaluate an optimality criterion over the entire tree; they just accept the tree from the stepwise search. In practice, virtually all cluster methods use distance data, either observed or corrected for inferred multiple changes. In principle, the methods could function on the original sequence data, and with either parsimony or ML.

NJ is the most popular cluster method. It selects two taxa (including previously clustered taxa) that give the biggest increase in 'net divergence' (Section 16.4.2). The pair with the largest internal edge is joined together and this new cluster is treated as a single taxon thereafter (hence the name, neighbor joining). For example, if building a tree of mammals, then humans and chimpanzees are joined on the tree and information about them averaged (more or less). Later in the search, this group may be joined to the gorilla and then this threesome forms a new cluster, etc. The search strategy for t taxa is fast, $O(t^3)$, because it searches just one pathway in building a tree. As mentioned in the previous paragraph, NJ could be implemented with many optimality criteria; it is basically a search strategy. One variation of the method takes in to account variances and covariances of distances, and another allows several trees to be stored during the search, thus considering a larger range of trees.

UPGMA is a search strategy that clusters the most similar pair of taxa, and unites them as a single taxon for subsequent rounds. When a molecular clock is a good description of the data then this strategy is effective, especially if the distances are *not* corrected for multiple changes. UPGMA is no longer consistent when there are differences in the rates

of evolution. An example of data where UPGMA will fail is shown Figure 16.2, which illustrates additive distances and their corresponding tree.

16.6.2.2 Addition Trees

Other limited search algorithms use the original data (not converted to distances). A simple method is to add taxa successively into an enlarging subtree, each time the new sequence is added into its (locally) optimal position. The 'random addition tree' selects taxa randomly, and adds them into the best place on the growing subtree. This can be repeated many times and gives a broader search of tree space. In both versions the fourth taxon is added to all three edges of the single tree for three taxa (see Figure 16.6). The fifth taxon is added to just the five edges of one best tree for four taxa, etc. Overall, $1 + 3 + 5 + 7 + \ldots + (2t - 5)$ trees and subtrees are evaluated, and this is proportional to t^2. But this is a vanishingly small fraction of the $(2t - 5)!!$ unrooted binary trees. A more general but slower version is to add all remaining taxa at each point, and select the taxon that has the most stable position in the subtree. In other words, a taxon that had a unique position two steps longer than the second best tree would be preferred to a taxon whose best position was only one step longer than the second best. The latter would be preferred over a taxon that had two equally good optimal positions.

Both cluster analysis and addition trees are technically 'greedy' algorithms; select the best choice at each step, but do not go back and re-evaluate earlier decisions. These tree(s) can be used as a starting point for more extensive explorations of tree space, as in the next section.

16.6.3 Heuristic Searches II–Hill-climbing and Related Methods

There is a major literature in Operations Research on searching effectively through a complex 'landscape'; there are thousands of major real-world problems that require effective solutions, even if the global optimum is unknown. For phylogenetics the simplest approach selects a tree randomly, then starts making slight changes to it. Every time a better tree is found the new tree is taken and the procedure repeated with changes to this new tree. The process is repeated until no further changes are found that lead to a better tree.

The two aspects of the algorithm are: moving through the space of all trees; and accepting (or not) the new tree. There are many ways of changing a tree slightly; randomly moving a taxon to a new position; collapsing an internal edge and re-expanding it (a commonly used technique for moving through tree space – a crossover or nearest neighbour interchange); and a cut-and-paste move (or tree bisection and reconnection) that breaks one internal edge (branch) of a tree and reconnects the two resulting subtrees in a different way. In the last two methods, the edges can be selected randomly, and if only approach is used to move through the space of all trees then it is a MCMC.

When it comes to searching for improved trees, the simplest strategies are basically 'hill-climbing' methods; either accepting any better tree, or accepting the tree with the largest improvement (steepest ascent). This continues until no further improvement is possible. Such searches are widely used, but are prone to being caught in a *local optimum* – a reasonable solution, but not the *global optimum*. Improved methods can initially accept slightly worse trees for a while – then resume hill climbing. They may eventually end up with a better tree. We will mention just three variants.

1. Simulated annealing (the Metropolis algorithm) has a probability of accepting a worse solution at any point in the search, but gradually reduces this probability as the search continues. Thus it will eventually stop when it has hill-climbed to an optimum.

2. The next variant is the Great Deluge search strategy that accepts any solution (better or worse) above a bound. However, the bound keeps increasing, faster in a good region of the search, more slowly in a poorer region (thus giving more time to escape).

3. The third is a tabu search, which hill climbs until it reaches an optimum, backs away from it by several steps, then resumes hill climbing. By recording how it backed away from the optimum (the tabu list) it avoids immediately re-climbing the last optimum.

The latter two strategies appear especially useful for tree searches. All can be coupled with a MCMC search, with the Metropolis algorithm it is called *Metropolis-coupled*, or *MCMCMC*.

Other approaches use a population of trees at any one time, and can use the best features of each. For example, hitchhiking can be combined with the options above. Several trees are being optimised simultaneously, some are drivers that are hill climbing, other trees are hitch-hikers that accept a better solution their driver finds – if it is also an increase for them. The hitchhikers periodically change drivers, effectively giving recombination possibilities. Charleston (2001) describes some of these search strategies, as well as giving properties of the search space that can be readily measured. Understanding the landscape of the search space with real data is of critical importance, but the problem is in need of much more study.

16.6.4   Quartets and Supertrees

Finally, there are two strategies that both involve building trees from subtrees, one from quartets of taxa, the other with any sized subsets. With just three taxa, there is only one unrooted tree (though a molecular clock version with three taxa is possible). Four taxa (a quartet) is the smallest subset that leads to a decision between unrooted trees; there are three choices to consider. It might be expected (hoped?) that only having three choices leads to a greater chance of getting the correct subtree. If all quartets were chosen correctly, then they could readily be joined into one large tree with all taxa included. If all quartets of t taxa are considered the algorithm is of order t^4. In practice, not all subsets will agree and it is necessary to form the best overall tree. The best-known approach is *quartet puzzling* that evaluates quartets using ML, and then searches for the best tree that agrees with as many subsets as possible. Equal weight needs not be given to all quartets; the relative advantage of the best tree over the second best is one subsidiary criterion that could weight the reliability of quartets.

A second approach in this category of searching tree space does not limit the quartets to four taxa, they can be of any size (Bininda-Emonds *et al.*, 2003). In many studies the sequences available for the taxa may differ. In such a case, trees can be inferred for each data set, and if there is sufficient overlap of taxa between subsets (and the trees from the subsets are in reasonable agreement), then 'supertrees' can be built from the subtrees. The algorithm works efficiently only if there is at least one species common to all the subsets; this taxon effectively acts as an artificial root for building the subtree.

In conclusion, searching through the space of all trees is the limiting feature in inferring trees. It is this aspect that stops any algorithm from being efficient. This is not really a

surprise; in Operations Research there are large numbers of problems for which no efficient algorithm is known, and others for which it is proven that no efficient algorithm can exist. But because there are so many such real-world problems, the range of techniques that are useful has been studied extensively. In this section we have considered branch-and-bound, local searches, greedy algorithms, hill-climbing methods (including those that can escape local maxima), and finally trees assembled from subtrees. The searching of tree space is a major study in its own right.

16.7   OVERVIEW AND CONCLUSIONS

Although this chapter is limited to parsimony and distance methods, it still encompasses a wide field. Our central theme is the need for careful analysis of the problems involved. Many areas of mathematics are involved, not just classical statistics. Trees and graphs are a well-understood part of graph theory. It really matters little if there are two uses of 'parsimony' in phylogenetics, as long as the particular use is made clear, and as long as the assumptions are understood. Real confusion has arisen when it is forgotten that a 'method' for inferring trees consists of three procedures, (1) an optimality criterion, (2) a search strategy, and (3) a procedure for handling multiple changes. This, by itself, has caused more confusion than any other aspect of the theory of tree reconstruction. Similarly, claiming an optimality criterion was, or was not, consistent, misses the point that it is the method of handling multiple changes that leads to consistency, or otherwise. Inferring divergences from millions of years ago is at the cutting edge of modern science and as long as we all learn, the subject will continue to progress.

There is still a range of topics in the quantitative study of trees that need to be understood. We require more information on objective 'tree comparison' methods and their distributions. These help in the evaluation of results, especially in the testing of hypotheses. They do not replace standard resampling (parametric and non-parametric bootstrap and jackknife) methods. Locating the root of the tree is still particularly susceptible to error. This is largely because some well-established groups (such as mammals, birds, and flowering plants) have been separated for many millions of years from their closest living relatives. Outgroups are very distant from the in-group, a classic case for a long-edge attraction problem. If a molecular clock were known to be a realistic description of the data, then 'centering' on the average midpoint of the unrooted tree is another approach.

It is necessary at all times to keep potential sources of error in mind. Perhaps there has been too much emphasis on convenient mathematical models, rather then checking them against biochemical processes. A classic example is assuming that sites are always in the same rate class over the whole tree. This is not expected based on 3D structure of proteins, which keeps evolving. Better estimates of dates of divergence, calibrated against the fossil record, are urgently needed to test a wider range of hypotheses.

Molecular data is now the most important data for phylogeny as it allows phylogenies for all organisms and is providing a large amount of data at relatively low cost. There is still a need for improved methods and in ensuring there is a thorough testing of the results. Phylogeny is now a part of normal science – it does not depend on subjective ideas of the research worker. Darwin's 'theory of descent' can now be established quantitatively, though still with exceptions such as lateral gene transfer. Phylogenetics will continue to

fascinate both theoretical and experimental biologists. This chapter illustrates the wide range of mathematics involved, and the need for careful analysis of the basis of the methods in use.

Evolutionary Quantitative Genetics

B. Walsh

Department of Ecology and Evolutionary Biology, Department of Plant Sciences, Department of Molecular and Cellular Biology, University of Arizona, Tuscon, AZ, USA

Evolutionary quantitative genetics is the study of how complex traits evolve over time. While this field builds on traditional concepts from quantitative genetics widely used by applied breeders and human geneticists (in particular, the inheritance of complex traits), its unique feature is in examining the role of natural selection in changing the population distribution of a complex trait over time. Our review focuses on this role of selection, starting with response under the standard infinitesimal model, in which trait variation is determined by a very large number of loci, each of small effect. We then turn to issues of measuring fitness (and hence natural selection) on both univariate and multivariate traits. We conclude by examining models that treat fitness itself as a complex trait.

17.1   INTRODUCTION

Evolutionary quantitative genetics is a vast field, ranging from population genetics at one extreme to development and functional ecology at the other. The goal of this field is a deeper understanding of not only the genetics and inheritance of complex traits in nature (traits whose variation is due to both genetic and environmental factors) but also the nature of the evolutionary forces that shape character variation and change in natural populations. Given the limitations of space, we have chosen to focus this review on evolutionary change, in particular estimation of the nature of selection and aspects of the evolutionary response to selection. A detailed treatment of the inheritance of complex traits in nature can be found in Lynch and Walsh (1998). Roff (1997) provides a good overview of the entire field, while the reader seeking detailed treatments of specific issues should consult Bulmer (1980) and Walsh and Lynch (2003). Bürger (2000) provides an excellent (but, in some places, highly technical) review of the interface between population and quantitative genetics.

17.1.1 Resemblances, Variances, and Breeding Values

A few summary remarks on quantitative genetics are in order to give the reader the appropriate background. A good introduction is Falconer and Mackay (1996), while a very detailed treatment is given by Lynch and Walsh (1998). **Chapter 18**, **Chapter 19**, **Chapter 20**, and **Chapter 21** in this Handbook also examine some of these issues in greater detail.

17.1.1.1 Fisher's Genetic Decomposition

Although Yule (1902) can be considered the first paper in quantitative genetics, the genesis of modern quantitative genetics is the classic paper by Fisher (1918). Fisher made a number of key insights, notably that with sexual reproduction only a specific fraction of an individual's genotypic value (the mean value of that genotype when averaged over the distribution of environments) is passed on to its offspring, and that we can estimate the variances associated with these various components by looking at the phenotypic covariances between appropriate relatives.

Fisher decomposed the observed phenotypic value z of an individual into a genotypic G and environment E value,

$$z = G + E. \tag{17.1a}$$

The genotypic value can be thought of as the average phenotypic value if the individual was cloned and replicated over the universe of environments it is likely to experience. As mentioned, Fisher noted that a parent does not pass along its entire G value to its offspring, as for any given locus a parent passes along only one of its two alleles to a particular offspring. Thus, the genotypic value can be further decomposed into a component passed on to the offspring A (the *additive genetic value*) and a nonadditive component, which includes the dominance D and any epistatic effects. We ignore the effects of epistasis here, whose complex features are extensively examined by Lynch and Walsh (1998) and Walsh and Lynch (2003). Thus,

$$z = \mu + A + D + E, \tag{17.1b}$$

where μ is the population mean (by construction, the mean values of A, D, and E equal zero). The additive values A are often referred to as *breeding values*, as the average value of an offspring is just the average breeding value of its parents. Hence, the expected value of an offspring is $\mu + (A_f + A_m)/2$, where A_f is the paternal (or sire) and A_m the maternal (or dam) breeding values.

17.1.1.2 Additive Genetic Variances and Covariances

When the phenotype can be decomposed as in (17.1b), Fisher showed that the phenotypic covariance between parent and offspring is half the population variance of breeding values, σ_A^2:

$$\sigma^2(z_p, z_0) = \frac{\sigma_A^2}{2}. \tag{17.2a}$$

Thus, twice the parent–offspring phenotypic covariance provides an estimate of σ_A^2, which is called the *additive genetic variance*. There are a number of potential complications in blindly applying (17.2a), such as shared environmental effects, and maternal effects when considering the mother–offspring covariance. See Falconer and Mackay (1996) and Lynch and Walsh (1998) for details on handling these complications. **Chapter 19** considers how to use not just parent–offspring information, but also at the same time all the information in general pedigrees in estimating the additive genetic variances.

The covariance in breeding values between two traits (say x and y), $\sigma_A(x, y)$, is needed for considering evolution of multiple traits. These *additive genetic covariances* can also be estimated from parent–offspring regressions, as the phenotypic covariance between one trait in the parent (p) and the other trait in the offspring (o) estimates half the additive genetic covariance of the traits, e.g.,

$$\sigma^2(x_p, y_o) = \sigma^2(y_p, x_o) = \frac{\sigma_A(x, y)}{2}. \tag{17.2b}$$

Two different mechanisms can generate a (within-individual) covariance in the breeding values of two traits: linkage and *pleiotropy*. Linked loci show an excess of parental gametes, creating a correlation between alleles at these loci. (If a parent has alleles A and B on one chromosome and a and b on the other homologous chromosome, this parent will produce more AB and ab parental gametes than Ab and aB recombinant gametes.) In this case, even if each linked locus affects only a single trait, the correlation between alleles (linkage disequilibrium) generates a short-term correlation between the breeding values of the traits. Over time these associations decay through recombination, randomizing allelic associations across loci. Alternatively, with pleiotropy a single locus can affect multiple traits. Covariances due to pleiotropic loci are stable over time.

17.1.2 Single Trait Parent–Offspring Regressions

17.1.2.1 Phenotypic and Genetic Regressions

Most of the theory of selection response in quantitative genetics assumes linear parent–offspring regressions that have homoscedastic residuals (i.e., the variance about the expected value is independent of the values of the parents). The simplest version considers the phenotypic value of the midparent, $z_{mp} = (z_m + z_f)/2$, with the offspring value z_o predicted as

$$z_o = \mu + b(z_{mp} - \mu), \tag{17.3a}$$

where μ is the population mean. Recalling that the slope b of the best linear regression of y on x, $y = a + bx$, is given by

$$b = \frac{\sigma(x, y)}{\sigma_x^2},$$

the slope of the midparent–offspring regression becomes

$$b = \frac{\sigma(z_o, z_{mp})}{\sigma^2(z_{mp})} = \frac{\sigma(z_o, z_m)/2 + \sigma(z_o, z_m)/2}{\sigma^2(x_m/2 + x_f/2)} = \frac{2\sigma_A^2/4}{2\sigma_z^2/4} = \frac{\sigma_A^2}{\sigma_z^2}. \tag{17.3b}$$

This ratio of the additive genetic variance to the phenotypic variance is usually denoted h^2 and is called the (narrow-sense) *heritability*. Thus, the midparent–offspring regression is given by

$$z_o = \mu + h^2(z_{mp} - \mu) = \mu + h^2 \left(\frac{z_m + z_f}{2} - \mu \right);$$ (17.3c)

this is the expected value for an offspring. The actual value for any particular offspring is given by

$$z_o = \mu + h^2(z_{mp} - \mu) + e,$$ (17.4a)

where the residual e has mean value zero and variance

$$\sigma_e^2 = \left(1 - \frac{h^4}{2} \right) \sigma_z^2.$$ (17.4b)

17.1.2.2 *Selection Differentials and the Breeders' Equation*

The parent–offspring regression allows us to predict the response to selection. Suppose the mean of parents that reproduce (μ_*) is different from the population mean before selection μ. Define the *directional selection differential* as $S = \mu_* - \mu$ (S is often simply called the selection differential). From (17.3c), the difference R between the offspring mean of these parents and the original mean of the population before selection is

$$R = h^2 S.$$ (17.5)

This is the *breeders' equation* which transforms the between-generation change in the mean (the selection response R) into the within-generation change in the mean (S). Notice that strong selection does not necessarily imply a large response. If the heritability of a trait is very low (as occurs with many life-history traits), then even very strong selection results in very little (if any) response. Hence, selection (nonzero S) does not necessarily imply evolution (nonzero R).

17.1.3 Multiple Trait Parent–Offspring Regressions

The (single-trait) parent–offspring regression can be generalized to a (column) vector of n trait values, $\mathbf{z} = (z_1, \ldots, z_n)^{\mathrm{T}}$. Letting $\mathbf{z}_o$ be the vector of trait values in the offspring, $\mathbf{z}_{mp}$ the vector of midparent-trait values (i.e., the ith element is just $(z_{f,i} + z_{m,i})/2$), and μ be the vector of population means, then the parent–offspring regression for multiple traits can be written as having expected value

$$\mathbf{z}_o = \mu + \mathbf{H}(\mathbf{z}_{mp} - \mu)$$ (17.6)

where the (i,j)th element in the matrix $\mathbf{H}$ is the weight associated with the value of trait i in the offspring and trait j in the midparent.

17.1.3.1 *The Genetic and Phenotypic Covariance Matrices*

In order to further decompose $\mathbf{H}$ into workable components, we need to define the phenotypic covariance matrix $\mathbf{P}$ whose (i,j)th element is the phenotypic covariance

between traits i and j. Note that $\mathbf{P}$ is symmetric, with the diagonal elements corresponding to the phenotypic variances and off-diagonal elements corresponding to the phenotypic covariances. In a similar manner, we can define the symmetric matrix $\mathbf{G}$, whose (i, j)th element is the additive genetic covariance (covariance in breeding values) between traits i and j. Using similar logic to that leading to (17.3b) (the slope of the single-trait regression), it can be shown that

$$\mathbf{H} = \mathbf{GP}^{-1}, \tag{17.7a}$$

giving the multitrait parent–offspring regression as

$$\mathbf{z}_0 = \boldsymbol{\mu} + \mathbf{GP}^{-1}(\mathbf{z}_{mp} - \boldsymbol{\mu}). \tag{17.7b}$$

17.1.3.2 The Multivariate Breeders' Equation

Letting $\mathbf{R}$ denote the column vector of responses (so that the ith element is the between-generation change in the mean of trait i), and $\mathbf{S}$ the vector of selection differentials, then (17.7b) allows us to generalize the breeders' equation to multiple traits,

$$\mathbf{R} = \mathbf{HS} = \mathbf{GP}^{-1}\mathbf{S}; \tag{17.8}$$

this equation forms the basis for discussions about selection on multiple characters (Section 17.6).

17.2 SELECTION RESPONSE UNDER THE INFINITESIMAL MODEL

17.2.1 The Infinitesimal Model

The breeders' equation predicts the change in mean following a single generation of selection from an unselected base population. The only assumption required is that the parent–offspring regression is linear, but the question remains as to when this linearity holds. Further, the breeders' equation focuses only on the change in mean, leaving open the question of what happens to the variance. The latter concern is of special relevance in evolutionary quantitative genetics, as stabilizing selection (which reduces the variance without necessarily any change in the mean) is thought to be common in natural populations. The infinitesimal model, introduced by Fisher (1918), provides a framework to address these issues.

17.2.1.1 Allele Frequency Changes under the Infinitesimal Model

Under the infinitesimal model, a character is determined by an infinite number of unlinked and nonepistatic loci, each with an infinitesimal effect. A key feature of the infinitesimal model is that while allele frequencies are essentially unchanged by selection, large changes in the mean can still occur by summing infinitesimal allele frequency changes over a large number of loci. To see this feature, consider a character determined by n completely additive and interchangeable loci, each with two alleles, Q and q (at frequencies p and $1 - p$), where the genotypes QQ, Qq, and qq contribute $2a, a$, and 0 (respectively) to

the genotypic value. The resulting mean is $2nap$ and the additive variance (ignoring the contribution from gametic-phase disequilibrium) is $\sigma_A^2 = 2na^2 p(1 - p)$. For σ_A^2 to remain bounded as the number of loci increase, a must be of order $n^{-1/2}$. The change in mean due to a single generation of selection is easily found to be $\Delta\mu = 2na\Delta p$. Assuming the frequency of Q changes by the same amount at each locus, $\Delta p = \Delta\mu/(2na)$. Since a is of order $n^{-1/2}$, Δp is of order $1/(n \cdot n^{-1/2}) = n^{-1/2}$, approaching zero as the number of loci becomes infinite. Thus the infinitesimal model allows for arbitrary changes in the mean with (essentially) no change in the allele frequencies at underlying loci.

What effect does this very small amount of allele frequency change have on the variance? Letting $p' = p + \Delta p$ denote the frequency after selection, the change in the additive genic variance is

$$\Delta\sigma_A^2 = 2na^2 p'(1 - p') - 2na^2 p(1 - p)$$
$$= 2na^2 \Delta p(1 - 2p - \Delta p)$$
$$\approx a(1 - 2p)\Delta\mu.$$

Since a is of order $n^{-1/2}$, the change in variance due to changes in allele frequencies is roughly $1/\sqrt{n}$ the change in mean. Thus, with a large number of loci, very large changes in the mean can occur without any significant change in the variance. In the limit of an infinite number of loci, there is no change in the genic variance ($\Delta\sigma_A^2 = 0$), while arbitrary changes in the mean can occur.

17.2.1.2 *Linearity of Parent–Offspring Regressions under the Infinitesimal Model*

Under the infinitesimal model, genotypic values (G) are normally (or multivariate normally if G is a vector) distributed before selection (Bulmer, 1971; 1976). Assuming environmental values (E) are also normal, then so is the phenotype z (as $z = G + E$) and the joint distribution of phenotypic and genotypic values is multivariate normal. In this case, the regression of offspring phenotypic value z_o on parental phenotypes (z_f and z_m for the father and mother's values) is linear and homoscedastic.

17.2.2 Changes in Variances

As mentioned, under the infinitesimal model (in an infinite population) there is essentially no change in the genetic variances caused by allele frequency change. Changes in allele frequencies, however, are not the only route by which selection can change the variance (and other moments) of the genotypic distribution. Selection also creates associations (covariances) between alleles at different loci through the generation of gametic-phase (or linkage) disequilibrium, and such covariances can have a significant effect on the genetic variance. Disequilibrium can also change higher-order moments of the genotypic distribution, driving it away from normality and hence potentially causing parent–offspring regressions to deviate from linearity.

17.2.2.1 *The Additive Variance under Disequilibrium*

The additive genetic variance σ_A^2 in the presence of linkage disequilibrium can be written as

$$\sigma_A^2 = \sigma_a^2 + d \tag{17.9}$$

where σ_a^2 is the additive genetic variance in the absence of disequilibrium and d the disequilibrium contribution. To formally define σ_a^2 and d, let $a_1^{(k)}$ and $a_2^{(k)}$ denote average effects of the two alleles at locus k from a random individual. Since σ_A^2 is the variance of the sum of average effects over all loci,

$$\sigma^2\left(\sum_{k=1}^{n}\left(a_1^{(k)} + a_2^{(k)}\right)\right) = 2\sum_{k=1}^{n}\sigma^2(a^{(k)}) + 4\sum_{k<j}^{n}\sigma(a^{(j)}, a^{(k)}) \qquad (17.10a)$$

$$= 2\sum_{k=1}^{n} C_{kk} + 4\sum_{k<j}^{n} C_{jk}, \qquad (17.10b)$$

where n is the number of loci and $C_{jk} = \sigma(a^{(j)}, a^{(k)})$ is the covariance between allelic effects at locus j and k. Thus $\sigma_a^2 = 2\sum C_{kk}$ is the additive variance in the absence of gametic-phase disequilibrium and the disequilibrium contribution $d = 4\sum_{j<k} C_{kj}$ is the covariance between allelic effects at different loci. The component of the additive genetic variance that is unaltered by changes in gametic-phase disequilibrium, σ_a^2, is often referred to as the *additive genic variance* (or simply the *genic variance*) to distinguish it from the additive *genetic* variance σ_A^2.

Under the infinitesimal model, selection does not change the C_{kk} (as this requires changes in the allele frequencies), and hence does not alter σ_a^2. However, selection does generate correlations between loci ($C_{ik} \neq 0$), and this can result in significant changes in the overall additive variance σ_A^2. Changes in the covariances C_{ij} between loci i and j (for $i \neq j$) are roughly of order n^{-2} (Bulmer, 1980; Turelli and Barton, 1990). Since there are n^2 terms contributing to d, the total disequilibrium is of order one ($n^2 \cdot n^{-2}$) and does not necessarily approach zero as the number of loci becomes infinite. The same reasoning holds for changes in the higher-order moments, which are caused by higher-order associations between groups of loci, and can also be nontrivial (Turelli and Barton, 1990).

17.2.2.2 Dynamics of Disequilibrium

Recall that the total genetic variance is the sum of the additive and dominance variances (plus any epistatic variances), so that $\sigma_G^2 = \sigma_A^2 + \sigma_D^2$. Under the infinitesimal model, disequilibrium changes the additive genetic, but not the dominance, variance (Walsh and Lynch, 2003). Hence, the phenotypic variance in generation t of selection is

$$\sigma_z^2(t) = \sigma_E^2 + \sigma_D^2 + \sigma_A^2(t) = \sigma_z^2 + d(t), \qquad (17.11a)$$

where $\sigma_z^2 = \sigma_z^2(0)$ is the phenotypic variance before selection in the initial (unselected) base population. The resulting heritability in generation t becomes

$$h^2(t) = \frac{\sigma_A^2(t)}{\sigma_z^2(t)} = \frac{\sigma_a^2 + d(t)}{\sigma_z^2 + d(t)}. \qquad (17.11b)$$

Assuming that the parent–offspring regression remains linear, the selection response in generation t becomes $R(t) = h^2(t)S(t)$. Assuming unlinked loci, Bulmer (1971) showed

that the change in disequilibrium is given by

$$d(t+1) = \frac{d(t)}{2} + \frac{h^4(t)}{2}\left(\sigma_{z^*(t)}^2 - \sigma_{z(t)}^2\right), \tag{17.12}$$

where $\sigma_{z^*(t)}^2 - \sigma_{z(t)}^2$ is the within-generation change in the phenotypic variance. The first term represents the removal of disequilibrium by recombination, while the second is the generation of disequilibrium by selection. Note that (17.12) is the variance analog of the breeders' equation, relating the between- $(d(t+1) - d(t))$ and within-generation $(\sigma_{z^*(t)}^2 - \sigma_{z(t)}^2)$ changes in the variance.

Starting with an unselected base population (where $d(0) = 0$), iterating (17.12) gives the disequilibrium (and hence the heritability, phenotypic variance, and response) in any desired generation. Under directional selection (selection only on the mean), most of the disequilibrium is generated in the first three to five generations, after which d is very close to its equilibrium value $\tilde{d}$. Once selection stops, the current disequilibrium is halved each generation, with the additive variation rapidly returning to its value before selection. This occurs because under the infinitesimal model, all changes in variances are due to disequilibrium, which decays via recombination in the absence of selection.

An important point regarding (17.12) is that there can be no change in the mean ($S = 0$) and yet selection can still act on the variance. Stabilizing selection, which removes extreme individuals and reduces the variance, is widely thought to be widespread in nature. The within-generation reduction in variance generates negative disequilibrium, which in turn reduces the additive variance. Under the infinitesimal model, once stabilizing selection stops, the variance returns (increases) to its initial value after a few generations. Likewise, under disruptive selection, individuals of intermediate value are selected against, increasing the variance. This generates positive d, increasing the additive variance. Again, when selection is stopped, the variance decays back to its initial (pre-selection) value.

Iteration of (17.12) allows any form of selection to be analyzed. For modeling purposes, it is often assumed that the within-generation change in the phenotypic variance can be written as

$$\sigma_{z^*(t)}^2 = (1 - \kappa)\sigma_{z(t)}^2, \tag{17.13}$$

where κ is a constant that does not change over time. Noting that $\sigma_{z(t)}^2 = \sigma_A^2(t)/h^2(t)$ and substituting (17.13) into (17.12) recovers the result of Bulmer (1974),

$$d(t+1) = \frac{d(t)}{2} - \frac{\kappa}{2}h^2(t)\sigma_A^2(t) = \frac{d(t)}{2} - \frac{\kappa}{2}\frac{[\sigma_a^2 + d(t)]^2}{\sigma_z^2 + d(t)}. \tag{17.14}$$

Again, simple iteration allows one to compute the variance in any generation.

17.2.2.3 Equilibrium Variances

The equilibrium variances, and hence the asymptotic rate of response under directional selection or the equilibrium variance under stabilizing or disruptive selection, are easily obtained. At equilibrium, (17.14) implies

$$\tilde{d} = -\kappa\tilde{h}^2\tilde{\sigma}_A^2 = -\kappa\frac{(\sigma_a^2 + \tilde{d})^2}{\sigma_z^2 + \tilde{d}}. \tag{17.15a}$$

Solving for $\tilde{d}$ gives the equilibrium additive genetic variance as

$$\tilde{\sigma}_A^2 = \sigma_z^2 \theta, \quad \text{where } \theta = \frac{2h^2 - 1 + \sqrt{1 + 4h^2(1 - h^2)\kappa}}{2(1 + \kappa)}, \tag{17.15b}$$

and the resulting heritability at equilibrium is

$$\tilde{h}^2 = \frac{\tilde{\sigma}_A^2}{\tilde{\sigma}_z^2} = \frac{\tilde{\sigma}_A^2}{\sigma_z^2 + (\tilde{\sigma}_A^2 - \sigma_A^2)} = \frac{\theta}{1 + \theta - h^2}. \tag{17.15c}$$

The simple picture that emerges from directional selection under the infinitesimal model is that while the heritability may decrease slightly from its initial value (due to generation of linkage disequilibrium), the response to selection continues without limit. Biological reality, of course, places limits on the character values that can be obtained by selection response. For example, selection may move the mean phenotype to a region on the fitness surface where stabilizing selection dominates (see Section 17.4). Likewise, selection on one character may be opposed by selective constraints imposed by other characters also under selection, and a limit can be reached despite significant additive variance and a nonzero S in the character being followed (Section 17.6).

