Any untoward alteration of the population of an animal species in a deciduous forest has a ripple effect which profoundly alters the sum of relationships that, taken together, lead to forest continuity of identity. For example, decreasing numbers of wolves in deciduous forests due to their hunting by humans has damaged food webs in forests, where their predation helped to prevent overpopulation of herbivores such as deer. Deer overpopulation, in turn, caused overgrazing of many forest areas, followed by starvation of the excessive number of deer. The overgrazing also has damaged the lives of many other plant and animal species because of the lack of the ability of such forests to provide for their needs. Thus it is crucial to assure that appropriate numbers of all plants and animals inhabit deciduous forests by suitable monitoring and conservation measures, if it is desired to maintain them in their primal states.

FOSSILS

Types of animal science: Classification, evolution
Fields of study: Evolutionary science, paleontology, systematics (taxonomy)

Fossils are the preserved remains of once-living organisms or the traces left by biological activity. They provide a record of the development of life through time and are used extensively in evolutionary studies as well as in the dating of rocks and the interpretation of past environments.

Principal Terms

BIOSTRATIGRAPHY: the dating of rocks using fossils
CAMBRIAN: the period of time between 544 and 505 million years ago
ICHNOLOGY: the study of trace fossils
PALEONTOLOGISTS: scientists who study fossils
TAPHONOMY: the study of the processes that lead to fossilisation
ZONE FOSSILS: fossils that characterize a period of time and can be used to provide a relative date for a rock

Fossils are now recognized as the remains of once-living organisms; however, in the past the term was not so restricted and included anything dug out of the ground (Latin *fossilis*, "to dig up"). Thus minerals, gems, and archaeological remains were all included as fossils. The record of fossils goes back 3.4 billion years to preserved single-celled organisms such as bacteria and blue-green algae. Complex organisms or metazoans did not appear until about 700 million years ago, and hard parts were not preserved until about 544 million years ago, at the base of the Cambrian when there was a tremendous development of organisms often called the Cambrian Explosion. Since then, a diverse assemblage of fossil organisms is available for study by paleontologists.

Recognition of Fossils

Early ideas about the source of fossils were that they were the remains of mythical animals or that they had grown in the rocks like crystals. Aristotle suggested that the fossils of fish were the remains of sea animals that had swum into cracks in the rocks and become stranded, while others thought that they developed from seeds or grew from fish spawn washed into cracks during Noah's Flood. These ideas remained an important influence until the Renaissance, when Leonardo da Vinci recognized that fossil shells in the Apennines represented ancient marine life, and Nicolaus Steno in the mid 1600's showed that "tongue stones," thought to be the petrified tongues of dragons, were actually ancient shark teeth. At about the same time that Steno was writing, the British scientist Robert Hooke studied and described fossils and used early microscopes to study their cellular structure. However, their ideas were slow to become accepted, and it was not until the mid 1700's that naturalistic concepts of fossils began to prevail; when Linnaeus published his classification of all organisms, the *Systema Naturae* (1735; *A General System of Nature*, 1800-1801), fossils were treated as living organisms. By 1800, Baron Georges Cuvier was able to apply comparative anatomy to fossil organisms, both showing their relation to modern organisms and arguing that they must represent extinct animals, as they had not been found living on even the most remote continents. Prior to this, the fact of extinction was not accepted, as it went against the view that

God would not allow any of his creations to become extinct. Cuvier also recognized that fossils occur in a regular succession and can thus be used to date the sediments in which they are found. At about the same time, this fact was also recognized by William Smith in England, who developed it to the point that he was able to produce geological maps of England and Wales in 1815. This was the basis of dating and mapping rocks, and by the time of the publication of Charles Darwin's *On the Origin of Species* in 1859, the understanding of the fossil record had reached the point where few scholars took biblical ideas about the history and evolution of life literally.

Fossilization

Fossilization is a rare occurrence, and it has been estimated that of the more than one million living species, only 10 percent are likely to be preserved as fossils. A single square meter of seafloor could, during a few million years, produce enough sea shells to swamp the museums of the world if they were all preserved. It must be appreciated, therefore, that the fossil record is selective and thus may be incomplete and biased. This is because some organisms with hard parts, such as shells or skeletons, tend to fossilize readily, and therefore much is known about their past. Others are soft-bodied and rarely if ever fossilize, so their fossil record is minimal. The study of how organisms become fossils, the study of death and decay, is called taphonomy. This is now an important area of paleontology, because to understand and interpret the fossil record it is necessary to understand the processes that have resulted in fossilization. Once an organism dies, its remains are subject to

Image Not Available

decay and perhaps transport and mechanical breakdown before they are buried. The more of that lost information that can be reconstructed, the more reliable the final hypothesis about the original community will be.

Preservation is dependent on a number of factors, of which the most important are the composition and structure of the organism, its abundance, the sedimentary environment in which it lives, and the postdepositional changes that occur. All organisms are composed of delicate tissues, known as soft parts, but many also have more resistant tissues, referred to as hard parts. The hard parts may be mineralized, as in the shell of bivalves, or composed of organic material, such as the chitin that makes up the exoskeleton of arthropods. Although in general the possession of mineralized hard parts is a prerequisite for fossilization, soft-part preservation can occur, and some fossil groups have only organic soft parts.

In a few exceptional cases, organisms are preserved entire, and this results from unusual preservational circumstances. Woolly mammoths have been preserved by freeze-drying, so that their soft tissues and even their last meals are preserved, and humans have been found completely preserved in peat bogs. Preservation in amber occurs when small organisms are trapped by tree resin that subsequently hardens around them, and in some cases the preservation is so good that original biomolecules can be extracted and deoxyribonucleic acid (DNA) sequencing carried out. Although this was the premise of the film *Jurassic Park* (1993), it is clear that the genetic material is so incomplete that it will never be possible to reconstruct a complete organism in this way.

In most cases, the soft tissue has been lost and some change has taken place to the hard tissues during the process of fossilization. Permineralization is the process by which the natural pores in wood, bone, or shell are filled with minerals by groundwater that percolates through them in the sediment. In this case, none of the original material is lost, and even in petrified wood there is still some of the original material, although the logs have been completely permeated by silica. Only part of the original material is preserved in carbonization, a process in which most of the volatile organic materials disperse, leaving a black carbon film. This may result in exceptional preservation in insects, for instance, or ichthyosaurs (marine reptiles) in which the outline of the body is preserved as a carbon film. More frequently, the hard tissues are recrystallized or are replaced by some other mineral. Recrystallization results in the loss of internal detail, and the same is true of replacement, as in both cases none of the detailed structure is left. However, replacement by more resistant minerals, such as the replacement of a calcite shell by silica, can improve the survival potential of a fossil and preserve delicate structures, such as spines, that might otherwise be lost.

Preservation Potential

The preservation potential of an organism is affected by a number of factors that operate at different stages in the process of fossilization. Necrolysis, or the breakup and decay of an organism after death, reduces the potential for preservation of all but the most resistant organisms, and it has been estimated that only 20 to 30 percent of shallow marine organisms are likely to be preserved. The numerical abundance of organisms is generally considered to be important as, all other things being equal, abundant organisms would seem to be more likely to be preserved than rare ones. However, in a number of cases this has been shown not to be true, and this differential preservation is often related to the preservability of the hard tissues. Mobile organisms tend to have lighter and less durable skeletons that would be more easily destroyed than those of static animals such as corals, in which the skeleton is formed of a solid mass of calcite.

A number of agents may operate to destroy even resistant skeletons. Biological agents include scavengers, which may break up shells and bones to extract nutrition, and burrowing organisms, which may use the hard tissues as a substrate and thus weaken them. Mechanical agents such as wind, waves, and currents can also be very effective, particularly in shallow environments where

Lagerstätten

Although generally only a small proportion of organisms become fossilized, there are a number of examples in the fossil record in which there are unusual concentrations of fossils or in which the fossils are remarkably well preserved. These are termed "fossil *Lagerstätten*," a term that derives from the German mining tradition in which *Lagerstätte* are rocks containing constituents of economic interest. These exceptional fossil occurrences are separated into concentration *Lagerstätten*, in which there are uncommon concentrations of fossils, although their preservation may be unremarkable, and conservation *Lagerstätten*, in which the individual quality of preservation is unusual. Concentration deposits often occur in situations in which fossils have been preserved initially in an unconsolidated sediment and then eroded and redeposited together with more recent material. Conservation deposits include some of the most celebrated and famous fossil occurrences, including the Late Jurassic Solnhofen Limestone in Germany, which has yielded fossils of *Archaeopteryx*, the earliest known bird, and the Burgess Shale in the Canadian Rockies, which provides a window on the development of organisms during the Cambrian, 530 million years ago. In the Burgess Shale, the organisms were transported from a carbonate bank area into deep, anoxic waters by submarine landslides, where they were buried in fine muds and thus protected from decay. This has resulted in the preservation of soft-bodied organisms as well as those with hard parts, and has provided evidence for the presence of many unique and sometimes bizarre animals that would otherwise be completely unknown. Although most of these fossils can be assigned to existing phyla, many are considered to be evolutionary experiments that did not survive into later periods, thus demonstrating that there was a great deal of experimentation in body plans during the Cambrian, most of which did not survive.

energy is highest. Experiments in which shells were tumbled with pebbles have shown that thin-shelled organisms break up quickly, while thicker shells last longer. Similar studies for terrestrial vertebrates have shown that the least durable parts of a skeleton are the ribs and vertebrae, while the skull, jaws, and particularly the teeth are the most resistant to breakdown. In general, it appears that the shape, density, and thickness of the bone or shell are the most important factors in determining its survival during mechanical transport.

Many apparently unfossiliferous rocks may have had fossils at one time but lost them during the changes that take place in sediments after deposition. Many snails and bivalves have shells composed of the unstable form of calcite called aragonite, and this may dissolve early, leaving no trace of the fossil, while other organisms composed of more stable calcite will not be dissolved. In these cases, therefore, the representation of the original community will be biased more by the chemical composition of shells than by their mechanical durability or by their relative abundance.

Trace Fossils

Trace fossils (or ichnofossils, from the Greek *ichnos*, "track") are sedimentary structures created by organisms and, therefore, reflect their behavior. They include tracks, trails, burrows, and borings and may occur in sediments that contain no body fossils, thus providing the only record of life and certainly the only record of soft-bodied organisms that are not normally preserved. One important aspect of trace fossils is that they are almost always preserved in place, as reworking would result in their destruction, and thus they can always be directly related to the sediments in which they are found. Because of this, trace fossils are particularly important in understanding and reconstructing paleoenvironments.

Trace fossils are difficult to classify, as they represent behavior rather than the remains of an animal. They are also difficult to relate to the animal that formed them, as traces are rarely found with the organism that made them, different organisms may form similar traces, and the same organism may form a variety of different traces in different circumstances. Because of these problems, traces are organized within behavioral categories, including dwelling structures made by organisms that feed outside their burrows; mining structures that are formed by animals feeding in the sediment; grazing traces made by animals feeding across a surface; locomotion traces formed by animals during travel; and resting traces formed by an animal during a temporary stop. Thus, dinosaur tracks would come within the locomotion category and the burrow of a filter-feeding worm would be recognized as a dwelling structure.

Understanding the behavioral genesis of trace fossils has enabled their use in reconstructing past environments. They are grouped in recurrent ichnofacies (traces reflecting a particular environment), and these are in turn linked to a set of environmental parameters, such as salinity, light level, and temperature, that are generally correlated with depth. This approach has been particularly valuable in recognizing shallow marine facies and has the advantage of being independent of time, as particular environments and, therefore, behavior persist through time, although the trace formers themselves may change.

The study of marine traces is relatively recent; however, terrestrial traces have been studied for much longer, as the first dinosaur tracks were reported in 1802, although they were misidentified as bird tracks at that time. Terrestrial trackways can give a considerable amount of information about the locomotion and behavior of the trace former, and can lead to quite precise information about speed, as well as insights into posture, activity levels, and metabolism. Relative speed is related to the length of the leg and the stride length (the distance between one foot impression and the next by the same foot). Hip height (calculated from foot length) is divided into the stride length (measured from the trackway) to give a proportional estimate of the speed. At 2.0 an animal moves from walking to trotting, and above 2.9 it is running, information that has been used in studies of dinosaur locomotion. In addition, the fact that trackways show dinosaurs moving together in herds has been used to suggest a level of social organization greater than that demonstrated by any modern reptiles.

Fossils and Time

In geology, both relative time and measured time are recognized. Measured time is obtained from the decay rates of certain radioactive minerals in rocks and gives a date in years. Relative time refers only to the sequence of strata, showing that some beds are older or younger than others. Although the relative age of rocks can be obtained from their sequence, as those lower in the sequence are older and those higher in the sequence are younger, the lithology of the rocks cannot be carried laterally, because sedimentary environments change over distance. This problem was resolved in the late 1700's in England by William Smith, who recognized that there was a sequence to the fossils in the sedimentary record and that this could be used to characterize the rocks and correlate them to each other over a distance. This recognition of "faunal succession," which represents the successive preservation of organisms as they evolved through time, has been extremely important in the development of the study of biostratigraphy, in which fossils are used to provide dates for rocks. In this system, the basic unit is the zone, which is represented by zone or index fossils that characterize a period of time. The potential of different organisms as zone fossils will vary, and to be most useful they should embody certain characteristics. They must have a high preservation potential, be relatively common, and also be distinctive, so that accurate identification is possible. They must also have a wide lateral distribution but a short vertical range, so that they characterize a short time period over a wide area. It is also helpful if they are independent of environment. Because of this and because most sediments are marine in origin, the organisms used are often planktonic, that is, they float near the surface of the ocean but will be preserved in various sedimentary environments when they die. Microfossils, such as spores and pollen, are very useful because they are wind-borne and thus may be found in both terrestrial and aquatic environments.

FOXES

Type of animal science: Classification
Fields of study: Anatomy, ecology, evolutionary science, physiology, reproduction science, systematics (taxonomy), wildlife ecology, zoology

There are approximately twenty-one species of fox, in the order Carnivora. Foxes constitute only 0.5 percent of the four thousand mammalian species, but play a very important role in the environment.

Principal Terms

CANID: doglike in appearance
ESTRUS: the period of maximum sexual receptivity
TEMPERATE: moderate with respect to temperature
TERRITORY: the area of land that an animal defends against intruders
VIXEN: a female fox

The fox is a canid, related to coyotes, jackals, and wolves. The fox is the smallest member of the dog family. It is also the most numerous and widespread carnivore in the world. Although primarily carnivorous, foxes will also eat fruits and grains. Foxes hold territories, the size of which depends on habitat. A dog fox, a vixen, and their cubs occupy each territory. A differing number of chromosomes eliminate the possibility of foxes interbreeding with other canids.

Fox populations fluctuate along with the population cycles of their prey. In many cases, availability of dens and secure sites for hiding will also play an important role in population size. Foxes have few natural predators. However, in mountainous regions, coyotes and cougars will sometimes attack foxes. In arid lands, wild dogs, large cats, and hyenas are problematic, and will often compete with foxes for food. In arctic regions, the wolf can also be a dangerous competitor.

Foxes appear to have characteristics of both dogs and cats. Some of their catlike characteristics include vertical slit eyes, partially retractable claws, light body weight, and a stalking and pouncing style of hunting. Foxes are also good tree climbers. Fox coloration varies among black, red, silver, silver-gray and white.

The Life Cycle of Foxes

During December and January, vixens leave scent marks that tell the male fox she is in estrus. The dog will follow the marks until he finds her. The courtship is very short, since the vixen is only fertile for about one week each year. Litter sizes are normally one to six. The dog fox helps the vixen

Fox Facts

Classification:
Kingdom: Animalia
Subkingdom: Deuterostomia
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Eutheria
Order: Carnivora
Family: Canidae
Genus: Vulpes, with twelve species
Geographical location: All continents except Antarctica
Habitat: Temperate climates, although some live in desert and Arctic regions; generally next to water, meadows, and forests
Gestational period: Fifty to sixty days
Life span: Up to six years in the wild; up to thirteen years in captivity
Special anatomy: Pointy muzzles, large ears, long thin bodies, long legs, long bushy tails

Foxes are territorial and will drive off outsiders who intrude on their range. (Corbis)

raise the cubs during the first two months. For the first month or so, the vixen depends entirely on the dog fox to bring her food. In the first two weeks, the cubs are unable to see or hear anything. They are fed by the mother's milk. The fur is short and black. After three weeks, the fur will slowly turn dark brown on the head, and gray on the body. The teeth break through the gum, and the cub starts to chew on anything. Soon the cub starts to show the first signs of social behavior, and the first fights are fought between the siblings. After four weeks, the cubs start exploring the world outside the den for the first time. Later, they start to follow their mother when she goes hunting. In the summer, the young foxes get more and more independent from the mother fox. After about three months, the dog fox will go back to his solitary lifestyle, but he will try to find the same vixen again when the mating season comes back. In the fall, the young foxes come into puberty and become sexually mature. It is then that the vixen begins to force the cubs out of the den.

Destructive and Beneficial Foxes

Foxes may cause serious problems for farmers. Losses may be heavy in small farm flocks of chickens, ducks, and geese. Damage by foxes can be difficult to detect because the prey is usually carried from the kill site to a den, or uneaten parts are buried. Foxes will also scavenge carcasses, making the actual cause of death difficult to determine.

Like other scavengers, foxes will clean up carcasses, or kill dying or weak animals for food. In this manner they are a major contributor to the processes of natural selection.

FROGS AND TOADS

Types of animal science: Anatomy, classification
Fields of study: Anatomy, conservation biology, herpetology, systematics (taxonomy)

The more than four thousand living species of frogs and toads are classified in the order Anura. Most species have a biphasic life cycle, in which a larval stage, the tadpole, develops in water (or land, in some species) and undergoes an abrupt metamorphosis into the adult body form.

Principal Terms

EXTERNAL FERTILIZATION: the union of eggs and sperm in the environment, rather than in the female's body

GRANULAR GLANDS: one of many kinds of glands in the skin of frogs and toads; granular glands secrete toxins for defense from predators

METAMORPHOSIS: an abrupt change from a larval body form, accompanied by many physiological changes, into an adult body form

REPRODUCTIVE MODE: a combination of life-history characteristics, including egg-deposition site and type of parental care

TADPOLE: the larval stage of frogs and toads

Frogs and toads, the Anura, are amphibians, a group of vertebrates that first evolved in the Devonian era, about 400 million years ago. Two other groups of amphibians are the Caudata, salamanders and newts, and the Gymnophiona, caecilians. More than four thousand species of frogs and toads currently inhabit the planet. In contrast, about 400 species of salamanders and newts and 165 species of caecilians are extant. Frogs and toads thus account for approximately 88 percent of all living amphibians.

Amphibians have many unique characteristics that separate them from other vertebrates. In terms of skeletal features, the skull articulates with the vertebral column by a specialized vertebra called the atlas, and ribs are lacking in most frogs and toads. Many amphibians have a two-phase life history, an aquatic larval stage and a terrestrial adult stage, although some species may be entirely terrestrial or entirely aquatic. Amphibian skin is unlike that of other vertebrates in that it is glandular and lacks scales, feathers, or hair. Respiration is by means of the skin, which is porous, freely permitting the exchange of oxygen and carbon dioxide, with gills in aquatic larvae and adults, and lungs in terrestrial species.

Scientists classify frogs and toads into twenty-five families. Although the terms "frog" and "toad" are commonly used, toads are simply a specialized group of frogs. The true toads are in the family Bufonidae. They are distinguished from other families by a number of osteological (bony) features, and they also typically have thick, glandular skin with wartlike pustules. Many species have large parotoid glands that produce toxic secretions located on the back of the head. In contrast, most frogs have smooth skin and no parotoid glands. Toads in the family Bufonidae can generally withstand drier conditions than frogs. Other kinds of frogs have common names that include the word "toad," such as spadefoot toads, which are in the family Pelobatidae, or narrow-mouth toads, which are in the family Microhylidae.

Anatomy of Adult Frogs and Toads

Frogs and toads are tailless amphibians. In general, they are small animals; the largest has a body length of about three hundred millimeters, whereas the smallest is under ten millimeters.

They have a truncated body with a greatly reduced number of vertebrae and elongated hindlimbs. The vertebrae in the lower part of the body are fused into a rodlike structure, which provides rigidity for their jumping mode of locomotion.

Two types of glands are present in the skin of all adult amphibians: mucous and granular. Mucous glands continuously secrete mucopolysaccharides, which function to keep the skin moist so that cutaneous respiration can occur. All amphibians, including frogs and toads, have granular or poison glands in their skin, and these glands produce a variety of toxic or noxious chemicals used for defense. The chemicals are broadly classified into four major groups, of which alkaloids are one. The great majority of these chemicals are not harmful or deadly to humans, but they can be irritating. For example, if a secretion from one of the tree frogs found in the eastern United States is rubbed into the eyes, an intense burning sensation will be felt for a short time. If a frog or toad is grabbed by a predator, such as a bird or a snake, it may be quickly released because of the bad-tasting secretion. Some predators have evolved an immunity to the secretions, however, so frogs and toads are not free from predation.

Anatomy of Tadpoles

Frogs and toads are unique among amphibians in that the young, called tadpoles, are very different from adults in morphology and physiology. Tadpoles typically have a round, globular body, with a long tapering tail. After a period of time that varies from one to two weeks to several years, depending on species, the larval forms undergo metamorphosis and change into adult frogs. Many radical changes, initiated by the hormone thyroxin, occur during this period. The most obvious of these is the loss of the tail, which is gradually absorbed, and the growth of the limbs. The hindlimbs begin to develop early in the tadpole stage, but are held flat against the body and are not used until they are quite large. The front limbs develop at the same rate, but they are hidden beneath the operculum, a thin layer of skin that covers the gills. At metamorphosis, as the tail is absorbed, the hindlimbs enlarge and the forelimbs break through the operculum.

The tadpoles of most species of frogs are herbivorous or detritivorous, and the digestive system consists of a long, coiled intestine. At transformation, the digestive system undergoes a radical modification,

Frog and Toad Facts

Classification:
Kingdom: Animalia
Phylum: Vertebrata
Class: Amphibia
Subclass: Lepospondyli
Order: Anura
Families: Twenty-five, including Ascaphidae (tailed frogs), Bufonidae (true toads), Centrolenidae (glass frogs), Dendrobatidae (poison frogs), Hylidae (treefrogs), Leptodactylidae (tropical frogs), Microhylidae (narrowmouth toads), Pelobatidae (spadefoot toads), Ranidae (true frogs)

Geographical location: Throughout the world, except for the Arctic, Antarctica, some oceanic islands, and some very dry deserts

Habitat: Many habitats, including forests, savannas, prairies, freshwater ponds and streams, and ephemeral pools

Gestational period: Varies among species; some toads and spadefoot toads have a tadpole stage that lasts only for ten days to two weeks; in other species, such as bullfrogs, the tadpole stage may last for three years; in many species, the tadpole stage extends for about two months

Life span: Varies among species; less than a year in many species to as much as six to thirty-six years in some species, particularly for individuals kept in captivity

Special anatomy: Truncated head and body with no neck; long back legs that facilitate jumping; tadpole anatomy, globose body with long tail, very different from adult body shape

Declines in frog populations may be linked to pollutants in the water where they live. (Adobe)

and the long, coiled intestine becomes greatly shortened and divided into a distinct esophagus, stomach, small intestine, and large intestine. The internal gills of the tadpole are lost, and the lungs become fully functional. In many species, the lungs begin to develop and become partially functional long before metamorphosis. Tadpoles of these species are frequently seen rising to the surface of the water to gulp air.

Tadpoles have unusual mouthparts, consisting of a fleshy disc surrounded by small papillae; the disc has rows of small "teeth" that are not the same as the teeth of the adult. The actual opening of the mouth is surrounded by beaklike structures that have sharp, serrated edges. The rows of teeth serve to anchor the disc, and the beak is used to scrape algae and other detritus from the substrate. The food is captured by strands of mucus in the mouth that carry it into the digestive tract. At metamorphosis, the tadpole's mouthparts are completely shed and the adult mouth develops.

Life History of Frogs and Toads

The life history of frogs and toads includes four stages: egg, larva, juvenile, and adult. Eggs consist of an egg cell supplied with yolk surrounded by a varying number of mucoid capsules. Because the eggs have no shells and are susceptible to drying out, they must remain in water or in a humid environment.

In temperate zones (nontropical areas), frogs and toads generally breed in the spring and summer when temperature and moisture conditions are suitable. Some, such as chorus frogs, spring peepers, and wood frogs, begin breeding very early, usually in February, while ponds are still covered with ice. Others, such as American toads and leopard frogs, breed later in the spring, and

Reproductive Modes of Frogs

Gladiator frogs are large treefrogs that construct nests in which eggs are deposited. Nests are made by males, who pivot around in soft sand or mud at the edge of a pond or stream to make a depression that fills with water. Eggs are deposited as a surface film in the nest.

Glass frogs deposit a small clutch of eggs on a leaf overhanging a small stream or river. When the eggs hatch, the tadpoles fall into the water below.

Leptodactylus frogs construct foam nests for their eggs. An amplexing male and female rotate their legs rapidly and secretions emitted with the eggs and sperm are whipped into a meringuelike froth. Eggs and tadpoles develop entirely within the foam; most predators cannot enter the sticky foam.

Poison frogs deposit their small clutches of eggs on land. The male (but sometimes the female) guards them. After the eggs hatch, the parent transports the tadpoles on his or her back to a small pool or stream where the tadpoles undergo the rest of their development.

Eleutherodactylus frogs deposit small clutches of eggs on land. Development of the egg to a small froglet occurs entirely within the egg capsule.

Gastric-brooding frogs swallow their eggs, and development of the tadpoles occurs in the mother's stomach. A chemical secreted by the developing tadpoles inhibits the production of gastric fluids so that the tadpoles are not digested.

still others, such as bullfrogs and cricket frogs, breed primarily in the summer months.

Most temperate-zone frogs migrate to ponds during rains to breed. Males arrive first and begin calling to attract females. Each species of frog and toad has a unique call, so it can be identified only by sound. Frogs make more than one kind of call. The most common calls, termed advertisement calls, are of three kinds: the courtship call, which is used to attract females; the territorial call, used in response to the call of a nearby male that may be intruding on the caller's territory; and the encounter call, used when two males in a breeding chorus are very close. The latter call may be accompanied by grappling or fighting between the two males.

Although female frogs do not make advertisement calls, those of some species (and males, too) can produce a very dramatic distress call when grabbed by a predator. This call is produced with the mouth wide open and is a very loud piercing scream. Some types of predators are startled by this call and will release the frog. Snakes, however, have no ears and do not seem to be affected by the distress call.

Frogs and toads have external fertilization. When a female approaches and nudges a calling male, he will climb atop her and clasp her with his arms behind her arms; this position is called amplexus. The pair floats in the water and simultaneously expels eggs and sperm in the water; thus, fertilization of the eggs occurs outside the female's body.

Eggs generally require several days to one week to hatch, depending on temperature and the species of frog or toad. After hatching, tadpoles of most species disperse throughout the pond to feed and grow. Tadpoles of some species, however, congregate together in schools, similar to fish. Many species of toads, for example, have small, black tadpoles that form tight schools in shallow water at the edges of ponds. Most tadpoles eat algae and other kinds of detritus that they scrape from the substrate of ponds or streams in which they live. A few kinds of tadpoles are predaceous and eat other tadpoles or mosquito larvae and other small aquatic insects. Tadpoles undergo a period of development and then metamorphose into the adult body shape.

Frogs and toads have evolved numerous ways of removing their eggs or tadpoles from aquatic situations, where, presumably, density of egg and tadpole predators is high. Scientists have identified thirty kinds of reproductive modes in frogs and toads, mostly in tropical species. Because tropical regions have high rainfall and warm temperatures, frogs can deposit their eggs on land without risk of desiccation.

Declining Amphibian Populations

Populations of frogs and toads in many parts of the world, even in pristine (undisturbed) locations, are declining and disappearing. The causes of these declines are numerous, and many scientists are now conducting research to determine the causes of the declines. Some of the causes are obvious. For example, habitat destruction is a major cause of loss of many animals and plants, not just amphibians. Most recently, frogs and toads of many species in rain forests in Central America and Australia are reported to have been killed by a type of fungus called a chytrid. The fungus normally infects decaying matter, so why it is now infecting frogs is not yet understood. One theory is that frogs are being stressed by some other environmental problem not yet identified; this stress may reduce the ability of their immune systems to fight disease.

Also being investigated as possible causes of frog population declines are the use of agricultural chemicals and pesticides, acid rain, ozone depletion leading to a rise in ultraviolet (UV-B) radiation, environmental estrogens, and introduction of fish that prey on eggs and tadpoles. It is possible that at any one location, one or several of these factors may be interacting.

FUR AND HAIR

Type of animal science: Anatomy
Fields of study: Physiology, zoology

Fur is the hairy covering of the skin of a mammal. This covering is called fur when its individual hairs are fine and spaced closely together; when the hair is soft, kinky, and matted together, it is called wool, which grows in a fleece, and when it consists of coarse, stiff hairs, it is called bristles, or when pointed, spines or quills. Its primary role is as protection, insulation, and ornamentation.

Principal Terms

CORTEX: the main part of a hair, made of pigment-containing cells, surrounding a central medulla

CUTICLE: the outermost layer of a hair, made of scales

EPIDERMIS: the dead, outermost portion of the skin

FOLLICLE: the saclike organ from which a hair grows; its blood vessels nourish the hair

KERATIN: a tough fibrous protein, seen in large quantities in epidermal structures such as hair

MEDULLA: the innermost layer of a hair

SHAFT: the main hair part, made of dead cells arranged in a complex fashion

The term fur is used in several ways. All are related to its being the hairy covering of the skin of a mammal. In its most common usage, fur is the dense, hairy body covering of a mammal. However, even the sparse hair covering on the arms and legs of humans may be viewed as fur, since it is the hairy covering of the skin of a mammal.

Each individual hair in a mammal is a threadlike epidermis outgrowth. Collectively, hairs form the body coverings (or pelage) of all mammals. Each hair is made mostly of a fibrous, sulfur-containing protein called keratin. The pelage is most correctly called fur when its individual hairs are fine and spaced closely together. In cases where the hair is soft, kinky, and matted together, the pelage is wool, which grows in a fleece. Coarse, stiff hairs are bristles, and when pointed (as in porcupines) they are spines or quills. Hair grows on most parts of the bodies of mammals. As their body covering, its primary role is as protection, insulation, and ornamentation, like bird feathers and reptile scales.

The Structure of a Hair

Any hair consists of two main parts, the root and the shaft. The shaft is the hair part outside of the skin. It contains the hair's unattached end. Hair shaft cross-sections range from round to flattened. Due to their composition, round and flat hairs are straight and curly, respectively. Hair shafts consist of dead epithelial cells, arranged in columns which surround a central medulla (or core), covered with flat scales. The scales—a hair's cuticle—overlap like roof shingles, but their free ends face upward, away from the hair's root. Beneath the cuticle is a second layer of dead cells, the cortex, which surrounds a central core made of yet other dead cells (the medulla).

The cortex, which makes up most of each hair, consists of many dead, longitudinally arranged, keratin-rich, spindle-shaped cells which are tightly attached to each other. Hair color results from pigments in cortex cells and light reflected from the medulla. The medulla is less dense than the cortex and its cells are only loosely attached to one another.

Wool and Woolens

Wool denotes soft, curly fleece fibers from domesticated sheep. It differs from hair in that its scales are more numerous, smaller, and pointy. Curliness makes wool very resilient. This high tensile strength and elasticity help wool fabrics to retain their shape. These properties, wool's lightness, and its fine insulating ability make wool fabrics desirable.

Wild sheep have sparse, woolly undercoats and coarse hair, useless in fabrics. The hair has been bred out in domestic breeds. Sheep fleeces are usually shorn annually, from late spring to early summer. The wool is cut off very close to the skin and removed in one piece, weighing nine to eleven pounds. Wool from different fleece parts varies in its fiber length, fineness, and structure. The shoulder and sides yield the best fibers. Merino sheep yield the best overall wool. It makes up 40 percent of all wool produced commercially. Crossbreeds of merino sheep and strains that produce longer, coarser wool yield most of the rest. Some apparel wool comes from alpacas, goats, and llamas.

Woolen cloth manufacture begins by pulling fleeces apart and choosing the best fibers for given uses. Next, fibers are cleaned to remove lanolin and dried-on sweat. The clean fibers are disentangled and drawn straight by carding, which entails passing them between rotating cylinders to yield a thin film or web. Web processing varies, depending on whether it will be used in tweed or worsted yarn. Tweeds, woven from bulky yarn made of short, randomly arranged fibers, are thick and fuzzy. Worsted fabrics such as gabardines are woven from web made of longer, thinner fibers, tightly twisted for smoothness.

At every hair's base is a saclike hair follicle. The hair grows from the bottom of the follicle, nourished by blood vessels in a structure called a papilla. The papilla extends into the follicle and into the hair's root. A tiny muscle is attached to each hair follicle. Action of the nervous system can cause the muscle to contract to make hair "stand on end."

Hair Growth and Replacement

A hair forms from cells that grow from the surface of the papilla, which means that it grows from the root, not the free end. As new cells develop, they push forward old ones, which become part of the shaft. Hair growth continues as long as follicle and papilla are functional. The lifetime of a hair from start of growth until it is shed depends upon the organism which produces it. When an old hair falls out a new one takes its place.

Hair follicles produce hairs in cycles of hair growth, in which the hair follicle and the shaft pass through a complex series of morphological changes. During hair growth, the follicle penetrates into the dermis, and cells of the shaft are joined together. In addition, the follicle's melanocyte cells deposit pigment into shaft cells. Once a hair shaft attains its characteristic length, the follicle contracts and a "dead" hair protrudes from it. The growth period of a single hair ranges from three years in humans to around two weeks in rodents.

Hairs are continually replaced, or shed, throughout the life of a mammal. However, their development and loss occur asynchronously, so mammals are never completely naked of pelage. In rodents, replacement is in waves, across the body. In primates, each follicle passes through the growth cycle, independent of those around it. Hormones control hair growth; however, there are other, as yet unknown components that must also affect the process, because hormones are carried in the blood, and if they acted alone they would simultaneously affect all follicles in the body. This would be disastrous, because if all follicles grew in together, at the same rate, all hairs would be shed at the same time. Then the mammal involved would have naked periods where it was deprived of hair's protection and insulation. Continuous growth of hairs can also be hazardous. For example, in merino sheep, long growth phases produce long-stranded wool. However, if these sheep strayed, were not minded well, or were sheared irregularly, they might starve to death from becoming entangled in underbrush.

Hair Origin and Function

Hair in the pelage of contemporary mammals acts mainly to insulate against temperature variation. It has been proposed that mammal hair evolved into pelage from "prehair" which had the same functions. One theory of hair origin is that it evolved from epidermal mechanoreceptors, a concept supported to some extent by the existence of sinus hairs in mammals. These hairs, whiskers (vibrissae) in mammals such as felines and rodents, have blood-filled sinuses in the skin around the follicle. This tissue, together with associated nerve fibers, engenders mechanoreception, which facilitates nocturnal movement. However, most mammal body hairs lack nerves and only insulate and protect. The basis for hair evolution from vibrissae is therefore unclear.

Certainly, mammalian hair has other functions today. For instance, it can serve the unusual protective function of the quills of porcupines, and perhaps it may more generally serve to attract mates. It seems possible that the change of prehairs into attractive pelage drove development into these main contemporary forms.

Protecting Endangered Fur-Bearers

The desire on the part of humans for fur garments has led to atrocities committed on many mammal species which have gorgeous pelage. One of many examples is clubbing young fur seals to death. Beyond that, many species have been hounded to near extinction by hunters. Classic examples of such endangered species are the big cats, such as

Domesticated sheep have been bred to produce the type of very soft, kinky hair called wool. (PhotoDisc)

The Unusual Porcupine

Porcupines, whose name derives from a French word meaning "spiny pig," are animals that possess very unusual hair coverings. Included in these coverings are quills, which are used for defense against predators. A coat of regular hairs serves the porcupine as thermal insulation.

An adult porcupine possesses between twenty-five thousand and thirty-five thousand quills. Each of the quills is actually a group of long, stiff hairs that have grown together very tightly. The quills range in length from three to eighteen inches, depending upon the porcupine species and the body positions of the quills. Quills have sharp barbs on their ends.

When a porcupine is attacked or otherwise disturbed, it arches its back and makes the quills stand up straight. Attacking predators are very likely to impale themselves painfully on the quills, which pull out of the porcupine's body quite easily. A porcupine can also swing its quill-filled tail at a predator. When the tail connects with the aggressor, quills enter the flesh of that animal deeply and are bound to do damage. When a quill hits an attacker's eye, it may cause blindness. If quills enter its jaw, they may prevent eating and lead to the predator's death by starvation. Porcupines grow new quills, as needed.

tigers and leopards, and rodents, such as the beaver. Many other mammals are threatened species, likely to become endangered in the foreseeable future.

Fortunately, several organizations have sought to protect these fur-bearing mammals. Efforts of organizations such as the World Wildlife Fund have focused public opinion and led to animal conservation legislation. Preeminent are the Endangered Species Act of 1973, and a 1977 Convention, signed by eighty nations, including the United States. These actions have led to agreement that furs will not move interstate or between signatory countries without proof that the species from which they were harvested is not threatened or endangered. This bodes well for the future of hair.

GAMETOGENESIS

Types of animal science: Development, reproduction
Fields of study: Cell biology, developmental biology, embryology, genetics, reproduction science

Gametogenesis is the process of sex cell formation. It includes the events that lead to a reduction in chromosome number so that the sex cells will have one-half the chromosomes that are found in normal body cells.

Principal Terms

DIPLOID: the number of chromosomes or the amount of genetic material normally found in the nucleus of body cells; this number is constant for a particular species of animal

GAMETE: a sex cell; the egg or ovum in the female and the sperm in the male

HAPLOID: one-half of the diploid number; the number of chromosomes or the amount of genetic material found in a gamete

MEIOSIS: reduction division of the genetic material in the nucleus to the haploid condition; it is the process used by animal cells to form the gametes

OOGENESIS: gamete formation in the female; it occurs in the female gonads, or ovaries

SPERMATOGENESIS: gamete formation in the male; it occurs in the male gonads, or testes

SPERMIOGENESIS: the structural and functional changes of a spermatid that lead to the formation of a mature sperm cell

Sexual reproduction is the predominant mode of reproduction in animals. Sexual reproduction involves the production of gametes: the eggs and sperm. In most animals, these gametes are produced in specialized organs called gonads (ovaries and testes). The sex cells in most animals are separate—that is, each individual animal contains either testes or ovaries, but not both. Such animals are said to be dioecious. In dioecious animals, the sex cells from two different individuals (one male and one female) will fuse together in a process known as fertilization to form the offspring. The advantage of sexual reproduction seems to be in its potential to produce variability in the gametes and therefore in the new organism.

Gametes are highly specialized cells that are adapted for reproduction. These egg and sperm cells develop by a process of gametogenesis, or gamete formation. Sperm cells are relatively small cells that are specialized for motility (movement); egg cells are larger, nonmotile cells that, in many species, contain considerable amounts of stored materials that are used in the early development of the zygote (fertilized egg).

In animals, gametogenesis consists of two major events. One involves the structural and functional changes in the formation of the gamete. The other involves the process of meiosis. Animal body cells normally contain the diploid amount of genetic material. Each species of animal has a characteristic diploid number that remains the same from generation to generation. Because fertilization involves the fusion of the egg and the sperm, bringing together each cell's set of genetic material, some mechanism must reduce the amount of genetic information in the gamete, or it would double every generation. Meiosis is a special nuclear division whereby the genetic material is reassorted and reduced to form haploid cells. Therefore, gametes are haploid, and gamete fusion during fertilization reestablishes the diploid content in the zygote.

Sperm

Sperm are highly motile cells that have reduced much of their cellular contents and are little more than a nucleus. Sperm are produced in the testes from a population of stem cells called spermatogonia. Spermatogonia are large diploid cells that reproduce by an equal division process called meiosis. Spermatogenesis is the process by which these relatively unspecialized diploid cells will become haploid cells; it is a continuous process that occurs throughout the sexually mature male's life. When a spermatogonium is ready to become sperm, it will stop dividing mitotically, enlarge, and begin the reduction division process of meiosis. These large diploid cells that begin to divide meiotically are known as primary spermatocytes.

The first step in the division process involves each primary spermatocyte dividing to form two secondary spermatocytes. Each secondary spermatocyte continues to divide, and each forms two spermatids. These spermatids are haploid cells. For each primary spermatocyte that undergoes spermatogenesis, four spermatids are formed. The spermatids are fairly ordinary cells; they must go through a process that will form them into functional sperm. The transformation process of a spermatid into a sperm is called spermiogenesis and involves several changes within the cell. The genetic material present in the nucleus begins to condense, while much of the cytoplasm and its subcellular structures are lost. The major exception to this latter event is the retention of mitochondria, cytoplasmic structures involved in energy production. The mature sperm has three main structural subdivisions: the head, the neck (or midpiece), and the tail. All are contained within the cell's membrane. The oval head has two main parts, the haploid nucleus and the acrosome. The acrosome comes in various shapes but generally forms a cap over the sperm nucleus. The acrosome functions differently in various animals, but generally its functions are associated with the fertilization process (union and subsequent fusion of egg nucleus and sperm nucleus). Acrosomes contain powerful digestive enzymes (organic substances that speed the breakdown of specific structures and substances) that allow the sperm to reach the egg's membrane. The midpiece of the sperm contains numerous mitochondria, which provide the energy for the sperm's movement. The tail, which has the same general organization as flagella or cilia (subcellular structures used for locomotion or movement of materials), uses a whiplike action to propel the sperm forward during locomotion. The structural changes that occur during spermiogenesis are meant to streamline and pare down the sperm cell for action of a special sort and of a limited duration. The sperm's function is to "swim" to the egg, to fuse with the egg's surface, and to introduce its haploid nucleus into the egg's interior.

Eggs

The female gamete, the egg or ovum, is produced by a process known as oogenesis. This process occurs in the female gonads, the ovaries. At first glance, oogenesis and spermatogenesis appear to be very similar, but there are some striking differences. The major similarity is that both processes form gametes, which contain genetic material that has been reduced to the haploid condition. To understand oogenesis, one must consider that its goal is to produce a cell that is capable of development. The mature egg in all animal cells is large in comparison with other cells, particularly with the sperm. There are two important features of the egg that must be considered: the presence of a blueprint for development and the means to construct an embryo from that blueprint. In other words, the egg must be programmed and packaged during oogenesis. The programming refers to the information that is coded within the structure of the egg. This information includes the genetic material as well as the cytoplasmic information. Together, the nucleus and cytoplasm provide the egg with the potential to transform a simple cell into a complex preadult form. Since it is within the egg that this transformation occurs, the programming must be within the organization of the egg, and the directions for development must be within that organization. The packaging refers to the presence of all the material necessary to build embryonic structures, to nourish this developing embryo, and to provide its energy until it can obtain nourishment on its own.

As happens in spermatogenesis, the potential eggs are formed from unspecialized stem cells, in this case called oogonia. Oogonia contain the diploid amount of genetic material and divide by the process of mitosis. At some point in their life, oogonia stop dividing mitotically, enlarge, and prepare to become eggs—that is, they begin meiosis. The cell that begins this reduction division process is called the primary oocyte. Each primary oocyte divides into two cells—one large cell, the secondary oocyte, and a very small cell, the first polar body. The secondary oocyte continues the final reduction phase of meiosis and forms two cells, one large one (the ovum) and one very small one (the second polar body). The first and second polar bodies are nonfunctional by-products of meiosis. The one functional cell, the mature egg, contains most of the cytoplasm of the primary oocyte and one-half of its genetic material. In many animals (primarily the vertebrates), all oogonia present in the ovaries enter meiosis at the same time; the initial events of oogenesis are synchronous within the animal. Oogenesis in many animals is not a continuous process, as is spermatogenesis in the male. Rather, the primary oocytes in the first stages of reduction division may remain inactivated for a long time—in some cases, for several decades. Therefore, in female animals with this format of oogenesis, a primary oocyte population is maintained, and eggs will mature as they are needed.

Thus far it appears that the egg's formation differs from the sperm's in three ways. First, in many female animals, there is a limited number of primary oocytes capable of going on to form eggs; second, this egg formation is not necessarily a continuous process; third, one primary oocyte yields one mature egg at the end of meiosis. Although these are three very important differences, there are other distinctly egg events that deal with the developmental programming and the packaging of materials in this potential gamete.

Eggs and RNA

Little is known about the egg's storage of developmental directions or the actual programming of information, but developmental and molecular biologists are beginning to elucidate events that occur during oogenesis that are concerned with function of the egg. One such event, fairly widespread among the animal kingdom, is the formation of so-called lampbrush chromosomes during oogenesis. The chromosome's backbone unravels at many sites so that regions, composed of specific genes, loop outward from the backbone. These loops give the chromosome its distinctive lampbrushlike appearance. Large amounts of a nucleic acid known as messenger ribonucleic acid (mRNA) are being made on each loop. This mRNA is then processed and sent into the developing eggs's cytoplasm, where most of it will be stored for use during early development. After fertilization, these maternal (egg-derived) mRNAs can be used to make specific proteins necessary for the embryo.

Another event present in some developing eggs is the mass production of another type of RNA known as ribosomal RNA (rRNA). Most of this rRNA will also be stored until fertilization. After fertilization, these rRNA particles will help form cytoplasmic structures called ribosomes (the sites of protein synthesis). In addition to these egg products, many animal eggs must become filled with yolk. Yolk is the general term that covers the major storage of material in the egg.

Because the maternal proteins (yolk and other protein components) and nucleic acids (various RNAs) form the bulk of the egg cytoplasm, they have profound influences on the development of the embryo. In particular, the positions of maternal mRNAs, ribosomes, and proteins affect the organization of the embryo. It is evident, then, that the maternal genetic information and the arrangement of the products of this information provide crucial developmental information that will control much of the course of embryonic development. Therefore, the egg contributes considerably more than a haploid nucleus to the zygote.

Studying Gametogenesis

There are several approaches to the study of gametogenesis. Early biologists employed cytological techniques (methods of preparing cells for the study of their structure and function) and microscopy to study gamete formation. These early studies were, in fact, observations of the actual events themselves. Although these early descriptive approaches gave much information about the cells involved at each stage of gamete formation, they did not provide any information about the control mechanisms for this process. Biochemical studies have contributed to the understanding of certain regulatory substances and how they function in gametogenesis. By enhancing or inhibiting the presence of these regulatory substances in the organism, investigators have been able to elucidate many of the normal events of gametogenesis.

Beginning at puberty, the hormones (substances released from endocrine glands, generally functioning to regulate specific body activity) of the hypothalamus, the pituitary gland, and the gonads interact to establish and regulate gametogenesis in the organism. Gonadotropin-releasing hormone (GnRH) from the hypothalamus stimulates the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior portion of the pituitary gland. All three of these hormones are necessary for spermatogenesis and oogenesis.

Surgical removal of the mammalian pituitary gland (hypophysectomy) in the male leads to degeneration of the testes. Testicular function can be restored in these hypophysectomized animals by administering the hormones FSH and LH. These studies suggest that FSH and LH are necessary for normal functioning of the testes. LH appears to stimulate the release of testosterone (male hormone) by certain cells (Leydig cells) of the testes. Both testosterone and FSH are necessary for spermatogenesis, but the exact role that each of these hormones plays in male sexual physiology has yet to be determined.

Oogenesis in the female has been the subject of intense investigation. At the beginning of each ovarian cycle, from puberty to menopause, one primary oocyte present in the female's ovaries is activated to continue the process of gamete formation. Release of GnRH from the hypothalamus at the beginning of each cycle stimulates the anterior portion of the pituitary gland to release FSH. FSH, in turn, affects the ovaries: It stimulates a primary oocyte to mature to the point that it can be released from the ovary, as a secondary oocyte, and it causes certain cells (follicle cells) in the ovary to produce estrogens, female hormones. High estrogen levels will cause the pituitary to inhibit FSH release, a negative feedback mechanism, and stimulate LH release. These estrogen-mediated events occur at approximately the middle of the ovarian cycle. LH also affects the ovaries. LH, however, is responsible for ovulation (the release of the oocyte from the ovaries) and for the formation of a cellular structure called the corpus luteum. LH also stimulates the corpus luteum to produce progesterone, another female hormone. Eventually, high levels of progesterone will inhibit LH release from the pituitary gland, and the cycle begins anew.

GAS EXCHANGE

Type of animal science: Physiology
Fields of study: Biochemistry, biophysics, cell biology

Gas exchange refers to the processes used by animals to take up oxygen and eliminate carbon dioxide. These processes are the basis for understanding how animals breathe, particularly in diverse conditions.

Principal Terms

DIFFUSION: the passive movement of a gas across a membrane from a region of high pressure to one of low pressure

EPITHELIUM: a thin layer of cells that lines a body surface, such as the lining of the lungs or the intestines

PARTIAL PRESSURE: that part of the atmospheric pressure caused by only a single gas of many in a mixture; it is determined by how much of the gas is present in the mixture

PERMEABILITY: the tendency, in this case of a membrane, to permit the movement of a gas across that membrane

RESPIRATORY MEDIUM: the water or air that contains the oxygen used by an animal to carry out biochemical reactions

VENTILATION: the movement of the respiratory medium to and across the site of gas exchange

Gas exchange is the uptake of oxygen and the loss (or elimination or excretion) of carbon dioxide. It refers to two major steps in the overall oxygen consumption (or carbon dioxide excretion) by the whole animal. These two steps are the movement of the respiratory medium (containing oxygen) past the site of gas exchange, known as ventilation, and the diffusion of oxygen across the gas-exchange surface into the animal. The final step in diffusion of oxygen into an animal always involves diffusion from a liquid into a liquid, even in air breathers. Both ventilation and diffusion depend on the design of the structures as well as the way in which the systems and structures work. The additional steps in the whole respiratory system are the internal counterparts to ventilation and diffusion. These are perfusion, or blood flow, and diffusion from the blood to the tissues.

Basically, gas exchange takes place at a respiratory surface where the source of oxygen, the respiratory medium, is brought into contact with the surface. Oxygen diffuses into the animal, carbon dioxide diffuses out, and the spent or used respiratory medium is removed. The movement of the respiratory medium is termed ventilation. Once oxygen is in the animal, it is transported to the site of oxygen utilization, the tissues. Carbon dioxide, on the other hand, must be transported from the tissues to the site of gas exchange for excretion in gaseous form.

Gas-Exchange Organs

Animals have three basic types of gas-exchange organs: skin, invaginations (inpocketings of the epithelium), and evaginations (outpocketings of the epithelium). All three show modifications to improve the conditions of gas exchange. Skin always permits gas exchange unless it is coated with some material that limits diffusion. The skin of a snake or a turtle is so coated and permits very little gas exchange. The skin of a worm or an octopus, on the other hand, is quite thin and permits gas exchange quite freely. Invaginations of the external epithelium are basically what lungs and insect tracheas are, but in a highly modified condition. Evaginations of the skin are represented by the gills of aquatic animals; even when inside a cavity, as are fish and crab gills, they are still evaginations.

There is only one way that animals take up oxygen from the external medium, regardless of whether that medium is air or water. Gas must passively diffuse across the membrane that separates the animal from its environment. That membrane is a type of tissue called epithelium and is similar in nature and structure to the tissue that lines other body surfaces. The different types of epithelia are classified according to their locations and functions; those lining gills, lungs, and certain other organs of gas exchange are all known as respiratory epithelia. The respiratory epithelium not only separates the internal and external fluids but also represents a barrier to the movement of materials such as gas.

Gas Diffusion

Diffusion of a gas across a membrane occurs according to the laws of physics. The driving force for gas diffusion is the difference in the partial pressure of the gas across the membrane. A high external partial pressure and low internal partial pressure will provide a large difference and will enhance diffusion. Oxygen makes up 20.9 percent of the air, so that 20.9 percent of the atmospheric pressure at sea level (14.72 pounds per square inch) is attributable to oxygen (3.08 pounds per square inch). At higher altitudes, atmospheric pressure and partial pressure of oxygen are reduced.

The other factors that determine the diffusion of a gas are the thickness of the membrane across which it diffuses, the membrane's total surface area, and the nature or composition of the membrane. Obviously, a thick membrane will retard diffusion of gas because the gas must move across a greater distance. The distance the gas must diffuse is known as the diffusion distance. Additionally, the total surface area of the membrane available for diffusion has a direct effect on the rate of diffusion from one place to another. The greater the surface area, the greater the quantity of gas that can diffuse in a given time. Finally, the composition of the membrane is of critical importance in determining the diffusion of a gas. The nature of the membrane is referred to as the permeability of the membrane to the gas in question. The greater the permeability, the more easily gas diffuses. A membrane with a layer of minerals (calcium, for example) on the cells will not be as permeable as one without such a layer.

A very important point to note is that gases diffuse according to the difference in the partial pressure of the gas and not according to the concentration of the gas in the liquid. Several scientists have proved this by constructing artificial systems with two dissimilar fluids separated by a membrane. The movement of oxygen is always from high partial pressure to low and not from a high concentration to low. The reason is that pressure is a measure of molecular energy, but concentration of a gas in a liquid depends on the amount of that gas that can dissolve in the liquid—its solubility.

A Fluid-Fluid Boundary

All gas exchange occurs across a fluid-fluid boundary—that is, from one liquid to another—even in air breathers. The explanation for this is that all respiratory epithelia are moist and are kept so by the cells that line the surface. If the surface were to dry out, the permeability to gases (and other materials) would be substantially reduced. Thus, in air breathers, oxygen must first dissolve in the thin fluid layer lining the surface before diffusion across the epithelium takes place.

Organs of gas exchange work as do radiators, except that a gas is exchanged instead of heat. In this system, there are two liquids, one the source and the other the sink for the transferred material, the gas. The source is the external supply, and the sink is the blood or other internal fluid. Both fluids are contained in vessels or tubes that channel and direct it, with a thin layer of epithelium between the two. In the most efficient transfer systems, both the source and the sink flow, and they flow in opposite directions. If they did not flow, then the two fluids would simply come to an equilibrium, with oxygen partial pressure the same in both of the fluids. By moving in opposite directions, each is renewed, and the difference between them is always maximized. This type of exchange system is a "countercurrent system," because the two fluids flow in opposite directions. The most efficient of the gas-exchange organs function this way.

Two other types of gas-exchange systems are based on fluids flowing in directions other than perfectly opposite to each other. Birds have a respiratory system in which blood and air do not flow in opposite directions; rather, the blood flows perpendicularly to the direction of the air flow. This is referred to as crosscurrent flow. While not as efficient as countercurrent flow, it provides for an acceptably high level of efficiency. A system in which the respiratory medium is not channeled, but the blood is instead in vessels, is known as a mixed volume system. The mammalian lung functions in this way; the air is pumped into sacs that are lined with tiny blood vessels, but the air does not flow.

Ventilation

Ventilation of gas-exchange organs is accomplished by a pumping mechanism that brings the respiratory medium to and across the gas-exchange surface. Both water and air breathers use ventilatory pumps, but water breathers must move a much heavier and denser medium than air breathers. Pumping mechanisms may be located at the inflowing end of the system or at the outflowing end. The former are positive pressure pumps that push respiratory medium, and the latter are negative pressure pumps that pull respiratory medium into the cavity. Negative pressure is used in mammalian lungs, insect tracheas, and crab gills, while positive pressure is used in some fish that push water from the mouth into the gill chamber.

There are two basic patterns of flow of the respiratory medium through gas-exchange organs: one-way and tidal. One-way flow is found in fish, crabs, clams, and a number of other aquatic animals. Interestingly enough, the bird respiratory system also uses one-way flow. In one-way flow systems, the medium is always moving and passes over the gas exchange surface only once. In tidal-flow systems, the respiratory medium moves in and out (like the tide) through the same passages and tubes. The mammalian and insect respiratory systems both utilize tidal ventilation. The respiratory medium is not always moving, and when it is exhaled, there is some amount remaining in the cavity. The remaining respiratory medium will contain more carbon dioxide and less oxygen than fresh respiratory medium, with which it will mix upon inhalation.

Measuring Gas Exchange

The total amount of oxygen used by an animal is a gross measure of gas exchange known as oxygen uptake or oxygen consumption. Its counterpart for carbon dioxide is carbon dioxide excretion. Oxygen uptake is expressed as the amount of oxygen used per minute per kilogram of animal mass. Carbon dioxide excretion is expressed in the same terms. In theory, oxygen uptake and carbon dioxide excretion will be numerically the same, but in live animals there are several circumstances that cause the two to differ. Measurement of both rates is accomplished in similar ways. One method is the use of a respirometer and involves placing an animal in a sealed container and measuring the rate at which oxygen is depleted or carbon dioxide produced by an animal. Alternatively, respiratory medium, either air or water, is pumped through the respirometer and the oxygen or carbon dioxide measured in the inflowing and outflowing medium; the difference will be the amount used by the animal. The flow rate of the air or water must also be known for the calculations. The use of a respirometer is preferable but may not be practical for large animals, such as a horse.

In the case of animals too large to use a respirometer, oxygen uptake or carbon dioxide excretion is determined by measuring the rate of flow of the respiratory medium through the gas exchange organ and measuring the oxygen in the inspired and expired air or water. The result is the ventilation rate and the amount of oxygen extraction, the product of which is the oxygen consumption rate. This measurement is straightforward in animals with one opening for inspired and another for expired respiratory medium, such as a fish or a crab. In animals that inhale and exhale through the same organ, however, there are complications that make the measurements more difficult. Still, it is possible to measure the flow of air in and out of a lung and to collect at least some of the gas and measure either the oxygen or carbon dioxide in that air.

There is an additional advantage to the latter technique, measuring ventilation and the oxygen in the water or air. That advantage is that another measure of gas exchange is provided in these measurements. The difference between the amount of oxygen in inspired and expired water or air is the extraction (the amount taken out) and assesses the efficiency of the gas exchange organ. The efficiency is usually given as the percentage of oxygen taken out of the respiratory medium (the amount removed divided by the amount in inspired air or water). There are numerous factors that affect extraction, and measuring the efficiency provides one piece of information.

Studies of gas exchange encompass all levels of organization of animals, from the cellular to the whole animal. One of the most important levels concerns the structure of the organ and the parts of the organ. For this, it is necessary to see the spatial relationships among the parts, measure distances and areas, and count structures. The surface area, the volume, the number of structures or substructures, and the diffusion distances must all be measured. The results describe the morphology and morphometrics of the organ. Both whole, intact animals, and preserved specimens are used to make these measurements. The techniques are those used in surgery and dissection, and the results are critical to an understanding of the basic function of the respiratory organ. The electron microscope has been a powerful tool in this regard, permitting the accurate measurement of cellular-level distances, such as the diffusion distance.

Measuring Partial Pressure Difference

Measuring the partial pressure difference between the inside and outside of the animal is critical because of the role that this pressure difference has in gas exchange. Partial pressure of oxygen may be measured in two ways: in the intact animal or in a sample removed from the animal and injected into an instrument. The instrument most commonly used for measuring oxygen or carbon dioxide partial pressure is an electrode that changes electrical output when oxygen diffuses across an artificial membrane into a salt solution. Some of these electrons have been miniaturized and are only four millimeters across, and they will fit in a syringe needle. Still, it is difficult to use one of these in an intact mammal. The other way to measure partial pressure of oxygen or carbon dioxide on either side of the respiratory epithelium is to withdraw a sample of the air or water on the outside or the blood from the vessels on the inside. This procedure may be routine (in animals such as fish and crabs) or somewhat difficult (as in a mammal). A small tube is threaded into the lung to withdraw the air sample.

Measuring Ventilation

The movement of the respiratory medium, ventilation, is an important measure in determining the rate at which oxygen is brought to the respiratory surface. The blood flow (perfusion) on the inside is the counterpart to ventilation and is equally important. Ventilation can be measured either indirectly (meaning it is calculated) or directly. Indirect determinations require measuring other functions and then calculating ventilation based on known equations. If the rate of oxygen uptake and the extraction are measured, for example, then ventilation can be calculated.

Direct measures of ventilation use an electronic sensing device to determine the flow of water or air at the site of intake or outflow of respiratory medium on the animal. A human subject can simply breathe into such an electronic or mechanical device. Nonhuman mammals are more difficult and frequently require indirect techniques.

Direct measures may be the flow rate of the respiratory medium, the frequency of breathing, the hydrostatic pressure in the respiratory chamber, or a change in shape and size of the respiratory chamber. Any of these measures can be used to monitor routine respiratory function, but all are needed to assess gas exchange completely and accurately.

It is also necessary to know the general pattern of water or air movement at the respiratory surface. To do so often requires some invasive technique and the use of an indicator, such as a dye in the respiratory medium. The movement of the medium can then be visualized to determine the pattern. In some animals, video cameras can be used to photograph flow patterns of dyed medium, particularly water.

Uses of Gas Exchange Study

Gas exchange is studied by researchers and health practitioners both to assess basic function and to determine the source and nature of limitations of the systems of the body. These two areas may seem quite different at first; one is applied research, and the other is considered basic research. Both, however, have the same bases and use the same equations and principles. Only the animals or conditions differ.

One of the clinical applications, or contexts, in which gas exchange is studied is in respiratory distress or pulmonary (lung) disease. In these cases, the respiratory epithelium may become inflamed and thickened. This will increase the diffusion distance and retard, or limit, oxygen uptake and carbon dioxide release at the lung. Secretion of mucus by a respiratory epithelium may have a similar result for the same reasons. Mucus secretion occurs in several diseases and also takes place in fish gills when irritated by noxious chemicals in the water.

Gas exchange is also studied in diverse animals to understand evolutionary trends and pressures. Animals that live at high altitudes, for example, are constantly faced with low oxygen pressure in the air, and therefore some adjustment must be made by the animal. Scientists study the respiratory systems of these animals to determine if one of the other factors that affects gas exchange, such as diffusion distance or total surface area, is altered to compensate for the lower pressure difference.

All animals have similar basic physiological needs, including a need for oxygen to fuel the conversion of food materials into energy and other substances. Many animals have unique or specific forms or structures enabling them to survive in a particular habitat. Some of these forms affect the respiratory system—as in the differences between the respiratory surface in land animals compared with similar species that live in water. Scientists have compared the gas-exchange systems in aquatic and terrestrial species to learn more about evolutionary processes.

Bibliography

Boutilier, R. G., ed. *Vertebrate Gas Exchange: From Environment to Cell*. New York: Springer-Verlag, 1990. Covers the comparative physiology of respiration in vertebrates.

Dejours, Pierre, ed. *Principles of Comparative Respiratory Physiology*. 2d ed. New York: Elsevier, 1981. An excellent book for professionals and for those who have mastered other readings in the field. Dejours gives the whole story, from basic concepts to more complex research, but the primary focus is clearly on the latter. He presents such a strong foundation that the information is not overwhelming. Uses equations freely and provides complete documentation for the graphs he has drawn from other scientists' work.

Hill, R. W., and G. A. Wyse. *Animal Physiology*. New York: Harper & Row, 1989. Provides a relatively complete discussion of the topic of gas exchange from first principles to application. The illustrations are of very high quality, and the explanations are neither too complex nor filled with jargon; they are understandable to entering college students. Additional readings are listed.

Prange, Henry D. *Respiratory Physiology: Understanding Gas Exchange*. New York: Chapman & Hall, 1996. Covers the biological, chemical, and physical principles of respiratory physiology. Takes a practical approach to explaining not only how gas exchange works, but why.

Rahn, H., A. Ar, and C. V. Paganelli. "How Bird Eggs Breathe." *Scientific American* 240 (February, 1979): 46-55. This application of basic diffusional-based gas exchange provides the fundamental concepts and an example of how these concepts are used to understand evolutionary processes.

Raven, P. H., and G. B. Johnson. *Biology*. 4th ed. Boston: McGraw-Hill, 1996. The chapter on respiration is not very long but has good illustrations and simple explanations of gas exchange. Others on various animal groups do provide additional comparative information in one text. Written at the introductory college level.

West, John B. *High Life: A History of High-Altitude Physiology and Medicine*. New York: Oxford University Press, 1998. An introduction to the field of high-altitude respiratory physiology, taking a historical approach to topics such as the understanding of acute high-altitude disease, the physiological effects of long-term high-altitude residence, and the origins of the field in the eighteenth and nineteenth century scientific investigation. Written for specialists.

GEESE

Type of animal science: Classification
Fields of study: Anatomy, ornithology, physiology, zoology

Geese are migratory water birds. Over two dozen species of geese have been identified; seven live in North America.

Principal Terms

BANDING: attachment of identification tags to individual birds
CLUTCH: number of eggs in the nest
COVERTS: feathers covering the bases of the large feathers of the wings and tail
FLEDGLING: young bird still unable to fly
LAMELLAE: toothlike structures in the beak, forming a strainer that permits birds to retain food particles while still enabling water to flow from the closed mouth
MANDIBLES: upper and lower beak parts
MOLTING: the loss of feathers that will be succeeded by new growth

Relatively difficult to identify, geese are perhaps best known for their migration, being harbingers of both summer and winter. Geese live comfortably at the intersection of water and land, eating a vegetarian diet of grasses, seeds, roots, berries, and aquatic plants. Unlike many birds, geese pair-bond and mate for life, building a simple nest in the ground and lining it with down. Depending on their species, geese lay a clutch of four to nine eggs, and fledglings remain grounded for forty to seventy-three days. Geese molt once a year after the breeding season; during this period the bird is unable to fly for four to five weeks.

Physical Characteristics of Geese

Geese are medium- to large-sized birds, between the size of ducks and swans. They have long necks and short legs in the center of their bodies. Because of this leg placement, geese do not waddle as much as other waterfowl when moving about on land. Their feet are webbed, which enables them to swim rapidly.

The bills of geese have serrations on the mandibles called lamellae; these are useful, because most geese gather some of their food while submerged. Because the bill is equipped with a horny covering at the tip of the upper mandible and because of the curved shape of the bill, geese can easily clip grasses, grains, or other foods.

Most species of geese are blackish in color, although many species have considerable white

Geese Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Class: Aves
Order: Anseriformes
Family: Anatidae
Subfamily: Anserinae
Tribe: Anserini (swans and geese, four genera, thirty-six species)
Geographical location: Primarily the Northern Hemisphere
Habitat: Land (fields, prairies, tundra, forests) and water (ponds, lakes, rivers, streams, inlets, tidal areas, oceans)
Gestational period: From three to four weeks
Life span: Most geese live about twenty years; can (rarely) reach fifty-five years
Special anatomy: Webbed feet, long necks, large bills

Migrating geese make stopovers en route, forming huge, seasonal flocks on lakes along their flyways. (PhotoDisc)

markings in their plumage, often restricted to their bellies or lower tail coverts. Even though each species has distinguishing physical characteristics, it is often difficult to identify a particular species in the field. Even Canada geese, which are probably the easiest to identify with their white chin straps, can be a source of frustration for bird watchers attempting to distinguish between the dozen or so subspecies of Canada geese. Male and female geese of each species resemble each other.

Goose Migration

Many species of birds migrate, but geese, because they are so visible, epitomize this phenomenon to most people. Geese migrate for survival: Their northern breeding grounds become inhospitable when water areas freeze over, making food unattainable, and their southern grounds cannot sustain large populations of birds year around. In the United States, geese migrate northward from February to March and southward from September to November.

Geese, like many birds, often return to the same summer and winter areas year after year. Clearly, geese make use of visual landmarks when migrating; even at night some landmarks, such as large bodies of water, can be seen from the air. Young geese learn about these landmarks, as well as about traditional migratory stopping places, from their elders. Landscape alone, however, is not all that helps geese navigate. The position of the sun and stars can help them, as can the wind and the earth's magnetic field.

Most species of geese fly in some sort of V-formation. Flocks of snow geese, for example, form U's, checkmarks, or irregular masses. Only Canada geese fly in an almost perfect V. These formations have less to do with aesthetics than aerodynamics. Just as bicycle racers will draft lead bikers by riding slightly behind and to the side of them, so a goose will draft the lead bird, the one doing most of the work by breaking the wind's resistance for the birds that follow. Lead birds change during a flight. Geese normally fly at about forty miles per hour, a speed that can change if the bird is in a hurry or being chased.

By plotting the origins and destinations of banded birds, biologists have discovered four main flyways used by geese in the United States: the Atlantic Flyway, the Mississippi Flyway, the Central Flyway and the Pacific Flyway. Banding geese in order to study them is more than an academic exercise. Knowing migration paths has allowed experts to make decisions on hunting quotas and on the location of wildlife refuges.

GENE FLOW

Type of animal science: Evolutionary science
Fields of study: Anthropology, ecology, genetics

In biology, "migration" refers to the movement of a member or many members of a species of animal or plant from one geographic location to another. If other members of the same species interbreed with the migrating species, either along the way or in the new location, an exchange of genes occurs. Biologists call this exchange "gene flow" and consider it to be fundamental to the evolutionary process.

Principal Terms

ALLELE: one of a group of genes that occurs alternately at a given locus

DEME: a local population of closely related living organisms

FOSSIL: a remnant, impression, or trace of an animal or plant of a past geologic age that has been preserved in the earth's crust

GENE POOL: the whole body of genes in an interbreeding population that includes each gene at a certain frequency in relation to other genes

MUTATION: a relatively permanent change in hereditary material involving either a physical change in chromosome relations or a biochemical change in the codons that make up genes

POPULATION: a grouping of interacting individuals of the same species

SPECIATION: the process whereby some members of a species become incapable of breeding with the majority and thus form a new species

SPECIES: a category of biological classification ranking immediately below the genus or subgenus, comprising related organisms or populations capable of interbreeding

Prior to the nineteenth century, religious dogmatism retarded the activities of most scientists investigating the origins and nature of life by insisting on the immutability of species created by God. Despite mounting fossil evidence that many species of flora and fauna that once inhabited the earth had disappeared and that many extant species could not be found in the fossil record, pre-nineteenth century naturalists could find no viable explanation (other than divine intervention) for the disappearance of life-forms and their replacement by other forms. Then, in 1859, Charles Darwin published his epochal *On the Origin of Species*, which proposed the theory that all contemporary life-forms have evolved from simpler forms through a process he called "natural selection."

Many individuals before Darwin had proposed theories of evolution, but Darwin's became the first to be widely accepted by the scientific community. His success resulted from the careful and objective presentation of an overwhelming amount of evidence showing that species can and do change, and his concurrent promulgation of a convincing explanation of the mechanism that produces that change—natural selection. Since Darwin, scientists have modified and added new concepts to his theory, especially concerning the ways in which species change (evolve) over time. One of those new concepts, which was only dimly understood in Darwin's lifetime, is the importance of genetics in evolution, especially the concepts of migration and gene flow.

Genes and Gene Exchange

Genes are elements within the germ plasm of a living organism that control the transmission of a hereditary characteristic by specifying the structure of a particular protein or by controlling the function of other genetic material. Within any breeding population of a species, the exchange of genes is constant among its members, ensuring genetic homogeneity. If a new gene or combination of genes appears in the population, it is rapidly dispersed among all members of the population through inbreeding. New alleles may be introduced into the gene pool of a breeding population (thus contributing to the evolution of that species) in two ways: mutation and migration. Gene flow is integral to both processes.

A mutation is the appearance of a new gene or the almost total alteration of an old one. The exact causes of mutations are not completely understood, but scientists have demonstrated that they can be caused by radiation. Mutations occur constantly in every generation of every species. Most of them, however, are either minor or detrimental to the survival of the individual and thus are of little consequence. A very few mutations may prove valuable to the survival of a species and are spread to all of its members by migration and gene flow.

When immigrants from one population interbreed with members of another, an exchange of genes between the populations ensues. If the exchange is recurrent, biologists call it "gene flow." In nature, gene flow occurs on a more or less regular basis between demes, geographically isolated populations, and even closely related species. Gene flow is more common among the adjacent demes of one species. The amount of migration between such demes is high, thus ensuring that their gene pools will be similar. This sort of gene flow contributes little to the evolutionary process, since it does little to alter gene frequencies or to contribute to variation within the species. Much more significant for the evolutionary process is gene flow between two populations of a species that have not interbred for a prolonged period of time.

Populations of a species separated by geographical barriers often develop very dissimilar gene combinations through the process of natural selection. In isolated populations, dissimilar alleles become fixed or are present in much different frequencies. When circumstances do permit gene flow to occur between two such populations, it results in the breakdown of gene complexes and the alteration of allele frequencies, thereby reducing genetic differences in both. The degree of this homogenization process depends on the continuation of interbreeding between members of the two populations over extended periods of time.

Hybridization

The migration of a few individuals from one breeding population to another may, in some instances, also be a significant source of genetic variation in the host population. Such migration becomes more important in the evolutionary process in direct proportion to the differences in gene frequencies—for example, the differences between distinct species. Biologists call interbreeding between members of separate species "hybridization." Hybridization usually does not lead to gene exchange or gene flow, because hybrids are not often well adapted for survival and because most are sterile. Nevertheless, hybrids are occasionally able to breed (and produce fertile offspring) with members of one or sometimes both the parent species, resulting in the exchange of a few genes or blocks of genes between two distinct species. Biologists refer to this process as "introgressive hybridization." Usually, few genes are exchanged between species in this process, and it might be more properly referred to as "gene trickle" rather than gene flow.

Introgressive hybridization may, however, add new genes and new gene combinations, or even whole chromosomes, to the genetic architecture of some species. It may thus play a role in the evolutionary process. Introgression requires the production of hybrids, a rare occurrence among highly differentiated animal species. Areas where hybridization takes place are known as contact zones or hybrid zones. These zones exist where populations overlap; in some cases of hybridization, the line between what constitutes different species and what constitutes different populations of the same species becomes difficult to draw. The significance of introgression and hybrid zones in the evolutionary process remains an area of some contention among life scientists.

Biologists often explain, at least in part, the poorly understood phenomenon of speciation through migration and gene flow—or rather, by a lack thereof. If some members of a species become geographically isolated from the rest of the species, migration and gene flow cease. The isolated population will not share in any mutations, favorable or unfavorable, nor will any mutations that occur among its own members be transmitted to the general population of the species. Over long periods of time, this genetic isolation will result in the isolated population becoming so genetically different from the parent species that its members can no longer produce fertile progeny should one of them breed with a member of the parent population. The isolated members will have become a new species, and the differences between them and the parent species will continue to grow as more ages pass. Scientists, beginning with Darwin himself, have demonstrated that this sort of speciation has occurred on the various islands of the world's oceans and seas.

Studying Gene Flow

Scientists from many disciplines are currently studying migration and gene flow in a variety of ways. For decades, ornithologists and marine biologists have been placing identifying tags or markers on members of different species of birds, fishes, and marine mammals to determine the range of their migratory habits in order to understand the role of migration and subsequent gene flow in the biology of their subjects. These studies have led, and will continue to lead, to important discoveries. Most studies of migration and gene flow, however, relate to human beings.

Many of the important discoveries concerning the role of gene flow in the evolution of life come from the continuing study of the nature of genes. A gene, in cooperation with such molecules as transfer ribonucleic acid (tRNA) and related enzymes, controls the nature of an organism by specifying amino acid sequences in specific functional proteins. In recent decades, scientists have discovered that what they previously believed to be single pure enzymes are actually groups of closely related enzymes, which they have named "isoenzymes" or "isozymes." Current theory holds that isozymes can serve the needs of a cell or of an entire organism more efficiently and over a wider range of environmental extremes than can a single enzyme. Biologists theorize that isozymes developed through gene flow between populations from climatic extremes and enhance the possibility of adaptation among members of the species when the occasion arises. The combination and recombination of isozymes passed from parent to offspring are apparently determined by deoxyribonucleic acid (DNA). Investigation into the role of DNA in evolution is one of the most promising avenues to an understanding of the nature of life.

A classic example of the importance of understanding migration and gene flow in the animal kingdom is the spread of the so-called killer bees. In the 1950's, a species of ill-tempered African bee was accidentally released in South America. The African bees mated with the more docile wild bees in the area; through migration and gene flow, they transmitted their violent propensity to attack anything approaching their nests. As the African genes slowly migrated northward, they proved to be dominant.

Further research into migration and gene flow promises to provide information indispensable to the attempt to unravel the mysteries of life. Coupled with the concept of mutation, gene flow is a crucial component of evolution.

Bibliography

Ammerman, A. J., and L. L. Cavalli-Sforza. *The Neolithic Transition and the Genetics of Populations in Europe*. Princeton, N.J.: Princeton University Press, 1984. This book is rather technical in its language, but it presents a thoughtful discussion of the influence of migration and gene flow on the Neolithic revolution and the complex workings of gene flow on human evolution.

Bailey, Jill. *Evolution and Genetics: The Molecules of Inheritance*. New York: Oxford University Press, 1995. An encyclopedia of the current understanding of genetics and evolution.

Cavalli-Sforza, Luigi Luca. *Genes, Peoples, and Languages*. Berkeley: University of California Press, 2000. Although this book focuses on humans and their languages, Cavalli-Sforza's introductory sections on genetics and gene flow are exceptionally clear and well written, accessible to nonspecialists, and applicable to all animal species.

Crow, J. F., and Motoo Kimura. *An Introduction to Population Genetics*. New York: Harper & Row, 1970. An excellent starting place for those whose knowledge of migration and gene flow and their influence on evolution is limited and who wish to learn more about the subject. The book is relatively free of the technical jargon that can make some biological texts difficult for the nonbiologist.

Endler, John A. *Geographic Variation, Speciation, and Clines*. Princeton, N.J.: Princeton University Press, 1977. Endler's book is valuable primarily because of an excellent chapter on gene flow and its influence on the evolutionary process. Endler sees evolution as a very slow and gradual process in which gene flow and small mutations cause massive change over long periods of time.

Hoffmann, Ary A., and Peter A. Parsons. *Evolutionary Genetics and Environmental Stress*. New York: Oxford University Press, 1991. Another excellent starting place for those whose knowledge of migration and gene flow and their influence on evolution is limited and who wish to learn more about the subject. The book is relatively free of the technical jargon that can make some biological texts difficult for the nonbiologist.

Raup, D. M., and D. Jablonski, eds. *Patterns and Processes in the History of Life*. New York: Springer-Verlag, 1986. Raup and Jablonski's book is a compilation of articles from the Dahlem workshop, "Patterns and Processes in the History of Life," held in Berlin in 1985. The articles in the book discuss the evidence concerning the role of migration and gene flow in the evolutionary process. Thought-provoking.

GENETICS

Types of animal science: Evolution, fields of study, reproduction
Fields of study: Biochemisty, cell biology, developmental biology, embryology, evolutionary science, reproduction science

Genetics is the study of inheritance of characteristics from one generation to the next. Humans have been studying genetics since prehistoric times with the first selective breeding of wolves for companion animals. In the 1800's, an Austrian monk, Gregor Mendel, described the basic laws that govern the inheritance of genetic traits. In the twentieth century, the field of molecular genetics was created as biologists determined the actual chemical makeup of genes.

Principal Terms

ALLELE: alternative forms of a single gene
CHROMOSOME: a long strand of DNA with supporting proteins, that contains many genes
DEOXYRIBONUCLEIC ACID (DNA): the chemical polymer that is the genetic material of multicellular organisms
GENE: factors in cells that are responsible for an observable characteristic of an organism
GENOME: all of the genetic material of an organism
GENOTYPE: the actual genetic makeup of an organism
MUTATION: any heritable change in the genetic material
PHENOTYPE: the observable characteristics of an organism (for example, black fur color in a cat)

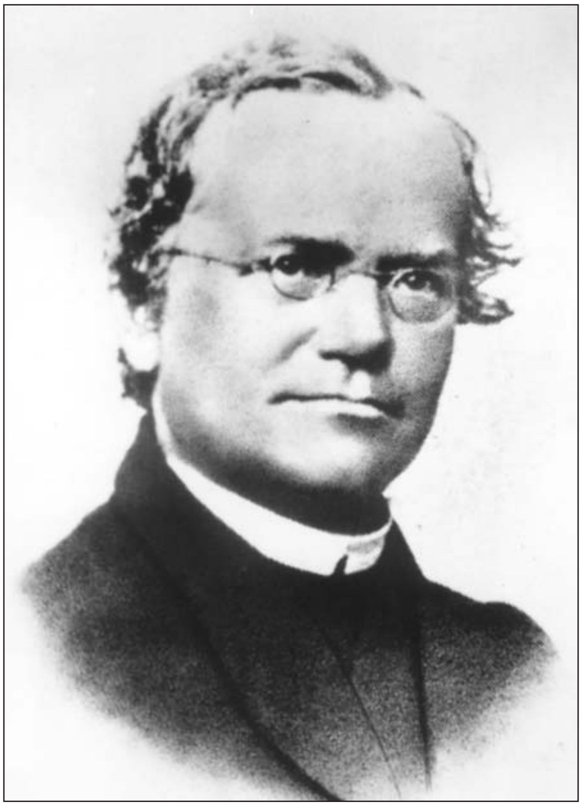
Before any recorded history, ancient man chose alert pups from a litter of wolves for breeding. This practice of selectively breeding the wolves that were good companions eventually gave rise to the domesticated dog. The oldest undisputed dog bones known, excavated from a twenty-thousand-year-old Alaskan settlement, demonstrate that prehistoric humans knew that traits could be passed from one generation to the next, and that selectively breeding animals (or plants) could produce an organism that possessed desired characteristics. This practice of deliberate breeding is known as artificial selection.

Humans have practiced artificial selection on numerous animals, including pigs, cattle, goats, and sheep. Homer and other Greek poets wrote about selective breeding, and part of the wealth of the ancient city of Troy was attributed to its expertise in horse breeding. Although humans had some control over the traits of domesticated animals through selective breeding, the results of matings were not always predictable, and nothing was known about the mechanism through which traits were passed from one generation to another until the mid-1800's.

Mendelian Genetics

Gregor Mendel, an Austrian monk, is the undisputed father of the science of genetics. Working with garden peas, Mendel analyzed thousands of breeding experiments to describe laws that governed the inheritance of traits. Though Mendel studied a plant, his laws for the inheritance of traits apply to all sexually reproducing organisms, including humans.

Mendel chose seven distinct traits to study in his garden peas: flower color, plant height, seed shape, seed color, pod shape, pod color, and flower position. He concluded that each of these



Gregor Mendel's experiments with garden peas laid the foundation for the study of genetics. (National Library of Medicine)

traits was determined by a single, discrete factor called a gene. For instance, there was a gene for flower color and a gene for seed shape. Each gene had several variations, or alleles. The gene for flower color had a white allele that produced white flowers and a purple allele that produced purple flowers.

Mendel's experiments revealed that organisms have two copies of any gene for a trait. Those two copies can be identical, two purple alleles of the flower color gene, for instance; or those two alleles can be different. A pea plant could have one purple allele of the flower color gene and one white allele of the flower color gene. When an organism has two identical alleles of a gene, it is homozygous for that gene. When an organism has two different alleles of a gene, it is heterozygous for that gene.

An organism inherits one allele, or copy of a gene, from one parent and one allele from the other parent. An organism, or cell, that has two copies of all of its genetic information is called diploid. In most sexually reproducing animals, the offspring are formed when a sperm cell from the male parent fertilizes an egg from the female parent. The sperm and the egg only contain half of all the genetic information. They are said to be haploid. However, the new organism they create is diploid because it gets one copy of the genetic information from the sperm and a second copy from the egg.

Mendel's first law, or the law of segregation, states that the two copies of each gene separate during the formation of gametes (eggs and sperm), and that fertilization of the egg by the sperm is a random event. Any sperm containing any allele of a gene can fertilize any egg of the same species, regardless of the allele carried by that egg.

Mendel noted that certain alleles seemed to dominate over others. For instance, when a plant had a purple allele for flower color and a white allele for flower color, the plant always had purple flowers. Mendel called the allele that was seen in the heterozygote, in this case the purple allele, the dominant allele. The allele that was hidden or masked, he called the recessive allele. In order to show a recessive allele, an organism has to have two identical copies of a gene, both containing the same recessive allele. This is known as the homozygous recessive condition. Garden peas that have white flowers are homozygous recessive for the white allele of the flower color gene.

Homozygous recessive describes the organism's genotype, or its genetic makeup. It has two copies of the recessive allele of the gene. The observable characteristic of the organism, having white flowers, is called its phenotype.

Mendel also demonstrated that the segregation of alleles of any one gene is not dependent on the segregation of alleles of any other gene. For instance, a gamete could receive a dominant allele for an eye color gene and a recessive allele for height, or that gamete could receive the recessive alleles for both genes or the dominant alleles of both genes. This is Mendel's second law, the law of independent assortment, and it applies to any genes that are located on separate chromosomes.

Mendel's work was far ahead of its time. Although Mendel published his research in the 1800's, it was not until after his death that his work gained recognition in the scientific community. In 1900, three other scientists, each working separately on inheritance, came across Mendel's work in the course of their research. They gave him credit for his insights, and Mendel's research provided the foundation for the new discipline of genetics.

Genes and Chromosomes

Although Mendel described the gene as the factor that was responsible for a particular trait, nothing was known about the physical makeup of a gene. One of the first questions scientists needed to answer was where genes are found in cells. Early studies in frogs and sea urchins indicated that the nucleus of the sperm and the nucleus of the egg combined with each other during fertilization. This observation suggested that the genetic material that determined how the fertilized egg would develop might reside in the nucleus.

As microscopes improved, scientists were able to distinguish structures within the nuclei of cells. These long, threadlike structures stained blue and were called chromosomes (Greek *chroma*, "color"). Several scientists observed that when animal and plant cells divided, the chromosomes duplicated, then separated, and each daughter cell inherited a complete set of chromosomes. The one exception to this was the cell division that produced the gametes (eggs and sperm). When an egg or a sperm cell was produced, it only contained half the number of chromosomes as the cell that produced it. If genetic information was carried on chromosomes, scientists reasoned that a sperm and an egg could each contribute half of the genetic information to the new organism at fertilization.

Some of the first evidence that chromosomes were linked to observable traits came from the studies of American graduate student Walter S. Sutton. Sutton studied grasshoppers, and his observations indicated that male grasshoppers always had an X and a Y chromosome, whereas female grasshoppers contained two X chromosomes. Several other scientists observed similar things in other organisms, such as fruit flies, and concluded that the physical characteristic of sex was determined by the kind of chromosomes an organism possessed.

Since chromosomes determined the trait of sex, it was possible that chromosomes contained the genes that Mendel had shown to determine physical characteristics. The first scientist to demonstrate that genes were located on chromosomes was Thomas Hunt Morgan, who showed that an eye-color gene in the fruit fly, *Drosophila melanogaster*, was located on the X chromosome.

Next, scientists wanted to know what kind of chemical molecule actually carried the genetic information. Chromosomes contain two kinds of molecules, protein and a weak acid called deoxyribonucleic acid (DNA). Experiments in the early 1930's first demonstrated that DNA is the genetic material. Oswald Avery, Colin MacLeod, and Maclyn McCarty showed that adding DNA to these bacterial cells could change their physical traits. In their experiments, they mixed a harmless strain of bacteria with DNA from bacteria that caused disease in mice. When they did this, the previously harmless bacteria changed (or transformed) into disease-causing bacteria. Two other scientists, Alfred Hershey and Martha Chase, later obtained similar results by studying a virus that infects *E. coli*.

Molecular Genetics

By the 1940's, scientists knew that genetic information was carried by genes made of DNA molecules inside cell nuclei. However, scientists did not know how the genetic information was copied accurately from one generation to the next—from one cell division to the next. Nor did scientists know how the DNA could account for the appearance of inherited changes or mutations. In order to answer these questions, scientists needed to know the precise chemical structure of DNA.

Many scientists contributed to the understanding of the structure of DNA. Erwin Chargaff obtained data that indicated that specific molecular components of the DNA molecule were always present in equal parts. These components were nitrogen-containing molecules (or nitrogenous bases). Chargaff determined that the nitrogen-containing bases adenosine and thymine were always present in a one to one ratio, and the bases guanine and cytosine were always present in a one to one ratio, no matter what species' DNA was analyzed.

Simultaneously, two scientists at Kings College in London, Rosalind Franklin and Maurice Wilkins, were attempting to make X-ray pictures of DNA molecules. Rosalind Franklin obtained an X-ray film that indicated that DNA was a helical molecule. Just previous to Franklin's work, an American chemist, Linus Pauling, had made a breakthrough in solving the structure of the protein alpha helix using a model-building approach.

Two scientists working at Cambridge University in England, James Watson and Francis Crick, decided to use Pauling's method of model building to attempt to solve the structure of the DNA molecule. Combining the data from a variety of sources including the data of Chargaff, Wilkins, and the crucial X-ray crystallography data of Rosalind Frankin, Watson and Crick solved the structure of the DNA molecule.

Watson and Crick created a model of DNA: a double helix, like a twisted ladder. The DNA molecule was a long polymer of repeating nucleotides. Each nucleotide contained three chemical parts: a sugar, a phosphate group, and a nitrogen-containing base. The sides of the double helix ladder were formed by alternating sugars and phosphates, and the rungs were formed on the inside of the helix by specific pairings of the nitrogen-containing bases. Adenine paired with thymine to form one kind of rung. Guanine paired with cytosine to form a second kind of rung.

The order of the bases provided the information within DNA. Certain combinations of bases could form "words" that stood for parts of proteins or other molecules encoded by the DNA. The double helix could unzip like a zipper, each strand serving as a template to guide the construction of a new strand. This provided an accurate means for copying the DNA molecules from a parent cell to a daughter cell.

Animal Model Genetic Organisms

ROUNDWORM (*Caenorhabditis elegans*): This millimeter-long worm allowed scientists to test the concepts of gene therapy, to develop methods for sequencing large amounts of DNA, and provided information about the biology of human diseases such as Alzheimer's disease and cancer. Research on this worm has also enabled scientists to develop effective control measures for plant and animal parasitic roundworms.

FRUIT FLY (*Drosophila melanogaster*): Studies in this organism allowed scientists to determine that genes reside on chromosomes, and gave insight into the nature of mutations. Studies of the development of complex structures such as the eye continue to provide insight into some of the ways cell specialization is regulated and directed by DNA.

ZEBRA FISH (*Danio rerio*): The zebra fish, with its transparent embryos, provides an excellent system in which to study the genes that regulate vertebrate development. Additionally, zebra fish have been used in studies investigating bioaccumulation of organic compounds in the environment.

COMMON MOUSE (*Mus musculus*): Mice are useful for genetic study because of the availability of hundreds of single gene mutations. Studies in mice demonstrated that Gregor Mendel's laws of inheritance were as applicable to mammals as to plants. Transgenic genetic analysis of mice has allowed the creation of mouse strains that mimic human genetic diseases.

Genetic Engineering

The details of how DNA is passed from one generation to the next, of how mutations arise, and of how the information of DNA is actually translated into the activities of cells forms the basis of genetic research at the beginning of the twenty-first century.

One of the most important scientific discoveries that led to modern genetic technology was the discovery of a particular kind of protein, a restriction enzyme, from bacteria that cuts DNA molecules at specific sequences of bases. These restriction enzymes gave scientists the tool they needed to break DNA down into smaller pieces, eventually allowing the isolation of individual genes from the huge amount of DNA inside the nucleus of the cell.

Herbert Boyer and Stanley Cohen combined their knowledge of restriction enzymes and bacterial transformation (getting bacteria to take up DNA from the environment) to clone genes. Gene cloning involves isolating a gene of interest by using a restriction enzyme to cut it away from other DNA, and placing it in a piece of DNA called a vector that can be taken up by bacterial cells. One of the first applications of this technology was the production of human insulin. Scientists isolated the gene that encodes the information for making insulin from human DNA, cloned it into a bacterial vector, and placed the vector with the insulin gene in *E. coli*. The *E. coli* cells were able to produce large quantities of insulin. This new insulin was considerably cheaper and safer than insulin purified from human tissue.

Variations on this technique of taking a piece of DNA from one species and inserting it into the cells of another species are involved in genetic engineering of multicellular organisms. In multicellular organisms such as plants or monkeys, the DNA vector is usually a modified virus. These techniques are the basis of human gene therapy.

In the last decade of the twentieth century, entire organisms have been cloned. In Scotland, Ian Wilmut and colleagues reported the first mammalian cloning of a sheep named Dolly. In Wisconsin and Japan, scientists have cloned cattle. When an organism is cloned, all of its DNA, usually contained within an intact nucleus from a cell of the adult animal, is transferred to an egg cell from which all the genetic information has been removed. The egg is then allowed to develop into a new organism. Although the new organism is young, it has the same DNA as the parent from which the nucleus was obtained.

Scientists have also developed techniques for sequencing DNA, determining the exact order and number of nitrogenous bases within the DNA of an organism's genome. In 2000, the Human Genome Project announced that the entire genome of the human had been sequenced. Many other genomes have been sequenced, including the roundworm, *C. elegans*, several plants, and even baker's yeast. The sequence of an organism gives scientists another tool in answering questions about how DNA regulates and determines the activities of cells.

The ethical consequences of genetic engineering are not clear. DNA forensic evidence is now used to convict or exonerate criminal suspects on a routine basis. The genetic engineering of food crops that are pest resistant or contain additional nutrients is fairly routine. With the cloning of entire organisms now possible, the cloning of a human is not science fiction. Parents can have an embryo tested for devastating genetic diseases before it is born. While many of these advances are clearly positive, many of them are double-edged swords, begging for informed public debate.

GIRAFFES

Type of animal science: Classification
Fields of study: Anatomy, behavior, ecology, physiology

Giraffes are even-toed, herbivorous mammals that are found exclusively in Africa. They have long necks and legs, and distinctive brown patches all over their bodies.

Principal Terms

BROWSER: feeds on shoots and leaves
DIURNAL: active during daylight hours
FLEHMEN: behavior involving curling and wrinkling of lips and nostrils, with the activation of the Jacobson's organ
HIERARCHY: a social structure in which animals are dominated by those higher on the linear ladder
JACOBSON'S ORGAN: a sense organ between the roof of the mouth and nasal passages, which detects chemical signals associated with reproduction

Because of their long necks and legs, giraffes are the tallest animals in the world. Patch coloration and shape can vary within their extensive habitat range. Females are distinguished from males in that the females have shorter, inward-curving horns. In both sexes, a long mane of stiff, brushlike hairs extends from the back of the head to the shoulders. Giraffes exhibit a unique, fluid gait. When walking, the fore and hind legs on the same side appear to move almost in unison. Swift and fleeting, giraffes can gallop up to thirty-three miles per hour. Their gallop can be described as a motion in which the front legs move together and their hind legs move forward and outward, enveloping the forelegs in a unique rhythmic pattern. Long and graceful, their sleek necks swing back and forth rhythmically with their legs. The neck has remarkable range of motion. A system of blood vessels and valves in the neck protects the brain and reduces blood pressure when the animal lowers its head.

Diet

Although some may feed at night, giraffes are classified as herbivorous diurnal eaters. They are browsers, and competition for food is greatly reduced because of the height at which they feed. The male feeds at greater heights, with his head stretched upward, whereas the female feeds at lower heights, often bending her head and neck to reach the leaves. Giraffes feed mainly on the highly nutritious leaves, fruit, and flowers of acacia trees. Their long, dexterous tongues strip leaves from the acacia twigs. Giraffes often consume soil and bones to balance the phosphorus and calcium in their blood. When feeding on sprouted vegetation and when drinking water, giraffes splay their front legs and bend their knees. In such a position, they are vulnerable to predators, especially lions. Giraffes can go without water for days.

Protection, Defense, and Communication

Generally docile creatures, giraffes may kill other animals with a kick of a fore or hind hoof. Their heads, used like a knight's mace, land formidable blows on the body or legs of opponents. The effective use of their heads as weapons is enhanced by the physical structure of horns and knobs. The skull bone is solid and thick, so that its force can result in a fatal blow. The giraffe's own head is protected by extensive sinuses, which absorb shock. Giraffes snort, grunt, bleat, bellow, and

Giraffe Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Artiodactyla
Family: Giraffidae
Genus and species: Giraffa camelopardalis, with nine subspecies

Geographical location: Africa, south of the Sahara

Habitat: Dry, open savanna biomes, covered with bush and acacia trees

Gestational period: About 450 days

Life span: Up to twenty-five years in the wild; up to twenty-eight years in captivity

Special anatomy: A long neck with seven vertebrae (characteristic of all mammals); adult height of between fifteen and eighteen feet; chestnut brown patches of various sizes and shapes; sloping back ending in a long, tufted tail; a pair of horns on top of the head

GOATS

Types of animal science: Anatomy, classification, reproduction
Fields of study: Anatomy, zoology

Goats, artiodactyls similar to sheep, can live on hills and mountains where sheep would starve. They were domesticated to provide meat, milk, and leather.

Principal Terms

ARTIODACTYLS: hoofed mammals with an even numbers of toes

GESTATION: pregnancy

HERBIVORE: an animal that eats only plants

KERATIN: a tough, fibrous major component of hair, nails, hooves, horns

RUMINANT: a herbivore that chews and swallows plants, which enter its stomach for partial digestion, are regurgitated and chewed again, and reenter the stomach for more digestion.

UNGULATE: any hoofed mammal

Goats are herbivorous artiodactyls—even-toed ungulates—of the family Bovidae, genus *Capra*, which usually have hooves and hollow horns. They are also ruminants, chewing and swallowing food, regurgitating it, and chewing and swallowing it again. This cud chewing allows them to get the most nutrients possible from the low-quality foods they eat.

Wild goats are mountain dwellers, adept at leaping between rocks, sure-footed due to their hoofs. The hoofs have a hard outer layer and a softer, inner layer that wears away quickly and leaves hard edges useful for climbing. Domesticated goats, raised for milk, meat, and leather, retain many of these characteristics. Swiss goats, the most common domesticated variety, have pointy ears and horns, while Nubians are hornless.

Physical Characteristics of Goats

Most adult goats weigh up to 125 pounds. They are not as large as sheep, which they resemble. Their horns are twisted flat and turn backward. Their hoofs are divided in two (cloven). Males are called rams or billies, while females are called does or nannies. Males emit strong odors during mating season. Males and most females have chin beards, leading to the name "goatee" for the similar style of facial hair in men. Goats are normally covered with straight hair, but some grow wool, such as angora goats. Their coats are red, brown, tan, or white. Goats find enough to eat on poor, dry land where horses, cows, and sheep would starve. Adult female goats reach lengths of 2.5 to 3.5 feet and are approximately 4 feet at the shoulder; they weigh between 100 and 120 pounds. Males are 20 percent larger and heavier than females and have longer horns.

Domesticated goats derive from ten wild goat species. They live on hills and mountains and are either goat antelope or true goats. All except the Rocky Mountain goat inhabit Europe and the Asian Himalayas. Rocky Mountain goats and chamois are goat antelope, having physical characteristics of both goats and antelope.

Types of Goats

Rocky Mountain goats are goat antelope inhabiting mountains from the American Northwest to Alaska. They live in snowy, craggy habitats and are excellent climbers, due to hoofs having soft pads with hard rims that work well on snow, ice, or rock. Rocky Mountain goats are about three moo to communicate. Because of their height, giraffes' sense of smell is not as keen as other animals. However, their sensitivity to sound and their visual acuity more than compensate for their underdeveloped sense of smell.

Reproduction and Birth

Mixed herds of variable numbers have been recorded in the field. Old males are often solitary. About a day before mating, the female becomes sexually attractive. At the onset of mating, the male licks the female's genitals and catches her urine on his tongue. Chemical signals in her urine are detected by flehmen as the male's Jacobson's organ becomes activated. The male remains with the female in heat unless he is displaced by a higher-ranking challenger. The female gives birth in cover, with her back legs bent to reduce the height from which the calf falls. Initially, the mother is alone with her calf, but later she may form a nursery group assisted by other females. The calf stands within five minutes of birth and suckles within the hour. The calf becomes independent of the mother around the sixteenth month. Play behavior, called nose-to-nose sniffing, between the young cements social bonds between them.

Giraffes are the tallest animals in the world, with long necks that allow them to eat leaves from the tops of trees unreachable by other herbivores. (Corbis)

Goat Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Artiodactyla
Family: Bovidae
Subfamily: Caprinae
Tribes: Rupicaprini (four genera, five species); Ovibonini (two genera, two species); Caprini (five genera, seventeen species)
Geographical location: Asia, Europe, North America, Africa, New Zealand, Australia
Habitat: Dry mountains or hills
Gestational period: Around 5.5 months
Life span: Fourteen to twenty years
Special anatomy: Permanent, hollow horns, ruminant stomach, very tough hooves

feet tall at the shoulder, with black horns, white, shaggy pelage, and goatees. They eat any plants available and are solitary, except during mating.

Chamois goat antelope have light brown pelage in the summer, which turns dark in winter. The males' deadly curved horns are eight inches long. Chamois are about the same size as Rocky Mountain goats and have similar hoofs. They live above mountain tree lines in Europe, Asia, and New Zealand and prefer eating grass and lichens. During winter, they eat pine needles and bark. Females form herds of up to one hundred, while males live alone except to mate. Chamois battle for mates, and defeated males often die after their belly and throat are ripped open by the victor's horns.

Angora goats, true goats, have body shapes like domesticated Swiss goats. They inhabit Turkey, South Africa, the United States, Argentina, Australia, and New Zealand. Horned and bearded, their long, thick, hair is used in mohair cloth. Angora goats grow approximately 80 percent of the size of Rocky Mountain goats. They live on hillsides, eating woody vegetation and grass.

Nubian goats, hornless true goats, have short hair and droopy ears, and the males have goatees. Adult males weigh up to 180 pounds, while females weigh up to 140 pounds. Males are about five feet tall at the shoulder. Their coats are black, tan, or red, sometimes with white spots. They eat briars, thistles, and brambles, as needed, with their tough mouths and teeth. Their splayed hooves aid climbing hills. Nubians live in large herds and males fight for mates.

Goat Life

Goats prefer eating leaves and grass, but can eat thistles, briars, and brambles with their tough mouths and teeth. Thus, they can survive where soft vegetation is scarce and other herbivores starve. Goats are sociable and live in groups of from a dozen to thousands of individuals.

Mountain goats are adept at leaping from rock to rock, balancing on their hooves. (PhotoDisc)

In the wild, males fight for mates and may die in such battles. Mating usually occurs in the spring among domesticated goats, while wild goats generally mate in the fall. The goat gestation period is about 5.5 months and yields one to four young, nursed for six months. Young goats are born with hair, eyes open, and can run and jump within twelve hours of birth. Goats can live for fourteen to twenty years.

A number of goat breeds are raised for meat, milk, leather. Goats are fine milk producers, and the milk is often used to make cheese. Their milk is sweet, nourishing, and easy to digest. It also has more fat and protein than cow milk and is helpful to persons with digestive troubles. More people throughout the world use goat milk than cow milk. Toggenburg and Saanen Swiss goat imports are popular milk goats in the United States. Toggenburgs are brown, with light side stripes, while Saanens are short-haired and white or cream-colored; both breeds produce around five quarts of milk per day. Goatskins also make high-grade leather; for instance, "Morocco leather" is chamois skin. Angora and cashmere goats are raised for their coats, which are used to make wool.

GOPHERS

Types of animal science: Anatomy, classification, reproduction
Fields of study: Anatomy, zoology

Gophers are small, burrowing rodents with fur-lined cheek pockets. When they eat bulbs and roots they become agricultural pests, damaging crops.

Principal Terms

GESTATION: time in which mammalian offspring develop in the uterus
HERBIVORE: an animal that only eats plants
INCISOR: a cutting tooth that acts like a scissors or chisel
RODENT: any gnawing animal

Gophers are small, herbivorous rodents. They are rat-sized, but somewhat more rotund than rats. They form the families Geomyidae and Thomomyini, which have eight genera, thirty-five species, and hundreds of subspecies. Gophers burrow in the ground and do not leave their burrows during daylight hours. Different species are found in deserts, shrublands, and grasslands across much of North and Central America, from central and southwestwern Canada through the western and southeastern United States, Mexico and south to the Panama-Colombia border.

Striped gophers (*Citellu tridecemlineatus*, prairie squirrels), which have thirteen body stripes, live from the western plains of the United States to Panama. Camas rats (*Thomomys bulbivorus*) are the largest gophers, reaching body lengths of over one foot. Plains pocket gophers (*Geomys bursarius*) are dark brown, and common in the Mississippi Valley.

French settlers in North America first noticed that gopher burrows honeycombed the soil and named them *gaufres* (French for "honeycomb"). These animals all have pouches (pockets) in their cheeks, and are more correctly called pocket gophers (pouched rats). Pocket gophers are divided into twenty-six Geomyini species and nine Thomomyini species. The main gopher types include eastern pocket gophers, yellow pocket gophers, and western pocket gophers.

Physical Characteristics of Gophers

Gophers are plump, ratlike rodents, up to 1.25 feet long and covered with soft, short, black and red-

Gopher Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Rodentia (rodents)
Family: Geomyidae (gophers)
Tribes: Geomyini (four genera, twenty-five species); Thomomyini (one genus, nine species)
Geographical location: North and Central America, from central and southwestern Canada, western and southeastern United States, Mexico, and south to the Panama-Colombia border
Habitat: Deserts, shrubby land, grasslands, agricultural areas, and tropical lowlands
Gestational period: About three weeks
Life span: Up to four years in the wild; up to six years in captivity
Special anatomy: Fur-lined pockets in cheeks, whiskers, strong incisor teeth, front claws for digging, tactile tails

brown to gray fur. All have whiskers, to help them navigate underground and at night, and two large, fur-lined pockets, one in each cheek. These pockets, used to carry food, lead to the name pocket gopher. The pockets are lined with fur, and a gopher can turn them inside out to clean them.

Gophers have wide, blunt heads, with underdeveloped ears and eyes. Their incisors are large and well designed for gnawing. Gophers have short limbs and feet with powerful claws, longer on the forefeet. They dig tunnels with the claws of the front feet. Their thick, almost hairless tails, about three inches long, are sensitive tactile organs, used to help them find their way around their tunnels when moving backward. Gophers are able to run backward about as quickly as forward. Their body lengths range from 4.5 to 17 inches, and they weigh between 0.75 and 2 pounds.

Gopher Life

Gophers eat leaves, grass, roots, nuts, tubers, buds, and farm vegetables. Their main foods, garnered in their tunnels, are roots and tubers. The other foods are gathered on nocturnal surface forays. They need water to survive, but when water is scarce in arid regions, they eat cacti to obtain it. The gophers store most of their food in the tunnels and chambers of their burrows. They carry the food to their burrows in their cheek pouches.

Gophers are solitary and males are territorial. They come together only to breed. Female gophers can have one or several litters each year. They birth two to ten young, depending on the species. Gestation is about three weeks. The young are totally dependent on their mothers at birth, weaned after a month, and have their own tunnels by age three to four months. Pocket gophers have life spans of one to seven years.

Image Not Available

Western Pocket Gophers

Western pocket gophers—like other gophers—have small, round bodies. They are tan to gray and live in deserts, meadows, and farmlands in Canada, the southwest United States, Mexico, and Central America. They like areas where the soil is easy to dig. These gophers eat plant leaves and underground roots and tubers. In dry areas, they eat cacti to obtain water. They travel on the surface at night, seeking and cutting through underground roots with sharp incisors. Western pocket gophers carry their food in their cheek pouches. They are territorial, and a given male's territory may be up to one thousand square feet.

Western pocket gophers can breed up to four times a year, once during each season of the year. Gestation is approximately three weeks, and young, born completely dependent on their mothers, develop their own burrows and territories within three months. These gophers live for four years in the wild and seven years in captivity.

Gophers are very destructive when they tunnel in farmland such as meadows, farms, and orchards. The tunnels are identified by the mounds of earth left along their courses. Very voracious, gophers eat all vegetation they find underground. They destroy food trees, tuber crops, and flower crops by gnawing roots, tubers, and bulbs.

GORILLAS

Type of animal science: Classification
Field of study: Anatomy

Gorillas, the largest, rarest, most powerful apes, are shy vegetarians living in bands in the wild. They have language and are an endangered species.

Principal Terms

BAND: A gorilla group of five to twenty apes, including males, females, and young

SILVERBACK: An older, male band leader, whose back hair has turned gray

Gorillas, the largest, strongest, rarest apes, look the most human of all other primates. They live in equatorial West African forests, from lowlands near the Cameroon Coast to highland altitudes of 10,000 feet in Rwanda, Zaire, and Uganda. All gorillas are believed to belong to one species, *Gorilla gorilla*.

Physical Characteristics of Gorillas

Males are 5.75 feet tall when on all fours, over six feet when standing erect, and thus are taller than the average man. They are much heavier, weighing three hundred to six hundred pounds. Unsurprisingly, their bone structure is heavier than that of humans. Females, a foot shorter than males, weigh half as much. Gorilla skin is dark and, except for the face and hands, covered with long, coarse, dark brown to black hair. This hair turns gray on the backs of older males, who are then called silverbacks.

Gorillas, especially males, look fierce, although they are timid unless mating, cornered, or threatened. Their fierce looks are due to hulking bodies and somber faces, with dark, hairless, strong jaws and long, powerful teeth. In addition, gorillas have brutish brow ridges which jut out above small eyes. Finally, the face of the male is dominated by a large, flat nose with coarse nostrils. Combined, these features produce what humans perceive as a somber and threatening expression.

Gorilla brain cases and brain sizes are smaller than in humans, promising lower intelligence. As to skeletal structure, the gorilla is similar to humans, but its bones are thicker. Its arms are much longer and its legs are much shorter. Gorilla spines lack the structures needed for a continual erect posture. Therefore, while gorillas can stand upright and walk erect, most often they walk on all fours, using the knuckles of their hands as supports.

Life and Sexual Cycles of Gorillas

Contrary to their legendary savagery, reinforced by their appearance, gorillas are shy, friendly creatures. Once they become used to unthreatening intruders, as Dian Fossey discovered, these individuals are accepted. Initially, males of gorilla groups charge intruders, growling and beating their chests. Intruders who run are often killed. Those who stand their ground and behave in an unthreatening manner are not harmed.

Gorillas live in families and extended families (bands) of five to twenty individuals. A band has a silverback leader, up to three subordinate males who help protect it, several mature females, and numerous young. The silverback drives most young gorilla males away at maturity. At these times all males are fierce and use their strength to attain and maintain supremacy. Males driven off form bachelor groups or join other bands. Silverbacks, challenged and defeated, live alone.

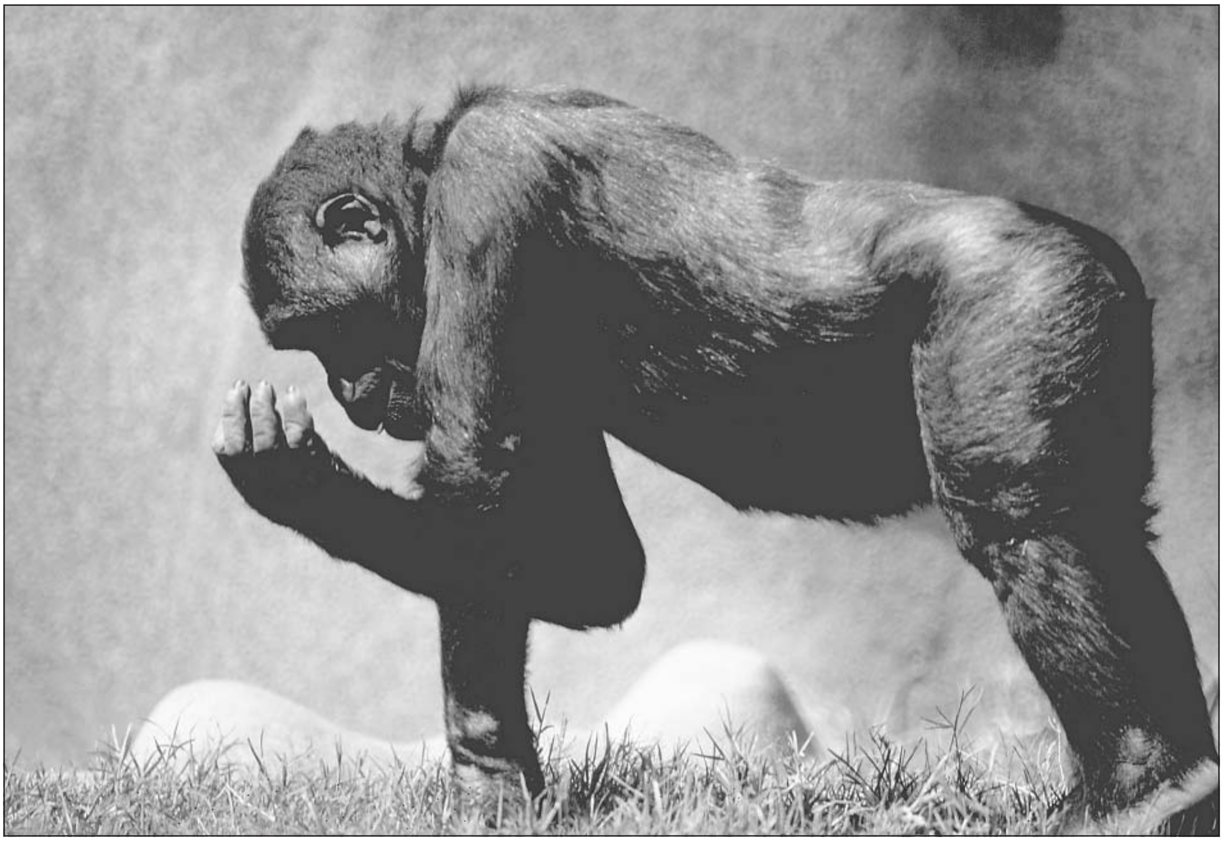
Gorilla bands each have a territory they allow

Gorilla Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Primates (apes, monkeys, and humans)
Family: Pongidae
Genus and species: Gorilla gorilla
Geographical location: Equatorial West Africa
Habitat: Lowland and highland forests
Gestational period: Nine months
Life span: Thirty to forty years in the wild, up to fifty years in captivity
Special anatomy: Long arms used to walk on all fours

others to enter. A band lacks permanent dwellings. Rather, its members build temporary shelters each night after a long day of travel to forage for the honey, eggs, plants, berries, bark, and leaves that make up the gorilla diet. In the wild or in captivity gorillas will eat meat, but do not seek it or kill other animals, except in self defense. When the terrain permits, females and young sleep on tree platforms of branches and leaves. Mature males nest at the bases of trees occupied by other band members.

Female gorillas, like women, menstruate monthly and mate successfully at any time. Pregnancy lasts 9.5 months and yields one or two young. Baby gorillas are suckled for a year. They are adults ten to eleven years later. Wild gorillas live for thirty to forty years. A few captive gorillas have attained more than fifty years.



The gorilla's spine lacks the support structures that would allow it to stand upright, so it usually uses its arms for support, resting on its knuckles. (Corbis)

Dian Fossey

Born: January 16, 1932; San Francisco, California
Died: December 26, 1985; Karisoke Research Center, Rwanda
Fields of study: Anthropology, zoology
Contribution: Fossey, an American zoologist, was a world authority on mountain gorillas.

Dian Fossey was born in San Francisco. After completing elementary and high school, she studied occupational therapy at San Jose State College, graduating in 1954. After this, she worked as a therapist in a children's hospital in Louisville, Kentucky.

In 1963, Fossey traveled to East Africa. There she met the famous anthropologist Louis Leakey and had her first exposure to mountain gorillas. Fossey returned to the United States and to her job, staying there until 1966. Then the persuasive Leakey convinced her to return to East Africa to study mountain gorillas in the wild, from the perspective of a trained therapist. Fossey began to work with these rare, elusive apes, which fascinated her and became her lifework. In 1967, she formalized this fascination by establishing the Karisoke Research Center in the solitude of Rwanda's Virunga Mountains. Initially she carried out her work alone, with no professional staff.

After expending a great deal of effort on the task, Fossey was able to accustom the gorillas to her presence in their midst and to study them quite extensively. The data that Fossey was able to accumulate greatly enlarged the scientific understanding of the mountain gorilla's lifestyle, habits, and methods of communication in the wild. To expand her scientific credentials, Fossey left Rwanda for England in 1970 to work on a doctorate in zoology at venerable Cambridge University. She received her degree in 1974, with a dissertation titled "The Behavior of the Mountain Gorilla."

Fossey soon returned to Rwanda and to her beloved apes. Several volunteer student aides accompanied her. This staff of educated assistants made possible much more extensive research on the mountain gorillas. During the course of her endeavors, one of Fossey's best and most-liked study subjects, the gorilla Digit, was killed by poachers. This motivated her to engage in a pitched battle against the poachers. In 1978, Fossey's efforts to this end began the international media coverage of the issue.

In 1980, she left Rwanda again, accepting a visiting associate professorship at Cornell University in Ithaca, New York. While teaching at Cornell, Fossey completed her well-known book *Gorillas in the Mist* (1983), which was made into a film of the same name (1988). Then she returned to her beloved Rwanda to resume the study of the mountain gorilla. Fossey also increased her campaign against the poachers. Sadly, in 1985 Dr. Fossey's dead body was found in the bush, presumably a murder victim of poachers whose activities she had sought so bravely to stop.

Gorilla Language and Intelligence

Gorilla language is composed of several sounds. Hooting signals alarm or indicates unusual events. Hooting by a silverback gains immediate attention from all band members. Other language sounds include sharp grunts that discipline young gorillas and low growls signifying pleasure. All gorillas beat their chests. In males, this is a symbol of power and intimidates other creatures.

The mental capacity of gorillas was long thought inferior to chimpanzees. Their intelligence is still being explored and testing is changing experimenters' opinions. Different techniques are needed to train gorillas, who are not as curious as chimpanzees. Trained correctly, gorillas have better memories and problem-solving skills than chimpanzees. They also discriminate between geometric shapes better. In addition, it is reported that they are most likely to perform tasks associated with intelligence out of interest, not for rewards. In exploration of communication via American Sign Language (ASL), some gorillas have mastered over one hundred words.

Gorillas' Endangered Status

Gorillas are close to extinction because of intrusion on their habitat of farmers, animal herders, and hunters. In the early 1970's, the estimated gorilla population was one thousand. About 25 percent were in Zaire's Kahuzi-Biega National Park (KBP) and 40 percent in its Mount Virunga area (MVA). The rest were scattered but relatively numerous in Rwanda's Parc des Volcans and Uganda's Gorilla Game Reserve.

In 1980, the number of gorillas in KBP was unchanged and those in MVA had dropped 40 percent. The implied decline, which may be continuing, is explained by increased farming and cattle herding in gorilla habitats. Also, killing and poaching of elephants and buffalo causes these animals to move into gorilla habitats, cutting down food sources for the great apes. The Rwandan Mountain Gorilla Project has slowed the decline in Rwanda. Similar efforts are in place elsewhere.

GRASSHOPPERS

Types of animal science: Anatomy, classification, reproduction
Fields of study: Anatomy, entomology, invertebrate biology

Grasshoppers, leaping insects of the order Orthoptera, include long-horned and short-horned species. They eat grasses and shrubs, as well as agricultural crops, and some human societies eat them.

Principal Terms

MANDIBLES: insect jaws
MOLTING: shedding an insect shell, to enable continued growth
NYMPH: a grasshopper larva

Grasshoppers, leaping insects of the order Orthoptera, include all locusts. However, not all grasshoppers are locusts. The main difference between the locusts and other grasshoppers is the length of their horns (antennae). Locusts (Acrididae) have shorter antennae than other grasshoppers (Tettigoniidae). The amazing leaps of grasshoppers are due to long, slender hind legs with large thighs. These leaps are each many times the grasshopper's body length.

Most grasshoppers also have large, straight, delicate hindwings, which enable flight. When a grasshopper is at rest, these wings are folded up and protected by tough front wings that cover them entirely. Grasshoppers are found in most areas of the world except for northern Canada, Greenland, northern Asia, northwest Africa, West Australia, and the Arctic and Antarctic regions.

Long-horned grasshoppers are herbivores and found wherever vegetation grows. Their threadlike antennae are longer than their bodies. They are related to katydids. When endangered, they spit out brown liquid called "tobacco juice," and take huge, vigorous leaps to escape. The green color of these grasshoppers conceals them in grass, where they eat pieces of grass leaves and stems.

Long-horned grasshoppers do not usually eat crop plants. Short-horned grasshoppers, locusts, are called true grasshoppers because they live only in grasses and leaves. They are well known for traveling in huge swarms that lay bare whole farms or whole regions of countries. The huge populations of swarms and the destruction they have caused are mentioned in the Bible. *Schistocera perigrina*, a North African locust, may have been the species described in the biblical account of the plagues of Egypt.

Physical Characteristics of Grasshoppers

Grasshoppers are one to eight inches long when fully grown. Some species undergo seasonal color changes, being green at some times and red, olive, or brown at others. Like other insects, the grasshopper body is divided into three parts: head; thorax, or mid-section; and abdomen, or hindsection. A grasshopper's antennae, which have tactile functions, are found on its head.

Each grasshopper has a pair of compound eyes with many lenses, located on the front of its head. Grasshoppers also have three pairs of legs, extending from the thorax. The last pair is much larger and longer than the others and enables jumping. Grasshoppers eat leaves, roots, and stems of grasses, herbs, and shrubs, chewing with strong mandibles (jaws), moving these jaws from side to side to break apart their food.

Most grasshoppers have two pairs of wings along the back of the abdomen. Two hard forewings serve as protection and two membranous hindwings are used to fly. When a grasshopper is not flying, its hindwings fold up and are covered and protected by its forewings. All long-horned

Grasshoppers' long, slender hind legs and strong thighs allow them to make amazing leaps many times the length of their bodies. (Digital Stock)

the process. Mature insects mate, and about a week later, females lay the eggs for the next generation. They die a few weeks after this.

Locusts, such as the Rocky Mountain locust (*Melanoplus spretus*), lay their eggs in holes in the ground in the fall. The eggs hatch in the spring, and young reach maturity in July or August. Those of long-horned grasshoppers, such as meadow grasshoppers (*Orchelimum vulgare*) are laid in low bushes or crevices in tree bark.

Not only do locusts eat human crops, but in turn, humans have eaten them for centuries. For example, Talmudic law exempts locusts and other grasshoppers

grasshoppers "sing" by rubbing the bases of their forewings together. Some male locusts make calls to females by rubbing their hind legs against their wings, and others do so by rubbing their hind legs or forewings against other parts of their bodies.

The hearing organs of long-horned grasshoppers are small growths just beneath the knee joints of their front legs. In short-horned grasshoppers, these ears are clear, circular areas on the abdomen at points just behind the junction of hind legs and body. In females, growths shaped like sickles are located at the rear of the abdomen. These ovipositors drill holes in grass, twigs, or the ground, where eggs are deposited. Ovipositors of short-horned grasshoppers are specially designed to deposit pouches of eggs in the ground.

Grasshopper Life Cycles

In the spring, grasshoppers hatch from eggs as pale, wingless nymphs (larvae). Then, within ninety days, they develop into full-grown locusts, molting four to five times in

Grasshopper Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Arthropoda
Class: Insecta
Order: Orthoptera (grasshoppers and related species)
Families: Include Acrididae (short-horned grasshoppers, locusts), Tettigoniidae (long-horned grasshoppers)

Geographical location: Most world locations, except Arctic and Antarctic regions, northern Canada, Greenland, northern Asia, northwest Africa, and West Australia

Habitat: Grass and shrubbery

Gestational period: Natural gestation time is uncertain, as eggs laid in the fall do not hatch until spring

Life span: A year in temperate to cool climates, indeterminate in the tropics

Special anatomy: Six legs, three on each side of the thorax; two pairs of wings, two hard forewings that serve as protection for two membranous hindwings used in flying; ears on or near legs; compound eyes from the taboo on eating flying or creeping creatures "going on all fours." Also, Shakespeare's play *Othello* mentions food "luscious as locusts." Candied locusts are eaten throughout China and the Philippines. In North Africa, locusts dried and ground into powder are mixed into flour used to bake bread.

GRASSLANDS AND PRAIRIES

Type of animal science: Ecology
Fields of study: Conservation biology, ecology, environmental science, wildlife ecology

Grasslands, including the prairies of North America, are a biome characterized by the presence of low plants, mostly grasses, and are distinguished from woodlands, deserts, and tundra. They support a great variety of plants and animals. At present, the remaining grasslands provide grazing for livestock and wildlife.

Principal Terms

BIOMASS: the dry weight of the living material in an organism, population, or community

BIOME: region with a particular climate and a characteristic community of living organisms

CARNIVORE: animal dependent on animal material in its diet

CARRYING CAPACITY: the maximum number of animals that a given area can support indefinitely

DENUDE: strip the covering from, as vegetation from overgrazed grassland

FERAL: once domesticated but no longer under the control of humans

HERBIVORE: animal dependent on plant material in its diet

RUMINANT: animal with four stomach compartments that regurgitates its food and rechews it

Grasslands occupied vast areas of the world over ten thousand years ago, before the development of agriculture, industrialization, and the subsequent explosive growth of the human population. They are characterized by the presence of low plants, mostly grasses, and are distinguished from woodlands, deserts, and tundra. They experience sparse to moderate rainfall and are found in both temperate and tropical climatic zones. The main grasslands of the planet include the prairies of North America, the pampas of South America, the steppes of Eurasia, and the savannas of Africa. Grasslands are intermediate between deserts and woodlands in terms of precipitation and biomass. The warmer tropical savannas average 60 to 150 centimeters (25 to 60 inches) of rain. The temperate grasslands range between twenty-five to seventy-five centimeters (ten to thirty inches) of precipitation, some of which may be in the form of snow. The biomass of grasslands, predominantly grasses, is quantitatively intermediate between that of deserts and woodlands, which produce 10 to 15 percent and 200 to 300 percent, respectively, of the amount of plant material. It should be recognized that the grassland biomes can be subdivided in terms of climate, plant species, and animal species. It should also be noted that grasslands do not always shift abruptly to deserts or woodlands, leading to gradations between them. In addition, grasslands do have scattered trees, often along streams or lakes, and low-lying brush.

Grasses have extensive root systems and the ability to become dormant. These permit them to survive low rainfall, including periodic droughts, or the winter cold typical of temperate regions. Furthermore, grasslands have always been subjected to periodic fires, but the deep root systems of grassland plants also permit them to regrow after fire. Grasses coevolved over millions of years with the grazing animals that depend on them for food. Ten thousand years ago, wild ancestors of cattle and horses, as well as antelope and deer, were on the Eurasian steppes; bison and pronghorn prospered on the North American prairies; wildebeest, gazelle, zebra, and buffalo dominated African savannas; and the kangaroo was the predominant grazer in Australia. Grazing is a symbiotic relationship, whereby animals gain their nourishment from plants, which in turn benefit from the activity. It removes vegetative matter, which is necessary in order for grasses to grow, facilitates seed dispersal, and disrupts mature plants, permitting young plants to take hold. Urine and feces from grazing animals recycle nutrients to the plants. The grassland ecosystem also includes other animals, including worms, insects, birds, reptiles, rodents, and predators. The grasses, grazing animals, and grassland carnivores, such as wolves or large cat species, constitute a food chain.

Humans have been an increasing presence in grassland areas, where over 90 percent of contemporary crop production now occurs and much urbanization and industrialization has taken place. Remaining grassland areas are not used for crops, habitation, or industry because of inadequate water supplies or unsuitable terrain but instead are used for grazing domesticated or wild herbivores. In addition, many woodland areas around the world have been cleared and converted to grasslands for crops, livestock, living, or working.

The Prairies of North America

Originally stretching east from the Rocky Mountains to Indiana and Ohio, and from Alberta, Canada to Texas, the prairies were the major grassland of North America. The short-grass prairie extended about two hundred miles (three hundred kilometers) east of the mountains, and the long-grass prairie bordered the deciduous forest along the eastern edge, while the mixed-grass prairie was between the two. Going from west to east, the amount of precipitation increases, causing changes in plant populations. The short-grass prairie receives only about twenty-five centimeters (ten inches) of precipitation each year, mostly as summer rain, and, as its name suggests, has short grass, less than sixty centimeters (two feet) tall. Today, it is used primarily for grazing because the soil is shallow and unsuited for farming without irrigation. The mixed-grass prairie receives moderate precipitation, ranging from 35 to 60 centimeters (14 to 24 inches) and has medium-height grasses, ranging from 60 to 120 centimeters (2 to 4 feet) tall. Much of it is now used for growing wheat. The tall-grass prairie receives more than 60 centimeters (24 inches) of precipitation, mostly in the summer, and had grasses that grow to over 150 centimeters (5 feet) tall. It has rich soil and has been mostly converted to very productive cropland, primarily for corn and soybeans. The prairies experience very cold winters (down to –45 degrees Celsius, –50 degrees Fahrenheit) and very hot summers (up to 45 degrees Celsius, 110 degrees Fahrenheit). They are often windy and experience severe storms, blizzards in winter, thunderstorms and tornadoes in summer.

Like other biomes, the prairies have a characteristic assortment of animals, herbivores that eat the plants and carnivores that prey on the herbivores. Before 1500 C.E., two ruminants, the bison (commonly but inaccurately called buffalo) and the pronghorn (not a true antelope), were the major grazers on the prairies. The prairie dog, a herbivorous rodent that burrows, lived in large communities on the prairies. The major predators were the wolf and coyote for bison and pronghorn, and the black-footed ferret and fox for prairie dogs. A variety of birds, herbivorous and carnivorous, reptiles, and insects also made their home on the prairie.

Overgrazing Grasslands

While grazing is of mutual benefit to plant and animal, overgrazing is ultimately detrimental to both the plant and animal populations, as well as the environment. Continued heavy grazing leads to deleterious consequences. Removal of leaf tips, even repeated, will not affect regeneration of grasses provided that the basal zone of the plant remains intact. While the upper half of the grass shoot can generally be eaten without deleterious consequences, ingesting the lower half, which sustains the roots and fuels regrowth, will eventually kill the plants. Overgrazing leads to denuding the land, to invasion by less nutritious plant species, to erosion due to decreased absorption of rainwater, and to starvation of the animal species. Because the loss of plant cover changes the reflectance of the land, climate changes can follow and make it virtually impossible for plants to return, with desertification an ultimate consequence. It is not just the number of animals, but the timing of the grazing that can be detrimental. Grasses require time to regenerate, and continuous grazing will inevitably kill them. Consumption too early in the spring can stunt their development.

Semiarid regions are particularly prone to overgrazing because of low and often unpredictable rainfall; regrettably, these are the areas of the world where much grazing has been relegated, because the moister grassland areas have been converted to cropland. Overgrazing has contributed to environmental devastation worldwide. Excessive grazing by cattle, sheep, goats, and camels is partly responsible for the desert of the Middle East, ironically the site of domestication for many animals and plants. Uncontrolled livestock grazing in the late 1800's and early 1900's negatively affected many areas of the American West, where sagebrush and juniper trees have invaded the grasslands. Livestock overgrazing has similarly devastated areas of Africa and Asia. In the early twenty-first century, feral horses in the American West and the Australian outback are damaging those environments. Overgrazing by wildlife can also be deleterious. The 1924 Kaibab Plateau deer disaster in the Grand Canyon National Park and Game Preserve is one such example, where removal of natural predators led to overpopulation, overgrazing, starvation, and large die-offs.

Riparian zones, the strips of land on either side of a river or stream, are particularly susceptible to overgrazing. Because animals naturally congregate in these areas with water, lush vegetation, and shade, they can seriously damage them by preventing grasses from regrowing and young trees from taking root, as well as trampling and compacting the soil and fouling the water course. The ecosystem can be devastated, threatening survival of plant and animal species and leading to serious erosion. While herding and fencing can be used to control animals in these areas, a less expensive method is to disperse the location of water supplies and salt blocks to encourage movement away from rivers or streams. If deprived of salt, grassland animals crave it and will seek it out.