17.2.3   The Roles of Drift and Mutation under the Infinitesimal Model

While selection does not change allele frequencies under the infinitesimal model, genetic drift (due to finite population size) and mutation can play very important roles in shaping the genetic variance. Inclusion of these two forces allows the infinitesimal model to be modified into a much more biologically realistic description of selection response.

17.2.3.1   Drift

Assuming no dominance or epistasis, with drift (assuming an effective population size of N_e) the expected genic variation σ_a^2 declines each generation from its initial value $\sigma_a^2(0)$, with the genic variance in generation t being

$$\sigma_a^2(t) = \sigma_a^2(0) \left(1 - \frac{1}{2N_e}\right)^t. \tag{17.16}$$

If dominance (or epistasis) is present, the additive variation can actually increase (at least while the level of inbreeding is moderate) before it ultimately declines to zero (Walsh and Lynch, 2003). Under the infinitesimal model, selection is so weak on any given underlying locus that the allele frequency dynamics are entirely governed by drift, and the change in the genic variance is given by (17.16).

Keightley and Hill (1987) show that, under drift, the change in the amount of disequilibrium is given by

$$\Delta d(t) = -\frac{d(t)}{2}\left(1 + \frac{1}{N_e}\right) - \frac{1}{2}\left(1 - \frac{1}{N_e}\right)\kappa h^2(t)\sigma_A^2(t). \tag{17.17}$$

Joint iteration of (17.16) and (17.17) allows for modeling of response with a finite population size. During the course of selection, genetic drift removes the initial variation,

driving the genic (and hence additive genetic) variance to zero. With directional selection a limit is reached, as the response stops as the heritability approaches zero. Robertson (1960) showed that the total change in the mean in this case is approximately $2N_e R(1)$, with $R(1)$ the response in the first generation. It takes approximately $1.4N_e$ generations for half this total response to occur.

17.2.3.2   Mutation

Balancing the removal of genetic variation by genetic drift is the introduction of new variation by mutation. The mutation variance σ_m^2 is defined as the per-generation contribution by mutation to the additive variance, with the average value of σ_m^2/σ_E^2 typically around 0.005 (Lynch and Walsh, 1998). When both mutation and drift occur, the additive variance eventually attains an equilibrium value of

$$\tilde{\sigma}_A^2 = 2N_e\sigma_m^2. \tag{17.18}$$

Assuming the infinitesimal model, completely additive loci, a base-population additive variance of $\sigma_A^2(0)$ and ignoring any effects of gametic-phase disequilibrium, the expected additive genetic variance at generation t is given by

$$\sigma_A^2(t) \simeq 2N_e\sigma_m^2 + [\sigma_A^2(0) - 2N_e\sigma_m^2]\exp(-t/2N_e). \tag{17.19a}$$

Setting $\sigma_A^2(0) = 0$ gives the additive variance contributed entirely from mutation as

$$\sigma_{A,m}^2(t) \simeq 2N_e\sigma_m^2[1 - \exp(-t/2N_e)]. \tag{17.19b}$$

Hence, the rate of response at generation t from mutational input is

$$R_m(t) = i\frac{\sigma_{A,m}^2(t)}{\sigma_z} \simeq 2N_e i\frac{\sigma_m^2}{\sigma_z}[1 - \exp(-t/2N_e)], \tag{17.19c}$$

with $i = S/\sigma_z$ (the selection intensity, which is discussed below). For $t \gg 2N_e$, the per-generation response approaches an asymptotic limit of

$$\tilde{R}_m = 2N_e i\frac{\sigma_m^2}{\sigma_z} = i\frac{\tilde{\sigma}_A^2}{\sigma_z}. \tag{17.19d}$$

A full treatment allowing for mutation, drift, and disequilibrium under the infinitesimal model is given by simply adding a σ_m^2 term to (17.16) and then jointly iterating (17.16) and (17.17).

17.3   FITNESS

Predicting the selection response under the infinitesimal model requires knowledge of the change in mean and variance after an episode of selection. In an artificial selection program, the breeder or experimentalist can not only measure these components, but also largely set their values. In nature, the currency of selection is fitness, and the change

in the phenotypic distribution is computed by first weighting individuals by their fitness values. Discussion of selection response in nature thus starts by trying to assign fitness values to particular character states. This is the linking step that allows use of the above machinery for prediction of selection response.

17.3.1　Individual Fitness

Loosely stated, the *lifetime* (or *total*) *fitness* of an individual is the number of descendants it leaves at the start of the next generation. When measuring the total fitness of an individual, care must be taken not to cross generations or to overlook any stage of the life cycle in which selection acts. To accommodate these concerns, lifetime fitness is defined as the total number of zygotes (newly fertilized gametes) that an individual produces. Measuring total fitness from any other starting point in the life cycle (e.g., from adults in one generation to adults in the subsequent generation) can result in a very distorted picture of true fitness of particular phenotypes (Prout, 1965; 1969). If generations are crossed, measures of selection on a particular parental phenotype in reality are averages over both parental and offspring phenotypes, which may differ considerably.

Systems for measuring lifetime fitness have been especially well developed for laboratory populations of *Drosophila* (reviewed by Sved, (1989)). Measurements of lifetime fitness in field situations are more difficult and (not surprisingly) are rarely made. Attention instead is usually focused on particular episodes of selection or particular phases of the life cycle. Fitness components for each episode of selection are defined to be multiplicative. For example, lifetime fitness can be partitioned as (probability of surviving to reproductive age)·(number of mates)·(number of zygotes per mating). Number of mates is a measure of *sexual selection*, while the viability and fertility components measure natural selection. A commonly measured fitness component is *reproductive success*, the number of offspring per adult, which confounds natural (fertility) and sexual selection (in males, the number of matings per adult). Clutton-Brock (1988) reviews estimates of reproductive success from natural populations.

Fitness components can themselves be further decomposed. For example, fertility in plants might be decomposed as (seeds per plant) = (number of stems per plant)·(number of inflorescences per stem)·(average number of seed capsules per inflorescence)·(average number of seeds per capsule). Such a decomposition allows the investigator to ask questions of the form: do plants differ in number of seeds mainly because some plants have more stems, or more flowers per stem, or are there tradeoffs between these?

Estimates of fitness can be obtained from either *longitudinal* or *cross-sectional* studies. A longitudinal study follows a cohort of individuals over time, while a cross-sectional study examines individuals at a single point in time. Cross-sectional studies typically generate only two fitness classes (e.g., dead versus living, mating versus unmated), and their analysis involves a considerable number of assumptions (Lande and Arnold, 1983; Arnold and Wade, 1984b). While longitudinal studies are preferred, they usually require far more work and may be impossible to carry out in many field situations. Age-structured populations pose further complications in that proper fitness measures require knowledge of the population's demography; see Charlesworth (1994), Lande (1982), Lenski and Service (1982), and Travis and Henrich (1986) for details.

17.3.2 Episodes of Selection

As mentioned, individuals are often measured over more than one episode of selection. Imagine that a cohort of n individuals (indexed by $1 \leq r \leq n$) is followed through several episodes. Let $W_j(r)$ be the fitness measure for the jth episode of selection for the rth individual. For example, for viability W_j is either zero (dead) or one (alive) at the census period. Let $\overline{W}_j$ denote the mean fitness of a random individual following the jth episode of selection. Relative fitness components $w_j(r) = W_j(r)/\overline{W}_j$ will turn out to be especially useful. At the start of the study, the frequency of each individual is $1/n$, giving for the first (observed) episode of selection

$$\overline{W}_1 = \frac{1}{n} \sum_{r=1}^{n} W_1(r). \tag{17.20a}$$

Caution is in order at this point as considerable selection may have already occurred prior to the life cycle stages being examined. Following the first episode of selection, the new fitness-weighted frequency of the rth individual is $w_1(r)/n$, implying

$$\overline{W}_2 = \sum_{r=1}^{n} W_2(r) \cdot w_1(r) \cdot \left(\frac{1}{n} \right). \tag{17.20b}$$

In general, for the jth episode of selection,

$$\overline{W}_j = \sum_{r=1}^{n} W_j(r) \cdot w_{j-1}(r) \cdot w_{j-2}(r) \ldots w_1(r) \cdot \left(\frac{1}{n} \right). \tag{17.20c}$$

Note that if $W_j(r) = 0$, further fitness components for r are unmeasured.

Letting $p_j(r)$ be the fitness-weighted frequency of individual r after j episodes of selection, it follows that $p_0(r) = 1/n$ and

$$p_j(r) = w_j(r) \cdot p_{j-1}(r) = \frac{1}{n} \prod_{i=1}^{j} w_i(r). \tag{17.21a}$$

Thus, (17.20c) can also be expressed as $\overline{W}_j = \sum W_j(r) \cdot p_{j-1}(r)$. Using these weights allows fitness-weighted moments to be calculated, e.g., the mean of a particular character following the jth episode is computed as

$$\mu_{z(j)} = \sum z(r) \cdot p_j(r), \tag{17.21b}$$

where $z(r)$ is the value of the character of individual r.

The directional selection differential S is computed as the difference between fitness-weighted means before and after an episode of selection, with the differential S_j for the jth episode given by

$$S_j = \mu_{z(j)} - \mu_{z(j-1)}. \tag{17.22a}$$

Selection differentials are additive over episodes, so that the total differential S following k episodes of selection is

$$S = \mu_{z(k)} - \mu_{z(0)} = (\mu_{z(k)} - \mu_{z(k-1)}) + \ldots + (\mu_{z(1)} - \mu_{z(0)}) = S_k + \ldots + S_1. \quad (17.22b)$$

17.3.3 The Robertson–Price Identity

As first noted by Robertson (1966), and greatly elaborated on by Price (1970; 1972a), the directional selection differential equals the covariance of phenotype and relative fitness,

$$S = \sigma(w, z). \quad (17.23)$$

This identity is quite useful for obtaining the selection differential in complex selection schemes and (as detailed below) forms the basis for a number of useful expressions relating selection and fitness.

To obtain the Robertson–Price identity, let μ_s be the fitness-weighted mean after selection and μ the mean before selection,

$$
\begin{aligned}
S = \mu_s - \mu &= \sum_{r=1}^{n} z(r) w(r) \cdot p(r) - \mu \\
&= E[zw] - 1 \cdot E[z] \\
&= E[zw] - E[w] \cdot E[z] \\
&= \sigma(w, z),
\end{aligned}
$$

where we have used the fact that (by construction) $E[w] = 1$.

17.3.4 The Opportunity for Selection

How does one compare the amount of selection acting on different episodes and/or different populations? At first thought, one might consider using the standardized selection differential,

$$i = \frac{S}{\sigma_z}, \quad (17.24)$$

which is just the directional selection differential scaled in terms of character standard deviations (i is often called the *selection intensity* and is widely used in breeding). The drawback with i as a measure of *overall* selection on individuals is that it is *character-specific*. Hence, i is appropriate if we are interested in comparing the strength of selection on a particular *character*, but inappropriate if we wish to compare the overall strength of selection on *individuals*. Two populations may have the same i value for a given character, but if that character is tightly correlated with fitness in one population and only weakly correlated in the other, selection is much stronger in the latter population. Further, considerable selection can occur without changing the mean (e.g., stabilizing selection). Standardized (quadratic) differentials also exist for the variance (Section 17.4.3), but the problem of character specificity still remains.

A much cleaner measure (independent of the characters under selection) is I, the *opportunity for selection*, defined as the variance in *relative* fitness:

$$I = \sigma_w^2 = \frac{\sigma_W^2}{\overline{W}^2}. \tag{17.25}$$

This measure was introduced by Crow (1958; reviewed in Crow (1989)), who referred to it as the *index of total selection*. Crow noted that if fitness is perfectly heritable (e.g., $h^2(\text{fitness}) = 1$), then $I = \Delta\overline{w}$, the scaled change in fitness. Following Arnold and Wade (1984a; 1984b), I is referred to as the opportunity for selection, as any change in the distribution of fitness caused by selection represents an opportunity for within-generation change. A key feature of I is that it bounds the maximal selection intensity i for *any* character. From the Robertson–Price identity (17.23), the correlation between any character z and relative fitness (which is bounded in absolute value by one) is

$$|\rho_{z,w}| = \frac{|\sigma_{z,w}|}{\sigma_z \sigma_w} = \frac{|S|}{\sigma_z \sqrt{I}} = \frac{|i|}{\sqrt{I}} \leq 1,$$

implying

$$|i| \leq \sqrt{I} \tag{17.26}$$

Thus, the most that the mean of any character can be shifted within a generation is $\sqrt{I}$ phenotypic standard deviations.

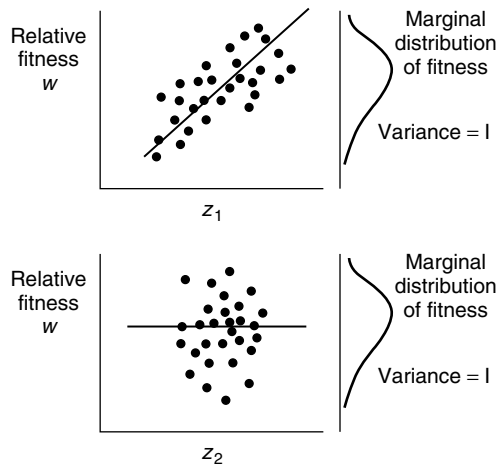
The usefulness of I as a bound of i depends on the correlation between relative fitness and the character being considered. Figure 17.1 shows scatterplots of relative fitness against two characters (z_1 and z_2) measured in the same set of individuals. The marginal distributions of fitness are identical for both characters (since the same set of individuals was measured for both traits), and hence both traits have the same opportunity


Figure 17.1 The fraction of the opportunity for selection I that is translated into a change in the mean depends on the correlation between relative fitness and the character. Characters z_1 and z_2 have the same marginal distribution of fitness, but only the regression of w on z_1 is significant.

for selection. The association between relative fitness and trait z_1 is fairly strong, while there is no relationship between relative fitness and z_2, so that z_1 realizes much, while z_2 realizes none, of the opportunity for change.

17.3.5   Some Caveats in Using the Opportunity for Selection

Despite its usefulness, there are some subtle issues in the interpretation of I. To begin with, even though I appears to remove scaling effects due to different types of fitnesses, for estimates of I to be truly comparable, they must be based on consistent measures of fitness (Trail, 1985). Second, if the variance in fitness is not independent of $\overline{W}$, comparisons of I values between populations are compromised. Such a lack of independence occurs in cross-sectional studies that measure sexual selection by simply counting the number of mating pairs. If the time scale is such that only single matings are observed, the fitness of any individual is either 1 (mating) or 0 (not mating). The resulting fitness of randomly drawn individuals is binomially distributed with mean p (the mean copulatory success for the sex being considered) and variance $p(1-p)$, hence

$$I = \frac{p(1-p)}{p^2} \simeq \frac{1}{p} \text{ if } p \ll 1. \tag{17.27}$$

The mean and variance in individual fitness are not independent, and the opportunity for selection depends entirely on mean population fitness. As the time window for observing mating pairs decreases, fewer matings are seen and p decreases, increasing I. Thus the opportunity for selection is often inflated if the observation period is short relative to the total mating period. Likewise, if one is only comparing viability selection (alive or dead after an episode of selection), (17.27) also holds.

Another example of the lack of independence between $\overline{W}$ and σ_W^2 was given by Downhower *et al.* (1987), who assumed that the number of mates for any given male follows a Poisson distribution. In this case, the variance in number of mates equals the mean number of mates, giving

$$I = \frac{\overline{W}}{\overline{W}^2} = \overline{W}^{-1}, \tag{17.28}$$

where $\overline{W}$ is the mean number of mates per male. Thus, differences in I between populations do not necessarily indicate *biological* differences in male mating ability. For example, in a population of 100 males, if only 5 females mate, average male mating success is $\overline{W} = 0.05$, while if 50 females mate, $\overline{W} = 0.5$. For this example, differences in I come solely from variation in the number of mating females, not biological differences between males in their ability to acquire mates. Downhower *et al.* conclude from this example that comparing I values with the Poisson prediction ($I = 1/\overline{W}$), or some other appropriate random distribution, may help clarify the interpretation of I. For this case, values of I less than the Poisson prediction indicate a more uniform distribution of fitness than expected if mate choice is random, while values in excess of this expectation indicate disproportionately high fitness among a limited set of individuals.

The Poisson mating example further points out that random variation (differences in individual fitness not attributable to intrinsic differences between individuals) reduces the correlation between phenotypic value and relative fitness. For this reason, measures of selection based entirely upon variance in mating success have been criticized (Banks

and Thompson, 1985; Sutherland 1985a; 1985b; Koenig and Albano, 1986). Although carefully controlled studies can reduce the error variance induced by chance (e.g., Houck *et al.*, 1985), accounting for inflation of the opportunity for selection by random effects remains a problem.

17.4   FITNESS SURFACES

17.4.1   Individual and Mean Fitness Surfaces

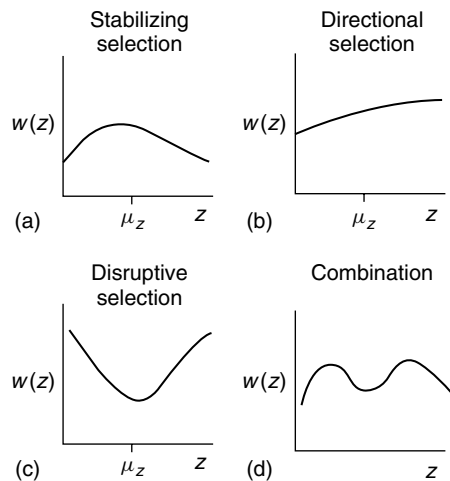
$W(z)$, the expected fitness of an individual with phenotype *z*, describes a *fitness surface* (or *fitness function*), relating fitness and character value. The *relative* fitness surface $w(z) = W(z)/\overline{W}$ is often more convenient than $W(z)$, and we use these two somewhat interchangeably. The nature of selection on a character in a particular population is determined by the local geometry of the individual fitness surface over that part of the surface spanned by the population (Figure 17.2). If fitness is strictly increasing (or decreasing) over some range of phenotypes, a population having its mean value in this interval experiences *directional selection*. If $W(z)$ contains a local maximum, a population with members within that interval experiences *stabilizing selection*. If the population is distributed around a local minimum, *disruptive selection* occurs. As is illustrated in Figure 17.2(d), when the local geometry of the fitness surface is complicated (e.g., multimodal) the simplicity of description offered by these three types of selection breaks down, as the population can experience all three simultaneously.


Figure 17.2   Selection is usually classified into three basic forms depending on the local geometry of $W(z)$: stabilizing (a), directional (b), and disruptive (c). As (d) illustrates, populations can simultaneously experience multiple forms of selection.

$W(z)$ may vary with genotypic and environmental backgrounds. In some situations (e.g., predators with search images, sexual selection, dominance hierarchies, truncation selection) the fitness of a phenotype depends on the frequency of other phenotypes in the population. In this case, fitnesses are said to be *frequency-dependent*.

Mean population fitness $\overline{W}$ is also a fitness surface, describing the expected fitness of the population as a function of the distribution $p(z)$ of phenotypes in that population,

$$\overline{W} = \int W(z) p(z) \, dz. \tag{17.29}$$

Mean fitness can be thought of as a function of the parameters of the phenotypic distribution. For example, if z is normally distributed, mean fitness is a function of the mean μ_z and variance σ_z^2 for that population.

To stress the distinction between the $W(z)$ and $\overline{W}$ fitness surfaces, the former is referred to as the *individual fitness surface*, the latter as the *mean fitness surface*. Knowing the individual fitness surface allows one to compute the mean fitness surface for any specified $p(z)$, but the converse is not true. The importance of the mean fitness surface is that it provides one way of describing how the population changes under selection – under the infinitesimal model, the derivative of $\overline{W}$ with respect to μ_z describes the change in mean (17.31b).

17.4.2 Measures of Selection on the Mean

A general way of detecting selection on a character is to compare the (fitness-weighted) phenotypic distribution before and after some episode of selection. Growth or other ontogenetic changes, immigration, and environmental changes can also change the phenotypic distribution, and great care must be taken to account for these factors. Another critical problem in detecting selection on a character is that selection on phenotypically correlated characters can also change the distribution. Keeping this important caveat in mind, we first examine measures of selection on a single character, as these form the basis for our discussion in Section 17.5 on measuring selection on multiple characters. Typically, selection on a character is measured by changes in the mean and variance, rather than changes in the entire distribution. While often only the mean is examined, considerable selection can occur without any significant change in the mean (e.g., stabilizing selection).

Two measures of within-generation change in phenotypic mean have been previously introduced: the directional selection differential S and the selection intensity i. A third measure is the directional selection gradient

$$\beta = \frac{S}{\sigma_z^2}. \tag{17.30}$$

As detailed in Section 17.4.6, β is the slope of the linear regression of fitness on phenotype. These three measures (i, S, β) are interchangeable for selection acting on a single character, but their multivariate extensions have very different behaviors (Section 17.5). In particular, the multivariate extension of β is the measure of choice, as it measures the amount of direct selection on a character, while S (and hence i) confounds direct selection with indirect effects due to selection on phenotypically correlated traits (17.48).

Recalling that $h^2 = \sigma_A^2/\sigma_z^2$, the response is often written by breeders as

$$R = h^2 \sigma_z i = \sigma_A h i. \tag{17.31a}$$

The response can also be expressed in terms of the directional selection gradient,

$$R = \sigma_A^2 \beta. \tag{17.31b}$$

17.4.3   Measures of Selection on the Variance

Similar measures can be defined to quantify the change in the phenotypic variance. At first glance this change seems best described by $\sigma_{z*}^2 - \sigma_z^2$, where σ_{z*}^2 is the phenotypic variance following selection. The problem with this measure is that directional selection reduces the variance. Lande and Arnold (1983) showed that

$$\sigma_{z*}^2 - \sigma_z^2 = \sigma[w, (z - \mu_z)^2] - S^2, \tag{17.32}$$

implying that directional selection decreases the phenotypic variance by S^2. With this in mind, Lande and Arnold suggest a corrected measure, the *stabilizing selection differential*,

$$C = \sigma_{z*}^2 - \sigma_z^2 + S^2, \tag{17.33}$$

that describes selection acting directly on the variance. As we will see below, the term 'stabilizing selection' differential may be slightly misleading, so following Phillips and Arnold (1989) we refer to C as the *quadratic selection differential*. Correction for the effects of directional selection is important, as claims of stabilizing selection based on a reduction in variance following selection can be due entirely to reduction in variance caused by directional selection. Similarly, disruptive selection can be masked by directional selection. Provided that selection does not act on characters phenotypically correlated with the one under study, C provides information on the nature of selection on the variance. Positive C indicates selection to increase the variance (as would occur with disruptive selection), while negative C indicates selection to reduce the variance (as would occur with stabilizing selection). As we discuss shortly, $C < 0$ ($C > 0$) is *consistent* with stabilizing (disruptive) selection, but not *sufficient*. A further complication in interpreting C is that if the phenotypic distribution is skewed, selection on the variance changes the mean. This causes a nonzero value of S that in turn inflates C (Figure 17.3).

Analogous to S equaling the covariance between z and relative fitness, (17.32) implies that C is the covariance between relative fitness and the squared deviation of a character from its mean,

$$C = \sigma[w, (z - \mu)^2]. \tag{17.34}$$

As was the case with S, the opportunity for selection I bounds the maximum possible within-generation change in variance (Arnold, 1986). Expressing C as a covariance and using the standard definition of a correlation gives $C = \rho_{w,(z-\mu)^2} \sigma_w \sigma[(z - \mu)^2]$. Since $\rho_{w,(z-\mu)^2}^2 \leq 1$, we have

$$C^2 \leq \sigma_w^2 \sigma^2[(z - \mu)^2] = I \cdot (\mu_{4,z} - \sigma_z^4).$$

Thus,

$$|C| \leq \sqrt{I(\mu_{4,z} - \sigma_z^4)}. \tag{17.35a}$$
Figure 17.3 Even when a population is under strict stabilizing selection, the mean can change if the phenotypic distribution is skewed. A standard fitness function for stabilizing selection is $W(z) = 1 - b(\theta - z)^2$. O'Donald (1968) found that, even if the population mean is at the optimum value ($\mu_z = \theta$), S is nonnegative if the skew is nonzero ($\mu_{3,z} \neq 0$) as $S = -(b\mu_{3,z})/(1 - b\sigma_z^2)$. (a) If phenotypes are distributed symmetrically about the mean ($\mu_{3,z} = 0$), the distribution after selection (stippled) has the same mean when $\mu_z = \theta$. (b) If, however, the distribution is skewed, more of the distribution lies on one side of the mean than the other. Since the distribution is 'unbalanced', the longer tail experiences more selection than the shorter tail, changing the mean.

If z is normally distributed, the fourth central moment $\mu_{4,z} = 3\sigma_z^4$, giving

$$|C| \leq \sigma_z^2 \sqrt{2I}. \tag{17.35b}$$

The quadratic analog of β, the *quadratic* (or *stabilizing*) *selection gradient* γ, was suggested by Lande and Arnold (1983),

$$\gamma = \frac{\sigma[w, (z - \mu)^2]}{\sigma_z^4} = \frac{C}{\sigma_z^4}. \tag{17.36}$$

As with β, γ is the measure of choice when dealing with multiple characters because it accounts for the effects of (measured) phenotypically correlated characters (Section 17.5.5).

17.4.4 Gradients and the Geometry of Fitness Surfaces

A conceptual advantage of β and γ is that they describe the average local geometry of the fitness surface when phenotypes are normally distributed. When z is normal and individual fitnesses are not frequency-dependent, β can be expressed in terms of the geometry of the *mean* fitness surface,

$$\beta = \frac{\partial \ln \overline{W}}{\partial \mu_z} = \frac{1}{\overline{W}} \frac{\partial \overline{W}}{\partial \mu_z}, \tag{17.37a}$$

so that β is proportional to the slope of the $\overline{W}$ surface with respect to population mean. β can also be expressed as a function of the *individual* fitness surface. Lande and Arnold (1983) showed, provided z is normally distributed, that

$$\beta = \int \frac{\partial w(z)}{\partial z} p(z) \, \mathrm{d}z, \tag{17.37b}$$

implying that β is the average slope of the individual fitness surface, the average being taken over the population being studied. Likewise, if z is normal,

$$\gamma = \int \frac{\partial^2 w(z)}{\partial z^2} p(z)\,\mathrm{d}z, \tag{17.37c}$$

which is the average curvature of the individual fitness surface (Lande and Arnold, 1983). Thus, β and γ provide a measure of the geometry of the individual fitness surface averaged over the population being considered.

A final advantage of β and γ is that they appear as the measures of phenotypic selection in equations describing selection response. Recall from (17.31b) that under the assumptions leading to the breeders' equation, $R = \Delta\mu = \sigma_A^2 \beta$. Similarly, for predicting changes in additive genetic variance under the infinitesimal model, the expected change in variance from a single generation of selection is

$$\Delta\sigma_A^2 = \frac{\sigma_A^4}{2}(\gamma - \beta^2), \tag{17.38}$$

which decomposes the change in variance into changes due to selection on the variance (γ) and changes due to directional selection (β^2).

While the distinction between differentials and gradients seems trivial in the univariate case (only a scale difference), when considering multivariate traits, gradients have the extremely important feature of removing the effects of phenotypic correlations.

17.4.5 Estimating the Individual Fitness Surface

We can decompose the fitness W of an individual with character value z into the sum of its expected fitness $W(z)$ and a residual deviation e,

$$W = W(z) + e.$$

The residual variance in fitness for a given z, $\sigma_e^2(z)$, measures the variance in fitness among individuals with phenotypic value z. Estimation of the individual fitness surface is thus a generalized regression problem, the goal being to choose a candidate function for $W(z)$ that minimizes the average residual variance $\mathrm{E}_z[\sigma_e^2(z)]$. Since the total variance in fitness σ_W^2 equals the sum of the within-group (phenotype) and between-group variance in fitness,

$$\frac{\sigma_W^2 - \mathrm{E}_z[\sigma_e^2(z)]}{\sigma_W^2}$$

is the fraction of individual fitness variation accounted for by a particular estimate of $W(z)$, and provides a measure for comparing different estimates. In the limiting case where fitness is independent of z (and any characters phenotypically correlated with z), $W(z) = \overline{W}$, so that the between-phenotypic variance is zero while $\sigma_e^2(z) = \sigma_W^2$.

There are at least two sources of error contributing to e. First, there can be errors in measuring the actual fitness of an individual (these are almost always ignored). Second, the *actual* fitness of a particular individual can deviate considerably from the *expected value* for its phenotype due to chance effects and selection on other characters besides those being considered. Generally, these residual deviations are heteroscedastic, with σ_e^2 often depending on the value of $W(z)$ (Mitchell-Olds and Shaw, 1987; Schluter,

1988). For example, suppose fitness is measured by survival to a particular age. While $W(z) = p_z$ is the probability of survival for an individual with character value z, the fitness for a particular individual is either 0 (does not survive) or 1 (survives), giving $\sigma_e^2(z) = p_z(1 - p_z)$. Unless p_z is constant over z, the residuals are heteroscedastic. Note in this case that even after removing the effects attributable to differences in phenotypes, there still is substantial variance in individual fitness.

Inferences about the individual fitness surface are limited by the range of phenotypes in the population. Unless this range is very large, only a small region of the fitness surface can be estimated with any precision. Estimates of the fitness surface at the tails of the current phenotypic distribution are extremely imprecise, yet potentially very informative, suggesting what selection pressures populations at the margin of the observed range of phenotypes may experience. A further complication is that the fitness surface changes with the environment, so that year-to-year estimates can differ (e.g., Kalisz, 1986) and cannot be lumped together to increase sample size.

17.4.6   Linear and Quadratic Approximations of $W(z)$

The individual fitness surface $W(z)$ can be very complex and a wide variety of functions may be chosen to approximate it. The simplest and most straightforward approach is to use a low-order polynomial (typically linear or quadratic).