Grassland Management

Grassland areas need not deteriorate if properly managed, whether for livestock, wildlife, or both. Managing grasslands involves controlling the number of animals and enhancing their habitat. Carrying capacity, which is the number of healthy animals that can be grazed indefinitely on a given unit of land, must not be exceeded. Because of year-to-year changes in weather conditions and hence food availability, determining carrying capacity is not simple; worst-case estimates are preferred in order to minimize the chances of exceeding it. The goal should be a healthy grassland achieved by optimizing, not maximizing, the number of animals. For private land, optimizing livestock numbers is in the long-term interest of the landowner, although not always seen as such. For land that is publicly held, managed in common, or with unclear or disputed ownership, restricting animals to the optimum level is particularly difficult to achieve. Personal short-term benefit often leads to long-term disaster, described as the "tragedy of the commons" by biologist Garrett Hardin.

Appropriate management of grasslands involves controlling animal numbers and enhancing grassland plants. Restricting cattle and sheep is physically easy through herding and fencing, although it can be politically difficult and expensive. Much more problematic is controlling charismatic feral animals, such as horses, or wildlife, when natural predators have been eliminated and hunting is severely restricted. As for habitat improvement, the use of chemical, fire, mechanical, and biological approaches can increase carrying capacity for either domesticated or wild herbivores. Removing woody vegetation by burning or mechanical means will increase grass cover, fertilizing can stimulate grass growth, and reseeding with desirable species can enhance the habitat. Plants native to a particular region can be best for preserving that environment. Effective grassland management requires matching animals with the grasses on which they graze.

GRIZZLY BEARS

Type of animal science: Classification
Fields of study: Anatomy, conservation biology, physiology, reproduction science, wildlife ecology

Grizzly bears are a kind of brown bear found in inland North America. Brown bears den during the winter and their reproduction includes a period of delayed implantation. While many brown bears are found in the world, their numbers have been decreasing.

Principal Terms

DELAYED IMPLANTATION: an extended period after fertilization, when an embryo stops developing, and before it attaches to the uterine wall and resumes development

DENNING: the period of winter sleep during which a bear does not eat, drink, urinate, or defecate

DIGITIGRADE: walking on the toes, with the heel raised

PLANTIGRADE: walking on the sole, with the heel touching the ground

Grizzly bear is a loose term used to describe a subspecies of brown bears found in inland North America. Around the world, brown bears vary in color from black to very light brown. Grizzly bears have a brown coat with silver-tipped hairs, which gives them a "grizzled" coloration. Grizzlies vary in weight, usually between four hundred and eight hundred pounds, but are generally smaller than brown bears found on the North American coast. In contrast, the largest brown bears in the world, found in coastal Alaska, sometimes weigh over one thousand pounds. Weight differences in brown bears are probably due to the availability of dietary protein. All brown bears have small, round ears, and large, round, dish-shaped faces with a large brow. They also have a characteristic hump over their shoulder that contains fat, and powerful digging muscles. Five long, nonretractable claws aid their digging. Unlike dogs and cats, which walk on their toes (digitigrade), bears walk flat on their whole foot (plantigrade), as humans do.

Denning

One of the most amazing characteristics of brown bears is their ability to den through the winter. During this time, bears appear to be asleep. Their heart and breathing rates slow dramatically, and their energy use is cut in half. They do not eat, drink, urinate, or defecate for three to five months. Although this is often referred to as hibernation, bears are not true hibernators. Their body temperature only falls a few degrees (to about 90 degrees Fahrenheit) and they are easily awakened.

In order to survive such a long period without eating and drinking, bears break down their fat stores. During the winter, they lose 15 to 30 percent of their body weight. In order to build up the fat needed to make it through the winter, brown bears must eat around ninety pounds of food per day during the fall. Most of this food consists of plant material, such as berries, grasses, nuts, and roots, which they unearth with their powerful digging muscles. They also eat some animal material, as available. This may include fish, deer, or elk, and small mammals, such as squirrels or insects. The denning period allows bears to survive winter, a time of food shortage, by using their own stores. Captive bears that are fed through the winter do not den.

Some scientists believe that understanding bears' denning abilities could aid human medicine. A person who must remain bedridden for several months will suffer from bone and muscle loss. Yet brown bears do this every winter with no ill consequences. They are able to go several months without urinating by reabsorbing water from the bladder and converting wastes back into proteins. Understanding this process could help humans who suffer from kidney diseases.

Reproduction and Distribution

Brown bears mate in the late spring or early summer each year. In the days after mating, the fertilized egg divides and grows into a small cluster of cells. Then, the embryo stops growing and remains free-floating in the uterus until the beginning of winter. This unusual process is known as delayed implantation. In winter, the embryo attaches to the uterine wall, and after a sixty-day pregnancy, cubs are born. Brown bears usually have two to three cubs at a time. The cubs weigh less than two pounds at birth, which is especially small compared to the size of the mother. Yet this is not surprising, because the mother is pregnant during the denning period, when she does not eat.

Brown bears are the most widely distributed species of bear. They are found in North America, Europe, and Asia, from the Canadian tundra to the Iraqi desert. However, brown bears have disappeared from about 50 percent of their original

Grizzly bears are characterized by a fatty lump over their shoulders, which helps sustain them through their winter hibernation. (PhotoDisc)

Grizzly Bear Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Carnivora
Family: Ursidae (bears)
Genus and species: Ursus arctos horribilus
Geographical location: Inland northwestern United States and Canada
Habitat: Varied, including temperate and Arctic grasslands, temperate forests, mountainous regions
Gestational period: A five-to-seven-month embryonic diapause, followed by a sixty-day gestation
Life span: Average twenty to twenty-five years in wild; record, thirty-five years
Special anatomy: A hump above the shoulders

range due to human activities. Accurate census data are difficult to obtain because of their wide distribution, large individual territories and solitary nature. In Japan, the Middle East, and Western Europe, several isolated populations have less than one hundred individuals. Larger populations, of a few thousand, are found in Turkey and Eastern Europe. Most of the world's brown bears live in Russia (around thirty thousand), Alaska (around thirty-five thousand) and Canada (around fifteen thousand). In the lower forty-eight states, brown bears have disappeared from 99 percent of their original habitat and are estimated to number around one thousand. Most of the United States and Canadian brown bears are grizzly bears.

GROOMING

Type of animal science: Behavior
Fields of study: Ethology, zoology

Grooming comprises the various actions by which animals clean and maintain their body surface and is vital to the health of individuals. In many species, grooming also plays an important social role in the interactions of animals and in the maintenance of the social organization of the species.

Principal Terms

ALLOGROOMING: mutual grooming or grooming between two individuals

ALTRUISM: a behavior that increases the fitness of the recipient individual while decreasing the fitness of the performing individual

CONSORTSHIP: a pairing of a male and a female

PHEROMONE: a chemical produced by one individual that influences the behavior of another individual of the group

SYMBIOSIS: a relationship between two species of organisms which is not necessarily advantageous or disadvantageous to either organism

THERMOREGULATION: the process by which animals maintain body temperatures within a certain range

Grooming serves a number of purposes. It is health related in that the activity cares for the skin, feathers, or fur. Grooming also serves a social function. Between members of a community, grooming reduces stress, communicates and signals social status, spreads pheromones, achieves thermoregulation or pain relief, increases or decreases arousal, self-stimulates, and prevents sexually transmitted diseases.

As grooming is similar through the various levels of animal taxa, it has been conjectured that grooming behavior is evolutionarily ancient. Most animals (mammals, birds, and insects) groom by moving their limbs over their own bodies or mouthing or licking their bodies. In some birds, sandbathing is quite common. With fish, a species with no limbs, it is not uncommon to see them rubbing or simply moving against rocks, branches, or sand, generally accomplishing what a sandbath does for a bird.

A bird preening its feathers, a cat licking its paws, or a bear brushing his back against a tree truck are all self-grooming. This is where the animal, alone, takes care of the grooming behavior without help from another animal. However, mutual grooming is quite common. In mammalian species, this is a form a display behavior, which helps to cement the social bonds between members of the group. Yet another kind of cleaning behavior, called cleaning symbiosis, occurs between certain species of fish and shrimp. Here, one species will eat the parasites off another species. The cleaner gets food, the recipient remains debris- and parasite-free.

Grooming as Cleaning Behavior

Observations and experiments performed on laboratory rats showed that pregnant rats spent an increasing proportion of their time grooming their ventral surface, which includes the nipple lines and anogenital areas. When the rats were fitted with collars so they could not reach these regions, their mammary development was inhibited. The conclusion to be drawn from this is that self-stimulating grooming is a necessary part of the preparation process for nursing.

A similar conclusion was reached when looking at the function of grooming in male rats.

Prepubertal males engaged in self-grooming of the anogenital area more than their female counterparts. When collars restricted the rats from grooming, their sexual development was significantly hampered. Again, the conclusion is that male rats needed to perform self-stimulating autogrooming in order to prepare for reproduction.

Another very important fact about self-grooming behavior is the appearance of a grooming pattern. For example, depending on the species, self-grooming may start around the head area and progresses downward until the entire body has been groomed. In experiments, it has been noted that a particular animal will not vary its grooming pattern. Studies on hamsters show that specific grooming tendencies evolve as the animal matures. Certain types of grooming behavior are always the result of some external stimuli, or they are the consequence of an aspect of the animal's natural behavior. A male rat invariably performs genital grooming after copulation. A dog, when aroused by some external stimuli (fear or excitement) will often groom its genitalia for de-arousal. Many animals, when afraid or nervous, will gnaw on their paws. Pigs often chew on other pigs' tails, it is thought, when they are bored or have an excess of nervous energy. The expression "licking one's wounds" originates from the observation that most animals will tend to an injury by licking the area, spreading an antiseptic found in saliva to reduce pain and decrease chances of infection. Insectivores, like solendons and shrews, spend a good deal of time grooming, using only their hind legs, to ensure thermoregulation.

Regardless of the lack of similarity between grooming species, grooming behavior is remarkably similar; reiterating that there has not been a great deal of diversification in the evolution of grooming behavior. Sea lions, seals, and walruses, regardless of whether the pelage is sparse or

Social grooming, where one animal grooms another, promotes social bonds and maintains hierarchies. (PhotoDisc)

Preening—More than Good Looks

Preening, for a human, conjures up a vision of someone preparing and dressing themselves carefully in preparation for a social event. People observing birds preen themselves tend to carry over that interpretation for explaining the observed activity. One function of a bird's preening is to remove various ectoparasites, such as fleas, lice, and ticks, as well as other debris on the body. Nonetheless, not all preening rituals are for cleaning alone. When birds preen themselves, they are actually discharging the secretions of the preen gland, also known as the urophgial or oil gland, onto the surface of the skin through several nipplelike pores. The preen gland is the only prominent skin gland in birds and is most developed in aquatic birds, including ducks and geese. Most birds have the gland, but it is almost completely lacking in the emu, ostrich, and several species of parrots, among others. The most common preening action for a bird is to rub its bill and head over the preen gland pore and then rub the collected oil over the feathers of the wings and body and the skin of the legs and feet. In this way, the down or underplumage, which is buoyant and serves as insulation for the bird, remains water-resistant, thereby allowing for thermoregulation. Some birds may preen themselves more than a dozen times a day. It is thought that the oil from the preen gland contains a chemical that is the antecedent to vitamin D. In the presence of sunlight, this substance is converted to vitamin D and the skin absorbs it. This promotes the health of the bird by preserving the integrity of its feathers, bill, and scales.

dense, spend much time grooming. This is typical of marine mammals. They accomplish this by a doglike scratching motion with their hind flippers and using their fore flipper to rub their head and neck while balancing on the other front flipper. They also nibble on their fur, much like dogs. It is common for these animals to rub against rocks or each other, similar to the activity of bears when they rub up against trees. Fish will also use this rubbing behavior against rocks or coral to scour their bodies free from debris.

Grooming as Social Behavior

Mutual grooming, also called allogrooming or allopreening, is when an animal cares for the body surface of another. Mutual grooming in animals is more a form of communication, a social act, than it is a cleansing one. Researchers have come to this conclusion because the time allocated to mutual grooming exceeds what is necessary for simple cleansing and sanitation. This behavior, especially in primates and social birds, promotes social bonding and establishes and maintains the hierarchy among members of the community.

Mutual grooming also brings attention to whether there is such a thing as animal altruism, which is the selfless delivery of service from one animal to another. Whenever one observes a parent grooming its young, the conclusion is that the motive behind the act is to tend to the health of the infant or young, which promotes the proliferation of the species. Nearly all mammals and many species of birds display this behavior. With marsupial births, the young of the Virginia opossum are in a semiembryonic state. The mother licks the embryon at birth so that the membrane encasing it will break. She then licks a trail from the birth canal to the pouch so that the neonate, using its developed olfactory senses, can find its way to the pouch without further aid by the mother. In altricial and semialtricial placental mammals, the young are usually born naked or with little fur. Most of these animal types, such as cats, dogs, mice, shrew, rats, and hamsters, lick the newborn to remove the birth membrane, break the umbilical cord, and eat the placenta after birth. They lick the newborn to clean the perineal region and to remove urine and feces, also aiding in thermoregulation.

When one observes animal and birds of a similar peer group performing grooming rituals, what appears to be unilateral or altruistic grooming behavior may in fact be mutual aid, in that over the long term, repayment may be expected. It is the expectation of reciprocation that establishes and maintains social status. For example, studies on nonhuman primates (mostly Old World monkeys such as rhesus macaques, stump-tailed macaques, and baboons) have shown that a competition exists among members of a group for animals considered to be excellent groomers. Alliances are formed between groomer and groomed; the groomed may provide excellent protection or be a skilled food gatherer. There is evidence of ranking among members of primate society and mutual grooming appears to assist in maintaining the social order and structure.

In primates that form consortships (Cercepethecines), grooming is important in the copulatory sequence, which is not the case in primates that do not form consortships. In general, sexual grooming serves as a male strategy to increase receptivity of an estrus female. In olive baboons and hamadryas, there is a high correlation between the age of the male and the grooming of the females, implying that this may be an alternative method of securing female cooperation in mating when direct agonistic approaches fail or are no longer an option.

Equids are well-known for mutual grooming. Horses, zebras, and similar animals groom each other by pairing off and standing nose-to-nose or head-to-tail, scratching and nibbling each other's neck, back, and tail with their teeth. The nose-to-nose greeting and rubbing of noses is also typical of tapirs and rhinoceros.

Interspecies Grooming

Humans have successfully exploited the horses' need for bonding by touch and grooming. Trainers often start training horses in spring when the animals are shedding. By brushing and grooming, the trainer develops a friendship and level of trust with the animal. This is an example of interspecies bonding through grooming. This behavior is widely noticed between any combination of humans, dogs, and cats. Sometimes licking another animal or human is simply a show of affection.

Symbiotic grooming, briefly mentioned above, occurs among some species where they pair off to assist one another in the grooming process. Pilot fishes and remoras are commensal fishes (a type of symbiosis) that attach themselves to sharks and other fish. Apart from eating the remnants of the host's meal, they also feed on the external parasites that plague the host fish. Fleas and lice are symbiotic groomers as they eat harmlessly on dead skin or feathers of mammals and birds.

Grooming behavior is an integral part of existence for all higher-order animals. It is such an important part of human behavior that if proper grooming is not taught at an early age and not performed, there are negative repercussions from peers and society in general. Grooming is such an important part of human community, that in the United States alone, the annual sales of men's and women's toiletries is a multibillion dollar industry. Scientists have only recently begun to study grooming behavior closely.

GROUPS

Types of animal science: Behavior, ecology, classification
Fields of study: Ecology, ethology, zoology

Animals form groups, or aggregations, for a variety of purposes. These groups can be temporary in nature, occurring only during specific seasons, or can last throughout the lifetime of the members and lead to highly organized societies.

Principal Terms

COMPETITION: interactions among individuals that attempt to utilize the same limited resource

CONSPECIFICS: members of the same species

DILUTION EFFECTS: the reduction in per capita probability of death from a predator due to the presence of other group members

ENCOUNTER EFFECTS: the reduction in the probability of death from a predator due to a single group of *N* members being more difficult to locate than an equal number of solitary individuals

INTERFERENCE: the act of impeding others from using some limited resource

PREDATION: the act of killing and consuming another organism

RESOURCE DEFENSE: the control of a resource indirectly or directly

SOCIALITY: the tendency to form and maintain stable groups

Some animals spend most of their time alone because the presence of other conspecifics would interfere with the use of a particular resource or a suite of resources. These animals only come together with another solitary individual to pair for reproduction. Others form groups ranging from pairs of animals to large herds. Finally, some animals are brought together by phenomena over which they have no control (winds, currents, or tides) and are simply clumped in space. Groups formed for whatever reason can be either temporary or permanent, and are generally theorized as being beneficial for a variety of reasons. Some associations are simply the result of congregating around a common food resource. Other associations arise for specific functions, such as finding mates, caring for young, providing for a learning environment for developing young, providing protection from the elements, thermoregulation or huddling, locomotory efficiency (swimming or flight), locating and subduing food items, resource defense against other groups or competing species, division of labor, population regulation, predator vigilance, and reduced predation risk via dilution, confusion, encounter, or group defense effects. While potential benefits can be many, aggregation can also result in distinct disadvantages for individuals making up the group. Such disadvantages include increased competition for resources (such as mates, food, or shelter), increased risk of disease and spread of parasites, and interference in reproductive behaviors.

Reproduction and Rearing Young

Living in groups can increase an individual's chance of finding a mate, but it often results in increased aggression between males who must compete for females. Because all females may come into estrus within a short time period, grouping together at specific mating territories ensures that all females will be mated. In such species, courtship rituals are often common. These rituals serve a dual purpose: They provide the male with information about the sexual receptivity of the female and they allow the female to assess the quality of the male prior to pairing with him. In some cases, the rituals also serve to bind the pair together for a breeding season, or in some species for longer periods of time. In other cases, males simply congregate at display grounds, attract, and court females. Females leave the display grounds after mating to nest elsewhere, while the males remain to court other females. This latter grouping strategy is known as lekking.

In some species, which both aggregate during mating seasons and form pair bonds, both male and female can care for the young. In some cases, a mating pair may have helpers at the nest—other members of the species (usually offspring) which aid the parents in raising the young. Helpers at the nest greatly contribute to the breeding success of the parental birds and gain experience themselves in rearing young. They can then use their experience to be successful parents in the next breeding season. Other examples, such as lions and elephants, include kin groups (generally sisters or a mother and her daughters) that help to raise whatever offspring are present in the group.

Colonial nesting and thus synchronous egg-laying produces offspring in large numbers, who are vulnerable to predators for only a short period of time. In this way, each parent lessens the chance that their offspring will be the ones taken by any predator (dilution effect). However, colonial nesting also presents the possibility that offspring may grow more slowly or run the risk of parasitism from fleas and mites. Some evidence exists that offspring of bank swallows gained weight more slowly if they were from large colonies versus small colonies, suggesting that large colonies were depleting their resources more rapidly. Nests from large colonies were also more often infested with fleas than those in small colonies.

Rearing young in a group gives the young opportunities to learn from more than one adult. It can also provide them with practice in tasks that later prove important when the offspring are on their own. Cooperative hunting can provide young with the opportunity to learn hunting skills from their elders. Generally, this benefit results in longer-lived species that produce only a few young per year.

Survival

Cold temperatures can cause physiological problems, particularly for animals that are ectothermic (relying upon the environment for heat). During the day, such animals can bask in the sun and maintain high body temperatures. At night, however, they may have difficulty staying warm, so many huddle together in large groups. This type of behavior allows ectotherms to continue to digest their food (a process requiring heat).

Ectothermic species are not the only ones that huddle—many birds and mammals do so as well. Some birds flock together on trees on particularly cold nights to reduce the surface area of their body that is exposed to the elements. Voles, which are normally asocial, huddle in groups during the winter to keep warm. Marmots can huddle underground in groups of twenty for up to seven months to avoid freezing temperatures in the mountain regions they occupy.

Lowered individual predation risk is theorized as a primary benefit leading to the evolution of gregarious behavior, particularly in the absence of kinship between group members. Three likely outcomes of grouping that can reduce rates of attack are the dilution effect, the confusion effect, and the encounter effect. In the dilution effect, the probability of a particular individual being killed or injured is reduced by the presence of other group members that might be attacked first. This helps to explain why ostriches lay eggs in communal clutches which only the first laying female incubates. The first female is not necessarily acting in an altruistic manner, because she is diluting the chance that predators will find her eggs and eat them or, after the chicks hatch, that predators will capture her chicks instead of those of another female. Individuals in a group may also benefit by putting other animals between themselves and the predator (the selfish herd effect). Grouping provides the opportunity to decrease the area of danger around each individual. If individuals within the group are acting in a selfish herd manner, the groups formed tend to be tightly clumped, as all individuals attempt to put other individuals on all sides around them.

Confusion effects benefit group members because predators may have difficulty in fixing upon a particular individual for attack. The time it takes for the predator to discern a particular individual from a mass of surrounding individuals may be enough for the entire group to scatter and to further confuse the predator.

In contrast, the encounter effect results when it is more difficult for a predator to find a single group of prey than an equal number of scattered individuals due to the apparent rarity of the grouped individuals. However, the actual result of aggregation may be increased risk of detection if the group becomes a more conspicuous entity, which is detrimental to the individuals making up the group, rather than beneficial.

Groups can also benefit by collective defense, which is seen in animals possessing weaponry such as horns or other piercing appendages. Commonly these groups will form a line (phalanx) or a rosette (circular structure) with weapons pointed outward toward the attacker(s). Common examples of these defensive groups include musk oxen, elephants, and spiny lobsters. The use of weapons in these defensive lines may enhance the probability of survival above that of mere dilution, since each defending animal is capable of inflicting damage on a predator.

An individual has to partition its time between foraging and being vigilant for potential predators. However, if that individual is within a group, it can spend more timing on foraging and less time on vigilance because its scan frequency for predators can decrease proportionate to the number of members of the group. Furthermore, because of the many eyes within the group, detection of predators with subsequent alerting of the danger is enhanced. Some species go so far as to alert other group members to danger by alarm calling. This may have evolved for several reasons: The

Lions are one of the few feline species that live in groups. These prides are composed of related females who share responsibility for raising all the young in the group. (PhotoDisc) caller benefits because it knows where the predator is and can position itself appropriately within the group to avoid being a target; the caller may enhance the probability of becoming the target, but at the same time, it reduces the probability that its kin will be targets (this works in kin groups); and/or the caller may attract attention to itself at the time of the call, but if it survives, it is entitled to a payback at a later date from some other individual in the group doing the same.

Communal Foraging and Hunting

Frequently, food being sought for exploitation is clumped in space. As a result, the animals that feed upon this food are also clumped, and this promotes aggregation into group structures, such as herds. Because animals can observe others of their species feeding, they can follow successful foragers to feeding groups and group for no other reason. This phenomenon may allow such foragers to exploit food resources in a more systematic way. Some evidence suggests that grasses clipped by herbivore herds actually grow faster and are more productive than grasses not so clipped, and by proceeding from one patch to another, the herds actually allow the grasses to grow back in a systematic fashion. This allows the food time to replenish itself before the herd passes by it again, and would be less likely to happen if individuals exploited the resource, isolated in time and space.

Other animals form groups to facilitate hunting and capture success. However, some of these groupings can be highly variable in time, based on the food supply and how a kill is partitioned between group participants. For example, sociality in lions is controlled by food supply. When wildebeests or zebra are especially numerous, lions concentrate their efforts upon capturing them, but solitary hunters are successful only 15 percent of the time, while groups of five are 40 percent successful. Furthermore, groups of five lions are better able to protect their kill from scavengers than are groups of two or three lions, even though a group of two or three lions will maximize their daily intake of food per successful kill, while a group of five will only secure the minimum daily requirement of food. Despite their propensity for sociality, lions will hunt alone or in pairs when the migratory wildebeests or zebras leave and only resident gazelles are left. Again, the success rate for a solitary lion hunting a gazelle is only 15 percent, while that for a pair is 30 percent; however, a gazelle can provide the minimum daily requirement of food for only two lions.

Similarly, groups of dogs (the African wild dog, Asian dhole, dingoes, or wolves) are able to kill prey larger than themselves by cooperatively hunting. These packs are composed of kin (parents and their offspring) and cover large distances in order to hunt their prey. The individual dogs will spread out around the prey in a phalanx and then approach until one member selects a victim and runs after it. Other members of the pack will run after the prey in relays until the prey is exhausted and can be subdued.

Communal spiders build webs larger than a single individual could spin and capture prey larger than any one could capture alone. They communally feed on the captured prey. Most spider species have a short interval after the spiderlings have hatched where they remained clumped in a group and live in a communal web. After a period of several days, the spiderlings disperse to take up a solitary life. In communal species, however, adults of the same species come together to form colonies of up to one thousand individuals.

Coordinated group hunting is also known in marine mammals, particularly killer whales (orcas) and humpback whales. Orcas live in matriarchal societies (pods) of two to twelve members and hunt other marine mammals. Single orcas will charge sea lions in the surf of a beach, while other pod members will wait offshore to ensnare any sea lions that respond to the charge by entering the water. Adults will also train juvenile orcas, in the process of play-stranding, to capture seals or sea lions by throwing a dead seal to a beached juvenile. Orcas will also attack baleen whales by surrounding them and biting and holding the whale underwater so that it will drown. Humpback whales are known for bubble feeding, where members of the pod surround a school of small

Migration and Crowd Control

The urge to migrate is under control of an internal clock that is species-specific and that regulates physiological and behavioral rhythms. While individuals making up a population in a specific locale may be solitary during most of the year, they begin to manifest migratory restlessness at the appropriate time to migrate. This results in all individuals expressing the migratory urge at the same time and causes even nonsocial species to group together in a migratory exodus. Some bird species, as well as monarch butterflies, migrate in large groups to warmer climates to avoid the cold; other birds migrate to colder climates to avoid the heat of summer; and monarch butterflies migrate up into the mountains to avoid the heat in the lowlands. Some fish come together to locate home streams (salmon) or other breeding groups; some pinnipeds form large herds on communal pupping grounds; herds of ungulates follow a specific resource such as water or food. For those groups that follow a food or water resource, there is frequent mixing of several species that all exploit the same resource.

Birds are thought to fly in V-shaped formations as a means of reducing the drag on the birds behind the lead flyers. This may be so, since vortex rings are shed off of the wings during the flight stroke as there exists a circulation pattern of air on the wing. Birds flying behind the lead birds in a flock would be buffeted by these vortex rings, and thus the drag on their bodies would increase. Moreover, the vortex rings may create turbulent patterns of airflow behind the lead birds that would detrimentally affect the laminar flow needed to create lift on the bodies and wings of the birds behind. To avoid this situation, birds will often fly in a V formation that allows birds to avoid the disruptions to the airflow made by their fellow members during migration, when energy expenditures are critical considering the long distances covered. Likewise, the individuals in a fish school are arranged so that one fish does not encounter the vortices shed from the lead fish's tail.

fish and release bubbles while spiraling upward. This bubble net concentrates the terrified fish into a tight ball, which the whales then eat as they approach the surface and open their mouths. Groups of dolphins herd fish into shallow waters and surround them so they can be easily picked off.

Even groups of mixed species are known to cooperatively hunt. This is common in shorebirds, where one species might herd the prey while another species either dives to prevent the prey's escape from below or stabs at the prey to prevent its escape along the banks of the water. Pelicans and cormorants, as well as grebes and egrets, are known to form these associations.

Colonial species, particularly those that are sessile and need space to spread out, need to be able to defend their resources. Among invertebrates, larger colonies may have the competitive advantage in excluding newcomers from unoccupied space, as well as pushing other colonial species out of the way, so that the space once occupied can be overrun. Corals are well known for their warlike actions as the space on a reef becomes scarce—they will use their stinging cells to attack adjacent coral species in an attempt to kill the polyps making up the other colony. Dense colonies of bryozoans are much more able to withstand overgrowth by other invertebrates than are bryozoan colonies that are more spread out. Mussel beds can overrun barnacle colonies in the intertidal zone if their main predator is not present in sufficient numbers to keep the mussel population low.

Division of Labor

In eusocial insects, colony members divide the labor amongst themselves. In worker bees, the labor done is dependent on the age of the bee. After emergence, a worker bee's first job is cleaning the hive. She then tends the brood, builds up the honeycomb, and guards the nest. Her final task is to forage for pollen and nectar. The change in her duties correlates to physiological changes in her nurse glands and wax glands.

Ant colonies comprise thousands of individuals, divided into workers, brood, and queen. In army ants, workers vary in size, and these size differences determine their role in the colony. Smaller workers spend most of their time tending to and feeding the larval broods; medium-sized workers make up the majority of the population and are responsible for making raids on other colonies and locating food. The largest workers are called soldiers because of their powerful jaws; they accompany the raiding parties but carry no food.

Naked mole rats are the only known vertebrate that lives in colonies like those of the social insects. Only one female breeds. Larger individuals remain in the colony and huddle to keep the entire colony warm. Smaller individuals are the worker caste and are responsible for nest building and foraging.

These examples serve to illustrate that grouping behavior of animals can serve a myriad of purposes, or can simply be the result of phenomena beyond the animal's control (patchy food resources, physical forces of nature). The functions that lead to cooperative activities are usually best explained by groups being composed of kin; however, cooperation can also evolve in the absence of kinship, provided the benefits to group members outweigh the costs.

Bibliography

Bertram, B. C. R. "Living in Groups: Predators and Prey." In *Behavioral Ecology: An Evolutionary Approach*, edited by J. R. Krebs and N. B. Davies. Sunderland, Mass.: Sinauer Associates, 1978. This article provides a good background of how living in groups can benefit both predators and their prey and how grouping behavior may have evolved for this purpose.

Halliday, Tim, ed. *Animal Behavior*. Norman: University of Oklahoma Press, 1994. It highlights the major activities performed by all animals and provides a series of examples to illustrate the variety of ways in which animals accomplish their goals.

Hamilton, W. D. "Geometry for the Selfish Herd." *Journal of Theoretical Biology* 31 (1971): 294-311. This landmark paper was the first to explore the idea that grouping may be the result of selfishly behaving individuals that are trying to avoid becoming the predator's meal.

Janson, C. H. "Testing the Predation Hypothesis for Vertebrate Sociality: Prospects and Pitfalls." *Behavior* 135 (1998): 389-410. This paper explores explanations of sociality among vertebrates, primarily primates, by attempting to invoke a predation hypothesis. It clearly articulates the problems involved in attempting to show that predation is driving the formation of groups.

Krebs, J. R., and N. B. Davies. *An Introduction to Behavioral Ecology*. 3d ed. Cambridge, Mass.: Blackwell Scientific, 1993. This classic book provides an excellent background tying together behavior and ecology in an attempt to explain why animals do what they do.

Pulliam, H. R., and T. Caraco. "Living in Groups: Is There an Optimal Group Size?" In *Behavioral Ecology: An Evolutionary Approach*, edited by J. R. Krebs and N. B. Davies. 2d ed. Sunderland, Mass.: Sinauer Associates, 1984. This seminal paper attempts to explain what might drive animals to form groups and what the benefits and disadvantages are to grouping.

GROWTH

Type of animal science: Development
Fields of study: Cell biology, zoology

Animal development begins with a single cell, the fertilized egg. Continued growth and formation through numerous cellular replications result in the formation of the complex animal body.

Principal Terms

DIFFERENTIATION: the process during development by which cells obtain their unique structure and function

FERTILIZATION: the union of two gametes (egg and sperm) to form a zygote

GAMETE: a functional reproductive cell (egg or sperm) produced by the adult male or female

GROWTH: the increased body mass of an organism that results primarily from an increase in the number of body cells and secondarily from the increase in the size of individual cells

MITOSIS: the process of cellular division in which the nuclear material, including the genes, is distributed equally to two identical daughter cells

ZYGOTE: a fertilized egg

Animal development has been a source of wonder for centuries. Development involves the slow, progressive changes that occur when a single cell—the zygote, or fertilized egg—undergoes mitosis. Mitosis is the process by which a cell divides into identical daughter cells. During development, mitosis occurs repeatedly, forming multiple generations of daughter cells. These cells increase in number and ultimately form all the cells in the body of a multicellular animal, such as a frog, mouse, or elephant. The simple experiment of opening fertile chicken eggs to observe the embryos on successive days of their three-week incubation period illustrates the process of embryonic development. A narrow band of cells can be seen increasing in number and complexity until the body of an entire, but immature, chick is seen.

Animal Growth and Development

An organism's growth occurs because of the increasing number of cells that form as well as because of the increasing size of individual cells. For example, a mouse increases from a single cell, the zygote, to about three billion cells during the period from fertilization to birth. Embryology is the study of the growth and development of an organism occurring before birth. Growth and development, however, continue after birth and throughout adulthood. Growth ceases only at death, when the life of the individual organism is ended. The bone marrow of human adults initiates the formation and development of millions of red blood cells every minute of life. About one gram of old skin cells is lost and replaced by new cells each day.

Development produces two major results: the formation of cellular diversity and the continuity of life. Cellular diversity, or differentiation, is the process that produces and organizes the numerous kinds of body cells. The first cell that determines an individual's unique identity, the zygote, ultimately gives rise to varying types of cells having diverse appearances and functions. Muscle cells, red blood cells, skin cells, neurons, osteocytes (bone cells), and liver cells are all examples of cells that have differentiated from a single zygote.

Reproduction

Morphogenesis is the process by which differentiated cells are organized into tissues and organs. The continued formation of new individual organisms is called reproduction. The major stages of animal development include fertilization, embryology, birth, youth, adulthood—when fertilization of the next generation occurs—and death. A new individual animal is begun by the process of fertilization, when the genetic material from the sperm, produced by the father, and the egg, produced by the mother, are merged into a single cell, the zygote. Fertilization may be external, occurring in freshwater or the sea, or internal, occurring within the female's reproductive tract. While fertilization marks the beginning of a new individual, it is not literally the beginning of life, since both the sperm and egg are already alive. Rather, fertilization ensures the continuation of life through the formation of new individuals. This guarantees that the species of the organism will continue to survive in the future.

Following fertilization, the newly formed zygote undergoes embryological development consisting of cleavage, gastrulation, and organogenesis. Cleavage is a period of rapid mitotic divisions with little individual cell growth. A ball of small cells, called the morula, forms. As mitosis continues, this ball of cells hollows in the middle, forming an internal cavity called the blastocoel. Gastrulation immediately follows cleavage. During gastrulation, individual cell growth as well as initial cell differentiation occur. During this time, three distinct types of cells are formed: an internal layer called the endoderm, a middle layer, the mesoderm, and an external layer, the ectoderm. These cell types, or germ-cell layers, are the parental cells of all future cells of the body.

Cells from the ectoderm form the cells of the nervous system and skin. The mesoderm forms the cells of muscle, bone, connective tissue, and blood. The endoderm forms cells that line the inside of the digestive tract as well as the liver, pancreas, lungs, and thyroid gland. The transformation of these single germ layers into functional organs is called organogenesis. Organogenesis is an extremely complex period of embryological development. During this time, specific cells interact and respond to one another to induce growth, movement, or further differentiation; this cell-to-cell interaction is called induction. Each induction event requires an inducing cell and a responding cell.

In the formation of the brain and spinal cord, selected cells from the ectoderm form a long, thickened plate at the midline of the developing embryo. Through changes in cell shape, the outer edges of this plate fold up and fuse with each other in the middle, forming a tubular structure (a neural tube). This tubelike structure then separates from the remaining ectoderm. At the head region of the embryo, the neural tube enlarges into pockets that ultimately form brain regions.

For differentiation and development to occur, cells must be responsive to regulatory signals. Some of these signals originate within the responding cell; these signals are based in the genetic code found in the cell's own nucleus. Other signals originate outside the cell; they may include physical contact with overlying or underlying cells, specific signal molecules, such as hormones, from distant cells, or specialized structural molecules secreted by neighboring cells that map out the pathway along which a responding cell will migrate.

Postnatal Development

Embryological development climaxes in the formation of functional organs and body systems. This period is concluded by birth (or hatching, in the case of some animals). Following birth, development normally continues. In some animals, such as frogs, newly hatched individuals undergo metamorphosis during which their body structures are dramatically altered. Newly hatched frogs (tadpoles), for example, are transformed from aquatic, legless, fishlike creatures into mature adults with legs that allow them to move freely on land.

In mammals, development and growth occur primarily after birth, as the individual progresses through the stages of infancy, childhood, adolescence, and adulthood. Mature adulthood is attained when the individual can produce his or her own gametes and participate in mating behavior.

Embryonic growth is especially impressive because the rate of cellular mitosis is so enormous. In the case of the mouse embryo, thirty-one cell generations occur during embryonic development. Thus, the zygote divides into two cells, then four, then eight, sixteen, thirty-two, and so on. This results in a newborn mouse consisting of billions of cells—produced in a period of only twenty-one days. When the newborn passes through its life stages to adulthood, its body cells may number more than sixty billion. One marine mammal, the blue whale, begins as a single zygote that is less than one millimeter in diameter and weighs only a small fraction of a gram. The resulting newborn whale (the calf) is about seven meters long and weighs two thousand kilograms: The embryonic growth represents a 200-millionfold increase in weight. Yet, for some animals, impressive growth periods also occur in the juvenile and adolescent stages of life.

In many cases, once an individual animal reaches its typical adult size, the rate of mitosis slows so that the number of new cells simply replaces the number of older, dying cells. At this maintenance stage, the individual no longer grows in overall size even though it continuously produces new cells. Since most of the cells in the mature adult have reached a final differentiated state, the function of mitosis is simply to replace the degenerating, aging cells. The slowing of the rate of cellular mitosis during this time may be attributable to the presence of specialized cell products called chalones. Chalones are thought to be local products of mature cells that inhibit further growth or mitosis.

Studying Growth

Historically, much study of animal development and growth was performed by simple observation. Aristotle, perhaps the first known embryologist, opened chick eggs during varying developmental periods. He observed and sketched what appeared to be the formation of the chick's body from a nondescript substance. With the invention of lenses and microscopes, growth and development could be studied on a cellular level. The concept of cellular differentiation arose, since investigators could see that embryonic muscle cells, for example, looked different from embryonic nerve cells. Again, much of the investigative information was descriptive in nature. Embryologists detailed the existence of the three germ-cell layers in gastrulation as well as the various tissues and primitive cells involved in organogenesis.

Experimentation as a method of investigating animal growth and development began during the nineteenth century. Lower animal species, such as the sea urchin and frog, were frequently investigated; their developmental patterns are simpler than those of mammals, their development occurs outside the maternal body, and they can be found in abundant numbers. Many of these experiments used separation or surgical techniques to isolate or regraft specific tissues or cells of interest. An attempt was made to determine how one tissue type would interact with and influence the development of another tissue type. Thus, the ideas of induction, in which some tissues affect other tissues, came into being. During this time, the descriptive and comparative observations resulting from these experimental manipulations were the major contributions of investigators.

The embryologists of the early twentieth century paid little attention to genetics. They believed that the major influences on development and growth were embryological mechanisms, although genes were thought to provide some nonessential peripheral functions. Chemical analyses of embryos attempted to establish the chemical basis for the cell-to-cell interactions that were seen during development and differentiation. During the middle portion of the twentieth century, geneticists began to investigate the role of the gene in cell function. The function of genes in the cellular manufacturing of specific proteins led to the hypothesis that each kind of cellular protein was the product of one gene. During this time, bacteria and fruit flies (*Drosophila*) were primary organisms of study because of their relatively simple genetic makeups.

In the latter part of the twentieth century, molecular biology techniques were applied to the study of development. Using techniques for transferring and replicating specific genes, researchers have greatly clarified the central importance of genes in development. Scientists came to believe that all the major developmental and differentiation influences that control cell growth are regulated through specific genes that are turned off or on.

Developmental Biology

The combination of molecular biology techniques with embryological investigations has led to a new field of study—developmental biology. New methods have been developed and used. Radioactive tracer technology has allowed the investigator to label particular genes or gene products and trace their movements and influences on cell growth through several generations. Recombinant deoxyribonucleic acid (DNA) technology has allowed the isolation and replication of significant genes that are important in development. Immunochemistry uses specific proteins (antibodies) to bind to differentiating cell products and quantify them. Cell-cell hybridization allows the introduction of specific genes into the nuclei of cells in alternate differentiation pathways.

Developmental biology, with its multidisciplinary approach, is solving many of the fundamental questions of development. As scientists become better able to understand the role of genetics and cell-to-cell interactions, they gain insight into the mechanisms that control cell growth and development. Consequently, the potential to control undesirable growth or to enhance underdeveloped growth is within reach.

The problem of cell aging is also under investigation. Questions about why mature cells stop dividing and growing and what the causes of aging are constitute important areas of developmental research. While various theories have been presented, the fundamental key to cellular aging remains to be discovered. One of the most challenging areas of continuing research is the determination of how developmental patterns guide evolutionary changes. Developmental principles may provide the answer to why evolution has given rise to animal diversity. In addition, developmental biology may give scientists the information needed to predict and determine future evolutionary trends. The individual animal is a growing organism that begins as a zygote and passes through the stages of embryonic development, birth, youth, adulthood, aging, and death. Preservation of the species depends on adult individuals' producing gametes that result in the formation of a future generation of zygotes and individuals. Remarkably, each zygote contains the necessary genetic instructions to regulate the orderly processes of growth and development. Thus, animal life continues from generation to generation.

Bibliography

Alberts, Bruce, Dennis Bray, Julian Lewis, Martin Raff, Keith Roberts, and James D. Watson. *Molecular Biology of the Cell*. 3d ed. New York: Garland, 1994. This encyclopedic college text is greatly enhanced by its superior diagrams and illustrations. While all aspects of cell biology are covered in great detail, of special interest are the chapters on cellular mechanisms of development and differentiated cells and the maintenance of tissues. Highly recommended for the serious student who wishes to understand developmental processes on a cellular level.

Balinsky, B. I. *An Introduction to Embryology*. Philadelphia: Saunders College Publishing, 1981. While somewhat dated, this very well-written text covers the essentials of classical animal embryology while integrating with them the cellular and molecular mechanisms that regulate them. Of specific interest is the chapter on growth, which integrates this topic into the study of developmental biology.

Baserga, Renato. *The Biology of Cell Reproduction*. Cambridge, Mass.: Harvard University Press, 1985. This illustrated book can be read by the layperson who is interested in understanding more fully the role of cell division and reproduction in growth. The basics of the cell cycle are covered in detail, as are many of the influences that regulate it. In the latter portion of the book, the author describes the genetic mechanisms involved in growth and development.

Gilbert, Scott F. *Developmental Biology*. 6th ed. Sunderland, Mass.: Sinauer Associates, 2000. This is a college-level text written for the upper-level student who has a serious interest in development. The author's approach to development uses a historical experimental analysis of the progress of investigators in the research field. About half of the text deals with specific cell or genetic mechanisms that regulate growth and development. An excellent resource for advanced and accurate information regarding the field of development.

_______, ed. *A Conceptual History of Modern Embryology*. Baltimore: The Johns Hopkins University Press, 1994. A collection of essays concentrating on historical aspects of research on embryonic induction and the relationship between experimental embryology and genetics.

Gilbert, Scott F., and A. M. Raunio. *Embryology: Contructing the Organism*. Sunderland, Mass.: Sinauer Associates, 1997. A college-level textbook on comparative embryology. The first two chapters introduce general terms and concepts, while the following twenty chapters each concentrate on a different animal group.

Hartwell, Leland H., and Ted A. Weinert. "Checkpoints: Controls That Ensure the Order of Cell Cycle Events." *Science* 246 (November 3, 1989): 629-634. An excellent review article describing the biochemical controls of cell division and cell proliferation. Information is a bit technical and is written at the level of the more advanced reader who has some background in biology.

Wessels, Norman K., and Janet L. Hopson. *Biology*. New York: Random House, 1988. The chapter on animal development gives an overview of classic embryology, including the role of growth. The chapter on developmental mechanisms and differentiation takes the reader through the major cellular and genetic regulatory mechanisms involved in development. This extremely well written introductory college text is easily read; it is well illustrated with color photographs and self-explanatory diagrams.

HABITATS AND BIOMES

Type of animal science: Ecology
Fields of study: Anthropology, environmental science, invertebrate biology, zoology

The biosphere is the sum total of all habitats on earth that can be occupied by living organisms. Descriptive and experimental studies of habitat components allow scientists to predict how various organisms will respond to changes in their environment, whether caused by humans or nature.

Principal Terms

ABIOTIC: the physical part of an ecosystem or biome, consisting of climate, soil, water, oxygen and carbon dioxide availability, and other physical components

BIOME: one of the widespread types of ecosystem on the earth, such as the Arctic tundra or the desert

BIOSPHERE: the sum of all the occupiable habitats for life on earth

BIOTIC: the living part of an ecosystem or biome, consisting of all organisms

COMMUNITY: a population of plants and animals that live together and make up the biotic part of an ecosystem

ECOSYSTEM: a relatively self-sufficient group of communities and their abiotic environment

ENVIRONMENT: the habitat created by the interaction of the abiotic and biotic parts of an ecosystem

HABITAT: the specific part of the environment occupied by the individuals of a species

POPULATION: a group of all the individuals of one species

SPECIES: a group of similar organisms that are capable of interbreeding and producing fertile offspring

Life in the form of individual organisms composed of one or more living cells is found in a vast array of different places on earth, each with its own distinctive types of organisms. Life on earth has been classified by scientists into units called species, whose individuals appear similar, have the same role in the environment, and breed only among themselves. The space in which each species lives is called its habitat.

Habitats, Communities, Ecosystems, and Biomes

The term "habitat" can refer to specific places with varying degrees of accuracy. For example, rainbow trout can be found in North America from Canada to Mexico, but more specifically they are found in freshwater streams and lakes with an average temperature below 70 degrees Fahrenheit and a large oxygen supply. The former example describes the macrohabitat of the rainbow trout, which is a broad, easily recognized area. The latter example describes its microhabitat—the specific part of its macrohabitat in which it is found. Similarly, the macrohabitat of one species can refer to small or large areas of its habitat. The macrohabitat of rainbow trout may refer to the habitat of a local population, the entire range of the species, or (most often) an area intermediate to those extremes. While "habitat," therefore, refers to the place an organism lives, it is not a precise term unless a well-defined microhabitat is intended. The total population of each species has one or more local populations, which are all the individuals in a specific geographic area that share a common gene pool; that is, they commonly interbreed. For example, rainbow trout of two adjacent states will not normally interbreed unless they are part of local populations that are very close to one another. The entire geographic distribution of a species, its range, may be composed of many local populations.

On a larger organizational scale, there is more than only one local population of one species in any habitat. Indeed, it is natural and necessary for many species to live together in an area, each with its own micro- and macrohabitat. The habitat of each local population of each species overlaps the habitat of many others. This collective association of populations in one general area is termed a community, which may consist of thousands of species of animals, plants, fungi, bacteria, and other one-celled organisms.

Groups of communities that are relatively self-sufficient in terms of both recycling nutrients and the flow of energy among them are called ecosystems. An example of an ecosystem could be a broad region of forest community interspersed with meadows and stream communities that share a common geographic area. Some ecosystems are widely distributed across the surface of the earth and are easily recognizable as similar ecosystems known as biomes—deserts, for example. Biomes are usually named for the dominant plant types, which have very similar shapes and macrohabitats. Thus, similar types of organisms inhabit them, though not necessarily ones of the same species. These biomes are easily mapped on the continental scale and represent a broad approach to the distribution of organisms on the face of the earth. One of the more consistent biomes is the northern coniferous forest, which stretches across Canada and northern Eurasia in a latitudinal belt. Here are found needle-leafed evergreen conifer trees adapted to dry, cold, windy conditions in which the soil is frozen during the long winter.

Clear-cutting forests is one of the many causes of habitat loss worldwide. (PhotoDisc)

North American Biomes

The biomes of North America, from north to south, are the polar ice cap, the Arctic tundra, the northern coniferous forest; then, at similar middle latitudes, eastern deciduous forest, prairie grassland, or desert; and last, subtropical rain forest near the equator. Complicating factors that determine the actual distribution of the biomes are altitude, annual rainfall, topography, and major weather patterns. These latter factors, which influence the survival of the living, or biotic, parts of the biome, are called abiotic factors. These are the physical components of the environment for a community of organisms.

The polar ice cap is a hostile place with little evidence of life on the surface except for polar bears and sea mammals that depend on marine animals for food. A distinctive characteristic of the Arctic tundra, just south of the polar ice cap, is its flat topography and permafrost, or permanently frozen soil. Only the top meter or so thaws during the brief Arctic summer to support low-growing mosses, grasses, and the dominant lichens known as reindeer moss. Well-known animals found there are the caribou, musk-ox, lemming, snowy owl, and Arctic fox.

The northern coniferous forest is dominated by tall conifer trees. Familiar animals include the snowshoe hare, lynx, and porcupine. This biome stretches east to west across Canada and south into the Great Lakes region of the United States. It is also found at the higher elevations of the Rocky Mountains and the western coastal mountain ranges. Its upper elevation limit is the "treeline," above which only low-growing grasses and herbaceous plants grow in an alpine tundra community similar to the Arctic tundra. In mountain ranges, the change in biomes with altitude mimics the biome changes with increasing latitude, with tundra being the highest or northernmost.

Approximately the eastern half of the United States was once covered with the eastern deciduous forest biome, named for the dominant broad-leaved trees that shed their leaves in the fall. This biome receives more than seventy-five centimeters of rainfall each year and has a rich diversity of bird species, such as the familiar warblers, chickadees, nuthatches, and woodpeckers. Familiar mammals include the white-tailed deer, cottontail rabbit, and wild turkey. The Great Plains, between the Mississippi River and the Rocky Mountains, receives twenty-five to seventy-five centimeters of rain annually to support an open grassland biome often called the prairie. The many grass species that dominate this biome once supported vast herds of bison and, in the western parts, pronghorn antelope. Seasonal drought and periodic fires are common features of grasslands.

The land between the Rockies and the western coastal mountain ranges is a cold type of desert biome; three types of hotter deserts are found from western Texas west to California and south into Mexico. Deserts receive fewer than twenty-five centimeters of rainfall annually. The hot deserts are dominated by many cactus species and short, thorny shrubs and trees, whereas sagebrush, grass, and small conifer trees dominate the cold desert. These deserts have many lizard and snake species, including poisonous rattlesnakes and the Gila monster. The animals often have nocturnal habits to avoid the hot, dry daytime.

Southern Mexico and the Yucatán Peninsula are covered by evergreen, broad-leaved trees in the tropical rain-forest biome, which receives more than two hundred centimeters of rain per year. Many tree-dwelling animals, such as howler monkeys and tree frogs, spend most of their lives in the tree canopy, seldom reaching the ground.

Aquatic biomes can be broadly categorized into freshwater, marine, and estuarine biomes. Freshwater lakes, reservoirs, and other still-water environments are called lentic, in contrast to lotic, or running-water, environments. Lentic communities are often dominated by planktonic organisms, small, drifting (often transparent) microscopic algae, and the small animals which feed on them. These, in turn, support larger invertebrates and fish. Lotic environments depend more on algae that are attached to the bottoms of streams, but they support equally diverse animal communities. The marine biome is separated into coastal and pelagic, or open-water, environments, which have plant and animal communities somewhat similar to lotic and lentic freshwater environments, respectively. The estuarine biome is a mixing zone where rivers empty into the ocean. These areas have a diverse assemblage of freshwater and marine organisms.

The Biosphere

All the biomes together, both terrestrial and aquatic, constitute the biosphere, which by definition is all the places on earth where life is found. Organisms that live in a biome must interact with one another and must successfully overcome and exploit their abiotic environment. The severity and moderation of the abiotic environments determine whether life can exist in that microhabitat. Such things as minimum and maximum daily and annual temperature, humidity, solar radiation, rainfall, and wind speed directly affect which types of organisms are able to survive. Amazingly, few places on earth are so hostile that no life exists there. An example would be the boiling geyser pools at Yellowstone National Park, but even there, as the water temperature cools at the edges to about 75 degrees Celsius, bacterial colonies begin to appear. There is abundant life in the top meter or two of soil, with plant roots penetrating to twenty-two meters or more in extreme cases. Similarly, the mud and sand bottoms of lakes and oceans contain a rich diversity of life. Birds, bats, and insects exploit the airspace above land and sea up to a height of about 1,200 meters, with bacterial and fungal spores being found much higher. Thus, the biosphere generally extends about 10 to 15 meters below the surface of the earth and about 1,200 meters above it. Beyond that, conditions are too hostile. A common analogy is that if the earth were a basketball, the biosphere would constitute only the thin outer layer.

Studying Habitats and Biomes

Abiotic habitat requirements for a local population or even for an entire species can be determined in the laboratory by testing its range of tolerance for each factor. For example, temperature can be regulated in a laboratory experiment to determine the minimum and maximum survival temperatures as well as an optimal range. The same can be done with humidity, light, shelter, and substrate type: "Substrate preference" refers to the solid or liquid matter in which an organism grows and/or moves—for example, soil or rock. The combination of all ranges of tolerance for abiotic factors should describe a population's actual or potential microhabitat within a community. Furthermore, laboratory experiments can theoretically indicate how much environmental change each population can tolerate before it begins to migrate or die.

Methods to study the interaction of populations with one another or even the interaction of individuals within one local population are much more complicated and are difficult or impossible to bring into a laboratory setting. These studies most often require collecting field data on distribution, abundance, food habits or nutrient requirements, reproduction and death rates, and behavior in order to describe the relationships between individuals and populations within a community. Later stages of these field investigations could involve experimental manipulations in which scientists purposely change one factor, then observe the population or community response. Often, natural events such as a fire, drought, or flood can provide a disturbance in lieu of a manipulation caused by man.

There are obvious limits to how much scientists should tinker with the biosphere merely to see how it works. Populations and even communities in a local area can be manipulated and observed, but it is not practical or advisable to manipulate whole ecosystems or biomes. To a limited extent, scientists can document apparent changes caused by civilization, pollution, and long-term climatic changes. This information, along with population- and community-level data, can be used to construct a mathematical model of a population or community. The model can then be used to predict the changes that would happen if a certain event were to occur. These predictions merely represent the "best guesses" of scientists, based on the knowledge available. Population

Habitat Destruction

One of the leading causes of species extinction or threatened extinction is habitat loss and destruction. Although there are many natural disturbances, such as earthquakes, volcanoes, and predators, that degrade or destroy habitats, the problem is most closely correlated with the increase in human population. Between 1850 and 2000, the population of the world increased from about one billion people to over six billion people. Accompanying that increase was the largest destruction of animal habitats and the largest extinction of animal species in the history of the world.

The greatest number of animal species occur in the tropical countries of Africa, South America, Central America, and Asia. Unfortunately, it is in these countries that human population growth continues at an alarming rate, posing an increasing threat in the form of the loss and destruction of animal habitats. In many tropical islands, most of the original habitats are gone, while over 50 percent of the natural habitats in approximately two-thirds of the countries in Asia and Africa have been destroyed.

Particularly threatened are the habitats in rain forests, wetlands, mangrove forests, and grasslands. Although rain forests occupy a small portion of Earth's surface area, they contain over 50 percent of its plant and animal species. Every year, rain forest area exceeding the size of the state of Florida is being lost to commercial logging, conversion to agriculture, and fuel wood production. At the present rate of loss, it is estimated that there may be no more rain forests by the year 2040.

One of the most important habitats for a large variety of vertebrate species are the wetlands and aquatic areas. In the United States, wetland areas account for about 15 percent of the threatened and endangered species. Many of these areas are being drained worldwide for development projects, agriculture, and dam projects. Over 50 percent of the wetlands that existed in the United States in 1800 are now destroyed.

Many aquatic species rely on mangrove forest habitats as breeding areas. Over 50 percent of the commercial species of fish and shrimp in the tropics depend on these areas, as well as many different species of birds. In addition, these special forest habitats, which exist along shallow intertidal coasts, are very important because they control erosion produced by storms. In order to produce more rice, agricultural products, firewood, and construction materials, many of the mangrove forests are being destroyed. In some countries, over 30 percent of these habitats have been lost or destroyed.

Grassland habitats are extremely important for supporting the biodiversity of many vertebrate species. Because these habitats generally occur in gentle terrain with excellent soils, they are frequently exploited for crop production, grazing land, and livestock production. Consequently, as the human population has grown, these areas have drastically shrunk in size.

Another contributing factor to the destruction of a habitat is the problem of habitat fragmentation. This occurs when contiguous habitats are broken into fragments, producing an increasing number of edge boundaries relative to the original habitat. Since many predators, including wolves, foxes, raccoons, and humans, often concentrate on habitat edges for hunting, more and more species become endangered as habitats are fragmented and eventually destroyed.

—Alvin K. Benson

ecologists often construct reasonably accurate population models that can predict population fluctuations based on changes in food supply, abiotic factors, or habitat. As models begin to encompass communities, ecosystems, and biomes, however, their knowledge bases and predictive powers decline rapidly. Perhaps the most complicating factor in building and testing these large-scale models is that natural changes seldom occur one at a time. Thus, scientists must attempt to build cumulative-effect models that are capable of incorporating multiple changes into a predicted outcome.

The biosphere, then, can be studied at different levels of organization, from the individual level through populations, communities, ecosystems, and biomes to the all-encompassing biosphere. Each level has unique relationships that require different methods of inquiry; in fact, these levels describe many of the subdisciplines within the science of ecology.

Biosphere and Biodiversity

Understanding the organization of the natural world of which man is a part is essential to the continued success of humankind. By understanding the abiotic and biotic relationships within and between each ecological level, from microhabitat to biosphere, scientists can partially explain why so many species of organisms have evolved over the last 3.5 billion years. This study of biodiversity may eventually be a key to maintaining a stable biosphere, in which there would be no drastic changes in climate or community relationships. For example, compare the diversity of microhabitats and species in a natural grassland biome with the established monoculture practices of agriculture, with the latter's emphasis on one species. In a wheat field, there are fewer microhabitats available, but those few are available in abundance. This leads to an increase in the population size of "pest" species that compete with man for an abundant food resource, wheat. Understanding the microhabitat requirements of pest species can lead to the reduction of crop losses.

The goal of the study of habitats, biomes, and the biosphere is the construction of predictive models. Once scientists have a general understanding of natural ecosystem processes, mathematical models may be able to predict future changes in the environment caused by the activities of civilization or natural climatic changes. For example, they may indicate whether increased human population size or increased large-scale agriculture in or near desert biomes will lead to the spread of desertlike conditions. On a biosphere scale, they may show whether the increase in the carbon dioxide content of the atmosphere caused by man's activities will lead to global warming. Both these effects are being predicted by many scientists. Prior to the relatively recent growth in the science of ecology and the general interest in it, man had little concern about the effects of the exploitation of natural resources such as forests, of synthetic chemical pollutants such as dichloro-diphenyl-trichloroethane (DDT), or even of the rapid growth of the human population size. With an increasing knowledge and understanding of habitat requirements, natural community interrelationships, and cycling of nutrients and pollutants within the biosphere, however, scientists have greater predictive power concerning the effects of economic development and human population growth. Ecologists are studying the effects of changing rain forests into agricultural land, the extinction of species, the loss of the ozone layer, and many other phenomena that have the potential to change the abiotic environment and therefore affect the stability of biotic communities. These results will be incorporated into future predictive models, giving them increased accuracy.

The challenge—both to scientists and to human civilization as a whole—is to use an understanding of the biosphere to maintain a level of economic growth that is ecologically sustainable. The study of communities and ecosystems may discover ways that civilization can better adapt to its current environment rather than attempt to mold the environment to fit its own preconceived, established ideas.

Bibliography

Allaby, Michael. *Biomes of the World*. 9 vols. Danbury, Conn.: Grolier International, 1999. Each volume offers systematic coverage of a biome of group of related biomes, including physical description, characteristic animal life, and environmental issues and threats. Illustrations, maps, photos, further reading lists, lists of Web sites, glossary, and index.

Bradbury, Ian K. *The Biosphere*. New York: Belhaven Press, 1991. Emphasizes the living organisms within the global ecosystem, including basic cell chemistry, genetics, and evolution. Outlines the way in which ecosystems work. Does not require a background in biology to understand.

Cox, George W. *Conservation Biology: Concepts and Applications*. 2d ed. Dubuque, Iowa: Wm. C. Brown, 1997. An introductory college-level textbook. Discusses terrestrial and aquatic ecosystems, including each system's characteristics, plant and animal life, and environmental problems.

Hanks, Sharon La Bonde. *Ecology and the Biosphere: Principles and Problems*. Delray Beach, Fla.: St. Lucie Press, 1996. A college-level textbook aimed at non-science majors. Covers what science is and what students need to know about it; what the biosphere is, how it works, and what its current problems are; and what students can do about the problems.

Luoma, Jon R. *The Hidden Forest: The Biography of an Ecosystem*. New York: Henry Holt, 1999. Focuses on the Andrews Experimental Forest, a 16,000 acre primal forest in central Oregon, which has been the subject of an intensive thirty-year study. A case study in the minutia of ecosystem research.

Miller, G. Tyler, Jr. *Living in the Environment*. 5th ed. Belmont, Calif.: Wadsworth, 1988. A college textbook that serves as an introduction to environmental science. Good coverage of the biosphere, ecosystem, and biome levels of ecology as well as an extensive annotated bibliography for each chapter.

Scientific American 261 (September, 1989). A special issue on managing the earth, with articles on the changing atmosphere, changing climate, threats to biodiversity, the growing human population, strategies for agriculture, and an ecologically sustainable economy. Emphasis is on the application of ecological knowledge.

Sutton, Ann, and Myron Sutton. *Eastern Forests*. New York: Alfred A. Knopf, 1986. Describes all the forest community types from the eastern deciduous and northern coniferous forest biomes. Unique in that it contains natural history information on insects, spiders, mushrooms, trees, wildflowers, reptiles, amphibians, birds, and mammals. Prefaced by a general description of each community type, written for the layperson.

Wetzel, Robert G. *Limnology*. 2d ed. Philadelphia: W. B. Saunders, 1983. The standard college textbook for freshwater lake ecology; contains extensive coverage of the abiotic environment of lakes. There is also a chapter on the interaction of zooplankton, fish, and bottom-dwelling animal communities. The book is somewhat technical, and background study in biology is helpful.

HABITUATION AND SENSITIZATION

Type of animal science: Behavior
Field of study: Ethology

Habituation is learning to ignore irrelevant stimuli that previously produced a reaction. Results of habituation studies have been used to explain, predict, and control behavior of humans and other organisms.

Principal Terms

ACETYLCHOLINE: a neurotransmitter produced by a nerve cell that enables a nerve impulse to cross a synapse and reach another nerve or muscle cell

APLYSIA: a large sluglike mollusk that lives in salt water and has been used in habituation experiments; its outer covering is called the mantle

IMPULSE: a "message" traveling within a nerve cell to another nerve cell or to a muscle cell

MOTOR NEURON: a nerve cell that causes a muscle cell to respond

NEUROTRANSMITTER: a chemical substance which enables nerve impulses to cross a synapse and reach another nerve cell or muscle cell

ORIENTING REFLEX: an unspecific reflex reaction caused by a change in the quantity or quality of a stimulus; it will disappear or decrease after repeated presentations of the stimulus

SENSITIZATION: an arousal or an alerting reaction which increases the likelihood that an organism will react; also, a synonym for loss of habituation with increased intensity of response

SYNAPSE: the minute space or gap between the axon of one nerve cell and the dendron of the next; also, the gap between a nerve cell and a muscle cell

Habituation is a simple form of nonassociative learning that has been demonstrated in organisms as diverse as protozoans, insects, *Nereis* (clam worms), birds, and humans. The habituated organism learns to ignore irrelevant, repetitive stimuli which, prior to habituation, would have produced a response. With each presentation of the habituating stimulus, the responsiveness of the organism decreases toward the zero, nonresponse level. If habituation training continues after the zero-response level, the habituation period is prolonged. Habituation to a particular stimulus naturally and gradually disappears unless the training continues. If training is resumed after habituation has disappeared, habituation occurs more rapidly in the second training series than in the first. Habituation is important for survival of the individual. Many stimuli are continuously impinging upon it: Some are important, others are not. Important stimuli require an immediate response, but those which result in neither punishment nor reward may be safely ignored.

Stimulus and Response

When a new stimulus is presented (when a sudden change in the environment occurs), the organism—be it bird, beast, or human—exhibits the "startle" or "orientation" response. In essence, it stops, looks, and listens. If the stimulus is repeated and is followed by neither reward nor punishment, the organism will pay less and less attention to it. When this happens, habituation has occurred, and the organism can now respond to and deal with other stimuli. On the other hand, if, during habituation learning, a painful consequence follows a previously nonconsequential stimulus, the organism has been sensitized to that stimulus and will respond to it even more strongly than it did before the learning sessions, whether they are occurring in the laboratory or in the field.

Young birds must learn to tell the difference between and respond differently to a falling leaf and a descending predator. A young predatory bird must learn to ignore reactions of its prey which pose no danger, reactions that the predator initially feared.

A theory known as the dual-process habituation-sensitization theory was formulated in 1966 and revised in 1973. It establishes criteria for both habituation and sensitization. Criteria for habituation (similar to those proposed by E. N. Sokolov in 1960) are that habituation will develop rapidly; the frequency of stimulation determines the degree of habituation; if stimulation stops for a period of time, habituation will disappear; the stronger the stimulus, the slower the rate of habituation; the frequency of stimulation is more important than the strength of the stimulus; rest periods between habituation series increase the degree of habituation; and the organism will generalize and therefore exhibit habituation to an entire class of similar stimuli. Stimulus generalization can be measured: If a different stimulus is used in the second habituation series, habituation occurs more rapidly; it indicates generalization.

Sensitization

Sensitization, a very strong response to a very painful, injurious, or harmful stimulus, is not limited to stimulus-response circuits but involves the entire organism. After sensitization, the individual may respond more strongly to the habituating stimulus than it did prior to the start of habituation training.

There are eight assumptions about sensitization in the dual-process theory. Sensitization does not occur in stimulus-response circuits but involves the entire organism. Sensitization increases during the early stages of habituation training but later decreases. The stronger the sensitizing stimulus and the longer the exposure to it the greater the sensitization; weaker stimuli may fail to produce any sensitization. Even without any external intervention, sensitization will decrease and disappear. Increasing the frequency of sensitization stimulation causes a decrease in sensitization. Sensitization will extend to similar stimuli. Dishabituation, the loss of habituation, is an example of sensitization. Sensitization may be time-related, occurring only at certain times of the day or year.

According to the dual-process theory, the response of an organism to a stimulus will be determined by the relative strengths of habituation and sensitization. Charles Darwin, the father of evolution, observed and described habituation, although he did not use the term. He noted that the birds of the Galápagos Islands were not disturbed by the presence of the giant tortoises, *Amblyrhynchus*; they disregarded them just as the magpies in England, which Darwin called "shy" birds, disregarded cows and horses grazing nearby. Both the giant tortoises of the Galápagos Islands and the grazing horses and cows of England were stimuli which, though present, would not produce profit or loss for the birds; therefore, they could be ignored.

The Neurology of Stimulus Response

Within the bodies of vertebrates is a part of the nervous system called the reticular network or reticular activating system; it has been suggested that the reticular network is largely responsible for habituation. It extends from the medulla through the midbrain to the thalamus of the forebrain. (The thalamus functions as the relay and integration center for impulses to and from the cerebrum of the forebrain.) Because it is composed of a huge number of interconnecting neurons and links all parts of the body, the reticular network functions as an evaluating, coordinating, and alarm center. It monitors incoming message impulses. Important ones are permitted to continue to the cerebral cortex, the higher brain. Messages from the cerebral cortex are coordinated and dispatched to the appropriate areas.

During sleep, many neurons of the reticular network stop functioning. Those that remain operational may inhibit response to unimportant stimuli (habituation) or cause hyperresponsiveness (sensitization). The cat who is accustomed to the sound of kitchen cabinets opening will sleep through a human's dinner being prepared (habituation) but will charge into the kitchen when she hears the sound of the cat food container opening (sensitization).

Researcher E. N. Sokolov concluded that the "orientation response" (which can be equated with sensitization) and habituation are the result of the functioning of the reticular network. According to Sokolov, habituation results in the formation of models within the reticular activating system. Incoming messages that match the model are disregarded by the organism, but those that differ trigger alerting reactions throughout the body, thus justifying the term "alerting system" as a synonym for the reticular network. Habituation to a very strong stimulus would take a long time. Repetition of this strong stimulus would cause an even stronger defensive reflex and would require an even longer habituation period.

The Role of Neurotransmitters

Neurotransmitters are chemical messengers that enable nerve impulses to be carried across the synapse, the narrow gap between neurons. They transmit impulses from the presynaptic axon to the postsynaptic dendrite(s). E. R. Kandell, in experiments with *Aplysia* (the sea hare, a large mollusk), demonstrated that as a habituation training series continues, smaller amounts of the neurotransmitter acetylcholine are released from the axon of the presynaptic sensory neuron. On the other hand, after sensitization, this neuron released larger amounts of acetylcholine because of the presence of serotonin, a neurotransmitter secreted by a facilitory interneuron. When a sensitizing stimulus is very strong, it usually generates an impulse within the control center—a ganglion, a neuron, or the brain. The control center then transmits an impulse to a facilitory interneuron, causing the facilitory interneuron to secrete serotonin.

Increased levels of acetylcholine secretion by the sensory neuron result from two different stimuli: direct stimulation of the sensory neurons of the siphon or serotonin from the facilitory interneuron. Facilitory interneurons synapse with sensory neurons in the siphon. Serotonin discharged from facilitory interneurons causes the sensory neurons to produce and secrete more acetylcholine.

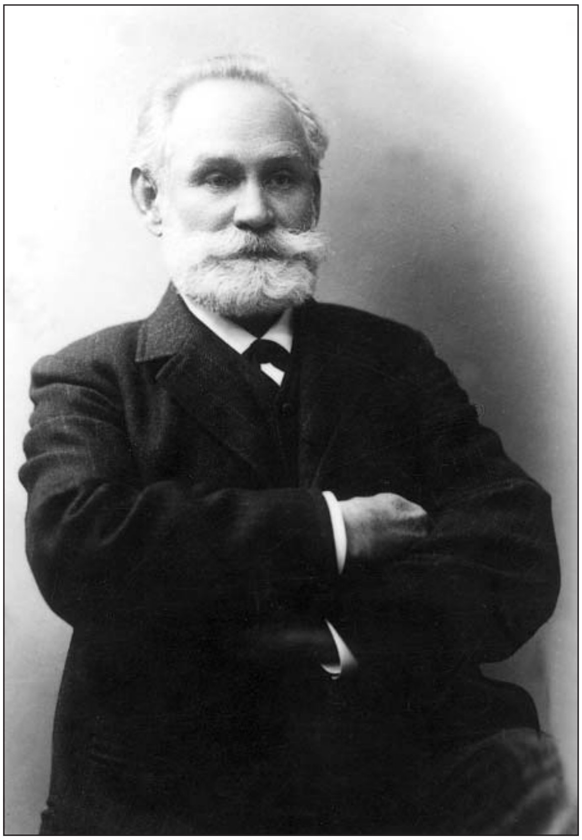
On the molecular level, the difference between habituation and adaption—the failure of the sensory neuron to respond—is very evident. The habituated sensory neuron has a neurotransmitter in its axon but is unable to secrete it and thereby enable the impulse to be transmitted across the synapse. The adapted sensory neuron, by contrast, has exhausted its current supply of neurotransmitter. Until new molecules of neurotransmitter are synthesized within the sensory neuron, none is available for release.

In 1988, Emilie A. Marcus, Thomas G. Nolen, Catherine H. Rankin, and Thomas J. Carew published the multiprocess theory to explain dishabituation and sensitization in the sea hare, *Aplysia*. On the basis of their experiments using habituated sea hares that were subjected to different stimuli, they concluded that dishabituation and sensitization do not always occur together; further, they decided, there are three factors to be considered: dishabituation, sensitization, and inhibition.

Habituation Studies

Habituation studies have utilized a wide variety of approaches, ranging from the observation of intact organisms carrying out their normal activities in their natural surroundings to the laboratory observation of individual nerve cells. With different types of studies, very different aspects of habituation and sensitization can be investigated. Surveying the animal kingdom in 1930, G. Humphrey concluded that habituation-like behavior exists at all levels of life, from the simple one-celled protozoans to the multicelled, complex mammals.

E. N. Sokolov, a compatriot of Ivan P. Pavlov, used human subjects in the laboratory. In 1960, he reported on the results of his studies, which involved sensory integration, the makeup of the orientation reflex (which he credited Pavlov with introducing in 1910), a neuronal model and its role in the orientation reflex, and the way that this neuronal model could be used to explain the conditioned reflex. Sokolov measured changes in the diameter of blood vessels in the head and finger, changes in electrical waves within the brain, and changes in electrical conductivity of the skin. By lowering the intensity of a tone to which human subjects had been habituated, Sokolov demonstrated that habituation was not the result of fatigue, because subjects responded to the lower-intensity tone with the startle or orientation reflex just as they would when a new stimulus was introduced. Sokolov concluded that the orientation response (which is related to sensitization) and habituation are the result of the functioning of the reticular network of the brain and central nervous system. Sokolov emphasized that the orientation response was produced after only the first few exposures to a particular stimulus, and it increased the discrimination ability of internal organizers. The orientation response was an alerting command. Heat, cold, electric shock, and sound were the major stimuli that he used in these studies.



Ivan Pavlov's groundbreaking work on habituation and sensitization, especially in dogs, earned him a Nobel Prize in Medicine in 1904. (Nobel Foundation)

E. R. Kandell used the sea hare, *Aplysia*, in his habituation-sensitization studies. *Aplysia* is a large sluglike mollusk, with a sheetlike, shell-producing body covering, the mantle. *Aplysia* has a relatively simple nervous system and an easily visible gill-withdrawal reflex. (The gill is withdrawn into the mantle shelf.) Early habituation-sensitization experiments dealt with withdrawal or absence of gill withdrawal. Later experiments measured electrical changes that occurred within the nerve cells that controlled gill movement. These were followed by studies which demonstrated that the gap (synapse) between the receptor nerve cell (sensory neuron) and the muscle-moving nerve cell (motor neuron) was the site where habituation and dishabituation occurred and that neurohormones such as acetylcholine and serotonin played essential roles in these processes. Kandell called the synapse the "seat of learning."

Charles Sherrington used spinal animals in which the connection between the brain and the spinal nerve cord had been severed. Sherrington demonstrated that habituation-sensitization could occur within the spinal nerve cord even without the participation of the brain. Pharmaceuticals have also been used in habituation-sensitization studies. Michael Davis and Sandra File used neurotransmitters such as serotonin and norepinephrine to study modification of the startle (orientation) response.

Habituation studies conducted in the laboratory enable researchers to control variables such as genetic makeup, previous experiences, diet, and the positioning of subject and stimulus; however, they lack many of the background stimuli present in the field. In her field studies of the chimpanzees of the Gombe, Jane Goodall used the principles of habituation to decrease the distance between herself and the wild champanzees until she was able to come close enough to touch and be accepted by them. The field-experimental approach capitalizes on the best of both laboratory and field techniques. In this approach, a representative group of organisms that are in their natural state and habitat are subjected to specific, known stimuli.

Learning to Survive

Habituation is necessary for survival. Many stimuli are constantly impinging upon all living things; since it is biologically impossible to respond simultaneously to all of them, those which are important must be dealt with immediately. It may be a matter of life or death. Those which are unimportant or irrelevant must be ignored.

Cell physiologists and neurobiologists have studied the chemical and electrical changes that occur between one nerve cell and another and between nerve and muscle cells. The results of those studies have been useful in understanding and controlling these interactions as well as in providing insights for therapies. Psychologists utilize the fruits of habituation studies to understand and predict, modify, and control the behavior of intact organisms. For example, knowing that bulls serving as sperm donors habituate to one cow or model and stop discharging sperm into it, the animal psychologist can advise the semen collector to use a different cow or model or simply to move it to another place—even as close as a few yards away.

Conservationists and wildlife protectionists can apply the principles of habituation to wild animals, which must live in increasingly closer contact with one another and with humans, so that both animal and human populations can survive and thrive. For example, black-backed gulls, when establishing their nesting sites, are very territorial. Males which enter the territory of another male gull are rapidly and viciously attacked. After territorial boundaries are established, however, the males in contiguous territories soon exhibit "friendly enemy" behavior: They are tolerant of the proximity of other males that remain within their territorial boundaries. This has been observed in other birds as well as in fighting fish.

Slater, P. J. B., and T. R. Halliday, eds. *Behavior and Evolution*. New York: Cambridge University Press, 1994. A textbook for upper-level undergraduate or graduate students. The first four chapters provide a general overview of the relationship between evolution and animal behavior. The final five chapters cover social systems, sexual behavior, kinship, and the evolution of intelligence.

HADROSAURS

Types of animal science: Classification, evolution
Fields of study: Anatomy, evolutionary science, paleontology, systematics (taxonomy)

Hadrosaurs are a group of bipedal dinosaurs that were the most diverse and widespread large-bodied herbivores of the Late Cretaceous. The presence of eggs and nests provides evidence for hadrosaur social behavior.

Principal Terms

ALTRICIAL: animals that need parental care after hatching

CLADISTICS: a method of analyzing biological relationships in which advanced characters of organisms are used to indicate closeness of origin

CRETACEOUS: a period of time that lasted from about 146 to 65 million years ago, the end of which was marked by the extinction of the dinosaurs

LAMBEOSAURINES: hadrosaurs in which the skull bears a large tubular crest

ORNITHISCHIA: one of the two main dinosaur groups, characterized by a pelvis in which the pubis is swung backward

PUBIS: one of the three bones that make up the pelvis (the others are the ischium and ilium)

The hadrosaurids, or "duck-billed" dinosaurs, were large, bipedal dinosaurs, with body lengths up to fifteen meters, that lived during the Upper Cretaceous across North and Central America, South America, Europe, and Asia. It is thought that they originated in Asia, but once they arose, they spread and diversified worldwide, quickly becoming the primary constituent of herbivorous dinosaur faunas. The first hadrosaur remains to be found were represented by a few fragments from Montana and South Dakota, described by Joseph Leidy in 1856. Shortly afterward, a partial skeleton was found in New Jersey, the first nearly complete dinosaur found anywhere, and described by Leidy in 1858 as *Hadrosaurus foulkii*.

Hadrosaurs are ornithopod (bird-footed) dinosaurs, a term that refers to their three-toed feet. They are thus part of the Ornithischia, one of the two major dinosaur subdivisions, and characterized by a pubis (one of the three bones of the pelvis) that is inclined backward. In cladistic terms, they are considered to be a monophyletic group; that is, they are all derived from a common ancestor. They are particularly characterized by a toothless front to the mouth, which is flared outward to form a broad, flat "bill," prompting early re-

Hadrosaur Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Reptilia
Order: Ornithischia
Suborder: Ornithopoda (bipedal herbivores)

Geographical location: Western and eastern North America, central and southern South America, Europe, Asia

Habitat: Terrestrial habitats

Gestational period: Unknown

Life span: Estimated at twenty-five years

Special anatomy: Large, bipedal dinosaurs in which the snout was developed into a beak and a crest was often developed on the head searchers to dub them the duck-billed dinosaurs. This bill was covered by a thick, horny sheath, and the rest of the jaws bore closely packed batteries of grinding teeth, up to four hundred on each side of each jaw. The postcranial anatomy of hadrosaurs is generally very similar and the really obvious differences lie in the crests that many species bear on the top of their heads. These are formed of outgrowths of the nasal bones, are frequently hollow, and are found particularly in the hadrosaurs known as lambeosaurines.

Hadrosaurid Lifestyle

More is known about the life history of hadrosaurids than about any other group of dinosaurs, due to information from skin impressions, trackways, and eggs and nesting sites. They were originally thought to be amphibious animals, inhabiting marshy areas and swimming and diving for soft aquatic plants. This was partly based on skin impressions from mummified specimens which appeared to show webbing between the digits. It was even suggested that the crested forms used the crests as snorkels and were able to breathe through them while underwater. More recent analyses of stomach contents and the function of the tooth batteries suggest, however, that they were adapted to efficiently process fibrous vegetation of low nutritional value, such as coniferous needles and twigs. The crests are now thought to have developed for a variety of purposes, including increased sensory area for an improved sense of smell, and to act as resonators for producing distinctive calls.

Image Not Available

In 1979, juvenile hadrosaurid bones were discovered in the Two Medicine Formation in Montana by Jack Horner. Subsequently, he discovered nesting sites with eggs that provide evidence for reproductive strategies in the hadrosaur *Maiasaura*. These animals appear to have built large, circular nesting mounds with concave centers in common nesting areas. There is evidence of site fidelity, indicating that the nesting sites were used from season to season. Up to twenty eggs were laid in the nest in a circular pattern, then covered by vegetation that kept the eggs warm as it decomposed. Bones of young have been found in some of the nests and these indicate from tooth wear that the animals had already been feeding on vegetation. Also, the ends of the bones were still poorly formed, showing that they were altricial or nest-bound for some period after they had hatched. During this period they would have been fed by adults, which in turn suggests social behavior in which the eggs were protected by adults who then fed and raised the nest-bound hatchlings.

THE HARDY-WEINBERG LAW OF GENETIC EQUILIBRIUM

Type of animal science: Evolution
Fields of study: Ecology, evolutionary science, genetics

The Hardy-Weinberg law of genetic equilibrium is one of the foundations of mathematical population genetics. A description of the genetic makeup of a population under ideal conditions, it acts as a benchmark against which the effects of natural selection or other evolutionary forces can be measured.

Principal Terms

ALLELE: one of several alternate forms of a gene; the deoxyribonucleic acid (DNA) of a gene may exist as two or more slightly different sequences, which may result in distinct characteristics

ALLELE FREQUENCY: the relative abundance of an allele in a population

DIPLOID: having two chromosomes of each type

GENE: a section of the DNA of a chromosome, which contains the instructions that control some characteristic of an organism

GENE POOL: the array of alleles for a gene available in a population; it is usually described in terms of allele or genotype frequencies

GENOTYPE: the set of alleles an individual has for a particular gene

GENOTYPE FREQUENCY: the relative abundance of a genotype in a population

HAPLOID: having one chromosome of each type

POPULATION: the individuals of a species that live in one place and are able to interbreed

RANDOM MATING: the assumption that any two individuals in a population are equally likely to mate, independent of the genotype of either individual

Genetics began with the study of inheritance in families: Gregor Mendel's laws describe how the alleles of a pair of individuals are distributed among their offspring. Population genetics is the branch of genetics that studies the behavior of genes in populations. The population is the only biological unit that can persist for a span of time greater than the life of an individual, and the population is the only biological unit that can evolve. The two main subfields of population genetics are theoretical (or mathematical) population genetics, which uses formal analysis of the properties of ideal populations, and experimental population genetics, which examines the behavior of real genes in natural or laboratory populations.

Population genetics began as an attempt to extend Mendel's laws of inheritance to populations. In 1908, Godfrey H. Hardy, an English mathematician, and Wilhelm Weinberg, a German physician, each independently derived a description of the behavior of allele and genotype frequencies in an ideal population of sexually reproducing diploid organisms. Their results, now termed the Hardy-Weinberg principle, or Hardy-Weinberg equilibrium, showed that the pattern of allele and genotype frequencies in such a population followed simple rules. They also showed that, in the absence of external pressures for change, the genetic makeup of a population will remain the same, at an equilibrium. Since evolution is change in a population over time, such a population is not evolving. Modern evolutionary theory is an outgrowth of the "New Synthesis" of R. A. Fisher, J. B. S. Haldane, and Sewall Wright, which was done in the 1930's. They examined the significance of various factors that cause evolution by examining the degree to which they cause deviations from the predictions of the Hardy-Weinberg equilibrium.

Assumptions and Predictions

The predictions of the Hardy-Weinberg equilibrium hold if the following assumptions are true: The population is infinitely large; there is no differential movement of alleles or genotypes into or out of the population; there is no mutation (no new alleles are added to the population); there is random mating (all genotypes have an equal chance of mating with all other genotypes); and all genotypes are equally fit (have an equal chance of surviving to reproduce). Under this very restricted set of assumptions, the following two predictions are true: Allele frequencies will not change from one generation to the next, and genotype frequencies can be determined by a simple equation and will not change from one generation to the next.

The predictions of the Hardy-Weinberg equilibrium represent the working through of a simple set of algebraic equations and can be easily extended to more than two alleles of a gene. In fact, the results were so self-evident to the mathematician Hardy that he at first did not think the work was worth publishing.

If there are two alleles (A, a) for a gene present in the gene pool, let p = the frequency of the A allele and q = the frequency of the a allele. As an example, if $p = 0.4$ (40 percent) and $q = 0.6$ (60 percent), then $p + q = 1$, since the two alleles are the only ones present and the sum of the frequencies (or proportions) of all the alleles in a gene pool must equal 1 (or 100 percent). The Hardy-Weinberg principle states that at equilibrium the frequency of AA individuals will be p^2 (equal to 0.16 in this example), the frequency of Aa individuals will be $2pq$, or 0.48, and the frequency of aa individuals will be q^2, or 0.36.

The basis of this equilibrium is that the individuals of one generation give rise to the next generation. Each diploid individual produces haploid gametes. An individual of genotype AA can make only a single type of gamete, carrying the A allele. Similarly, an individual of genotype aa can make only a gametes. An Aa individual, however, can make two types of gametes, A and a, with equal probability. Each individual makes an equal contribution of gametes, since all individuals are equally fit and there is random mating. Each AA individual will contribute twice as many A gametes as each Aa individual. Thus, to calculate the frequency of A gametes, add twice the number of AA individuals and the number of Aa individuals, then divide by twice the total number of individuals in the population (note that this is the same as the method to calculate allele frequencies). That means that the frequency of A gametes is equal to the frequency of A alleles in the gene pool of the parents.

The next generation is formed by gametes pairing at random (independent of the allele they carry). The likelihood of an egg joining with a sperm is the frequency of one multiplied by the frequency of the other. AA individuals are formed when an A sperm joins an A egg; the likelihood of this occurrence is $p \times p = p^2$ (that is, $0.4 \times 0.4 = 0.16$ in the first example). In the same fashion, the likelihood of forming an aa individual is $q^2 = 0.36$. The likelihood of an A egg joining an a sperm is pq, as is the likelihood of an a egg joining an A sperm; therefore, the total likelihood of forming an Aa individual is $2pq = 0.48$. If one now calculates the allele frequencies (and hence the frequencies of the gamete types) for this generation, they are the same as before: The frequency of the A allele is $p = (2p^2 + 2pq)/2$ (in the example, $(0.32 + 0.48)/2 = 0.4$), and the frequency of the a allele is $q = (1 - p) = 0.6$. The population remains at equilibrium, and neither allele nor genotype frequencies change from one generation to the next.

Ideal Versus Real Conditions

The Hardy-Weinberg equilibrium is a mathematical model of the behavior of ideal organisms in an ideal world. The real world, however, does not approximate these conditions very well. It is important to examine each of the five assumptions made in the model to understand their consequences and how closely they approximate the real world.

The first assumption is infinitely large population size, which can never be true in the real world, as all real populations are finite. In a small population, chance effects on mating success over many generations can alter allele frequencies. This effect is called genetic drift. If the number of breeding adults is small enough, some genotypes will not get a chance to mate with one another, even if mate choice does not depend on genotype. As a result, the genotype ratios of the offspring would be different from the parents'. In this case, however, the gene pool of the next generation is determined by those genotypes, and the change in allele frequencies is perpetuated. If it goes on long enough, it is likely that some alleles will be lost from the population, since a rare allele has a greater chance of not being included. Once an allele is lost, it cannot be regained. How long this process takes is a function of population size. In general, the number of generations it would take to lose an allele by drift is about equal to the number of individuals in the population. Many natural populations are quite large (thousands of individuals), so that the effects of drift are not significant. Some populations, however, especially of endangered species, are very small: The total population of California condors is less than twenty-five, all in captivity.

The second assumption is that there is no differential migration, or movement of genotypes into or out of the population. Individuals that leave a population do not contribute to the next generation. If one genotype leaves more frequently than another, the allele frequencies will not equal those of the previous generation. If incoming individuals come from a population with different allele frequencies, they also alter the allele frequencies of the gene pool.

The third assumption concerns mutations. A mutation is a change in the DNA sequence of a gene—that is, the creation of a new allele. This process occurs in all natural populations, but new mutations for a particular gene occur in about one of 10,000 to 100,000 individuals per generation. Therefore, mutations do not, in themselves, play much part in determining allele or genotype frequencies. Yet, mutation is the ultimate source of all alleles and provides the variability on which evolution depends.

The fourth assumption is that there is random mating among all genotypes. This condition may be true for some genes and not for others in the same population. Another common limitation on random mating is inbreeding, the tendency to mate with a relative. Many organisms, especially those with limited ability to move, mate with nearby individuals, which are often relatives. Such individuals tend to share alleles more often than the population at large.

The final assumption is that all genotypes are equally fit. Considerable debate has focused on the question of whether two alleles or genotypes are ever equally fit. Many alleles do confer differences in fitness; it is through these variations in fitness that natural selection operates. Yet, newer techniques of molecular biology have revealed many differences in DNA sequences that appear to have no discernible effects on fitness.

Theoretical and Experimental Genetic Studies

The field of population genetics uses the Hardy-Weinberg equations as a starting place, to investigate the genetic basis of evolutionary change. These studies have taken two major pathways: theoretical studies, using ever more sophisticated mathematical expressions of the behavior of model genes in model populations, and experimental investigations, in which the pattern of allele and genotype frequencies in real or laboratory populations is compared to the predictions of the mathematical models.

Theoretical population genetics studies have systematically explored the significance of each of the assumptions of the Hardy-Weinberg equilibrium. Mathematical models allow one to work out with precision the behavior of a simple, well-characterized system. In this way, it has been possible to estimate the effects of population size or genetic drift, various patterns of migration, differing mutation rates, inbreeding or other patterns of nonrandom mating, and many different patterns of natural selection on allele or genotype frequencies. As the models become more complex, and more closely approximate reality, the mathematics becomes more and more difficult. This field has been greatly influenced by ideas and tools originally devised for the study of theoretical physics, notably statistical mechanics. Some of the most influential workers in this field were trained as mathematicians and view the field as a branch of applied mathematics, rather than biology. As a consequence, many of the results are not easily understood by the average biologist.

Experimental population genetics tests predictions from theory and uses the results to explain patterns observed in nature. The major advances in this field have been determined, in part, by some critical advances in methodology. In order to study the behavior of genes in populations, one must be able to determine the genotype of each individual. The pattern of bands on the giant chromosomes found in the salivary glands of flies such as *Drosophila* form easily observed markers for groups of genes. Since these animals can be easily manipulated in the laboratory, as well as collected in the field, they have been the subjects of much experimental work. Using population cages, one can artificially control the population size, amount of migration, mating system, and even the selection of genotypes, and then observe how the population responds over many generations. More recently, the techniques of allozyme or isozyme electrophoresis and various methods of examining DNA sequences directly have made it possible to determine the genotype of nearly any organism for a wide variety of different genes. Armed with these tools, scientists can address directly many of the predictions from mathematical models. In any study of the genetics of a population, one of the first questions addressed is whether the population is at Hardy-Weinberg equilibrium. The nature and degree of deviation often offer a clue to the evolutionary forces that may be acting on it.

Understanding Genotypes

As the cornerstone of population genetics, the Hardy-Weinberg principle pervades evolutionary thinking. The advent of techniques to examine genetic variation in natural populations has been responsible for a great resurgence of interest in evolutionary questions. One can now test directly many of the central aspects of evolutionary theory. In some cases, notably the discovery of the large amount of genetic variation in most natural populations, evolutionary biologists have been forced to reassess the significance of natural selection compared with other forces for evolutionary change.

In addition to the great theoretical significance of this mathematical model and its extensions, there are several areas in which it has been of practical use. An area in which a knowledge of population genetics is important is agriculture, in which a relatively small number of individuals are used for breeding. In fact, much of the early interest in the study of population genetics came from the need to understand the effects of inbreeding on agricultural organisms. A related example, and one of increasing concern, is the genetic status of endangered species. Such species have small populations and often exhibit a significant loss of the genetic variation that they need to adapt to a changing environment. Efforts to rescue such species, especially by breeding programs in zoos, are often hampered by an incomplete consideration of the population genetics of small populations. A third example of a practical application of population genetics is in the management of natural resources such as fisheries. Decisions about fishing limits depend on a knowledge of the extent of local populations. Patterns of allele frequencies are often the best indicator of population structure. Population genetics, by combining Mendel's laws with the concepts of population biology, gives an appreciation of the various forces that shape the evolution of the earth's inhabitants.

Bibliography

Audesirk, Gerald, and Teresa Audesirk. *Biology: Life on Earth*. 5th ed. Upper Saddle River, N.J.: 1999. An introductory college textbook designed for nonscience majors. The chapter on the processes and results of evolution includes a complete explanation of basic population genetics, presented in a nontechnical way. The chapter is well illustrated and includes a glossary and suggestions for further reading.

Avers, Charlotte J. *Process and Pattern in Evolution*. New York: Oxford University Press, 1989. A text that introduces modern evolutionary theory to students who already have a background in genetics and organic chemistry. Covers basic population genetics and introduces most of the techniques used in the study of evolution. Includes references to original research, as well as other suggested readings.

Ayala, Francisco J., and John A. Kiger, Jr. *Modern Genetics*. 2d ed. Menlo Park, Calif.: Benjamin/Cummings, 1984. This genetics text assumes an audience that has had college-level biology and some chemistry. It provides a good description of classical as well as molecular genetics. Covers most of the methods and major results of population genetics. Chapters include a bibliography as well as problem sets, and there is a glossary.

Dobzhansky, Theodosius. *Genetics of the Evolutionary Process*. New York: Columbia University Press, 1970. An older book, this text is an introduction to experimental population genetics, by one of the architects of the field. There are numerous references to the original literature and many examples. The book is suitable for anyone with at least some introduction to biology and provides one of the clearest explanations of the major concepts of modern evolutionary thought.

Futuyma, Douglas J. *Evolutionary Biology*. 3d ed. Sunderland, Mass.: Sinauer Associates, 1998. An advanced text in evolution for students with previous exposure to calculus and a strong biology background, including genetics and various courses in physiology and ecology. The great strength of this book is in the presentation of areas of current research and argument in evolution, rather than a cut-and-dried array of "facts." There are numerous references to original research and a glossary.

Hartl, Daniel L. *A Primer of Population Genetics*. 3d ed. Sunderland, Mass.: Sinauer Associates, 2000. This text is intended for students with a college-level knowledge of biology but does not require prior exposure to genetics, statistics, or higher mathematics. There are examples of the significance of population genetics ideas in many areas of biology and medicine, and each chapter has problem sets with answers. There are numerous references to original research.

Nagylaki, Thomas. *Introduction to Theoretical Population Genetics*. New York: Springer-Verlag, 1992. A college-level textbook, using elementary mathematics to investigate theoretical population genetics. Uses calculus and linear algebra, but does not require a background in genetics.

Starr, Cecie, and Ralph Taggart. *Biology: The Unity and Diversity of Life*. 9th ed. Pacific Grove, Calif.: Brooks/Cole, 2001. A textbook for an introductory college biology course. The chapter on population genetics, natural selection, and speciation covers population genetics and mechanisms of evolution. The book is well provided with examples and many striking photographs.

Svirezhev, Yuri M., and Vladimir P. Passekov. *Fundamentals of Mathematical Evolutionary Genetics*. Translated by Alexey A. Voinov and Dmitrii O. Logofet. Boston: Kluwer Academic Publishers, 1990. Offers a clear exposition of the mathematical material in historical perspective. Part 1 covers deterministic models and part 2 uses stochastic models.

HAWKS

Type of animal science: Classification
Fields of study: Anatomy, ornithology

Hawks are a diverse group of birds adapted to exploit a wide variety of habitats, prey, and climatic conditions. All hawks are distinguished by sharp, strongly hooked bills, a fleshy cere, and strong legs with sharp talons. Most are active and efficient hunters that use their keen vision to target and track suitable prey.

Principal Terms

CERE: the covering of the nostrils, typical of all hawklike birds of prey.

CREPUSCULAR: active in the twilight periods of dawn and dusk

FLEDGING: time period when young hawks and owls develop the ability to fly

FOVEA: specific area with an exceptionally dense concentration of light-sensitive cells in eyes of animals

FRATRICIDE: deliberate killing of one sibling by another sibling

HABITAT SELECTION: process of choosing a home range, territory, nesting site, or feeding site on the basis of specific features of the habitat that the raptor is best adapted to exploit

HOME RANGE: geographic area used by an individual, pair, or group for their daily, seasonal, and sometimes their yearly activities; the defended portion of the home range is called a territory

TALONS: the long, curved, sharply pointed claws of a bird of prey, used for slashing and killing, holding, and carrying prey, and for defense

TERRITORIALITY: all behaviors involved with the establishment, proclamation, and defense of a specific area

WING LOADING: ratio of weight to lifting area of wing

Hawks are a diverse group of birds adapted to exploit a wide variety of habitats, prey, and climatic conditions. Although varying in size from the 75-gram male tiny hawk (*Accipiter superciliosus*) and pearl kite to the 6.5-kilogram female harpy eagle (*Harpia* spp.), all hawks are distinguished by sharp, strongly hooked bills, a fleshy cere, and strong legs with sharp talons or claws. Most are active and efficient hunters that use their keen vision to target and track suitable prey.

The 237 species of hawks are placed in the avian order Falconiformes. Families within this order include the booted eagles, harpy eagles, buteo hawks, subbuteos, chanting goshawks, accipiters, harriers, and kites. Only the fifty-four species of accipiters are strictly considered true hawks, but most raptor biologists and hawk enthusiasts also include the buteo hawks, called buzzards in Europe, within the category of hawks, while the most liberal definition incorporates the kites, harriers, and eagles as well.

Habitats and Lifestyles

Hawks are a widespread and successful group that occurs on all continents and the larger islands. They are absent only from Antarctica, the ice-covered mountaintops, and the most remote oceanic islands. Hawks are primarily birds of woodland and woodland-edge habitats, and reach their greatest diversity in the rain forests of the tropics. They are components of all temperate woodlands of varying density and diversity, but some species occur in a wide variety of more open habitats, including chaparral, grasslands, desert, and tundra. Many species take readily to conifer plantations and ornamental conifer stands, provided that sufficient food is nearby. Black kites (*Milvus migrans*), Cooper's (*Accipiter cooperi*), red-tailed (*Buteo jamaicensis*), and Swainson's hawks (*Buteo swainsoni*) exemplify species that tolerate human-modified habitats, especially farmlands, pastures, and orchards. Given their need for large territories and abundant prey, few species have either the tolerance or ability to exploit urban landscapes, although wooded suburbs and city open-space habitats do attract an occasional furtive nesting or roosting pair of red-tailed hawks or brahminy kites (*Hiliastur indus*).

The daily lives of hawks center around finding food and avoiding enemies. To ensure an adequate food base, most hawks maintain large home ranges for at least part of the year, and some remain on territory throughout the year. If prey populations suffice, hawks are sedentary, but if they decline, hawks must move elsewhere. Some species are nomadic, often wandering widely in search of food, but most northern species move southward in spectacular migrations along traditional flyways each fall. Red-tailed hawks migrate only a few hundred miles but others, such as the lesser spotted eagle (*Aquila pomarina*) and Eurasian buzzard *(Buteo buteo*), fly thousands of miles to their wintering grounds. Their return migration in spring is timed to ensure arrival on the breeding grounds when weather conditions and prey populations are optimal.

Most hawks are entirely carnivorous, or nearly so, and use their remarkable eyesight and intimate knowledge of their territory to locate, pursue, and capture food. Their large eyes are set forward in the head with overlapping fields of vision. Each eye has a long focal length from lens to retina, which produces a telescopic vision that enables hawks to spot prey at great distances. Hawk eyes also have two concentrations of visual cells, called fovea, instead of one, as in other birds and mammals. The central fovea and lateral fovea apparently permit the simultaneous estimate of both distance to and movement of prey, thereby increasing hunting efficiency when pursuing agile, fast-moving animals.

Most hawks are larger—some considerably larger—than the prey that they take. Many species exhibit pronounced sexual dimorphism, with the female being larger than the male. Bigger females can better incubate eggs and protect young, but the sexual size difference enables exploitation of a much wider prey range. Sexual dimorphism is best illustrated in the bird-eating accipiter hawks, in which the larger female takes grouse and duck-sized prey while the smaller male pursues the smaller and more agile birds. Conversely, insectivorous and scavenger hawks show little or no sexual dimorphism.

Almost all hawks that hunt live animals have comparatively light bodies on large wings for a low wing loading, which facilitates extended periods of soaring in search of prey and also for carrying prey. Many species show subtle differences in overall size and wing shape that reveal differences in hunting techniques or diet. For example, the long, narrow wings and light bodies of swallow-tailed (*Elanoides forficatus*) and plumbeous (*Ictinia plumbea*) kites enhance their aerial maneuverability for catching insects just above the rain forest canopy. In contrast, the long, broad wings of hawks and eagles maximize lift needed to soar for hours or to carry medium-sized mammals and birds, along with an occasional reptile or amphibian. The larger hawks and eagles take correspondingly bigger prey up to the size of rabbits, hares, hyraxes, sloths, small antelope, foxes, and young deer.

The long tails and rounded wings of bird hawks such as goshawks, sparrow hawks, hawk-eagles (*Spizaetus* spp.) and bat hawks (*Macheirhamphus alcinus*) provide just the right combination of speed and agility to pursue birds through the often cluttered microhabitat just beneath the woodland canopy.

The long, dihedral wings of harriers (*Circus* spp.) provide a stable flying platform for slow quartering flight over open grasslands and marshes. Harriers use both eyes and ears to hunt small mammals in the tall grasses and, like owls, have a distinctive facial ruff that helps gather sounds to pinpoint prey in the tall grasses.

Hunting and dietary specializations abound in this group. At least twelve species of kites are insectivorous or nearly so, but many other hawks and eagles feed opportunistically on abundant locusts, and grasshoppers, ants, termites, and locust swarms invariably attract a variety of hawks and other birds. Reptile specialists include the snake eagles (*Circateus* spp) and serpent eagles (*Spilornatus* spp.), which sit quietly for hours, patiently watching for the slow and stealthy movements of snakes. Possibly the most extreme dietary specialist is the rufous crab-hawk (*Buteogallus aequinoctialis*), which picks through aerial roots of mangroves in search of crabs, but snail kites (*Rostrhamus sociabilis*) and slender-billed kites (*Rostrhamus hamatus*) focus almost exclusively for pulmonate snails, which they extract with their long, hooked bills.

Hawk Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Subphylum: Vertebrata
Class: Aves
Order: Falconiformes
Families: Accipitridae
Subfamilies: Elaninae (white-tailed kites, five genera, eight species); Milvinae (kites, eight genera, fifteen species); Accipitrinae (hawks, five genera, twenty-two species); Circinae (harriers, three genera, eight species); Pandioninae (ospreys, one genus, seven species)
Geographical location: All continents except Antarctica
Habitat: Woods and woodland edges, rain forests; may also inhabit chaparral, grasslands, deserts, and tundra
Gestational period: One to two months, depending on species
Life span: Eighteen to fifty years, depending on species
Special anatomy: Talons; exceptionally keen eyesight; nostril coverings (cere); sharp, hooked bills

Courtship and Nesting

Most hawks breed each year, but some of the larger tropical eagles and snake eagles may breed once every several years. All phases of the breeding cycle of hawks are dependent on prey abundance: In low prey years pairs often do not nest and may not even establish a territory, while in high prey years nesting success, measured by the number of eggs produced, hatched, and young fledged, is highest. Tropical hawks may nest at any time of year, but usually do so during the dry season. Temperate species are more strictly tied to a spring and early summer nesting cycle when prey abundance is maximal and longer days permit extended hunting periods.

The breeding cycle of temperate species begins when males or mated pairs claim and advertise territories by often extravagant displays that may include sky dancing, dives and swoops, perches, calling, and posturing. Unmated males court females with aerial displays such as circling, following flights, sky dancing, and food transfers from males to females. As courtship proceeds, the pair bond is cemented by synchronized flights, following flights, mutual preening, food begging by the female, and courtship feeding.

Territory size depends on food needs and prey density. Smaller tropical hawks may limit their breeding activities to a hundred acres or so, while the larger eagles that inhabit open habitats, such as the Scottish golden eagles, sometimes establish home ranges of thousands of acres on the moors and grasslands. Most hawk territories are cone-shaped, with little or no overlap permitted near the base of the cone, which is typically centered near the nest site or feeding site.

Hawks build stick nests in trees (for example, Cooper's hawks, sharp-shinned hawks), on cliffs (ferruginous hawks, *Buteo regalis*), bluffs and outcrops (Swainson's hawks, *Buteo swainsoni*), on structures (ospreys, red-tailed hawks), or directly on the ground (harriers). Depending on habitat, some species are flexible in choice of substrate;

Hawks, such as this red-tailed hawk, spend most of their day flying over fields, using their keen eyesight to search for the small animals that are their prey. (PhotoDisc)

thus, red-tailed hawks may build their nests in trees, on ledges, less frequently on structures, or directly on the ground. Many hawks (ferruginous hawks, Swainson's hawks) readily accept artificial platforms such as bridge abutments, piers, telephone poles, and towers.

Both members of a pair bring sticks to the nest site, but the female does the actual work of nest building, arranging the materials into a compact nesting platform with a shallow bowl. Many species refurbish one or more nests year after year, sometimes resulting in massive nesting platforms of sticks and branches after many years of use. Nests are generally lined with dried grasses or mosses and many may decorate them with sprigs of greenery.

Depending on species, from one to ten eggs are laid at two- to four-day intervals, and incubation begins immediately. In most species, the female incubates the eggs while the male supplies her with food, which he may deliver to her or to a nearby site. In some species the male may replace her for brief periods of time to allow her to rest, roost, or forage.

The female is often highly secretive during this nesting phase as she hunkers down to incubate the eggs. The young hatch in about one month in the smaller accipiters and kites, and up to two months in the larger eagles. Eggs hatch asynchronously, producing a nest of uneven-aged young. The female keeps constant company with the newly hatched young, brooding them and feeding them with food supplied by the male. As the young grow, their food demands increase and both male and female spend most of their time hunting food to feed the young.

Adults become increasingly aggressive with young in the nest. Generally, both adults participate in nest defense, although the female is almost invariably the most aggressive. Warning cries (most hawks), power dives (many buteos), and determined slashing attacks (goshawks) can drive all but the most determined intruders away, but unfortunately have little effect on humans intent on destruction of the nest and young. Otherwise, the only natural predators of eggs and young are nest-robbing birds, chiefly corvus species, mammals, other larger diurnal raptors, and the larger owls, especially the *Bubo* species, which take young during the night.

Survival of the young depends entirely on the ability of the adults to find sufficient food. If prey is sufficient, all of the young successfully fledge, but if prey populations decline, one or all of the smallest and weakest young of a nest die of starvation. Nestling fratricide has been observed in many species and may help ensure survival of the strongest young at the expense of their younger or weaker nestlings.

After leaving the nest, the young usually stay with the adults for several weeks or longer—a year or more in some tropical eagles—learning how to perfect their hunting skills and avoid enemies. Many retain a streaked or spotted juvenile plumage for several years that may help conceal them from potential enemies. This plumage is replaced at sexual maturity by adult coloring that probably promotes sexual advertisement and territorial displays.

Conservation and Economic Importance of Hawks

Humans are the most consistent and potent threat to hawks. Historically, huge numbers of hawks were slaughtered by farmers, hunters, gamekeepers, and trappers for sport and as control measures designed to increase game and poultry populations. Many hawks still fall victim to illegal shooting by hunters and sportsman who prefer live target practice, while accipiter hawks are sometimes shot by pigeon fanciers or grouse managers to protect their interests. Generally, the larger buteo hawks and eagles are at greater risk because of their size and habit of selecting open, conspicuous perches for territorial posturing and while hunting. Globally, some hawks are still slaughtered for the taxidermy market, some are taken for falconry, and some are captured as part of the lucrative international trade in zoo specimens, despite the fact that they are all federally protected in most countries of the world.

Hawks also fall victim to pesticides and industrial wastes, which accumulate within their tissues and eventually reach harmful levels that result either in death of the bird or reduction of its productivity. Toxic levels of chemicals have been documented in almost every hawk species on every continent and have particularly affected populations and productivity of fish-eating hawks, such as the osprey and bald eagle.

While all of these forms of deliberate and inadvertent human persecutions take an annual toll, the most persistent threat to hawk populations results from habitat destruction or fragmentation and deforestation. Habitat losses are especially critical for hawks, which require large areas of undisturbed habitat for home range to provide a food base for themselves and their young.

Although no species have become extinct in the last several hundred years, twenty-nine species are on the current list of endangered or threatened species, and it took concerted efforts by state and federal programs on many levels to save several species, such as the bald eagle and osprey. Bans on dichloro-diphenyl-trichloroethane (DDT) and other environmental poisons, along with extensive programs of captive breeding, nesting platforms, and reintroduction programs have helped reestablish bald eagles (*Haliaetus leucocephalus*) in North America and red kites and white-tailed sea eagles (*Haliaetus albicilla*) in Scotland. Conservation programs continue to target the protection and recovery of many species throughout the world, including the harpy eagle in Latin America and the Philippine eagle (*Pithecophaga jefferyi*) of the Philippine Islands.

Bibliography

Brown, Leslie, and Dean Amadon. *Eagles, Hawks, and Falcons of the World*. 2 vols. New York: McGraw Hill, 1968. Somewhat dated now, but still considered by many to be the defining work on diurnal birds of prey by two of the acknowledged world experts. Each species is exhaustively treated with range maps. Includes great paintings of each of the world's diurnal raptors.

Del Hoyo, Josep, Andrew Elliott, and Jordi Sargatal, eds. *New World Vultures to Guineafowl*. Vol. 2 in *Handbook of the Birds of the World*. Barcelona, Spain: Lynx Edicions, 1994. Twenty authors contributed to this massive, oversized volume that summarizes information about all of the diurnal birds of prey of the world. Each group—falcons, accipiters, eagles, and so forth—is preceded by a detailed summary that includes information on habits and habitat, relationships to humans, conservation status, and other timely information.

Johnsgard, Paul A. *Hawks, Eagles, and Falcons of North America*. Washington, D.C.: Smithsonian Institution Press, 1990. Interesting and entertaining descriptions of all of the diurnal birds of prey of North America. Drawing extensively from the scientific literature, Johnsgard summarizes all that is known about the distribution, subspecies, description, identification, habitats and ecology, diet, social behavior, breeding biology, evolutionary relationships, and status of each species. Also includes several introductory chapters tracing evolution and comparing foods and feeding, behavior and reproductive biology, and ecology. Appendices contribute a key, origins of names, glossary, twelve pages of drawings detailing anatomy and field identification, and an extensive list of references.

Newton, Ian. *Population Ecology of Raptors*. Vermillion, S.Dak.: Buteo, 1979. Good analysis of factors affecting raptor populations. Of the many chapters in this book, the sections on population biology and behavior are particularly good. Excellent presentation of appropriate figures, charts, and tables complement the major points.

Palmer, Ralph S., ed. *Handbook of North American Birds*. 5 vols. New Haven, Conn.: Yale University Press, 1962- . The ecology and life history of each North American species of diurnal raptor is succinctly summarized in volumes 4 and 5. Includes a very complete review of the literature.

HEARING

Types of animal science: Anatomy, physiology
Fields of study: Anatomy, biophysics, neurobiology, physiology

One of the five major senses, hearing is utilized by animals to detect sound in the environment through the transduction of sound waves to the universal language of the nervous system, the nerve impulse.

Principal Terms

AUDITORY NERVE: the cranial nerve that conducts sensory impulses from the inner ear to the brain

PITCH: the frequency of sound—the higher the frequency, the greater its pitch

SOUND FREQUENCY: the distances between crests of sound waves measured in hertz

SOUND INTENSITY: the loudness of a sound directly related to the amplitude of the sound waves measured in decibels

SYNAPSE: the functional connection between nerve cells or an effector cell, such as a sensory receptor and a nerve cell

TETRAPODS: vertebrates with four limbs

Sensory perception provides the only means of communication between the external world and the nervous system. The process of sensory perception begins in the sense organs, where specially designed receptor cells are stimulated by various types of energy. These receptor cells are highly selective for specific forms of stimulus energy. For example, the photoreceptors in the eye are specific for light energy and largely ignore other forms of stimuli. Each receptor cell transduces (changes) the stimulus into an electrical charge (nerve impulse) which travels through nerve fibers to the brain, where the electrical impulse is translated into a particular sensation. The major types of sensory receptor cells are the chemoreceptors (sense chemical energy), mechanoreceptors (sense mechanical energy), photoreceptors (sense light energy), thermoreceptors (sense thermal energy), and electroreceptors (sense electrical energy). The sensory receptors for the organs of hearing are called hair cells, which are extraordinarily sensitive mechanoreceptors. Tiny filaments (like hair follicles, only much smaller) called cilia project from the ends of the receptor cell. This filament bends in response to mechanical pressure, and the bending generates the nerve impulse.

Through the course of evolution, the sensory systems developed from single, independent receptor units into complex sense organs, such as the vertebrate ear, in which receptor cells are organized into a tissue associated with accessory structures. The organization of the receptor cells and the architecture of the accessory structures allow far more intricate and accurate sampling of the environment than is possible by independent, isolated receptor cells. While invertebrates possess receptor cells that sense vibrational (mechanical) energy, the true sense of hearing originated with the vertebrates.

The Vertebrate Ear

All vertebrates possess a pair of membranous labyrinths (cavities lined by a membrane) embedded in the cranium, lateral to the hindbrain. This region is often referred to as the inner ear. Each labyrinth consists of three semicircular canals, a utriculus, and a sacculus, which, during development, become filled with a fluid called endolymph. The semicircular canals and utriculus are primarily associated with equilibrium, but the sacculus has evolved into an organ of hearing. In fishes, the lagena, a depression in the floor of the sacculus, has its own maculae (patches of hair cells) which respond to vibratory stimuli of relatively high frequency (sound waves). In tetrapods, the lagena has evolved into an additional fluid-filled duct of the labyrinth called the spiral duct or cochlea. With the evolution of the cochlea, the sensory region enlarged into the organ of Corti. The hair cells are located in the organ of Corti. Most of the structures of the ear assist in the transformation of sound waves (airborne vibrations) into movements of the organ of Corti, which stimulate the hair cells. These hair cells then excite the sensory neurons (nerve cells) of the auditory nerve.

Mammals are the only vertebrates to possess a true cochlea, but birds and crocodilians have a nearly straight cochlear duct that contains some of the same features, including an organ of Corti. Detection of sound in the lower vertebrates that have no cochlear ducts is carried out by hair cells associated with the utriculus and lagena. The cochlea is coiled somewhat like the shell of a snail and is divided into three longitudinal compartments. The two outer compartments, the scala tympani and the scala vestibuli, are filled with a fluid called perilymph and are connected to one another by a structure called the helicotrema. The scala media, filled with endolymph, is located between the two outer compartments and is bound by the basilar membrane and Reissner's membrane. The organ of Corti lies within the scala media and sits upon the basilar membrane. Four rows of hair cells are present in adult mammals—one inner and three outer rows. The cilia of the inner row are thought to be sensitive primarily to the velocity (speed) at which they are displaced by sound waves. The cilia of the outer rows are more sensitive and can detect the degree of deflection as well as the speed.

Sound waves are transported to the inner ear via the outer ear and middle ear. The outer ear consists of the tympanic membrane (ear drum), which is situated on the surface of the head in frogs and toads. In reptiles, birds, and mammals, the tympanic membrane is located deeper in the head at the dead end of an air-filled passageway called the outer ear canal or external auditory

Comparison of Hearing Organs

Jawless fishes: These primitive vertebrates have only two semicircular canals within the inner ear. In jawless fishes, the structures of the inner ear are more associated with equilibrium than hearing.

Gnathostome fishes: All fishes possess membranous labyrinths embedded in the auditory region of the skull. The labyrinths consist of the utriculus and sacculus and three semicircular canals. The inner ear serves primarily as an organ of equilibrium in fishes, but a few species have developed an accessory function of detecting sound transmissions.

Amphibians: The hearing organ of amphibians is considerably advanced over that of the fishes. In frogs and toads, the outer ear consists of a tympanic membrane in the adults that lies flat on the head. The middle ear is an air-filled chamber with a small movable bone. The inner ear consists of a utriculus, a sacculus, a lagena, and three semicircular canals filled with endolymph and perilymph. The hair cells are located at the base of each canal.

Reptiles and birds: Hearing is well developed in reptiles and especially birds. There is a tympanic membrane, a well-developed middle ear, and a straight-tubed cochlea and spiral organ. Some birds can hear ultralow frequencies that may be important in navigating.

Mammals: The membranous labyrinth and the sense of hearing are highly developed in mammals. Mammal ears consist of all of the components discussed in the text. Mammals are keenly adapted to hearing. Humans can hear in a range of sixteen to twenty thousand hertz, but bats can detect frequencies up to one hundred thousand hertz.

meatus. In mammals, there is also an outer appendage, the pinna, which collects sound waves and directs them into the outer ear canal. The tympanic membrane makes contact with the bones (ossicles) of the air-filled inner ear. In amphibians, birds, and reptiles, there is a single bone called the columella (or stapes). In mammals, there is a series of three bones. The malleus (hammer) is in contact with the tympanic membrane at one end and articulates with a second bone, the incus (anvil). The incus then articulates with a third bone, the stapes (stirrup), which connects to a structure called the oval window of the cochlea.

Mammals have a mobile outer ear appendage, called a pinna, which catches and funnels sound waves into the interior ear to increase hearing acuity. (Digital Stock)

Detection of Sound

Sound waves striking the tympanic membrane cause it to vibrate. These vibrations are transmitted through the auditory ossicles of the middle ear and through the oval window to the perilymph. The bones of the middle ear amplify the pressure of the vibrations set up in the eardrum by airborne vibrations. Vibrations reaching the oval window pass through the cochlear fluids and the Reisner's and basilar membranes separating the cochlear compartments before dissipating their energy through the membrane-covered round window of the cochlea. The distribution of pertubations (disturbances) within the cochlea depends on the frequencies of the vibrations entering the oval window. Very long, low frequencies travel through the perilymph of the scala vestibuli, across the helicotrema to the scala tympani, and finally toward the round window. Short wave frequencies take a shortcut from the scala vestibuli through the Reissner's membrane and the basilar membrane to the perilymph of the scala tympani. Movement of perilymph from the scala vestibuli to the scala tympani produces displacement of both Reissner's membrane and the basilar membrane. Movement of Reissner's membrane does not directly contribute to hearing, but displacement of the basilar membrane is required for pitch discrimination. Displacement of the basilar membrane into the scala tympani produces vibrations of the basilar membrane. Each region of the basilar membrane vibrates with maximum amplitude to a different sound frequency. Sounds of higher frequency (pitch) cause maximum vibrations of the basilar membrane at the apical region (closest to the stapes), while sounds of low frequency produce maximum vibrations at the distal region of the basilar membrane.

The sensory hair cells are situated on the basilar membrane with the cilia projecting into the endolymph of the cochlear duct. The cilia of the outer hair cells are embedded with the tectorial membrane located above the hair cells within the cochlear duct. Displacement of the cochlear duct by pressure waves of perilymph produces a shearing force between the basilar membrane and the tectorial membrane. This causes the cilia to bend, and the bending of the cilia produces a nerve impulse in the sensory nerve endings that synapse with the hair cells. The higher the intensity of the sound, the greater the displacement of the basilar membrane, which results in greater bending of the cilia of the hair cells. Increased bending of the cilia produces a higher frequency of nerve impulses in the fibers of the cochlear nerve that synapse with hair cells. Since a specific region of the basilar membrane is maximally displaced by a sound of a particular frequency, those nerve cells that originate in this region will be stimulated more than nerve cells which originate in other regions of the basilar membrane. This mechanism results in a neural code for pitch discrimination. Within the brain, sensory neurons of the eighth cranial (auditory) nerve synapse with neurons in the medulla which project to the inferior colliculus of the brain. Neurons from this region of the brain project into the thalamus, which in turn sends nerve fibers to the auditory cortex of the temporal lobe of the brain. Through this pathway, neurons in different regions of the basilar membrane stimulate neurons in corresponding areas of the auditory cortex. Hence, each area of this cortex represents a different part of the basilar membrane and a different pitch.

HEART

Types of animal science: Anatomy, physiology
Fields of study: Anatomy, biochemistry, cell biology, genetics, histology, pathology, physiology, zoology

The heart is a muscular pump that moves blood throughout the body to deliver oxygen and nutrients to the tissues, remove metabolic waste products, and warm the animal by distributing metabolic heat.

Principal Terms

ATRIUM (AURICLE): a thin-walled muscular heart chamber that receives blood returning to the heart

CLOSED CIRCULATION: a circulation system made of arteries, capillaries, and veins that returns blood flow back to the heart

DIASTOLE: period of heart muscle relaxation and declining pressure

HEART: general term for a muscular vessel segment or organ that contracts and provides for unidirectional movement of blood or hemolymph

OPEN CIRCULATION: an open-ended sinus or arterial vessel system in which the circulation system does not return blood or hemolymph directly back to the heart

SYSTOLE: period of heart muscle contraction and peak pressure

VENTRICLE: a thick-walled muscular heart chamber that receives blood from the atrium and pumps blood into the circulation

The heart beats with a lifelong, continual rhythm to supply a constant flow of oxygen and nutrients, as well as to remove metabolic waste products from every cell in the body. The interstitial fluid that surrounds each cell keeps a constant supply of these factors and prevents a buildup of waste products by communicating with the blood. However, the blood can only keep the interstitial fluid in balance by remaining in motion. If the blood flow stops, the oxygen and nutrients are quickly depleted and harmful waste products accumulate. In adult humans, the heart beats about seventy times per minute, or one hundred thousand times per day. Each heartbeat moves about seventy milliliters of blood, which equals over seven thousand liters of blood per day, or enough blood to fill 7,400 quart-sized milk cartons.

Heart Structure

Hearts vary in their complexity, from simple pulsing vessel segments in insects to the complex four-chambered heart in birds and mammals. Hearts typically have a rhythmic contraction rate determined by specialized muscle cells and can even beat outside the body. A strong, saclike structure called the pericardium encloses, supports, and aids the heart in refilling during diastole by creating negative pressures in the atria and ventricles. Fluid is secreted into the space between the outside wall of the heart and the pericardium. This fluid lubricates and reduces friction during contraction and relaxation. When the heart contracts and ventricular pressure develops, pressure valves made from strong, thin, fibrous tissue are arranged to open and close in such a manner that blood or hemolymph flows in one direction out of the heart (unidirectional flow). When the heart relaxes and ventricular pressure decreases, the valves close to prevent flow reversal from the arteries, and other valves open to allow flow into the heart from the tissues.

Heart chambers fill with blood during diastole and pump blood during systole. One complete heart cycle involves one phase of relaxation and one phase of contraction. The highest pressure developed in the ventricle during contraction is called the systolic pressure, and the lowest pressure in the arteries just before the next contraction is called the diastolic pressure.

The fluid pumped by the heart can be divided into two categories: blood and hemolymph. Blood has two major components: the liquid plasma and cells. The red cells contain hemoglobin for oxygen transport, while the white cells defend against invading germs and viruses. Hemolymph, on the other hand, lacks red blood cells and has hemoglobin freely dissolved in the circulating fluid. In addition, hemolymph flows directly around each cell, whereas blood exchanges nutrients and oxygen across the capillary wall to the interstitial fluid that surrounds cells.

Heart Rate

A heart will rhythmically contract even when removed from the animal. This property is called automaticity and results from a specialized collection of cells in the upper part of the right atrium called the sinoatrial node. The sinoatrial nodal cells spontaneously generate an electrical impulse or action potential that travels throughout the heart by specialized heart muscle cells called conduction fibers. The conduction fibers provide for a uniform and effective heart contraction. Intercalated disks connect each heart muscle cell together and conduct the electrical impulse. Intercalated disks assure all of the heart muscle cells will contract together and effectively pump the blood.

Heart rate varies by animal size. Elephants have a slow, thirty-five beats per minute rate, while the smallest mammal, the shrew, has a heart rate of over six hundred beats per minute. The tiny hummingbird's heart beats at over 1,200 beats per minute while in flight.

The rate at which the sinoatrial node generates impulses can be modified by the autonomic nervous system. The sympathetic branch of the autonomic nervous system increases the heart rate, for example, during exercise or when frightened, while the parasympathetic branch slows the heart down, for example, during sleep.

Different Beats for Different Beasts

One of the simplest hearts is a rhythmically contracting muscular section in the dorsal vessel of the annelid worm, grasshopper and other arthropods. This "heart" contracts and pumps hemolymph into open-ended sinuses that distribute the hemolymph throughout the body. The hemolymph fluid does not directly return to the heart, but is drawn in through ostia or pores in the heart during the relaxation phase (open circulation).

Mollusks and octopuses have a greater diversity of heart structure, with many having two chambers. The thin-walled chamber that collects blood from venous vessels is called an auricle or atrium. The thick-walled muscular chamber that receives blood from the atrium and propels blood to the body is called a ventricle. The open circulation system in these animals delivers blood flow through several main arteries to important regions such as the kidney, head, and digestive tract.

The two-chambered fish heart has one atrium and one ventricle and represents a slight increase in complexity compared to mollusks and crustaceans. The sinus venosus collects blood at the convergence point of great veins and empties into the atrium. The bulbus arteriosus in teleosts (bony fishes), or the conus arteriosus in elasmobranchs (cartilaginous fishes), stores pressure energy from the ventricular ejection and helps to maintain a steady blood flow through the circulation during diastole.

The fish atrium receives deoxygenated blood and the ventricle pumps blood to gills, where the blood releases carbon dioxide and picks up oxygen from the water. The oxygenated blood then leaves the gills and circulates through the rest of the body. A significant amount of pressure is lost as the blood travels through the small capillaries in the gills. So, movements of the fish's body are important to help move the blood through the body and back to the heart.

Fish have a single path of circulation, from the ventricle through the gills and then to other body organs and tissues. In contrast, air-breathing animals have two separate circulations, one through the lungs (pulmonary circulation) and another to the rest of the body (systemic circulation). Lungfish (dipnoan lungfish) have the first indications of two separate circulations where oxygenated and deoxygenated blood are separated by a ridge of tissue in the ventricle. This diverts deoxygenated blood to the lungs and oxygenated blood to the rest of the body or systemic circulation.

Amphibians, Reptiles, Birds, and Mammals
Amphibians have an increased distinction between systemic and pulmonary circulations, with two separate atria. The right atrium receives deoxygenated blood from the systemic circulation, and the left atrium receives oxygenated blood from the lung or pulmonary circulation. The ventricle is partially divided into a right and left side by a muscular wall called a septum. The septum keeps the oxygenated blood coming in from the lungs separate from the deoxygenated blood returning from systemic circulation. Differential flow timings also help to separate deoxygenated and oxygenated blood. The ventricle delivers blood into a divided artery, with the pulmonary circuit leading to the lungs and skin (frogs receive some oxygen from the skin circulation on their backs), and the systemic circuit leading to all organs except the lungs. The amphibian heart is relatively weak, with spongy, poorly muscularized ventricles compared to mammals.

Most reptiles also have two separate atria, similar to amphibians; however, the sinus venosus is no longer a distinct structure and is incorporated into the right atrium. In contrast, adult crocodiles have a completely divided ventricle, thus having

Heart Valves

The heart valves provide for unidirectional blood flow and separate the atria from the ventricles and the heart from the arterial blood vessels. The valves are made of thin, strong, fibrous tissue, and each flap is called a leaflet or cusp. The valve cusps close by pressure differences across their opening. The valves that separate the atria from the ventricles are called the atrioventricular valves. In the four-chambered mammalian heart, the right atrioventricular valve is called the tricuspid valve, and the left atrioventricular valve is called the mitral or bicuspid valve. As indicated by their names, the tricuspid valve has three cusps, while the bicuspid or mitral valve has two. Another characteristic of the atrioventricular valves is their support structures, the chordae tendinae and the papillary muscles. The chordae tendinae attach to the valve cusps and, during the high pressures created by ventricular contraction, prevent the valve cusps from being forced open into the atrium. The papillary muscles are specialized heart muscles that arise from the inside of the heart and attach to the chordae tendinae. These muscles contract with each heartbeat and pull down the leaflets to keep the valve closed, and further prevent their opening into the atria.

The valves that separate the heart from the pulmonary artery and the aorta are called the semilunar valves. These valves prevent blood that has been ejected into the arteries from flowing backward into the ventricles during diastole, when the ventricular muscle is relaxed. The semilunar valves, in contrast to the atrioventricular valves, lack additional supportive structures such as the chordae tendinae and papillary muscles. Instead, their three cusps meet together and form a tight seal between the artery and ventricle.

The rhythmic "lub-dub" sounds associated with the heartbeat result from the vibration of the valve cusps and rapid blood flow through the valve just as it narrows and then closes. The first heart sound, or the "lub," is associated with the closing of the atrioventricular valves. The second heart sound, or the "dub," is associated with the closing of the semilunar valves. The term "heart murmur" refers to the hissing sound of blood squirting through a defective valve.

completely separate pulmonary and systemic circulations, similar to birds and mammals.

Birds and mammals are characterized by two completely separate atria and ventricles. The right atrium receives deoxygenated venous blood from the systemic veins, and the right ventricle pumps blood through the pulmonary circulation to pick up oxygen. The left atrium receives the oxygenated blood from the pulmonary veins, and the left ventricle pumps this blood throughout the systemic circulation (all organs except the lungs).

With the complete separation of the right and left ventricles, the pressures between the two can be different. The ventricles are highly muscularized, with the left ventricle being approximately six times thicker than the right ventricle, and this reflects the greater pressures needed to circulate blood through the systemic and pulmonary circulations. However, the volume of blood pumped by each ventricle needs to be the same, because each ventricle returns blood to the other. For example, the right ventricle pumps blood through the pulmonary circulation that returns to the left ventricle. If the right ventricle pumps a larger volume of blood than the left, blood will accumulate in the pulmonary circulation. In humans, a heart attack involving the left ventricle weakens the muscle, which decreases the volume of blood pumped. The right ventricle pumps normally and blood accumulates in the pulmonary circulation, causing breathing problems.

During flight, birds can have an increase in oxygen demand of ten- to fifteen-fold to power their flight muscles. Birds have very powerful hearts that can deliver five to seven times more blood to active muscles compared to similarly sized mammals.

HERBIVORES

Types of animal science: Anatomy, classification, ecology, reproduction
Fields of study: Anatomy, ecology, zoology

Herbivores, animals which eat only plants, include insects and other arthropods, fish, birds, and mammals. They keep plants from overgrowing and are food for carnivores or omnivores.

Principal Terms

CARNIVORE: any animal that eats only the flesh of other animals

GESTATION: the term of pregnancy

METAMORPHOSIS: insect development into adults, passing through two or more dissimilar growth forms

RUMINANT: a herbivore that chews and swallows plants, which enter its stomach for partial digestion, are regurgitated, chewed again, and reenter the stomach for more digestion

Herbivores are animals whose diets consist entirely of plants. They have two ecological functions. First, they eat plants and keep them from overgrowing. Second, they are food for carnivores, which subsist almost entirely upon their flesh, and omnivores, which eat both plants and animals. Herbivores live on land or in oceans, lakes, and rivers. They can be insects, other arthropods, fish, birds, or mammals.

Wild Herbivores

Insects are the largest animal class, with approximately one million species. Fossils show their emergence 400 million years ago. Insects occur worldwide, from pole to pole, on land and in fresh or salt water. They are the best developed invertebrates, except for some mollusks. They mature by metamorphosis, passing through at least two dissimilar stages before adulthood. Metamorphosis can take up to twenty years or may be complete a week after an egg is laid.