Consider first the simple linear regression of *relative* fitness w as a function of phenotypic value z. Since the directional selection gradient is

$$\beta = \frac{S}{\sigma_z^2} = \frac{\sigma(w, z)}{\sigma_z^2}, \tag{17.39a}$$

it follows from regression theory that β is the slope of the least-squares linear regression of relative fitness on z,

$$w = a + \beta z + e. \tag{17.39b}$$

Hence the best linear predictor of relative fitness is $w(z) = a + \beta z$. Since the regression passes through the expected values of w and z (1 and μ_z, respectively), this can be written as

$$w = 1 + \beta(z - \mu_z) + e, \tag{17.39c}$$

giving $w(z) = 1 + \beta(z - \mu_z)$. Assuming the fitness function is well described by a linear regression, β is the expected change in relative fitness given a unit change in z. The fraction of variance in individual fitness accounted for by this regression is

$$r_{z,w}^2 = \frac{\text{cov}^2(z, w)}{\text{var}(z) \cdot \text{var}(w)} = \hat{\beta}^2 \frac{\text{var}(z)}{\hat{I}}. \tag{17.40}$$

If the fitness surface shows curvature, as might be expected if there is stabilizing selection or disruptive selection, a *quadratic regression*,

$$w = a + b_1 z + b_2(z - \mu_z)^2 + e, \tag{17.41a}$$

is more appropriate. Since the regression passes through the mean of all variables,

$$w = 1 + b_1(z - \mu_z) + b_2[(z - \mu_z)^2 - \sigma_z^2] + e. \tag{17.41b}$$

The regression coefficients b_1 and b_2 nicely summarize the local geometry of the fitness surface. Evaluating the derivative of (17.41) at $z = \mu_z$ gives

$$\left.\frac{\partial w(z)}{\partial z}\right|_{z=\mu_z} = b_1 \quad \text{and} \quad \left.\frac{\partial^2 w(z)}{\partial z^2}\right|_{z=\mu_z} = 2b_2. \tag{17.42}$$

Hence b_1 is the slope and $2b_2$ the second derivative (curvature) of the best quadratic fitness surface around the population mean. $b_2 > 0$ indicates that the best-fitting quadratic of the individual fitness surface has an upward curvature, while $b_2 < 0$ implies the curvature is downward. Lande and Arnold (1983) suggest that $b_2 > 0$ indicates disruptive selection, while $b_2 < 0$ indicates stabilizing selection. Their reasoning follows from elementary geometry in that a *necessary* condition for a local minimum is that a function curves upward in some interval, while a necessary condition for a local maximum is that the function curves downward. Mitchell-Olds and Shaw (1987) and Schluter (1988) argue that this condition is not *sufficient*. Stabilizing selection is generally defined as the presence of a local maximum in $w(z)$ and disruptive selection by the presence of a local minimum, while b_2 indicates curvature, rather than the presence of local extrema.

Recalling the covariances given by (17.23) and (17.34), the least-squares values for b_1 and b_2 become

$$b_1 = \frac{(\mu_{4,z} - \sigma_z^4) \cdot S - \mu_{3,z} \cdot C}{\sigma_z^2 \cdot (\mu_{4,z} - \sigma_z^4) - \mu_{3,z}^2}, \tag{17.43a}$$

$$b_2 = \frac{\sigma_z^2 \cdot C - \mu_{3,z} \cdot S}{\sigma_z^2 \cdot (\mu_{4,z} - \sigma_z^4) - \mu_{3,z}^2}. \tag{17.43b}$$

Provided z is normally distributed before selection, the skew $\mu_{3,z} = 0$ and the kurtosis $\mu_{4,z} - \sigma_z^4 = 2\sigma_z^4$. In this case, $b_1 = \beta$ and $b_2 = \gamma/2$, giving the univariate version of the *Pearson–Lande–Arnold regression*,

$$w = 1 + \beta(z - \mu_z) + \tfrac{\gamma}{2}((z - \mu_z)^2 - \sigma_z^2) + e, \tag{17.44}$$

developed by Lande and Arnold (1983), motivated by Pearson (1903). The Pearson–Lande–Arnold regression provides a connection between selection differentials (directional and stabilizing) and quadratic approximations of the individual fitness surface.

An important point from (17.43a) is that if skew is present ($\mu_{3,z} \neq 0$), $b_1 \neq \beta$ and the slope term in the linear regression (the best *linear* fit) of $w(z)$ differs from the linear slope term in the quadratic regression (the best *quadratic* fit) of $w(z)$. This arises because the presence of skew generates a covariance between z and $(z - \mu_z)^2$. The biological significance of this can be seen by reconsidering Figure 17.3, in which the presence of skew in the phenotypic distribution results in a change in the mean of a population under strict stabilizing selection (as measured by the population mean being at the optimum of the individual fitness surface). Skew generates a correlation between z and $(z - \mu_z)^2$, so that selection acting only on $(z - \mu_z)^2$ generates a correlated change in z. From the Robertson–Price identity (17.23), the within-generation change in mean equals the covariance between-phenotypic value and relative fitness. Since covariances measure the amount of *linear* association between variables, in describing the change in mean, the correct measure is the slope of the best *linear* fit of the individual

fitness surface. If skew is present, using the linear slope b_1 from the quadratic regression to describe the change in mean is incorrect, as this quadratic regression removes the effects on relative fitness from a linear change in z due to the correlation between z and $(z - \mu_z)^2$.

17.5 MEASURING MULTIVARIATE SELECTION

Typically, investigation of the effects of natural selection involves measuring a suite of characters for each individual. In this setting, the phenotype of an individual is a vector $\mathbf{z} = (z_1, z_2, \ldots, z_n)^{\mathrm{T}}$ of the n measured character values. The major aim of a multivariate character analysis is to partition the total change in a trait into the effect from direct selection and the change due to selection on phenotypically correlated characters. Indeed, an unstated assumption of a univariate analysis is that there is no indirect selection on the trait induced by direct selection on unmeasured correlated characters. This assumption is also required for a multivariate analysis, as one cannot correct for the effects of any *unmeasured* selected characters phenotypically correlated to one (or more) of the traits under consideration.

Our development is based on the multiple regression approach of Lande and Arnold (1983). Similar approaches based on path analysis have also been suggested (Maddox and Antonovics, 1983; Mitchell-Olds, 1987; Crespi and Bookstein, 1988). We denote the mean vector and covariance matrix of $\mathbf{z}$ before selection by $\boldsymbol{\mu}$ and $\mathbf{P}$, and after selection (but before reproduction) by $\boldsymbol{\mu}^*$ and $\mathbf{P}^*$.

17.5.1 Changes in the Mean Vector: The Directional Selection Differential

The multivariate extension of the directional selection differential is the vector

$$\mathbf{S} = \boldsymbol{\mu}^* - \boldsymbol{\mu}, \tag{17.45a}$$

whose ith element is S_i, the differential for character z_i. As with the univariate case, the Robertson–Price identity (17.23) holds, so that the elements of $\mathbf{S}$ represent the covariance between character value and relative fitness, $S_i = \sigma(z_i, \omega)$. This immediately implies (17.26) that the opportunity for selection I bounds the range of S_i,

$$\frac{|S_i|}{\sigma_{z_i}} \leq \sqrt{I}. \tag{17.45b}$$

As is illustrated in Figure 17.4, $\mathbf{S}$ confounds the direct effects of selection on a character with the indirect effects due to selection on phenotypically correlated characters. Suppose that character 1 is under direct selection to increase in value while character 2 is not directly selected. As Figure 17.4 shows, if z_1 and z_2 are uncorrelated, there is no within-generation change in μ_2 (the mean of z_2). However, if z_1 and z_2 are positively correlated, individuals with large values of z_1 also tend to have large values of z_2, resulting in a within-generation increase in μ_2. Conversely, if z_1 and z_2 are negatively correlated, selection to increase z_1 results in a within-generation decrease in μ_2. Hence, a character not under selection can still experience a within-generation change in its phenotypic distribution due to selection on a phenotypically correlated character (indirect selection). Fortunately, the *directional selection gradient* $\boldsymbol{\beta} = \mathbf{P}^{-1}\mathbf{S}$ accounts for indirect selection

Figure 17.4 Selection on a character can result in a within-generation change in the mean of other phenotypically correlated characters not themselves under direct selection. Assume that character 1 is under simple truncation selection so that only individuals with $z_1 > T$ reproduce. (a) When z_1 and z_2 are uncorrelated, $S_2 = 0$. (b) When z_1 and z_2 are negatively correlated, $S_2 < 0$. (c) When z_1 and z_2 are positively correlated, $S_2 > 0$.

(a)

(b)

(c)
due to phenotypic correlations, providing a less biased picture of the nature of directional selection acting on $\mathbf{z}$.

17.5.2   The Directional Selection Gradient

From regression theory, the vector of partial regression coefficients for predicting the value of y given a vector of observations $\mathbf{z}$ is $\mathbf{P}^{-1}\boldsymbol{\sigma}(\mathbf{z}, y)$, where $\mathbf{P}$ is the covariance matrix of $\mathbf{z}$, and $\boldsymbol{\sigma}(\mathbf{z}, y)$ is the vector of covariances between the elements of $\mathbf{z}$ and the variable y. Since $\mathbf{S} = \boldsymbol{\sigma}(\mathbf{z}, \omega)$, it immediately follows that

$$\mathbf{P}^{-1}\boldsymbol{\sigma}(\mathbf{z}, \omega) = \mathbf{P}^{-1}\mathbf{S} = \boldsymbol{\beta} \qquad (17.46)$$

is the vector of partial regression for the best linear regression of relative fitness ω on phenotypic value $\mathbf{z}$, viz.,

$$\omega(\mathbf{z}) = 1 + \sum_{j=1}^{n} \beta_j (z_j - \mu_j) = 1 + \boldsymbol{\beta}^{\mathrm{T}}(\mathbf{z} - \boldsymbol{\mu}). \qquad (17.47)$$

Since β_j is a partial regression coefficient, it represents the change generated in relative fitness by changing z_j while holding all other character values in $\mathbf{z}$ constant – a one-unit

increase in z_j (holding all other characters constant) increases the expected relative fitness by β_j. Provided all characters under selection are measured (i.e., we can exclude the possibility of unmeasured characters influencing fitness that are phenotypically correlated with **z**), a character under no directional selection has $\beta_j = 0$ – when all other characters are held constant, the best linear regression predicts no change in expected fitness as we change the value of z_j. Thus, **β** accounts for the effects of phenotypic correlations only among the *measured* characters. Provided we measure all characters under selection and there are no confounding environmental or genetic effects, **β** provides an unbiased measure of the amount of directional selection acting on each character.

Since $\mathbf{S} = \mathbf{P}\boldsymbol{\beta}$, we have

$$S_i = \sum_{j=1}^{n} \beta_j P_{ij} = \beta_i P_{ii} + \sum_{j \neq i}^{n} \beta_j P_{ij}, \tag{17.48}$$

illustrating that the directional selection differential confounds direct selection on that character (β_i) with indirect contributions due to selection on phenotypically correlated characters (β_j). Equation (17.48) implies that, if two characters are phenotypically uncorrelated ($P_{ij} = 0$), selection on one has no within-generation effect on the phenotypic mean of the other.

17.5.3 Directional Gradients, Fitness Surface Geometry, and Selection Response

When phenotypes are multivariate normal (MVN), **β** provides a convenient descriptor of the geometry of both the individual and mean population fitness surfaces. Lande (1976; 1979) showed that

$$\boldsymbol{\beta} = \nabla_{\boldsymbol{\mu}}[\ln \overline{W}(\boldsymbol{\mu})] = \overline{W}^{-1} \cdot \nabla_{\boldsymbol{\mu}}[\overline{W}(\boldsymbol{\mu})], \tag{17.49}$$

which holds provided fitnesses are frequency-independent. Here $\nabla_{\boldsymbol{\mu}}$ is the *gradient* (or *gradient vector*) with respect to the vector of population means,

$$\nabla_{\boldsymbol{\mu}}[f] = \frac{\partial f}{\partial \boldsymbol{\mu}} = \begin{pmatrix} \dfrac{\partial f}{\partial \mu_1} \\ \vdots \\ \dfrac{\partial f}{\partial \mu_n} \end{pmatrix}.$$

The gradient at point $\boldsymbol{\mu}_0$ corresponds to a vector indicating the direction of steepest ascent of the function at that point (the multivariate slope of f at the point $\boldsymbol{\mu}_0$). Thus **β** is the gradient of mean population fitness with respect to the mean vector $\boldsymbol{\mu}$. Since **β** gives the direction of steepest increase in the mean population fitness surface, mean population fitness increases most rapidly when the change in the vector of means $\Delta\boldsymbol{\mu} = \boldsymbol{\beta}$. If fitnesses are frequency-dependent (individual fitnesses change as the population mean changes), then for $\mathbf{z} \sim \text{MVN}$,

$$\boldsymbol{\beta} = \nabla_{\boldsymbol{\mu}}[\ln \overline{W}(\boldsymbol{\mu})] + \int \nabla_{\boldsymbol{\mu}}[\omega(\mathbf{z})]\phi(\mathbf{z})\, d\mathbf{z}, \tag{17.50}$$

where the second term accounts for the effects of frequency-dependence and ϕ is the MVN density function (Lande, 1976). Here **β** does not point in the direction of steepest increase

in $\overline{W}$ unless the second integral is zero. If we instead consider the individual fitness surface, we can alternatively express $\boldsymbol{\beta}$ as the gradient of individual fitnesses averaged over the population distribution of phenotypes,

$$\boldsymbol{\beta} = \int \nabla_{\mathbf{z}}[\omega(\mathbf{z})]\phi(\mathbf{z})\, d\mathbf{z}, \tag{17.51}$$

which holds provided $\mathbf{z} \sim \text{MVN}$ (Lande and Arnold, 1983). Equation (17.51) holds regardless of whether fitness is frequency-dependent or frequency-independent.

Kingsolver *et al.* (2001) and Hoekstra *et al.* (2001) reviewed estimates of β (the univariate elements of $\boldsymbol{\beta}$) from selection in natural populations. They observed that the distribution for $|\beta|$ is close to exponential, with estimated selection gradients tending to be small (they found the median value for $|\beta|$ was 0.15). Interestingly, they found that the selection gradients for sexual selection (mate choice) tend to be larger than those for viability selection (survivorship). Most of the difference was due to a much higher frequency of values of $|\beta| < 0.1$ for viability selection. They further noted that estimated β values are highly correlated with their estimated selection intensities, i. Since i is a univariate measure that incorporates both direct and indirect effects of selection, while β removes any indirect effects from *measured* characters, they concluded that indirect selection is generally modest at best. The caveat with this conclusion is that correlated character under direct selection, but not included in the study, can falsely create an impression of direct selection on the actual traits measured.

17.5.4 Changes in the Covariance Matrix: The Quadratic Selection Differential

Motivated by the univariate case (17.34), define the multivariate *quadratic selection differential* to be a square ($n \times n$) matrix C whose elements are the covariances between all pairs of quadratic deviations $(z_i - \mu_{z_i})(z_j - \mu_{z_j})$ and relative fitness w:

$$C_{ij} = \sigma[w, (z_i - \mu_{z_i})(z_j - \mu_{z_j})]. \tag{17.52a}$$

Lande and Arnold (1983) showed that

$$\mathbf{C} = \sigma[w, (\mathbf{z} - \boldsymbol{\mu})(\mathbf{z} - \boldsymbol{\mu})^{\mathrm{T}}] = \mathbf{P}^* - \mathbf{P} + \mathbf{SS}^{\mathrm{T}}. \tag{17.52b}$$

If no quadratic selection is acting, the covariance between each quadratic deviation and fitness is zero and $\mathbf{C} = \mathbf{0}$. In this case (17.52b) gives

$$P_{ij}^* - P_{ij} = -S_i S_j, \tag{17.53}$$

demonstrating that the $S_i S_j$ term corrects C_{ij} for the change in covariance caused by directional selection alone.

As was the case for $\mathbf{S}$, the fact that C_{ij} is a covariance immediately allows us to bound its range using the opportunity for selection. Since $\sigma^2(x, y) \leq \sigma^2(x)\,\sigma^2(y)$,

$$C_{ij}^2 \leq I\sigma^2[(z_i - \mu_{z_i})(z_j - \mu_{z_j})]. \tag{17.54a}$$

When z_i and z_j are bivariate normal, then (Kendall and Stuart, 1983)

$$\sigma^2[(z_i - \mu_{z_i})(z_j - \mu_{z_j})] = P_{ij}^2 + P_{ii}P_{jj} = P_{ij}^2(1 + \rho_{ij}^{-2}), \tag{17.54b}$$

where ρ_{ij} is the phenotypic covariance between z_i and z_j. Hence, for Gaussian-distributed phenotypes,

$$\left| \frac{C_{ij}}{P_{ij}} \right| \leq \sqrt{I} \sqrt{1 + \rho_{ij}^{-2}}, \tag{17.55}$$

which is a variant of the original bound based on I suggested by Arnold (1986).

17.5.5   The Quadratic Selection Gradient

Like **S**, **C** confounds the effects of direct selection with selection on phenotypically correlated characters. However, as was true for **S**, these indirect effects can also be removed by a regression. Consider the best quadratic regression of relative fitness as a function of multivariate phenotypic value,

$$w(\mathbf{z}) = a + \sum_{j=1}^{n} b_j z_j + \frac{1}{2} \sum_{j=1}^{n} \sum_{k=1}^{n} \gamma_{jk} (z_j - \mu_j)(z_k - \mu_k) \tag{17.56a}$$

$$= a + \mathbf{b}^{\mathrm{T}} \mathbf{z} + \frac{1}{2} (\mathbf{z} - \boldsymbol{\mu})^{\mathrm{T}} \boldsymbol{\gamma} (\mathbf{z} - \boldsymbol{\mu}). \tag{17.56b}$$

Using multiple regression theory, Lande and Arnold (1983) showed that the matrix $\boldsymbol{\gamma}$ of quadratic partial regression coefficients is given by

$$\boldsymbol{\gamma} = \mathbf{P}^{-1} \boldsymbol{\sigma} [w, (\mathbf{z} - \boldsymbol{\mu})(\mathbf{z} - \boldsymbol{\mu})^{\mathrm{T}}] \mathbf{P}^{-1} = \mathbf{P}^{-1} \mathbf{C} \mathbf{P}^{-1}. \tag{17.57}$$

This is the *quadratic selection gradient* and (like $\boldsymbol{\beta}$) removes the effects of phenotypic correlations, providing a more accurate picture of how selection is operating on the multivariate phenotype.

The vector **b** of linear coefficients for the quadratic regression need not equal the vector $\boldsymbol{\beta}$ of partial regression coefficients obtained by assuming only a linear regression. As was true for the univariate case (17.43) when skew is present in at least one of the components of the phenotypic distribution, **b** is a function of both **S** and **C**, while $\boldsymbol{\beta}$ is only a function of **S**. When skew is absent, $\mathbf{b} = \boldsymbol{\beta}$, recovering the multivariate version of the Pearson–Lande–Arnold regression,

$$w(\mathbf{z}) = a + \boldsymbol{\beta}^{T} \mathbf{z} + \frac{1}{2} (\mathbf{z} - \boldsymbol{\mu})^{\mathrm{T}} \boldsymbol{\gamma} (\mathbf{z} - \boldsymbol{\mu}). \tag{17.58}$$

Since the γ_{ij} are partial regression coefficients, they predict the change in expected fitness caused by changing the associated quadratic deviation while holding all other variables constant. Increasing $(z_j - \mu_j)(z_k - \mu_k)$ by one unit in such a way as to hold all other variables and pairwise combinations of characters constant, relative fitness is expected to increase by γ_{jk} for $j \neq k$ and by $\gamma_{jj}/2$ if $j = k$ (the difference arises because $\gamma_{jk} = \gamma_{kj}$, so that γ_{jk} appears twice in the regression unless $j = k$). The coefficients of $\boldsymbol{\gamma}$ thus describe the nature of selection on quadratic deviations from the mean for both single characters and pairwise combinations of characters. $\gamma_{ii} < 0$ implies fitness is expected to decrease as z_i moves away (in either direction) from its mean. As was discussed previously, this is a necessary, *but not sufficient*, condition for stabilizing selection on character i. Similarly, $\gamma_{ii} > 0$ implies fitness is expected to increase as z_i moves away

from its mean, again a necessary, but not sufficient, condition for disruptive selection. Kingsolver *et al.* (2001) examined the distribution of estimated γ_{ii} values reported in the literature. Surprisingly, they found this distribution to be symmetric about zero, implying that disruptive selection ($\gamma_{ii} > 0$) is reported as often as stabilizing selection ($\gamma_{ii} < 0$), which is quite contrary to the widely hide view that stabilizing selection is perhaps the most common mode of selection in natural populations. Further, most of the estimated γ_{ii} values are small, with the median value for $|\gamma|$ being 0.10. Thus, the widely held notion of strong stabilizing selection being common in nature is (presently) not supported by the published data.

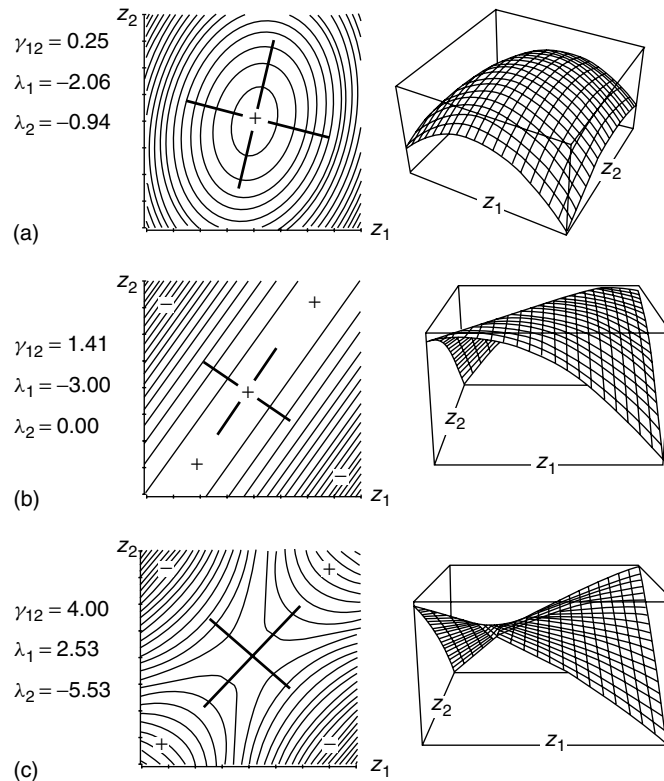
Turning to combinations of characters, nonzero values of $\gamma_{jk}(j \neq k)$ suggest the


Figure 17.5 Three quadratic fitness surfaces, all of which have $\gamma_{11} = -2$, $\gamma_{22} = -1$ and $b = 0$. On the left are curves of equal fitness values, with peaks being represented by $+$ and valleys by $-$. Axes of symmetry of the surface (the canonical or principal axes of $\boldsymbol{\gamma}$) are denoted by the thick lines. These axes correspond to the eigenvectors of $\boldsymbol{\gamma}$. On the right are three-dimensional plots of individual fitness as a function of the phenotypic values of the characters z_1 and z_2. (a) $\gamma_{12} = 0.25$. This corresponds to stabilizing selection on both characters, with fitness falling off more rapidly (as indicated by the shorter distance between contour lines) along the z_1 axis than along the z_2 axis. (b) $\gamma_{12} = \sqrt{2} \simeq 1.41$, in which case $\boldsymbol{\gamma}$ is singular. The resulting fitness surface shows a ridge in one direction with strong stabilizing selection in the other. (c) When $\gamma_{12} = 4$, the fitness surface now shows a saddlepoint, with stabilizing selection along one of the canonical axes of the fitness surface and disruptive selection along the other.

presence of *correlation selection*: $\gamma_{jk} > 0$ suggests selection for a positive correlation between characters j and k, while $\gamma_{jk} < 0$ suggests selection for a negative correlation. Although it seems straightforward to infer the overall nature of selection by looking at these various pairwise combinations, this can give a very misleading picture about the geometry of the fitness surface (Figure 17.5). We discuss this problem and its solution in Section 17.5.8.

Finally, we can see the effects of phenotypic correlations on the quadratic selection differential. Solving for $\mathbf{C}$ by post- and premultiplying $\boldsymbol{\gamma}$ by $\mathbf{P}$ gives $\mathbf{C} = \mathbf{P}\boldsymbol{\gamma}\mathbf{P}$, or

$$C_{ij} = \sum_{k=1}^{n} \sum_{\ell=1}^{n} \gamma_{k\ell} P_{ik} P_{\ell j}, \tag{17.59}$$

showing that within-generation changes in phenotypic covariance, as measured by $\mathbf{C}$, are influenced by quadratic selection on phenotypically correlated characters.

17.5.6 Quadratic Gradients, Fitness Surface Geometry, and Selection Response

When phenotypes are multivariate normally distributed, $\boldsymbol{\gamma}$ provides a measure of the average curvature of the individual fitness surface,

$$\boldsymbol{\gamma} = \int \mathbf{H_z}[w(\mathbf{z})]\phi(\mathbf{z}) \, d\mathbf{z}, \tag{17.60a}$$

where $\mathbf{H_z}[f]$ denotes the Hessian of the function f with respect to $\mathbf{z}$ and is a multivariate measure of the quadratic curvature of a function (recall that the (i, j)th element of the Hessian is $\partial^2 f/\partial z_i \partial z_j$). This result, due to Lande and Arnold (1983), holds for both frequency-dependent and frequency-independent fitnesses. When fitnesses are frequency-independent (again provided $\mathbf{z} \sim$ MVN), $\boldsymbol{\gamma}$ provides a description of the curvature of the *log mean population* fitness surface, with

$$\mathbf{H_\mu}[\ln \overline{W}(\boldsymbol{\mu})] = \boldsymbol{\gamma} - \boldsymbol{\beta}\boldsymbol{\beta}^{\mathrm{T}}. \tag{17.60b}$$

This result is due to Lande (cited in Phillips and Arnold, (1989)) and points out that there are two sources for curvature in the mean fitness surface: $-\boldsymbol{\beta}\boldsymbol{\beta}^{\mathrm{T}}$ from directional selection and $\boldsymbol{\gamma}$ from quadratic selection.

The careful reader will undoubtedly have noted a number of similarities between direction and quadratic gradients. Table 17.1 summarizes these and other analogous features of measuring changes in means and covariances.

17.5.7 Estimation, Hypothesis Testing, and Confidence Intervals

Even if we can assume that a best-fit quadratic is a reasonable approximation of the individual fitness surface, we are still faced with a number of statistical problems. Unless we test for, and confirm, multivariate normality, $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ must be estimated from separate regressions – $\boldsymbol{\beta}$ from the best linear regression, $\boldsymbol{\gamma}$ from the best quadratic regression. In either case, there are a large number of parameters to estimate – $\boldsymbol{\gamma}$ has $n(n + 1)/2$ terms and $\boldsymbol{\beta}$ has n terms, a total making of $n(n + 3)/2$. With 5, 10, and 25 characters, this corresponds to 20, 65, and 350 parameters. The number of

Table 17.1   Analogous features of directional and quadratic differentials and gradients.

Changes in means (directional selection)	Changes in covariances (Quadratic selection)

Differentials measure the covariance between relative fitness and phenotype

$$S_i = \sigma[w, z_i] \qquad\qquad C_{ij} = \sigma[w, (z_i - \mu_i)(z_j - \mu_j)]$$

The opportunity for selection bounds the differential

$$\frac{|S_i|}{\sigma(z_i)} \leq \sqrt{I} \qquad\qquad \left|\frac{C_{ij}}{P_{ij}}\right| \leq \sqrt{I}\sqrt{1 + \rho_{ij}^{-2}}$$

for any distribution of $\mathbf{z}$ provided $\mathbf{z} \sim$ MVN

Differentials confound direct and indirect selection

$$\mathbf{S} = \boldsymbol{\mu}^* - \boldsymbol{\mu} = \mathbf{P}\boldsymbol{\beta} \qquad\qquad \mathbf{C} = \mathbf{P}^* - \mathbf{P} + \mathbf{S}\mathbf{S}^\mathrm{T} = \mathbf{P}\boldsymbol{\gamma}\mathbf{P}$$

Gradients measure the amount of direct selection

$$\boldsymbol{\beta} = \mathbf{P}^{-1}\mathbf{S} \qquad\qquad \boldsymbol{\gamma} = \mathbf{P}^{-1}\mathbf{C}\mathbf{P}^{-1}$$

Gradients describe the slope and curvature of the mean population fitness surface, provided
  $z \sim$ **MVN and fitnesses are frequency-independent**

$$\beta_i = \frac{\partial \ln \overline{W}(\boldsymbol{\mu})}{\partial \mu_i} \qquad\qquad \gamma_{ij} = \frac{\partial^2 \ln \overline{W}(\boldsymbol{\mu})}{\partial \mu_i \partial \mu_j} + \beta_i \beta_j$$

Gradients describe the average curvature of the individual fitness surface, provided
  $\mathbf{z} \sim$ **MVN** (with $p(\mathbf{z})$ the density function),

$$\beta_i = \int \frac{\partial w(\mathbf{z})}{\partial z_i} p(\mathbf{z})\, d\mathbf{z} \qquad\qquad \gamma_{ij} = \int \frac{\partial^2 w(\mathbf{z})}{\partial z_i \partial z_j} p(\mathbf{z})\, d\mathbf{z}$$

Gradients appear as coefficients in fitness regressions

$$w(\mathbf{z}) = a + \mathbf{b}^\mathrm{T}(\mathbf{z} - \boldsymbol{\mu}) + \tfrac{1}{2}(\mathbf{z} - \boldsymbol{\mu})^\mathrm{T}\boldsymbol{\gamma}(\mathbf{z} - \boldsymbol{\mu})$$

$$w(\mathbf{z}) = a + \boldsymbol{\beta}^\mathrm{T}(\mathbf{z} - \boldsymbol{\mu})$$

$\boldsymbol{\gamma} =$ the quadratic coefficient of the best

$\boldsymbol{\beta} =$ slope of best linear fit

quadratic fit; $\mathbf{b} = \boldsymbol{\beta}$ when $\mathbf{z} \sim$ MVN

Gradients appear as coefficients in evolutionary equations when $(\mathbf{z}, \mathbf{g}) \sim$ MVN

$$\Delta\boldsymbol{\mu} = \mathbf{G}\boldsymbol{\beta} \qquad\qquad \mathbf{G}^* - \mathbf{G} = \mathbf{G}(\boldsymbol{\gamma} - \boldsymbol{\beta}\boldsymbol{\beta}^\mathrm{T})\mathbf{G}$$

observations should greatly exceed $n(n + 3)/2$ in order to estimate these parameters with any precision.