Many insects are herbivores. Some feed on many different plants; others depend on one plant variety or a specific plant portion, such as leaves or stems. Relationships between insects and the plants they eat are frequently necessary for plant growth and reproduction. Among the insect herbivores are grasshoppers and social insects such as bees.

Artiodactyls are hoofed mammals, including cattle, pigs, goats, giraffes, deer, antelope, and hippopotamuses. Most are native to Africa, but many also live in the Americas, Europe, and Asia. Artiodactyls walk on two toes. Their ancestors had five, but evolution removed the first toe and the second and fifth toes are vestigial. Each support toe—the third and fourth—ends in a hoof. The hippopotamus, unique among artiodactyls, stands on four toes of equal size and width.

Artiodactyls are herbivores, lacking upper incisor and canine teeth, but pads in upper jaws help the lower teeth grind food. Many are ruminants, such as antelope, cattle, deer, goats, and giraffes. They chew and swallow vegetation, which enters the stomach for partial digestion, is regurgitated, chewed again, and reenters the stomach for more digestion. This maximizes nutrient intake from food.

Deer are hoofed ruminants whose males have solid, bony, branching antlers that are shed and regrown yearly. The deer family, approximately 40 species, occurs in Asia, Europe, the Americas, and North Africa. Deer live in woods, prairies, swamps, mountains, and tundra. Their size ranges from the seven-foot-tall moose to the one-

Buffalo, like all herbivores, spend much of their time grazing. The low nutrient content of grass requires most herbivores to opt for quantity over quality in their digestive strategy. (PhotoDisc)

foot-tall pudu. Deer first appear in the fossil record ten million years ago. Deer eat the twigs, leaves, bark, and buds of bushes and saplings, and grasses. Females have one or two offspring after ten-month pregnancies. Common species are the white-tailed and mule deer in the United States; wapiti in the United States, Canada, Europe, and Asia; moose in North America and Europe; and reindeer in Russia, Finland, and Alaska.

Antelope, a group of approximately 150 ruminant species, have permanent, hollow horns in both sexes. Most are African, although some are European or Asian. They eat grass, twigs, buds, leaves, and bark. There are no true antelope in the United States, where their closest relatives are pronghorns and Rocky Mountain goats (goat-antelope with both goat and antelope anatomic features). The smallest antelope, the dik-dik, is rabbit-sized. Elands, the largest antelope, are ox-sized. Unlike deer horns, antelope horns are unbranched. Most antelope run rather than fighting, and are all swift. Antelope live on plains, marshes, deserts, and forests. Females birth one or two offspring per pregnancy. Impala and gazelles, such as the springbok, are found in Africa. In Asia, Siberian saigas and goat antelope (takin) inhabit mountain ranges. Chamois goat antelope live in Europe's Alps.

Giraffes and hippos are unusual artiodactyls. Giraffes inhabit dry, tree-scattered land south of the Sahara. Their unusual features are their very long legs and necks. Males are over sixteen feet tall, including the neck. Both sexes have short, skin-covered horns. Long necks, flexible tongues, and upper lips pull leaves—their main food—from trees. Giraffes have brown blotches on buff coats and blend with tree shadows. They live for up to twenty years. They have keen senses of smell, hearing, and sight, and can run thirty-five miles per hour. Due to their two-ton weights, they live on hard ground. Giraffes rarely graze, and go for months without drinking, getting most of their water from the leaves they eat, because it is difficult for them to reach the ground or the surface of a river with their mouths. Females have one offspring after a fifteen-month gestation.

The unusual feature of hippos is that they walk on all four toes of each foot. Perhaps this is because they weigh three to four tons. Hippos are short-legged, with large heads, small eyes, small ears, and nostrils that close underwater. Huge hippo mouths hold long, sharp incisors and canines in both jaws. Hippos once lived throughout Africa. Now they are rarer, due to poaching for ivory. A hippo can be fifteen feet long and five feet high at the shoulder. Semiaquatic, hippos spend most daylight hours nearly submerged, eating aquatic plants. At night they eat land plants. Females bear one offspring at a time.

Elephants

Herbivorous elephants, the largest land animals, eat three hundred pounds per day of grass, fruits, leaves, flowers, roots, twigs, branches, and bark. Elephants are African or Asian. African males reach twenty-five feet long, eleven feet tall, and weigh seven tons. Females are shorter and half the weight of males. Asian elephants exhibit anatomic differences, including smaller ears, tusks, and overall size.

Elephants lift trees with their trunks and have long been domesticated to carry things. Elephants also grab food from the ground and trees via the ends of their trunks, with nostrils and grasping lips. They also suck water into their trunks and squirt it into their mouths or on their bodies. The showers keep them cool. Their ivory tusks, several feet long, are used to dig roots, peel edible tree bark, and fight enemies and male competitors. The use of tusk ivory in jewelry leads poachers to kill males. Elephant ears have keen hearing and act as cooling fans.

Adult males live alone. Females and young form herds, led by a sagacious female. Herd members breed with visiting males, protect each other, and raise young. Gestation, two years, produces one offspring, which nurses for three years. Elephants can live for sixty years in the wild and eighty years in captivity, but only 10 percent of wild elephants reach age forty.

Aquatic Herbivores

Fish are aquatic vertebrates, having gills, scales and fins. They include rays, lampreys, sharks, lungfish, and bony fishes. The earliest vertebrates, 500 million years ago, were fishes. They comprise over 50 percent of all vertebrates and have several propulsive fins: dorsal fins along the central back; caudal fins at tail ends; and paired pectoral and pelvic fins on sides and belly. Fish inhabit lakes, oceans, and rivers, even in Arctic and Antarctic areas. Most marine fish are tropical. The greatest diversity of freshwater species is found in African and rain-forest streams.

Fish vary in length from half an inch to fifty feet, and some weigh seventy-five tons. Many, including giant whale sharks, are herbivores. Fish respiration uses gills, through which blood circulates. When water is taken in and expelled, oxygen enters the blood via the gills and carbon dioxide leaves. Fishes reproduce by laying eggs that are fertilized outside the body, or by internal fertilization and development with the birth of well-developed young.

Domesticated Artiodactyls

Bovids are domesticated artiodactyls. Most have horns and hooves. Bovid horns are spiraled, straight, tall, or L-shaped from the sides of the head. All have hooves to help them grip the ground. Most are ruminants. Their breeding habits are similar. Males fight over females and the strongest wins. Gestation, four to eleven months, yields two to three young. The young nurse for several months and then join the herd. Young males leave female herds to live with other bachelors.

Cattle are domesticated bovids, raised for meat, milk, and leather. Modern cattle come from European, African, and Asian imports. Breeding modern cattle began in Europe in the mid-1800's.

Today, three hundred breeds exist. Dairy cattle, such as Holsteins, make copious milk. Beef cattle, such as Angus, were bred to yield meat. As of 1990, about 1.3 billion cattle were found worldwide.

Sheep are also artiodactyls. Wild sheep occur in some places, such as the North American bighorn and Mediterranean mouflon. Sheep were domesticated eleven thousand years ago from mouflon. Today, domesticated sheep have a world population of approximately 1.3 billion and inhabit most countries, being more widely distributed than any other domesticated animal. These ruminants have paired, hollow, permanent horns. Male horns are massive spirals; those of females are smaller. Adult body length is five feet and weights are 250 to 450 pounds. Females birth two or three young after five-month gestations. Sheep can live for up to twenty years.

Sheep provide wool, meat, and milk. About eight hundred domesticated breeds exist, in environments from deserts to the tropics. Those bred for wool, half the world's sheep, live in semiarid areas, are medium sized, and produce fine wool. Most are in Australia, New Zealand, and South America. Mutton-type sheep, 15 percent of the world sheep population, produce meat. Fat-tailed sheep, 25 percent of the sheep population, produce milk. In 1990, the five leading sheep countries were Australia, China, New Zealand, India, and Turkey. The United States raised less than 1 percent of the world total.

Goats are ruminants, closely related to sheep, but have shorter tails, different horn shape, and bearded males. They eat grass, branches, and leaves and breed from October to December. A five-month gestation yields two offspring. Numerous goat breeds are domesticated worldwide for meat and milk, and as pets and burden carriers. Domesticated Angora goats yield silky mohair. Goat milk is as nutritious as cow milk and used in cheese-making.

It is clear that wild herbivores are ecologically important to food chains. This is because they eat plants, preventing their overgrowth, and they are eaten by carnivores and omnivores. Domesticated herbivores—cattle, sheep and goats, used for human sustenance—account for three to four billion living creatures. Future production of better strains of domesticated herbivores via recombinant deoxyribonucleic acid (DNA) research may cut the numbers of such animals killed to meet human needs. Appropriate species conservation should maintain the present balance of nature and sustain the number of wild herbivore species living on earth.

—Sanford S. Singer

Horses, Donkeys, and Zebras

The horse, donkey, and zebra (HDZ) family lives in habitats from grasslands to deserts. Wild specimens inhabit East Africa and the Near East to Mongolia. Domesticated horses and donkeys are used for food, meat, leather, drayage, and racing worldwide. Zebras are too savage to domesticate. All HDZ have long heads and necks, slender legs, and manes on their necks, as well as long tails to swat insects. They have good wide-angle day and night vision. Their sense of smell is also excellent. The smallest family members are African wild donkeys, 4.0 feet tall, 6.5 feet long, with 1.5-foot tails, weighing five hundred pounds. The largest are Grevy's zebras, 5 feet tall at the shoulder, 9 feet long, with 1.5-foot tails, and weights up to nine hundred pounds.

Zebras have black or brown and white vertically striped coats. All HDZ family members are herbivores. Donkeys eat bark, leaves, buds, fruits, and roots. Horses and zebras mostly eat grasses, and some bark, leaves, buds, and fruits. Wild HDZ spend their waking hours foraging for and eating food. When attacked, they bite, kick, or run off at speeds up to forty miles per hour.

Wild donkeys and horses live in herds with a male leader and female mates. Young stay in a herd until two years old for females or four years old for males. Males join bachelor groups until winning a herd. Females join another herd. Donkeys usually live alone. Most HDZ mate in spring and summer. A twelve-month gestation yields one offspring, which nurses for a year.

HERDS

Types of animal science: Behavior, ecology
Fields of study: Ecology, ethology, population biology, wildlife ecology, zoology

Herds are associations of animals, usually the same species, that keep, feed, or move together. Generally, the use of the word "herd" is reserved for large, terrestrial animals.

Principal Terms

CARNIVORES: animals that eat the flesh of other animals

DILUTION EFFECTS: the reduction in per capita probability of death from a predator due to the presence of other group members

HERBIVORES: animals that eat plants and show specializations of teeth and digestive tracts to do so

PHALANGES: the free toes of the foot; some can be modified to bear claws, hoofs, or nails

SUBUNGULATES: nonhoofed mammals that support their weight on more than the terminal phalanges; some, such as elephants and hyraxes, have pads under their metatarsals, and others, such as the sirenians, have forelimbs modified into flippers

UNGULATES: hoofed mammals that support their weight only on the hoof-clad terminal phalanges and have teeth specialized for clipping vegetation

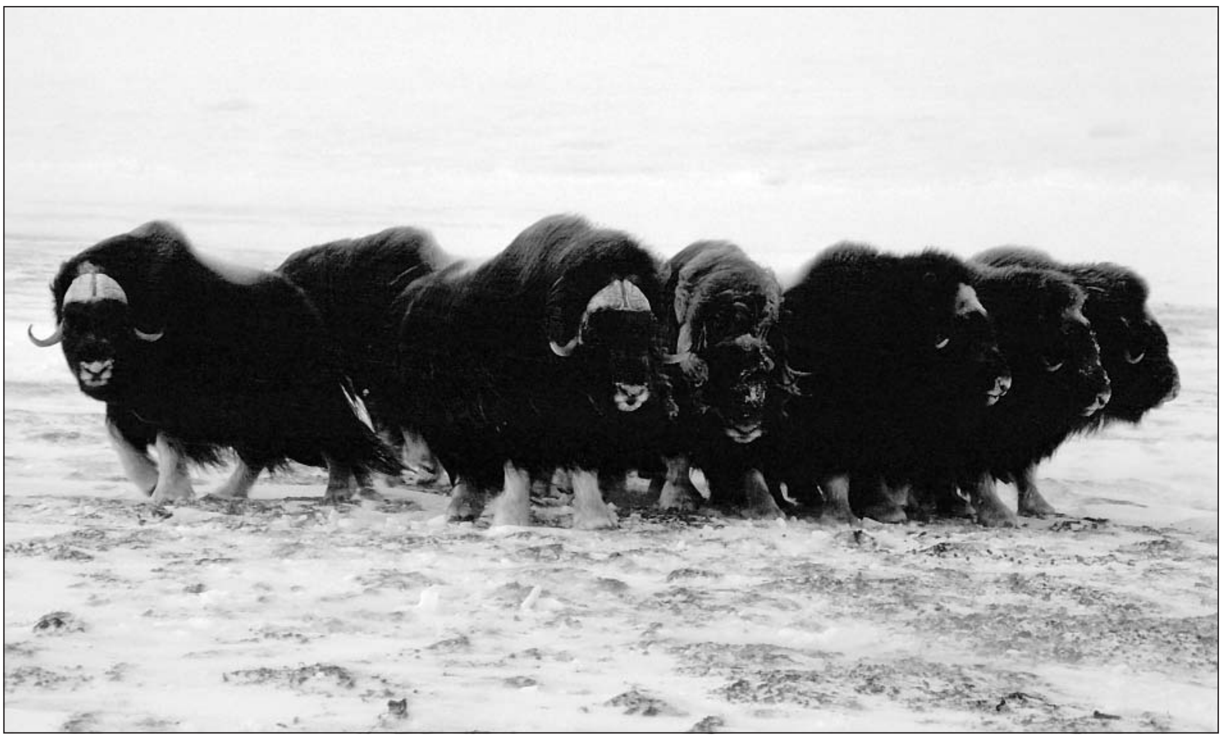
Herding in animals serves several purposes, most commonly exploitation of food resources and reduction of the probability of predation via dilution effects. When food is spaced irregularly into patches and cannot be easily defended, individuals of a particular species will form a herd, simply as a result of coming together to feed on the same resource in the same location. Sizable grazing mammals are well known for forming some of the largest and most dense herds seen. The most familiar of these include African ungulates (wildebeests, zebra, gazelle, wild horses, rhinos, hippopotami) and subungulates (elephants, sirenians, the extinct mastadons); bison, buffalo, caribou, elk, moose, and deer in North America; kangaroo in Australia; and deer, elk, moose, antelope, wild horses, sheep, goats, pigs, boars, and peccaries in Eurasia. In addition to large mammalian herbivores, small grazers that exploit vegetation in herds include marine and freshwater snails, tortoises and turtles, geese, and hyrax.

Those grazers that feed indiscriminately tend to form herds that vary in density with season and density of foliage. Furthermore, these herds tend to vary their densities and vegetation utilization patterns with the type of vegetation exploited and its productivity potential. In seasons or areas where rainfall is common, herds tend to congregate together and exploit small patches of grass, which they clip into grazing lawns. Maintaining grazing lawns increases the productivity of the plants via increased nitrogen content and increased digestibility in freshwater, marine, and terrestrial environments. When rainfall is scarce, the herds disperse over vast areas, which allows some grasses to grow into tall meadows. The benefits to individuals in a herd from grazing a larger area and creating a grazed lawn are greater than those to a lone individual that would only be able to graze a small patch of grass and that would, presumably, be at greater risk of predation than one individual surrounded by many others. Furthermore, if the lone individual were subject to a greater risk of predation, there would be less likelihood of it being able to return to the same patch over and over again to keep it as a grazed lawn. Thus, by grouping, an individual benefits twice: once by the gain in nutrition from a grazed lawn and again from the dilution effect, where the risk of predation is diluted by the number of members forming the group.

Herding to Avoid Predation

The large herbivores that most commonly form herds are clearly visible to predators. Predation risk reduction via the dilution effect or the selfish herd effect is the other main benefit of herding. In the dilution effect, the probability of a particular individual being killed or injured is reduced by the presence of other group members that might be attacked first. In other words, there is safety in numbers. Individuals in a group may also benefit by putting other animals between themselves and the predator (the selfish herd effect). Grouping thus provides the opportunity to decrease the area of danger around each individual. If individuals within the group are acting in a selfish herd manner, the groups formed tend to be tightly clumped, as all individuals attempt to put other individuals on all sides around them and move into a central location. Finally, formation of a herd can make it more difficult for a predator to select one specific individual from the crowd for attack, or once an attack is initiated and herd members scatter during flight, can make it difficult for the predator to decide who it should chase.

Herd members also benefit by a reduction in the time necessary to scan for predators while foraging. An individual foraging has to split its time between consuming as much food as possible and avoiding becoming another animal's meal. Thus, a solitary individual has to be much more vigilant than does a member of a group who can rely on many other eyes and thus reduce its own scan



Musk oxen form a tightly packed clump characteristic of the selfish herd effect, where animals try to put as many others as possible between themselves and potential predators. (Corbis)

Dinosaur Herds

Dinosaur fossils have been known for over a century and yet little is known about their daily life when they were alive. Paleontologists, however, argue that discoveries made since the late 1970's indicate that some, if not many, dinosaurs might have been social organisms. Fossil beds of duck-billed dinosaurs not only revealed scooped-out, mud-filled nests with as many as fifteen offspring, but also showed that the nests were closely spaced, strongly suggesting communal nesting grounds, as are seen in birds. Within the nests were offspring of varying ages, suggestive of parental care.

Dinosaur footprints are also used to infer that many species grouped together in herds, some of which may have migrated long distances in what are known as trackways. Trackways preserve the footprints of a number of individuals in mud, which was later fossilized. These trackways show dozens of animals traveling in the same direction at roughly the same speed. Such trackways have been found for *Eubontes* (a Jurassic dinosaur), *Triceratops*, *Iguanodon*, and others.

The final piece of evidence that paleontologists use to infer herding in dinosaurs is the presence of horns and superfluous appendages. Observations of extant herding species indicate that males most often display horns, tusks, or other features that are used in male dominance fights over sexually receptive females within the herd. Paleontologists use these modern-day rituals to hypothesize that dinosaurs may have used their horns in a similar fashion.

rate. Because of this advantage and the advantage in the reduction of the rate of per capita predation, even herds that simply congregate around a resource benefit greatly.

Migratory and Social Herds

Many large herbivores migrate in response to food availability in different seasons. Red deer, caribou, wildebeest, mountain goats, northern fur seals, and humpback whales are examples of animals that all migrate in response to seasonal changes in rainfall or food abundance. Some of these migrations are over incredible distances: Wildebeests travel about six hundred miles; northern fur seals and humpbacks can travel three to four thousand miles. During these migrations, small herds unite with bigger herds to form even larger herds. While terrestrial herbivores migrate to follow food, some marine mammals, such as gray whales and humpbacks, migrate south to calf and breed (but do not feed, living off food reserves instead) and migrate north to abundant feeding grounds.

Some herding species display social organization beyond that expected by mere association. This social organization tends to break a herd into smaller units (matrilineal groups, harems, or small territories controlled by one or several males) that are clustered within the entire herd. These species include the horses, zebras, pronghorn sheep, walruses, sea lions, seals, and elephants. Horse and zebra herds are composed of a number of small groups of females and their foals. These individual groups are overseen by a single stallion; young males leave these groups to form bachelor herds. Group members distinguish each other via a "corporate smell." Stallions generally control a group of females and will fight with challenging stallions in elaborate rearing displays. If a stallion is challenged and loses after inseminating the females in his group, the challenger will mount the females and rape them to induce them to abort. They will then come into estrus quickly and he will remate them. Stallions will groom females to cement their relationship with them; likewise, mares will groom their foals for the same purpose. Male impalas and gazelle maintain harems during the breeding season; male wildebeest do the same, but if the herd is large, the defense of the harem may be accomplished by several males, rather than one. Male elk are divided into four main categories: Primary bulls are the first to establish harems, but as they become exhausted from challenges and herding and mating females, all the while not eating, the harems are taken over by secondary bulls. Once the secondary bulls become exhausted, tertiary bulls take over. The fourth category, opportunistic bulls, only mate with females by chance.

Pinniped herds (sea lions, seals, and walruses) form breeding herds, where males establish territories. In some groups, females are herded together in harems to remain in the male's territory; in other groups, females are free to move from territory to territory. Males vigorously defend their territories against intruding males.

Sirenians, the dugong and manatee, have proved difficult to study, but dugongs often form large herds for unknown reasons. During mating, a series of males follows a receptive female to form a cluster of up to twenty animals. Males then initiate fighting to determine who will mount the female. Following mating, the main social unit is the female and her calf. A similar situation exists in the manatee, with females and their calves being the main social unit and females in estrus becoming the focus of a mating herd of males.

Herding serves important purposes for animals: utilization of a common resource (usually food) and predator reduction via a safety-in-numbers principle. Herds can also be formed during migrations or for breeding purposes. While many herds are simply loose associations of animals, some are more highly organized into a number of social units such as harems or matrilineal groups.

HERMAPHRODITES

Types of animal science: Anatomy, development, physiology, reproduction
Fields of study: Developmental biology, ethology, invertebrate biology, marine biology, neurobiology, reproduction science, zoology

Hermaphrodites are individuals having both male and female reproductive organs. Depending on the species, individuals may be simultaneously both male and female, or may change from one sex to the other.

Principal Terms

GONAD: the organ that produces reproductive cells (sperm or eggs)
PROTANDRY: the condition of starting out male with the potential to become female
PROTOGYNY: the condition of starting out female with the potential to become male
SEQUENTIAL HERMAPHRODITE: species or individual with the potential to change from one sex to the other
SEX-LIMITED TRAITS: features that are only expressed in one sex
SEXUAL DIMORPHISM: the existence of anatomical, physiological, and behavioral differences between the two sexes of a species
SIMULTANEOUS HERMAPHRODITISM: the condition of being simultaneously male and female

In most species, reproduction involves sex—that is, the joining of genetic material from two individuals to create new, genetically unique offspring. In sexually reproducing species, females are those individuals which produce relatively large sex cells that are full of nutrients (eggs), and males are those individuals which produce relatively small sex cells that have little or no nutrients, but which can be produced in much greater numbers (sperm). Generally there are other differences between the sexes as well—differences in hormones, anatomy, body shape, size, color, and behavior. Such distinguishing features are referred to as sex-limited traits because they appear in only one sex; collectively, they result in sexual dimorphism—literally the two sexual forms of a single species.

Whether an individual animal develops into a male or a female depends on which genes get turned on early in development. In mammals, genes for maleness get turned on in individuals with an X and a Y chromosome, while genes for femaleness get turned on in individuals with two X chromosomes. In other animals, sex determination may depend on other factors. For example, in many reptiles, development into a male or a female depends upon the temperature of the embryo as it develops in its egg.

Hermaphrodites are individuals that have both male and female reproductive organs—that is, they have both ovaries to produce eggs and testes to produce sperm. In most animals, hermaphroditism is a result of abnormal development and is extremely rare. In some species, however, hermaphroditism is normal.

Simultaneous Versus Sequential Hermaphroditism

Depending on the species, hermaphroditism can be found in either simultaneous or sequential form. In species with simultaneous hermaphroditism, individuals are simultaneously both male and female; each adult has the ability to produce both sperm and eggs. Depending on the species, a single reproductive encounter between simultaneous hermaphrodites may involve both partners exchanging sperm and eggs (for example, earthworms) or may involve the partners taking turns as male and female (for example, some coral reef fishes).

On the other hand, individuals of species with sequential hermaphroditism start life as either male or female, but have the ability to change sex at some later point. In protandrous species, individuals start out as male and have the potential to later change to female. These are typically species which require large body bulk before they can produce eggs, so individuals start out as male and change to female only if they get old enough and large enough to make eggs. In protogynous species, individuals start out as female and have the potential to later change to male. These are typically species in which males must defend a harem or a territory in order to mate, so individuals start out as female and change to male only if they get large enough to fight and win.

Image Not Available

Triggers for Sex Change

In both protandrous and protogynous species, the trigger for sex change may relate not only to body size but also to the social structure of the individual's community. For example, a large female of a protogynous species may not change to male if there is an even bigger male present who would clearly win every fight. On the other hand, a relatively small female might change to male if she is the biggest female around and the larger local males suddenly died or disappeared. Thus, body size is a relative, not an absolute trigger for sex change, and in a very few species individuals can revert back to their original sex if social circumstances change again.

When a sequential hermaphrodite changes sex, it changes not only its reproductive organ or gonad, but also all the other sexually dimorphic aspects of its anatomy, physiology, and behavior. Hormones and behavior are the first things to change; then, over a period of time, the hormonal changes induce changes in the gonad and other tissues, including the brain. As a hermaphroditic fish, for example, switches from one sex to another, it may change the size and shape of its fins, its color, its aggression level, and its sexual preferences and rituals. These miraculous changes provide visible proof of the (generally silent) presence in both sexes of sex-limited genes for both male and female attributes.

HETEROCHRONY

Type of animal science: Evolution
Fields of study: Development, evolutionary science, physiology

Neoteny is a heterochronic effect in which descendants grow more slowly than their ancestors and thus appear to be juveniles relative to their ancestors. It is one of several different heterochronic phenomena that can involve differential rates and duration of growth for ancestral and descendant species.

Principal Terms

ACCELERATION: a faster rate of growth during ontogeny that causes a particular characteristic to appear earlier in a descendant ontogeny than it did in the ancestral ontogeny

HETEROCHRONY: any phenomenon in which there is a difference between the ancestral and descendant rate or timing of development

HYPERMORPHOSIS: a phenomenon in which the rate and initiation of growth in the descendant are the same as in the ancestor but the cessation of development takes place later

ONTOGENY: the life history of an individual, including both its embryonic and postnatal development

PHYLOGENY: the history of a lineage of organisms, often illustrated by analogy to the branches of a tree

POSTDISPLACEMENT: a form of paedomorphosis in which the initiation of growth in a descendant occurs later than in the ancestor, ensues at the ancestral rate, and ceases at the ancestral point

PREDISPLACEMENT: a form of peramorphosis in which the initiation of growth in a descendant occurs earlier than in the ancestor, ensues at the ancestral rate, and ceases at the ancestral point

Heterochronic phenomena are processes by which changes in the timing, rate, and duration of an ancestral pattern of growth and development result in changes in descendants. One of the six types of heterochrony is neoteny, in which a descendant's slower rate of development causes it to be an immature or truncated expression of its ancestor.

Paedomorphosis and Peramorphosis

The six types of heterochrony fall into two general patterns: paedomorphosis and peramorphosis. In these patterns, ancestral and descendant ontogenetic trajectories are compared. If the descendant morphology exceeds or surpasses the ancestral morphology, this is called peramorphosis. There are three types of peramorphosis: acceleration, hypermorphosis, and predisplacement. In acceleration, the beginning and end of development occurs at the same time in both the ancestral and descendant ontogenetic trajectories. The rate of development is faster in the descendant, however, so its morphology transcends that of the ancestor. In hypermorphosis, development begins at the same time and ensues at the same rate in both the ancestor and descendant; however, the descendant continues development for a longer interval—that is, it stops growing later. In predisplacement, the descendant begins development earlier than the ancestor, and the rate of development and the time at which growth ceases remain the same. The result of both predisplacement and hypermorphosis is a longer interval of growth. In acceleration, however, the interval of growth is the same in both the ancestor and its descendant; only the rate of growth has changed.

If a descendant morphology is a truncated or an abbreviated version of ancestral morphology, this is called paedomorphosis. There are also three types of paedomorphosis: neoteny, progenesis, and postdisplacement. In progenesis, descendant development begins and proceeds at the ancestral rate but stops sooner. In postdisplacement, the ancestral rate of development and the time of cessation are the same in the descendant; however, development begins later. Thus, for postdisplacement and progenesis, the time interval over which the descendant morphology develops is truncated when compared to the ancestral ontogenetic trajectory. In contrast, neoteny is characterized by a slower descendant rate of development but an unchanged time interval for growth and development.

The Contributions of Von Baer and Haeckel

Two scientists of the nineteenth century were especially important contributors to the early ideas concerning development and its impact on evolutionary change. Karl Ernst von Baer suggested that the features that appear early in ontogeny are those that are shared by the most organisms, whereas the features that appear later in ontogeny are those that are shared by successively smaller groups of organisms. This maxim has been called von Baer's law. Ernst Heinrich Haeckel held a different, more restricted, concept of ontogeny. He popularized the phrase "ontogeny recapitulates phylogeny." By this he meant that the ontogenetic or developmental phases through which an organism passes can be interpreted as being equal to the sequence of events that occurred during the evolutionary history of that particular organism. Haeckel's narrower concept of the relationship between ontogeny and phylogeny has been rejected by modern biologists in favor of von Baer's law.

Von Baer and Haeckel laid the foundation for ideas of heterochrony, but it was not until the later twentieth century that the subject of heterochrony was once again an area of active research. An important book by Stephen Jay Gould entitled *Ontogeny and Phylogeny* (1977) was instrumental in reopening the discussion initiated a century earlier. One of the most important things accomplished in Gould's book was the distinction that was made between different types of paedomorphosis. Frequently, in earlier works dealing with species with a juvenile appearance, no distinction was made among neoteny, postdisplacement, and progenesis: All three were discussed as neoteny. This confusion prevented generalization.

Organisms for which neoteny is used as an explanation for their origins include some salamanders of the family Ambystomatidae and the primates of the family Hominidae (the family that includes humans). In the latter case, *Homo sapiens* is considered a juvenilized anthropoid; the reduction in the amount of hair and the longer period of infancy can be used as evidence for this supposition.

Studying Heterochronic Change

Two kinds of information are necessary for documenting heterochronic processes of change. Because frequent reference must be made to ancestral and descendant ontogenetic trajectories, it is of crucial importance to have available, for the organisms under study, an estimate of their phylogenetic, or evolutionary, history. This is not an easily obtained body of evidence, and much scientific debate has occurred over the procedures that should be followed in seeking to unravel phylogenetic history. Some researchers even doubted that it would ever be possible to obtain evidence sufficient for the task. Nevertheless, some small consensus has emerged. This is especially gratifying for students of heterochrony, who depend so much upon the phylogenies that anchor their conclusions.

It is also necessary to document ontogeny, development, and/or growth in either a quantitative or qualitative sense. The quantitative measurement of growth is relatively straightforward. Measurements are taken from specimens of known ages. It is most desirable that measurements be taken from the same individual specimens throughout their ontogenies. This is not always possible, nor is it always possible to obtain accurate ages for the available specimens. Another problem is that the ages of the specimens of different species might not be directly comparable. These are among the factors that complicate the otherwise simple process of measuring the sizes and shapes of specimens over time—that is, measuring in various places along an ontogenetic trajectory. Assuming that appropriate measurements have been gathered, a variety of statistical procedures can then be applied to the accumulated data. These procedures include some rather sophisticated multivariate statistics that have only become feasible with the advent of computers.

The qualitative documentation of an ontogenetic trajectory suffers from many of the same sources of complication. In this approach, ontogenies are conceptualized as a series of discrete stages, phases, events, or appearances. These sequences are determined for the organisms under examination, and the stages that bear close resemblance are sometimes considered identical. The problem with this view is that it conceives of ontogeny as being composed of static sequences; this is a largely Haeckelian view. In fact, ontogenies are best viewed as dynamic, which makes it conceptually difficult to compare isolated parts of an indivisible ontogeny.

An unanswered question of evolutionary biology concerns the processes by which new morphologies and new organisms originate. Although many promising inroads have been made, none has been more hopeful than the idea of heterochrony. The conjecture is that small shifts in the timing, rate, and duration of ontogeny contribute to the appearance of new structures or perhaps even new organisms. This approach has so far proved both effective and promising, but it has not yet been applied to a sufficient range of organisms. Thus, it is not yet possible to tell whether heterochrony will prove to be a universally applicable approach to the study of the origin of new structures and species.

Alberch, Pere, Stephen Jay Gould, George F. Oster, and David B. Wake. "Size and Shape in Ontogeny and Phylogeny." *Paleobiology* 5 (1979): 296-317. This paper expands upon and formalizes a model based upon the earlier work of Gould (1977). The authors try to present a unified concept of morphological evolution by fusing ideas of developmental biology and evolutionary ecology. Their model is technical and includes mathematical equations as its foundation. Examples used to illustrate their approach include limb development patterns in salamanders, reptiles, and birds, skull ontogeny in salamanders, and gonopodial development in a fish.

Gould, Stephen Jay. *Ontogeny and Phylogeny*. Cambridge, Mass.: Belknap Press, 1977. This volume was responsible for the reawakening of interest in heterochrony. The text is divided into two sections: The six chapters in the first section are a history of ideas pertaining to ontogeny, and the last five chapters recast these older ideas in a modern form. Although extremely specialized material is covered, the writing can be easily understood by the layperson. More than seventy illustrations, and many references to earlier work. Bibliography, glossary, and index.

Humphries, C. J., ed. *Ontogeny and Systematics*. New York: Columbia University Press, 1988. Seven separately authored articles deal with the ways in which ontogenetic information might be treated by a systematist. Issues discussed include homology and epigenetics. Each contribution is illustrated and includes a separate section of literature cited. Index.

McKinney, Michael L., ed. *Heterochrony in Evolution: A Multidisciplinary Approach*. New York: Plenum Press, 1988. This book includes sixteen specialized chapters by recognized authorities in the study of heterochrony. Chapters are grouped into three sections. The first section includes six chapters and deals mostly with the means by which one measures ontogenetic trajectories. The second section (seven chapters) is devoted to specific studies of heterochrony in selected groups, including some plants, ammonites, gastropods, rodents, and primates. The final section includes three chapters that summarize understanding of heterochrony. One chapter discusses how variation in heterochronic parameters (initiation and cessation of growth, rate of growth) are genetically controlled; another surveys the fossil record for instances of heterochrony.

McKinney, Michael L., and Kenneth J. McNamara. *Heterochrony: The Evolution of Ontogeny*. New York: Plenum Press, 1991. Defines categories of changes in timing of development, with examples for each category, and attempts to correlate types of developmental timing changes with ecological changes. Includes an extensive literature review. Illustrated.

_______, ed. *Evolutionary Change and Heterochrony*. New York: John Wiley & Sons, 1995. Overviews of current research in heterochrony in the fields of biology, paleontology, and anthropology, written by experts in their fields. Covers molecular and cell biology, macroevolution, speciation, ecology, sexual selection, and behavior.

HIBERNATION

Type of animal science: Behavior
Fields of study: Biochemistry, genetics, zoology

Hibernation is a dormancy into which some animals enter as winter approaches, remaining in a state of suspended animation until the weather moderates.

Principal Terms

ANESTHESIOLOGIST: a physician who administers anesthetics during surgical procedures

CELSIUS: a scale for measuring temperature in which freezing is zero degrees and boiling is one hundred degrees, abbreviated C

FAHRENHEIT: a scale for measuring temperature in which freezing is 32 degrees and boiling is 212 degrees, abbreviated F

HIBERNACULA: the winter habitats of brown bats

SYNCHRONIZATION: causing events to occur simultaneously

VERTEBRATES: animals with brains and spinal cords

As winter approaches, some animals enter a barely living state. Whereas the body temperature of warm-blooded animals is generally about 37 degrees Celsius (98.6 degrees Fahrenheit), some of the larger vertebrates, such as bears, enter a restful state for several of the colder months, during which body temperatures sink to about 30 degrees Celsius (88 degrees Fahrenheit).

In another class of smaller animals, notably the brown bat, the body temperature hovers just above freezing, usually between 1 and 3 degrees Celsius (34 to 38 degrees Fahrenheit). At these levels, the animal is barely alive. It does not bleed when cut. It breathes infrequently. Its heartbeat drops dramatically.

Groundhogs and chipmunks are found in areas where there may be sporadic periods of warm weather during the winter, at which times these animals awaken from their torpor temporarily. Their body temperatures, which will have sunk to about 10 degrees Celsius (50 degrees Fahrenheit), increase as the temperature outside their underground lairs rises. When the temperature sinks again, these animals resume their sleep.

Animals such as bears, brown bats, some rodents, hummingbirds, whippoorwills, chipmunks, ground squirrels, skunks, and marmots have built-in mechanisms that prevent their temperatures from sinking below the levels their systems can withstand. When their temperatures approach life-threatening levels, they begin to shiver, thereby maintaining or raising their temperatures without wakening them from their slumbers.

The Why and How of Hibernation

During hibernation the body shuts down and requires little energy. All of its systems, including endocrine, circulation, respiration, and elimination, are reduced to the barest essentials necessary to maintain life. Animals living in this state require almost no nutrition. They draw what nourishment they need from stores of fat that they accumulate by eating a great deal immediately before hibernating. They conserve their body heat by rolling themselves into balls.

The mechanisms that trigger hibernation mystify scientists. Some sort of internal clock, probably responding to light and temperature, clicks in at given times, determining the beginning of hibernation and its extent. This mechanism is far from precise. Some animals that have been maintained from year to year under consistent conditions may lose their synchronization, entering hibernation possibly in spring or summer.

The Light Sleepers

On hearing the word "hibernation," people think immediately of bears, who enter periods of dormancy as winter approaches. By the time they enter their lair for their winter's sleep, they have gained considerable weight and have added to their bodies layers of fat to provide them with the nutritional reserves they will require to survive the next three or four months.

During this period of dormancy, the bear's temperature drops less than 10 degrees Fahrenheit. Some scientists resist designating as hibernation the period during which such animals as bears, chipmunks, raccoons, and skunks sleep beneath ground. This period is sometimes called "winter lethargy."

The Hibernation Inducement Trigger

Scientists studying hibernation note that the hibernation inducement trigger (HIT) springs into action in three specific circumstances, occurring singly or in combination: when the days grow shorter in autumn, restricting the amount of light to which organisms are subjected; when temperatures drop, which often happens when the days grow shorter; and when food becomes scarce.

Questions about how HIT works have increased rather than decreased in recent years. Blood extracted from squirrels during hibernation that is preserved and injected into other squirrels in the spring, when hibernation would normally be ending, triggers an offseason onset of hibernation in the second group of squirrels. This experiment points to the existence of some sort of biochemical basis for hibernation, although its precise workings are little understood. Although the results are known, the causes remain shrouded in mystery.

Animals whose body temperatures do not drop dramatically during their dormant period may waken from their sleep several times during the winter. When the weather moderates, they often leave their lairs and scurry about seeking food. When cold weather resumes, they return to their lairs to continue their slumbers.

The eastern chipmunk is among the light sleepers. Unlike bears, it does not accumulate excess body fat to see it through its three or four dormant months. Rather, it stores food in its burrow as winter approaches, building its nest on top of the food it has gathered. It wakens frequently in winter to eat and to defecate in a section of the burrow away from the food supply.

The male chipmunk usually ends its sleep late in February. Leaving the burrow, it first seeks food and water, then looks for a mate, who produces from two to five babies one month after mating.

Skunks are also among the light sleepers. When the outside temperature approaches 10 degrees Celsius (50 degrees Fahrenheit), skunks retreat to their dens for the winter. They may take over an abandoned woodchuck's nest, but often they build their own dens below the frost line, at depths of between six and twelve feet. They line the den with dried leaves and grasses, creating a cozy nest. Although skunks are solitary in summer, they often live in groups during the winter, huddling together to keep warm.

Raccoons enter a dormant state in cold climates but are active throughout the year in milder ones, undergoing fewer body changes in winter than other true hibernators. Their body temperature drops minimally. Their heartbeat, while decreasing slightly, remains close to normal. Raccoons sleep as long as cold weather persists. They stir during warm spells but sleep again when the temperature drops.

In winter, raccoons, usually solitary dwellers, change that pattern and share their dens with other raccoons for their body warmth. Regardless of the weather, male raccoons become active late in January, which is mating season. After mating, they return to their dens for more sleep before spring.

During hibernation, the body temperature of ground squirrels drops approximately 50 degrees Fahrenheit, to a point only a few degrees above freezing. (Corbis)

The Heavy Sleepers

Some species undergo significant changes during dormancy that qualify them as true hibernators. In these animals, heartbeat, temperature, and respiration drop so dramatically during winter that life is barely sustained. These heavy sleepers do not respond to temporary increases in outside temperature, rather sleeping soundly through the months of their hibernation.

The most renowned of the heavy sleepers is the woodchuck, also known as the groundhog. People watch groundhogs' burrows every February 2 to determine whether the groundhog will see his shadow. If he does, legend has it, he will return to his den and there will be six more months of winter. The groundhog actually leaves its burrow in February seeking a mate.

Woodchucks accumulate as much body fat as possible before hibernation, sometimes achieving a weight of ten pounds. During their deep sleep, they take nourishment from their layers of fat, although they may waken at times to nibble seeds stored in their dens. By the time they emerge from hibernation, most have lost between 35 to 50 percent of their weight.

The den into which woodchucks retreat when winter arrives may have a forty-foot tunnel, camouflaged at its entry, that leads into the den. The winter den is below the frost line, usually about five feet deep. The winter rooms are high in the tunnel so that they cannot flood.

When the woodchuck enters its den for hibernation, it seals off the tunnel leading into it. The outer tunnel may become the winter dwelling of skunks or rabbits. During hibernation, the woodchuck, which normally breathes about thirty-five times a minute, breathes about once in five minutes. Its body temperature drops from about 36.7 degrees Celsius (98 degrees Fahrenheit) to 3.3 degrees Celsius (38 degrees Fahrenheit), only slightly above freezing. Its heart, beating in warm weather at about eighty times a minute, now beats four times a minute.

Woodchucks have a layer of brown fat that builds up around their vital organs. When it is time for hibernation to end, the animal receives an instant jolt of energy from this brown fat. It begins to shiver, which gradually warms it up. Its supply of oxygen increases steadily, resulting in increased blood flow, which warms the woodchuck. It takes a few hours for it to move from its dormant state to its spring time state.

In mild climates, ground squirrels are active all year. The bodies of those that do hibernate change slowly from their summer to their winter phase. Their body temperature, around 32.2 degrees Celsius (90 degrees Fahrenheit) in summer, drops a couple of degrees every day until it approaches 4.4 degrees Celsius (40 degrees Fahrenheit). An internal mechanism keeps the squirrel's body temperature from dropping below that number. Brown bats enter hibernation when the air temperature stabilizes around 10 degrees Celsius (50 degrees Fahrenheit), entering their win-

Humans and Hibernation

Considerable research related to hibernation and its implications for humans is ongoing. Noting that when animals' bodies approach the freezing point, they feel little pain and bleed little, if at all, when they are cut, anesthesiologists and other physicians have begun to simulate some conditions of hibernation in the operating room.

Only in the last third of the twentieth century was it possible to perform some kinds of delicate, lifesaving surgery by packing the body in ice and chilling it to the point that most vital signs are significantly reduced. Open-heart and transplant surgery have advanced considerably by using such techniques. The loss of blood accompanying such surgery in earlier eras has been substantially reduced by operating on chilled bodies, then gradually warming them to normal temperatures. The need for anesthetics also has been greatly reduced, thereby eliminating much of the risk that anesthetization frequently carries.

Hibernation among humans would be useful in space travel, where reducing their vital functions for extended periods would curtail the need for oxygen and food among space venturers.

ter quarters, or hibernacula, in swarms. In these caves, the temperature remains constant and is above freezing, which is crucial to the bats' survival, because bats subjected to lower temperatures develop fatal ice crystals in their blood.

Brown bats hang upside down in their caves in winter. Their bodies become stiff and appear to be dead. Their heartbeats drop from over five hundred beats a minute to between seven and ten beats a minute. They hibernate for three to four months, waking occasionally for water and any insects they can find to devour. In dormancy, brown bats' bodies assume the temperature of the atmosphere surrounding them.

The jumping mouse is another true hibernator. Late in October, it seals itself into its den, having gorged on all the food it can find in the weeks prior to hibernation. It curls up into a ball, placing its head between its hind legs. During hibernation, it breathes just once every fifteen minutes.

HIERARCHIES

Type of animal science: Behavior
Fields of study: Anthropology, evolutionary science, population biology

Hierarchies, systems of establishing dominance and subordination, are important in maintaining social order in many species of animals.

Principal Terms

ADAPTION: in evolutionary biology, any structure, physiological process, or behavior that gives an organism an advantage in survival or reproduction in comparison with other members of the same species

AGGRESSION: a physical act or threat of action by one individual that reduces the freedom or genetic fitness of another

COMPETITION: the active demand by two or more organisms for a common resource

DOMINANCE: the physical control of some members of a group by other members, initiated and sustained by hostile behavior of a direct, subtle, or indirect nature

FITNESS: in the genetic sense, the contribution to the next generation of one genotype in a population relative to the contributions of other genotypes

SOCIOBIOLOGY: the study of the biological basis of the social behavior of animals

All animal species strive for their share of fitness. In this struggle for reproductive success, there is often competition among the individuals that make up the population. This competition is generally for some essential resource such as food, mates, or nesting sites. In many species, the competition over resources may lead to actual fighting among the individuals. Fighting, however, can be costly to the individuals involved. The loser may suffer real injury or even death, and the winner has to expend energy and still may suffer an injury. In order to prevent constant fighting over resources, many animal species have adapted a system of dominance, or what students of sociobiology call a dominance hierarchy or social hierarchy. The dominance hierarchy is a set of aggression-submission relationships among the animals of a population. With an established system of dominance, the subordinate individuals will acquiesce rather than compete with the dominant individuals for resources.

General Characteristics of Hierarchies

The simplest possible type of hierarchy is a despotism where one individual rules over all other members of the group and no rank distinctions are made among the subordinates. Hierarchies more frequently contain multiple ranks in a more or less linear fashion. An alpha individual dominates all others, a beta individual is subordinate to the alpha but dominates all others, and so on down to the omega individual at the bottom, who is dominated by all of the others. Sometimes, the network is complicated by triangular or other circular relationships where two or three individuals might be at the same dominance level. Such relationships appear to be less stable than despotisms or linear orders.

Hierarchies are formed during the initial encounters between animals through repeated threats and fighting, but once the issue of dominance has been determined, each individual gives way to its superiors with little or no hostile exchange. Life in the group may eventually become so peaceful that the existence of ranking is hidden from the observer until some crisis occurs to force a confrontation. For example, a troop of baboons can go for hours without engaging in sufficient hostile exchanges to reveal their ranking, but in a moment of crisis such as a quarrel over food the hierarchy will suddenly be evident. Some species are organized in absolute dominance hierarchies in which the rank orders remain constant regardless of the circumstances. Status within an absolute dominance hierarchy changes only when individuals move up or down in rank through additional interaction with their rivals. Other animal societies are arranged in relative dominance hierarchies. In these arrangements, such as with crowded domestic house cats, even the highest-ranking individuals acquiesce to subordinates when the latter approach a point that would normally be too close to their personal sleeping space.

The stable, peaceful hierarchy is often supported by status signs. In other words, the mere actions of the dominant individual advertise his dominance to the other individuals. The leading male in a wolf pack can control his subordinates without a display of excessive hostility in the great majority of cases. He advertises his dominance by the way he holds his head, ears, and tail, and the confident face-forward manner in which he approaches other members of his pack. In a similar manner, the dominant rhesus monkey advertises his status by an elaborate posture which includes elevated head and tail, lowered testicles, and slow, deliberate body movements accompanied by an unhesitating but measured scrutiny of other monkeys he encounters. Animals not only utilize visual signals to advertise dominance, but they also use acoustic and chemical signals. For example, dominant European rabbits use a mandibular secretion to mark their territory.

Special Properties of Dominance Hierarchies

A stable dominance hierarchy presents a potentially effective united front against strangers. Since a stranger represents a threat to the status of each individual in the group, he is treated as an outsider. When expelling an intruder, cooperation among individuals within the group reaches a maximum. Chicken producers have long been aware of this phenomenon. If a new bird is introduced to the flock, it will be subjected to attacks for many days and be forced down to the lowest status unless it is exceptionally vigorous. Most often, it will simply die with very little show of fighting back. An intruder among a flock of Can-

Pecking Orders in Domestic Fowl

Among common barnyard chickens, social behavior is a relatively simple system based on the dominance hierarchy. A power struggle begins soon after a new flock is established. The chickens quickly form a hierarchy that is quite literally a pecking order. The chickens establish their status by pecking or by threatening actions toward an opponent with the obvious intention of attacking in this manner. Superior genetic fitness is attained by the high-ranking birds. They enjoy more freedom of movement, and they have priority of access to food, better nesting sites, and favored roosting places. While the dominant males mate far more frequently than the subordinates, the dominant females actually mate less, because the subordinate females more readily display submissive and receptive postures to the males. The fitness of the dominant females is still enhanced due to the advantages gained in access to food and nesting sites. Males establish a separate hierarchy above that of the females. The adaptive advantage to this behavior lies in the fact that males who are subordinate to females will not be able to mate. It has been well documented that fighting ability among fowl is an inherited trait, and significant genetic variation in this trait can be observed both between and within the various species of fowl. It is advantageous for chickens to live in a stable hierarchy. If the hierarchy of the flock is intentionally disrupted, the chickens will eat less food, lose more weight, and lay fewer eggs.

ada geese will be met with the full range of threat displays and repeated mass approaches and retreats.

In some primate societies, the dominant animals use their status to stop fighting among subordinates. This behavior has been observed in rhesus and pig-tailed macaques and in spider monkeys. This behavior has been observed even in animal societies, such as squirrel monkeys, that do not exhibit dominance behavior. Because of the power of the dominant individual, relative peace is observed in animal societies organized by despotisms, such as hornets, paper wasps, bumblebees, and crowded territorial fish and lizards. Fighting increases significantly among the equally ranked subordinates as they vie for the dominant position when the dominant animal is removed.

Young males are routinely excluded from the group in a wide range of aggressively organized mammalian societies such as baboons, langur monkeys, macaques, elephant seals, and harem-keeping ungulates. At best, these young males are tolerated around the fringes of the group, but many are forced out of the group and either join bachelor herds or wander as solitary nomads. As would be expected, these young males are the most aggressive and troublesome members of the society. They compete with one another for dominance within their group and often unite into separate bands that work together to reduce the power of the dominant males. Males in the two groups show different behaviors. Among the Japanese macaques, the dominant males stay calm and aloof when introduced to a new object so as to not risk loss of their status, but the females and young males will explore new areas and examine new objects.

Nested hierarchies are often observed in some animal species. Societies that are divided into groups can display dominance both within and between the various components. For example, white-fronted geese establish a rank order of several subgroups including parents, mated pairs without young, and free juveniles. These hierarchies are superimposed over the hierarchy within each of the subgroups. In wild turkeys, brothers establish a rank order among their brotherhood, but each brotherhood competes for dominance with other brotherhoods on the display grounds prior to mating.

Dominants and Subordinates

To be dominant is to have the priority of access to the essential resources of life and reproduction. In almost all cases, the superior dominant animals will displace the subordinates from food, mates, and nest sites. In the matter of obtaining food, for example, wood pigeons are flock feeders. The dominant pigeons are always found near the center of the flock when feeding and feed more quickly than the subordinate birds at the edge of the flock. The birds at the edge of the flock accumulate less food and often obtain just enough to sustain them through the night. Among sheep and reindeer, the lowest-ranking females are also the worst-fed animals and among the poorest of mothers. Baby pigs compete for teat position on the mother and once established will maintain that position until weaning. Those piglets that gain access to the most anterior teats will weigh more at weaning than those who have to settle for posterior teat positions. In gaining access to mates, one study with laboratory mice has shown that while the dominant males constituted only one third of the male population, they sired 92 percent of the offspring.

Life is still not all that hopeless for the subordinates. Oftentimes the loser in the battle for dominance is given a second chance, and in some of the more social species, the subordinate only has to await its turn to rise in the hierarchy. In some species, cooperation among subordinate groups, especially kin groups, can lead to the formation of a new colony and a new opportunity to establish dominance. In other species, it may well be advantageous for the subordinate to stay with the group. For example, individual baboons and macaques will not survive very long if they are away from the group's sleeping area, and they will have no opportunity to reproduce. It has been shown that even a low-ranking male eats well if he is part of a troop, and he may occasionally have the opportunity to mate. In addition, the dominant male will eventually lose prowess, and the subordinate will have a chance to move up in the dominance hierarchy.

HIPPOPOTAMUSES

Type of animal science: Classification
Fields of study: Anatomy, wildlife ecology, zoology

The Hippopotamidae family has two genera, each with a single species. The two genera differ greatly in size, but both are characterized by a round tubular body, short stocky legs, broad snout, and a very large mouth.

Principal Terms

BLOOD SWEAT: oily secretion from mucous glands serving a protective function
CALF CRÈCHE: group of newborn calves in a place of protection
DUNG SHOWERING: behavior by bulls to show dominance over other males
NONRUMINATING: digesting grasses without chewing cud

The name hippopotamus means "river horse," and these mammals spend most of their time in the water. They have inflated-looking bodies that resemble barrels, supported on short, pillarlike legs with four toes ending in hooflike nails. The tail is short and bristled, with flattened sides. The belly is carried only a few inches above the ground. The eyes are raised on top of a flat head, the ears are small, and the nostrils are slits high up on the muzzle and can be closed when the animal is submerged. The two species, *H. amphibius* and *C. liberiensis* (pygmy hippopotamus) differ greatly in size, with the former up to 5.5 feet high and weighing seven thousand to ten thousand pounds. The pygmy hippopotamus is much smaller, with an average height of 2.5 to 3 feet, and weighing 350 to 600 pounds.

Hippopotamus Life

Hippopotamuses must submerge frequently because their naked skin is vulnerable to overheating and dehydration. They can stay submerged up to thirty minutes. Their skin has a brown to gray-purple coloration with pinkish creases. The pygmy hippopotamus is black-brown to purple in color with the cheeks often tinted pink. Unlike the pygmy hippopotamus, which is a solitary mammal dwelling in rivers and forests, *H. amphibius* is a huge animal that can be found in herds of up to eighty members.

Seeking food, *H. amphibius* travels at night from the rivers for grazing, but will return before dawn to spend the day digesting and socializing in the riverbeds. During the forays from the water,

Hippopotamuses spend most of their day in the water because their bare skin makes them prone to dehydration in the hot African sun. (Corbis)

Hippopotamus Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Subphylum: Vertabrata
Class: Mammalia
Order: Ariodactyla
Suborder: Suiformes
Family: Hippopotamidae
Genus and species: Hippopotamus amphibius (hippopotamus), *Choeropsis liberiensis* (pygmy hippopotamus)

Geographical location: Although once numerous in the rivers throughout Africa, *H. amphibius* can now be found only south of Khartoum and north of the Zambezi River; the pygmy hippopotamus is found in West African lowland rain forests

Habitat: Hippopotamuses live in short grasslands, rivers, and lakes; pygmy hippopotamuses live in lowland forests and swamps

Gestational period: Eight months for hippopotamuses, seven months for pygmy hippopotamuses

Life span: Up to forty-two years in the wild, past fifty in captivity

Special anatomy: The genera differ greatly in size, but both have a broad snout, a very large mouth, a short round body, and short stocky legs; the smooth, hairless skin is covered with special pores that secrete a pinkish substance known as blood sweat, which is protective when in the water or dry land; large canine teeth enlarge into tusks that grow continually; the stomach is three-chambered but is nonruminating; hippopotamuses appear to have good eyesight, hearing, and smell

the animals typically travel two to three miles. *H. amphibius* eats up to ninety pounds of grass on a nightly basis, often mowing twenty-inch-wide swaths with its muscular lips and mouth. The pygmy hippopotamus prefers to seek food on high, dry ground and is most active between 6 P.M. and midnight. They have home ranges that may cover between one hundred and four hundred acres. Most movements are along established paths in their home range, and rarely do they cross paths with others of their own species. During these forays, they seek water plants, grasses, fallen fruits and leaves.

For *H. amphibius*, their watery homelands are partitioned into individual mating territories by mature bulls that defend defined sections. These territories can remain fixed for years. Dung showering is used to mark territories and express dominance. Other behaviors that signal threats can include water scooping, head shaking, grunting, roaring, explosive exhaling, and charging. Submission is signaled by turning tail, approaching in a crouched position, lying prone on the land, or diving and swimming away from the dominant male.

Reproduction

Herds usually breed between ten to fifteen hippopotamuses. Nonbreeding males are tolerated in the territories if they do not bother the cows. Cows and calves associate in nursery herds and establish calf crèches, which serve as protection against predation from crocodiles, lions, and hyenas. Mating takes place during the dry season while the animals are in the water. After the birth of a calf, either on land or in the water, the cow remains with the calf for about a month before returning to the herd. Baby hippopotamuses are able to nurse underwater until they are weaned, at around eight months of age.

During mating season, the solitary pygmy hippopotamus seeks out a receptive female who tolerates the male's presence when in heat. One to four copulations may take place over a period of two days on both land and in the water. The young are born on land or in the water and remain concealed for three to four weeks. The main predator for the pygmy hippopotamus is the leopard. The pygmy hippopotamuses are considered to be in jeopardy for survival because of hunting and destruction of habitat by logging.

HOME BUILDING

Type of animal science: Behavior
Fields of study: Entomology, marine biology, ornithology, zoology

A home is the place or physical structure in which an animal lives, eats, finds a safe haven, and raises its family. The nature of animal homes varies greatly.

Principal terms

ARTIODACTYL: a hoofed mammal with an even number of toes
CARNIVORE: an animal that eats only animal flesh
HERBIVORE: an animal that eats only plants
MOLE HILL: an earth mound a mole dug up in search of food.
OMNIVORE: an animal that eats plant and animal matter
SOLITARY: living alone

The term "home" designates the area, place, or physical structure in which an animal lives, finds a safe haven, and raises its family. The nature of animal homes varies greatly. The very simplest example might be a spot on an ocean bottom where a marine sponge attaches to the sand and grows. Other sea animals, such as gastropods (snails) live in their shells and take their homes wherever they go. Crustaceans, such as lobsters, or land arthropods, such as scorpions, live in simple burrows in the oceans or in the earth. However, a large number of lake, ocean, and river dwelling species, such as fish and whales, have no fixed homes.

Land animals often live in more complex homes. For example, social insects such as bees, termites, and wasps inhabit nests or hives. Birds also build nests. They nest in trees, on the ground, or on rocky mountain terrain. In contrast, grazing animals such as deer and antelope live on the ground, wherever their search for food takes them on a given day. In the case of small mammals, individuals or groups often live in complex underground burrows such as mole holes. Larger carnivores and omnivores often inhabit dens that are underground burrows, as do members of the weasel family, or in caves and other natural formations, as do bears and big cats.

Insect and Bird Homes

Social insects such as bees, ants, and some wasps live in nests of differing sizes which are made of wax, paper, or dried mud. Social wasps, for example, live in spherical paper nests that are a foot in diameter. These nests are seen in trees or under the porch roofs of human habitations. A wasp colony lasts only one year because wasps do not store food as do ants and bees. Only a few fertilized females, queens-to-be, survive the winter to begin new colonies in spring. Many solitary wasps live alone, except for breeding. Then, females build small brood nests of materials other than paper. For example, potter wasps use mud and saliva, and stone-working wasps mix small pebbles, mud, and saliva.

Termites, also social insects, are known for damaging wood homes. Most species are tropical, but some inhabit the Americas and Europe. They live in huge, long-lasting colonies that may hold millions of inhabitants. These colonies (called nests or termitaries) vary greatly. Tropical species build huge mounds with walls of soil particles and dried saliva. Inside the mounds are many chambers, passages, and good ventilation and drainage systems. Termites are often subterranean, burrowing up into logs and wood structures.

Image Not Available

Many birds, such as the commonly seen crows, robins, sparrows, doves, and other small to medium birds, nest in trees or warm places around human homes. For instance, doves may nest atop porch lights. Nests of such birds are most often made of intertwined pieces of grass, twigs, and human trash. The nests are often abandoned yearly and in some cases are reused by other species. Also of interest are the nests of woodpeckers, which are located in tree holes.

Flamingos nest along shores of shallow, saltwater lagoons and lakes. The nest is a foot-tall mound of mud with a depression at its top. Flamingos are monogamous, and couples use the same nest over and over. In contrast, vultures usually live on bare ground under mountain overhangs or in caves, building no nests, and laying eggs on bare rock of these spartan home sites. Vultures are also monogamous and will live in a home site for up to forty years. An exception to the "bare rock" rule occurs with lammergeiers of Europe, Asia, and Africa. These bearded vultures build several nests per pair. They are conical in shape, located on rock ledges or in caves, and are used many times, in cycles, as home sites and to raise families.

Mammal Homes

Mammals have a wide variety of home sites. In many cases, such sites are temporary and are simply the last place the mammal found itself each day. Creatures living in this way are usually herbivores, ranging from hippopotamuses to deer and other artiodactyls. This is because every day, these animals range over areas of several square miles or more seeking food. The other end of the home site range is seen with many omnivores and carnivores. These creatures have specific home sites or dens, which may be burrows in the ground, caves, logs, and natural crevices. Small mammals that live like this include gophers and moles. They dig burrows or tunnels with the sharp claws of their front feet. Gophers store food in chambers in the burrows. They are solitary and territorial, coming together only to breed. Females use their burrows to live in and raise young.

The homes of moles are more complex. Moles are voracious and solitary, continually burrowing in the ground for food, which includes insects, worms, slugs, snails, and spiders. They defend their homes when other moles—even of their own species—intrude. Moles only socialize when entering tunnels of females to mate.

Mole burrows or holes are close to the ground surface and may be recognized by large, central earth mounds. These "mole hills" are the earth that has been dug up in search of food. The burrows are very elaborate, holding warmly lined central nest chambers, connected galleries, bolt holes that allow escape from enemies, and many passageways.

Wolves and spotted hyenas are somewhat similar, related species. These carnivores tend to live in dens and claim large hunting territories. Wolf and hyena homes and living habits are different. Wolves live in dens or lairs that may be caves, hollow tree trunks, crevices under large fallen logs, or holes they dug in the ground. Few improvements are made in the natural dens wolves inhabit. They are shelters used for safety, protection from the elements, and for raising offspring.

Spotted (laughing) hyenas, in contrast, are much more communal. They live in clans of up to one hundred individuals and inhabit shared communities comprising many dens. In the dens they sleep, mate, and socialize. Dens may be caves on rocky ground or holes dug by individuals, as a clan grows. The individual cave or tunnel dens are most often inhabited by one individual or a female with cubs. This is because extended pairing is unusual in spotted hyenas.

Lions and tigers, the largest predatory land carnivores, often roam through large territories in search of game and inhabit dens of varying permanence. The dens are dense thickets, groups of rocks surrounded by thick underbrush, or caves whose entrances are screened by thorn bushes or dense underbrush. Very often, dens are used to birth offspring and protect the big cats from the elements.

Primate Homes

Monkeys, which live in Africa, Asia, and South and Central America, live in bands which most often inhabit trees, sheltering in the forks between branches. African baboons are large, more highly organized, ground-living primate species. They live in groups called troops, which are often found living in rocky terrain or on cliffs. In many cases, group members inhabit convenient caves.

Gorillas, the largest, strongest, rarest apes, look almost human. They inhabit West African forests from lowlands to altitudes of ten thousand feet. Gorillas live in bands of up to twenty individuals. Each band claims a territory, which may be viewed as the band's neighborhood. A band forages over several square miles each day and lacks permanent dwellings. Instead, its members build temporary shelters each night after a day of foraging for the honey, eggs, plants, berries, bark, and leaves that are their diet. When terrain and time permit, females and young sleep on temporary tree platforms made of branches and leaves. Mature males nest at the bases of these trees, to protect them.

Beavers: Engineers of the Animal World

An example of animal engineering at its best is the beaver home. These herbivores live in streams, ponds, or lakes near woods. Beaver home building starts with making dams where water flows steadily but slowly. Dams create deep water pools used for food storage. Beavers work in groups—usually extended families—to build their dams. Their sharp incisor teeth are used to cut down nearby softwoods such as aspens and willows. The trees are interwoven with mud, stones, and sticks to form and seal the dam.

Inside or near the dam, the beavers build lodge chambers and tunnels to live in. Nearby they store piles of tree branches underwater to use as winter food. A lodge may be on an island, a pond bank, or the shore of a lake. An island lodge holds a central chamber, with its floor a little above water level. A pond lodge, built partly on the bank, has a front wall rising up from the pond bottom. A lake lodge is built on the lake shore. Beaver lodges are made of sticks, grass, and moss, interwoven and plastered with mud. Their interiors are often nine feet square and over three feet tall.

Homes, Lifestyles, and Forms

The homes of animals depend upon their lifestyles, habitats, and forms. Many herbivores and omnivores range widely to find sustenance. Hence, they often lay themselves down to sleep wherever the search for food takes them. Animals that live in hot, relatively dry climates often sleep out of doors. However, similar species inhabiting cool to cold climates very often build or find burrows or dens to live in. Some animals have forms and eating habits that cause them to live outdoors regardless of world location. This is typical of animals, such as zebras and reindeer, that graze daily over large areas and cannot restrict themselves to homes where they return each evening. In contrast, animals that hunt often prefer to have a safe haven where they can bring their catch home to devour in peace, while animals that live in cold climates use their homes to store food for the long winter.

HOMEOSIS

Type of animal science: Development
Fields of study: Developmental biology, embryology, genetics, physiology, reproduction science

Homeotic genes determine the identity of different body segments early in development. Research on these genes provides insight into how complex body patterns are established during development and how these patterns have evolved.

Principal Terms

EMBRYO POLARITY GENES: genes whose expression in maternal cells results in products being stored in the egg that establish polarity, such as the anterior-posterior axis, after fertilization

GAP RULE GENES: expressed in the zygote, these genes divide the anterior-posterior axis of fruit flies into several regions

HOMEOBOX: one of 180 nucleotide pairs that code for a protein called the homeodomain, found in such diverse organisms as insects, frogs, and humans; they are known to influence body plan formation in fruit flies

HOMEOSIS: a process that results in the formation of structures in the wrong place in an organism, such as a leg developing in place of a fly's antenna

HOMEOTIC SELECTOR GENES: genes that determine the identity and developmental fate of segments established in fruit flies by a hierarchy of genes

IMAGINAL DISK: a small group of cells that differentiate adult fruit fly structures after the last larval molt

PAIR-RULE GENES: segmentation genes of fruit flies that divide the anterior-posterior axis into two-segment units

SEGMENTATION GENES: these include the gap rule, pair-rule, and segment polarity genes

The body plans of advanced animals and plants can be viewed as a series of segments with unique identities. This is especially obvious in the annelids (segmented worms), but even in vertebrates the muscular regions and the backbone are segmented. Occasionally, a segment takes on the identity of another segment of the organism. This is called homeosis, and it was first described in 1984. Numerous examples of homeosis have been cited, including the Antennapedia mutant of the fruit fly, which has a leg developing in the antennal socket of the head. Much has been learned about developmental patterns in organisms, and about the evolution of these patterns, from the study of homeotic mutants.

The Genetic Control of Body Plans

The role of homeosis in elucidating genetic control of overall body plans is best illustrated in the development of the fruit fly. Early in its embryogenesis, the basic plan for the adult fly form is established, and this information is stored in imaginal disks (an adult fly is called an imago) through three larval stages and associated molts. Imaginal disks are small groups of cells that differentiate adult structures after the last larval molt. The early determination of these imaginal disks for specific developmental fates is controlled by a hierarchy of genes. This hierarchy of gene regulation has been carefully documented for the establishment of the anterior-posterior axis (a line running from the head to the abdomen) of larval and adult fruit flies. Three levels of genetic control—egg polarity genes, segmentation genes, and homeotic selector genes—result in an adult fly with anterior head segments, three thoracic segments, and eight abdominal segments.

Egg polarity genes are responsible for establishing the anterior-posterior axis. Mutations of these genes result in bizarre flies that lack head and thoracic structures or lack abdominal structures. Maternal egg polarity genes are transcribed, and the resulting ribonucleic acid (RNA) is translocated into the egg and localized at one end. This RNA is not translated into protein until after fertilization. Following translation, the proteins are dispersed unequally in the embryo, forming an anterior-posterior gradient that regulates the expression of the segmentation genes.

Segmentation genes represent the second tier of the genes that establish the body plan of the fly. Within the segmentation genes, there are three levels of control—gap genes, pair-rule genes, and segment polarity genes—resulting in progressively finer subdivisions of the anterior-posterior axis. While there is hierarchical control within the segmentation genes, genes in a given level also interact with one another. Gap genes of the embryo respond to the positional information of the gradient established by the maternal egg polarity genes. Gap genes form boundaries that specify regional domains, and several gap genes with distinct regions of influence have been identified.

Pair-rule genes follow next in the sequence; they appear to function at the level of two-segment units. Mutant pair-rule genes are responsible for flies that have half the normal number of segments. Ultimately, the larval fly body is divided into visible segments, but while the patterns are forming, genes appear to exert their influence on parasegments. A parasegment is half a segment that is "out of phase" with the visible adult segments. Parasegments include the posterior of one segment and the anterior of the adjacent segment. Developmental programming of parasegments ultimately gives rise to visibly distinct segments. The final level of control of the segmentation genes focuses on individual segments and is controlled by the segment polarity genes. In response to the pair-rule genes, the segment polarity genes subdivide each segment into anterior and posterior compartments. Thus, the segmentation genes create a series of finely tuned boundaries.

Homeotic Selector Genes

It is the third tier of genes, however, the homeotic selector genes, that actually specify segment identity. Segmentation gene mutations result in missing body parts, whereas mutations of the homeotic selector genes result in a normal number of segments, but segments with abnormal identities. Homeotic selector genes are found in two gene clusters, the *Antennapedia* complex and the bithorax complex, both of which were identified based on mutant phenotypes. Genes associated with the *Antennapedia* complex appear to determine the fate of segments associated with the anterior body segments, whereas the bithorax complex is responsible for the more posterior segments, such as the abdominal segments. The pattern that arises is modulated both by interactions among the homeotic selector genes and by interactions with the segment polarity genes.

The genes found within the *Antennapedia* and bithorax complexes have been identified based on mutations that have arisen. These genes function within smaller regions of the anterior or posterior axis, much as pair-rule genes subdivide regions established by the gap genes. It is intriguing that the genes within the two complexes appear to be lined up in the same order that they function spatially. That is, the position of an *Antennapedia* complex gene on the chromosome relative to other *Antennapedia* complex genes correlates with the actual position of the segments controlled by the gene. Recent analyses of homeotic mutants in beetles indicate that the homeotic genes are also physically organized in a left-to-right sequence corresponding to the location of the segments they control on the anterior-posterior axis. Unlike the fruit fly, however, the beetle has a single homeotic gene complex controlling the entire anterior-posterior axis.

The interactions between homeotic selector genes and other genes in the hierarchy may, in part, be controlled by the homeodomain protein coded for by the "homeobox" associated with many of these genes. The homeobox is a 180-nucleotide-pair sequence that is included in many of the homeotic selector genes as well as in some segmentation genes (including the pair-rule gene). The homeodomain protein has a unique structure that may bind the deoxyribonucleic acid (DNA) and affect its transcription. It is possible that this allows genes to regulate expression of themselves and other related genes. For example, a pair-rule gene known as *fushi tarazu* (meaning "not enough segments" in Japanese) is found in the *Antennapedia* complex and has a homeobox, although *fushi tarazu* is not a homeotic selector gene. Its homeodomain can bind to the *Antennapedia* gene and thus can regulate when this gene is turned on and off. *Antennapedia*, a homeotic selector gene, was first identified when a mutation of it resulted in the replacement of an antenna with a leg. Thus, the ability of the homeodomain to bind to DNA provides a way for the hierarchical control of homeotic selector genes by segmentation genes to occur.

The homeotic selector genes are ultimately linked with gene expression that leads to the development of specific structures associated with different segments. It is not known exactly how homeotic selector genes regulate segment differentiation. Although the homeotic selector genes are active early in development, they appear to be involved in programming cells for fates that are not expressed until much later.

Studying Homeosis Through Mutations

Most of what is known about homeosis has been learned from studying mutations. Sometimes these mutations have arisen spontaneously; sometimes they have been induced by exposing organisms to mutagenic substances, such as chemicals or X ray or ultraviolet radiation. The large number of mutations identified in fruit flies accounts for the wealth of information on homeosis in this organism, in sharp contrast to the limited information on humans, for whom ethical considerations prohibit mutagenesis. Mutations affecting segmentation and determination of segment identity represent defective developmental switches and provide insight into the normal developmental sequence.

Classical genetic approaches have been used with homeotic mutants to map genes to chromosomes and to identify interactions between genes. For example, it can be determined whether two genes are on the same chromosome by making a series of specific matings between flies with mutations in these genes and wild-type ("normal") flies. If the genes are not on the same chromosome, offspring with one mutation will not necessarily have the other mutation. If the mutations are both on the same chromosome, they will be inherited together, except in rare situations where there is recombination between chromosomes. Geneticists use the frequency of recombination to assess how close together two genes are on a chromosome. This approach helped geneticists determine the order of genes within the *Antennapedia* and bithorax complexes. Matings between different mutants have also established the hierarchy of genetic control among egg polarity, segmentation, and homeotic selector genes. For example, a pair-rule mutant will have no effect on gap genes, but a gap gene mutant will affect pair-rule genes.

To visualize the results of these crosses of hierarchical mutants, researchers employed a second technique: in situ hybridization. To investigate the effect of gap genes on pair-rule genes, a wild-type fly embryo and one with a gap mutation affecting the middle section were exposed to radioactively labeled DNA that was a copy of the pair-rule gene *fushi tarazu*. The DNA hybridized (bound) to *fushi tarazu* RNA, and it thus labeled tissues where the *fushi tarazu* gene was turned on and was making RNA copies of itself. Excess radioactive DNA was washed away, and a photographic emulsion that was then placed over the tissue was exposed by the bound radioactive DNA. This permitted researchers to see that the *fushi tarazu* gene was being expressed in the middle of the wild-type embryo, but not in the gap mutant embryo. When this experiment was repeated using radioactive gap gene DNA in a pair-rule mutant, no effect on gap gene expression was observed.

In situ hybridization has also provided information on how egg polarity genes provide segmentation genes with positional information. The egg polarity gene bicoid was identified by mutations resulting in a fly with abdominal structures but no head or thoracic structures. When radioactive DNA copies of the bicoid gene were hybridized to eggs, it was found that all the RNA was located at the anterior tip after being transferred from the mother. When this RNA was translated into protein, the protein was tagged with an antibody specific for the bicoid protein. Tagging the protein with an antibody is similar to tagging RNA with a radioactive DNA segment; both techniques allow researchers to see how the RNA or protein is distributed in tissues. In this case, the bicoid protein formed an anterior to posterior gradient after the egg was fertilized, with more protein being found at the anterior end.

Homeotic genes have been isolated and used for in situ hybridization studies. In addition, the sequence of nucleotides in the DNA in these genes has been established. A variety of techniques is available for DNA sequencing. Generally the DNA is broken into smaller segments that can be more readily identified. Cutting the DNA yields overlapping segments, and the overall sequence can be established by piecing these overlapping fragments back together. The presence of the homeobox was established by comparing DNA sequences from different genes in flies and other organisms. It was evident, based on these types of data, that the homeobox sequence differs by only a small number of nucleotides even between very distantly related organisms.

The role of the homeobox was investigated by inserting DNA containing a homeobox from the *fushi tarazu* gene into a bacteria in such a way that the bacteria then produced large amounts of the homeodomain protein. This protein was then tested for its ability to bind the DNA and was found to bind to specific fragments of DNA that were involved in homeosis, such as the *Antennapedia* gene. Homeodomain protein from a mutant *fushi tarazu* gene was defective in its DNA binding ability. This provided evidence that the homeobox may regulate gene expression via the direct binding of the homeodomain to DNA. This is only one of numerous examples illustrating how researchers have utilized genetic mutants and molecular biology to investigate the role of homeotic genes in the development of segmented organisms.

Implications of Homeotic Research

Research on homeosis and homeoboxes has made significant contributions to the fields of developmental biology and evolution. Since all higher animals and plants exhibit some form of segmented development, the common link of the homeobox has intrigued scientists interested in how body plans are established. Questions concerning the evolution of segmentation patterns in animals have also arisen as more is understood about the genes affecting segmentation and how they are regulated.

Significant similarities both among the homeoboxes identified in fruit flies and among the homeoboxes of distantly related species have been found. In fruit flies, homeoboxes have been identified in homeotic selector genes, segmentation genes, and egg polarity genes. Whether homeoboxes affect gene regulation and segmentation in other organisms is an exciting, and open, question. Segmented worms, leeches, earthworms, sea urchins, frogs, mice, and humans all have homeoboxes. Different mouse homeobox genes have been shown to be expressed in specific regions during embryogenesis. Relatively little is known about the process of segmentation in vertebrates, so it is more difficult to interpret the results of such experiments. Also, it appears that segmentation in vertebrates and in fruit flies (and other invertebrates) evolved separately. Thus, the presence of a homeobox may or may not indicate a common developmental process for segmentation among animals.

There is an intriguing possibility that addition and modification of homeotic selector genes were responsible for the evolution of insects from segmented worms. The presence of two homeotic gene complexes in fruit flies, contrasted with one in beetles, suggests that duplication of the gene complex, followed by subsequent specialization, may have allowed for greater fine-tuning of segmental identity. Evolutionary alterations of the initial homeotic gene complex may have been responsible for the addition of legs to a wormlike creature composed of similar segments, giving rise to a millipede-like creature. The reduction of all legs except for the walking legs in the thoracic region and, ultimately, the addition of wings to the thoracic region could also reflect changes in homeotic selector genes. Parts of this evolutionary journey can be reconstructed with homeotic fruit fly mutants that bear similarities to their ancestors. This is exemplified by the deletion of the *Antennapedia* gene, which results in a wingless fly; winged insects presumably arose from nonwinged insects. It is impossible, however, to create a millipede from a fly via mutations of the homeotic selector genes, so caution must be taken in speculating on the role of homeotic selector genes in insect evolution.

Bibliography

Alberts, Bruce, Dennis Bray, Julian Lewis, Martin Raff, Keith Roberts, and James D. Watson. *Molecular Biology of the Cell*. 3d ed. New York: Garland, 1994. Provides details on the molecular analysis of segment formation and specification. Illustrations of in situ hybridizations are especially helpful. Numerous examples using specific mutants are informative for college students.

Duboule, Denis, ed. *Guidebook to the Homeobox Genes*. New York: Oxford University Press, 1994. Provides a comprehensive overview of research on the homeobox genes, summarizing dispersed findings and listing key references. Gives an historical account of the discovery of the homeobox, an introduction to its role in development, and the classification and structural organization of the genes, plus an alphabetical description of individual genes.

French, Vernon, Phil Ingham, Jonathan Cooke, and Jim Smith, eds. *Mechanisms of Segmentation*. Madison, Conn.: Research Books, 1988. Provides a good explanation of homeodomain binding studies and details on the spatial expression of mouse homeodomain genes. Clear illustrations and accompanying reference lists.

Gilbert, Scott F. *Developmental Biology*. 6th ed. Sunderland, Mass.: Sinauer Associates, 2000. Chapter 18 provides extensive coverage of segmentation in fruit flies with a somewhat general approach. The section on the evolution of homeotic genes would be good preparation for reading the text by Raff and Kaufman.

Raff, Rudolf A., and Thomas C. Kaufman. *Embryos, Genes, and Evolution*. New York: Macmillan, 1983. Chapter 8 is an exciting chapter focusing on the role of homeotic selector genes in the evolution of insects from segmented worms. Excellent illustrations provide the reader with a clear understanding of ancestral morphologies. Suitable for college students.

Russo, V. E. A., et al. *Development: The Molecular Genetic Approach*. New York: Springer-Verlag, 1992. A collection of essays covering molecular events responsible for specific processes in the major model systems, control of fundamental processes, the regulation of genes in time and space, the roles of homeobox and oncogenes, and the potential practical benefits of developmental biology.

Villee, Claude A., Eldra Pearl Solomon, Charles E. Martin, Diana W. Martin, Linda R. Berg, and P. William Davis. *Biology*. 2d ed. Philadelphia: W. B. Saunders, 1989. An introductory college text that is also suitable for high school students. Chapter 16 provides details on the development of the fruit fly from egg to adult and summarizes the hierarchy of gene control involved in segmentation. There is an excellent photograph of the *Antennapedia* mutant.

Watson, James D., Nancy H. Hopings, Jeffrey W. Roberts, Joan Argetsinger Steitz, and Alan M. Weiner. *Molecular Biology of the Gene*. Menlo Park, Calif.: Benjamin/Cummings, 1987. Provides a well-illustrated analysis of the genes associated with segmentation and the determination of segment identity. A clear explanation of maternal effects on embryo development is presented that provides additional insight into egg polarity genes. Suitable for an introductory-level college student.

HOMINIDS

Type of animal science: Anthropology
Fields of study: Anatomy, anthropology, evolutionary science, human origins, systematics (taxonomy)

Though understanding of human ancestry is rudimentary at best, an astonishing series of discoveries since the nineteenth century has created a lively field of knowledge where there was none before.

Principal Terms

APES: large, tailless, semierect anthropoid primates, including chimpanzees, gorillas, gibbons, and orangutans, and their direct ancestors—but excluding man and his ancestors

AUSTRALOPITHECINES: nonhuman hominids, commonly regarded as ancestral to present-day humans

DRYOPITHECINES: extinct Miocene-Pliocene apes (sometimes including *Proconsul*, from Africa) found in Europe and Asia; their evolutionary significance is unclear

HUMANS: hominids of the genus *Homo*, whether *Homo sapiens sapiens* (to which all varieties of modern man belong), earlier forms of *Homo sapiens*, or such presumably related types as *Homo erectus* and the still earlier (and more problematic) *Homo habilis*

PRIMATES: placental mammals, primarily arboreal, whether anthropoid (humans, apes, and monkeys) or prosimian (lemurs, lorises, and tarsiers)

The idea that humankind might be significantly older than the six thousand years previously allotted by biblical scholars, who tried to calculate the generations of man since Adam, was not widely maintained until 1859, when human stone tools and the bones of extinct animals were found lying close to each other in France. Charles Darwin's *On the Origin of Species* appeared on November 1 of the same year, but it suggested only that "light will be thrown on the origin of man and his history" by the theory of evolution he had just proposed.

A series of important and widely noticed books then followed, including J. Boucher de Perthes' *De l'homme antédiluvien et de ses œuvres* (1860; of antediluvian man and his works); Thomas Henry Huxley's *Evidence as to Man's Place in Nature* (1863); and Charles Lyell's *Antiquity of Man* (1863), with others later by John Lubbock, James Geikie, and W. Boyd Dawkins. In *The Descent of Man* (1871), Darwin sagely hypothesized that the human line evolved in Africa (not Asia, as had previously been assumed) from a long-tailed, probably arboreal, ancestor. Yet, in Darwin's time only two fossil apes were known at all, together with some controversial bones of a creature known as Neanderthal man. Extinct species such as the australopithecines and *Homo erectus* had not been discovered.

Humans and Other Primates

The scientific name for mankind is *Homo sapiens sapiens* (wise man); the taxonomic family is the Hominidae, which also includes chimpanzees and gorillas. This classification is reasonable because, bone for bone, their skeletons are almost identical to human skeletons. On other evidence as well, man and his cousins appear to be remarkably alike. The protein sequences in chimpanzee and human hemoglobin, for example, are identical; there are only two chemical differences between gorilla and human hemoglobin. Between humans and all other animals, there are more than two. Strands of deoxyribonucleic acid (DNA) from chimpanzees and humans, moreover, are 99 percent identical. Chimpanzees, finally, are second only to humans in intelligence; their brains closely resemble those of humans. These remarkable similarities attest a common ancestry for all the Hominidae, as the classification itself would imply, and a fairly recent differentiation among its members. Some biochemists have argued that man, the chimpanzee, and the gorilla shared a common ancestor no more than six or eight million years ago.

Whatever the timing may have been, it is almost universally accepted that the link between humans and their protosimian ancestors was a now extinct genus of ape-men, the australopithecines (southern apes). The first of these, called, originally, the Taung child, was discovered in South Africa by Robert Dart in 1924. Its identity and significance remained controversial until 1936, when further discoveries by Robert Bloom convinced skeptical professionals and the public. Today, *Australopithecus* and *Homo* (man) are often grouped together as Hominini, as opposed to the Pongidae (apes), to which the chimpanzee and gorilla belong.

The Australophithecines

The australopithecines arose at least 4 million years ago, probably from dryopithecine ancestors. They lasted until two million years ago, evolving into a series of species. Of these, *Australopithecus afarensis* (found in the Afar region of Ethiopia) was the oldest and smallest. Males stood no taller than four feet, and the females were smaller. Most significantly, however, *afarensis* was fully bipedal; unlike the apes, it walked upright, with increasingly specialized hands, and with legs a bit longer than arms. Chimpanzee-like hips, together with curved toe and finger bones, suggest that it was essentially a tree-dweller living on fruits and seeds. A remarkably complete skeleton of *afarensis*, familiarly called Lucy, was found in 1974; it is about three million years old and is the oldest hominine skeleton yet found. *Afarensis* died out around 2.5 million years ago; it is thought to be ancestral to the later australopithecines and to modern humans.

Australopithecus africanus, deriving from Africa some three to one million years ago, probably evolved from *afarensis*. Most specimens come from Sterkfontein in South Africa, though others have been found in Ethiopia, Kenya, and Tanzania. This species was about the same size as *afarensis*, but it had a less apelike face. The arms were proportionately longer than a modern human's, yet shorter than those of *afarensis*; hands and teeth show similar "modernization." Dart's Taung child was the first (and is still the most famous) example of this species.

Australopithecus robustus (robust southern ape), found only in South African caves thus far, was once thought identical to *Australopithecus boisei*; in older literature, it was also known as *Paranthropus* (past man). Larger and more strongly built than *africanus*, *robustus* was more than a foot taller and had a larger brain. His teeth indicate that *robustus* was a plant eater. There is also a remarkable specimen (discovered by C. K. Brain at Swartkrans) of a child's skullcap in which the imprint of a leopard's lower canines can be seen. Since an exact-fit leopard's jaw was found nearby, it is assumed that the leopard killed the child and was then itself killed by an adult *robustus* armed with some kind of weapon. (A diorama at the Transvaal Museum, Pretoria, reconstructs this hypothetical incident.) *Australopithecus boisei*—a famous discovery by Mary Leakey, named for the Leakeys' sponsor, Charles Boise—called *Zinjanthropus*, was even bigger than *robustus* and lived at the same time, though in East Africa. A *boisei* skull discovered in 1985 in Kenya proved not only to be particularly massive but also considerably older (2.5 to 2.6 million years) than any known *robustus* specimen. *Australopithecus boisei* must therefore have been a separate and earlier species probably not descended from *africanus*. If so, then there was more than one australopithecine lineage, and the previously held idea that the australopithecines became increasingly robust through time must be reversed. As a result of this one find, there no longer are widely accepted ideas as to who gave rise to whom.

Throughout their history, the australopithecines manifest a regular progression from apelike characteristics to human ones. All the australopithecines walked upright, a fact that evidently encouraged increasing height, hand specialization, and brain development. Gradual changes in australopithecine dentition, moreover, suggest not only changing diet but revised habits as well. With advanced hands and evolving arms and shoulders, *Australopithecus* probably carried loads and used weapons, regardless of whether he was capable of making them. Though australopithecines may have done some hunting, they probably depended primarily upon foraging and scavenging—filching from leopard kills, for example.

The Evolution into *Homo*

At what point *Australopithecus* evolved into *Homo* is unclear, in part because the distinction between them is rather arbitrary. Though still regarded by some researchers as an advanced form of *Australopithecus* (that is, as more than one species) *Homo habilis* (handy man), another Leakey family discovery, is otherwise usually accepted as the earliest member of a distinctly human line. He was still only about five feet high (perhaps an optimum height for the environmental conditions), but had a larger brain, a rounder head, a less projecting face, advanced dentition, reduced jaws, and essentially modern feet. Stone artifacts have been found in close association with his remains; *habilis*, who lived between 2 and 1.5 million years ago, almost certainly made tools, hunted, built shelters, gathered plants, and scavenged. He is assumed to be ancestral to *Homo erectus*, and may have exterminated *Australopithecus*.

In 1859, when the prehistory of humankind was first broadly acknowledged, the only remains then known belonged to Neanderthal man (now called *Homo sapiens neanderthalensis*). Until 1924, when *Australopithecus* was discovered, all the intervening finds (excluding "Piltdown man," a deliberately planted fake) have since been classified as varieties of *Homo erectus* (erect man—a designation assuming that its predecessors stooped). Of these, the two best-known are Java man, discovered in 1891 by Eugène Dubois in Java, and Peking man, found in China by Davison Black in 1926. Only after a number of specimens had accumulated was it realized that Java man and Peking man were examples of the same species. An exceptionally complete *Homo erectus* skeleton was discovered in Kenya in 1984 and dated at 1.6 million years old. Overall, *Homo erectus* lived from some time before 1.6 million years ago to as recently as two hundred thousand years ago. He probably evolved in Africa but migrated from there (as no previous hominid had) to Europe and the Pacific shores of Asia. This species was as tall as modern humans, but more robust overall, with a noticeably thicker, somewhat "old-fashioned" skull that still included prominent brow ridges and a sloping forehead. He had large, projecting jaws, no chin, teeth that were larger than ours; he also had a bigger brain. *Homo erectus* was not only widespread in distribution, but also showed considerable regional variation. His success as a colonizer was attributable in large part to his intelligence, which was manifested in standardized but increasingly sophisticated toolkits, big-game hunting (almost certainly cooperative), the use of fire, and advanced housing. He lived during the Pleistocene, or glacial, epoch, and was probably stimulated to use his creative abilities by the deteriorating environments he sometimes encountered. Very late examples of *Homo erectus* are sometimes alternatively classified as *Homo sapiens*. Despite some continuing opposition, it is now usually accepted that *Homo erectus* gave rise to *Homo sapiens*.

Searching for the Fossil Remains

Considering the efforts that have been made to find them, hominid fossils are remarkably few. This is the case for three main reasons: First, the early hominids (unlike modern humans) did not exist in huge numbers; second, the majority of their bones were not preserved as fossils; and third, it is certain that only a small proportion of the hominid fossils that do exist have been found.

The hominid line evolved in Africa, and its earlier members (including the australopithecines and *Homo habilis*) have been found only there. *Homo erectus* was both more widespread and more numerous, but none of these types practiced ritual burials (Neanderthals were the first to do that), so the most usual agent of presentation was some sort of nonhuman carnivore. Predators, such as the large cats, might actually have hunted the early hominids; in any case, they certainly scavenged hominid carcasses. Hyenas and other cleanup animals then grabbed what they could, taking the leftover pieces to their dens in limestone caves. (There must be some truth to this scenario, because leopards and hyenas have left their toothmarks on australopithecine bones.) The gnawed bones, now thoroughly disarticulated, were scattered about the cave—and eventually solidified by limy deposits into a bone breccia.

When twentieth century investigators find such embedded hominid bones, or suspect their presence, they collect chunks of the breccia and dissolve the limy matrix with acetic acid, a procedure that does no harm to fossil bones. It is unlikely that any of the latter will be whole. Once the fragmented bones have been freed from the matrix, they are cleaned, preserved, sorted by type, and tallied. Whether big or small, routine or not, each must be identified. By far the great majority of the bones will belong to antelope of various kinds; less than one in a thousand, normally, proves to be hominid.

Such procedures are standard when dealing with cave deposits at the famous South African australopithecine sites of Sterkfontein, Kromdraai, and Swartkrans, all of which are adjacent to each other and to Pretoria. At Olduvai Gorge in Tanzania, where the Leakeys and others have found both australopithecine and *Homo habilis* remains, the geology is entirely different. Here, the

erosive power of a now-defunct river has exposed primarily volcanic sediments that once bordered a shifting saline lake. The disadvantage of this site is that it lacked any obvious place for the location of bones; years of determined effort were required to locate productive sites. The advantages of the site were that the presence of early humans was virtually assured because stone tools were scattered about plentifully (whole campsites were eventually found); the bones involved had not been dragged about and disarticulated by animals; and the involved stratigraphy made fairly precise dating at least theoretically possible. In general, a specimen from Olduvai Gorge brings with it more useful information than does one found in the South African caves. Still other sites have provided additional unique information.

The collection, preservation, and interpretation of hominid fossil bones is very much a multidisciplinary effort. In particular, detailed geological understanding of the site is essential. Only through stratigraphical analysis, usually, can the age and situation of the discovered fossil be understood. Stratigraphy aside, certain rocks can also be dated according to the radioactive elements they contain. More often, bones can be dated approximately because they occur in association with a particular assemblage of animal bones, the animal species themselves being of reliable short-term ages. In some cases, pollen samples have been of use. All this additional information, together with comparative anatomical analysis, helps to give hominid fossils a defensible identity.

Homo sapiens Facts

Classification:
Kingdom: Animalia
Subkingdom: Metazoa
Phylum: Chordata
Subphylum: Vertebrata
Superclass: Tetrapoda
Class: Mammalia
Subclass: Theria
Infraclass: Eutheria
Order: Primates
Suborder: Anthropoidea
Superfamily: Hominoidea
Family: Hominidae
Genus and species: Homo sapiens
Geographical location: Originally Africa, now spread to all continents
Habitat: Originally savannas, now spread to all habitats
Gestational period: Nine months
Life span: Originally a maximum of twenty-five years; now over one hundred years, with averages from forty to eighty years, depending on habitat
Special anatomy: Large, well-developed brain; upright, bipedal posture; opposable thumbs; larynx, vocal chords, and tongue adapted to produce a wide variety of sounds for language

The Search for Ancestors and Origins

Thinking human beings have always been fascinated with the concept of origins, and of all origins, none has been of more interest than that of humans. Human groups have asserted deeply meaningful identities by attributing their present being to a particular origin. Most of these psychologically necessary genealogies relied upon some divine agency to explain human existence. From a surprisingly early time, however, civilized humans (such as the Greeks) recognized that there had been a time when humankind did not know the use of metals. Subsequently, many thinkers took the concept of cultural evolution for granted.

By the seventeenth century C.E., anatomy had become a popular field of study. Comparisons soon established how like human anatomy that of the higher primates was. By the mid-eighteenth century, Carolus Linnaeus, the originator of modern biological classification, even ventured to place man and the apes within the same family. Yet this classification did not imply any necessary common ancestry. Linneaus and others of his time created the notion that individual species arose through a special, divine plan. The idea of special creation lost credibility when the fact of extinction became established at the end of the eighteenth century and as the diversity of species and varieties came increasingly to be appreciated. Nature, moreover, was no longer seen to be a benign reflection of its creator. As opinions of a distinctly human nature likewise declined, the realization that humans are animals encountered lessening resistance.

Before human evolution was generally accepted during the twentieth century, the evolution of cultures, language, law, institutions, and at least some animals had already been established. Though the idea was there, reliable evidence for the biological evolution of humans remained elusive. Before 1891, the only known prehistoric human bones belonged to Neanderthals; they were quickly and effectively dismissed as pathological freaks. Since Raymond Dart's Taung child of 1924 was likewise dismissed with ridicule, only a few specimens of what would later be recognized as *Homo erectus* (Java man and Peking man) survived to satisfy the now fashionable quest for a "missing link." (There are still innumerable missing links, but the essential connection between ancestral apes and man was confirmed by the discovery of australopithecines.) It was Robert Broom who, during the 1930's, established the reality of the australopithecines and, by implication, of human evolution.

Though the evolution of the hominid line is certainly a worthwhile scientific topic, it has always been regarded as much more than that, because the claims to ancestry define humanity. Yet the formal constraints of science are limited. In a remarkable series of thirty-nine papers (published between 1949 and 1965), for example, Raymond Dart promulgated an interpretation of the australopithecines as aggressive, predatory, and cannibalistic hunters. Because of the recurrent wars in which civilization had engaged during this period and shortly before, this image of human (or almost human) nature appealed to the popular imagination—so much so that less technical restatements of the same views by Robert Ardrey were not only commercially successful but also politically influential. Interpretations of australopithecine and early hominid behavior have subsequently changed, however—many now see these species as abject scavengers disputing the possession of already picked-over animal corpses with hyenas. It is arguable whether such changing interpretations are attributable to scientific advances or are the result of changing philosophical views of humanity.

Bibliography

Brain, C. K. *The Hunters or the Hunted? An Introduction to African Cave Taphonomy*. Chicago: University of Chicago Press, 1981. In a sophisticated but readable style, Brain reports the evidence about the australopithecines—what they hunted and what hunted them. (Taphonomy is the study of entire bone assemblages.) His study is intended primarily for graduate students and professionals in the field.

Campbell, Bernard. *Humankind Emerging*. 8th ed. Boston: Allyn & Bacon, 2000. A readable college-level text that is useful for its treatments of historical, biological, and anthropological topics. No other book presents so much information so well. Graphics and other illustrations are excellent. Campbell also includes topical bibliographies and a glossary. Chapters 7 through 10 are especially relevant.

Day, Michael H. *Guide to Fossil Man*. 4th ed. Chicago: University of Chicago Press, 1986. Despite some abstruse language (a glossary is included), this authoritative compilation can be of significant help. Organized geographically, it lists and often illustrates all known hominid fossils. Conflicting interpretations are reported but seldom reconciled. This is not, therefore, a book for those seeking the fast answer. Bibliographies accompany each section of the text. For college-level students and professionals, this is a standard work.

Johanson, Donald, and Maitland A. Edey. *Lucy: The Beginnings of Humankind*. Reprint. New York: Simon & Schuster, 1990. Intended for a broad audience, this popular account re-creates the excitement and explains the significance of the finding of an extraordinary specimen, known technically as *Australopithecus afarensis*. It is the oldest hominid whole skeleton extant.

Johanson, Donald, Lenora Johanson, and Blake Edgar. *Ancestors: In Search of Human Origins*. New York: Villard Books, 1994. A companion to the three-part *Nova* television series. Chronological coverage of *Australopithecus*, *Homo habilis*, *Homo erectus*, archaic *Homo sapiens*, the Neanderthals, and *Homo sapiens*. Focuses on the australopithecines and early *Homo*. Lavishly illustrated.

Jordan, Paul. *Neanderthal: Neanderthal Man and the Story of Human Origins*. Stroud, U.K.: Sutton, 1999. A clear exposition of a complex subject, highlighting the ideas involved in the study of human evolution and the relationship of Neanderthal Man to *Homo sapiens*.

Kurten, Bjorn. *Our Earliest Ancestors*. Translated by Erik J. Friss. New York: Columbia University Press, 1993. A succinct overview of hominid evolution. Focuses on the major changes in anatomy and culture that have marked the development of hominids from *Homo habilis* through *Homo sapiens*, including the emergence of bipedalism, stone toolmaking, and articulate speech. Numerous maps, charts, and drawings.

Leakey, Maeve, et al. "New Hominin Genus from Eastern Africa Shows Diverse Middle Pliocene Lineages." *Nature* 410 (March 22, 2001): 433-440. A new skeleton, dated to 3.5 million years ago and differing from the roughly contemporary *Autralopithecus afarensis*, throws the lineage of modern man into even further confusion.

Lewin, Roger. *Bones of Contention: Controversies in the Search for Human Origins*. New York: Simon & Schuster, 1987. This lucid but sophisticated treatment reviews scholarly debates regarding the Taung child (*Australopithecus africanus*), *Ramapithecus* (a fossil ape) and "Lucy" (*Australopithecus afarensis*). Too specialized for most high school students, it will appeal primarily to college graduates and professionals. Lewin has also written *Human Evolution: An Illustrated Introduction* (1984) and coauthored three popular books with Richard Leakey: *Origins* (1977), *People of the Lake* (1979), and *The Making of Mankind* (1981).

Mellars, Paul, ed. *The Emergence of Modern Humans: An Archaeological Perspective*. Ithaca, N.Y.: Cornell University Press, 1990. A volume of proceedings from a 1987 conference on the origins of modern humans and the adaptations of hominids. Concentrates on the archaeology of hominids in western and central Europe.

Reader, John. *Missing Links: The Hunt for Earliest Man*. Boston: Little, Brown, 1981. Organized chronologically, chapters cover the discoveries of the major hominids. Outstanding original photographs by the author are featured. Though other treatments have been more detailed (and more technical), Reader's agreeable combination of history and science makes his book irresistible. For readers at all levels.

Szalay, Frederick S., and Eric Delson. *Evolutionary History of the Primates*. New York: Academic Press, 1979. Though not intended for beginners, and now somewhat dated in places, this remains a standard reference.

Tattersall, Ian. *The Fossil Trail: How We Know What We Think We Know About Human Evolution*. New York: Oxford University Press, 1995. The reconstruction of human evolution on the basis of interpreting fossil remains, including the Laetoli footprints, Lucy, Turkana Boy, and others. Good coverage of the development of dating techniques such as fluorine analysis and mitochondrial DNA.

Theunissen, Berg. *Eugène Dubois and the Ape-Man from Java: The History of the First "Missing Link" and Its Discoverer*. Boston: Kluwer Academic, 1989. Java man, discovered by Dubois in 1891 (with one important discovery the previous year), was the first example of *Homo erectus* to be recovered. Theunissen's account of this historic addition to our knowledge of early man is detailed but nontechnical, suitable for readers at the high school level and beyond.

HOMO SAPIENS AND HUMAN DIVERSIFICATION

Type of animal science: Anthropology
Fields of study: Anthropology, evolutionary science, ecology, genetics, human origins, systematics (taxonomy)

By studying fossil, cultural, and genetic evidence, scholars have attempted to trace the evolutionary development of the human species. It is believed that the earliest form of Homo sapiens *appeared about 350,000 years ago and that the first modern humans (*Homo sapiens sapiens*) appeared somewhat before 100,000 years ago, with racial diversification following thereafter.*

Principal Terms

GENE POOL: the total collection of genes available to a species

GENERALIZED: not specifically adapted to any given environment; used to describe one group of Neanderthal humans

HOMINID: any living or fossil member of the taxonomic family Hominidae ("of man") possessing a human form

HOMINOID: referring to members of the family Hominidae and Pongidae (apes) and to the taxonomic superfamily of Hominoidae

MORPHOLOGY: the scientific study of body shape, form, and composition

NATURAL SELECTION: any environmental force that promotes reproduction of particular members of the population that carry certain genes at the expense of other members

PLEISTOCENE EPOCH: the sixth of the geologic epochs of the Cenozoic era; it began about three million years ago and ended about ten thousand years ago

WÜRM GLACIATION: the fourth and last European glacial period, extending from about seventy-five thousand years ago to twenty-five thousand years ago

All human beings on the earth today are highly adaptive animals of the genus and species *Homo sapiens sapiens* (Latin for "wise, wise human"). In terms of physical structure and physiological function, *Homo sapiens sapiens*—modern humans—are classified taxonomically as members of the order Primates, which is part of the class Mammalia. Since humans and other members of Primates (monkeys and apes) are biologically related, scientists presume both groups to be the products of an evolutionary process similar to that which affected other divergent categories of animals. The evolutionary process that produced *Homo sapiens sapiens* from previously existing species is also believed to account for diversifications within the modern human population such as racial differentiation.

Modern humans and modern apes (the two most closely related of modern primate species) are believed to possess a common biological ancestry, or line, that diverged perhaps five or six million years ago. The scanty fossil record of this early period, in conjunction with modern genetic studies, seems to indicate that the branch of hominoid evolution which eventually led to *Homo sapiens sapiens* first gave rise to the earliest hominid type, called *Ramapithecus*.

Next to appear, several million years ago, during the late Pliocene epoch, were the early forms of *Australopithecus*, which existed in Africa. They share certain characteristics with both humans and apes. Their brains are larger than those of apes but smaller than those of humans. There have been four species of *Australopithecus* identified.

The Emergence of the Genus *Homo*

Examples of the first undisputed members of the genus *Homo*—true human (though not *sapiens*)—appear in the fossil record about 1.5 million years ago. Samples of *Homo erectus* ("upright human") have been found in China, Africa, Java, and Europe. This creature habitually walked upright, made shelters, and used sophisticated tools. *Homo erectus* is also very important, since it is the first hominid to have used fire purposefully. It was suggested by John E. Pfeiffer, in a 1971 article entitled "When *Homo erectus* Tamed Fire, He Tamed Himself," that this first domestication of a natural force was a tremendous evolutionary step, changing the fundamental rhythms of life and human adaptability to environments. Most scholars accept the premise that *Homo erectus* was the hominid grade intermediate between the australopithecines and *Homo sapiens*.

Exactly when, where, and how advanced members of the species *Homo erectus* evolved into *Homo sapiens* are key questions in the study of human evolution, and they are questions that resist resolution. It might be thought that the closer one comes, in terms of time, to modern man, the easier it would be to find the answers. In actuality, such is not the case. The ancestral line or lines leading to modern man become hazy beginning approximately 500,000 years ago. Direct fossil evidence of the earliest members of the species *Homo sapiens* is scarce; moreover, finds of modern human fossils in the Middle East have intensified the debate about the immediate ancestry of *Homo sapiens sapiens*. All the evidence indicates, however, that the middle to upper Pleistocene epoch (beginning about 350,000 years ago), known as the Paleolithic or old stone age in archaeological terms, witnessed the emergence of early *Homo sapiens*.

The Earliest *Homo Sapiens*

In 1965, hominid fossil remains were found at a site named Vértesszöllös, near Budapest. They consisted of some teeth and an occipital bone (a bone at the back of the skull). The site also yielded stone tools and signs of the use of fire. Several features of the find recall *Homo erectus*, but the estimated cranial capacity of 1,400 cubic centimeters is well into the normal range for *Homo sapiens*. The age of the site was established at 350,000 years B.P. (before the present). These remains have been attributed to a *sapiens-erectus* intermediate type on the grounds that the remains, and the site, show a mixture of elements reflective of the transitional hominid evolutionary process. Such an assessment places Vértesszöllös man at the root of the *Homo sapiens* evolutionary line, some 100,000 years earlier than other specimens.

A better-known example of early *Homo sapiens* comes from a gravel deposit at Swanscombe near London, England. In 1935, 1936, and 1955, three related skull pieces were unearthed that fit together perfectly to form the back of a cranial vault with an advanced (over *Homo erectus*) cranial capacity of about 1,300 cubic centimeters. This has been dated to around 275,000 to 250,000 years B.P. A more complete skull of approximately the same age (dated to the Mindel-Riss interglacial period about 250,000 years B.P.) was found at Steinheim, in southern Germany, in 1933. Swanscombe's and Steinheim's advanced morphological characteristics, in combination with relatively primitive ones, such as low braincase heights, suggest that they are primitive members of the species *sapiens* and are representatives of a population intermediate between *Homo erectus* and *Homo sapiens*.

The finds at Swanscombe and Steinheim have been augmented by others from France and Italy, and especially from the Omo River region in southern Ethiopia. One Omo skull displays more mixed features (between *erectus* and *sapiens*) including flattened frontal and occipital areas, a thick but rounded vault, large mastoid processes (pointed bony processes, or projections, at the base of the skull behind the ears), and a high cranial capacity. Another skull is more fully *sapiens*, or modern in appearance. Some paleoanthropologists assert that the Omo group of fossils also helps bridge the gap between advanced *Homo erectus* and *Homo sapiens*.

Neanderthal Man

The best-known examples of early *Homo sapiens* come from a group of fossils known collectively as Neanderthal man. Their name derives from the place where the first fossil type was discovered in 1865, the Neander Valley near Düsseldorf, Germany. Similar Neanderthal fossil types have been found at more than forty sites in France, Italy, Belgium, Greece, the Czech Republic Slovakia, the former Soviet Union, North Africa, and the Middle East.

Neanderthal fossils tend to show an aggregate of distinctive characteristics that at one time led to their being regarded as a separate human species, *Homo neanderthalensis*. They are generally regarded as a subspecies of humans, with the designation *Homo sapiens neanderthalensis*. The characteristic features of their morphology include large heads with prominent supraorbital tori (thick brow ridges), receding jaws, stout and often curved bones, and large joints.

Most important Neanderthal fossils disclose large brain capacities (1,500 cubic centimeters) and are found in sites revealing complex and sophisticated cultures. These two facts clearly separate Neanderthal humans from more primitive "presapiens" species that exhibit some of the same morphological features. Neanderthalers generally stood fully erect between 1.5 and 1.6 meters in height; they were not the stoop-shouldered brutes of early characterizations. They lived during the last glaciation (the Würm glacial stage) in Eurasia. The sites from which most examples of the Neanderthalers have been recovered have commonly yielded tools of the Mousterian complex, a stone-tool industry named for the kind found at Le Moustier, France, and dating from about 90,000 to about 40,000 years B.P.

In fact two groups of Neanderthal humans seem to have existed. The first are referred to as classic Neanderthalers from such sites as Germany, France, Italy, Iraq (Shanidar man), and the former Soviet Union. The second group, known as either generalized or progressive Neanderthalers, lived contemporaneously with, as well as later than, classic Neanderthal humans. They display a combination of modern *sapiens* features and typical Neanderthal characteristics (especially the prominent supraorbital torus, the forehead ridge). Included in this category for the sake of simplification are those specimens termed neanderthaloid. Examples include Rhodesian man (from Zambia, formerly Northern Rhodesia) and Solo man (from Java), both unearthed at upper Pleistocene deposits (100,000 to 10,000 B.P.). Neanderthalers were cave dwellers and were well adapted to cold conditions (especially the classic Neanderthal variety). They used fire, manufactured stone flake tools, and buried their dead with care. They also seem to have practiced fairly complex religious rituals.

Cro-Magnon Man

Neanderthals were a successful group for many thousands of years, flourishing from about 127,000 B.P. to 37,000 B.P., with a wide distribution geographically. Neanderthal traces suddenly and mysteriously disappear from the fossil record, however, and they seem to have been superseded around 37,000 B.P. by other *Homo sapiens* with a more advanced culture and different morphology. In Europe, these are known as the Cro-Magnon peoples, so named for the Cro-Magnon cave near Les Eyzies in southwestern France, where the first skeletons were found in 1868 and where more than one hundred skeletons have since been discovered. Indeed, Cro-Magnon skeletal anatomy is virtually the same as that of modern European and North African populations. The skull is relatively elongated, with a large cranial capacity of about 1,600 cubic centimeters; the brow ridges are only slightly projecting. The average height of Cro-Magnon man was between 1.75 and 1.8 meters.

Cro-Magnon humans produced a culture that, in variety and elegance, far exceeded anything created by their predecessors. They made weapons and tools of bone and stone, stitched hides for clothing, and lived in freestanding shelters as well as caves. Some Cro-Magnon people produced beautiful cave paintings (they have been found in southwestern France and northern Spain) and bone carvings, and they modeled in clay. Though Cro-Magnon samples are the best-known examples of early *Homo sapiens sapiens*, mounting fossil evidence from sites outside Europe as well as genetic research performed in the 1980's suggests a much older date of origin for the emergence of modern man.

At Qafzeh, a cave near Nazareth, Israel, anatomically modern fossils classified as *Homo sapiens sapiens* were discovered in 1988 and reliably dated to 92,000 years B.P. In addition, newer fossil finds of progressive Neanderthalers from Kebara Cave in Israel, taken together with earlier Neanderthal finds from the caves of et-Tabun and es-Skhul, also in Israel, make it certain that progressive Neanderthalers and modern humans coexisted for many thousands of years.

Anthropologists have puzzled over the disappearance of the Neanderthals and, more important, over where they fit in the human family tree. It appears unlikely that classic Neanderthal humans were in the direct ancestral line of modern *Homo sapiens sapiens*. Reasons for their sudden disappearance are believed to include a combination of factors: extinction because of disease, lack of adaptation to the warmer climate following glaciation, and annihilation by the more advanced sapient groups.

Many scholars have considered the classic Neanderthals to be a cold-adapted, specialized side branch from the modern human line that became extinct as the climate became warmer. The generalized or progressive Neanderthals are considered by some to have avoided this specialization, perhaps continuing to exist through adaptation and ultimately being absorbed by flourishing modern human populations during the late Pleistocene epoch.

The Emergence of Modern Humans

Although the exact time place, and mode of the origin of the modern human species cannot yet be determined, genetic studies point to a date before 100,000 years B.P. Examination of mitochondrial DNA (mtDNA) from a sampling of present-day humans representing five broad geographic regions has allowed researchers to propose a genetic family tree and calculate roughly (assuming a fairly constant mutation rate) a temporal origin for the modern human population. Further studies seem to indicate that the modern human ancestral line emerged between 280,000 years and 140,000 years B.P. Genetic evidence, in concert with fossil finds, makes it plausible that a common ancestral population for *Homo sapiens sapiens* appeared in sub-Saharan Africa or the Levant (in the eastern Mediterranean region). Regional differentiation occurred, followed by radiation outward to other areas. The range of genetic and anatomical variability exhibited by fossil remains of modern humans is no greater than that known for the extant races of modern times.

During the late Pleistocene epoch (approximately 40,000 to 11,000 years B.P.) five different racial groups seem to have developed on the Eurasian and African landmasses. The last glaciation, approximately 30,000 to 10,000 years B.P., absorbed enough water to lower the oceans ninety meters below present levels. Emerging land bridges allowed people to move from Asia into North America, Australia, and elsewhere. In time the major racial groups became subdivided into smaller ones that resulted in the major races seen in modern times.

This view of racial diversification emphasizes the effectiveness both of geographic barriers in reducing free gene flow among varied groups of *Homo sapiens* and of environmental pressure in selecting different adaptive responses from the gene pool. These are also key factors in the entire evolutionary process by which modern humans developed over epochs into their present taxonomic position in the animal kingdom.

The Study of Paleoanthroplogy and Physical Anthropology

The study of human evolution is primarily the concern of the physical anthropologist and the paleoanthropologist. Evolution may be defined as change in the genetic composition of a population through time. Because evolution is thought to operate according to several principles and factors, modern human evolutionary theory is studied in the light of ideas and practices taken from different disciplines, including archaeology, biochemistry, biology, cultural anthropology, ecology, genetics, paleontology, and physics.

Early investigations into human evolution sought to establish the sequence of the human ancestral line through chronological and morphological analyses of hominid fossil remains (bones and teeth), thus placing them in their proper phylogenetic context (their natural evolutionary ordering). This remains the principal method of study, but it has been augmented by sophisticated techniques in fossil dating and new avenues of exploration into the evolutionary process, such as genetic research.

Image Not Available

Determination of the accurate age of a fossil is most important, since it sets the fossil in a correct stratigraphic context that allows comparison with remains from the same geologic layer or level a great distance away. Accurate dating also has helped determine the order of succession for fossils that could not be established on morphological grounds alone.

The most valuable absolute dating methods are the radioactive carbon technique, which can effectively date specimens between 60,000 years B.P. and the present; the potassium-argon technique, which most easily dates material older than 350,000 years B.P.; and the fission-track method, which helps bridge the gaps between other methods. These methods are based on the constant or absolute rates at which radioactive isotopes of carbon, potassium, and argon decay. When absolute dating is impossible, investigators have ascribed a relative age to fossil remains by noting the contents of the layer of rock or the deposit in which the remains were found. A layer containing remains of extinct animals is likely to be older than one containing remains of present forms.

In conjunction with dating, anatomical studies of fossil remains and comparisons with the morphological features of known hominid types, as well as comparisons to primate skeletal structures, have been primary approaches to the study of the evolutionary path of *Homo sapiens*. The species *Homo sapiens* (of which the modern human races compose a number of geographical varieties) may be defined in terms of the anatomical characteristics shared by its members. In general, these include a mean cranial capacity of about 1,400 cubic centimeters, an approximately vertical forehead, a rounded occipital (back) part of the skull, jaws and teeth of reduced size, and limb bones adapted to fully erect posture and bipedalism. Scientists assume that any skeletal remains which conform to this pattern and cannot be classified in other groups of higher primates must belong to *Homo sapiens*.

It is striking that the anatomical differences observed between *Homo erectus* and *Homo sapiens* have been confined to the skull and teeth. The limb bones thus far discovered for both are similar (though *erectus* appears more robust). Cranial capacity and morphology continue to be the dominant determining boundary separating sapient and presapient human species.

The Contribution of Other Sciences and Social Sciences

Human adaptability studies, using techniques from physiology, demographics, and population genetics, investigate all the biological characteristics of a population that are caused by such environmental stresses as altitude, temperature, and nutrition. It is believed that these normal stresses acted as genetic selectors in prehistoric times and continue to do so. Such racial variants as skin color and body hair are observable products of these stresses. The investigation of climatic changes during prehistoric epochs as revealed in the geologic record is important for understanding those pressures affecting the evolutionary history of man.

Genetic studies have become indispensable to the study of human evolution. Four forces have been identified as fundamental in the evolutionary process: mutation, natural selection, gene flow, and genetic drift. Since mtDNA is inherited through the female, it is possible to calculate how much time has elapsed since the mutations that gave rise to present variations originated in prehistoric populations.

Also important to the study of the evolution of *Homo sapiens* is the examination and classification of cultural remains preserved at hominid fossil sites. Not only can the relative date of a fossil be supported, but sometimes it is also possible to reconstruct the environmental situation that may have influenced the evolutionary process operating in a population. Cultural response is an integral part of hominid adaptation, and it in turn influences natural selection. Technology changes the physical and economic environment, and economic changes alter the demographic situation. Humans continue to promote or influence their own evolution by willingly or unwillingly altering the environment to which they must adapt.

The modern methods useful for investigating the evolutionary history of *Homo sapiens* are multidisciplinary. While each of them reveals an aspect of the emergence of modern man and complements the other methods of study, emphasis is placed on careful fieldwork, accurate dating, and comparative morphological analyses of hominid fossil remains. Increasing in importance, however, is the accumulating wealth of genetic data on human population relationships.

Human Evolution in the Context of Animal Evolution

Increasing attention is being given to the biological and behavioral changes that led to the emergence of *Homo sapiens sapiens*—the last major event in human evolution. Mounting evidence continues to push backward in time the point at which modern *Homo sapiens* made his appearance in the evolutionary scheme. The finds at Qafzeh, for example, indicated that modern man arose fifty thousand years earlier than had previously been thought. A clearer understanding of the evolutionary history of modern *Homo sapiens* has not only helped to define the place of the modern human species more accurately in relation to the rest of the animal kingdom but also helped to illuminate the pressures, adaptations, and changes that have made humans what they are.

The accumulating data on the evolutionary appearance of *Homo sapiens* have allowed biologists and anthropologists to see the rise of modern man as part of the evolutionary development of the animal kingdom in general and of primates in particular. The primates that exist today make up a remarkable gradational series that links *Homo* *sapiens sapiens* with small mammals of very primitive types.

Through the pressures and process of evolution (including adaptation and natural selection), *Homo sapiens* has become one of the most successful and adaptive animals that ever lived, because he came to possess an elaborate culture (culture is based on learned behavior). The key is *Homo sapiens*' superior mental capacity. Only human beings can assign arbitrary descriptions to objects, concepts, and feelings and can then communicate them unambiguously to others. In the late Middle Pleistocene, the hominid branch that gave rise to early *Homo sapiens* witnessed an increase in brain size, complex social organizations, continual use of fire, and perhaps even language. As to what initiated these changes, many have suggested tool use and, in turn, a hunting economy.

In a classic article published in 1960, entitled "Tools and Human Evolution," Sherwood Washburn argued that the anatomical structure of modern man is the result of the change, in terms of natural selection, that came with the tool-using way of life. He stated that tools, hunting, fire, and an increasing brain evolved together. Washburn also argued that effective tool use led to effective bipedalism—another significant characteristic of *Homo sapiens:* Man is different from all other animals because he became a user of increasingly complex tools.

The other behavioral pattern that is seen to have been of utmost importance to sapient evolution is big-game hunting. Early *Homo sapiens* was undoubtedly a big-game hunter, as were all of his successors until approximately 8,000 years ago. It has been argued that human intellect, interests, emotions, and basic social life are the evolutionary products of the success of hunting adaptations. Success in hunting adaptation dominated the course of human evolution for hundreds of thousands of years. The agricultural revolution and the industrial and scientific revolutions are only now releasing human beings from conditions characteristic of 99 percent of their evolutionary history.

Scholars have suggested that research into human origins and development is much more relevant than is often realized. It has been argued that, although man no longer lives as a hunter, he is still physically a hunter-gatherer. Some investigators in the field of stress biology, the study of how the human body reacts to stressful situations, feel that man is biologically equipped for one mode of life (hunting) but lives another. Thus, there would be some link between an emotional reaction, such as explosive aggression, and human evolutionary history. Tools and more efficient hunting helped produce great change in hominid evolution and made man what he is. Humans continue to be users of increasingly complex tools, such as computers, and perhaps this continued development of technology may determine the future evolutionary path of *Homo sapiens*.

Brauer, Gunter, and Fred H. Smith, eds. *Continuity or Replacement: Controversies in "Homo Sapiens" Evolution*. Brookfield, Vt.: A. A. Balkema, 1992. A collection of technical papers from a 1988 international symposium on the biological and cultural evolution of hominids.

Cann, R. L., M. Stoneking, and C. A. Wilson. "Mitochondrial DNA and Human Evolution." *Nature* 325 (January 1, 1987): 31-36. Though written for the knowledgeable student of human evolution, this important article presents the results of a major study using DNA to trace genetic differences in widely varied samples of the present population and, by constructing an evolutionary family tree, to propose a time and place for the emergence of modern man. It shows the increasing importance of genetics for the study of the modern human evolution.

Eldredge, Niles, and Ian Tattersall. *The Myths of Human Evolution*. New York: Columbia University Press, 1982. In fewer than two hundred pages the authors give the nonspecialist a brief, comprehensive look at human evolutionary history, while attempting to show that the once-standard expectations of evolution—slow, steady, gradual progress—are not supported by the evidence. According to the authors, fossil evidence shows human evolution to be the result of long periods of stability interrupted by abrupt change, occurring in smaller populations. The thesis is an important consideration presented in well-written form.

Johanson, Donald, Lenora Johanson, and Blake Edgar. *Ancestors: In Search of Human Origins*. New York: Villard Books, 1994. A companion to the three-part *Nova* television series. Chronological coverage of *Australopithecus*, *Homo habilis*, *Homo erectus*, archaic *Homo sapiens*, the Neanderthals, and *Homo sapiens*. Focuses on the australopithecines and early *Homo*. Lavishly illustrated.

Leakey, Richard E. *The Making of Mankind*. New York: E. P. Dutton, 1981. This book, by the son of Louis and Mary Leakey, is written from the perspective of one who grew up with famous physical anthropologists and scientists who were tracing human origins. The text is complemented with many color photographs. Chapters discussing the development of language and early *Homo sapiens* culture are important. It also distills and synthesizes important ideas of others.

Lewin, Roger. *The Origin of Modern Humans*. New York: Scientific American Library, 1998. Overview of the key concepts in the origin of modern humans, including the molecular biology and archaeology supporting the out-of-Africa hypothesis versus the multiregional hypothesis of human evolution.

Mellars, Paul, ed. *The Emergence of Modern Humans: An Archaeological Perspective*. Ithaca, N.Y.: Cornell University Press, 1990. A volume of proceedings from a 1987 conference on the origins of modern humans and the adaptations of hominids. Concentrates on the archaeology of hominids in western and central Europe.

Phenice, Terrell W. *Hominid Fossils*. Dubuque, Iowa: Wm. C. Brown, 1973. One of the best introductory illustrated keys of hominid fossil remains of the Pleistocene epoch. The drawings are all oriented the same way, and each fossil illustration is listed with its measurements and with information concerning tools found at the respective sites. This book (and similar types of atlases) is very helpful to the nonspecialist.

Tattersall, Ian. *The Fossil Trail: How We Know What We Think We Know About Human Evolution*. New York: Oxford University Press, 1995. The reconstruction of human evolution on the basis of interpreting fossil remains, including the Laetoli footprints, Lucy, Turkana Boy, and others. Good coverage of the development of dating techniques such as fluorine analysis and mitochondrial DNA.

Waechter, John. *Man Before History*. Oxford, England: Elsevier-Phaidon, 1976. This is a concise, readily accessible volume on the evolutionary history of humans. It contains some of the finest visual and graphic representations (photographs and illustrations) on the subject found in any single work on the evolutionary journey of the human species. It also contains an extensive glossary of terms with numerous illustrations. Particularly strong in its discussion and representation of late prehistoric culture (especially art), it is an excellent reference work geared toward the nonspecialist.

HORMONES AND BEHAVIOR

Type of animal science: Physiology
Fields of study: Ethology, neurobiology

Hormones exert a tremendous influence on behavior by heightening perceptions, altering motivational levels, and controlling drives, including hunger, sex, and the urge to migrate.

Principal Terms

ABLATION: the technique of removing a gland to determine its function and observe what effects its removal will precipitate

ANDROGENS: masculinizing hormones, such as testosterone, responsible for male secondary (anatomical) sex characteristics and masculine behavior

BEHAVIOR: an animal's movements, choices, and interactions with other animals and its environment

BIOLOGICAL CLOCK: a timekeeping mechanism that is "endogenous" (a part of the animal) and capable of running independently of "exogenous" timers such as day-night cycles or seasons, although the clock is normally set by them

ENDOCRINE SYSTEM: a collection of glands that secrete their products into the bloodstream

ESTROGEN: a feminizing hormone responsible for female secondary (anatomical) sex characteristics and sex-related behaviors

PROLACTIN: a hormone responsible for secretions of milk from the mammary glands of mammals and from the crops of birds

RECEPTOR MOLECULE: a molecule on the cell membranes of target tissues that binds to the hormone molecule and initiates the action of the hormone

Behavioral differences are usually attributed to two causes: differences in experience (learning) and differences in heredity (genes). Hormonal interaction involving an organism, its experience, and the highly specific behaviors that result are well illustrated by Daniel Lehrman's 1964 study of the ring dove, a small relative of the domestic pigeon.

A male ring dove begins courtship by bowing and cooing to the female when they are placed together in a cage. Toward the end of the first day of courtship, the birds choose a location and start building a nest. The doves court, nest-build, and mate, and the female lays an egg about five o'clock in the afternoon on the seventh to eleventh day. A second egg is laid about nine o'clock the next morning. The male sets for about six hours at midday, and the female occupies the nest the rest of the time. After fourteen days of incubation, the eggs hatch, and the parents feed the squabs crop milk, secreted from the lining of the adult dove's crop (enlarged gullet). At about two weeks of age the squabs (fledgling birds) begin pecking at grain, and the adults feed them less and less. With feeding chores diminished, the male begins bowing and courting, the pair start nest-building, and the cycle repeats itself.

The Hormonal Triggers of Behavior

The simplicity of this description belies the hormonal ferment going on beneath the placid exterior. The courtship ritual causes the production and release of estrogen and progesterone, hormones responsible for setting behavior and for the development of the oviduct. The oviduct develops from eight hundred milligrams, when the doves are placed together, to four thousand milligrams, when the first egg is laid. Birds presented with nests already containing eggs when they are first paired will build nests on top of the eggs. Even if the eggs are returned to the top of the nest by the investigator, the doves will not set until they have engaged in nest-building for five to seven days. On the other hand, if the doves are first injected with progesterone, 90 percent will set within three hours after pairing. Courtship and nest-building play a vital role in creating the hormonal conditions necessary for setting behavior. Development of the crop is, in turn, initiated when setting begins. Setting behavior causes the release of prolactin, which stimulates crop development and feeding behaviors. Unpaired doves injected with prolactin will develop crop milk and will feed squabs when exposed to them even if they have not mated. While they will feed squabs, however, they will not sit on eggs, because they have not courted, engaged in nest-building, or developed the hormonal balance necessary to support setting behaviors.

This ring dove study indicates that the behavior of one individual can alter the behavior and the hormonal balance of another individual; that an individual's behavior can alter its own hormonal balance and, hence, its own behavior; and that inanimate aspects of the environment (nest and eggs, for example) can alter an individual's hormonal balance and, hence, its behavior. The interactions among these three factors are complex. For example, the male's behavior (courting) changes the female's behavior (nest-building), which changes her hormonal balance (estrogen and progesterone), which causes her to alter the external environment (lay eggs in the nest), which affects the pair's behavior (setting), which changes their hormonal balance (prolactin), which stimulates them to feed the squabs.

Fetal Hormones Affecting Adult Behavior

Hormones produced by developing organisms have marked effects on adult behaviors. In mammals, the fetal testis becomes active and produces testosterone, then becomes inactive before birth and remains so until puberty. The changes resulting from this brief surge of testosterone are remarkable. They include the anatomical features that distinguish male and female genitalia, changes in neural anatomy, and the sensitivity of nervous (and other) tissues to adult hormones.

Rat and mouse fetuses have several littermates, which develop side by side in a common uterus, like peas in a pod. Male mice that develop between two male embryos are more aggressive as adults than males developing between females. Similarly, females that develop between two male embryos are more aggressive as adults than females that develop between other females. In another study, females from litters that were predominantly male showed more masculine behavior (such as the mounting of other females) than females from predominantly female litters. The explanation is that testosterone produced by the male embryos' testes is absorbed into the bloodstream of sibling embryos, altering their nervous systems and hence their behaviors. In cattle, testosterone produced by a bull calf twin affects the development of his heifer twin to the extent that she is usually sterile.

Scientists have shown that pregnant rhesus monkeys treated with testosterone produced offspring that showed rougher play and more threat behavior than usual. Male rhesus monkeys experience a decrease in blood testosterone levels within six hours after losing a fight to another male and are more submissive. These studies indicate that hormones play an important role in determining male-female behavioral differences.

Many biological phenomena are repeated or change intensity over and over again throughout the life of an individual. Examples include sleep-wake cycles, menstrual cycles, and the migration cycles of birds; these are repeated approximately once a day, once a month, and once a year, respectively. The regularity of these cycles led biologists to propose a "biological clock." The golden-mantled ground squirrel avoids freezing temperatures by going into hibernation once a year. Even if these squirrels are kept in constant conditions of light and temperature to deprive them of seasonal cues, they will enter hibernation once a year. These and other data lead researchers to believe that the clock resides within the animal. Although it can be reset by environmental cues, it can also run independently of them.

Hormones, Seasons, and Mating Behavior

A white-crowned sparrow, nesting in central Alaska, experiences dramatic seasonal changes and migrates to the southern United States or Mexico (more than three thousand kilometers) to avoid freezing. Central Alaska's short summer demands that the sparrow fly north as early in the spring as is safe and that it be prepared for mating and rearing chicks when it arrives. During the winter, the gonads atrophy to 1 percent or less of their breeding season weight. The bird's ability to sense the approach of spring depends on its sensing the increase in daylight. During the short winter days, the sparrow is content to stay in Arizona or Mexico, but as day length increases to fourteen or fifteen hours, the bird's hypothalamus releases hormones that stimulate the pituitary to release prolactin and gonadotropic hormones. The gonads respond by increasing in size and producing additional hormones, which stimulate the bird to begin its long migration.

When the male white-crown arrives at his breeding grounds in central Alaska, he chooses a nesting territory, attacks any male territorial intruders, and attempts to attract a mate with his constant singing. Each female chooses a mate and helps him defend the nesting site. In the next few days she feeds to gain nutrients for egg production, and her estrogen levels rise rapidly, stimulating her to solicit mating. Once the eggs are laid, the gonads of both birds begin to atrophy, estrogen and testosterone levels decline, and prolactin levels increase and stimulate feeding of the young. As the gonads atrophy, the birds become less aggressive and the male stops singing.

As the young become independent, both parents enter a "sexual refractory period," during which the gonads will not respond to artificially increased day length as they would in the spring. The birds feed voraciously, increasing body fat, which serves as fuel for the long trip south. In the next year, by early spring, the birds will have passed through the refractory period and be primed to respond to the increasing day length with a fresh hormonal flurry which will set them off on the long journey north.