A second problem is multicollinearity – if some of the characters being measured are highly correlated with each other, the phenotypic covariance matrix $\mathbf{P}$ can be nearly singular, so that small errors in estimating $\mathbf{P}$ result in large differences in $\mathbf{P}^{-1}$, which in turn gives a very large sampling variances for the estimates of $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$. One possibility is to use principal components (PCs) to extract a subset of the characters that explains most of the phenotypic variance of $\mathbf{P}$. Fitness regressions using the first few PCs as the characters can then be computed. This approach also reduces the problem of the number of parameters to estimate, but risks the real possibility of removing the most important characters. Further, PCs are often difficult to interpret biologically. While the first PC for morphological characters generally corresponds to a general measure of size, the others are typically much more problematic. Finally, this technique can spread the effects of selection on one character over several PCs, further complicating interpretation.

Another statistical concern with fitness regressions is that residuals are generally not normal – viability data typically have binominally distributed residuals, while count data

are often Poisson. Hence, many of the standard approaches for constructing confidence intervals on regression coefficients are not appropriate. Mitchell-Olds and Shaw (1987) suggest using the delete-one jackknife method for approximating confidence intervals in this case. Randomization tests and cross-validation procedures are other approaches. Multivariate tests of the presence of a single mode in the fitness surface are discussed by Mitchell-Olds and Shaw (1987).

17.5.8 Geometric Interpretation of the Quadratic Fitness Regression

In spite of their apparent simplicity, multivariate quadratic fitness regressions have a rather rich geometric structure. Scaling characters so that they have mean zero, the general quadratic fitness regression can be written as

$$w(\mathbf{z}) = a + \sum_{i=1}^{n} b_1 z_i + \frac{1}{2} \sum_{i=1}^{n} \sum_{j=1}^{n} \gamma_{ij} z_i z_j = a + \mathbf{b}^{\mathrm{T}} \mathbf{z} + \frac{1}{2} \mathbf{z}^{\mathrm{T}} \boldsymbol{\gamma} \mathbf{z}. \tag{17.61}$$

If $\mathbf{z} \sim \mathrm{MVN}$, then $\mathbf{b} = \boldsymbol{\beta}$ (the vector of coefficients of the best *linear* fit). Note that if we regard (17.61) as a second-order Taylor series approximation of $w(z)$, $\mathbf{b}$ and $\boldsymbol{\gamma}$ can be interpreted as the gradient and Hessian of individual fitness evaluated at the population mean (here $\boldsymbol{\mu} = \mathbf{0}$ by construction). The nature of curvature of (17.61) is determined by the matrix $\boldsymbol{\gamma}$. Even though a quadratic is the simplest curved surface, its geometry can still be very difficult to visualize.

We start our exploration of this geometry by considering the gradient of this best-fit quadratic fitness surface, which is

$$\nabla_{\mathbf{z}}[w(\mathbf{z})] = \mathbf{b} + \boldsymbol{\gamma} \mathbf{z}. \tag{17.62}$$

Thus, at the point $\mathbf{z}$ the direction of steepest ascent on the fitness surface (the direction in which to move in phenotype space to maximally increase individual fitness) is given by the vector $\mathbf{b} + \boldsymbol{\gamma} \mathbf{z}$ (when $\boldsymbol{\mu} = \mathbf{0}$). If the true individual fitness surface is indeed a quadratic, then the average gradient of individual fitness taken over the distribution of phenotypes is

$$\int \nabla_{\mathbf{z}}[w(\mathbf{z})] p(\mathbf{z}) \, \mathrm{d}\mathbf{z} = \mathbf{b} \int p(\mathbf{z}) \, \mathrm{d}\mathbf{z} + \boldsymbol{\gamma} \int \mathbf{z} p(\mathbf{z}) \, \mathrm{d}\mathbf{z} = \mathbf{b} \tag{17.63}$$

as the last integral is $\boldsymbol{\mu}$ (which is zero by construction). Hence, if the true fitness function is quadratic, the average gradient of individual fitness is given by $\mathbf{b}$, independent of the distribution of $\mathbf{z}$.

Solving $\nabla_{\mathbf{z}}[w(\mathbf{z})] = 0$, a point $\mathbf{z}_0$ is a candidate for a local extremum (stationary point) if $\boldsymbol{\gamma} \mathbf{z}_0 = -\mathbf{b}$. When $\boldsymbol{\gamma}$ is nonsingular,

$$\mathbf{z}_0 = -\boldsymbol{\gamma}^{-1} \mathbf{b} \tag{17.64a}$$

is the unique stationary point of this quadratic surface. Substituting into (17.61), the expected individual fitness at this point is

$$w_0 = a + \frac{1}{2} \mathbf{b}^{\mathrm{T}} \mathbf{z}_0 \tag{17.64b}$$

as obtained by Phillips and Arnold (1989). Since $\partial^2 w(\mathbf{z})/\partial z_i \partial z_j = \gamma_{ij}$, the Hessian of $w(\mathbf{z})$ is just $\boldsymbol{\gamma}$. Thus $\mathbf{z}_0$ is a local minimum if $\boldsymbol{\gamma}$ is positive definite (all eigenvalues are positive), a local maximum if $\boldsymbol{\gamma}$ is negative definite (all eigenvalues are negative), or a saddlepoint if the eigenvalues differ in sign. If $\boldsymbol{\gamma}$ is singular (has at least one zero eigenvalue) then there is no unique stationary point. An example of this is seen in Figure 17.5(b), where there is a ridge (rather than a single point) of phenotypic values having the highest fitness value. The consequence of a zero eigenvalue is that the fitness surface has no curvature along the axis defined by the associated eigenvector. If $\boldsymbol{\gamma}$ has k zero eigenvalues, then the fitness surface has no curvature along k dimensions. Ignoring fitness change along these dimensions, the remaining fitness space has only a single stationary point, which is given by (17.64a) for γ and $\mathbf{b}$ reduced to the $(n-k)$-dimensional subsurface showing curvature. While the curvature is completely determined by $\boldsymbol{\gamma}$, it is easy to be misled about the actual nature of the fitness surface if one simply tries to infer it by inspection of $\boldsymbol{\gamma}$, as Figure 17.5 illustrates.

17.5.8.1 Canonical Form of the Quadratic Fitness Surface

As Figure 17.5 shows, visualizing the individual fitness surface (even for two characters) is not trivial and can easily be downright misleading. The problem is that the cross-product terms (γ_{ij} for $i \neq j$) make the quadratic form difficult to interpret geometrically. Removing these terms by a change of variables so that the axes of new variables coincide with the axes of symmetry of the quadratic form (its canonical axes) greatly facilitates visualization of the fitness surface. Motivated by this, Phillips and Arnold (1989) suggest using two slightly different versions of the canonical transformation of $\boldsymbol{\gamma}$ to clarify the geometric structure of the best-fitting quadratic fitness surface. If we consider the matrix U whose columns are the eigenvalues of $\boldsymbol{\gamma}$, the transformation $\mathbf{y} = \mathbf{U}^T \mathbf{z}$ (hence $\mathbf{z} = \mathbf{Uy}$ since $\mathbf{U}^{-1} = \mathbf{U}^T$ as U is orthonormal, and $\mathbf{U}^T \boldsymbol{\gamma} \mathbf{U} = \boldsymbol{\Lambda}$, a diagonal matrix whose elements correspond to the eigenvalues of $\boldsymbol{\gamma}$) removes all cross-product terms in the quadratic form,

$$
\begin{aligned}
w(\mathbf{z}) &= a + \mathbf{b}^T \mathbf{U} \mathbf{y} + \frac{1}{2} (\mathbf{U}\mathbf{y})^T \boldsymbol{\gamma} (\mathbf{U}\mathbf{y}) \\[4pt]
&= a + \mathbf{b}^T \mathbf{U} \mathbf{y} + \frac{1}{2} \mathbf{y}^T (\mathbf{U}^T \boldsymbol{\gamma} \mathbf{U}) \mathbf{y} \\[4pt]
&= a + \mathbf{b}^T \mathbf{U} \mathbf{y} + \frac{1}{2} \mathbf{y}^T \boldsymbol{\Lambda} \mathbf{y} \\[4pt]
&= a + \sum_{i=1}^{n} \theta_i y_i + \frac{1}{2} \sum_{i=1}^{n} \lambda_i y_i^2,
\end{aligned}
\tag{17.65}
$$

where $\theta_i = \mathbf{b}^T \mathbf{e}_i$, $y_i = \mathbf{e}_i^T \mathbf{z}$, with λ_i and $\mathbf{e}_i$ the eigenvalues and associated unit eigenvectors of $\boldsymbol{\gamma}$. Alternatively, if a stationary point $\mathbf{z}_0$ exists (e.g., $\boldsymbol{\gamma}$ is nonsingular), the change of variables $\mathbf{y} = \mathbf{U}^T (\mathbf{z} - \mathbf{z}_0)$ further removes all linear terms (Box and Draper, 1987), so that

$$
w(\mathbf{z}) = w_0 + \frac{1}{2} \mathbf{y}^T \boldsymbol{\Lambda} \mathbf{y} = w_0 + \frac{1}{2} \sum_{i=1}^{n} \lambda_i y_i^2,
\tag{17.66}
$$

where $y_i = \mathbf{e}_i^T(\mathbf{z} - \mathbf{z}_0)$ and w_0 is given by (17.64b). Equation (17.65) is called the *A canonical form* and (17.66) the *B canonical form* (Box and Draper, 1987). Both forms represent a rotation of the original axis to the new set of axes (the canonical axes of $\boldsymbol{\gamma}$) that align them with axes of symmetry of the quadratic surface. The B canonical form further shifts the origin to the stationary point $\mathbf{z}_0$. Since the contribution to individual fitness from $\mathbf{b}^T\mathbf{z}$ is a hyperplane, its effect is to tilt the fitness surface. The B canonical form 'levels' this tilting, allowing us to focus entirely on the curvature (quadratic) aspects of the fitness surface.

The orientation of the quadratic surface is determined by the eigenvectors of $\boldsymbol{\gamma}$, while the eigenvalues of $\boldsymbol{\gamma}$ determine the nature and amount of curvature of the surface along each canonical axis. Along the axis defined by y_i, the individual fitness function has positive curvature (is concave) if $\lambda_i > 0$, has negative curvature (is convex) if $\lambda_i < 0$, or has no curvature (is a plane) if $\lambda_i = 0$. The amount of curvature is indicated by the magnitude of λ_i: the larger $|\lambda_i|$ the more extreme the curvature.

Returning to Figure 17.5, we see that the axes of symmetry of the quadratic surface are the canonical axes of $\boldsymbol{\gamma}$. For $\boldsymbol{\gamma}_{12} = 0.25$ (Figure 17.5a), $\lambda_1 = -2.06$ and $\lambda_2 = -0.94$, so that the fitness surface is convex along each canonical axis, with more extreme curvature along the y_1 axis. When $\gamma_{12} = \sqrt{2}$ (Figure 17.5b), one eigenvalue is zero while the other is -3, so that the surface shows no curvature along one axis (it is a plane), but is strongly convex along the other. Finally, when $\gamma_{12} = 4$ (Figure 17.5c), the two eigenvalues differ in sign, being -5.53 and 2.53. This generates a saddlepoint, the surface being concave along one axis and convex along with other, with the convex curvature being more extreme.

If $\lambda_i = 0$, the fitness surface along y_i has no curvature, so that the fitness surface is a ridge along this axis. If $\theta_i = \mathbf{b}^T\mathbf{e}_i > 0$ this is a rising ridge (fitness increases as y_i increases), if $\theta_i < 0$ it is a falling ridge (fitness decrease as y_i increase), and if $\theta_i = 0$ it is flat. Again returning to Figure 17.5 the effect of b is to tilt the fitness surface. Denoting values on the axis running along the ridge by y_1, if $\theta_1 > 0$ the ridge rises so that fitness increases as y_1 increases. Even if $\boldsymbol{\gamma}$ is not singular, it may be nearly so, with some of the eigenvalues being very close to zero. In this case, the fitness surface shows little curvature along the axes given by the eigenvectors associated with these near-zero eigenvalues. The fitness change a particular axis (here given by $\mathbf{e}_i$) is $\theta_i y_i + (\lambda_i/2)y_i^2$. If $|\theta_i| \gg |\lambda_i|$, the curvature of the fitness surface along this axis is dominated by the effects of linear (as opposed to quadratic) selection. Phillips and Arnold (1989) present a nice discussion of several other issues relating to the visualization of multivariate fitness surfaces, while Box and Draper (1987) review the statistical foundations of this approach.

17.5.9   Unmeasured Characters and Other Biological Caveats

Even if we are willing to assume that the best-fitting quadratic regression is a reasonable approximation of the individual fitness surface, there are still a number of important biological caveats to keep in mind. For example, the fitness surface can change in both time and space, often over short spatial/temporal scales (e.g., Kalisz, 1986; Stewart and Schoen, 1987; Scheiner, 1989; Jordan, 1991), so that one estimate of the fitness surface may be quite different from another estimation at a different time and/or location. Hence, considerable care must be used before pooling data from different times and/or sites to improve the precision of estimates. When the data are such that selection gradients can be estimated separately for different times or areas, space/time by gradient interactions can be tested for in a straightforward fashion (e.g. Mitchell-Olds and Bergelson, 1990).

Population structure can also influence fitness surface estimation in other ways. If the population being examined has overlapping generations, fitness data must be adjusted to reflect this (e.g. Stratton, 1992). Likewise, if members in the population differ in their amount of inbreeding, measured characters and fitness may show a spurious correlation if both are affected by inbreeding depression (Willis, 1996).

Perhaps the most severe caveat for the regression approach of estimating $w(z)$ is unmeasured characters – estimates of the amount of direct selection acting on a character are biased if that character is phenotypically correlated to unmeasured characters also under selection (Lande and Arnold, 1983; Mitchell-Olds and Shaw, 1987). Adding one or more of these unmeasured characters to the regression can change initial estimates of β and γ. Conversely, selection acting on unmeasured characters that are phenotypically *uncorrelated* with those being measured has no effect on estimates of β and γ.

17.6   MULTIPLE TRAIT SELECTION

17.6.1   Short-Term Changes in Means: The Multivariate Breeders' Equation

By combining (17.8) and (17.46), we can express the multivariate breeders equation as

$$\mathbf{R} = \mathbf{G}\mathbf{P}^{-1}\mathbf{S} = \mathbf{G}\boldsymbol{\beta}. \tag{17.67}$$

Presented in this form, the equation nicely demonstrates the relationship between the two main complications with selection on multiple characters: the *within-generation* change due to *phenotypic* correlations and the *between-generation* change (response to selection) due to *additive genetic* correlations. Cheverud (1984) makes the important point that although it is often assumed that a set of phenotypically correlated traits responds to selection in a coordinated fashion, this is not necessarily the case. Since $\boldsymbol{\beta}$ removes all the effects of phenotypic correlations and $\mathbf{R} = \mathbf{G}\boldsymbol{\beta}$, phenotypic characters will only respond as a group if they are all under direct selection or if they are *genetically* correlated.

17.6.2   The Effects of Genetic Correlations: Direct and Correlated Responses

While the use of $\boldsymbol{\beta}$ removes any further evolutionary effect of phenotypic correlations, additive genetic correlations strongly influence the response to selection. If n characters are under selection, and g_{ij} is the additive genetic covariance between traits i and j, then the response in character i to a single generation of selection is

$$R_i = \Delta\mu_i = \sum_{j=1}^{n} g_{ij}\beta_j = g_{ii}\beta_i + \sum_{j\neq i} g_{ij}\beta_j, \tag{17.68}$$

so that the response has a component due to direct selection on that character ($g_{ii}\beta_i$) and an additional component due to selection on all other genetically correlated characters.

If direct selection only occurs on character i, a genetically correlated character also shows a *correlated response to selection*. For example, for trait j, its response when only trait i is under selection is

$$R_j = g_{ij}\beta_i. \tag{17.69a}$$

Thus, the ratio of the expected change in two characters when only one is under direct selection is

$$\frac{R_j}{R_i} = \frac{g_{ij}}{g_{ii}} = \rho_{ij}^g \sqrt{\frac{g_{jj}}{g_{ii}}}. \tag{17.69b}$$

If both characters have the same additive genetic variance ($g_{ii} = g_{jj}$), the ratio of response simply reduces to ρ_{ij}^g, the correlation between additive genetic values.

17.6.3 Evolutionary Constraints Imposed by Genetic Correlations

One immediate consequence of (17.67) is that a character under selection does not necessarily change in the direction most favored by natural selection. For example, fitness may maximally increase if μ_2 decreases, so that $\beta_2 < 0$. However, if the sum of correlated responses on z_2 is sufficiently positive, then μ_2 will increase. Thus, a character may be dragged off its optimal fitness trajectory by a correlated response generated by stronger selection on other traits. As these other characters approach their equilibrium values, their β values approach zero, reducing their indirect effects on other characters, eventually allowing β_2 to dominate the dynamics (and hence ultimately μ_2 decreases).

Recall that the direction the mean vector must be changed to give the greatest change in mean fitness is β (as β is the gradient of $\overline{W}$ with respect to the mean vector; see (17.49)). However, generally $\mathbf{R} \neq \beta$, and thus the effect of the additive genetic covariance matrix $\mathbf{G}$ is to constrain the selection response from its optimal value. The mean vector changes in the direction most favored by selection if and only if

$$\mathbf{G}\beta = \lambda\beta, \tag{17.70}$$

which only occurs when β is an eigenvector (with associated eigenvalue λ) of $\mathbf{G}$. Note that even if $\mathbf{G}$ is a diagonal matrix (there is no correlation between the additive genetic values of the characters under selection), (17.70) is usually not satisfied. In fact, only when we can write $\mathbf{G} = \sigma_A^2 \mathbf{I}$ is (17.70) satisfied for arbitrary β. Thus, only when all characters have the same additive genetic variance and there is no additive genetic covariance between characters is the response to selection in the directional most favored by natural selection. Differences in the amounts of additive genetic variances between characters, in addition to nonzero additive genetic covariances, also impose constraints on character evolution.

17.6.4 Inferring the Nature of Previous Selection

Providing the breeders' equation holds over several generations, the cumulative response to m generations of selection is just

$$R^{(m)} = \sum_{t=1}^{m} R(t) = \sum_{t=1}^{m} \mathbf{G}(t)\beta(t). \tag{17.71a}$$

In particular, if the genetic covariance matrix remains constant, then

$$R^{(m)} = \mathbf{G}\left(\sum_{t=1}^{m} \beta(t)\right). \tag{17.71b}$$

Hence, if we observe a total response to selection of $\mathbf{R}_{\text{total}}$, then we can estimate the cumulative selection differential as

$$\boldsymbol{\beta}_{\text{total}} = \sum \boldsymbol{\beta}(t) = \mathbf{G}^{-1}\mathbf{R}_{\text{total}}. \tag{17.71c}$$

For example, if one observes a difference in the mean multivariate phenotype between two diverged populations, then provided we can assume that the genetic covariance matrix remains roughly constant, the history of past selection leading to the divergence (assuming it is entirely due to selection) can be inferred from (17.71c).

17.6.5 Changes in G under the Infinitesimal Model

17.6.5.1 Within-Generation Change in G

If the vector of breeding values g is multivariate normal with covariance matrix $\mathbf{G}$ before an episode of selection, then it can be shown (e.g., Lande and Arnold, 1983) that the covariance matrix $\mathbf{G}^*$ of breeding values after selection (but before reproduction) satisfies

$$\mathbf{G}^* - \mathbf{G} = \mathbf{G}\mathbf{P}^{-1}(\mathbf{P}^* - \mathbf{P})\mathbf{P}^{-1}\mathbf{G}. \tag{17.72a}$$

We show in (17.75) that

$$\mathbf{G}^* - \mathbf{G} = \mathbf{G}(\boldsymbol{\gamma} - \boldsymbol{\beta}\boldsymbol{\beta}^{\mathrm{T}})\mathbf{G}. \tag{17.72b}$$

Thus, when the breeders' equation holds, $\boldsymbol{\gamma}$ and $\boldsymbol{\beta}$ are sufficient to describe how phenotypic selection changes (within a generation) the additive genetic covariance matrix. Equation (17.72b) shows that the within-generation change in $\mathbf{G}$ has a component from directional selection and a second due from quadratic selection, as

$$\mathbf{G}^* - \mathbf{G} = -\mathbf{G}\boldsymbol{\beta}\boldsymbol{\beta}^{\mathrm{T}}\mathbf{G} + \mathbf{G}\boldsymbol{\gamma}\mathbf{G} = -\mathbf{R}\mathbf{R}^{\mathrm{T}} + \mathbf{G}\boldsymbol{\gamma}\mathbf{G}. \tag{17.72c}$$

In terms of the change in covariance for two particular characters, this can be factored as

$$G_{ij}^* - G_{ij} = -\left(\sum_{k=1}^{n} \beta_k G_{ik}\right)\left(\sum_{k=1}^{n} \beta_k G_{jk}\right) + \sum_{k=1}^{n}\sum_{\ell=1}^{n} \gamma_{k\ell} G_{ik} G_{\ell j}$$

$$= -\Delta\mu_i \cdot \Delta\mu_j + \sum_{k=1}^{n}\sum_{\ell=1}^{n} \gamma_{k\ell} G_{ik} G_{\ell j}. \tag{17.73a}$$

Thus the within-generation change in the additive genetic variance of character i is given by

$$G_{ii}^* - G_{ii} = -(\Delta\mu_i)^2 + \sum_{k=1}^{n}\sum_{\ell=1}^{n} \gamma_{k\ell} G_{ik} G_{i\ell}. \tag{17.73b}$$

17.6.5.2 The Response (Between-Generation Change) in G

While (17.72) and (17.73) describe how the covariance structure of breeding values changes within a generation, the between-generation change must consider how recombination alters any gametic-phase disequilibrium generated by selection. Recall our

treatment of the change in the additive variance in the univariate case (Section 17.2.2), in which all changes in variances occur due to gametic-phase disequilibrium d_t changing the additive variance. In this case, $\sigma_A^2(t) = \sigma_A^2(0) + d_t$, and hence $\sigma_z^2(t) = \sigma_z^2(0) + d_t$. Moving to multiple characters, disequilibrium is now measured by the matrix $\mathbf{D}_t = \mathbf{G}_t - \mathbf{G}_0$. Thus D_{ij} is the change in the additive genetic covariance between characters i and j induced by disequilibrium. Likewise, the phenotypic covariance matrix is given by $\mathbf{P}_t = \mathbf{P}_0 + \mathbf{D}_t$. Tallis (1987) and Tallis and Leppard (1988) extend Bulmer's result to multiple characters, showing that

$$\Delta \mathbf{D}_t = \tfrac{1}{2}(\mathbf{G}_t \mathbf{P}_t^{-1}(\mathbf{P}_t^* - \mathbf{P}_t)\mathbf{P}_t^{-1}\mathbf{G}_t - \mathbf{D}_t). \tag{17.74}$$

The first term represents the within-generation change in $\mathbf{G}$, the second the decay in $\mathbf{D}$ due to recombination.

We can also express (17.74) in terms of the quadratic and directional selection gradients, $\boldsymbol{\gamma}$ and $\boldsymbol{\beta}$. Recalling the definitions of $\mathbf{C}$, $\boldsymbol{\beta}$, and $\boldsymbol{\gamma}$, we have

$$\mathbf{P}^* - \mathbf{P} = \mathbf{C} - \mathbf{s}\mathbf{s}^{\mathrm{T}}.$$

Hence

$$\begin{aligned}
\mathbf{P}^{-1}(\mathbf{P}^* - \mathbf{P})\mathbf{P}^{-1} &= \mathbf{P}^{-1}(\mathbf{C} - \mathbf{s}\mathbf{s}^{\mathrm{T}})\mathbf{P}^{-1} \\
&= \mathbf{P}^{-1}\mathbf{C}\mathbf{P}^{-1} - (\mathbf{P}^{-1}\mathbf{s})(\mathbf{P}^{-1}\mathbf{s})^{\mathrm{T}} \\
&= \boldsymbol{\gamma} - \boldsymbol{\beta}\boldsymbol{\beta}^{\mathrm{T}}.
\end{aligned} \tag{17.75}$$

Substituting into (17.74) gives

$$\Delta \mathbf{D}_t = \tfrac{1}{2}(\mathbf{G}_t(\boldsymbol{\gamma}_t - \boldsymbol{\beta}_t\boldsymbol{\beta}_t^{\mathrm{T}})\mathbf{G}_t - \mathbf{D}_t). \tag{17.76a}$$

Finally, recalling (17.72b), we can also express this as

$$\Delta \mathbf{D}_t = \frac{1}{2}(\mathbf{G}_t^* - \mathbf{G}_t) - \frac{\mathbf{D}_t}{2}. \tag{17.76b}$$

Equation (17.76b) shows that only half of the disequilibrium deviation in $\mathbf{G}$ from the previous generation ($\mathbf{D}_t$) is passed on to the next generation, as is half the within-generation change induced by selection in that generation. This is expected since the infinitesimal mode assumes unlinked loci and hence each generation recombination removes half of the present disequilibrium. The disequilibrium component converges to

$$\hat{\mathbf{D}} = \hat{\mathbf{G}}(\hat{\boldsymbol{\gamma}} - \hat{\boldsymbol{\beta}}\hat{\boldsymbol{\beta}}^{\mathrm{T}})\hat{\mathbf{G}} = (\mathbf{G}_0 + \hat{\mathbf{D}})(\hat{\boldsymbol{\gamma}} - \hat{\boldsymbol{\beta}}\hat{\boldsymbol{\beta}}^{\mathrm{T}})(\mathbf{G}_0 + \hat{\mathbf{D}}), \tag{17.77}$$

where have place carets over $\boldsymbol{\gamma}$ and $\boldsymbol{\beta}$ to remind the reader that these depend on $\mathbf{P}$, and hence on $\mathbf{D}$.

17.6.6 Effects of Drift and Mutation

17.6.6.1 Drift

If $\mathbf{G}_t$ changes strictly by drift, the multivariate analog to (17.16) is

$$\mathbf{G}_t = \left(1 - \frac{1}{2N_e}\right)^t \mathbf{G}_0. \tag{17.78}$$

This assumes that only additive genetic variance is present. Hence, ignoring the effect of disequilibrium, under the infinitesimal model the expected change after t generations of selection and drift is

$$\boldsymbol{\mu}_t - \boldsymbol{\mu}_0 = \sum_{k=0}^t \mathbf{G}_t \boldsymbol{\beta} = \mathbf{G}_0 \boldsymbol{\beta} \sum_{k=0}^t \left(1 - \frac{1}{2N_e}\right)^k$$

$$\simeq 2N_e (1 - e^{t/2N_e}) \mathbf{G}_0 \boldsymbol{\beta}. \tag{17.79}$$

17.6.6.2 Mutation

Let $\mathbf{U}$ be the matrix of per-generation input from mutations to the additive genetic variances and covariance. The expected equilibrium covariance matrix under drift and mutation becomes

$$\hat{\mathbf{G}} = 2N_e \mathbf{U}. \tag{17.80}$$

Under the assumptions of the infinitesimal model (selection is sufficiently weak that the dynamics of changes in allele frequencies are completely driven by drift and mutation), the additive genetic variance–covariance matrix at generation t is

$$\mathbf{G}_t = \hat{\mathbf{G}} + (\mathbf{G}_0 - \hat{\mathbf{G}}) e^{-t/2N_e}, \tag{17.81}$$

giving the cumulative response to t generations of constant directional selection $\boldsymbol{\beta}$ as

$$\mathbf{R}_t = \boldsymbol{\mu}_t - \boldsymbol{\mu}_0 = [t\hat{\mathbf{G}} + 2N_e (1 - e^{-t/2N_e})(\mathbf{G}_0 - \hat{\mathbf{G}})] \boldsymbol{\beta}. \tag{17.82a}$$

Note if there is no mutational input $\mathbf{U} = \mathbf{0}$, then the total response by generation t is given by

$$\mathbf{R}_t = 2N_e (1 - e^{-t/2N_e}) \boldsymbol{\beta} \mathbf{G}_0 = 2N_e (1 - e^{-t/2N_e}) \mathbf{R}_0, \tag{17.82b}$$

giving, at the limit,

$$\mathbf{R}_\infty = 2N_e \mathbf{R}_0, \tag{17.82c}$$

$2N_e$ times the initial response, as was found (Robertson, 1960) for univariate selection.

17.7 PHENOTYPIC EVOLUTION MODELS

The above machinery for selection response has been widely used by evolutionary biologists to model the dynamics of complex traits under selection. Under the assumptions

of the infinitesimal model, one only needs to specify the nature of selection, the starting mean and the initial covariance matrix. Further genetic details do not enter (unless one wishes to include mutation, when the additional composite parameter, σ_m^2, enters). Such analyses are often called *phenotypic evolution models*, given that the genetic details can be handed with a few composite parameters. As with the entire field of evolutionary quantitative genetics, this is a rather large enterprise. We will concern ourselves here with two applications: testing whether an observed pattern seen in the fossil record is due to selection or drift, and examining the consequences of stabilizing selection on mean population fitness. The goal is to give the reader a feel for the flavor of such modeling. A much more detailed treatment can be found in Walsh and Lynch (2003).

17.7.1 Selection versus Drift in the Fossil Record

One of the more interesting applications of phenotypic selection models is in trying to make inferences about the forces that shaped morphological evolution on extinct organisms. Obviously, one cannot perform the required crosses to estimate heritabilities on traits of interests. However, one might reasonably use the average heritability values for similar traits in (hopefully close) relatives of the extinct species. A variety of tests for whether an observed pattern of morphological change in the fossil record is consistent with drift (as opposed to having to invoke selection) have been proposed, and we briefly discuss a few here. An excellent overview of the many pitfalls of this general approach is given by Reyment (1991). Despite these concerns, this approach offers a powerful method of analysis to gain insight into the evolution of species long extinct.

17.7.1.1 Lande's Test

Lande (1976) offered the first test for whether an observed amount of morphological divergence was consistent with simple random genetic drift. If the mean is changing strictly under genetic drift, then if the distribution of breeding and environmental values is bivariate normal, the resulting distribution for the mean at generation t, $\mu(t)$, is normal with mean $\mu(0)$ (the initial mean) and variance $t\sigma_A^2/N_e$. Letting the observed divergence in means be $\Delta\mu = \mu(t) - \mu(0)$, then the largest effective population size consistent (at the 5% level) with this divergence being due strictly to drift is

$$N_e^* = \frac{(1.96)^2 h^2 t}{(\Delta\mu/\sigma_z)^2} = 3.84 \frac{th^2}{(\Delta\mu/\sigma_z)^2}. \tag{17.83}$$

This follows since the probability that a unit normal exceeds 1.96 is just 5%, and we have written $\sigma_A^2 = h^2\sigma_z^2$. Thus, provided that the heritability remains roughly constant, one can apply (17.83) to see if the maximal effective population size required for this amount of drift is exceeded by our reasonable estimate of the actual population size. If this is the case, then we can rule out drift as the sole agent for the observed divergence.