Recognizing the existence of a refractory period is important. It underscores the ideas that while birds do respond to environmental conditions (day length), there is a given set of events through which the physiological machinery passes and that specific time parameters are dictated by the biological clock. White-crowned sparrows can be expected to show hormonal changes and migratory restlessness during springtime even if they had been caged and maintained in constant conditions. It is to the bird's advantage, however, to experience and recognize the seasonal changes in day length, because biological clocks tend to run a bit fast or slow. The actual measuring of day lengths allows the bird to reset that clock and arrive in Alaska at the most advantageous time for rearing a family of sparrows.

Studies of a closely related bird, the white-throated sparrow, indicate that the changes of behavior and physiology are primarily the result of two hormones: corticosterone from the adrenal cortex and prolactin from the anterior pituitary. Both hormones have daily peaks of secretion, but the timing of these daily peaks (relative to each other) changes with the seasons. If injections of these hormones are given with timing differences characteristic of specific seasons, the physiological and behavioral changes seen in the birds are characteristic of the seasons that the injections mimic.

Experimental Endocrinology

The earliest report of experimental endocrinology, in the mid-nineteenth century, demonstrated that replacements of testicular tissue would maintain comb growth and sexual behavior in castrated roosters. Techniques for determining endocrine function used today include ablation and replacement.

Hormones trigger many kinds of animal behavior, including bird migration. (Digital Stock)

Ablation (removal) of endocrine tissue results in deficiency symptoms. The effects of ablation are not always unambiguous. If the testes and accessory tissues are not completely removed when a horse is castrated, for example, tissue capable of producing testosterone remains, and the consequence is an infertile gelding that behaves like a stallion.

Hormones produced by different glands can have similar physiological effects. Both the adrenal glands and the testes produce androgens (masculinizing hormones). Sexually experienced male cats do not lose their sex drive if castrated, and researchers do not have a satisfactory answer as to why this occurs. Perhaps the adrenal hormones are sufficient to maintain established feline male sexual behavior but not sufficient to initiate it in inexperienced cats. The ablation of the adrenal glands, however, has severe consequences in terms of electrolyte and blood glucose imbalances that are life threatening. Replacement of ablated endocrine tissue can reinstate normal function. If a male cat is castrated as a kitten, it will not develop normal male sexual behaviors. If, however, a normal testis is later transplanted to the abdominal cavity (or elsewhere), normal behavior will develop.

In the early 1960's, Janet Harker became convinced that the "biological clock" controlling the daily activity cycle of the cockroach was contained in the subesophageal ganglion, a patch of nervous tissue the size of a pin head resting just below the esophagus. When she ablated this ganglion, the cockroach became arrhythmic. Harker removed the legs from a normal roach and glued the roach on top of the arrhythmic roach, surgically uniting their body cavities so that the same body fluids circulated through both roaches. The arrhythmic roach ran about the cage with an activity rhythm dictated by the rhythm of hormones released into the body fluids by the legless roach on its back.

Most hormone and behavior studies involve nonhuman species and most involve sexual behaviors. Most behaviors are oriented toward perpetuating one's species. Only those individuals with behaviors conducive to rearing offspring will provide the genetic basis for behaviors represented in the next generation. It may seem that wild, unrestrained mating would be selected for, but that makes no real sense. Mate selection, shelter-seeking, feeding, maintenance of social position, and a host of other behaviors are critical to the success of one's progeny. Individuals that produce more offspring than they can feed or protect usually rear fewer than those who produce fewer to begin with. Many predator species (owls and wolves, for example) tend not to mate in years when prey is scarce. This ultimately maximizes reproduction by reserving energies that can best be spent later. This restraint is mediated by adjusting hormonal levels. Hormones have been called the ultimate arbiters of sexual behavior.

The Endocine System, the Nervous System, and Behavior

The nervous system is usually thought of as the mediator of behavior, but the endocrine system is also a major player. Arguing that one system is more important would be like deciding whether height, width, or depth is more important in describing a box. It is useful, however, to discuss their differences. The nervous system has a shorter response time. Nerve impulses travel at speeds of up to 120 meters per second. Hormonal effects are much slower but are less transitory. If frightened by a false alarm, an animal may jump and run as a direct consequence of nervous system activity, but even after it recognizes that there is no real threat, it will be "keyed-up." This is a consequence of hormonal activity: Fright triggered the release of epinephrine (adrenaline) and norepinephrine from the adrenal glands. These hormones cause increased cardiac output; increased blood supply to the brain, heart, and muscles; decreased blood flow to the digestive tract; dilation of airways to breath more efficiently; and a significant increase in metabolic rate.

This is called the "fight or flight reaction," and it will affect behavior for several minutes and possibly for hours. These hormones enhance perceptions and elevate the responsiveness of the nervous system. In the final analysis, the understanding of hormones, what determines their ebb and flow, how they are affected by the environment, how hormones interact with one another, and how their levels are controlled by genetic programs of the individual and of the species is essential for the understanding of behavior.

Bibliography

Adler, Norman T., ed. *Neuroendocrinology of Reproduction*. New York: Plenum, 1981. A chapter by E. Adkins-Regan, entitled "Early Organizational Effects of Hormones: An Evolutionary Perspective," presents a very comprehensive review of the developmental effects of hormones on behavior. It has broad taxonomic coverage, ranging from coelenterates to mammals.

Alcock, John. *Animal Behavior: An Evolutionary Approach*. 6th ed. Sunderland, Mass.: Sinauer Associates, 1998. This is a popular, well-written textbook covering the general area of animal behavior. Chapters 4 and 6 contain especially interesting and valuable material on hormones and sexual behavior.

Becker, Jill B., S. Marc Breedlove, and David Crews. *Behavioral Endocrinology*. Cambridge, Mass.: MIT Press, 1992. Introductory textbook for undergraduates, drawing on both vertebrate and invertebrate systems. Covers sexual, courtship, and parental behavior, aggression, stress response, ingestive behavior, and biological rhythms.

Crews, David, ed. *Psychobiology of Reproductive Behavior: An Evolutionary Perspective*. Englewood Cliffs, N.J.: Prentice-Hall, 1987. This book deals with the many facets of reproductive behavior—their proximate and ultimate causes. It has good material in several chapters about the effects of hormones on behavior.

Drickamer, L. C., and S. H. Vessey. *Animal Behavior: Concepts, Processes, and Methods*.4th ed. Boston: McGraw-Hill, 1996. Chapters on the nervous system and behavior and hormones and behavior will be of interest to anyone interested in the topic of hormones and behavior.

Nelson, Randy Joe. *An Introduction to Behavioral Endocrinology*. 2d ed. Baltimore: The Johns Hopkins University Press, 2000. A textbook for upper-level undergraduates and graduate students. Explores the evolution of the anatomy, physiology, and biochemistry of human and animal endocrine systems. Discusses sex differences, reproductive and parental behavior, biological rhythms, and the role of hormones in learning and memory.

Schulkin, Jay. *Neuroendocrine Regulation of Behavior*. New York: Cambridge University Press, 1999. Discusses the roles of steroids and neuropeptides in regulating behavior. Uses model animal systems to study the influence of hormones on the brain, and generalizes to other animals and humans. Aimed at upper-level undergraduate and graduate students, professors, and medical healthcare professionals.

Svare, Bruce B., ed. *Hormones and Aggressive Behavior*. New York: Plenum, 1983. A series of review articles pulling together much important work on the effects of hormones on aggressive behaviors to appear in the 1970's and 1980's.

HORMONES IN MAMMALS

Type of animal science: Physiology
Fields of study: Developmental biology, zoology

Mammals use chemical messengers called hormones for information transfer and control between different body regions. These molecules, produced and secreted from endocrine glands into the bloodstream for transport, play important roles in mammalian development from conception to death.

Principal Terms

ENDOCRINE SYSTEM: an array of ductless glands scattered throughout the mammalian body that produce and secrete hormones directly into the bloodstream

HOMEOBOX: a set of genes that encode proteins involved in development of a wide range of animal species, from nematodes to insects to mammals

HOMEOSTASIS: the maintenance of constant conditions within the internal environment of an organism, a process controlled by antagonistic hormone pairs

HYPOPHYSIS: the pituitary gland, or "master" gland, which produces and secretes at least eight protein hormones influencing growth, metabolism, and sexual development

HYPOTHALAMUS: a brain region just below the cerebrum that interconnects the nervous and endocrine systems of mammals, thereby controlling most hormone production and many body functions

NEUROTRANSMITTER: a signaling molecule that provides neuron-to-neuron communication in animal nervous systems; some double as hormones

PROTEIN HORMONE: a hormone type composed of protein, a long chain of amino acids encoded by a gene

STEROID HORMONE: a hormone type derived from cholesterol, a type of fat molecule

Mammals are vertebrate animals that have fur (hair) and that nourish their young with milk by means of mammary glands, which are modified sweat glands. Mammals include, among other animals, primates (such as humans and chimpanzees), cetaceans (such as whales and dolphins), and marsupials (such as kangaroos, koalas, and opossums). Mammals are sexually reproducing and diploid (having two copies of every chromosome). During fertilization, a sperm from the male parent unites with an egg from the female parent to produce a diploid single-celled zygote. The zygote contains all the genetic information for all the cells of the future individual. The zygote divides first into two cells, then four, eight, sixteen, thirty-two, and so on.

As the cells divide, they begin to specialize, so that different groups of cells assume unique functions. Some cells become nerve cells, others skin cells, and others blood cells. A number of factors, including hormones, contribute to differentiation.

Throughout the development of the organism, profound changes such as birth, puberty, menopause, aging, and death occur. Progressive changes in cell functions contribute to these sequential processes. Many of these developmental changes are controlled by hormones, chemical messengers that provide communication between cells located in different portions of the body via the bloodstream.

The Endocrine System

Hormones fall into the two principal categories of protein hormones and steroid hormones. Protein hormones are composed of protein—long chains of amino acids encoded by genes. Steroid hormones are derivatives of cholesterol. Both hormone types function in the same fashion: They control genes. Hormones are produced and secreted from a source endocrine gland and are then transported through the bloodstream to a target tissue, where they penetrate cells and concentrate on the control regions of genes located on chromosomes. Once at a control region, a given hormone either activates or inactivates the gene. If a gene is activated, messenger RNA will be produced, leading to protein production. If a hormone inactivates a gene, protein production will cease. A given hormone may activate certain genes and inactivate others.

Endocrine glands are ductless glands (glands that lack channels for secreting their products) that produce and secrete hormones into the bloodstream. Major mammalian endocrine glands include the hypothalamus, hypophysis, thyroid, parathyroids, thymus, pancreas, adrenals, and gonads. The hormones secreted from these glands influence many cells and each other during mammalian development.

Homeostasis, the maintenance of a constant internal environment, is a major objective of endocrine hormones. They work antagonistically (against each other) to maintain various body conditions (such as blood sugar and calcium levels) in equilibrium. Endocrine hormones work principally, but not exclusively, by negative feedback. For example, a region of the brain called the hypothalamus reacts to various body conditions by releasing hormones that stimulate the nearby hypophysis (the pituitary gland) to release certain of its hormones. The hypophyseal hormones direct other glands and tissues to respond in a particular fashion. Once bodily conditions are back to normal, the hypothalamus terminates its initial stimulatory hormones, thereby stopping the entire sequence of events.

The hypothalamus controls a number of critical body functions, including the activities of endocrine glands, body temperature, wake and sleep cycles, and appetite. Ultimately, all these functions involve some type of hormones. When various conditions occur in the body (for example, hyperthermia, which is increased body heat), genes in certain hypothalamic cells synthesize special proteins called releasing factors that are sent into the bloodstream to activate target cells in glands (in the example cited, sweat glands) located elsewhere in the body. Often, the target of hypothalamic releasing factors is a nearby endocrine gland called the hypophysis, also known as the pituitary, or "master gland."

Regulating the Reproductive Cycle

The eight hormones known to be released from the hypophysis gland are vasopressin (the "antidiuretic hormone"), oxytocin, prolactin, growth hormone, thyrotropin, adrenocorticotropic hormone (ACTH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH). Vasopressin is released in response to low water levels in the blood; it stimulates the kidneys to retain water, reduce urine output, and increase blood pressure until blood water levels return to normal, upon which it will no longer be produced. Oxytocin causes muscular contractions in the uterus during childbirth and in the breast for the secretion of milk for an infant. Prolactin is present in males and females, but it is functional only in females. It stimulates milk production from fat deposits in the breast. Growth hormone causes growth in children; it is present in adults, but contributes only to the control of metabolic rate. Thyrotropin stimulates the thyroid gland to produce and secrete various hormones that control metabolism (examples: thyroxine and triiodothyronine). Adrenocorticotropic hormone stimulates the adrenal cortex, located above each kidney, to release its metabolism-controlling steroid hormones. At puberty, follicle-stimulating hormone stimulates the female ovarian follicle to mature and begin producing the steroid hormone estrogen; it directs the male testes to begin producing sperm. Also at puberty, luteinizing hormone stimulates the ovary to begin producing eggs and the steroid hormone progesterone; it directs the testes to begin producing the steroid hormone testosterone.

The hypophyseal hormones, all proteins encoded by genes, have a major impact upon metabolism and development in mammals. This is especially true for the sexual-cycle hypophyseal hormones FSH and LH. In females, puberty begins with the first menstrual cycle. Each menstrual cycle is the female body's way of preparing for a possible pregnancy. At the beginning of the cycle, the hypophysis produces high concentrations of FSH, which stimulates the ovarian follicle to develop and produce estrogen, a steroid hormone that increases body fat in regions such as the buttocks and breasts. Simultaneously, increased LH production matures the egg in the ovarian follicle and stimulates progesterone production. Progesterone causes the endometrium (the lining of the uterus) to increase its blood vessel content and thickness for receiving and maintaining a fertilized egg and for the subsequent long gestation period (nine months in humans). If the egg is fertilized by sperm, it will adhere to the endometrium, and progesterone will continue to be secreted to maintain the endometrium and the pregnancy. If the egg is not fertilized, progesterone levels will drop, estrogen levels will rise, the endometrium will be sloughed away (menstrual bleeding will occur), and the cycle will start all over again.

The primate female menstrual cycle is only one very complex example of how hormones are intricately involved in mammalian developmental processes. There are many subtler aspects of the menstrual cycle that still are not well understood, such as the identity of the hormonal signal from the fertilized egg that stimulates the female ovary to continue progesterone production for continuation of the pregnancy. All mammalian hormones are interconnected by cause-and-effect relationships. Tremendous research remains before a clear and complete picture of hormonally controlled mammalian development will emerge.

Regulating Other Functions

The thyroid gland, located in the throat region, produces several hormones (examples: thyroxine and triiodothyronine) that elevate the body's metabolic rate. The thyroid also secretes a hormone called calcitonin, which works antagonistically with the hormone parathormone produced by the adjacent parathyroid glands. When blood calcium is high (as in a condition called hypercalcemia), the calcitonin gene in thyroid cells begins producing the protein hormone calcitonin, which stimulates bone cells called osteoblasts to build more bone, thereby removing calcium from the bloodstream. Once blood calcium levels are back to normal, calcitonin production halts. In hypercalcemia, the parathormone gene in parathyroid cells begins producing parathormone (also a protein hormone) that stimulates bone cells called osteoclasts to break down bone, thereby restoring blood calcium levels but possibly contributing to osteoporosis (bones that are brittle because of calcium deficiency) and other bone-related disorders. Parathormone production is stopped once blood calcium levels are back to normal.

The islets of Langerhans in the pancreas secrete two antagonistic protein hormones, insulin and glucagon. In response to high glucose levels in the blood (as in hyperglycemia), genes in beta cells produce and secrete insulin, which directs body cells, especially liver cells, to absorb glucose and store it as a polysaccharide called glycogen. Insulin production will stop once blood glucose levels are reduced to normal. An insulin deficiency leads to prolonged hyperglycemia, a serious and often fatal disorder called diabetes mellitus. When blood glucose levels are too low (as in hypoglycemia), genes in the alpha cells of the islets of Langerhans produce and secrete glucagon, which directs body cells to break down their glycogen reserves and begin releasing glucose back into the bloodstream until normal blood glucose levels are reached, upon which glucagon production ceases.

Further endocrine glands include the adrenal cortex, located on top of each kidney, which secretes three major classes of steroid hormones: the glucocorticoids such as cortisol, which controls fat and protein metabolism; the mineralocorticoids such as aldosterone, which controls blood sodium levels; and the androgens (male sex steroids). The adrenal medulla, located internally to the adrenal cortex, is derived from nervous tissue and secretes two hormones, epinephrine and norepinephrine, that double as excitatory neurotransmitters at nerve axon endings; chemical energy transmission between nerve cells occurs at synapses, or gaps, between adjacent neurons. Neurotransmitters are protein hormones that relay electrical impulses from one neuron (nerve cell) to another throughout the trillion-cell nervous systems of mammals. Other neurotransmitters include the excitatory acetylcholine and inhibitors glycine, enkephalin, and gamma-aminobutyric acid.

The kidney secretes the protein hormone erythropoietin when the blood has a low red blood cell level; erythropoietin stimulates the undifferentiated stem cells called hemocytoblasts in the red bone marrow of flat bones (ribs, sternum) to differentiate and develop into mature red blood cells. Platelet-derived growth factor (PDGF) is released from damaged blood vessels to activate platelet cells to begin blood clotting. Macrophage colony stimulatory factor and eosinophil chemotactic factor are two hormones that both activate and attract certain respective immune system cells to the site of an infection or allergic reaction. Histamine is released from damaged tissue and causes blood vessel dilation, so that the vessels are more leaky, thus allowing hormones and other molecules to reach the injury site, eventually leading to the inflammation and itching associated with wound healing.

The hormone prostaglandin helps inflammation and contracts some smooth muscles located throughout the body; nerve growth factor stimulates the growth of sensory nerves throughout the body; and epidermal growth factor stimulates the growth of the epidermis, the outermost skin layer that is constantly being shed and replaced. Sunlight exposure to skin produces cholecalciferol, or vitamin D, which helps to stimulate bone growth and maintenance.

The hormone prolactin is responsible for stimulating milk production in mammals. (PhotoDisc)

Developing the Full Hormonal Picture

The tally of mammalian hormones extends well beyond the molecules just discussed. What is most puzzling is how the many hormones are interconnected during the control of development. Hormones control gene activities of target cells, and some simple hormone systems act antagonistically (calcitonin-parathormone, insulin-glucagon). Yet there has not emerged a clear and complete picture of the overall interactions. Hormones control an incredibly complex array of cellular activities from conception to death.

Mammalian developmental hormones have been studied using a variety of biochemical and physiological experiments: isolation and purification experiments, injection into experimental animals, studies of metabolic disorders in animals, and molecular genetics experiments. Protein structures based upon genetic and biochemical studies are well understood. Steroid hormone structures have been unraveled from studies of cholesterol biochemistry.

Dissections of experimental animals yield intact endocrine glands (such as the thyroid and pancreas) that can be used to show function. Chemical secretions from these glands can be extracted and separated into the various hormone components by several biochemical techniques such as electrophoresis, chromatography, and centrifugation. The isolated hormones can be further purified by rerunning them through these separatory techniques.

Electrophoresis involves the separation of molecules in an electric field based upon their sizes and charges. Large molecules move slowly, whereas small, compact molecules move more quickly. Protein hormones move from the negative pole to the positive pole in electrophoretic gels. Affinity chromatography involves placing membrane hormone receptor proteins on a vertical column containing a porous resin. The specific hormone type that binds to this particular target receptor protein will stick to the resin. Nonbinding hormones will wash through the column. Finally, ultracentrifugation separates molecules based upon size in incredibly high-spinning gravity fields measuring about 100,000 times the earth's gravity. These three techniques, plus a few others, are very effective in isolating and purifying hormones as well as other important molecules.

Isolated hormones have been injected into experimental organisms and organ extracts, followed by observation and recording of the animal's physiological responses. For example, injection of vasopressin reduces an animal's urine output while simultaneously producing a slight blood pressure rise. Injection of insulin lowers blood sugar levels, which is why diabetics are prescribed insulin. Such experiments require the use of experimental animals, and extracts from these animals, which has sparked considerable controversy and debate concerning animal rights. These studies are important in understanding the physiology of the human body.

Genetic studies such as cloning and DNA sequencing have identified genes that may encode other developmental hormones. Discovery of the homeobox within the genes of all mammals indicates that there are some proteins (hormones) that control basic pattern development in mammals during early embryonic development. Some researchers believe that there may be certain hormones that accelerate aging and cause death in later life.

Hormones as a Key to Understanding Genes

All mammals start as a single-celled zygote—an egg that has been fertilized by a sperm—that undergoes a rapid sequence of mitotic divisions until it reaches the stage of a hollow, microscopic ball of identical cells called the blastula. Signaling molecules called hormones stimulate the blastula to fold in upon itself and form layers of tissue that gradually become differentiated into organs because of the presence of other hormones, which affect the tissue in sequence. Still other hormones later influence the interactions of organ systems for the smooth function of the organism. Knowledge of the chemical mechanisms and sequences through which hormones exert their effects will provide the key to understanding the action of genes, which in a more fundamental way are responsible for the various stages of life. Hormones direct cellular differentiation and development in the organism for the rest of its life. Hormones will be crucially involved in fetal development, birth, early growth and development, puberty, reproductive cycles, aging, and eventually death. Hormones control virtually all aspects of an organism's life.

If certain relevant mammalian developmental hormones can be identified, then target cells—cells that respond to the hormones in discrete but interrelated ways—may also be determined. A "developmental profile" for any organism would then be a real possibility, and the control of any organism's development, even behavior, could result, although this may pose ethical problems.

Currently, there is some detailed knowledge of the functions of many developmental hormones. Many hormones remain to be identified, however, and the overall scheme of hormonal control of development is still sketchy. Extensive research will be needed in the future.

Bibliography

Alberts, Bruce, Dennis Bray, Julian Lewis, Martin Raff, Keith Roberts, and James D. Watson. *Molecular Biology of the Cell*. 3d ed. New York: Garland, 1994. As an intermediate-level undergraduate textbook, this outstanding work is a comprehensive, clear discussion of molecular and developmental biology. It contains excellent photographs and diagrams. Chapter 13, "Chemical Signaling Between Cells," provides detailed information concerning hormones and neurotransmitters.

Gehring, Walter J. "The Molecular Basis of Development." *Scientific American* 253 (October, 1985): 152B-162. As part of a special *Scientific American* issue called "The Molecules of Life," this article is a discussion of research into the homeobox, a region of genetic molecules that control early embryonic development in a variety of organisms, from nematodes to humans. Gehring describes several important experiments and major theories concerning early development.

Malven, Paul V. *Mammalian Neuroendocrinology*. Boca Raton, Fla.: CRC Press, 1993. A concise presentation of the way that nervous and endocrine systems interact to regulate physiological processes, using a comparative approach with rodents, domestic ungulates, and primates. Summarizes the neural influences and endocrine feedback mechanisms of each hormone.

Sang, James H. *Genetics and Development*. London: Longman, 1984. This text is suitable both as a graduate level textbook and as a heavily cited reference source for developmental geneticists. It clearly and precisely presents current theories of determination, differentiation, and development. Chapter 8, "Tissue Origins," and chapter 11, "Sex Differences," are excellent discussions of development.

Snyder, Solomon H. "The Molecular Basis of Communication Between Cells." *Scientific American* 253 (October, 1985): 132-141. As part of a special *Scientific American* issue called "The Molecules of Life," this article is a clear, comprehensive survey of mammalian endocrine systems and hormones, including both protein and steroid hormones. Mechanisms of hormone action, hormone transport, and experimental studies are presented in this beautifully illustrated, well-diagrammed article.

Stryer, Lubert. *Biochemistry*. 4th ed. New York: W. H. Freeman, 1995. Stryer's classic work is an outstanding textbook for advanced undergraduate students in biology, biochemistry, and physiology. The book is very clearly written and well illustrated. It has tremendous value as a reference tool. Chapter 35, "Hormone Action," is a thorough survey of hormone types and their mechanisms of action.

Wallace, Robert A., Jack L. King, and Gerald P. Sanders. *Biosphere: The Realm of Life*. 2d ed. Glenview, Ill.: Scott, Foresman, 1988. This is an excellent introductory biology textbook for both science and nonscience majors. It is clearly written and comprehensive in its coverage, although it is not too detailed to be understood by the general reader. The chapter on chemical messengers in animals is a concise but thorough survey of mammalian hormones.

Zubay, Geoffrey. *Biochemistry*. 4th ed. Dubuque, Iowa: Wm. C. Brown, 1998. As a graduate biochemistry textbook, this work is very detailed, although the illustrations and tables are excellent. The chapter on hormone action provides considerable information for protein and steroid hormone structures and actions, including a good discussion of negative feedback homeostasis.

HORNS AND ANTLERS

Type of animal science: Anatomy
Fields of study: Anatomy, physiology, zoology

Horns are hard, pointed outgrowths from the frontal bones of the heads of male ruminant herbivores, used for protection and to attract mates. They are permanent (true horns) or temporary (antlers) appendages. Antlers are shed yearly. In a few cases, horns are made of fused hair.

Principal Terms

ANDROGEN: a male hormone (especially testosterone) made by the testes
FRONTAL BONE: the bone which, vertically, makes up the forehead and is important, horizontally, to formation of the top (roof) of the orbital and nasal cavities
KERATIN: a tough, fibrous protein which is a major component of hair, nails, hooves, and the outer covering of true horns
PEDICLE: a small bone spur from which an antler grows (for example, in deer)
RUMINANT: a hoofed animal, with a stomach divided into four parts, that chews a cud of regurgitated, partly digested food
TRUE HORN: the permanent horns found in animals such as cattle, sheep, and goats

Horns are found in many ruminant herbivores. They are hard, pointed outgrowths that arise at the front of the heads of many herbivores. Horned animals include cattle, deer, giraffes, antelope, and rhinoceroses. In some cases, horns are permanent appendages that enlarge the bony front of the skull, as in cattle. In others, they are temporary bones arising on—but separate from—the skull, falling off every year, as in deer. In yet other cases, such as rhinoceroses, they are permanent groups of fused hairs, which become very hard.

Regardless of species, horns serve very important protective functions, both for the individuals having them and for the family groups or herds to which the individuals belong. Often, males use their horns to fight other males in the group for ascendency. In many horned species, an ascendant male does not fight much but faces down rivals with gestures, including displaying and threatening to use his horns.

The protective function of horns may explain why, most often, it is the males within a species who have horns, while the females are hornless. The males protect the herds or other family groups from predators. Although horns are most often found in males, females may have horns as well, for example, giraffes and oxen. When females of a species have horns, they are almost always much smaller than those found in males of the same species.

The nature of horns also differs from species to species. For example, in deer, their temporary horns, or antlers, are made of naked bone. In contrast, the permanent horns of cattle are made of bone covered with hard tissue. In the giraffe, the bony horns are covered with hairy skin. Also, in some cases a horn is not made of bone—the rhinoceros horn is made of hair.

The True Horns

True horns are pointed, permanent, bony structures most often seen on the heads of male ruminant mammals. The horns of females, where present, are smaller. Most horned animals—cattle, sheep, goats, and antelope—have paired horns. True horns have cores of bone which are extensions of the skull's frontal bone. Atop the bone core is a layer of skin, rich in a very tough, fibrous protein, keratin. The high keratin content in this skin makes it an extraordinarily tough and durable covering for the underlying bone.

Males and females of many animal species grow horns. The horns range from straight spikes to elaborately curved varieties. However, except in pronghorn antelope, the horns do not form branches, as in deer and other animals which shed their antlers every year. Animals having horns keep them for life. In pronghorn antelope the horn coverings are shed and grow again every year. This allows horn enlargement that would otherwise not occur.

Antlers

Antlers are horns which are shed each year and then grow again. In most antlered species only males have antlers. Like true horns, antlers grow out of the bones of the skull. They arise from permanent frontal bone structures called pedicles. At first the antlers have soft, velvetlike coverings of skin over their bone. Instead of hardening, as in true horns, this covering dies off and is rubbed away by the animal. The rubbing is believed to be due to itching caused by the dead velvet. Many zoologists propose that an advantage associated with rubbing off dead velvet is the development of good spatial perception of a stag's antler size and shape that helps to keep him from entanglement in underbrush and forests. Antlers have the same functions as true horns: protection, and use or display to develop ascendancy in a herd.

Antlers begin their growth in early summer, on the skull's frontal bone. They begin as small nubs that increase in length over time. The growing antler, sensitive to the touch, is covered with velvet, soft, smooth, and full of blood vessels. This gives it an abundant blood supply, carrying to growing antlers all the nutrients required for the two to three months of the growing period. At first, antlers are made of connective tissue. As time goes on, this tissue calcifies and becomes solid bone.

Antler growth is greatest in the late summer. At that time, hard tissue grows around the base of each antler, cutting off its blood supply. This kills the velvet, which loosens and is rubbed off by the stag. Antlers reach their full glory in the mating season, when they can be used to impress potential mates and to vanquish other males. Zoologists observe that the blood running through antler velvet cools down and this cool blood makes stags and bulls more comfortable on hot days. Antlers are shed between January and February, just following the mating season, when they are no longer useful.

Bone

Horns and antlers are made mostly of bone. About 70 percent of the matter in bone is an inorganic mineral material, hydroxyapatite, composed of calcium phosphate and calcium carbonate. Much of the remainder is a fibrous protein, collagen. The mineral and the protein together are called bone matrix. Within bone matrix, three types of specialized cells ensure its formation, its remodeling as needed, and its continuity throughout the life of any organism having a bony skeleton.

The first cell type, the osteoblast, produces bone matrix and surrounds itself with matrix, making collagen and stimulating mineral deposition. The second type, the osteocyte, is branched and becomes embedded in bone matrix. Osteocytes are interconnected and act to control the mineral balance of the body. Finally, osteoclasts destroy bone matrix whenever it is remodeled (rebuilt) during skeleton growth or the repair of bone breaks and fractures.

The conversion of connective tissue to bone begins when connective tissue cells arrange themselves in rows, enlarge, and change. This is followed by the synthesis of collagen and by mineral deposition around them. Osteoblasts needed for bone formation develop below the inner surfaces of a membrane that surrounds bone-to-be. Simultaneously, osteoclasts set the stage for formation of additional bone.

Who Has Horns and Antlers?

Bighorn sheep have true horns in individuals of both genders. Rams' huge, back-curved horns show growth rings that tell their age. Ewes have smaller, lighter horns that they use to protect their offspring. Rams use their horns to attract females, assert ascendancy, and battle predators.

Caribou of both genders have antlers, though those of females are small. Males shed their antlers in the winter, while females do not do so until spring. Females may use this advantage to oust males from winter feeding areas, in order to assure the continuation of the species by their offspring.

Elk antlers occur only in males. Bull elk use them to battle any predators who seek to harm the herds they lead, display them to attract females, and use them to assert ascendancy.

Moose antlers occur only in males. The huge, scoop-shaped antlers are mostly for show and to attract mates. Moose do not travel in herds and have relatively weak familial instincts.

American pronghorns of both genders have permanent horns that share attributes of both true horns and antlers. Doe antlers are short spikes. In males, the pronghorns—true horns—can become quite large. The coverings, but not the horns, are shed yearly. This leaves bone cores attached to the head. Then the bare core enlarges and its covering grows again. The horns of males have the usual protective, display, and assertive functions.

The first growth of antlers occurs when a stag or bull elk is one to two years old. At first, the antlers are small, straight, and spikelike. At that time young males are often called spikehorns by hunters. As an antlered male grows older its yearly antler crop branches out, having more prongs (points). In old, antlered males these horns may spread to widths of six feet and be several feet tall.

Antler growth is regulated by hormone secretions from the pituitary gland and the testes. The growth begins outside of the breeding season, when the testes are inactive. When the testes begin to make androgens, in preparation for breeding, both antler calcification and velvet tissue death occur. Decreased androgen production in winter leads to shedding of antlers.

Antlers, Horns, and Species Life Cycles

In the fall (September to October), American elk—called wapiti by Native Americans—mate, after crashing battles between bull elk, who joust with many-pointed antlers. This identifies winners, who thoroughly impress cow elk. Then each bull mates with his harem of cows and they wander off to form part of a huge winter herd of elk of both genders and all ages.

By early winter, bull elk shed their heavy, four- to six-foot-wide antlers, unneeded burdens that would diminish their chances of surviving the cold winter. Winter passes and by the late spring (May and June) the cows give birth to young, usually one per mother. At this time, new antlers begin to sprout from the pedicles on foreheads of bulls over a year old.

The antlers of elk follow the same growth pattern as in deer, leaving the bull elk with a strong bony rack of antlers in the fall, just right for jousting at the mating season. With some variation, in other antlered species—pronghorns who never lose bone cores of horns, and horned sheep, goats and bovines—the overall story is about the same. Offspring are conceived in the fall after jousts using antlers, pronghorns or horns, and life goes on. In some species females have horns or antlers, and in others small family groups are formed. Sometimes males hardly interact with females after copulation. However, a common thread to all their lives is the possession of true horns, pronghorns, or antlers.

HORSES AND ZEBRAS

Type of animal science: Classification
Fields of study: Anatomy, genetics, zoology

Horses and zebras are herbivorous, hoofed mammals that represent five species of the Equidae family.

Principal Terms

CECUM: pouch in intestinal tract
CROWN: external tooth surface above gums
GELDING: castrated male
HAND: ten-centimeter (four-inch) measuring unit
UNGULATE: hoofed animal

Horses and zebras, members of the Equidae family, share common anatomical traits such as hard hooves, strong spinal columns, muscular arching necks, sloping shoulders, wide hindquarters, high-crowned teeth, slender legs, and elongated heads. Size and coloration varies according to specific horse breeds developed through selective breeding. Similar differences in zebra species have evolved due to natural selection and environment. Horses and zebras are related to wild asses and donkeys and represent five species of the genus *Equus*.

Anatomy Development

Eohippus was the ancestor of both domestic and wild horse species. A leaf-eating mammal as small as a fox, *Eohippus* lived during the Eocene epoch and had several toes on its feet. Descendants gradually grew larger, lost toes, and became grass grazers. Przewalski's horse, indigenous to Mongolia but not seen in the wild since 1968, links ancient and modern horses. Because it has sixty-six chromosomes and domestic horses have sixty-four, Przewalski's horse is a separate wild horse species and not an ancestor of modern horses. A hybrid produced by a horse and a Przewalski has sixty-five chromosomes and is fertile.

Modern horses and zebras are distinguished by a single hoof on each foot. Vestigial remains of prehistoric toes are located above hooves. Horses and zebras have long skulls and jaws that hold approximately forty to forty-four permanent teeth, including incisors to bite grass and molars to chew roughage. The teeth have long crowns that slope with age and can be examined to determine how old an animal is. Horses use their teeth to eat, groom, and fight.

The horse's digestive system is bigger and more efficient than that of carnivores, and has approximately 40 meters (131 feet) of intestines with a meter-long cecum attached to the colon. Horses and zebras live on grasslands ranging between sea level and mountains and eat mostly fibrous food such as hay, grain, and oats. Food ferments in the cecum, which can hold as much as thirty-eight liters (ten gallons). Horses eat an average of sixteen hours per day to sustain their systems.

The average horse's heart weighs about 3 kilograms (6.6 pounds), and the surface area of a horse's lungs measures approximately 2,500 square meters (8,200 square feet). Horses' weight varies from minimums of nearly 500 kilograms (1,000 pounds) to maximums of more than 908 kilograms (1 ton). Fifty-one vertebrae are in horses' spines from the top of the skull to the base of the tail.

Horses' eyes are placed on the sides of their heads, enabling them to see the horizon without moving their head. Their eyesight is better than that of dogs. Horses depend on hearing more than sight, but rely most on the sense of smell. The flehmen response is when the horse raises its upper lip to indicate it has smelled something interesting.

Social Behavior

Depending on the age, female horses are called fillies and mares, and males are colts, stallions, and geldings. Horses attain sexual maturity at two to three years old and usually produce a single foal after eleven months of gestation. Multiple births are rare, with twins occurring on average once per 1,500 births. Foals are able to stand within an hour of birth. Stallions fight while competing for mares, and one stallion may mate with several mares during a season. Mares usually come into heat one week after giving birth. Foals are weaned before they are one year old.

Horses are herd animals and rely on this social relationship, as well as on speed and endurance, as protection from predators. Domesticated horses enjoy the companionship of horses and other animals. Wild horses form a family group of one stallion, several mares, and their offspring. Young stallions sometimes form a bachelor group led by an older stallion. These groups forage in an area where they can find food, water, and shelter, and a pecking order maintains a hierarchy of rank within the group. Several groups often share the same range. Horses communicate by whinnying and nickering.

Vulnerable to wild animals, horses can run an average speed of forty-five to sixty kilometers (twenty-eight to thirty-seven miles) per hour. Their legs are slender and angled forward so that their weight is carried forward to enhance quick motion. Horses' shoulders absorb shock, while their powerful hindquarters provide impulsion. Horses naturally move at the gaits of walk (four beat), trot and pace (two beat), canter (three beat), and gallop (an extended canter), with several other natural gaits including pacing and the running walk.

Horse and Zebra Facts

Classification:
Kingdom: Animalia
Subkingdom: Metazoa
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Eutheria
Order: Perissodactyla
Suborder: Hippomorpha
Family: Equidae
Genus: Equus
Subgenera: Equus (horses), *Asinus* (asses), *Hippotigris* (zebras), *Dolichohippus* (zebras)
Species: Equus przewalskii (Przewalksi's horse), *Equus caballus* (domestic horse), *Equus africanus* (African ass), *Equus hemionus* (Asiatic ass), *Equus burchelli* (plains zebra), *Equus zebra* (mountain zebra), *Equus grevyi* (Grevy's zebra)
Geographical location: Horses can be found on all continents except Antarctica; zebras live in southeastern Africa
Habitat: Grasslands in tropical, temperate, and subarctic regions
Gestational period: Eleven months for horses; thirteen months for some zebras
Life span: Ten to twenty-five years, up to thirty-five in captivity
Special anatomy: One-toed feet, high-crowned teeth

Appearance

Domesticated horses are described by three types: heavy or draft, light, and pony. Humans genetically developed specific breeds for different tasks and degrees of hardiness, stamina, and versatility. Most horse breeds are derivatives of Arabians and thoroughbreds. Draft horses (often referred to as cold-blooded, which is not physiologically accurate), usually stand over sixteen hands high at the withers (the ridge between the shoulder blades) and have sturdy, thick dimensions, useful for pulling loads. Light horses, sometimes called hot bloods, are at least 14.2 hands high and tend to be streamlined. Ponies are shorter than 14.2 hands and vary in conformation according to breed. Welsh ponies tend to be more delicate, while

Each zebra has a distinctive pattern of stripes as individual as human fingerprints. (Corbis)

Shetland ponies are more rotund. Miniature horses are extremely small ponies that are often less than one meter tall.

Coat colors range from shades of brown and red to solid black and white, with some horses, such as Appaloosas and pintos, having spots and others being gray or roan. Spotted patterns are linked to genes that also often produce mottled noses, eyelids, and genitalia, blue eyes, and striped hooves. Lipizzans are born black and turn completely white by age two years. Some horses have dorsal stripes and zebra stripes on their legs. Various white facial and leg markings also distinguish horses.

African Cousins

Zebras belong to the horse family and are represented by three species, the plains, Grevy's, and mountain zebras. Several subspecies exist according to geographic range, herd behavioral differences, and physical variations such as dewlaps. Zebras are smaller than horses and have erect manes, longer ears, and thinner tails. The average zebra stands 140 centimeters (55 inches) high and weighs 300 kilograms (660 pounds). These striped animals exist in herds that graze in southeastern Africa's grasslands and also live in nearby deserts.

Each zebra species is determined by a specific stripe pattern of black, brown, and white markings. Individual zebras have unique striping somewhat like the uniqueness of human fingerprints. Scientists have determined that zebras, from the moment of birth, are drawn to striped objects, a type of imprinting which has led to speculation that stripes might be a factor in herd cohesiveness and sociability. Previous hypotheses that stripes are for camouflage and to confuse predators have been discredited. The exact purpose of stripes remains a scientific mystery. Researchers are aware that abnormally striped zebras are often shunned by herds, which threatens their survival.

Herds can include several zebras, often a male and females with their offspring or a group of

North American Wild Horses

Considered the symbol of the freedom of the American West, mustangs roam prairies, in addition to isolated areas along the East Coast and in the Midwest. In the early twentieth century, the federal government ordered the extermination of mustangs. Velma "Wild Horse Annie" Johnston lobbied Congress in the 1950's to stop wild horse slaughters. Congress passed the Wild Free-Roaming Horse and Burro Act in 1971 to protect wild horses under the jurisdiction of the Bureau of Land Management (BLM). The Wild Horse Act of 1999 assured federal protection for a feral horse herd in Missouri.

Although wild horses are romanticized in books and movies, realistically they pose problems such as uncontrolled population increase, encroachment on urban areas, and destruction of rural landscapes. They also are at risk from animal predators, microscopic diseases, and human poachers. Droughts and wildfires in the late twentieth century depleted food sources, resulting in many mustangs starving. Roundups by helicopters drive wild horses toward government corrals, where they are fed and offered for adoption to the public. Approximately forty-six thousand wild horses roamed the American West in 1999, and seven thousand were adopted.

Such dispersal, however, is controversial. Some of the mustangs are actually sold for slaughter because horse meat is a popular food in Asia and Europe, due to concerns about bovine spongiform encephalopathy (mad cow disease). Critics of the BLM suggest that agency will inadvertently cause the extinction of America's wild horses.

young males. Herds can expand to hundreds of zebras. Typically passive animals, male zebras occasionally fight for females during breeding season by kicking, biting, and shoving each other. Female zebras attain sexual maturity at age three and usually reproduce annually throughout their lives, while males reach breeding age at five years. Gestation lasts approximately eleven to thirteen months, and twins are rarely foaled. The life span of wild zebras can extend to twenty-two years, and zebras kept in captivity can live longer.

Zebra foals weigh approximately thirty-two to thirty-six kilograms (seventy to eighty pounds) at birth. Able to stand soon after being born, zebra foals eat grass which adds about 0.45 kilograms (1 pound) of body weight per day until they reach physical maturity. Zebra foals develop more quickly than horse foals and become independent sooner.

Defense Mechanisms

The herd protects zebras from predators, primarily large cats, such as lions and cheetahs, in addition to hyenas. Humans also hunt zebras for their hides. While other zebras sleep, a guard zebra watches for potential hazards and is aided by its keen night vision, comparable to an owl's, and tall ears which can rotate to pick up sounds. Zebras' primary defense mechanism is to run away from danger, and they can reach speeds as high as sixty-five kilometers (forty miles) per hour, which is much slower than most of their enemies.

Zebras also are at risk from reduced water resources and grasslands due to ranching and farming and compete with livestock for basic nutritional needs. While the common zebra remains abundant, the Grevy's zebra and the mountain zebra are considered endangered species and another type of zebra, the quagga, became extinct in 1883. A century later, the Quagga Breeding Project attempted to revive the quagga because genetic researchers determined that quagga and plains zebra deoxyribonucleic acid (DNA) was similar, and hypothesized that the quagga was not a separate species but rather a variation of the plains zebra. Zebroids are horse-zebra hybrids that are sterile.

HORSESHOE CRABS

Type of animal science: Classification
Fields of study: Anatomy, invertebrate biology, marine biology, systematics (taxonomy)

Horseshoe crabs are not crabs at all, being more closely related to spiders and scorpions. They have been around for at least 400 million years—before dinosaurs walked the earth—and have changed relatively little in that time.

Principal Terms

CEPHALOTHORAX: the forward segment of the horseshoe crab's body
CHELATE: pincerlike
CHELICERAE: appendages with pincers
DIOECIOUS: having separate sexes
EXOSKELETON: the external shell of horseshoe crabs and their relatives
GNATHOBASE: the part of the leg closest to the horseshoe crab's body

There are four species of horseshoe crabs, and all are members of the class Merostomata, aquatic animals with two body segments and a spikelike telson at the tail end. Perhaps the best-known representative is *Limulus polyphemus*, the common horseshoe crab native to the northwest Atlantic coast and the Gulf of Mexico. These animals live in shallow water to depths of one hundred feet and prefer soft sand or mud bottoms, through which they slowly plow as they scavenge for food.

Horseshoe crabs, unlike true crabs, do not have antennae. However, like crabs, they do have jointed appendages and a hard shell, or exoskeleton, made of chitin, which must be periodically shed to accommodate the growing body of the individual.

Horseshoe Crab Anatomy

The body of horseshoe crabs is divided into two segments: a large, helmet-shaped, forward section called the cephalothorax or prosoma, and a rear abdomen or opisthosoma, to which is attached the lancelike telson. Despite its threatening appearance, the telson is not used for defense, but rather for pushing and righting the body if the animal is overturned.

There are two lateral and two median eyes on the upper surface of the prosoma. Although horseshoe crabs may be able to detect movement, there is little evidence that they can form images. The unique and relatively simple anatomy of horseshoe crab eyes make them favorite subjects for nervous system research.

Under the cephalothorax there is a pair of small, pincerlike chelicerae, followed by five pairs of walking legs. The first four pairs are chelate and the fifth pair is for pushing away mud and silt during burrowing. The first four pairs also have spines along the joints closest to the body. These gnathobases are used to shred and macerate food and move it toward the mouth.

The abdomen has six pairs of appendages, five of which are modified as thin, flaplike gills. In addition to providing oxygen to the animals, the gills function as paddles during upside-down swimming in small individuals.

Reproduction in Horseshoe Crabs

Horseshoe crabs are dioecious, meaning there are separate sexes. During warm months, females migrate into the intertidal zone to rendezvous with the smaller males. The males crawl onto the shell of the females and cling to them while the females scoop out depressions in the sand and deposit two hundred to three hundred small green eggs, which the male then fertilizes. The location of this

Image Not Available

egg burying is of critical importance: too high up the beach and the eggs will dry out; too low and they will die in the oxygen-poor sand.

After a lunar month a small (about one centimeter), swimming larva hatches which little resembles the adult. After successive molts the adult body form is eventually achieved, with sexual maturity being reached after three years.

Economic and Scientific Importance of Horseshoe Crabs

The economic value of horseshoe crabs has been recognized since at least the nineteenth century, when millions were harvested annually from Delaware Bay to be ground up as fertilizer. By the 1950's, the population of horseshoe crabs had decreased to the tens of thousands. Since then, controls have been put in place to protect this animal. In Japan, it has been declared a national monument to shield it from extinction.

Today the horseshoe crab is used for bait in the fishing industry. It is also valuable in biomedical research because of its blue, copper-based blood. An extract of this blood, called limulus amebocyte lysate (LAL), is used in detecting bacterial contamination of drugs and medical devices. There are many other chemicals derived from horseshoe crabs that may prove useful against human diseases.

Horseshoe Crab Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Arthropoda
Subphylum: Chelicerata
Class: Merostomata
Subclass: Xiphosura
Order: Xiphosurida
Suborder: Limulina
Family: Limulidae
Genus and species: Limulus polyphemus

Geographical location: *L. polyphemus*, the most common species, is distributed along the northwestern Atlantic coast and the Gulf of Mexico; other species are native to Asian coasts, from Japan and Korea south through the East Indies and the Philippines

Habitat: Shallow water with soft bottoms

Gestational period: One lunar month for the eggs to hatch

Life span: Approximately thirty-five years

Special anatomy: Two distinct body segments, a rigid telson at the tail end, four eyes, a median frontal organ

Sargent, William. *The Year of the Crab*. New York: W. W. Norton, 1987. A charming, reflective collection of essays dedicated to the horseshoe crab. Lovingly written, this is a wonderful introduction to these unique animals.

Sherman, Irwin W., and Vilia G. Sherman. *The Invertebrates: Function and Form*. 2d ed. New York: Macmillan, 1976. Arguably the finest invertebrate zoology laboratory manual ever published in English. Chapter seven contains instructions for studying both living and preserved horseshoe crabs.

Zorpette, Glenn. "Mesozoic Mystery Tour." *Scientific American* 278, no. 6 (June, 1998): 14-15. An illustrated first-hand account of horseshoe crab mating and spawning in Brooklyn, New York. Also discusses some of their unique characteristics. For a general audience.

HUMAN EVOLUTION ANALYSIS

Type of animal science: Evolution
Fields of study: Anthropology, evolutionary science, genetics, human origins, systematics (taxonomy)

The study of human evolution traces the descent of the hominids from their primate ancestors and focuses particularly on the most recent stages that led to modern Homo sapiens.

Principal Terms

DEOXYRIBONUCLEIC ACID (DNA): the large molecular chains of nucleic acid that make up genetic material

GRACILE: slender and light-framed, as opposed to robust

HOMINID: belonging to the taxonomic family Hominidae, which includes all humans and their evolutionary ancestors as far back as the split from the great apes

MITOCHONDRIA: self-replicating units in a cell that are responsible for the metabolic generation of energy for cell processes

About fifteen million years ago, there was a great flowering of diversity among the primates. One branch of this evolutionary spurt gave rise to the family Pongidae (gorillas, orangutans, and chimpanzees). A second branch led to the family Hominidae. Fossil evidence suggests that the hominids diverged from the common ancestral primate at about the same time as the pongids, but according to molecular analysis of the genes of modern humans and gorillas, the divergence may have been much later—perhaps as recently as two million or three million years ago. The earliest known examples of the hominid family have been named *Ramapithecus*. Fossils of this creature, more ape than human, have been found in India, Greece, Africa, Turkey, and Pakistan. It is likely that this genus evolved into another hominid group, *Australopithecus*. Many australopithicine fossils have been found, mostly in Africa, and the genus is divided into two types, the large, heavy-boned robust species and the smaller, gracile types exemplified by "Lucy," the nearly complete skeleton discovered by Donald Johanson in 1974. The current view is that the robust australopithicines became extinct but that the smaller forms gave rise to the genus *Homo*, leading to modern humans.

The earliest discovery of a fossil of the *Homo* genus was given the species name *erectus* by its discoverer, Eugène Dubois, in 1891. It was found not in Africa but in Java. Dubois believed that Java man, as he called his find, was the first hominid to walk erect. Later discoveries showed that the more primitive *Australopithecus* had already achieved the erect stance of modern humans, but the name *Homo erectus* persists for the link between *Australopithecus* and more modern hominids.

Tool Use and Culture

The genus *Homo* was the first to leave clear evidence of toolmaking. Pebble tools of *Homo erectus* were described by Louis Leakey, and he named the collection of artifacts "Oldowan" culture, from the Olduvai Gorge where some of his most famous excavations were done. On the basis of his collection of African fossils dated to between one million and two million years ago, Leakey proposed a new species, *Homo habilis*, which would be intermediate between *Homo erectus* and *Homo sapiens*, but there were too few fossils from this critical period to make the sequence clear. In any case, the simple pebble tools of the earliest members of the human genus were gradually supplanted by somewhat more sophisticated implements made by chipping both sides, along with a growing preference for flint over softer stones. There are many more examples of flint tools than there are of actual bones of human ancestors from this period. The techniques used for making these tools were evidently handed down from generation to generation, and the patterns were quite conservative, so tools from a given culture can be identified wherever they are found. The tools and artifacts of the later members of *Homo erectus* are known as the Acheulian culture. The most characteristic tool of this culture is the hand axe, used for chopping, cutting, scraping, and possibly even as a weapon.

The species to which modern humans belong first appeared between 200,000 and 300,000 years ago. In 1856, when the first example of *Homo sapiens* was discovered, it was named Neanderthal man because the skeleton was found in a cave by the Neander Valley near Düsseldorf, Germany. Neanderthals were a robust species with a somewhat larger brain than modern humans. They wandered widely, leaving their remains over much of Europe, Asia, and Africa. The name Mousterian culture was coined to describe their artifacts, which were much more sophisticated than Acheulian tools.

Finally, perhaps as recently as fifty thousand years ago, Neanderthals were replaced by fully modern humans. The two groups can be separated into the subspecies *Homo sapiens neanderthalensis* and *Homo sapiens sapiens*. At about the same time the Neanderthals disappeared, the Mousterian artifacts were replaced by much more complex and widely varied implements of the Aurignacian culture. The explosion of cultural innovation—including cave paintings, carvings, and other artistic and technological inventions—had a remarkable effect on life.

The first fossils of the *sapiens* subspecies were found in a limestone cliff at Cro-Magnon in southern France in 1868. They and numerous later finds from the same period were given the name Cro-Magnon man, and from the very beginning, they were recognized as being fully modern in form.

Evolutionary Controversies

Controversy over the relationship between the modern human subspecies and the Neanderthals centers around the fact that the two groups overlapped in time. Evidently some subpopulation of Neanderthal evolved into Cro-Magnon while the more primitive type was still flourishing. For some unknown period, both types existed, but eventually—quite abruptly on a geological time scale—Neanderthals vanished from the face of the earth, and *Homo sapiens sapiens* reigned alone. Some anthropologists put the divergence between Neanderthals and the *sapiens* subspecies quite early and suggest that most of the known fossils of Neanderthals represent a dead end of evolution and not human ancestors. A few fossils that appear to be of the modern human type are tentatively dated much earlier than fifty thousand years ago, which is the time most of the fossil evidence would indicate that modern humans first appeared. Whether humans evolved from early or late Neanderthals, there is certainly no other candidate for an immediate ancestor nor any evidence of an alternative link between *Homo erectus* and modern humans.

The Neanderthal question is one of three major controversies about the details of human evolution. Another is over the site of major stages in human evolution. The "out-of-Africa" view is that Africa, with its rich store of fossil evidence, had to be the place where, successively, *Australopithecus*, *Homo erectus*, and modern humans emerged. Countering this is the fact that fossils and artifacts of each stage of human evolution are found in many regions of the globe. Some authorities feel that it is more probable that this mobile, adaptive, wide-ranging species was already dispersed during the final million years or so of human evolution rather than exclusively in Africa.

The third major disagreement among anthropologists is about how to interpret evidence from molecular biology. The random mutation of deoxyribonucleic acid (DNA) chains provides a molecular clock because the mutations cause a genetic drift. In an interbreeding population, the genetic changes are shared by all members, but if a population divides, the genetic changes vary between the two groups, resulting in more and more differences as the time since the separation increases. Studies of DNA differences among humans and between humans and the great apes suggest that the genetic divergence between humans and the gorillas has taken only about three million years. This is a much shorter period than fossil evidence would indicate. However, the time scale for DNA changes is not well enough established to persuade many of the geologists and fossil hunters to give up their chronology. In 1987, the even more disturbing claim was made that all living humans had descended from one woman and that this "Eve" had lived in Africa as recently as 200,000 years ago. The work that led to this announcement was based on the study of mitochondrial DNA, which is much less variable than the DNA in the nucleus of the cell.

Each tiny mitochondrion has its own set of genes, and they divide independently of the cell nucleus. Because the sperm does not contribute any mitochondria to the fertilized egg, mitochondrial DNA is inherited only through the female line of descent. In one study, mitochondrial DNA from 147 individuals, representing populations in Africa, Europe, Asia, Australia, and New Guinea, was compared. The samples seemed to fall into two major groups when analyzed by a computer program: a group containing the African samples and one holding all the rest. The group containing the African individuals appeared to be the more primitive. From the rate of mutations in mitochondrial DNA, it was calculated that the observed variations in the samples would have occurred over a time span of about 200,000 years.

The convergence of molecular evidence and fossil interpretation has given a boost to the out-of-Africa hypothesis for human origins. Africa is certainly a rich source of fossils of the earliest progenitors of the human species. It is also the home of most of the great apes. The controversy is mainly about when the migration of humans or proto-humans into the rest of the world occurred. Fossils of every stage of human evolution have been found in many parts of Europe and Asia and even Australia. It is possible, of course, that sample populations of each stage of human evolution emigrated from Africa, leaving their bones and their tools scattered all over Eurasia, only to be replaced by successive waves of emigrants from later stages. There is no hypothesis to suggest why the further evolution of these intermediate species should not have taken place outside Africa.

Fossils and Paleoanthropology

The major technique for the study of human evolution is the analysis of fossils and the artifacts associated with human activities. Fossil hunting is more an art than a science, and many of the major finds have been accidental. However, knowing where to look and the use of systematic excavation have been very fruitful. Dating the fossils and artifacts is the most critical part. When fossils are excavated from undisturbed layers of sediment, the dating can be determined by knowledge of the geological strata. Layers of lava from volcanic eruptions, sediment from floods, the presence of other fossils of plants or animals of known periods all contribute to the determination of the age of the deposit. Radioactive decay provides another method. Radioactive carbon-14 is continuously produced in the upper atmosphere and is absorbed by plants. The carbonate in fresh bone contains about one atom of radioactive carbon for every one hundred forty atoms of the inactive isotope. The radioactive isotope decays at a constant rate and is reduced to half of its original concentration in about five thousand years. The radioactivity of bones (or charcoal or other organic debris) can be measured, and the older the sample, the smaller the proportion of radioactive to nonradioactive carbon atoms will be. Unfortunately, the sensitivity of the method limits its usefulness to materials less than about thirty thousand years old. Also, it is often hard to rule out the possibility of contamination by groundwater or organic sources of "fresh" carbon. Older materials can sometimes be dated by other radioactive isotopes such as argon. Another dating method is to use the accumulation of atomic dislocations caused by cosmic ray bombardment in hard materials, especially stone and pottery. Such dislocations "heal" when the material is heated, so measuring the amount of cosmic ray damage in a material can reveal its age since the last heating. This method is good for much longer time periods than radiocarbon dating.

Molecular biology is relatively new, and its use as a method for studying human evolution is still experimental. The basic premise on which it operates is that mutations of DNA molecules are random events, relatively independent of environmental factors, and therefore relatively constant in time. Although exposure to natural or artificial radiation or certain chemical mutagens can increase the rate of DNA change, it is assumed that such factors would not be likely to affect a whole population; therefore, the assumption of a uniform slow rate of genetic drift is probably justified statistically.

DNA molecules are very large, and with modern techniques, it is possible to detect small changes in the molecule that may not produce any observable mutation in the organism. This means that chemical comparison of DNA samples from two individuals is a much more sensitive measure of their degree of relatedness than simple comparison of visible features. Analysis of DNA differences (and similarities) correlates well with older techniques of classification. Human DNA, for example, is much more similar to sheep DNA than to earthworm DNA. Monkey DNA is much closer to human DNA than is sheep DNA. By assuming that DNA changes at a uniform rate, these differences can be interpreted in terms of evolutionary time since humans and monkeys or humans and sheep shared a common ancestor.

The Implications of Human Origins

The study of human origins has social, intellectual, religious, and philosophical implications. The fact that humans are all one subspecies, with a remarkably homogeneous genetic makeup, should minimize the importance of race, culture, or language differences. Anthropology is the discipline that studies the origins of humans. Anthropologists also study living human cultures, and there is a two-way transfer of information between cultural anthropologists and physical anthropologists. Knowledge of human descent deepens understanding of the diversity of cultures and capabilities among living humans. Studies of contemporary and recent cultures give great insight into how Stone Age ancestors might have lived and worked. Even the study of developmental psychology provides insights into the ways the modern mind might have evolved.

Naturalist Charles Darwin's theory of human evolution met with powerful resistance not only

Image Not Available

because it was contrary to a literal interpretation of the Christian scriptural story of human creation but also because it seemed to make humans helpless products of random processes. Humans may be powerless to control their biological evolution, but they are fully in control of the spectacular cultural evolution that provided people with language, knowledge, and civilization.

Although many people still see a conflict between religious beliefs about human origins and the scientific view, others have been able to reconcile the two doctrines and are comfortable with both their religious faith and their scientific knowledge.

Philosophers have always discussed what it means to be human and the origins of humankind. Scientific knowledge of human origins has had immeasurable impact on philosophy. Modern philosophy emphasizes the importance of language to humans, and anthropological studies of human evolution also point to the critical importance of language development in the final stages of human evolution. There is a growing conviction that the acquisition of language was the single most important step in the final evolutionary jump from Neanderthal to modern human. Language made it possible for humans to communicate with others and to pass along the accumulated wisdom and experience of one generation to the next. Language helped the pace of cultural development accelerate to a point where further biological evolution became irrelevant. Clothing and fire substituted for fur in a cold climate. Weapons were better than sharp claws and long teeth. Human evolution thus became cultural evolution.

Cann, R. L., M. Stoneking, and A. C. Wilson. "Mitochondrial DNA and Human Evolution." *Nature* 325 (1987): 31-36. This brief article presents a computer analysis of the mitochondrial DNA studies and makes the conclusion that all living humans descended from one African woman who lived about two hundred thousand years ago.

Johanson, D., and M. Edey. *Lucy: The Beginnings of Humankind*. New York: Simon & Schuster, 1981. This is the exciting story, told by a world-famous anthropologist, of his discovery of "Lucy," the diminutive three-and-a-half-million-year-old skeleton of one of humankind's australopithecine ancestors. Also gives a readable account of the state of modern research into human evolution, with careful explanations, diagrams of dating methods, and chronologies. Contains many pictures and diagrams, an appendix, and a good bibliography of books and scientific papers.

Jolly, Alison. *Lucy's Legacy: Sex and Intelligence in Human Evolution*. Cambridge, Mass.: Harvard University Press, 1999. Traces four major transitions in human evolution, all based in cooperation, and posits that we are in the process of undergoing a fifth, incorporating specieswide, global communication.

Leakey, Mary. *Disclosing the Past*. New York: Doubleday, 1984. This is Mary Leakey's autobiography, but it serves as an unsurpassed history of field research into human origins over the past fifty years, told by an individual who was at the forefront of that story. The book contains photographs, maps, diagrams, and a completely captivating narrative of human evolution. Contains a list of twelve books for further reading.

McKee, Jeffrey K. *The Riddled Chain: Chance, Coincidence, and Chaos in Human Evolution*. New Brunswick, N.J.: Rutgers University Press, 2000. In contrast to the traditional top-down approach, McKee takes a bottom-up view of human evolution, in which each genetic variation must be tested through successive levels within a species. He argues that the large size of the current human population poises us for a rapid rate of evolution.

McKie, Robin. *Dawn of Man: The Story of Human Evolution*. New York: Dorling Kindersley, 2000. Published in conjunction with the Learning Channel series. Clearly written for a general audience, with many photographs and illustrations.

Shreeve, J. *The Neanderthal Enigma*. New York: William Morrow, 1995. The author wrote this book after spending many months interviewing leading anthropologists. The book presents the controversies over Neanderthal interpretation in an exciting and readable fashion. One may disagree with the author's hypothesis, but he tells a truly fascinating story. Contains an extensive bibliography of both research articles and books.

Smith, C. G. *Ancestral Voices: Language and the Evolution of Human Consciousness*. Englewood Cliffs, N.J.: Prentice-Hall, 1985. This book is written for the general reader and presents a fusion of anthropology, linguistics, and neuroscience to describe the final emergence of the human species from its animal background. It emphasizes the importance of cultural evolution in shaping modern humans. Contains many illustrations, a list of references, and a list of suggested readings.

Solecki, R. S. *Shanidar, the First Flower People*. New York: Alfred A. Knopf, 1971. Solecki was the anthropologist who excavated a Neanderthal skeleton that pollen analysis revealed to have been laid on a bed of flowers. This is a poetic book, with interesting speculation about the "humanness" of the Neanderthals, and a very good story about the process of excavation. Solecki has been an authority in the field of late human evolution and gives a good account of the state of knowledge in the 1960's. Bibliography, pictures, and diagrams.

HUMMINGBIRDS

Types of animal science: Anatomy, behavior, classification, physiology, reproduction
Fields of study: Ornithology, physiology, population biology, wildlife ecology

Hummingbirds are found only in North and South America. Classified in the general order Apodiformes, they have unique coloration and many of their feathers are iridescent. The rapid beating of their wings, which enables them to hover, produces a distinctive, recognizable hum.

Principal Terms

BANDING: technique for studying the movement, survival, and behavior of birds
COVERTS: small feathers at the base of the wings and tail
GORGET: patch of feathers between the bird's throat and breast
PRIMARY FEATHERS: flight feathers on the outer joint of the wing
RECTRICES: tail feathers
SECONDARY FEATHERS: flight feathers on the inner wing

Over four hundred species of hummingbirds have been identified in North and South America, forming the Western Hemisphere's second largest family of birds. These exceptionally small birds have the greatest comparative energy output of any warm-blooded animal. In one day, they often consume more than half their total weight in food and twice their weight in water. The smaller species have the fastest wing beat of all birds. Unlike other birds, their wing upstroke is as powerful as their downstroke. They can fly forward, backward, and briefly, upside down.

The range of the hummingbird stretches from Alaska to Tierra del Fuego, Chile. Because of a constant supply of nectar and insects, tropical hummingbirds rarely migrate. Those hummingbirds that do migrate sometimes travel enormous distances. The rufous hummingbird flies over two thousand miles from its winter home in Mexico to the Pacific Northwest and Alaska.

Physical Characteristics of Hummingbirds

Hummingbirds are extremely small, weighing from two to twenty grams. The bee hummingbird is the world's smallest bird. Their long, slender bills, which are often slightly decurved, and their long bitubular tongues give them easy access to flower nectar, their main source of food.

Although their feather structure is among the most specialized of birds, hummingbirds have the fewest feathers. The primary flight feathers de-

The hummingbird's long, pointed beak and bitubular tongue allow it to suck nectar from deep within trumpet-shaped flowers. (Corbis)

Hummingbird Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Class: Aves
Order: Trochiliformes
Family: Trochilidae (hummingbirds, sixty-two genera, eighty-eight species)
Geographical location: North and South America, with most living near the equator
Habitat: Wooded areas, mountain slopes, plateaus, canyons, often near water
Gestational period: Usually one breeding cycle in a year
Life span: Average is five years, though observations of banded and captive birds show they can live ten or more years
Special anatomy: Ten primary flight feathers; six to ten secondary wing feathers; ten rectrices; extremely large sternums; long bills, often decurved

crease in size from the outer feathers inward toward the secondary feathers. Hummingbirds are able to rotate each of their wings in a circle. To hover, they move forward and backward in a repeated figure eight. They can move in any direction instantaneously. Their feet, which are more suited for perching than walking, have three toes directed forward and one pointed back.

Hummingbird feathers are iridescent. Depending on the viewing angle, the colors will change from red to gold or from green to turquoise. Adult males have the most intensely colored feathers and in full sunlight seem to glow. Some feathers are also modified to produce sound, so that as the birds fly, a soft humming sound is heard.