17.7.1.2 The Turelli–Gillespie–Lande and Bookstein Tests

Turelli *et al.* (1988) noted that Lande's test has the hidden assumption that the additive genetic variance is independent of the population size. Recall from (17.18) that the

equilibrium additive genetic variance under mutation and drift is $\sigma_A^2 = 2N_e\sigma_m^2$, where σ_m^2 is the polygenic mutation rate. Hence, after a sufficient number of generations, the additive variance should scale with N_e (if no other evolutionary forces are acting), in which case the drift variance becomes

$$\sigma^2[\mu(t)] = t\frac{\sigma_A^2}{N_e} = t\frac{2N_e\sigma_m^2}{N_e} = 2t\sigma_m^2. \tag{17.84}$$

The variance expression given by (17.84) transforms Lande's test from a critical maximal effective population size to one based on a critical minimum mutational variance. In particular, (17.83) is replaced by

$$\sigma_m^2 = \frac{(\Delta\mu)^2}{2t(1.96)^2} = 0.130\frac{(\Delta\mu)^2}{t}. \tag{17.85}$$

Drift is rejected at the 5 % of the suspected value of σ_m^2 is less than this value.

Turelli *et al.* also make the important point that the test for drift is really a two-sided test. While the tests (17.83) and (17.85) ask whether the observed divergence is too large under drift (as might be expected under directional selection), we can also ask if the observed divergence is *too small* under drift, as would be expected if stabilizing selection constrains the change on the mean. Noting that for a unit normal random variable U that $\Pr(|U| < 0.03) = 0.025$ and $\Pr(|U| > 2.24) = 0.025$ suggests the following two-sided test: if

$$\sigma_m^2 < \frac{(\Delta\mu)^2}{2t(2.24)^2} = 0.0858\frac{(\Delta\mu)^2}{t} \tag{17.86a}$$

the rate of evolution is too fast to be explained by drift, while if

$$\sigma_m^2 > \frac{(\Delta\mu)^2}{2t(0.03)^2} = 509\frac{(\Delta\mu)^2}{t} \tag{17.86b}$$

the rate of divergence is too slow for drift.

If one has access to a sample of generation means (as opposed to a starting and end points), then Bookstein (1989) notes that a more powerful test can be obtained (from the theory of random walks) by considering $\Delta\mu^*$, the largest absolute deviation from the starting mean anywhere along the series of t generation means. Here, the rate of evolution is too fast for drift if

$$\sigma_m^2 < \frac{(\Delta\mu^*)^2}{2t(2.50)^2} = 0.080\frac{(\Delta\mu^*)^2}{t}, \tag{17.87a}$$

while it is too slow for drift when

$$\sigma_m^2 > \frac{(\Delta\mu^*)^2}{2t(0.56)^2} = 1.59\frac{(\Delta\mu^*)^2}{t}. \tag{17.87b}$$

Note by comparison with (17.86) that the tests for too fast a divergence are very similar, while Bookstein's test for too slow a divergence (a potential signature of stabilizing selection) is much less stringent than the Turelli–Gillespie–Lande test.

17.7.2 Stabilizing Selection

17.7.2.1 The Nor-Optimal Fitness Function

A widely used fitness function in the evolutionary genetics literature is the *nor-optimal* or *normalizing* fitness function,

$$W(z) = \exp\left(-\frac{z^2}{2\omega^2}\right). \tag{17.88}$$

This is proportional to a normal density function with mean zero and variance ω^2, and implies that fitness decreases with increasing values of z^2, with the maximal fitness occurring for an individual with trait value $z = 0$. Typically, one scales the trait so that the optimal value occurs as zero, but more generally we can replace z^2 with $(z - \mu_0)^2$, where the optimal fitness now occurs at μ_0. Besides being a reasonable model for stabilizing selection, the main reason for the popularity of (17.88) in the literature is that if the phenotypic distribution is normal (with mean μ and variance σ^2) before selection, then the distribution of trait values after selection is normal with mean and variance

$$\mu^* = \frac{\omega^2\mu}{\sigma^2 + \omega^2} \text{ and } \sigma_*^2 = \frac{\omega^2\sigma^2}{\sigma^2 + \omega^2}. \tag{17.89a}$$

The expected response to selection (measured by the change in mean) in generation t is

$$R(t) = h^2(t)S(t) = h^2(t)[\mu^*(t) - \mu(t)] = -h^2(t)\frac{\mu(t)\sigma^2(t)}{\sigma^2(t) + \omega^2}. \tag{17.89b}$$

Selection thus drives the mean toward the optimal value of $\mu = 0$. When μ is nonzero, there is both directional selection (nonzero S) and stabilizing selection.

Turning to the dynamics of the variance, the change in the phenotypic variance (due to stabilizing selection generating disequilibrium) is given by (17.12),

$$\Delta d(t) = d(t + 1) - d(t)$$
$$= -\left(\frac{d(t)}{2} + \frac{h^2(t)}{2}[\sigma^2(t) - \sigma_*^2(t)]\right)$$
$$= -\left(\frac{d(t)}{2} + \frac{h^2(t)\sigma^4(t)}{2(\sigma^2(t) + \omega^2)}\right). \tag{17.89c}$$

Recalling from (17.11) that $\sigma_A^2(t) = \sigma_a^2 + d(t)$ and $\sigma_z^2(t) = \sigma_z^2 + d(t)$, at equilibrium ($\Delta d(t) = 0$) (17.89c) reduces to a quadratic equation whose admissible solution is given by

$$\hat{\sigma}_z^2 = \sigma_z^2\left(1 - \frac{2 + h^2 + \omega^2/\sigma_z^2 - \sqrt{8h^2 + (2 + h^2 + \omega^2/\sigma_z^2)^2}}{4}\right). \tag{17.89d}$$

Here σ_z^2 and h^2 are the values for the base population before selection. Figure 17.6 shows the reduction in the phenotypic variance at equilibrium. As expected, the reduction is more severe with higher heritabilities and/or stronger selection (smaller values of ω^2/σ^2).
Figure 17.6 The equilibrium reduction in phenotypic variance under the infinitesimal model with nor-optimal selection (17.88). The curves correspond to initial heritability values ranging from 0.1 to 0.7. Stabilizing selection creates negative disequilibrium which reduces the additive genetic (and hence phenotypic) variance below its initial value. The reduction in phenotypic variance is greatest when the initial heritability is large and/or selection is strong (the width of the selection function is narrow relative to the initial width of the phenotypic distribution, i.e., $\omega^2 \ll \sigma^2$).

17.7.2.2 The Cost of Stabilizing Selection

Charlesworth (1984) examined the so-called cost of stabilizing selection by computing the selective load – the reduction in the mean fitness from the maximal value ($W = 1$ in this case). The load is given by $L = 1 - \overline{W}$ and measures the fraction of the population suffering selective mortality in a particular generation. The mean population fitness is obtained by integrating the fitness function over the distribution of phenotypes,

$$\overline{W} = \int p(z) W(z) \, dz = \sqrt{\frac{\omega^2}{\sigma^2 + \omega^2}} \exp\left[-\frac{\mu^2}{2(\sigma^2 + \omega^2)}\right], \tag{17.90a}$$

as found by Charlesworth. After selection has driven the phenotypic mean to zero, the load becomes

$$L = 1 - \sqrt{\frac{\omega^2}{\sigma^2 + \omega^2}} = 1 - \sqrt{\frac{\Lambda}{1 + \Lambda}}, \quad \text{where } \Lambda = \omega^2/\sigma^2. \tag{17.90b}$$

Charlesworth's expression for the load (17.90b) ignores the reduction in the phenotypic variance due to the generation of linkage disequilibrium (17.89c). A more precise expression for the load (when the population is at equilibrium) is

$$L = 1 - \sqrt{\frac{\omega^2}{\sigma_*^2 + \omega^2}} = 1 - \sqrt{\frac{\Lambda}{\sigma_*^2/\sigma^2 + \Lambda}}, \tag{17.90c}$$
Figure 17.7   The selective load for an equilibrium population under nor-optimal selection. The solid upper curve is Charlesworth's approximation, while the four lower curves correspond to initial heritabilities ranging from 0.3 to 0.9.

where σ_*^2 is the equilibrium phenotypic variance. Figure 17.7 plots the corrected load for various values of initial heritability and different strengths of selection ω^2/σ^2. As expected, the selective loads are reduced when the disequilibrium is taken into account, as the negative disequilibrium generated by selection reduces the phenotypic variance, and this narrowing of the phenotypic variance increases the mean fitness. The reduction in the load is most dramatic for strong selection ($\omega^2 \ll \sigma^2$) and high heritabilities.

17.8   THEOREMS OF NATURAL SELECTION: FUNDAMENTAL AND OTHERWISE

Our final comments in this brief overview of evolutionary quantitative genetics concern the ultimate quantitative trait: individual fitness. What general statements, if any, can we make about the behavior of multilocus systems under selection? One oft-quoted is Fisher's *fundamental theorem of natural selection*, which states that 'the rate of increase in fitness of any organism at any time is equal to its genetic variance in fitness at that time'. This simple statement from Fisher's (1930) has generated a tremendous amount of work, discussion, and sometimes heated arguments. Fisher claimed his result was exact, a true theorem. The common interpretation of Fisher's theorem, that the rate of increase in fitness equals the additive variance in fitness, has been referred to by Karlin as 'neither fundamental nor a theorem' as it requires rather special conditions, especially when multiple loci influence fitness.

Since variances are nonnegative, the classical interpretation of Fisher's theorem (namely, $\Delta \overline{W} = \sigma_A^2(W)/\overline{W}$) implies that mean population fitness never decreases in a constant environment. As we discuss below, this interpretation of Fisher's theorem holds *exactly* only under restricted conditions, but is often a good approximate descriptor. However, an important corollary holds under very general conditions (Kimura, 1965; Nagylaki, 1976; 1977b; Ewens, 1976; Ewens and Thomson, 1977; Charlesworth, 1987): in the absence of new variation from mutation or other sources such as migration, selection is expected to eventually remove all additive genetic variation in fitness. If the population is at equilibrium, the average excess (in fitness) for each allele is zero as all segregating alleles have the same marginal fitness and hence $\sigma_A^2 = 0$ (Fisher, 1941).

17.8.1   The Classical Interpretation of Fishers' Fundamental Theorem

We first review the 'classical' interpretation and then discuss what Fisher actually seems to have meant.

To motivate Fisher's theorem for one locus, consider a diallelic (alleles A and a) locus with constant fitnesses under random mating. Let p denote the frequency of A, and denote the fitnesses for the three genotypes as W_{AA}, W_{Aa}, and W_{aa}. The mean population fitness is given by

$$\overline{W} = p^2 W_{AA} + 2p(1-p)W_{Aa} + (1-p)^2 W_{aa}, \tag{17.91a}$$

and the change in allele frequency can be expressed in terms of Wright's formula as

$$\Delta p = \frac{p(1-p)}{2\overline{W}} \frac{d\overline{W}}{dp} = \frac{p(1-p)}{2} \frac{d \ln \overline{W}}{dp}. \tag{17.91b}$$

Turning now to fitness, if the allele frequency change Δp is small, a first-order Taylor series approximation gives

$$\Delta \overline{W} = \overline{W}(p + \Delta p) - \overline{W}(p) \simeq \overline{W}(p) + \frac{\partial \overline{W}}{\partial p} \Delta p - \overline{W}(p) \tag{17.92a}$$

Applying (17.91b),

$$\Delta \overline{W} \simeq \frac{\partial \overline{W}}{\partial p} \Delta p = \frac{p(1-p)}{2\overline{W}} \left(\frac{\partial \overline{W}}{\partial p} \right)^2. \tag{17.92b}$$

From (17.91a),

$$\frac{\partial \overline{W}}{\partial p} = 2p W_{AA} + 2(1-2p)W_{Aa} + 2(p-1)W_{aa}$$

$$= 2[p(W_{AA} - W_{Aa}) + (1-p)(W_{Aa} - W_{aa})] = 2(\alpha_A - \alpha_a),$$

where the last equality follows the average effects of alleles A and a on fitness,

$$\alpha_A = p W_{AA} + (1-p)W_{Aa} - \overline{W} \quad \text{and} \quad \alpha_a = p W_{AA} + (1-p)W_{Aa} - \overline{W}.$$

The quantity $\alpha = \alpha_A - \alpha_a$ is the *average effect of an allelic substitution*; the difference in the average effects of these two alleles gives the mean effect on fitness from replacing

a randomly chosen a allele with an A allele. The additive genetic variance is related to α by $\sigma_A^2 = 2p(1 - p)\alpha^2$, giving

$$\Delta\overline{W} \simeq \frac{p(1 - p)(2\alpha)^2}{2\overline{W}} = \frac{\sigma_A^2(W)}{\overline{W}}. \tag{17.93}$$

Hence, the change in mean population fitness is proportional to the additive genetic variance in fitness.

As an example of the implication of Fisher's theorem, consider a diallelic locus with overdominance in fitness ($W_{AA} = 1$, $W_{Aa} = 1 + s$, $W_{aa} = 1$), giving the additive and dominance variance in fitness as

$$\sigma_A^2(W) = 2p(1 - p)s^2(1 - 2p)^2 \quad \text{and} \quad \sigma_D^2(W) = [2p(1 - p)s]^2.$$

As plotted in Figure 17.8, these variances change dramatically with p. The maximum genetic variance in fitness occurs at $p = 1/2$, but none of this variance is additive, and heritability in fitness is zero. It is easily shown that $\Delta p = 0$ when $p = 1/2$, and at this frequency $\sigma_A^2(W) = 0$, as the corollary of Fisher's theorem predicts. Thus, even though *total* genetic variation in fitness is maximized at $p = 1/2$, no change in $\overline{W}$ occurs as the *additive* genetic variance in fitness is zero at this frequency.

Even if Fisher's theorem holds exactly, its implication for character evolution can often be misinterpreted, as the following example illustrates. Suppose that locus A completely determines a character under stabilizing selection. Let the genotypes AA, Aa, and aa have discrete phenotypic values of $z = -1, 0$, and 1, respectively (so that this locus is strictly additive), and let the fitness function be $W(z) = 1 - sz^2$. If we assume no environmental variance, this generates very nearly the same fitnesses for each genotype as those given above, as the fitnesses can be normalized as $1 : (1 - s)^{-1} : 1$, where $(1 - s)^{-1} \simeq 1 + s$ for small s. The additive genetic variance for the trait z is maximized at $p = 1/2$, precisely the allele frequency at which the additive genetic variance in fitness $\sigma_A^2(W) = 0$. This stresses that Fisher's theorem concerns additive genetic variance in *fitness*, not in the *character*. In this example, the transformation of the phenotypic character value z to fitness W takes a character that is completely additive and introduces dominance when fitness is considered.

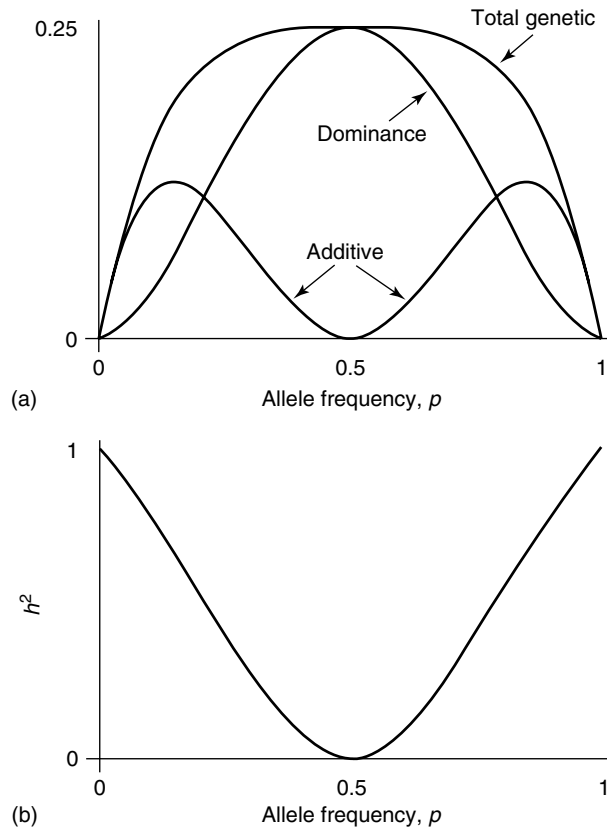
The above derivation of Fisher's theorem was only approximate. Under what conditions does the classical interpretation actually hold? While it is correct for a single locus with random mating, a single locus with no dominance under nonrandom mating (Kempthorne, 1957), and multiple additive loci (no dominance or epistasis: Ewens, 1969), it is generally compromised by nonrandom mating and departures from additivity (such as dominance or epistasis). Even when the theorem does not hold exactly, how good an approximation is it? Nagylaki (1976; 1977a; 1977b; 1991; 1992; 1993) has examined ever more general models of fitnesses when selection is weak (the fitness of any genotype can be expressed as $1 + as$, with s small and $|a| \ll 1$) and mating is random. Selection is further assumed to be much less than the recombination frequency c_{min} for the closest pair of loci ($s \ll c_{min}$). Under these fairly general conditions, Nagylaki shows that the evolution of mean fitness falls into three distinct stages. During the first $t < 2 \ln s / \ln(1 - c_{min})$ generations, the effects of any initial disequilibrium are moderated, first by reaching a point where the population evolves approximately as if it were in linkage equilibrium and then reaching a stage where the linkage disequilibria remain relatively constant. At this point, the change


Figure 17.8 Genetic variances in a model with overdominance. Here, the heterozgyote has fitness $1 + s$, while both homozygotes have fitness 1. As (a) shows, the additive genetic variance is zero at allele frequency 0.5, but this is also the value where the total genetic variance is maximized. (b) shows that the heritability goes to zero as the allele frequency approaches 0.5. Thus, even though the genetic variance in fitness has maximal value at allele frequency 0.5, there is no response to selection, as none of the genetic variance is additive.

in mean fitness is

$$\Delta \overline{W} = \frac{\sigma_A^2(W)}{\overline{W}} + O(s^3), \tag{17.94}$$

where $O(s^3)$ means that terms of order s^3 have been ignored. Since additive variance is expected to be of order s^2, Fisher's theorem is expected to hold to a good approximation during this period. However, as gametic frequencies approach their equilibrium values, additive variance in fitness can be much less than order s^2, in which case the error terms of order s^3 can be important. During the first and third phases, mean fitness can decrease, but the fundamental theorem holds during the central phase of evolution.

17.8.2 What did Fisher Really Mean?

Fisher warned that his theorem 'requires that the terms employed should be used strictly as defined', and part of the problem stems from what Fisher meant by 'fitness'. Price

(1972b) and Ewens (1989; 1992) have argued that Fisher's theorem is always true, because Fisher held a very narrow interpretation of the change in mean fitness (see also Edwards, 1990; 1994; Frank, 1995; Lessard and Castilloux, 1995). Rather than considering the *total* rate of change in fitness, they argue that Fisher was instead concerned only with the *partial* rate of change, that due to changes in the contribution of individual alleles (specifically, changes in the average excesses/effects of these alleles). In particular, Ewens (1994) states:

> I believe that the often-made statement that the theorem concerns changes in mean fitness, assumes random-mating populations, is an approximation, and is not correct in the multi-locus setting, embodies four errors. The theorem relates the so-called partial increase in mean fitness, makes no assumption about random mating, is an exact statement containing no approximation, and finally is correct (as a theorem) no matter how many loci are involved.

What exactly is meant by the partial increase in fitness? A nice discussion is given by Frank and Slatkin (1992), who point out that the change in mean fitness over a generation is also influenced by the change in the 'environment', E. Specifically,

$$\Delta \overline{W} = (\overline{W}'|E') - (\overline{W}|E), \tag{17.95a}$$

where the prime denotes the fitness/environment in the next generation, so that the change in mean fitness compounds both the change in fitness and the change in the environment. We can partition out these components by writing

$$\Delta \overline{W} = [(\overline{W}'|E) - (\overline{W}|E)] + [(\overline{W}'|E') - (\overline{W}'|E)], \tag{17.95b}$$

where the first term in brackets represents the change in mean fitness under the initial 'environment' while the second represents the change in mean fitness due to changes in the environmental conditions. Fisher's theorem relates solely to changes in the first component, $(\overline{W}'|E) - (\overline{W}|E)$, which he called the change in fitness due to natural selection. Price (1972b). notes that Fisher had a very broad interpretation of 'environment', referring to both physical and genetic backgrounds. In particular, Fisher

> regarded the natural selection effect on fitness as being limited to the additive or linear effects of changes in gene (allele) frequencies, while everything else – dominance, epistasis, population pressure, climate, and interactions with other species – he regarded as a matter of the environment.

Hence the change in fitness referred to by Fisher is solely that caused by changes in allele frequencies and nothing else. Changes in gamete frequencies caused by recombination and generation of disequilibrium beyond those that influence individual allele frequencies are consigned to the 'environmental' category by Fisher. Given this, it is perhaps not too surprising that the strict interpretation of Fisher's theorem holds under very general conditions as nonrandom mating and nonadditive effects generate linkage disequilibrium, changing gametic frequencies in ways not simply predictable from changes in allele frequencies.

Nagylaki (1993) suggests that the statement $\Delta \overline{W} = \sigma_A^2(W)/\overline{W}$ be referred to as the *asymptotic fundamental theorem of natural selection*, while Fisher's more narrow (and correct) interpretation be referred to as the *Fisher–Price–Ewens theorem of natural*

selection. This distinction seems quite reasonable given the considerable past history of confusion.

17.8.3 Heritabilities of Characters Correlated with Fitness

The corollary of Fisher's theorem, that selection drives the additive variance in fitness to zero, makes a general prediction. Characters strongly genetically correlated with fitness should thus show reduced h^2 relative to characters less correlated with fitness (Robertson, 1955), reflecting the removal of additive variance by selection (which is partly countered by new mutational input). Because of the past action of natural selection, traits correlated with fitness are expected to have reduced levels of additive variance, while characters under less direct selection are expected to retain relatively greater amounts of additive variance. How well does this prediction hold up? Many authors have noticed that characters expected to be under selection (e.g., life-history characters, such as clutch size) tend, on average, to have lower heritabilities than morphological characters measured in the same population/species (reviewed by Robertson, 1955; Roff and Mousseau, 1987; Mousseau and Roff, 1987; Charlesworth, 1987). However, some notable exceptions are also apparent (Charlesworth, 1987). The difficulty with these general surveys is knowing whether a character is, indeed, highly genetically correlated with lifetime fitness. Clutch size, for example, would seem to be highly correlated with total fitness, but if birds with large clutch sizes have poorer survivorship, the correlation with lifetime fitness may be weak. Negative genetic correlations between components of fitness allow significant additive variance in each component at equilibrium, even when additive variance in total fitness is zero (Robertson, 1955; Rose, 1982).

17.8.4 Robertson's Secondary Theorem of Natural Selection

While the fundamental theorem predicts the rate of change of mean population fitness, we are often more interested in predicting the rate of change of a particular *character* under selection. Using a simple regression argument, Robertson (1966; 1968; see also Crow and Nagylaki, 1976; Falconer, 1985) suggested the *secondary theorem of natural selection*,

$$R = \mu'_z - \mu_z = \sigma_A(z, w),$$

namely, that the rate of change in a character equals the additive genetic covariance between the character and fitness (the covariance between the additive genetic value of the character and the additive genetic value of fitness). If this assertion holds, it provides a powerful connection between the fundamental theorem and the response of a character under selection. For example, it predicts that the character mean should not change when additive variance in *fitness* equals zero, regardless of the additive variance in the *character*.

To examine the conditions under which the secondary theorem holds, we first examine a single–locus model in some detail before considering what can be said for increasingly general multilocus models. Assuming random mating, a single generation of selection changes the frequency of allele A_i from p_i to $p'_i = p_i(1 + s_i)$, where s_i is the average excess in relative fitness for allele A_i. To map these changes in allele frequencies into changes in mean genotypic values, decompose the genotypic value of $A_i A_j$ as $G_{ij} = \mu_G + \alpha_i + \alpha_j + \delta_{ij}$, where α_i is the average effect of A_i on character value and

δ_{ij} the dominance deviation. Putting these together, the contribution from this locus to the change in mean after a generation of selection is

$$
\begin{aligned}
R &= \sum_{i,j} G_{ij} p_i' p_j' - \sum_{i,j} G_{ij} p_i p_j \\
&= \sum_{i,j} G_{ij} p_i (1 + s_i) p_j (1 + s_j) - \sum_{i,j} G_{ij} p_i p_j \\
&= \sum_{i,j} (\alpha_i + \alpha_j + \delta_{ij}) p_j p_i s_i + \sum_{i,j} (\alpha_i + \alpha_j + \delta_{ij}) p_i p_j s_i s_j.
\end{aligned}
\tag{17.96}
$$

The careful reader will note that we have already made an approximation by using G_{ij} instead of G_{ij}' in the very first sum. Since α_i and δ_{ij} are functions of the allele frequencies, they change as p_i changes, but we assume these are much smaller than the change in p_i itself (so we have assumed $\alpha_i' \simeq \alpha_i$ and $\delta_{ij}' \simeq \delta_{ij}$). A little more algebra (Nagylaki, 1989; 1991) simplifies the two sums in (17.96) to give the expected contribution to response as

$$
R = \sum_j \alpha_j s_j p_j + \sum_{i,j} \delta_{ij} p_i s_i p_j s_j.
\tag{17.97}
$$

The first sum is the expected product of the average effect α_j of an allele on character value times the average excess s_i of that allele on relative fitness. Since (by definition), $E[\alpha_j] = E[s_i] = 0$, the first sum is just the covariance between the average effect on the character with the average excess on fitness, in other words, the additive genetic covariance between *relative* fitness and character. Hence we can express (17.96) as

$$
R = \sigma_A(z, w) + B = \frac{\sigma_A(z, W)}{\overline{W}} + B.
\tag{17.98}
$$

If the character has no dominance (all $\delta_{ij} = 0$), the correction term B vanishes, recovering Robertson's original suggestion. If $\sigma_D^2(z)$ denotes the dominance variance in the trait value, Nagylaki (1989) shows that

$$
|B| \leq \frac{\sigma_D(z) \cdot \sigma_A^2(w)}{2},
\tag{17.99}
$$

where $\sigma_A^2(w)$ is the additive variance in relative fitness. Assuming no epistasis, Nagylaki (1989; 1991) shows that (17.98) holds for n loci, with the error term being

$$
B = \sum_{k=1}^{n} \sum_{i,j}^{n_k} \delta_{ij}(k) p_i(k) s_i(k) p_j(k) s_j(k),
\tag{17.100}
$$

where k indexes the loci, the kth of which has n_k alleles. This also holds when linkage disequilibrium is present, but the dominance deviations and average excesses in fitness are expected to be different than those under linkage equilibrium. Nagylaki (1991) shows that (17.100) is bounded by

$$
|B| \leq \left(\sum_{k=1}^{n} \sigma_{D(k)}(z) \right) \cdot \frac{\sigma_A^2(w)}{2}
\tag{17.101a}
$$

where $\sigma_{D(k)}^2(z)$ is the dominance variance in the character contributed by locus k. If all loci underlying the character are identical (the *exchangeable model*), this bound reduces to

$$|B| \leq \frac{\sigma_D(z) \cdot \sigma_A^2(w)}{2\sqrt{n}}. \tag{17.101b}$$

Hence, for fixed amounts of genetic variances, as the number of loci increases, the error in the secondary theorem becomes increasingly smaller.

Finally, the most general statement on the validity of the secondary theorem is due to Nagylaki (1993) for weak selection and random mating, but arbitrary epistasis and linkage disequilibrium. Similar to the weak selection analysis of Fisher's theorem discussed above, after a sufficient time the change in mean fitness is given by

$$R = \sigma_A(z, w) + O(s^2). \tag{17.102}$$

As with the fundamental theorem, when gametic frequencies approach their equilibrium values, terms in s^2 can become significant and mean response can differ significantly from Robertson's prediction.

17.9   FINAL REMARKS

Quantitative genetics is a very broad enterprise, comprising a number of distinct subfields – plant breeding, animal breeding, human genetics, and evolutionary quantitative genetics. The focus of this review has been on some of the unique aspects of evolutionary quantitative genetics that are likely to be less well known, but nonetheless potential very useful, to practitioners of these other subfields. For example, methods for estimating the nature of natural selection on traits are certainly of interest to plant and animal breeders, as they try to account for natural selection in the face of artificial selection. Likewise, evolutionary quantitative geneticists are also starting to draw upon some of the machinery developed in other subfields (such as best linear unbiased predictor estimation of breeding values). This is an encouraging trend, as each subfield of quantitative genetics has developed much useful machinery that deserves to be much more widely known (e.g. Walsh, 2002).

Animal and Plant Breeding

18

Quantitative Trait Loci in Inbred Lines

R.C. Jansen

Groningen Bioinformatics Centre, University of Groningen, Groningen, The Netherlands

Quantitative traits result from the influence of multiple genes (quantitative trait loci) and environmental factors. Detecting and mapping the individual genes underlying such 'complex' traits is a difficult task. Fortunately, populations obtained from crosses between inbred lines are relatively ideal for this – at least far more ideal than livestock and human populations – and true multigenic models are now available and have been applied successfully. In this chapter we will introduce the reader to statistical tools for segregation analysis and genetic mapping with the aid of molecular markers.

18.1 INTRODUCTION

18.1.1 Mendelian Factors and Quantitative Traits

The breeding experiments of Mendel in the late nineteenth century led to the foundation of modern genetics. He crossed white- and purple-flowering pea plants, and proposed a simple theory to explain the observed frequencies of white- and purple-flowering plants from generation to generation. With today's knowledge, we can conclude that *one* gene with *qualitative* effect encoded the flower colour studied by Mendel. If many genes and/or genes with quantitative effects encode a trait of interest, then the effects of the individual genes can hardly be distinguished. Therefore dissection of truly quantitative variation into the underlying 'Mendelian factors' is difficult on the basis of phenotypic information only. In this chapter we will see what modern statistical and molecular tools we have in our toolbox for studying quantitative or complex traits in inbred line crosses. These tools are of prime importance for plant breeding, livestock improvement and medical research using model organisms, because application of advanced tools offers great opportunities for understanding and manipulation of complex biological processes. Genes underlying quantitative or complex traits are commonly called *quantitative trait loci* (hereafter QTLs).

We start with a very limited description of inbred line genetics and breeding – all you need to know about inbred lines, seen through a statistician's spectacles – and the reader can generalise if he or she wishes. The next sections deal with what we think are the essentials for proper statistical modelling and analysis, first for so-called segregation analysis and second for genetic mapping of QTLs with the aid of genetic markers. The reader will see that similar statistical models and algorithms will be used for segregation analysis as for QTL mapping with the aid of molecular markers. We will introduce much of the relevant statistical machinery in the section on the simpler 'marker-free' case of segregation analysis.

There is a large amount of literature, and within the scope of this chapter it is hardly possible to refer to all statistical methods and applications published. The author has made his own selection, but hopes that this text, the bibliography and references give the reader sufficient entries to find his own favourite way in the world of QTLs in inbred lines. We sometimes get the feeling that the statistical theory of genetics is presented with a semblance of mystery, as if it were very special and complex. We believe there is no reason for this in the case of QTLs in inbred lines – almost all the theory is closely related to standard analysis of variance (ANOVA) and regression analysis. Nevertheless, we will make numerous cautionary remarks – standard methods can still be greatly abused.

18.1.2   The Genetics of Inbred Lines

In order to understand the genetics of inbred lines, we first need to define what one commonly understands by the terms *inbred* and *line*, and then we can discuss what 'sort of genetics' is involved. Here, we consider only inbred line crosses of diploid organisms. The reader may generalise to similar theoretical results for polyploid organisms and biparental crosses between outbreeding lines. In all cases we start with two parental lines, say P_1 and P_2, and intercross them in order to generate new genetic combinations.

In the genetics literature a *line* is a set of genetically related individuals, which are maintained under one and the same breed identification and/or commercial name. Chromosomes occur in homologous pairs, one originating from the mother, the other from the father. A line P_1 is *homozygous* if at any given gene the maternal and paternal states or *alleles* are identical, say a_1a_1. Thus, any offspring from crossing or mating within the P_1 pool will have the same P_1 genotype. The genotype of P_2 is denoted by a_2a_2. How do you get a line to become homozygous? For instance, in plants by following a single-seed-descent strategy over multiple generations: each generation you randomly take, grow and self a single individual in order to generate the seeds of the next generation of the line. By expectation, the number of heterozygous loci, a_1a_2, will be halved each generation. After eight to ten generations one can stop as the breeding process has led to an (almost) homozygous 'inbred line'. Of course, this scheme is typical of plants and cannot be used in animals. For model animals (mice, rats, hamsters) and livestock animals (chickens) simple designs of brother–sister mating can be used. Various plant species (apple, strawberry, pine) and most animal species (cattle, horses) can hardly be manipulated this way, because it would take too much time and money, because the organism would suffer from severe inbreeding depression, and, last but not least, because it would be immoral (humans). Although we focus here on biparental crosses between divergent inbred lines, most of the theory also applies to the case of a biparental cross between divergent outbreeding lines. In the latter case, there can be up to four different alleles per locus. We present theory for the simpler two-allele situation and thus leave the extension to four alleles to the reader.

There follows a short description of a number of mating designs. All start with a cross between two divergent inbred lines P_1 and P_2, which generates heterozygous filial F_1-offspring ($a_1a_1 \times a_2a_2 \to a_1a_2$). In the backcross (BC) design, the F_1 is (back)crossed to one of the parents, say female F_1 to male P_1 ($a_1a_2 \times a_1a_1 \to a_1a_2$ and a_1a_1 for each locus). In the doubled haploids (DH) design, either male or female gametes of the F_1 are artificially doubled by some kind of treatment, giving rise to homozygous recombinant offspring in one step ($a_1a_2 \to a_1a_1$ and a_2a_2 per locus). In the BC and DH design one can only trace segregation and recombination events in either the male or the female F_1 gamete. In the filial F_2 design, the F_1 is selfed or two F_1 individuals are crossed, in order to generate offspring, resulting from recombination events in both male and female gamete production ($a_1a_2 \times a_1a_2 \to a_1a_1$, a_1a_2 and a_2a_2 in the ratio $1:2:1$ per locus). Finally, in the recombinant inbred line (RIL) design one first generates the F_2 progeny and then each F_2 enters individually a single-seed-descent inbreeding programme ($a_1a_2 \times a_1a_2 \to a_1a_1$ or a_2a_2 per locus). From here on we us the notation A, H and B for a_1a_1, a_1a_2 and a_2a_2, respectively.

18.1.3 Phenotype, Genotype and Environment

The basic model of quantitative genetics is

$$P = G + E,$$

or, in words, the phenotype (trait) is the sum of genetic and environmental factors. By taking two divergent lines, we have a high chance that the two lines have different states (alleles) at all the genes underlying the traits of interest. Unfortunately, the trait difference between the two parents reflects the total effect of the their genes and not their individual gene effects. In statistical terms, the effects of the genetic factors are *confounded*, the factors are *aliased* or *collinear*. The genetic reproduction mechanism will yield us offspring with new allele combinations, generated by independent segregation of different chromosomes and by recombination within chromosomes. Therefore in the offspring, genes on different chromosomes are independent stochastic variables (*unlinked* genes). In contrast, the genes on the same chromosome will show statistical dependence or *linkage association*, although this may be negligible if they are far apart, and we speak of *linked* genes. Unlinked genes will become orthogonal factors (in infinite populations) and closely linked genes become factors with a high degree of collinearity. Any recombination between two flanking genes increases our chance of dissecting their effects. The distance between two loci is usually reported in units of *morgans* (M) or *centimorgans* (cM) using Haldane's mapping function. According to Haldane, a recombination frequency of r between two loci corresponds to a map distance of m morgans, with

$$m = -\frac{1}{2}\ln(1 - 2r);$$

conversely, a distance of m morgans corresponds to a recombination frequency r of

$$r = \frac{1}{2}(1 - \exp(-2m)).$$

For small distances the relation is more or less proportional ($m = 0.01$ M $\sim r = 0.01$, in which case one in 100 individuals of a DH population will show up as recombinant).

18.2   SEGREGATION ANALYSIS

18.2.1   Visualisation of Quantitative Variation in a Histogram

Our first step, once we have collected the phenotypic data, will most probably be to rank the data and draw a histogram to visualise the results for the trait under study. This is 'just' descriptive statistics, but it is an important step, as conclusions drawn from descriptive statistics often have more practical impact than those from inferential statistics.

Figure 18.1 shows typical histograms. What can we learn from these pictures? And, are there any pitfalls? What we know from lessons in genetics is that homologous chromosomes segregate randomly, creating opportunity for 2^n different egg or sperm cells per meiosis and an equal amount of possible homozygous genotypes for an organism with n chromosomes pairs. Nature is even cleverer than that, and devised the crossover mechanism as the result of which the total number of possible genotypes is much bigger even than 2^n so that usually no two individuals in the population have the same genotype. What we see in Figure 18.1 is a 'mixture' of as many different genotypes as there are individuals.

Figure 18.1(a) clearly shows a bimodal distribution for a segregating DH population. If this is the case for our trait, we will probably be excited! We recognise that the mixture of genotypes falls into two different groups, which can be labelled A and B, respectively. Of course, it is likely that the two labels correspond to the two *genotypes* A and B at a yet unmapped major gene. One might say that the action of this gene is semiqualitative or semiquantitative, i.e. somewhere between pure qualitative, as with Mendel's pea genes, and pure quantitative, as with many complex traits such as body weight or crop yield. The action of our major gene may or may not be modified by other genes of minor effect, but the information in the histogram is too limited for us to come to conclusions on this aspect. In some cases trait values of a number of individuals for each of the parents are available. If a parent line is homozygous, all individuals of that line are genetically identical and any variation observed among them must therefore be environmental in origin. This
Figure 18.1   Mixture distributions plotted on top of the histograms (a) for a DH population, (b–c), for F_2 populations. The component distributions for each of the genotypes A, H and B are also plotted in (b) and (c).

would make it possible to compare within-parents variation, which is supposed to be environmental and not genetic, to within-A and within-B variation, which is the sum of environmental and possibly residual genetic variation.

Figure 18.1(b) shows a histogram with a unimodal distribution for a segregating F_2 population. It is not unlikely that our first reaction will be 'a real pity, my trait is complex, probably encoded by many genes of small action'. If many genes encode our trait, then we would expect a 'normal' distribution, as shown in Figure 18.1(b). Again, comparing with parental data, we can get an idea of the amount of genetic variation relative to environmental variation. However, our questions 'how many genes of what sizes of effects', will not be answered unless we invoke the aid of molecular techniques – this will be the topic of the next sections. Are there any potential pitfalls? The reader may feel misled, but the histogram in Figure 18.1(b) actually represents the case of a single additive major gene explaining half of the total variation! The segregating population consists of a mixture of genotypes A, H (heterozygote) and B in the ratio $1 : 2 : 1$. Thus even if we observe a unimodal distribution, we may still hope that the underlying genetics is not too complex.

Figure 18.1(c) shows another histogram with a unimodal distribution for a segregating F_2 population, but this time the distribution is skewed. This may give us a hint of dominant major gene action! Suppose individuals with genotypes A and H group together (i.e. have the same mean value) and underlie the main body of the distribution. The other individuals, with genotype B, underlie the 'shoulder' of the distribution. There is little by way of a proof in the picture, but we may think there is a lot of evidence for our hypothesis of a single dominant gene. Again, there is a chance of a serious pitfall. We may have made the implicit assumption that the error distribution or 'component distribution' is symmetric or even 'normal'. Many traits have a natural lower bound (often zero), and variances often increase with the mean. In reality our histogram was generated under a (polygenic) model with a skewed residual error distribution. Thus, seeing a skewed distribution may lead us to believe erroneously that there is a dominant major gene. Some researchers are aware of this pitfall and transform their data, for instance they take the natural logarithm of all trait values, thereby changing the scale of the x axis to a logarithmic scale on which the distribution looks more symmetrical. Is this a good procedure? Not necessarily, because there is the danger of throwing out the baby with the bathwater: we may loose power for detecting dominant gene action. However, there may sometimes be good biological reasons to log transform. To check the type of distribution one can best look at parental (non-mixture) data and use standard statistical techniques to help find an optimal data transformation – see Atkinson (1985), Jansen and Den Nijs (1993) and Jansen *et al.* (1993) for illustrative examples in the case of mixture models. Choice of mixing distribution becomes more critical when the model becomes more complex (e.g. if models include gene interactions). It is well known, for instance, that significant interactions can arise as statistical artefacts: the interactions try to compensate for wrong model assumptions. Still, distribution checks are only occasionally reported in genetic analysis.

Quantitative data are not always continuous data. Typically, quantification of disease scores may lead to count data (e.g. number of spots on a leaf), categorical or ordinal data (e.g. a disease score $1-5$) or proportions (e.g. number of affected individuals per DH line being tested on multiple seedlings). In many cases the distribution is close to normal after appropriate data transformation (e.g. log, square root, or probit). The type of transformation should preferably be chosen on the basis of non-mixture data. See McCullagh and Nelder (1989) for generalised linear models (GLMs) for many types of distribution.

Finally we refer the readers to Allard (1999) for several illustrative graphs (his Figures 18.1 and 18.2), showing qualitative and quantitative variation resulting from segregation for one, two, or more genes with or without dominance and/or in the presence or absence of environmental noise.

18.2.2   Plotting Mixture Distributions on Top of the Histogram

Histograms may show bimodality or skewness and as such they can indicate segregation of major genes. Still we cannot unambiguously assign individuals to genotypes. In statistical terms, a QTL is a latent unobserved categorical variable. Let us look again at Figure 18.1. How can we model, fit and plot the mixture distributions on top of the histogram?

Let us start with a relatively simple model for Figure 18.1(b): a model with a single QTL with *additive* allele effect and normal error in an F_2. Let y_i denote the trait value of the ith individual. We do not know its QTL genotype. There are three possible genotypes, each with its own probability of occurrence and component probability density function (PDF):

			P	*PDF*
1	y_i	A	0.25	$\phi(y_i; \mu_A, \sigma^2)$
2	y_i	H	0.50	$\phi(y_i; \mu_H, \sigma^2)$
3	y_i	B	0.25	$\phi(y_i; \mu_B, \sigma^2)$

Here

$$\phi(y; \mu, \sigma^2) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp(-(y - \mu)^2/2\sigma^2),$$

is the PDF of the normal (Gaussian) distribution with mean μ and variance σ^2, and

$$\mu_H = \tfrac{1}{2}(\mu_A + \mu_B),$$

because we assumed additivity of allele effects. Taking the weighted sum over the three components, we get the mixture PDF

$$f_{\text{mix}}(y_i) = \frac{1}{4}\phi(y_i; \mu_A, \sigma^2) + \frac{1}{2}\phi\left(y_i; \frac{\mu_A + \mu_B}{2}, \sigma^2\right) + \frac{1}{4}\phi(y_i; \mu_B, \sigma^2).$$

The simultaneous mixture likelihood of observations $y_1, y_2, \ldots, y_n$ is the product of the individual likelihood contributions:

$$L = \prod_{i=1}^{n} f_{\text{mix}}(y_i).$$

In order to shorten the notation we will often use $\phi_A(\cdot)$, $\phi_H(\cdot)$ and $\phi_B(\cdot)$ to denote the distributions for genotypes A, H and B, respectively.

Suppose – for the moment – that we know the parameter values. How do we show the fit of the model to the data? That is fairly easy: calculate $f_{\text{mix}}(\cdot)$ for values ranging from the minimum to the maximum trait value, multiply by the number of individuals n, and by the width w of the groups of the histogram to account for scaling, and finally plot this on top of the histogram. It will become a little more complicated if we want to show the histogram on the original scale of measurement, while we think that it is more appropriate to fit the mixture of normal distributions on a different scale. Suppose that

we fit the normal mixture model to the transformed trait values $T(y_i)$, i.e. on a different scale than the original scale of measurement. The protocol is now as follows: calculate $f_{\text{mix}}(T(\cdot))$ for values ranging from the minimum to the maximum trait value on the original scale of measurement, multiply by the Jacobian $T'(\cdot)$ to calculate the likelihood on the original scale of measurement, next multiply by n and by w, and finally plot this on top of the histogram. The Jacobian $T'(\cdot)$ is the first-order derivative of the transformation function – e.g. if $T(y) = \ln(y)$, then $T'(y) = 1/y$.

18.2.3 Fitting Mixture Distributions

What remains is the question of how we estimate the parameters of the finite (normal) mixture distribution. The standard maximum likelihood (ML) approach consists of finding the parameter values which maximise the simultaneous (log) likelihood. To achieve this we can take the first-order derivatives of the log likelihood l and set these to zero:

$$0 = \frac{\partial}{\partial\theta} l = \frac{\partial}{\partial\theta} \log\left(\prod_{i=1}^{n} f_{\text{mix}}(y_i)\right) = \sum_{i=1}^{n} \frac{\partial}{\partial\theta} \log f_{\text{mix}}(y_i).$$

We continue with our example of a single QTL with additive effect in an F_2. Now note that

$$\begin{aligned}
\frac{\partial}{\partial\theta} \log f_{\text{mix}}(y_i) &= \frac{1}{f_{\text{mix}}(y_i)} \frac{\partial}{\partial\theta}[0.25\phi_A(y_i) + 0.50\phi_H(y_i) + 0.25\phi_B(y_i)] \\
&= \frac{0.25}{f_{\text{mix}}(y_i)} \frac{\partial}{\partial\theta}\phi_A(y_i) + \frac{0.50}{f_{\text{mix}}(y_i)} \frac{\partial}{\partial\theta}\phi_H(y_i) + \frac{0.25}{f_{\text{mix}}(y_i)} \frac{\partial}{\partial\theta}\phi_B(y_i) \\
&= \frac{0.25\phi_A(y_i)}{f_{\text{mix}}(y_i)} \frac{\partial}{\partial\theta} \log\phi_A(y_i) + \frac{0.50\phi_H(y_i)}{f_{\text{mix}}(y_i)} \frac{\partial}{\partial\theta} \log\phi_H(y_i) \\
&\quad + \frac{0.25\phi_B(y_i)}{f_{\text{mix}}(y_i)} \frac{\partial}{\partial\theta} \log\phi_B(y_i) \\
&= P(A|y_i)\frac{\partial}{\partial\theta} \log\phi_A(y_i) + P(H|y_i)\frac{\partial}{\partial\theta} \log\phi_H(y_i) + P(B|y_i)\frac{\partial}{\partial\theta} \log\phi_B(y_i),
\end{aligned}$$

which you can recognise as a sum of weighted 'normal' likelihood contributions, where the weights are conditional probabilities of the genotype given the observed phenotype $P(A|y)$, $P(H|y)$ and $P(B|y)$, which depend on the unknown θ (to shorten the notation we write $P(\cdot)$ instead of $P_\theta(\cdot)$). Unfortunately the likelihood equations cannot be solved analytically. But there is a simple – thus popular – algorithm, called the *expectation-maximisation* (EM) algorithm – for short the EM algorithm. Dempster *et al.* (1977) considered the mixture problem as one of many examples in which data are incomplete. They interpreted mixture data as incomplete data by regarding an observation on the mixture as missing its component of origin. See their Section 4.3 on finite mixtures. In our context the information on QTL genotype is missing (with three components A, H and B). The basic idea of the iterative EM algorithm is to replace the incomplete observation y_i by its three complete observations (y_i, A), (y_i, H) and (y_i, B), weighting the three complete observations by specified or updated (conditional) probabilities. Iteration consists of two steps:

(E step) Specify or update weights $P(A|y_i)$, $P(H|y_i)$ and $P(B|y_i)$.

(M step) Update estimates of μ_A, μ_B and σ^2.

In the E step, conditional probabilities are calculated by using the current parameter estimates. The M step consists of weighted regression analysis on the triplicate data set, which can be done with most statistical packages, and which requires no more than a routine for weighted least squares. The explicit solution of the M step can be written as

$$\hat{\mu}_A = \frac{\sum_{i=1}^{n}\left[P(A|y_i)y_i + P(H|y_i)\frac{1}{2}y_i\right]}{\sum_{i=1}^{n}\left[P(A|y_i) + P(H|y_i)\frac{1}{2}\right]}, \quad \hat{\mu}_B = \frac{\sum_{i=1}^{n}\left[P(B|y_i)y_i + P(H|y_i)\frac{1}{2}y_i\right]}{\sum_{i=1}^{n}\left[P(B|y_i) + P(H|y_i)\frac{1}{2}\right]},$$

and

$$\hat{\sigma}^2 = \frac{1}{n}\left[P(A|y_i)(y_i - \hat{\mu}_A)^2 + P(H|y_i)\left(y_i - \frac{1}{2}(\hat{\mu}_A + \hat{\mu}_B)\right)^2 + P(B|y_i)(y_i - \hat{\mu}_B)^2\right].$$

Setting parameters equal to (well-chosen) initial values conveniently starts the algorithm.

We will now use the above rather simple example to introduce the general concept of data completion (augmentation) and parameter estimation via iterative reweighted least squares. Hopefully this will help the reader to understand the more complicated cases that will appear in later sections. Let $\mathbf{y}^{(c)}$ denote the $1 \times 3n$ vector of augmented trait data $(y_1, y_1, y_1, y_2, y_2, y_2, \ldots, y_n, y_n, y_n)'$, where the superscript (c) is used for 'complete'. Furthermore, let $\boldsymbol{\beta}$ denote the $1 \times p$ vector of regression parameters, $\mathbf{X}^{(c)}$ the corresponding design matrix of size $3n \times p$, $\mathbf{e}^{(c)}$ the vector or residuals, and finally $\mathbf{W}^{(c)}$ is the diagonal matrix of conditional probabilities $(P(A|y_1), P(H|y_1), P(B|y_1), P(A|y_2), P(H|y_2), P(B|y_2), \ldots, P(A|y_n), P(H|y_n), P(B|y_n))'$. Note that for the ith individual the model is

$$\begin{pmatrix} y_i \\ y_i \\ y_i \end{pmatrix} = \begin{bmatrix} 1 & 0 \\ 0.5 & 0.5 \\ 0 & 1 \end{bmatrix} \begin{pmatrix} \mu_A \\ \mu_B \end{pmatrix} + \begin{pmatrix} e_{i1} \\ e_{i2} \\ e_{i3} \end{pmatrix}, \quad \text{weighted by} \begin{pmatrix} P(A|y_i) \\ P(H|y_i) \\ P(B|y_i) \end{pmatrix},$$

or in matrix notation $\mathbf{y}^{(c)} = \mathbf{X}^{(c)}\boldsymbol{\beta} + \mathbf{e}^{(c)}$ with weight matrix $\mathbf{W}^{(c)}$. The M step is

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}^{(c)\prime}\mathbf{W}^{(c)}\mathbf{X}^{(c)})^{-1}\mathbf{X}^{(c)\prime}\mathbf{W}^{(c)}\mathbf{y}^{(c)}$$

and

$$\hat{\sigma}^2 = \frac{1}{n}(\mathbf{Y}^{(c)} - \mathbf{X}^{(c)}\hat{\boldsymbol{\beta}})'\mathbf{W}^{(c)}(\mathbf{y}^{(c)} - \mathbf{X}^{(c)}\hat{\boldsymbol{\beta}}).$$

18.2.4 Wanted: QTLs!

We want to discover all about the QTLs underlying quantitative variation for our trait(s) of interest. How many genes are involved? Where are they located on the chromosomes? What type of (inter)action do they show? It is clear from the Figure 18.1(b), that for truly quantitative variation the effects of the individual genes can hardly be distinguished. But there are clever ways to tackle this problem: use molecular markers, and this is the topic

of the following sections! Thus, we now proceed to apply the mixture model tools in a new context where we have partial information, provided by molecular markers, on the underlying genotypes.

18.3 DISSECTING QUANTITATIVE VARIATION WITH THE AID OF MOLECULAR MARKERS

18.3.1 Molecular Markers

Since the early 1980s new ways to unravel complex traits have emerged (Botstein *et al.*, 1980; Beckmann and Soller, 1983). The magic phrase is 'molecular marker'. Remember that a QTL is – in a statistical sense – a categorical variable whose values remain unobserved. A molecular marker is also a locus on the genome, but the genotype can be observed with molecular tools. From the statistical point of view it hardly matters how this molecular technique works; the only important point is that a marker is a categorical variable with observable state. Nowadays hundreds, not to say thousands, of molecular markers are available or will become available over the next few years, all with more or less *known* positions on the genome. In this chapter the focus will be on dense or ultradense marker maps. Which means that there is almost always a marker almost on top of any QTL. By 'on top' we mean that in the segregating population no recombination events between the given marker and QTL have appeared.

Markers are often just non-functional or selectively neutral sites. So why should it help to collect information about such loci? It will not help if our population is similar to a random mating population in *linkage equilibrium*, which means that genotypes at different loci are statistically independent. But in this chapter we deal with inbred line crosses for which linkage disequilibrium is at its maximum, i.e. there is maximum statistical correlation between the genotypes at linked loci. For example, between an observable marker that does not affect the phenotype and an unobservable QTL that does affect the trait. Say the homozygous parents P_1 and P_2 have marker-QTL genotype $m_1a_1//m_1a_1$ and $m_2a_2//m_2a_2$, respectively (chromosomes occur in pairs, and the symbol '//' separates the alleles of the first and second chromosome of the pair; the marker has alleles m_1 and m_2; the QTL has alleles a_1 and a_2). The F_1 genotype is $m_1a_1//m_2a_2$. It will produce a mixture of non-recombinant gametes (m_1a_1 or m_2a_2) with probability $1 - r$, and recombinant gametes (m_1a_2 or m_2a_1) with probability r. Figure 18.2 is based on the same data as shown in Figure 18.1(a), and shows the effect of tight linkage between marker and QTL on the mixture distribution ($r = 0.01$). There would be weak or no association if the marker and QTL were far apart. Thus, if the marker is close to or on top of a QTL, then the two marker genotype groups (say, A for m_1m_1 and B for m_2m_2) will clearly show different means for the trait. The basic and simple idea is to reverse this statement – if the two marker classes clearly show different means, then there is evidence for 'QTL activity' in the neighbourhood. Note that we have made the reverse statement a little less strong, i.e. we cannot claim that there is only one *isolated* QTL involved – there is much more to say about this, but we will postpone this to one of the later sections of this chapter.

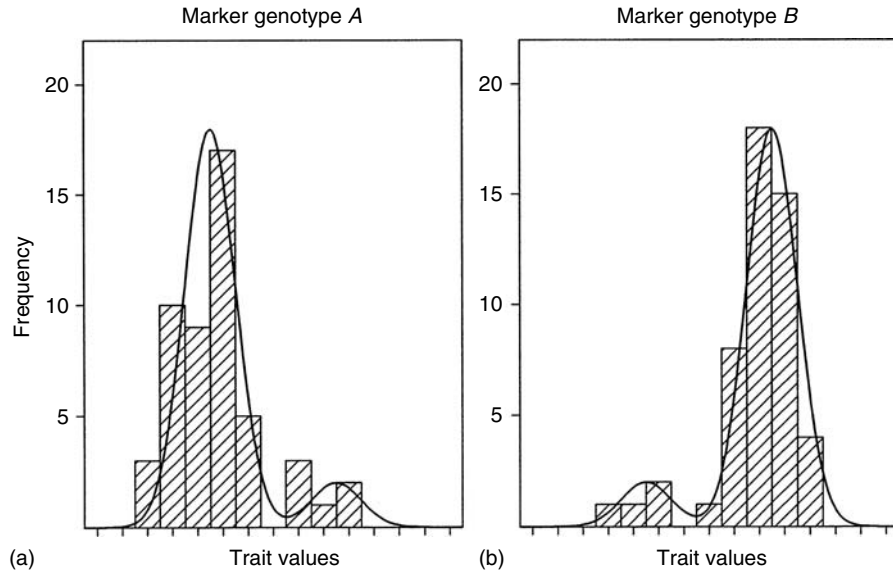
Whether two marker classes indeed show different means (or not) can be tested with standard Analysis Of Variance ANOVA and regression tools. Suppose that we fit a single QTL at a fully informative marker in an F_2 population. The one-way classification model


Figure 18.2 Mixture distributions plotted on top of the histograms per marker genotype for the same data as shown in Figure 18.1(a). The marker is close to a QTL, but a few recombinations have occurred. Therefore, the distribution given the marker genotype is a mixture over recombinant (probability r) and non-recombinant individuals (probability $1 - r$).

reads $y_{ij} = \mu + \beta_i + \varepsilon_{ij}$ for the jth individual of the ith genotype ($i = 1, 2, 3$; A, H and B at the marker). This model can easily be extended to two or more marker factors (Cowen, 1989; Stam, 1991). Assuming that all scores of marker factors are known – i.e. their data are complete – the general model for regression on multiple markers is $\mathbf{y}^{(c)} = \mathbf{X}^{(c)}\boldsymbol{\beta} + \mathbf{e}^{(c)}$. A characteristic of ANOVA and regression models is that they often are overparameterised, containing more parameters than needed to represent the effects. Usually, setting the sum of allele effects to zero or, equivalently, working in terms of main effect and allele substitution effects compensates for this. The parameters are commonly estimated by the least-squares method, i.e.

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}^{(c)\prime}\mathbf{X}^{(c)})^{-1}\mathbf{X}^{(c)\prime}\mathbf{y}^{(c)}$$

and

$$\hat{\sigma}^2 = \frac{1}{n - p}(\mathbf{y}^{(c)} - \mathbf{X}^{(c)}\hat{\boldsymbol{\beta}})'(\mathbf{y}^{(c)} - \mathbf{X}^{(c)}\hat{\boldsymbol{\beta}}).$$

Note that in the latter formula one divides by $n - p$, the degrees of freedom (df) of the residual error, and not by n; n is the population size, p is the number of regression parameters in $\boldsymbol{\beta}$.

18.3.2 Mixture Models

What happens if some marker scores are missing? ANOVA and regression models do not allow for missing values in the explanatory variables. We could eliminate any individual with one or more missing marker scores and then perform an analysis on the remainder

of the data set. But in real experiments most individuals are missing at least some marker scores, so this approach does not seem to be very attractive. Of course, we can think of filling in the gaps *prior to ANOVA analysis* by using the map information. How does this work? Look at the markers flanking the marker with a missing score. If the markers are close together, we can be pretty sure how to fill in the score and then we can apply ANOVA and regression! This is an *ad hoc* procedure, which works well for ultradense maps, but there are more sophisticated methods available for sparse maps. As we have seen in Section 18.2, data completion can be integrated with analysis of quantitative variance – and the type of models we need are mixture models.

We should not be surprised if up to 5 % of the marker scores are missing in a real experiment. Often some markers or some individuals are difficult to score. This can be caused by various technical failures such as a given individual's bad DNA sample or problems with the fingerprint image. The statistician assumes that the scores are missing at random, or at least that there is no tendency that one score, say A, is relatively more frequently missing than B or H. Another type of incomplete data occurs when one or more markers are *dominant* and scored in, for instance, an F_2 population. Such a dominant marker still has three different states A, H and B, like a codominant marker. However, for technical reasons either A and H cannot be discriminated, which is often labelled as 'not-B' or just D, or H and B cannot be discriminated, labelled as 'not-A' or just C. A dominant marker is, in statistical terms, an observable categorical variable with two observable states. We can therefore use such a variable straightforwardly in ANOVA. On the other hand, we may want to complete the marker data by again using information from neighbouring markers. For instance, a 'not-A' observation means that the genotype is B or H, and the first one is more likely if we know that an adjacent marker has score B. How successfully can we complete data? This can be quantified by what one calls the *multilocus information content*; this will be defined later. We finish by remarking that the distinction between dominant and codominant markers is not always so absolute. Some types of marker may yield A, H, B, C and D, that is there are five categories (e.g. AFLP$^{©}$ markers).

Currently, marker maps are still not ultradense, and this brings us to the third type of incomplete data. Suppose that we have complete marker data, but that our marker map is sparse, that is the markers are spread coarsely over the genome. Our data will show many recombinants between any pair of flanking markers and, if there is a QTL in between, then it is likely that none of the markers is 'on top' of the QTL. In other words, a flanking marker can have the same genotype as the QTL, but not for all individuals at the same time. Therefore, ANOVA on a flanking marker is no longer identical to ANOVA on the QTL. ANOVA may still work relatively well, but the results are biased or less powerful, because we have built-in errors by ignoring one or more recombinations between the marker and the QTL. Does statistics offer a solution to this problem? Any locus with incomplete data can be added to the model, whether it is a marker (as discussed above) or a QTL (which is a locus with all its scores missing). The statistical trick of data completion will work in any case, and it will help us to exploit the full multilocus information content. Basically, there is no obstacle to using multiple-QTL models. Over the past decade most theoretical papers on QTL mapping have been devoted to the sparse map situation. The older papers dealt with single-QTL mixture models only (see Weller, 1986; Jensen, 1989; Lander and Botstein, 1989; Simpson, 1989), methods that became known as *interval mapping* (IM). Jansen (1992) developed a general approach for fitting multiple-QTL models, an approach that became later known as *MQM* (multiple-quantitative trait loci mapping), and

was elaborated in a number of papers (Jansen, 1993b; 1994b; Jansen and Stam, 1994). Zeng (1994) published a similar strategy and called it *composite interval mapping* (CIM).

Let us now work out an example. For convenience, but without loss of generality, we will zoom in on one F_2 individual with trait value y_i and five loci with scores

$$A\ A\ D\ U\ A,$$

where D means *not-B* and U means *genotype unknown*. We suppose that the loci 1, 2, 3 and 5 are markers, and that the fourth locus is a QTL, which is located at a map position within the interval between loci 3 and 5. All genotype scores of the QTL are unknown. The observed data can be completed for the missing locus information, giving rise to six different complete genotypes:

		1	2	3	**4**	5	Simultaneous genotype probability	Component density
1	y_i	A	A	A	**A**	A	$\frac{1}{4}(1-q)^2(1-r)^2(1-s)^2(1-t)^2$	$\phi_A(y_i)$
2	y_i	A	A	A	**H**	A	$\frac{1}{4}(1-q)^2(1-r)^2\,2(1-s)s(1-t)t$	$\phi_H(y_i)$
3	y_i	A	A	A	**B**	A	$\frac{1}{4}(1-q)^2(1-r)^2s^2t^2$	$\phi_B(y_i)$
4	y_i	A	A	H	**A**	A	$\frac{1}{4}(1-q)^2\,2(1-r)r(1-s)s(1-q)^2$	$\phi_A(y_i)$
5	y_i	A	A	H	**H**	A	$\frac{1}{4}(1-q)^2\,2(1-r)r((1-s)^2+s^2)(1-t)t$	$\phi_H(y_i)$
6	y_i	A	A	H	**B**	A	$\frac{1}{4}(1-q)^2\,2(1-r)r(1-s)st^2$	$\phi_B(y_i)$

Suppose you know the frequencies of recombination q, r, s and t between the loci. The multilocus genotype probabilities can be derived straightforwardly: $\frac{1}{4}$ for 'genotype A at the first locus, then $(1-q)^2$ for no recombination between A on the first locus and the A at the second locus, etc. For the moment, our model will include only one explanatory variable – the fourth locus is a QTL – and we can assign component densities $\phi_A(y_i)$, $\phi_H(y_i)$ and $\phi_B(y_i)$. By multiplying each of the six genotype probabilities with the corresponding component densities, and then summing these products over the six genotypes, we can see that the contribution of this individual to the *multilocus* or *multipoint* simultaneous likelihood is

$$f_{\text{mix}}(y_i, AADUA) = P(AAAAA)\phi_A(y_i) + P(AAAHA)\phi_H(y_i) + P(AAABA)\phi_B(y_i)$$
$$+ P(AAHAA)\phi_A(y_i) + P(AAHHA)\phi_H(y_i) + P(AAHBA)\phi_B(y_i).$$

The crux is that we complete the explanatory variable(s), here the fourth locus, so that we can perform an ANOVA-like analysis. There is no need to complete the data for the other non-explanatory loci, and we can rewrite the above expression as

$$f_{\text{mix}}(y_i, AADUA) = [P(AAAAA) + P(AAHAA)]\phi_A(y_i)$$
$$+ [P(AAAHA) + P(AAHHA)]\phi_H(y_i)$$
$$+ [P(AAABA) + P(AAHBA)]\phi_B(y_i).$$

The genotype probabilities can easily be calculated recursively. The regression model for the ith individual is

$$\begin{pmatrix} y_i \\ y_i \\ y_i \end{pmatrix} = \begin{bmatrix} 1 & 0 \\ 0.5 & 0.5 \\ 0 & 1 \end{bmatrix} \begin{pmatrix} \mu_A \\ \mu_B \end{pmatrix} + \begin{pmatrix} e_{i1} \\ e_{i2} \\ e_{i3} \end{pmatrix}, \text{ weighted by } \begin{pmatrix} P(A|y_i) \\ P(H|y_i) \\ P(B|y_i) \end{pmatrix},$$

in which

$$P(A|y_i) = \frac{[P(AAAAA) + P(AAHAA)]\phi_A(y_i)}{f_{\mathrm{mix}}(y_i)},$$

and $P(H|y_i)$ and $P(B|y_i)$ are calculated analogously. It is easy to add extra QTLs to the model. For instance, we can insert a second QTL (a locus with only U scores) in the first marker interval. Doing so, the PDF of the ith individual is

$$f_{\mathrm{mix}}(y_i, AUADUA) = \sum_{\substack{u=A,H,B \\ v=A,H,B}} [P(AuAAAvA) + P(AuAAHvA)]\phi_{uv}(y_i).$$

The general regression model, for all individuals together and for any number of markers and QTLs, reads $\mathbf{y}^{(c)} = \mathbf{X}^{(c)}\boldsymbol{\beta} + \mathbf{e}^{(c)}$, with weight matrix $\mathbf{W}^{(c)}$. The parameters can be conveniently estimated via the EM algorithm by iterating in two steps, similar to what we have seen for the marker-free case of segregation analysis:

(E step) Specify or update weights $P(\text{multilocus genotype } |y_i)$.

(M step) Update estimates of $\boldsymbol{\beta}$ and σ^2.

In the E-step conditional multipoint genotype probabilities are calculated by using the current parameter estimates. The M step is

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}^{(c)\prime}\mathbf{W}^{(c)}\mathbf{X}^{(c)})^{-1}\mathbf{X}^{(c)\prime}\mathbf{W}^{(c)}\mathbf{y}^{(c)}$$

and

$$\hat{\sigma}^2 = \frac{1}{n}((\mathbf{y}^{(c)} - \mathbf{X}^{(c)}\hat{\boldsymbol{\beta}})'\mathbf{W}^{(c)}(\mathbf{y}^{(c)} - \mathbf{X}^{(c)}\hat{\boldsymbol{\beta}}).$$

In our small example presented above, data augmentation for the given individual gave rise to six different complete genotypes. However, different individuals may have different amounts of missing genetic (QTL and marker) information. In this augmentation approach there is no restriction on multiplying any other individual with any other value (3, 6, 10, 100, etc.) within the same analysis. For instance, 'triplicate' the jth individual with observed data $(y_j, AAAUA)$ to complete data $\{(y_j, AAAAA), (y_j, AAAHA), (y_j, AAABA)\}$.

Use of the EM algorithm (generally) yields Maximum Likelihood (ML) estimates $\hat{\boldsymbol{\beta}}$ and $\hat{\sigma}^2$. Jansen (1994b) proposed to use restricted ML, i.e. adjust the ML estimate $\hat{\sigma}^2$ for the df used. Divide by the df of residual error instead of by n, just as in ANOVA and regression analysis:

$$\hat{\sigma}^2 = \frac{1}{n-p}(\mathbf{y}^{(c)} - \mathbf{X}^{(c)}\hat{\boldsymbol{\beta}})'\mathbf{W}^{(c)}(\mathbf{y}^{(c)} - \mathbf{X}^{(c)}\hat{\boldsymbol{\beta}}).$$

As we will see in a later section, this can lead to several appealing advantages during selection and inference, at least if multipoint linkage information is high.

We would like to emphasise that we model the *simultaneous* likelihood of the trait and of multiple markers and QTLs. Genotypes are *multilocus* and genotype probabilities, are *unconditional* (Jansen, 1992; 1993b; 1994b). This is in contrast to most literature on inbred line analysis, in which one usually calculates the likelihood of the trait *conditional* on the two markers flanking the interval study (e.g. Lander and Botstein, 1989). If the flanking marker scores are missing or incomplete for a given individual, then the nearest informative marker in the same direction is taken. This 'conditional marker-QTL-marker approach' works well for simple single-QTL models, but is definitely less 'transparent' for multiple-QTL models. Only unconditional multilocus likelihoods can form the basis for direct comparison of the fit of several competing models.

How do we define multilocus information content at a given map location? In the ideal case, one of the conditional probabilities $P(A|y_i)$, $P(H|y_i)$, or $P(B|y_i)$ is 1 and the two others are 0. This happens only if the QTL is on top of a complete-data marker. In the worst case of no marker data, the three probabilities are 0.25, 0.50 and 0.25. One simple way to visualise the quality of the data works as follows. Take for each individual the most likely genotype and average the corresponding probabilities over all individuals. If the average is close to 1, then our data are excellent at the given map position. If it is close to 0.5, then the multimarker information is really poor. This is just our own definition of information content, and others exist. See, for instance, the definition, based on variances of conditional probabilities, in Spelman *et al.* (1996). Is it a major problem if the information content is substantially lower than 1? This has not been studied in much detail in the QTL literature, but it may not be much of a problem: Redner and Walker (1984) pointed out that small to moderate proportions of completely informative individuals are sufficient for good ML estimation in mixture problems.

18.3.3 Alternative Regression Mapping

Let us look again at our simple example in which the fourth locus was the QTL and

$$f_{\text{mix}}(y_i, AADUA) = [P(AAAAA) + P(AAHAA)]\phi_A(y_i)$$
$$+ [P(AAAHA) + P(AAHHA)]\phi_H(y_i)$$
$$+ [P(AAABA) + P(AAHBA)]\phi_B(y_i).$$

Note that $f_{\text{mix}}(y_i, AADUA) = f_{\text{mix}}(y_i|AADUA)P(AADUA)$. Conditional on observed genotype, the expected trait value of the ith individual, μ_i, is given by

$$P(AADUA)\mu_i = [P(AAAAA) + P(AAHAA)]\mu_A$$
$$+ [P(AAAHA) + P(AAHHA)]\tfrac{1}{2}(\mu_A + \mu_B)$$
$$+ [P(AAABA) + P(AAHBA)]\mu_B$$
$$= [P(AAAAA) + P(AAHAA) + \tfrac{1}{2}P(AAAHA) + \tfrac{1}{2}P(AAHHA)]\mu_A$$
$$+ [P(AAABA) + P(AAHBA) + \tfrac{1}{2}P(AAAHA) + \tfrac{1}{2}P(AAHHA)]\mu_B,$$

which we can write as

$$\mu_i = p_1\mu_A + p_2\mu_B.$$

Haley and Knott (1992) and Martinez and Curnow (1992) proposed to use the regression model for the ith individual

$$y_i = [p_1 p_2] \begin{pmatrix} \mu_A \\ \mu_B \end{pmatrix} + \varepsilon_i,$$

and parameters can be estimated easily by the least-squares approach, if p_1 and p_2 are assumed to be known. Here we refer to this method as 'regression mapping'. In an ML framework, their approach would be equivalent to approximating the mixture density $f_{\text{mix}}(y_i)$ by a normal distribution $\phi(y_i; \mu_i, \tau^2)$. Figure 18.2 visualises the worst case of a major QTL for which the approximation can only be poor. In many cases, however, this approach works reasonably well. Where the EM algorithm often requires five to seven iterations of iterative weighted least squares, the regression approach obviously only needs one step.

18.3.4 Highly Incomplete Marker Data

Let us now briefly discuss problems with *highly* incomplete genetic data (e.g. if many marker scores are missing or if we postulate multiple QTLs). The PDF is then a sum over many different candidate genotypes, in which case computation may become time consuming. In the above example, the complete genotypes *AAABA* (no. 3) and *AAHBA* (no. 6) have negligibly small probabilities compared to the most likely genotype *AAAAA*. We can set some threshold for simply ignoring relatively unlikely genotypes, to save us a lot of computer time in genuine multilocus problems. An alternative approach is to use so-called Markov Chain Monte Carlo (MCMC) sampling techniques. Such techniques have been developed for the more complex situation of outbred line crosses (e.g. Jansen, 1996). The basic MCMC idea is simple: if you cannot enumerate all possible genotypes, then just sample a representative set. We refer to our Bibliographic Notes (Section 18.5) and to **Chapters 19** and **26** for more details.

18.3.5 ANOVA and Regression Tests

Now suppose that we fit a single QTL at a fully informative marker in an F_2 population. As before, the one-way classification model reads $y_{ij} = \mu + \beta_i + \varepsilon_{ij}$ for the jth individual of the ith genotype ($i = 1, 2, 3$; A, H and B). The ANOVA table is shown in Table 18.1. We refer to Soller *et al.* (1976) and Soller and Genizi (1978) for some of the early references.

The test statistic

$$F_{\text{QTL}} = \frac{\text{MS between}}{\text{MS within}},$$

Table 18.1 Analysis of variance table for a single QTL at a fully informative marker in an F_2 population.

Source	df	SS	MS	E(MS)
Between QTL genotypes	2	$\sum_{i=1}^{3} n_i (\bar{y}_i - \bar{y})$	s_{QTL}^2	$\sigma_{\text{e}}^2 + \frac{1}{2} \sum_{i=1}^{3} n_i \beta_i^2$
Within QTL genotypes	$\sum_{i=1}^{3} (n_i - 1) = n - 3$	$\sum_{i=1}^{3} n_i (y_{ij} - \bar{y}_i)^2$	s_{e}^2	σ_{e}^2
Total	$\left(\sum_{i=1}^{3} n_i \right) - 1 = n - 1$	$\sum_{i=1}^{3} \sum_{j=1}^{n_i} (y_{ij} - \bar{y})^2$		

has an F distribution with 2 and $n - 3$ df under the null hypothesis of no segregating QTL (i.e. a ratio of two independent χ^2 variables, $(\chi_2^2/2)/(\chi_{n-3}^2/(n-3))$). The ANOVA model can easily be extended to two or more factors, but the interpretation of the table is now complicated by the possible collinearity of the putative QTLs. Each sum of squares represents the variation accounted for by the given QTL, having eliminated all the effects of the QTLs above it in the table, but ignoring any terms of QTLs below it (e.g. McCullagh and Nelder, 1989). Thus, in the case of strong collinearity the order of fitting terms in the model may affect the sum of squares value of a given QTL. Alternatively, we can tabulate sum of squares values representing the variation accounted for by a given QTL having eliminated all the effects of the other QTLs postulated in the model (no matter whether they are tabulated above or below the given QTL).

18.3.6   Maximum Likelihood Tests

Let us now look at the same one-way QTL classification, but use ML procedures for estimation of the parameters of the normal distributions involved. We still assume that we fit a single QTL at a fully informative marker. The *full* model (fitting the QTL) reads $y_{ij} = \mu + \beta_i + \varepsilon_{ij}$ with residual variance σ_{full}^2, whereas the *reduced* model (omitting the QTL) simply reads $y_{ij} = \mu + \varepsilon_{ij}$ with residual variance $\sigma_{\text{reduced}}^2$. Suppose that the marker data are complete. ML estimates can be obtained via least-squares analysis as usual. Note that

$$\hat{\sigma}_{\text{full}}^2 = \frac{\text{SS within}}{n}$$

and

$$\hat{\sigma}_{\text{reduced}}^2 = \frac{\text{SS total}}{n}.$$

Then, the log likelihood of the full model, l_{full}, is

$$l_{\text{full}} = \sum \left(\log \frac{1}{\sqrt{2\pi\hat{\sigma}_{\text{full}}^2}} - \frac{(y_{ij} - x_i'\hat{\beta})^2}{2\hat{\sigma}_{\text{full}}^2} \right) = -\frac{1}{2}n \log(2\pi\hat{\sigma}_{\text{full}}^2) - \frac{1}{2}n;$$

and the log likelihood of the reduced model, l_{reduced}, is

$$l_{\text{reduced}} = \sum \left(\log \frac{1}{\sqrt{2\pi\hat{\sigma}_{\text{reduced}}^2}} - \frac{(y_{ij} - \hat{\mu})^2}{2\hat{\sigma}_{\text{reduced}}^2} \right) = -\frac{1}{2}n \log(2\pi\hat{\sigma}_{\text{reduced}}^2) - \frac{1}{2}n.$$

The likelihood ratio (*LR*) test statistic is

$$LR = 2 \log \frac{L_{\text{full}}}{L_{\text{reduced}}} = 2(l_{\text{full}} - l_{\text{reduced}}) = n \log \frac{\hat{\sigma}_{\text{reduced}}^2}{\hat{\sigma}_{\text{full}}^2} = n \log \frac{\text{SS total}}{\text{SS within}}.$$

It is asymptotically χ^2 distributed with 2 df (Wilks, 1938). In general, in a combined test for p parameters, the LR test is χ^2 distributed with p df. The models can easily be extended to two or more factors (QTLs). In all cases one tests on the basis of *LR* between a full model and a reduced model.

Some readers may not be familiar with the calculation of *LR* test statistic values on a natural logarithm scale. In applied genetics literature one frequently uses the logarithm with 10 as base, in which case one uses the notation *log-odds* (*LOD*) instead of *LR*. It is defined as

$$LOD = \log_{10} \frac{L_{\text{full}}}{L_{\text{reduced}}}.$$

We can easily convert a score on one scale to a score on the other scale via

$$LR = 2 \times \log_e(10) \times LOD \approx 4.6 \times LOD.$$

For large *n* the *F* test is approximately distributed as $\chi^2(2)/2$ under the null hypothesis of no QTL (Lynch and Walsh, 1998), in which case $2LR \sim F$. Thus, in general QTL detection via ANOVA/regression is not identical to QTL detection via ML – slightly different outcomes may be expected, even for complete data!

18.3.7 Analysis-of-deviance Tests

We will now describe a procedure which can be used for complete data and also for *incomplete* data, i.e. all cases in which we do not fit a QTL at a fully informative marker (Jansen, 1994b). We refer the readers to the textbook by McCullagh and Nelder (1989) on *Generalized Linear Models* Generalized Linear Models for more information.

In comparing a sequence of models, an unbiased estimate of the residual variance can be obtained from the full 'most complex' model. This estimate is used for all models in the sequence to make the comparison fair, between the *full* model and any *reduced* model and amongst reduced models. We can then generate an ANOVA-like table, which in the GLM literature is commonly called an *analysis-of-deviance table*, where the term *deviance* is used for the difference $2(l_{\text{full}} - l_{\text{reduced}})$. The procedure has three steps (Jansen, 1994b):

1. Calculate ML estimates $\hat{\beta}_{\text{full}}$ and $\hat{\sigma}^2_{\text{full}}$. Adjust $\hat{\sigma}^2_{\text{full}}$ for bias, i.e. divide by the residual df and not by *n*.

2. Calculate ML estimates $\hat{\beta}_{\text{reduced}}$ given 'known' residual error as estimated in the full model ($\hat{\sigma}^2_{\text{full}}$ in step 1).

3. Calculate the deviance (*LR* test statistic).

Let us look again at the simple one-way ANOVA for complete data. The log likelihood of the *full* model (QTL model) reads, as before,

$$l_{\text{full}} = \sum \left(\log \frac{1}{\sqrt{2\pi\hat{\sigma}^2_{\text{full}}}} - \frac{(y_{ij} - x_i'\hat{\beta})^2}{2\hat{\sigma}^2_{\text{full}}} \right).$$

The real difference comes for the log likelihood of the *reduced* model (the no-QTL model), which now reads

$$l_{\text{reduced}} = \sum \left(\log \frac{1}{\sqrt{2\pi\hat{\sigma}^2_{\text{full}}}} - \frac{(y_{ij} - \hat{\mu})^2}{2\hat{\sigma}^2_{\text{full}}} \right).$$

Next we calculate the deviance

$$Deviance = 2(l_{\text{full}} - l_{\text{reduced}}) = \frac{\text{SS total} - \text{SS within}}{\hat{\sigma}^2_{\text{full}}} = 2 \times \frac{\text{MS between}}{\text{MS within}},$$

where the LR test has an F distribution with 2 and $n - 3$ df. In general,

$$Deviance = p \times \frac{\text{MS between}}{\text{MS within}} = pF,$$

where p is the difference between the parameter numbers in the two models being compared. The maximum achievable likelihood is

$$l_{\text{max}} = -0.5n \log(2\pi\hat{\sigma}^2_{\text{full}}),$$

which we obtain if we use as many parameters as we have individuals. If our model contains all the important parameters, the deviance $2(l_{\text{max}} - l_{\text{model}})$ will be close to the difference between the number of individuals, n, and the number of parameters in the model, p. One can use this as a measure for goodness of fit (McCullagh and Nelder, 1989).

We have described the analysis-of-deviance approach for a simple one-factor model, but this can easily be extended to two or more factors. The analysis-of-deviance approach is a unified approach, which can be applied to many types of data (McCullagh and Nelder, 1989). It can also be applied to incomplete data, provided that at least a proportion of the individuals are completely informative at the region under study (Jansen, 1994b). Of course, with rather incomplete information the fitting of many parameters becomes dangerous and therefore undesirable; one can then use the ML approach. We close this section with a remark on the use of non-segregating data. If we have data from parental or F_1 populations, we can estimate the environmental variance, $\hat{\sigma}^2_{\text{e}}$, in the non-segregating populations. It could be an option to use $\hat{\sigma}^2_{\text{e}}$ instead of $\hat{\sigma}^2_{\text{full}}$ during the selection procedure, or at least to define the maximum achievable likelihood as

$$l_{\text{max}} = -0.5n \log(2\pi\hat{\sigma}^2_{\text{e}}).$$

18.3.8   How Many Parameters Can We Fit Safely?

To obtain a good estimate of the residual error variance in ANOVA and regression analysis, it is necessary to have at least 10 residual error df, and many statisticians would take $12-20$ df as their preferred lower limit. Increasing the residual error df makes little difference to the significance threshold in F tests. Say we have a DH population of 100 individuals and suppose our organism has 10 chromosomes of length 200 cM each (e.g. maize). We can then spend as many as 80 df on explanatory variables, for instance by postulating eight QTLs per chromosome equally spaced every $\sim$20 cM.

How many parameters can we fit in the ML approach? In the case of large numbers of parameters, residual error variance can be severely underestimated and asymptotic relations such as the χ^2 approximations do not necessarily hold. Therefore the number of parameters should not be too large, preferably less than $2\sqrt{(\text{number of observations})}$ (Jansen and Stam, 1994). In a DH population of 100 individuals, we have df for fitting approximately $2\sqrt{100} = 20$ QTLs, considerably less than in the ANOVA and regression framework. A critic could well state that we are wasting our resources by not asking

enough questions of our data. Fortunately, this serious disadvantage of the ML approach can be overcome by the general analysis-of-deviance approach described above, by which we can fit up to 80 QTLs (Jansen and Stam, 1994).

18.4   QTL DETECTION STRATEGIES

18.4.1   Model Selection and Genome Scan

Having read the previous sections you have almost all the statistical tools in hand for building the QTL model and for estimating its parameters. You may think the major hurdles have been overcome, and that all that remains – mapping of all QTLs – must be more or less straightforward from the statistical point of view. Here are some cautionary remarks. There are several different statistical techniques for mapping and they do not necessarily all lead to the same answer. Moreover, by no means should the results from statistical analysis be considered as a proof of how nature shaped our trait – any model is wrong because it is a simplification and the possibility of ending up with erroneous conclusions must be kept in mind. The more complex the model, the greater the dangers.

Suppose that we have formulated and fitted a number of different models; which one should we adhere to? Probably the model with a good fit to the data and the lowest number of parameters. In statistics this is called the *principle of parsimony*. Unfortunately there is no general theory for testing one model against another, and as such no claim such as 'this is the significantly best model at a confidence level of 95 %' is possible.

In the ideal case all genetic variance of the trait is explained by detected QTLs only. In practice, a number of QTLs may be missed (error type 2) and at the same time a number of false positives may occur, indicating QTLs at map positions (or regions) where actually no QTLs are present (error type 1). The actual balance between the cost of false positives and the benefit of detected QTLs depends on the aim of the experiment (e.g. map-based cloning or marker-assisted breeding). Nevertheless, one often strives to keep the probability of a type 1 error below 5 %. At the same time one should minimise the probability of an error of type 2. Approaches for QTL mapping generally comprise one or both of the following two steps:

- *Model selection*: Compare different QTL models and select the best one(s).

- *Genome scan*: Plot QTL likelihood along the genome using the selected model.

In our opinion the first step is the more critical one, whereas the second step is merely a good way of visualising QTL results along the genetic map.

In the model selection step we will try to relate the trait variable to one or more explanatory loci (possibly at marker positions) or 'factors'. Different sets of factors can be considered as competing statistical models and many statistical criteria and selection approaches can be used. It is important to note that in genetic mapping one has a major advantage over many other model selection applications. In most applications there is no theory explaining the fact that two or more factors are correlated. But markers and QTLs are known to be located on the genome map, and thus genetic linkage theory tells us that we can replace one factor in the model by another one from the same region without much changing the fit of the model. When two or more explanatory factors are strongly

correlated to one other, it is difficult to disentangle their individual effects – this is known as *multicollinearity* – but this is less of a problem in QTL analysis and in some sense simplifies the difficult task of model selection.

In this section we will review several major techniques in use for model selection and inference in QTL mapping: single-marker analysis; IM; CIM and MQM. With our cautionary remarks in mind, one can safely apply the procedures as given, without being too concerned with the actual significance levels.

18.4.2   Single-marker Analysis and Interval Mapping

We have depicted QTL mapping as a problem of selection among many possible models. Despite the potential benefits of genuine multifactor approaches, its statistical complications lead some users to adopt single-factor ANOVA analyses. How does it work? Suppose we have our known map with markers covering part or all of the genome. We then calculate the QTL likelihood (*F* or *LR* score) at each marker position and plot it along the map. In statistical terms, we produce the likelihood profile along the map. Next we look at our plot and we think there is evidence for QTL activity in regions where the QTL likelihood peaks and exceeds a significance threshold. If the markers are sparse, we can also calculate QTL likelihood at any position within a marker interval to get a smooth QTL likelihood curve, by using IM (see our Figure 18.3; Lander and Botstein, 1989) or the regression mapping approach (Haley and Knott, 1992; Martinez and Curnow, 1992). In this section we will discuss several features of this single-factor type of analysis.

What can we do in order to avoid reporting too many false positives (i.e. non-existing QTLs)? The significance of an effect plays a dominant role in the genetics literature. The common rule is that reviewers will accept a QTL which is significant at a 95 % experimen-twise confidence level ($\alpha = 0.05$). We do multiple tests, and what we obviously need is
Figure 18.3   QTL likelihood profile obtained with interval mapping for the case of an isolated QTL. Marks below the *x* axis indicate positions of markers along the chromosome under study. The bar indicates the 2 *LOD* support interval for the QTL. The genome-wide significance threshold is ∼14.

therefore a chromosome-wide or genome-wide significance threshold. Test scores at linked markers are strongly correlated. No unifying analytical solutions for the genome-wide distribution of the test statistic in a general inbred line cross are known. Several authors developed (complex) formulae for specific cases (Lander and Botstein, 1989; Rebaï *et al.*, 1994; Doerge and Rebaï, 1996), while others published tables resulting from extensive simulations (van Ooijen, 1999). We can also use simple permutation strategies (Churchill and Doerge, 1994) or bootstrap strategies (Jansen, 1993b; 1994b; Visscher *et al.*, 1996b). Suppose that we use one of these methods. Let us briefly look at permutation and the bootstrap. In both approaches new sets of data will be generated and analysed over many runs. In each run the 'old' marker data will be completed with 'new' trait data. The artificial data set is then analysed for QTLs and the maximum test score over the genome is calculated and stored. The entire procedure is repeated many (say, 1000–10 000) times in order to generate an empirical cumulative distribution for the test statistic. In the permutation approach, observed trait data are reshuffled over the individuals under the null hypothesis of no QTL, thereby breaking down any existing marker – QTL associations. Under the null hypothesis any of the trait data for any of the individuals could have come equally well from either of the marker or QTL classes. In the parametric bootstrap approach new trait data are generated from a standard normal distribution postulating no QTL.

Suppose that we have detected a 'genuine' QTL. If we replicated the experiment, the gene's location would of course remain identical, but the size of its effect can easily change significantly due to QTL by environment interaction. Therefore we believe that the gene's location and the sign of its effect are probably the most relevant parameters. Thus, we question the value of putting standard errors on effects, but we would certainly like to report a 95 % confidence region for the QTL location. The inverse of Fisher's information matrix is the standard tool in a statistician's ML toolbox for calculation of standard errors. Computation of this matrix is a difficult task in the case of mixture models, but at relatively low cost the matrix can be approximated by using first – order partial derivatives, which are directly available from the EM algorithm (Redner and Walker, 1984; Jansen and Stam, 1994). But there is a more direct way to construct a confidence region for the QTL location. We usually calculate and plot the QTL likelihood profile at each map position along the map. A clear peak in this profile is taken as the most likely QTL position. Suppose we have a clear peak in the profile. According to standard ML theory, a 95 % confidence region for QTL location is then bounded by the map positions where the profile is $\chi^2_{0.05}(1) = 3.84$ less than at the peak (equivalent to 0.84 *LOD*). Let us call this region a *support region* (Figure 18.3). This region is a 95 % confidence region if and only if the confidence interval falls within one marker interval. What is the critical problem? If the confidence region spans more than one interval, then we actually compare several different statistical models. But ML properties only hold within one model and not across models. In other words, we have no general theory to guarantee that the support interval is a 95 % confidence region. Various simulation studies have shown that a 2 *LOD* support interval is a safe choice in most cases yielding at least 95 % confidence regions (e.g. van Ooijen, 1992).

Here are some more warnings. Most of them are pretty obvious from the statistical point of view, knowing that what can go wrong in ANOVA and regression analysis is often due to multicollinearity. Suppose that you have used the appropriate genome-wide significance threshold and detected a significant QTL at a certain map position where the test score peaks highest. You may yell 'Hurray, I have found a QTL!'. But you have only found a statistical association and not a gene, and there are at least four traps that

may lead you to erroneous inference. The first trap is that there are actually two or more linked QTLs with effects of equal sign (QTLs are in coupling phase), in which case it is not unlikely that the analysis will reveal a single QTL in the middle of the two true QTLs. This is known as the *detection of a ghost QTL* (Martinez and Curnow, 1992), an error of type 1. The second trap is that an unlinked major QTL has inflated the test score. Incidental association can arise due to deviations from expected segregation ratios for any pair of loci on the genome. This is especially probable in the case of severe segregation distortion, or in small populations where larger deviations from expected segregation ratios may arise as the result of natural sampling variation. Of course, this is another example of a ghost QTL, but the general user less often anticipates it. The third trap is even nastier than the other two, although it can be considered as the multi-QTL extension. What we test with IM is nothing more or less than an *average* effect of all QTLs in the region under study. With IM there is no way to dissect their effects; any effect detected can be the sum of many possibly small QTL effects instead of the effect of an isolated QTL. If we repeat our experiment, the effects of the QTLs can be modulated in different ways and therefore the average effect may give rise to a peak of the test score at another map location. Furthermore, if two or more QTLs have effects of different sign (QTLs are in repulsion phase), then the joint effect can be close to zero. In other words, in such cases (major) QTLs will remain undetected. Finally, the fourth trap has to do with variable information content. Suppose that the information content is relatively low in a region containing a QTL. What may happen is that the peak is shifted towards more informative regions (Knott and Haley, 1992).

18.4.3   Composite Interval Mapping

Is there a way to avoid the traps described above? In fact we have already seen almost all the essentials for such an approach. In Section 18.3 we mentioned the solution: tabulate the variation accounted for by a given QTL, having eliminated all the effects of the other QTLs postulated in the model. (Recall the DH example, in which we postulated up to eight QTLs per chromosome, equally spaced every ∼20 cM.) As in Section 18.4.2, we calculate the QTL likelihood at each marker position, plot it along the map and look for peaks. If the marker map is sparse, we can calculate QTL likelihood at multiple positions within a marker interval to get a smooth QTL likelihood profile. In principle we can postulate QTLs at any position we like – on top of markers or inside marker intervals (Jansen, 1992; Kao *et al.*, 1999). In the practice of working with dense maps we often place them on top of markers. We perform a genome scan by moving a QTL along the chromosomes while using a pre-identified set of markers as cofactors (Jansen, 1992; 1993b; Zeng, 1994). Or, in other words, for the sparse map case, we combine IM with multiple regression on markers. Stam (1991), and later Rodolphe and Lefort (1993) and Zeng (1993), demonstrated that in regression the effect of a QTL is absorbed only by its flanking cofactors, at least if progeny size is large. So, suppose we test for the presence of a QTL at a certain map position with a cofactor at some distance on the left and one on the right-hand side of the QTL. The test is now asymptotically unaffected by any QTLs located to the left of the left cofactor and to the right of the right cofactor (Stam, 1991).

Let us first pay some attention to what is known about setting the genome-wide significance threshold. Zeng (1994) studied the sparse map case and proposed to use all markers as cofactors, except the ones flanking the interval under study. Thus, the

model for the ith individual in a DH population is

$$y_i = \mu + \sum_{j=1}^{M} x_{ij}\beta_j + x_{i0}\beta_0 + \varepsilon_i,$$

where summation is over M marker cofactors not flanking the interval under study, x_{ij} are 0–1 indicator variables and β_j are substitution effects for the jth marker cofactor ($j = 1, \ldots, M$), or for the QTL ($j = 0$). Zeng (1994) used ML and called the method *composite interval mapping*. Simulation work with BC populations demonstrated that $\chi^2_{\alpha/M}(2)$ can be used as an upper bound for the $100\alpha\%$ genome-wide threshold on a genome with M marker intervals, unless the number of parameters is too large (Zeng, 1994; see his Figure 1). The $\chi^2_{\alpha/M}(2)$ relation does not hold if the number of parameters exceeds $2\sqrt{}$(number of observations) (Jansen and Stam, 1994). With the analysis-of-deviance approach (Jansen and Stam, 1994), however, there is no limitation on the number of parameters and $2F_{a/M}$ (2, df) can be used as an upper bound, where df are the degrees of freedom for estimating the residual error variance.

Although attractive in properly disentangling the effects of multiple (linked) QTLs, the precision mapping approach has some serious drawbacks. Suppose there is a QTL located in the interval currently under study. What can happen? First, any linked cofactor in the (wide) neighbourhood of our testing position will absorb at least part of the effect of the QTL, because we use conditional tests. Second, in models with many cofactors it is even likely that a linear combination of unlinked cofactors explains a considerable part of the variation of our QTL (Jansen, 1994b). Third, the genome-wide threshold is a function of the number of intervals M, which means that the significance threshold increases with the number of cofactors. Putting the pieces together, the conclusion is that with too many cofactors we will simply end up with high precision (we will make no type 1 errors), but no power (we will miss most QTLs). In a later paper Kao *et al.* (1999) proposed an alternative version of CIM, which they called *multiple-interval mapping* (MIM), and which included a stepwise selection phase. Such strategies will be discussed in more detail in the next subsection.

18.4.4 Multiple-QTL Mapping

Parsimony of parameters is one of the basic paradigms in statistics. A parsimonious model does not include parameters which are unnecessary or which (even worse) decrease the chance (power) of reaching our goals (Draper and Smith, 1981; McCullagh and Nelder, 1989). In our context, we do not want the model to include cofactors in regions where there are no QTLs. There is no unique best statistical method for finding the 'important' cofactors, but there are several good and general criteria, penalising the use of extra parameters (e.g. Akaike's information criterion (AIC)). But selection of a useful set of cofactors from a large set of possible cofactors to form a parsimonious model is a non-trivial task with both statistical and computational problems. Below we will discuss forward selection, backward elimination and stepwise regression. We think that selection is the most important step in QTL analysis. Subsequent to cofactor selection, we perform a genome scan by moving a QTL along the chromosomes while using a preselected set of markers as cofactors (Jansen, 1993b; 1994b; Jansen and Stam, 1994). If the moving QTL gets close to a cofactor, say within a preset window of 10 or 20 cM, then we drop
Figure 18.4 QTL likelihood (deviance) profile obtained with MQM mapping for the case of two linked QTLs. Marks below the *x* axis indicate positions of markers along the chromosome under study. Triangles indicate positions of selected cofactors. Different tests for the presence of a QTL are performed in regions indicated by '1', '2' and '3', respectively. In region '1' the test is conditional on the cofactors at 36 and 76 cM. In region '2' it is conditional on the cofactor at 76 cM, and in region '3' it is conditional on the cofactor at 36 cM. Regions '2' and '3' are chosen (i) symmetrically around their respective cofactor, and (ii) wide enough to span their respective 2*LOD* support interval for the QTL (support intervals not shown). The genome-wide significance threshold is ∼14.

the cofactor (Figure 18.4). This approach is called *multiple-QTL mapping*. Zeng (1994) also suggested the use of a thinned set of cofactors (e.g. via stepwise regression), and elaborated on it in detail in Kao *et al.* (1999).

We mentioned three selection strategies: forward, backward and stepwise. In the forward selection approach, at each stage the best new cofactor satisfying the selection criterion is added until no further candidates remain. This approach is often used in QTL analysis, on top of the IM approach. Once we have found one or more QTLs with IM, we add them to our model and rerun the genome scan. Although a natural procedure, we do not recommend it for two reasons. First, because we do not avoid the traps described above for the single-QTL analysis. Second, the approach does not exploit power to the full: each test is based on the ratio between variance explained by the factor under study and the unexplained variance. In a forward selection approach unexplained variance contains environmental plus as yet unexplained genetic variance, which decreases power relative to a backward elimination procedure.

The backward elimination procedure starts with a multiple regression model, using a full set of cofactors (putative QTLs/markers) evenly spread over the genome. The unimportant or least important cofactors are dropped one by one until all remaining cofactors are essential given the selection criterion. This is a satisfactory approach, especially if we wish to see all the variables in the model in order 'not to miss any QTL'. The full model gives an unbiased estimate of the maximum amount of variance explainable by (non-interacting) cofactors (QTLs). In order to exclude redundant cofactors, the selection criterion should be stringent, but not so stringent that important cofactors (those flanking the QTLs) are

thereby excluded. We can use one of the two approaches that we described above: the ML approach (Jansen, 1993b; Zeng, 1994; Kao *et al.*, 1999) or the analysis-of-deviance approach (Jansen and Stam, 1994; Jansen, 1994b).

For the ML approach, Jansen (1993b) proposed to maximise the log likelihood (l) minus the number of free parameters (k) in the model; this is equivalent to minimising AIC, given by $-2(l - k)$. In general, a penalty in the range of k to $3k$ may provide plausible initial models (McCullagh and Nelder, 1989). In 'ordinary' regression with adequate df to estimate σ^2, a penalty of k is equivalent to the use of (about) the 16 % point of the F test for the comparison of two nested models, which differ only by the inclusion of one free parameter; a penalty of $3k$ is equivalent to the use of (about) the 2 % point (McCullagh and Nelder, 1989). Note that we can also compare *non-nested* models by using the AIC. And we can even compare several models fitted on different scales, having multiplied $f_{\mathrm{mix}}(T(\cdot))$ by its Jacobian $T'(\cdot)$. Finally, we recall here that there are two disadvantageous features of the ML approach. First, the number of parameters should remain relatively small – less than $2\sqrt{(\text{number of observations})}$. Second, there is the danger of overfitting and thereby underestimating the error variance.

In the analysis-of-deviance approach, one can use partial F-tests conditional on the other cofactors in the current model. Note that the same approach is valid for regression mapping (Haley and Knott, 1992; Martinez and Curnow, 1992). The partial F-test values are calculated for each cofactor. The cofactor with the lowest partial F-test value is removed if its effect is less significant than a preset significance level. This process is repeated until all remaining cofactors have a partial F-test value exceeding the threshold. Jansen (1994b) used a 2 % threshold in simulations. It was demonstrated that this penalty is stringent, since no or only a few cofactors are generally selected in the case of no QTLs segregating. Moreover, it was shown that this penalty is still not too stringent, since cofactors are selected for those QTLs that considerably affect the test statistic in their nearby region; the effects of such QTLs are satisfactorily eliminated by selected cofactors. Because of this feature, the IM thresholds, which were obtained for the case that no QTLs are segregating, are also suitable for MQM mapping. These thresholds can be used when no QTLs are segregating, since in that case no or only a few cofactors will be selected; moreover, these thresholds can still be used when there are QTLs segregating, the effects of which are eliminated by cofactors. Detection and unravelling of the separate QTL effects in the case of linked loci is much easier in MQM mapping than in IM (Jansen, 1994b).

One of the disadvantages of the backward elimination procedure is that for a cofactor 'once out' means 'always out'. Backward elimination followed by a stepwise procedure, including new cofactors and dropping old ones, may help to overcome this – at the cost of more computation. Alternatively, replacing important cofactors by neighbours, not present in the initial set of cofactors, can also help in fine-tuning the model.

We emphasise one important difference between MQM, on the one hand, and IM and CIM, on the other hand, that arises because of MQM's use of a fixed residual error for both full and reduced models. Suppose we compare two nested models, in the simplest case a model with a QTL versus a model with no QTL. In regression mapping and MQM the *LR* test or the equivalent F test is based on the fit of the full model versus that of a reduced model with the residual error fixed at the value estimated from the full model. If the QTL has a major effect, then the no-QTL model will fit badly and the test score will be high. If the (putative) QTL has a minor or no effect, then the residual variance estimate of the full model is fully satisfactory for the no-QTL model. What happens in

CIM? The residual error variance in the no-QTL model is not fixed, but it is estimated and it will absorb the QTL variation. As a result the test score will not be as high as in the MQM and regression mapping approaches. A minor detail? Not really, because the effect on the test score can be considerable. For instance, in Figure 18.3 the test score is 50 for IM and 66 for MQM (the latter is not shown). Only one QTL was simulated on the whole genome. Thus in this case the difference between IM and MQM is solely due to the way the residual variance is treated.

18.4.5 Uncritical use of Model Selection Procedures

We would like to emphasise the following warning often posted in the statistical literature: *the uncritical use of the results of selection procedures can be very dangerous.* Here is one example of what can go wrong. Suppose we fit two cofactors, which are not far apart on the map; say that there is only one recombinant individual in a DH population. What can happen? The model for the ith individual is

$$y_i = \mu + x_{1i}\beta_1 + x_{2i}\beta_2 + \varepsilon_i,$$

where x_{ki} and β_{ki} are the 0–1 indicator variables and effect variables for the two closely linked cofactors, respectively. For all individuals but one, $x_{1i} = x_{2i}$, that is either

$$y_i = \mu + \varepsilon_i$$

or

$$y_i = \mu + \beta_1 + \beta_2 + \varepsilon_i$$

holds. In the latter case only the sum $\beta = \beta_1 + \beta_2$ is relevant. Suppose the single recombinant individual has $x_{1i} = 0$ and $x_{2i} = 1$, in which case

$$y_i = \mu + \beta_2 + \varepsilon_i.$$

For a given value of μ and β, we can obtain a perfect fit for the ith individual by setting

$$\beta_2 = y_i - \mu,$$
$$\beta_1 = \beta - \beta_2.$$

If there are no real QTLs in this region, then one would expect that $\beta = \beta_1 + \beta_2 = 0$. But we can still get large values $\beta_1 = -\beta_2$, which we might take as evidence for two linked QTLs with opposite effects. In some cases this may be true, but more frequently we probably just misinterpret what is actually no more than a statistical artefact. Other artificial patterns of near collinearity between sets of cofactors can arise. Moreover, any real data set will contain erroneous trait and marker scores (genotypic misscores, phenotypic outliers and so forth), for which our models may want to compensate for by an increase in the number of parameters. Several things can be done to avoid serious problems – on the biological and on the statistical side of the problem. First, make sure that the trait and marker data are very well checked! We prefer that labels U, C or D replace suspicious marker scores. Second, avoid simultaneous fitting of closely linked cofactors. For instance, in a DH population of 100 individuals we should make sure that simultaneously fitted cofactors stay at least 10–20 cM apart. If we do so, then there are 10–20 recombinants expected between any pair of cofactors. Third, we can set the

genome-wide significance threshold by an empirical (permutation or bootstrap) strategy, in which we mimic the complete selection protocol at each run. See also Piepho and Gauch (2001), Hwang and Nettleton (2002), Broman and Speed (2002), Jansen *et al.* (2002) and Bogdan *et al.* (2004) for further discussions about the best criterion for model selection (e.g. AIC or Bayesian information criterion). .

18.4.6   Final Comments

What if the trait is encoded by many QTLs, say 40, each of small effect? It will definitely be hard to decompose the phenotypic variation into the underlying QTL components. The number of recombinants is the limiting factor, and the only way out is to generate more of them by increasing the population size or by choosing another type of cross with more informative meioses. See Beavis (1996) and Visscher *et al.* (2000) for some illustrative examples of the hard job of dissecting polygenic variation.

Last but not least, we would like to state that the proof of the QTL pudding is not in the eating of the results from statistical QTL analysis. It is in the eating of results from cross-validation and/or new biological experiments.

18.5   BIBLIOGRAPHIC NOTES

18.5.1   Statistical Approaches

During the past two decades, a number of important papers have been published on QTL analysis with sparse marker maps. We list some of the early and most influential papers: Lander and Botstein (1989), in which the name 'interval mapping' was coined; Haley and Knott (1992) and Martinez and Curnow (1992), with the 'regression mapping' approach; Jansen (1992; 1993b; 1994b) and Jansen and Stam (1994), in which he general GLM framework for QTL analysis and the MQM approach was developed; Zeng (1993; 1994) and Kao *et al.* (1999), with CIM and MIM; and finally, Churchill and Doerge (1994) and Doerge and Churchill (1996), with the permutation test for setting the genome-wide significance threshold. There are various software packages available, for example, Map Manager, MapMaker/QTL, MapQTL, Multi-QTL, PlabQTL, QTL Cartographer, and MCQTL (further information can easily be found on the Worldwide Web). The textbook *Genetics and Analysis of Quantitative Traits* by Lynch and Walsh (1998) also provides a wealth of information for the interested reader. The book brings together basic biology and many methods of statistical analysis. From a statistical viewpoint, there is not much special to QTL modelling in inbred lines. If we look in our statistical toolbox, we will see, for instance, tools for interaction models, for mixed models with random and fixed effects, for multivariate instead of univariate analysis, and for Bayesian analysis. In this chapter, QTL analysis in inbred lines is accomplished by embedding it in a more or less standard statistical framework of GLMs. For general discussion of linear models, refer to the textbook *Applied Regression Analysis* by Draper and Smith (1981), and the textbook *Generalized Linear Models* by McCullagh and Nelder (1989). GLMs provide a unified analysis of diverse types of trait data (e.g. normal, binary, ordinal) via a simple approach of iterative reweighted least squares. Jansen (1993a; 1994a) embedded mixture models in the GLM framework, which is of prime importance to segregation analysis

and QTL analysis, where one deals with mixtures of different genotypes. For extensive rigorous statistical treatment of mixture models, we refer to the review by Redner and Walker (1984), the textbook by Titterington *et al.* (1985) and Dempster *et al.*'s (1977) paper on the EM algorithm. Here we have focused on QTL analysis in inbred lines for normally distributed traits; see, for instance, Hackett and Weller (1995) for QTL analysis in inbred lines with ordinal trait data and Visscher *et al.* (1996a) for QTL analysis with binary data. In most experiments, two or more traits are scored on the same individual. Jiang and Zeng (1995), Korol *et al.* (1995) and Lange and Whittaker (2001) are good entries for multitrait QTL analysis. For correlated traits, a higher resolution can be obtained by multitrait analysis than by separate univariate analyses. Bayesian modelling of mixtures with an unknown number of underlying components has made enormous progress (Richardson and Green, 1997) and is beginning to have an impact on various applications, including genetics. Undoubtedly, the popularity is largely due to the (MCMC) algorithms that enable the estimation of complex genetic models. Bayesian methods are particularly good for missing data augmentation (which we have emphasised here for the EM and MCEM algorithm). With ultradense maps, we can obtain nearly complete data, and the use of Bayesian methods in the relatively simple case of inbred line genetics is perhaps overkill. However, we have seen that model selection – how many QTLs and on which map positions – is still a hard problem, and Bayesian methods are becoming more prominent in this regard. We refer to Green (1995), certainly one of the pioneering papers on Bayesian model selection. Satagopan *et al.* (1996) described the first Bayesian method for inbred line crosses. In their approach, models with different (fixed) numbers of QTLs were compared via Bayes factors (similar to the LR test). Sillanpää and Arjas (1998) allowed for a variable number of linked QTLs on the chromosome under study. The effects of unlinked QTLs were taken into account by fixed preselected cofactors (as in CIM and MQM). Stephens and Fisch (1998) allowed for a variable number of linked and unlinked QTLs. See Boer *et al.* (2002) for a semi-Bayesian and Xu (2003) and Ter Braak *et al.* (2005) for Bayesian methods, estimating polygenic QTL effects with the aid of all markers of the entire genome. There is much more to be said about the potential of Bayesian methodology, and we refer the interested reader to **Chapters 19** and **20** for further details.

18.5.2   Learning More about Important Genetic Parameters

The advent of the molecular markers and the development of statistical QTL tools have opened up new ways for studying the complexity of traits in more detail. Several issues are of prime importance to plant breeders, mouse geneticists and others studying inbred line crosses: how do the genes talk to each other (interaction between QTLs)? are they influenced by the environment (interaction between QTL and environment)? and are QTL findings consistent across multiple crosses (interaction between QTL and genetic background)? Here we list a number of key papers. QTL by QTL epistatic interaction is the first important type of interaction. See, for instance, Chase *et al.* (1997), Fijneman *et al.* (1996), Kao *et al.* (1999), Carlborg *et al.* (2000) and Carlborg and Andersson (2002). One of the major obstacles with epistatic interactions is the increase in the number of parameters, which is generally not compensated by a similar increase in the population size. Jannink and Jansen (2001) developed a one-dimensional genome search strategy for detecting epistatic QTL in diallel crosses; by combining information from the different crosses, QTL of high interaction with genetic background can be identified in a first

step, and QTL by QTL interaction in a second step. Boer *et al.* (2002) developed a one-dimensional genome strategy for searching QTL by QTL interaction in a single population, bounding the dimension of the search via penalised likelihood methods. Yi *et al.* (2003) use Bayesian methodology and variable selection methods to develop strategies for searching for multiple QTLs with complex interaction patterns. QTL by environment interaction is the second important type of interaction. In breeding programs, this interaction needs to be characterised so that target QTLs can be effectively utilised in them. We refer to Jansen (1992), Jansen *et al.* (1995), Tinker and Mather (1995) and Jiang and Zeng (1995) for early work on QTL by environment. Wang *et al.* (1999) combine QTL by environment and additive QTL by QTL interaction and propose the use of fixed effect terms for the QTL, and random effect terms for cofactors and interactions. A wide range of models for 'traditional' genotype by environment interaction (GEI) had been developed in quantitative genetics, e.g. modelling the interaction as products of genotype sensitivities and environmental characterisations (e.g. van Eeuwijk *et al.*, 1996). These traditional models and the QTL models were later integrated by several authors e.g. Korol *et al.* (1998), Malosetti *et al.* (2004) and Piepho and Pillen (2004). The third important type of interaction is that between QTL and genetic background. In a single cross, inferences about QTLs and their estimated effects are limited to the particular cross. A breeder, however, usually produces many crosses instead of one. A multipopulation analysis would allow us to extend inferences across populations. Rebaï and Goffinet (1993) dealt with QTL analysis of diallel crosses between inbred lines, Xu (1998) with multiple unrelated families, and Liu and Zeng (2000) with diverse cross designs involving multiple inbred lines. Jansen *et al.* (2003) developed an approach based on haplotyped putative QTL alleles, where the haplotype information was recovered from the marker data. A similar approach was taken by Crepieux *et al.* (2004). Recent studies in mouse (Li *et al.*, 2005) and in maize (Blanc *et al.*, 2006) illustrate the potential benefits of analysing the different populations jointly: one can extract a lot more relevant QTL information from the whole than from the individual parts. We refer the readers to **Chapter 19** for a more general theory about QTL analysis in complex populations.

18.5.3 QTL Analysis in Inbred Lines on a Large Scale

We conclude by pointing out a booming field of application for QTL mapping: genetical genomics (Jansen and Nap, 2001). Recent biomolecular technologies allow for the high-throughput profiling of thousands of transcripts, proteins and/or metabolites. Costs have already dropped down to a level where it is possible to profile hundreds of individuals. A logical step – at least for a quantitative geneticist – is then to profiling segregation of populations. The abundance of each of thousands of genes, proteins and metabolites can be treated as a quantitative trait. Therefore, the statistical analysis tools described in this chapter are useful to map eQTLs underlying variation in expression of genes, pQTLs underlying variation in protein abundance, and mQTLs underlying variation in metabolite abundance. Running thousands of QTL analyses imposes new challenges, e.g. how to handle the dramatically increased problem of multiple testing that may lead to many false positive QTLs, or how to exploit the results of all these QTL analyses to narrow down organisms-level phenotypic QTLs to the genes and to reconstruct regulatory, developmental and metabolic pathways. Storey and Tibshirani (2003) proposed the 'q value' to control the false discovery rate (FDR). De la Fuente *et al.* (2004), Zhu *et al.* (2004) and Bing and Hoeschele (2005) have developed methods to uncover gene

regulatory networks in genetical genomics studies, from either expression profiles or QTL profiles. Schadt *et al.* (2003), Klose *et al.* (2003) and Keurentjes *et al.* (2006) reported the first detailed studies of eQTL, pQTL and mQTL in inbred line crosses, respectively. We refer the readers to Doerge (2002), Jansen (2003) and Rockman and Kruglyak (2006) for reviews, and to **Chapter 9** for more general theory about eQTL analysis of gene expression on a large scale.

Mapping Quantitative Trait Loci in Outbred Pedigrees

I. Höschele

Virginia Bioinformatics Institute and Department of Statistics, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

In this chapter, we present statistical methods for mapping quantitative-trait loci (QTLs) in outbred or complex pedigrees. Such pedigrees exist primarily in livestock populations, also in human populations, and occasionally in experimental animal or plant populations. The main focus of this chapter is on linkage mapping, but methods for linkage disequilibrium (LD) and combined linkage/LD mapping are also discussed. We describe least-squares and maximum likelihood (ML) methods for estimating QTL effects, and variance-components analysis by approximate (residual) ML for estimating QTL variance contributions. We describe Bayesian QTL mapping, its prior distributions and other distributional assumptions, its implementation via Markov chain Monte Carlo (MCMC) algorithms, its inferences, and contrast it with frequentist methodology. Genotype sampling algorithms using genotypic peeling, allelic peeling or descent graphs are described. Genotype samplers are a critical component of MCMC algorithms implementing ML and Bayesian analyses for complex pedigrees. Lastly, fine-mapping methods including chromosome dissection and LD mapping using current and historical recombinations, respectively, are outlined, and recently developed methods for joint LD and linkage mapping of disease genes and QTL are discussed.

19.1 INTRODUCTION

In this chapter, the focus is on statistical methods for mapping of quantitative-trait loci (QTLs) in populations which have not been formed recently by line crossing, and which have pedigree information available over multiple generations. Methods suitable for QTL mapping in (inbred) line crosses are described in **Chapter 18**. Pedigrees are used for QTL mapping in livestock and human populations, where the development and crossing of inbred lines is not feasible. Therefore, the methods discussed here have applications primarily in mapping genes for quantitative traits of economic importance in livestock and complex disease risk factors in humans. Examples include milk production in dairy

cattle and cholesterol measures in humans. Occasionally, complex pedigrees also arise in experimental animal populations and plants.

In outbred populations, which have not been formed recently, and for a moderate-resolution marker map (e.g. a 10 cM map), disequilibrium measures between markers and QTLs must be expected to be zero. For a moderate-resolution map, distances between QTLs and markers often exceed 1 cM, and therefore any disequilibrium resulting from an event in the not very recent history of a population will have eroded over time. As a consequence, QTL effects cannot be estimated across the population but rather must be estimated within parents, or phase-known QTL genotypes must be inferred for each parent. Consider a parent which is heterozygous at marker M with alleles M_1 and M_2. Suppose we have a large number of offspring from this parent (a half-sib design in cattle). Then if we compare the phenotypes of the two offspring groups inheriting the alternative marker alleles, we may find (1) that M_1 offspring have a higher average phenotype, (2) that M_2 offspring have a higher average phenotype or (3) that there is no detectable difference between the two offspring groups. If we assume that there is a biallelic QTL located near this marker, then in case (1) the allele increasing the phenotype is linked with the M_1 allele, while in (2) it is linked with M_2. In case (3), the parent is homozygous at the QTL. In several of the QTL mapping methods – maximum likelihood (ML), Bayesian – to be presented later, QTLs are often assumed to be biallelic. Although in outbred populations the number of QTL alleles is unknown and may exceed two, the assumption of a biallelic QTL is often invoked because it is difficult to infer the exact number of QTL alleles, and because it may be a good approximation. The latter conjecture results from the fact that a QTL must be detectable, and therefore must have at least one allele with an effect on phenotype clearly distinguishable from the effects of the other alleles. Other QTL mapping methods, such as least-squares (LS) or variance-components analyses, do not make any specific assumption about the number of QTL alleles.

The power of detecting a QTL is limited in outbred pedigrees by the degree of informativeness of the markers and of the QTL. The informativeness of a single marker is measured by its polymorphism information content (PIC) (Botstein *et al.*, 1980; Dekkers and Dentine, 1991; Hoeschele and Romano, 1993). PIC combines heterozygosity of parents with fraction of offspring for which the inheritance at a marker is known. Inheritance is unknown if an offspring has the same marker genotype as both of its parents, or as one of the parents with the other parent unknown. Moreover, these considerations apply to a single marker only. When using multiple linked markers, phases or haplotypes will be unknown and will have to be inferred. For example, a base or founder individual with observed genotype 12/45 at two linked markers ('/' separating the loci) may have phases $1 - 4/2 - 5$ or $1 - 5/2 - 4$ ('/' now separates haplotypes across loci); that is to say, the founder's haplotype pair is either $1 - 4$ and $2 - 5$ or $1 - 5$ and $2 - 4$. If an individual is a descendant, then we need to know not only phase but also parental origin of its haplotypes, i.e. its paternal and maternal haplotypes. These are known if the individual has a known, ordered genotype at each locus. A single-locus genotype is ordered if the parental origin of its two alleles is known (it is 12 (45) if 1 (4) was inherited from the father, or 21 (54) if 2 (5) was inherited from the father).

The degree of heterozygosity at a QTL is also influential in its detection. When the frequency of a detectable QTL allele is very low or very high, a pedigree is likely to contain only families which are not segregating for this allele, and hence the QTL will not be detected. On the other hand, with the additive variance at a biallelic QTL being

$2p(1 - p)a^2$ (p is allele frequency, a is substitution effect), the same amount of variance is explained with p near 0.5 and a smaller a value, and with p low or high and a larger a value, and this may improve the detection of a QTL due to the larger a effect.

When analyzing a pedigree consisting of multiple families, we have two options: (1) analyze each family separately; or (2) analyze all families jointly. Option (1) is not available when family size is small, as is the case in human populations. In certain livestock populations (dairy cattle), however, a single half-sib family may have several hundreds or even thousands of members. However, selecting just one or a few very large families may prevent us from detecting a QTL, unless this QTL happens to be segregating in these few families. Furthermore, analysis of single families limits sample size and hence power of QTL detection.

The complexity of statistical methods for QTL mapping in outbred populations depends on the structure of the population. For analysis of individual large families, or for joint analysis of a small number of such families and when ignoring genetic ties among families, simpler methods used for analysis of (inbred) line crosses (see **Chapter 18**) can be adapted quite easily, e.g. by choosing only informative markers and allowing for offspring with uncertain marker allelic inheritance. In contrast, multigenerational pedigrees, potentially with substantial amounts of missing data, require much more sophisticated methods of analysis.

19.2 LINKAGE MAPPING VIA LEAST SQUARES OR MAXIMUM LIKELIHOOD AND FIXED EFFECTS MODELS

19.2.1 Least Squares

In least-squares (LS) analysis, QTL allelic or genotypic effects are treated as fixed effects. Here we consider LS analysis for half-sib designs. Different markers will be informative in different families. However, different families can be analyzed jointly if a marker map and all-marker interval mapping are used, where a certain QTL position is evaluated in all families irrespective of where the flanking markers are located (i.e. different flanking markers may be selected in different families as the markers must be informative). For an analysis across half-sib families, the following linear regression models have been employed (see also Knott *et al.*, 1994):

$$y_{ij} = \mu_i + p_{ij}\alpha_{i1} + (1 - p_{ij})\alpha_{i2} + e_{ij} = \mu_i^* + p_{ij}\alpha_i + e_{ij}, \qquad e_{ij} \sim \text{iid}N(0, \sigma_e^2),$$
(19.1)

where

$$\alpha_{ik} = \sum_m q_m \mu_{ik,m} \quad \text{for} \quad k = 1, 2; \qquad \alpha_i = \alpha_{i1} - \alpha_{i2}; \qquad \mu_i^* = \mu_i + \alpha_{i2},$$

in which α_{ik} is the additive effect of allele k ($k = 1, 2$) in parent i, $\mu_{ik,m}$ is the expected phenotypic deviation of individuals with genotype $Q_{ik}Q_m$, q_m is the population frequency of allele m, p_{ij} is the probability that offspring j of parent i inherited QTL allele 1 given the marker information or $p_{ij} = E(x_{ij}|\mathbf{M}_{\text{obs}})$ with $x_{ij} = 1$ (0) if $Q_{i1}(Q_{i2})$ was inherited,