Reproductive Biology and Behavior

Hormonal changes prompt the female hummingbirds to begin nest building as ova ripen in their ovaries. In the male, hormonal changes enlarge their testes to many times their normal weight. Following mating, the female takes from one day to two weeks to complete building her nest, and soon after, she lays her eggs. Most hummingbirds lay two eggs, two days apart. The tiny, elliptical white eggs weigh less than 0.02 ounce. Depending on the species, incubation lasts fifteen to twenty days. Newly hatched hummers are featherless and do not open their eyes for two weeks. By two and a half weeks they are covered with feathers and can groom themselves. After testing their wings, at three weeks they are able to leave the nest, although the mother continues feeding them for two to four more weeks.

Hummingbirds are highly territorial. Particularly when they are migrating, they aggressively protect their sources of nectar. A nesting female will attack any interloper approaching her nest.

Hummingbirds have adapted to living in diverse areas. Like most birds, hummingbirds eat vast quantities of food. They have taste receptors on their tongues and salivary glands, and prefer flower nectars with a high sugar content. Throughout the day, hummingbirds eat frequently. At night, in order to conserve energy, they enter a state of torpor, which is a short-term form of hibernation. In this state they are unable to flee from predators. To resume a normal state requires enough energy to warm their organs and tissues. The birds need to monitor their energy reserves so they can recover from their torpid state.

HYDROSTATIC SKELETONS

Types of animal science: Anatomy, evolution, physiology
Fields of study: Anatomy, invertebrate biology, physiology, zoology

Hydrostatic skeletons use the incompressibility of water to create a transient skeleton. This is accomplished in animals by contracting muscles around a fluid-filled space.

Principal Terms

CIRCULAR MUSCLE: muscle fibers that run in a circular pattern around the body perpendicular to the long axis of the body

COELENTERON: the fluid-filled gastrovascular cavity of Cnidarians

COELOM: the body cavity of higher invertebrate and vertebrates, where mesodermal tissues enclose a fluid-filled space

LONGITUDINAL MUSCLE: muscle fibers that run along the longitudinal or anterior-posterior axis of the body

PSEUDOCOEL: a fluid-filled body cavity that is bounded by mesodermal muscle on the outside and endodermal epithelium on the internal boundary

The most primitive form of skeletal support evolved is mostly hydrostatic skeletons because no mineralization process is necessary for their formation. Hydrostatic skeletons have been evolved in a wide range of organisms including plants, protists, and animals. The basis of all hydrostatic skeletons has to do with the material properties of water. Water cannot be compressed under biological conditions and thus can act as a support and locomotory transient skeleton. Essentially, all hydrostatic skeletons act in a similar fashion, that is, water is contained in a compartment and is subjected to pressure. In this way, the compartment can become stiff and act as a skeleton. The method used to create the pressure differs among groups.

Among the Protozoa, hydrostatic skeletons are found in the members of the phylum Sarcomastigophora. Within this group are the amoeboid types that form pseudopodia, false feet that are transient structures formed by hydrostatic pressure within the cell. It is hypothesized that contractile proteins within the cell direct fluid toward the cell periphery in channels, and in so doing cause the cell membrane to bulge outward as a pseudopod. Thick pseudopodia, termed lobopodia, are found in the shell-less amoebas. In this case, there appears to be a chemical difference in the fluid used in pseudopodia formation. Plasmasol has less viscosity and is pushed into the pseudopodia; when it is distributed laterally it turns to plasmagel. In thin pseudopodia termed actinopodia, cytoplasm is forced along microtubules termed axonemes. These types of pseudopodia are normally found among foraminiferan and radiolarian amoebas.

Worm Hydrostatic Skeletons

In the animal phyla, hydrostatic skeletons are developed in the Cnidaria and function in relationship to the gastrovascular cavity. In the polyp forms of colonial forms and especially within the Anthozoa, such as sea anemones, the myoepithelial cells surrounding the coelenteron make up a circular muscle band and thus are able to put pressure on the water in the coelenteron to extend the body or maintain the form of the polyp. This coelenteron extends into the tentacles of these forms and thus, via contraction of the myoepithelium, can elongate the tentacles to capture food.

Various types of flatworms comprise the phylum Platyhelminthes. Despite the lack of a coelom, these worms are still considered to have a hydrostatic skeleton. Since the longitudinal and circular muscles lie external to fluid-filled parenchyma tissue, the pressure exerted by this muscle extends the body by elongating this tissue. In this way, the worms can undulate in swimming or have peristaltic motion while moving along a substrate.

The nematode worms as well as other members of the Pseudocoelomate group have developed a fluid-filled body cavity. This cavity in most members of this group has a space with an outer boundary of mesodermal muscle and an inner boundary composed of endodermal cells. In nematodes, the muscle layer is arranged in a longitudinal pattern beneath a cuticle that is composed of layers, including fibrous collagen to maintain the shape of the worm under muscular pressure. Although less flexible than in true worms, contraction of the muscle layer can act against the pseudocoel fluid, thereby causing the body to undulate. Most nematodes need to act against a surface to have effective locomotion.

A more effective method of locomotion using a hydrostatic skeleton has been developed by annelid worms. These worms are segmented and have developed a true coelom. This means that the body cavity or coelom is bounded on all sides by mesodermally derived tissue: circular and longitudinally arranged muscles on the external boundary and membranes wrapping the gut tube. In addition, the coelom is divided in each segment into right and left halves and each segment has a membrane that separates the coelom in one segment from that of another segment. Thus, the circular musculature can constrict one side of the body while the other side is relaxed and stretched. As a result, undulation is more effective in this group than in the pseudocoelomates. When such bending is coupled with setae or segmentally arranged parapodial extensions on the body, the undulations could be used for crawling and swimming, although the latter locomotory ability is poor in some groups.

Using the hydrostatic skeleton in burrowing necessitates another evolutionary strategy involving the coelom. Here the intersegmental partitions or septa are lost or are perforated. This accomplishes the movement of coelomic fluid between segments during muscle contraction. Thus, circular muscles in posterior segments can drive fluid anteriorly, swelling and elongating the anterior portion of the animal. The posterior segments left behind can catch up with the anterior segments when the longitudinally arranged fibers contract. In this way burrowing is effected. Similar contractile wave patterns are used by terrestrial oligochaetes such as earthworms to create peristaltic-type contractions that drive the animal forward. The contraction of circular and longitudinal muscles alternate to create thick and thin areas of the body. This corresponds with elongation and subsequent contraction of the body segments. In earthworms, the segments retain their intersegmental septa. The Hirudinida or leeches have done away with their intersegmental septa and thus the coelomic space is continuous. Constriction of the circular muscles extends the body forward and the subsequent contraction of the longitudinal muscles will bring the rest of the body to meet it. The movement is accomplished by first attaching the posterior sucker, then elongating, attaching the anterior sucker and then pulling the rest of the body forward in the direction of the anterior sucker.

The Hydrostatic Skeletons of Arthropods, Bivalves, and Echinoderms

The development of an exoskeleton requires a change from a coelom-driven locomotion to one that uses muscles. The reduction of the coelom is a characteristic of the diverse arthropod taxon, but hydrostatic skeletons are still used in certain body areas. Flying insects, when attaining their adult state, emerge from their cocoons with folded wings. The insect must pump hemolymph into veins within the wing in order to expand them before they harden. These veins remain in the wings, and their walls and hydrostatic pressure may act to maintain the shape of the wing during flight. The ability of spiders to run fast even though they do have eight legs may lie in the hydraulic systems in their legs. Spiders have replaced extensor muscles with hydraulic spaces that, under pressure, automatically extend the legs. Thus, muscles are normally only used for flexion of the leg segments, and the legs can be moved faster than if muscles were used in both extension and flexion of the leg segments.

Although mollusks have a reduced coelom, hydrostatic skeletons are developed in certain members of this phylum. Bivalves normally burrow into the substrate and send up siphons through which water is brought in and out of the clam. In some species, water pressure is used to open and extend these siphons. In addition, the foot of the clam contains a blood sinus that, under pressure, fills with blood and expands in two ways. The foot can be extended into the substrate with subsequent swelling of the distal end. This action anchors the foot so that the clam can pull itself into the substrate. Among other mollusks, it is thought that the extension of tentacles to capture prey by squid and cuttlefishes is based upon hydraulic action of muscles on these structures.

Most echinoderms have a well-developed water vascular system derived from the coelom. This system is composed of sieve plate opening to the water. This plate is then connected via a stony tube to a ring canal. In asteroids or sea stars, this ring canal extends into the arms via radial canals. From the radial canal located in each, there extend bilaterally arranged lateral canals that enter a tube foot structure. The tube foot has two functional parts, an upper, bulblike ampulla and a lower tube foot. Contraction of the ampulla drives water into the podium, extending it and causing its tip to form a suctionlike disc that attaches to the substrate or prey. Relaxation of the ampulla withdraws water back into the ampulla, retracting the podial portion of the tube foot. In this way many echinoderms move along the ocean bottom and manipulate prey.

Vertebrate Hydrostatic Skeletons

Like mollusks and arthropods, vertebrates have largely abandoned the coelom. Their endoskeletons have taken the place of hydrostatic skeletons. However, hydrostatic skeletons still occur, particularly in the reproductive system. The penis or hemipenes of mammals and reptiles contain spongy tissue that can engorge with blood. Venous return of the blood is largely prevented, extending the length and stiffness of the intromittent organ so that it may be inserted into the female's reproductive tract.

How Hydrostatic Skeletons Work

Although hydrostatic skeletons operate on the basis of fluid pressure, there are certain constraints as to how this pressure can be generated and on the makeup of the body wall resisting the pressure.

First, sets of muscles that will exert the pressure on the body must be located external to the fluid compartment or tissue that will function as the hydrostatic skeleton. Second, there have to be reinforcement fibers arranged in a helical pattern around the hydrostatic tissue or space. If fibers are just arranged in a circular or longitudinal pattern, bending of the structure may cause the creation of kinks or possibly bulges in the wall, due to pressure exerted on the body wall. In both cases, deleterious effects can occur on body organs or an aneurysm may form in the wall that may lead to compromising the structure through its rupture. To prevent such adverse conditions, fibers are arranged in a helix around the body wall. This same type of reinforcement is seen in the construction of the walls of high-pressure hoses. Since the fibers are wound at an angle around the structure, bending does not cause an aneurysm to form and there is no chinking of the wall. This type of fiber arrangement is found in the walls of annelids, nemertines, and flatworms, among others. The fibers are often composed of collagen, a helical protein.

"Biomechanics of Hydroskeletons: Lessons Learned from Studies of Crawling in the Medicinal Leech." In *Biomechanics and Neural Control of Posture and Movement*, edited by Jack M. Winters and Patrick Crago. New York: Springer-Verlag, 2000. This chapter gives an account of the neural control of the body elongation of the leeches. The hydroskeleton of these worms is discussed with relationship to the distribution of the coelom, its extension throughout the body of the leech, and how it functions in locomotion.

Ruppert, E. E., and R. D. Barnes. *Invertebrate Zoology*. 6th ed. New York: Saunders College Publishing, 1994. While this book is a standard textbook on invertebrate morphology and life habit strategies, Ruppert and Barnes take a functional approach to the underlying reasons why structures have evolved and how they work. This text has a section devoted to how hydroskeletons work in terms of the fiber arrangements that help contain the pressurized fluid.

HYENAS

Types of animal science: Classification, ecology, reproduction
Fields of study: Anatomy, ecology, zoology

Hyenas are wolflike carnivore-scavengers whose useful ecological functions derive from their diet of carrion and live animals from termites to antelope.

Principal Terms

CARRION: dead animals
GESTATION: time in which mammalian offspring develop in the uterus
MUSK: bad-smelling liquids made to mark territory or for self-defense
PERINEAL: located between scrotum and anus in males or equivalent region in females

Hyenas comprise four carnivore species of the family Hyaenidae, with body shapes similar to wolves; awkward-looking hind legs shorter than the front legs; good hearing; good vision; and a good sense of smell. Sizes range from small aardwolves to large spotted hyenas. All inhabit grasslands and shrubby areas in Africa, the Middle East, and Arabia.

Some species form packs; others live alone. Most scavenge anything they find, including carrion. Aardwolves eat carrion but prefer termites. Hyenas mate year round and have two- to four-month gestation periods, depending on species.

Physical Characteristics of Hyenas

The physical characteristics of three of the four hyena species are exemplified by the spotted hyena, the largest, strongest species. Their maximum length is six feet, height three feet, and weight 175 pounds. Spotted hyena hind legs are shorter than their front legs, making them look awkward. They also have four-toed paws and manes of coarse hair on the neck, shoulders, and back. The adults are a brown-gray with brown spots, and have large heads, bone-crushing jaws, and an eerie, "laughing" cry, like hysterical human laughter.

Laughing (spotted) hyenas were long thought to be carrion-eaters only. It is now clear that they are major predators of live herbivores such as zebras. They attack in packs at night, bite their victims, and hold on until the prey stumbles. They

Hyena Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Carnivora
Family: Hyaenidae (hyenas and aardwolf)
Genus and species: Crocuta crocuta (spotted hyena); *Hyaena brunnea* (brown hyena), *H. hyaena* (striped hyena); *Proteles cristatus* (aardwolf)
Geographical location: Asia, Africa, and parts of the former Soviet Union
Habitat: Deserts, grasslands, shrubby areas, forests, and mountains
Gestational period: Depending on species, two to four months
Life span: Fourteen to twenty-five years in the wild, twenty-five to forty-five years in captivity
Special anatomy: Manes; four- or five-toed paws; hind legs shorter than forelegs; most have teeth able to crush bones, but the aardwolf eats only insects

kill by tearing open the belly of the prey. Spotted hyenas kill other carnivores as well, such as striped and brown hyenas.

Striped and brown hyenas have manes, short hind legs, and bone-crushing teeth. They are smaller and less aggressive than laughing hyenas, inhabiting grassy and shrubby areas of Africa, India, and the former U.S.S.R. Their gray-brown, black-striped fur is fine camouflage. Like other hyaenids, striped hyenas eat carrion. They also eat fruit, small mammals, birds, and sometimes large herbivores, such as antelope. They grow to maximum lengths of 5.5 feet, heights of 2.5 feet, and weights of 125 pounds. Spotted hyenas hunt at night in small packs.

Brown hyenas are dark brown with gray heads and striped legs. Their maximum length is 4.5 feet, and they reach 120 pounds. They inhabit the dry, rocky Southern African deserts, usually traveling alone. As scavengers they eat anything available, including carrion and bones picked clean by vultures, using strong teeth to crack bones for marrow.

Aardwolves, honorary hyenas, inhabit much of Africa. They are hyaenid by appearance, as their backs slope down from shoulder to tail due to short hind legs. They have reddish, black-striped fur and manes on their necks and shoulders. When attacked, aardwolves erect the mane to look fiercer and spray evil-smelling musk from perineal glands.

Aardwolves differ from hyenas in having five-toed front feet. Aardwolf teeth are small and suitable only for eating their main food, termites and other insects. Their maximum length is 2.5 feet, their height is 1.5 feet, and their weight is twenty-five pounds. The termites that aardwolves eat are active at night, so aardwolves are nocturnal and eat termites with their long, sticky tongues. Aardwolves live alone and mark territories with musk, denning in empty burrows of other animals.

The spotted hyena's maniacal, eerie cry has led to it being called the "laughing" hyena. (Digital Stock)

The Life Cycle of Hyenas

There are similarities and differences in hyena species lives. Spotted hyenas form groups of up to one hundred: a few males, many females, and numerous young. Females conceive year round, birthing two or three pups that can see and run immediately, after a four-month gestation. Females, larger than males, select short-term mates. Striped hyenas fight within groups, sometimes killing group members. Maximum life spans are twenty-five years in the wild and forty years in captivity.

Like spotted hyenas, striped hyenas mate year round. They live in small groups or alone. A three-month gestation yields two to five young born with the eyes not yet open. Mothers nurse offspring until they can feed themselves. Life spans are up to twenty-five years in captivity. Brown hyena life cycles and reproductive habits are nearly the same as in striped hyenas. However, they live alone except when mating or nursing young.

Aardwolves live in groups. They have a mating season when males fight for females and winners mate. Gestation is two months and yields two to five young, nursed for two months. Aardwolves live for fifteen years in captivity.

Spotted, striped, and brown hyenas eat carrion, preventing its decay and its endangerment of humans and other animals. Aardwolves eat termites, preventing damage to the wilderness and human habitations. These activities are their main ecological function. As spotted and striped hyenas eat live food, they also kill injured or weak members of other species, helping the species eaten to enhance their long-term survival.

HYRAXES

Types of animal science: Anatomy, classification, reproduction
Fields of study: Anatomy, zoology

Hyraxes, rabbit-sized, furry mammals, look like rodents but are more closely related to elephants. Their foot pads optimize traction on rocks and in trees.

Principal Terms

DIURNAL: active during the day
GESTATION: duration of pregnancy
NOCTURNAL: active at night
PELAGE: animal fur
SOLITARY: lives alone

Hyraxes are rabbit-sized mammals that look like rodents. Strangely, they are closely related to elephants. There are three kinds of hyraxes, all found in Africa: rock hyraxes, bush hyraxes, and tree hyraxes. These vegetarians eat different kinds of food and differ in social interactions. Some live in groups and others are often solitary.

Image Not Available

Physical Characteristics of Hyraxes

Hyraxes are one to two feet long and weigh three to fourteen pounds. They have stumpy tails, brown to gray fur on their backs, and lighter pelage on their sides. Hyrax fur is short on individuals living in warm, dry regions, and thick and soft on those living in colder areas.

The three types of hyraxes walk on all fours and are excellent climbers, because their feet end in rubbery pads having sweat glands. When hyraxes run, their feet sweat, and the resultant lubrication improves traction on rocks or trees. However, hyraxes also have small hooves on the first and third toes of their hind feet. All hyraxes have a gland in the middle of the back, surrounded by a ring of erectile, dark brown to yellow fur. When a hyrax becomes excited, this hair stands on end.

Life Cycles of Hyraxes

Bush and rock hyraxes are social animals which live in family groups of up to three dozen members. Each group is led by a dominant male. Its other members are adult females and young of various ages. Group members care for each other. The dominant male marks off their territory and defends it, using scent markers to warn off other hyraxes.

Single groups of bush and rock hyraxes may share a territory peacefully, even using the same burrows. They cluster together for warmth. The young of both species play together. Part of the basis for this coexistence is that they do not compete for food. Although hyraxes can eat grasses or other soft plants, bush hyraxes eat soft plants but not grasses, and rock hyraxes eat grasses. However, while the two species live together, they do not interbreed, since both their mating behaviors and the anatomy of their sex organs differ.

Tree hyraxes differ from the other types in being usually solitary. However, they may live with one or two others. They never live in large groups or with other kinds of hyraxes. This is partly due to their habitats in trees. Rock and bush hyraxes are diurnal, while the tree hyraxes are nocturnal.

In all types of hyrax, mating season depends on species and habitat. Gestation is seven to eight months. All females in a family group of rock or bush hyraxes give birth within a few weeks of each other, each having one to four young which are nursed for five months. Tree hyraxes litter one or two young. The offspring of all species can mate at approximately sixteen months old. Females join rock or bush hyrax groups, and males leave by age 2.5 years. Tree hyrax offspring are solitary after weaning. Hyraxes can live for nine to twelve years.

The Three Types of Hyrax

Rock hyraxes (dassies) live in diurnal family groups among rocks and boulders, from dry lowlands to mountains 14,000 feet high. They inhabit and hide in rocks or their crevices. Dassies are one to two feet long and weigh four to fourteen pounds. Their back fur is light to dark brown and the erectile fur around their midback glands is dark brown or yellow-orange. Rock hyraxes eat grasses. Their eyes can look right into the sun, enabling them to escape avian predators. They can live for nine to twelve years.

Bush hyraxes are diurnal and live amid rocks and boulders or in hollow trees from south to northeast Africa. Up to two feet long, they weigh three to twelve pounds, have light gray back fur, and yellow fur around the midback glands. These hyraxes eat soft plants and live in groups of up to thirty-four. Often they share territory with rock hyraxes. They can live for ten to twelve years.

Tree hyraxes (dendrohyraxes) live in Africa. Eastern tree hyraxes inhabit Kenya's coast and Zanzibar. Southern tree hyraxes inhabit southeastern and East Africa. Western tree hyraxes live in West and Central Africa. All make tree nests in savannas, rain forests, and evergreen forests at altitudes up to 12,000 feet. They are up to two feet long, and weigh three to nine pounds, less than rock or bush hyraxes. Their long, dark brown back fur and dark yellow erectile fur around midback glands blend with shadows in trees. They eat soft plants, are nocturnal and hide during daylight, are most often solitary, but may live with one or two others.

Hyrax Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Hyracoidea (hyraxes)
Family: Procaviidae
Genera: Procavia (rock hyrax, five species); *Heterohyrax* (bush hyrax, three species); *Dendrohyrax* (tree hyrax, three species)

Geographical location: Africa and the Middle East up to Syria

Habitat: Among rocks and boulders, from dry lowlands to mountains fourteen thousand feet high, in trees near coasts, in rain forests, and evergreen forests twelve thousand feet high

Gestational period: Seven to eight months

Life span: Nine to twelve years

Special anatomy: Feet with rubbery pads containing sweat glands; rudimentary hooves on the first and third toes of the rear feet; a midback gland, surrounded by erectile fur

Hyraxes and Their Predators

Hyraxes are of relatively little interest to humans, though some Africans eat them. All hyraxes are preyed on by eagles, lions, leopards, jackals, hyenas, and snakes. Other predators are more selective in hyrax predation, due to their different habitats. For example, special predators of tree hyraxes include civet cats, servals, and caracals.

ICHTHYOSAURS

Types of animal science: Anatomy, classification, evolution
Fields of study: Anatomy, paleontology

Ichthyosaurs are extinct marine reptiles of the Mesozoic era. They were highly adapted to the marine habitat, having evolved a dorsal fin, flippers, and a tail fin. These fleshy features are often preserved in spectacular fossils from the Holzmaden and Solnhofen deposits in Germany.

Principal Terms

CARANGIFORM SWIMMING: a method of swimming where the tail is moved while the body is held rigid

DIAPSID: having two bone openings in the temporal region used for jaw adductor attachment; a supratemporal opening and an infratemporal opening

EURYAPSID: having only a single temporal bone opening above the squamosal and postorbital bone; the supratemporal opening of a diapsid condition

HYPERDACTYLY: a condition whereby the number of digits is increased above the normal five to create a wing

HYPERPHALANGY: a condition whereby the number of phalanges is increased in each digit

INIA TYPE: ichthyosaurs with a tunalike tail fin and possible carangiform swimming or forelimb flyer

NEOCERATODUS TYPE: ichthyosaurs with undulating tails and forelimb wings

Ichthyosaurs were the most marine-adapted type of all the reptiles. When they first make their appearance in the fossil record in the Triassic, they are already recognizable as ichthyosaurs adapted to an aquatic existence. For this reason, their ancestry has remained a mystery since their discovery in the eighteenth century. Ichthyosaurs ranged in size from less than a meter to over ten meters in length. Early ichthyosaurs had already modified their forelimbs and hindlimbs into winglike structures. The limbs in ichthyosaurs had hyperphalangeal conditions, whereby there was an increase in the usual number of phalanges in each finger. Some ichthyosaurs expanded the width of the wing by adding extra rows of fingers, a condition known as hyperdactyly. The tails had reevolved a fin that either extended from the middorsal surface to the midventral surface or formed a semilunate tail. In these ichthyosaurs, the body plan already was porpoiselike, with a barrel-shaped thorax and tapering tail. Along these lines, icthyosaurs reevolved a dorsal fin. The skull, with its beaklike rostrum, had a narrow snout with large orbits, with sclerotic plates for maintaining the shape of the eyes. The nostrils had migrated backward to lie in front of the orbits and the temporal region was reduced. The skull behind the large eyes was much reduced. The ichthyosaurs retained one large temporal fenestra (bone opening) that housed the pseudotemporalis muscle. The other main jaw adductor, the pterygoideus, originated on the palate. Based upon the temporal fenestral pattern, these forms were classified as either their own class of reptiles or were considered to be a member of the Euryapsida. Evidence from the skull and reproductive strategy point to another ancestry. The ichthyosaur skull shows the loss of the lower temporal opening of the diapsid skull condition. In addition, ichthyosaurs were live bearers of their young, with a placenta-like structure. The only reptilian group with the loss of the lower temporal fenestra and loss of the eggshell is the diapsid Lepidosauria. All other reptilian groups use the eggshell for the main source of cal-

Ichthyosaur Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Subphylum: Craniata
Class: Reptilia
Subclass: Lepidosauria
Order: Ichthyopterygia
Family: Ophthalmosauria
Genus and species: Ophthalmosaurus icenicus
Geographical location: Oceans of the Mesozoic Era
Habitat: Marine
Gestational period: Unknown
Life span: Unknown
Special anatomy: Limbs transformed to flippers (wings) that employ hyperphalangy to elongate flipper; reevolve dorsal fin and tail fluke in some; smooth skin without scales; rostrum elongate with conical labyrinthodont teeth; live-bearing

cium for the skeletal development of the embryo, and thus the eggshell cannot be eliminated in their reproductive cycle.

Types of Ichthyosaurs
Ichthyosaurs are typed according to their mode of locomotion or by the morphology and shape of the pectoral flippers. The *Neoceratodus* type, or lungfish type, is so called because their straight tails resembled the tails of lungfish. These types had equally sized pectoral and pelvic flippers. It is considered that these forms had a flexible body with some degree of tail undulation possible for locomotion. The winglike forelimbs, with their hyperphalangy condition, gave them a hydrodynamic shape, and may have been their main propulsion system, acting as wings. Jurassic ichthyosaurs saw the development of a tunalike semilunate tail fin. These types, known as *Inia* type, named after the Amazon dolphin, were considered to be faster and more maneuverable swimmers than the *Neoceratodus* type. The hind limbs are reduced in these forms, and it is considered by some that the forelimbs were used as wings and the tail was used as a steering device. Others consider that the semilunate tail was used in a form of swimming used by tunas, known as carangiform swimming, using rapid movements of the tail. The vertebral column here extended into the lower lobe of the tail. A cartilage ray extended into the leading edge of the upper lobe of the tail, as seen in beautifully preserved tail found in the upper Jurassic deposits around Solnhofen, Germany. These forms also had a well-developed dorsal fin to aid in the prevention of rolling during swimming. It is thought that these ichthyosaurs had a more rigid body and thus had less drag on the body during swimming. Another ichthyosaur form, the *Leptopterygius* type, had well-developed hind limb flippers and pelvic girdle, and slightly reduced pectoral flippers. Undulation of the tail was con-

Image Not Available

sidered the main propulsion system of these ichthyosaurs. Finally, in the *Mixosaurus* type, undulation of the body seems to have been the mode of locomotion. In this body form, a series of elongated neural spines supported the tail fin. There seem to be two opposing views of ichthyosaur swimming speed and prey capture. Some authors believe that ichthyosaurs were high-speed swimmers, while others feel that ichthyosaurs were slower moving but highly maneuverable, and perhaps capable of short, high-speed swimming bursts.

Much is known about the diet of ichthyosaurs through the preservation of stomach contents. Many ichthyosaur species relied heavily on squid and, to a lesser degree, fish. There are reports of pterosaur remains preserved in the guts of ichthyosaurs as well.

Surprisingly, much is also known concerning the reproductive habits of ichthyosaurs. Because of their wing limbs and their round-girthed bodies, it is unlikely that ichthyosaurs came out of the water. How then did they give birth? The answer to this question lay in some of the most spectacular fossils of ichthyosaurs housed in the Stuttgart Museum in Germany. Female ichthyosaurs were preserved in the act of giving birth, whether from problems arising in the birthing process or possibly from poisonous dinoflagellate blooms that killed the ichthyosaurs during the birthing process. In some of these fossils the preserved offspring can be seen lying in a placenta-like structure expelled from the female's body. Other baby ichthyosaurs are often seen in the abdominal area of the ichthyosaur, and were previously thought to be the result of cannibalism. However, it is more likely that these were developing fetuses.

IMMUNE SYSTEM

Type of animal science: Physiology
Fields of study: Cell biology, immunology, pathology

The immune system distinguishes "self" from "nonself" in the body, fighting off foreign invaders such as bacteria, viruses, and parasites. It works through the production of proteins called antibodies, and of cells that recognize and kill foreign pathogens.

Principal Terms

ANTIBODY: protein produced by lymphocytes, with specificity for a particular antigen

ANTIGEN: chemical that stimulates the immune system to respond in a very specific manner

CELL-MEDIATED IMMUNITY: production of lymphocytes that specifically kill cells with foreign antigens on their surfaces

HUMORAL IMMUNITY: production of antibodies specifically reactive against foreign antigens carried in body fluids (humors)

LYMPHOCYTE: white blood cell that produces either cell-mediated or humoral immunity in response to foreign antigens

MACROPHAGE: mature phagocytic cell that works with lymphocytes in destroying foreign antigens

An animal must keep itself distinct from its environment, recognizing its own tissues and keeping them from being invaded or mixed with tissues of other organisms. There are two types of protection used by animals in keeping out invaders and resisting foreign substances, nonspecific and specific defenses. In both types, the body distinguishes between cells that belong to the animal, which are "self," and anything that does not belong, or "nonself."

Nonspecific Defenses

Even animals as primitive as sponges have the ability to recognize and maintain self-integrity. Scientists have broken apart two different sponges of the same species in a blender, intermixing the separated cells in a dish. Cells crawled away from nonself cells and toward self cells, reaggregating into clusters of organized tissues containing cells of only one particular individual. Phagocytic cells that engulf and destroy foreign invaders were first identified by a scientist who had impaled a starfish larva on a thorn. He observed that, over time, large cells moved to surround the thorn, apparently trying to engulf and destroy it, recognizing it as nonself. Even earthworms have the ability to recognize and reject skin grafts from other individuals. If the graft comes from another worm of the same population, the skin is rejected in about eight months, but rejection of skin from a worm of a different population occurs in two weeks. Phagocytic cells in earthworms have immunological memory, enabling a worm to reject a second transplant from the same foreign source in only a few days.

Barriers, chemicals, and phagocytic cells are nonspecific protective mechanisms, which do not distinguish among different kinds of invaders. Tough outer coverings such as skin, hide, scales, feathers, or fur provide surface barriers. Nonspecific defenses also include secretions of mucus, sweat, tears, saliva, stomach acid, and urine, as well as body-fluid molecules, such as complement and interferon. Damaged tissues or bacterial invaders signal other cells to produce inflammation, a nonspecific response characterized by heat, redness, swelling, and pain. Cellular defenses associated with inflammation include phagocytes such as neutrophils and macrophages, which engulf and digest bacteria and debris, and natural killer cells, which destroy cancer cells or virally infected cells by poking holes in them.

Immunity

The only specific defense in vertebrates is provided by the immune system, in which the component parts react against particular antigens on invaders, such as individual strains of bacteria or types of viruses. This more sophisticated protection is produced by lymphocytes that provide either cell-mediated or humoral immunity against particular antigens. Cell-mediated immunity depends on T lymphocytes (T cells) that become mature as they pass through the thymus, from which they get the "T" of their name. Humoral immunity is the function of antibodies, proteins released by B lymphocytes (B cells) that have matured and developed into plasma cells. The B lymphocytes reach maturity in the bursa of Fabricius in birds, where they were first recognized and from which they were named. Other vertebrates lack the bursa of Fabricius, and B cells mature in the bone marrow instead, so the name "B lymphocyte" still applies.

Antigen molecules are usually proteins or glycoproteins (proteins with sugars attached) that generate either an antibody response or a cellular immune response when they are foreign to the responding animal. So-called self antigens are molecules on cell membranes that identify the cells as belonging to the animal itself. An animal would not normally produce an immune response against its own antigens, but the same antigens would generate an immune response if placed in another animal to whom they were foreign. These antigens are the means by which self and nonself distinctions are made by the immune system, so the system can determine whether to ignore cells or attack them. Occasionally, self antigens, for some reason, are no longer recognized by the animal's immune system, and are attacked as if they were foreign. This causes an autoimmune disease, where the immune system destroys the body's own tissues.

Scientific understanding of how the immune system functions is largely dependent on work done using laboratory animals, including rabbits,

Five Classes of Antibodies

IgM is produced first in a response to foreign antigen, but its concentration declines rapidly. With five Y-shaped monomer subunits forming a pentamer structure, IgM is very effective in binding many copies of the same antigen and agglutinating them, but is too big to cross the placenta.

IgG is the most abundant class of antibodies in circulating blood, a monomer capable of passing through vessel walls to protect cells and tissues. In some species, including humans, it crosses the placenta to pass on the mother's immune protection to the fetus. Produced after IgM in an immune response, it is much more effective against bacteria, viruses, and toxins.

IgA is secreted as a dimer (two subunits) into milk, sweat, saliva, and tears. It is especially important in colostrum, the secretion before milk production begins that is the only way some newborn animals receive their mother's antibodies. IgA prevents bacteria and viruses from binding to epithelial cell surfaces, especially in the digestive tract.

IgE antibodies bind to the surfaces of mast cells and basophils with the arms of the Y-shaped monomer extended. Foreign antigens bind to the ends of the Y arms and trigger these cells to release histamine and other chemicals that cause the inflammation of allergy. IgE is also the antibody that attacks parasites inside the body, such as worms.

IgD molecules are monomers located mainly on the surfaces of B cells, apparently acting as receptors for the antigen that is recognized by each B cell and triggers its activation.

mice, and hamsters. Laboratory mice have been highly inbred into strains where all the animals are genetically identical and their genes and antigens are well known. Studies on these mice have been essential in determining how the immune system normally works, and how it fails to work in autoimmune diseases and the inability to prevent cancer cells from proliferating.

Antigen Presentation and Receptors

Central to the functioning of the immune system in mammals is a system of genes called the major histocompatibility complex (MHC). These genes encode a collection of cell-surface glycoproteins that are the self antigens by which the immune system recognizes its own body cells. Class I MHC molecules are expressed on the surfaces of all nucleated cells, while Class II MHC markers are produced only by specialized cells, including cells of the thymus, B lymphocytes, macrophages, and activated T lymphocytes. Both Class I and Class II MHC molecules identify the cells bearing them as self, and these also serve as the context in which the immune system recognizes foreign antigens that are presented on the cell surface. Cells with self antigens are tolerated by the immune response of that individual animal, while cells that show foreign antigens are attacked and destroyed. Rejection of a graft or transplanted organ is reduced with more closely matched tissues, which are better tolerated by the immune system.

When bacteria evade protective barriers and chemicals to enter an animal's body, the animal's macrophages attack, engulfing and digesting the invaders. One bacterium may have thousands of different antigenic segments that can be recognized on its surface or inside the cell. Small parts of these digested cells, the individual antigens, are joined to the macrophage's newly formed MHC Class I and Class II before they are exposed on the cell surface. The foreign antigens fit into a space or pocket within the MHC molecule and are recognized by T cells that have the same MHC molecules and can respond specifically to the foreign antigen. Cytotoxic T cells (T) react to antigens held in the pocket of a Class I molecule, while helper T cells (T) respond to those presented by Class II molecules. T cells are the agents of cellular immunity, producing perforin molecules that puncture and kill cells bearing the foreign antigen against which the T cells are specific. T cells, when activated by encountering their specific antigens presented with Class II molecules, release cytokines that help to activate both T cells and B lymphocytes. Activated B cells divide to produce memory B cells and lymphocytes that mature into plasma cells, which secrete about two thousand antibody molecules per second over their active lifespan of four or five days.

Both T and B lymphocytes can react with their specific foreign antigens because the antigen-MHC complex binds to receptor molecules on the lymphocyte surfaces. Each clone of lymphocytes has the genetic ability to respond to a particular shape that fits its receptors. There may be millions of different receptors among the lymphocytes of a single animal, capable of binding millions of different antigens, even artificial chemicals not existing in nature. This enormous variability in response capability makes the immune system of each animal protective against many kinds of foreign invaders. Since each individual has its own set of immune responses, a population is less likely to have all its members die in an epidemic. Certain animals will be more resistant to the pathogens, so some will survive to reproduce and keep the population from extinction.

Primary and Secondary Immune Responses

When a foreign antigen is encountered by an animal for the first time, both T and B cells that can bind the antigen are activated, but not immediately. In a series of reactions, macrophages first break down the antigen-bearing cell, processing and presenting the antigen on its surface with MHC. The T cell specific to that antigen then encounters the antigen-MHC complex on the macrophage and divides to produce a clone of memory T cells and a clone of effector (activated) T cells. Activated T cells release cytokines that activate T and B cells so that they can attack the same foreign antigen. The first encounter with antigen produces a slow primary response, taking more than a week to reach peak effectiveness. During the time needed to generate this response, pathogenic bacteria or viruses can produce disease in the animal under attack. The memory T and memory B cells remain alive but inactive until the same foreign antigen is encountered again, even years later. The secondary response that results immediately when these memory cells are activated occurs so quickly that the disease process does not recur.

The importance of the immune system is seen in humans who lack its function, those with acquired immunodeficiency syndrome (AIDS). Human immunodeficiency virus (HIV) is the causative agent of AIDS, and is similar to viruses that attack other species in the same way. Most who die with AIDS really succumb to one of many opportunistic infections that cause diseases in HIV-positive individuals, but which are eradicated by the immune system in normal individuals.

Paul, William E. *Fundamental Immunology*. 4th ed. Philadelphia: Lippincott-Raven, 1999. Despite the name, this medical text covers all aspects of human immune function in over 1,500 pages. Regulation of the immune system and its functions in fighting disease are discussed extensively.

Roitt, Ivan, Jonathan Brostoff, and David Male. *Immunology*. 5th ed. Philadelphia: C. V. Mosby, 1998. Both vertebrate and invertebrate immune functions are discussed in Chapter 15, "Evolution of Immunity." Good color photos and diagrams help explain cellular and molecular aspects of immunology.

Staines, Norman, Jonathan Brostoff, and Keith James. *Introducing Immunology*. 2d ed. St. Louis: C. V. Mosby, 1993. For readers with no previous knowledge of immunology, this primer covers the complex language without using jargon and explains the information clearly.

IMPRINTING

Type of animal science: Behavior
Fields of study: Ethology, neurobiology, zoology

Imprinting is the process of very rapid attachment between parents and offspring during a brief period that alters the offspring's behavior permanently. Imprinting involves behavior that is necessary to the survival of the animal under natural conditions.

Principal Terms

CONSPECIFICS: animals of the same species

CRITICAL PERIOD: a very brief period of time in the development of an animal during which certain experiences must be undergone; the effects of such experiences are permanent

INNATE: inborn, unchangeable

NIDIFUGOUS BIRDS: ground-nesting birds

PRECOCIAL: possessing, as infants, well-developed sense organs, the capability of locomotion, and the ability to contribute substantially to the establishment of bonds between them and their parents

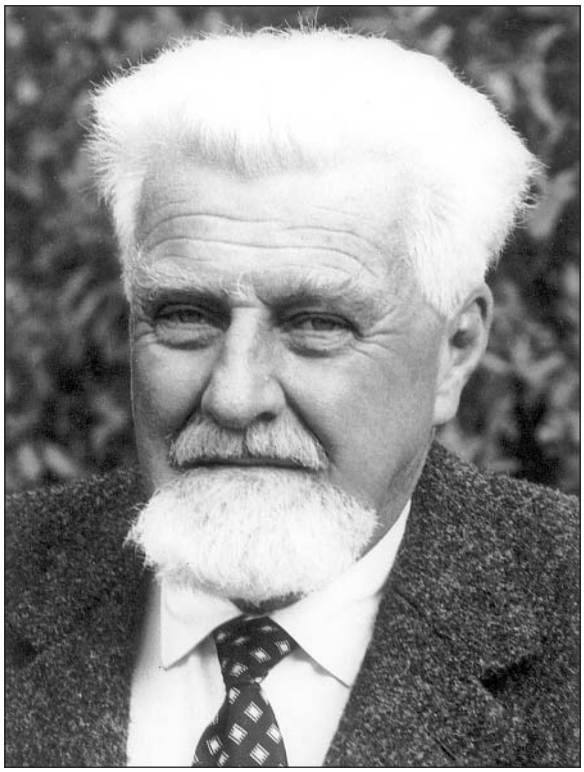
RELEASER: a stimulus that releases a sequence of reflexes that always occur in the same order and manner

SCHEMA (pl. SCHEMATA): an innate releasing mechanism; a neural process that programs an animal for receiving a particular sign stimulus and causes a specific behavioral response

SENSITIVE PERIOD: a period during which a given event produces a stronger effect on development or in which a given effect can be produced more rapidly than it can earlier or later

Imprinting is the process of very rapid attachment between parents and offspring, during a brief sensitive period, that alters the offspring's behavior permanently. This period is found only in precocial birds and a very few mammals. The significance of imprinting is the development of behavioral patterns that will enable the animal, as it matures, to recognize its own species (for future mating), to socialize and cooperate with other conspecifics, and to locate food and territory.

Konrad Lorenz, the first scientist to investigate the phenomenon of imprinting thoroughly, drew attention to the process by which young duck-



Konrad Lorenz's studies of imprinting in young animals contributed to his sharing the Nobel Prize in Physiology or Medicine in 1973. (Nobel Foundation)

Konrad Lorenz

Born: November 7, 1903; Vienna, Austria
Died: February 27, 1989; Altenburg, Austria
Fields of study: Ethology, physiology, zoology
Contribution: Lorenz, the founder of ethology, developed a deep understanding of the behavior patterns in animals, notably imprinting in young birds.

Konrad Lorenz, the son of an orthopedic surgeon, received a medical degree in 1928 and a Ph.D. in zoology in 1933. Both were earned at the University of Vienna. Lorenz studied animal behavior by means of comparative zoological methods, a field now known as ethology. Many of his observations came from establishing and watching colonies of birds, particularly the jackdaw and greylag goose. He published numerous papers based on his observations of these birds.

In the mid 1930's, Lorenz reported his findings about learning behavior in young ducklings and goslings. The survival of a young bird requires an extremely rapid establishment of the behavioral bond between it and a parent. Lorenz discovered that a newly hatched bird learns within a few hours to follow real or foster parents. This process, known as imprinting, may occur with a human, or even an inanimate object, if the bird's parent is not present. Although the behavior itself is genetically determined, the bird learns the object. Through imprinting, many young animals follow the first moving object they encounter.

To demonstrate the process of imprinting, Lorenz imitated a mother duck's quacking sounds in the presence of newly hatched mallard ducklings. The ducklings responded to Lorenz as their mother and followed him accordingly. After numerous studies, Lorenz concluded that when a young bird is imprinted to a member of another species, the imprinted bird will adjust its own functional cycles to that of its adopted parent. Once accomplished, the behavior pattern is very stable and may be irreversible in some cases.

In 1937, Lorenz taught comparative anatomy and animal psychology at the University of Vienna and became the coeditor of the leading journal for ethology. After World War II, Lorenz headed the Institute of Comparative Ethology at Altenberg, Austria. From 1961 to 1973, he served as the director of the Max Planck Institute for Behavior Physiology in Seewiesen, Austria. Lorenz developed the concepts of animal behavior that led to the modern scientific understanding of how behavioral patterns evolve in a species. He advanced the concepts of how these patterns develop and mature during the lifetime of an individual organism.

In 1963, Lorenz published his book *Das sogenannte Böse* (1963; *On Aggression*, 1966), in which he argued that the aggressive behavior in humans may be modified or channeled, but in other animals, it is primarily survival motivated. Based on his insights and discoveries associated with animal behavioral patterns, Lorenz shared the 1973 Nobel Prize in Physiology or Medicine with Karl von Frisch and Nikolaas Tinbergen.

In 1973, Lorenz was appointed as the director of the department of animal sociology at the Institute for Comparative Ethology of the Austrian Academy of Sciences in Altenberg, where he continued to apply his ideas about the behavior of humans as members of a social species. In 1978, he published *Vergliechende Verhaltensforschung: Grundlagen der Ethologie* (*The Foundations of Ethology*, 1981), a comprehensive review and assessment of his major contributions to science.

—Alvin K. Benson

lings and goslings follow the parent soon after hatching. By doing this, the young become sensitive to the visual and auditory stimulus pattern presented by the parent. This process is remarkably confirmed when a young bird fostered to a parent of another species establishes a permanent bond with the foster species and excludes members of the bird's own kind. The bond is so lasting that Lorenz called the process which gives rise to it *Prägung*, or imprinting. This single experience imprints the pertinent object of the infantile instinctive behavior patterns in a young bird that does not recognize the object instinctively. The object can be imprinted only during a quite definite period in the bird's life. From this observation, Lorenz set forth two principles of imprinting: First, that there is a critical time period in which the young offspring must form the attachment and after which no imprinting stimulus is effective, and second, that once formed, the attachment to a specific object, whether it be to its parent, a person, or an inanimate object, is permanent and irreversible. Several ethologists who have since studied imprinting do not totally accept Lorenz's conclusions that imprinting is irreversible and unchangeable, believing instead that the "critical period" is more flexible and is not necessarily dictated by inheritance. Thus, the term, "sensitive period" has gained popularity and become more widely accepted.

The Imprinting Process

Imprinting processes occurring during this sensitive period are basically different from the processes that occur after the sensitive period is over. The differences can be observed both in the immediate behavior and in the long-range effects of these experiences. The order in which these imprinting events occur has little relevance to the sequence in which they are later manifested. In jackdaws, the sensitive period for sexual imprinting comes well before the sensitive period for imprinting of the approach and follow responses. In this bird, sexual imprinting occurs while the nestling sits in the nest still half-naked, showing no responses to conspecifics other than that of gaping at its parents when they arrive to feed it. The sensitive period for imprinting of following behavior occurs immediately before fledgling. The effect of sexual imprinting, however, does not become obvious until two years later, whereas the following response is observable only a few days after imprinting.

A variety of stimuli may elicit the imprinting responses; most responses are to either auditory or visual stimuli. Some authors have suggested that auditory imprinting is especially important in the song-learning of birds. In many species, the song is completely innate, while in others it is learned; in still others, a combination of learned and innate factors is necessary. In some species where there are learned components, there seems to be a sensitive or receptive period during which songs are normally learned permanently and irreversibly. Lorenz found that ducklings respond to both visual and auditory stimuli but that the strongest responses are to their mother's call. More often, however, when both auditory and visual cues are provided, the extent of successful imprinting exceeds that attained with either stimulus provided singly. Not to be ignored are those cases in which the olfactory sense plays a role in imprinting, particularly in those animals with high olfactory acuity. In these animals, the olfactory sense may regulate relationships between members of the same species (as in sexual behavior), promote predator or prey recognition, and help identify food or territory when conspicuous visual aspects are absent.

Experimenting with Imprinting

The law of effort says that the more energy a bird expends during the primary attachment formation, the stronger the imprinting will be. To observe this effect, researchers may manipulate the energy expenditure in at least three ways: by using a moving object rather than a nonmoving one, by providing continuous rather than spaced training sessions with the object being imprinted, and by having longer training sessions using a stimulus that moves around the arena more quickly. Ducklings placed in a runway with ten-centimeter hurdles were forced to exert more effort than animals that followed an object in an ordinary runway; it was found that birds compelled to go over the hurdles in order to keep up with the moving model later achieved higher imprinting scores than did control birds.

Other experiments seem to indicate that movement by the subject is not always necessary for imprinting to take place. In one such study, ducklings were exposed to a moving object but were not allowed to follow it, while control subjects were permitted to follow the object. Both experimental and control animals exhibited poor responses to the new object. The role of movement in imprinting was also tested by placing ducklings in wooden stocks that restricted movement, then exposing them individually either to a moving object or to a stationary one. Despite the restriction of their movement, the animals became imprinted. The way the object was moved made no difference to the extent of approach and follow-on testing, but ducklings that had been exposed to a stationary object did not follow as well. This experiment showed that, while movement of the subject was immaterial, movement of the object was important for imprinting. In most cases, birds that expend more energy are more successfully imprinted.

Recognition and discrimination are the primary means to determine whether imprinting has occurred: If a bird is given a choice between known and unknown figures, it will choose the known. This is considered the standard test for imprinting; birds will usually run to their mother. Observations other than recognition and discrimination may also be worthwhile in assessing the amount of imprinting. One of these is distress at separation. Young chicks and ducklings, when separated from the mother or companions, make specific distinctive calls. Another evaluation can be made upon recognition at reunion: Approach and follow responses are clearly shown by birds that, upon hatching, are visually exposed to that figure. When a chick or duckling is placed in a runway with a moving object and is left there for a number of hours or even days, it will eventually stop following the object and otherwise occupy itself, maybe eating or drinking or wandering about. Disruption of the familiar, however—by a noise, by placing a piece of paper on one of the runway walls, or by the appearance of a strange object—will cause the bird to run to the familiar object, where it will remain for a time.

Theories to explain the ending of the ability to imprint can be divided into four categories. The first category is end of sensitivity because of maturation; that is, the tendency to approach and follow naturally decreases as the animal ages, and this lessened tendency is internally determined, rather than being caused by any impact of experiences. The second category is inhibition through socialization. Evidence so far presented indicates that the sensitive period for imprinting is likely to continue until a firm imprinting experience has occurred. Once imprinting of the approach and follow responses to a particular stimulus has occurred, it tends to inhibit approach and imprinting to new figures. Third, growth of timidity or fear responses eventually represses approach and follow responses. This is perhaps the most popular theory. Last, the ending of imprinting may be shown by an end to varied, restless activity that is not performed to achieve a goal.

Innate Versus Learned Behavior

That imprinting behavior occurs is not debatable, but controversy has arisen pitting Lorenz and his followers, who believe that the process is wholly innate, against a host of later investigators who conclude that imprinting is actually a form of learning. Those who say that imprinting is innate base their opinion on observations that the drive to imprint is strikingly different from other instinctive behavior patterns, whose releasing schemata are not innately determined but are acquired like conditioned reflexes. Lorenz states that imprinting is different from learning in that imprinting can occur only during a very definite, and perhaps short, period in the animal's life and, therefore, is dependent on a specific physiological developmental condition in the young bird. He further asserts that imprinted recognition, even after the critical period, is the same as innate behavior because the recognition response cannot be forgotten (as opposed to learned processes, which can be forgotten). Others, however, believe that imprinting involves a behavior that is absolutely necessary for the survival of the animal under normal conditions. In the case of both social and food imprinting, this is clear. The desire to follow the parent or to want to eat a particular food (as well as to learn what objects are the targets) motivates these behaviors. The urge to learn these objects is so strong that the associated processes which fulfill this learning are contradictory to those associations usually involved in this rote-type learning.

If imprinting is a learned behavior, then can it be considered conditioning? Conditioning involves the building of associations between stimuli and responses. A wide variety of stimuli may initiate the imprinting process by innate unconditioned approach responses. The particular stimulus continues to elicit filial responses, but eventually any new stimuli begin to be ignored and later even feared. There is no selective pairing of stimuli and responses, as in conditioning. In imprinting, the primary bond between stimuli and responses continues to be strengthened and becomes exclusive.

The Study of Imprinting

The earliest documentation of the imprinting process was by the seventh century English monk Saint Cuthbert, who spoke of it as "object fixation." Sigmund Freud later discovered the process independently of ethologists, but several ethologists take credit for its discovery and subsequent investigations. Most means of study practiced by ethologists investigating this phenomenon have been patterned after techniques employed by Eckhard Hess. Experiments have usually been conducted using models that do not closely resemble any real animals, let alone the parent model. Each subject is individually "trained" with a particular figure. Then, all the subjects are individually presented with a situation in which they can choose between two figures. Imprinting has occurred when an animal is drawn to the figure that is familiar. (If only one figure were used to train all the animals, a later choice test would be invalid because, if the figure was favored on the test, the investigator would not know whether the attraction was caused by imprinting or by some other impression of the figure.) Earliest observations showed that moving animals, persons, or even inanimate objects could evoke approach and follow responses in newly hatched nidifugous birds. Goslings, for example, have been found to follow people if the mother goose is absent. Incubator-hatched ducklings will follow anybody who encourages them to do so by tapping the ground and/or calling while moving away from them.

Another much-copied method that Hess used employs ducklings hatched in the dark and kept isolated until trained to the test stimulus. They then are placed on a circular track and allowed to follow a moving, sound-producing object around the runway for a determined time or distance. Later, the ducklings are tested for adequacy of the imprinting by allowing them to choose between two models to see which is approached. It is important to know what external stimuli arouse the strongest following response. The stimulus may be size of the object: If the object is too large, the duckling will flee. The duckling will simply peck at an object that is too small. Another factor is color; blue objects are the first choice for chicks, followed by red, then yellow. A third aspect is shape; strangely, adding immovable wings, tail, and head to a sphere actually reduces its effectiveness in generating a response.

Early investigators attempted to model releasers after parent birds. They discovered that a noisy moving object tended to elicit stronger responses than a silent one. Approach and follow responses in ducklings succeed intermittent noises, but to be most effective the noises should be simple, rhythmical, and monosyllabic, and given in rapid succession. Such stimuli are, overall, quicker than visual stimuli in eliciting approach from ducklings. In fact, ducklings that fail to imprint to moving models occasionally do imprint to noise-making ones—enough so that they will continue to follow its movement even when the noise ceases. Generally speaking, it is necessary for sound to accompany visual stimuli, though ducklings and goslings do not appear to imprint on sound alone.

Some scientists wonder whether all this laboratory study has really been relevant to the study of natural imprinting. Laboratory procedures are undoubtedly useful in helping to determine the behaviors of young animals; however, because the animals are given such an overwhelming number of inappropriate stimuli, it may be difficult to assess how the animal would react under normal conditions. Observations of animals in their natural settings are difficult to make and analyze, but the known data reveal several differences from laboratory tests. For example, hatched ducklings normally stay in the nest with the female mallard long past the earlier laboratory-assigned critical period, and, as a result, they are both visually and auditorially attached to the parent by the time they leave the nest. This enhances their ability to survive on their own. Continued investigation into imprinting must occur, but it should take place in an animal's natural setting.

The Complexity of Imprinted Behaviors

The imprinting process has a much broader significance for the animal than merely giving it the tendency to follow moving objects. Behaviors usually associated with imprinting are following and approach responses, sexual identification, species recognition, and socialization among conspecifics. Following behavior is far from a simple behavior; there are many degrees, from close, nonfearful following, through hesitant following mixed with fear responses, to strong escape behavior in which only a minimum of following can be observed. Following can also be balanced by aggressive behavior, and the actual behavior of the young bird is largely determined by the interplay between these competing tendencies. Following behavior is important to those duck species that build their nests at a distance from the water, the eventual home of the birds; mother and young may move to the water within several weeks of hatching. The use of species-specific visual or auditory signals in imprinting may enable young birds to follow the mother successfully through dense vegetation from the nest to the water. When the young are ready to leave the nest, generally located several feet above the ground in a tree hole or other suitable site in a pond or swamp, the mother goes down to the water and calls her ducklings. In response to the call, the ducklings jump to the nest opening and then down to the water to follow the mother. The same imprinting patterns may also aid the ducklings in avoiding predators. Quickly following the mother to safety in a few seconds between the time the predator is sighted and an attack may mean the difference between life and death.

Imprinting may serve as a species-identifying mechanism and, even more narrowly, as a species-isolating mechanism. The sexual preferences of birds have been shown, by appropriate exposure to an imprinting stimulus and later testing, to be imprinted to stimuli to which they were exposed. For virtually all species in nature, encounters with birds of other species during the first few days or even weeks after hatching are limited; this alone ensures that young birds will imprint on members of their own species and that when, as mature adults, they begin to engage in reproductive activities they will court only conspecifics. Therefore, imprinting helps guarantee that reproductive energy investments and gametes are not wasted on nonproductive mating endeavors. The overall recognition of conspecifics that can occur as a result of imprinting may also be important for the socialization of young birds and for general cooperation of conspecifics in a social organization. Associating with conspecifics, in turn, may be a significant means of increasing survival, by aiding in processes such as locating food, finding shelter, and migrating.

The aim of this book, translated from German, is to discuss the framework of ethology—its history as perceived by one of the pioneers in the field. Only students with advanced ethological knowledge could truly appreciate the complex concepts that Lorenz sets forth. Bibliography.

_______. *Studies in Animal and Human Behavior*. Translated by Robert Martin. Vol. 1. Cambridge, Mass.: Harvard University Press, 1970. This is the first volume of the collected papers of Lorenz. Written during the years 1931 to 1942, these six papers provide a rich source of information on the development of his ethological approach. Lorenz defines a range of behavioral acts: innate, instinctive, conditioned, and insight-controlled. He then analyzes their manner of interrelation in the overall behavior of a species of animal.

Sluckin, W. *Imprinting and Early Learning*. 2d ed. Chicago: Aldine, 1973. A brief but good review of early historical literature and easily understood descriptions of the full range of experiments that have been done. Imprinting is considered side by side with related concepts and empirical studies. The second edition expands the first (1964) by adding more up-to-date developments in the field. Complete bibliographical references are cited at the conclusion of the book.

INFANTICIDE

Types of animal science: Behavior, evolution
Fields of study: Ecology, ethology, wildlife ecology, zoology

Infanticide, the killing of immature members of the same species, is one of the more disturbing phenomena seen in animals, including humans. However, it follows from the evolutionary logic of individuals striving to maximize reproductive success.

Principal Terms

CONSPECIFIC: a member of the same species
GENERA: plural of genus, a grouping of animals above the species level
GESTATION: the period when the young are nourished within the mother's body; pregnancy
LACTATION: the period when mammal mothers produce milk to nourish their infants
OVICIDE: killing of fertilized eggs
RAPTORS: predatory birds such as hawks and eagles
SIBLICIDE: infanticide committed by the siblings of the individual killed

Infanticide is the intentional killing of dependent immatures by a member of the same species, or a conspecific. Victims may be as young as fertilized eggs or nearing independence from their parents. The infanticidal attackers may be strangers or relatives. The motive is always selfish competition, but sometimes the young are direct competitors and sometimes indirect competitors with the killers. Infanticide occurs in every class of animal, but mammals and birds seem to have evolved the most pervasive and pernicious form, sexually selected infanticide. Wherever it is seen, infanticide reveals the darker side of evolutionary adaptation. There are three scientific explanations for infanticide, each of which applies to particular circumstances.

Infanticide by Genetic Relatives

The first circumstance occurs when related individuals kill dependent young. For example, extreme sibling rivalry occurs in spotted hyenas (*Crocuta crocuta*) and many raptors. The unpredictability of resources or extreme competition for parental care may lead siblings to fight to the death in the den or nest. Even parents may act infanticidally. When parents have larger numbers of offspring than they can feed, the parents themselves may neglect or inflict damage on the smallest or least vigorous young, so as to reduce the number of offspring and increase each survivor's chances of success. Sibling rivalry and parental neglect or abuse of young can lead to infanticide in extreme cases when resources, such as food or parental time and energy, are in short supply. The brutal logic of natural selection shows that selfishness and lethal competition can divide even close kin. However, in most animal species, unrelated individuals are more dangerous to the young.

Infanticide by Direct Competitors

The second circumstance in which infanticide arises is referred to as local resource competition. When immatures use resources that unrelated animals need, aggression may be severe and directed to killing the infants. All ages of infants are vulnerable, even independent juveniles. In the burying beetle (*Nicrophorus orbicollis*), male and female pairs compete for access to rotting meat in which to lay eggs. If defenders of such a resource are displaced by an intruding pair, the intruders proceed to kill and eat the eggs (ovicide) or larvae of the previous pair. Similarly, many birds, such as black-and-white casqued hornbills (*Bycanistes subcylindricus*), compete for rare tree hole nesting sites. If adults encounter another nest with eggs in such a tree hole, they will roll these eggs out or crush them and lay their own eggs. Finally, cannibalism of unrelated young has been seen in many amphibians, fish, reptiles and even in chimpanzees. Stepchildren suffer much higher rates of severe neglect and homicide than a parent's biological children. All of these cases represent extreme competition where resources are scarce and vulnerable young are eliminated or eaten by unrelated killers. The behavior patterns seen in this type of infanticide often resemble predation, are directed at young of any age, and can be performed by adults of either sex.

Sexually Selected Infanticide

The third circumstance in which infanticide occurs is motivated by sexual competition among adults. In a wide range of mammals, including over twenty genera of primates, adult males will kill unrelated infants if they can then mate with the mother. The mother of that infant does not usually reject the infanticidal male even though he has inflicted a tremendous cost on her. Typically, it takes female mammals many months—even years—to nurse young to independence. During this period of infant dependency, the mother is generally physiologically incapable of reproducing. An infanticidal male benefits if he can cut short this period so that he can fertilize the female's next egg. Therefore, a successful infanticidal male eliminates another male's offspring and advances his own reproductive career. Sexually selected infanticide is not restricted to mammals, although the best-documented cases come from lions (*Panthera leo*), langur monkeys (*Semnopithecus entellus*), and rodents (order Sciurognathi). Some birds may also behave infanticidally. For example, the wattled jacana (*Jacana jacana*) shows a fascinating reversal. In this species, the adult females may commit ovicide and infanticide against unrelated young. Adult male jacanas incubate eggs on the nest and protect the young from predators, so females strive to monopolize the parental care donated by males. To do this, a female must eliminate the young of another female and lay her own eggs in the care of the male. Typically, the behavioral patterns seen in sexually selected infanticide differ from those in local resource competition. The young are virtually never eaten and permanent separation of mother and young is the primary goal—whereupon attacks usually cease.

Evolutionary Consequences of Infanticide

Infanticide is widespread and may reach high frequencies in certain species, but it is not universal. Siblicide and parental neglect are found in a very restricted subset of birds and very few mammals. Local resource competition is more common, found in most classes of animals. Finally, sexually selected infanticide is most common in mammals, but even here there are many orders of mammals that never display infanticide. Species that have a very long period of lactation relative to their gestation period are most vulnerable to sexually selected infanticide. The reason for this is that infanticidal attacks are risky because of maternal defense and counterattacks by allies. Therefore, infanticidal behavior will only evolve when the males gain substantially by shortening lactational infertility of the mother.

Clearly, infants and their parents have a very strong motivation to avoid infanticide. Evolution has favored various mechanisms to reduce the risk. In general, infants avoid strangers, even in humans. In some primates, it seems that infants are born with unusual coat colorations that may impede males' efforts to determine which infants are theirs and which were fathered by other males. Parents are normally very protective of their young, both because of predators and because of the risk of attack by conspecifics. This parental protection is expressed through frequent proximity, carrying, and physical defense. One of the most fascinating consequences of a high risk of infanticide is the tendency for the father and mother to establish a long-lasting relationship whose primary benefit is protection of the young from conspecifics. This is seen in burying beetles and many primates. Alternatively, groups of mothers may cooperate in protection against infanticidal males, as in lions and langurs. Therefore, infanticide is one of the few evolutionary pressures that favors complex social relationships.

Bibliography

Butynski, T. M. "Harem-Male Replacement and Infanticide in the Blue Monkey (*Cercopithecus mitis stuhlmanni*) in the Kibale Forest, Uganda." *American Journal of Primatology* 3 (1982): 1-22. A study of infanticide by male monkeys of infants not their own.

Hausfater, Glenn, and Sarah Blaffer Hrdy, eds. *Infanticide: Comparative and Evolutionary Perspectives*. New York: Aldine, 1984. This was the first book that compiled a mass of evidence that sexually selected infanticide was a real strategy with important evolutionary consequences. Although many of its chapters are scholarly and rich in data, there are also several review chapters that synthesize information and can be understood by an educated lay reader. This book also tackles and lays to rest the historical debate over infanticide as a social pathology.

Parmigiani, Stefano, and Frederik S. vom Saal. *Infanticide and Parental Care*. Langhorne, Pa.: Harwood Academic Press, 1994. This volume spans a variety of animal species that display infanticide. In particular, it shows the intricacy of the behavioral mechanisms underlying infanticide in rodents. It also presents the best information on infanticide in lions. As always, primates are well-represented in this book aimed at a scientific audience.

Van Schaik, Carel P., and Charles H. Janson, eds. *Infanticide by Males and Its Implications*. New York: Cambridge University Press, 2000. This most recent compilation devotes most chapters to primates. It is aimed at the scientific audience, but also has some review chapters that are accessible to any educated reader. This book presents the state of the science in its most up-to-date form, debunking misconceptions about infanticide and making a strong case that infanticide is an evolutionary pressure of equal importance to predation.

INGESTION

Type of animal science: Physiology
Fields of study: Biochemistry, ecology, neurobiology

Ingestion is the process of taking food into the body. The animal kingdom possesses myriad strategies for this process, reflecting the diversity of available food sources and how they are utilized.

Principal Terms

CARNIVORE: any organism that eats animals or animal tissues

DETRITUS: small bits of dead matter derived from decay of plants and animals

HERBIVORE: any animal that eats plants or plant material

INVERTEBRATE: any animal that lacks a backbone

OMNIVORE: any animal that eats both plants and animals or their tissues

PARASITE: any organism that lives on or in other living organisms and obtains its food from them

PLANKTON: microscopic plants and animals that float in water

PREDATOR: any organism that kills another living organism to eat it

PROTOZOAN: a single-celled animal-like organism

SAPROVORE: any organism that consumes dead or decaying plant or animal matter

TAXONOMY: a classification scheme for organisms based primarily on structural similarities; taxonomic groups consist of genetically related animals

Ingestion is the process of taking food into the body to satisfy nutritional and energy needs. Although basic nutritional requirements are remarkably similar for all animals, mechanisms of ingestion are exceedingly diverse. This diversity stems from the varied nature of available food sources and the resulting behavioral adaptations and specific body forms required to procure adequate nutrition. Because it is convenient to classify feeding strategies by the type of food consumed, organisms are often described as herbivores, carnivores, omnivores, and saprovores. Although very descriptive, these terms alone are not sufficient to describe fully the feeding adaptations used by animals, especially when considering invertebrates, which make up more than 97 percent of all animal species. Accordingly, this section will expand on these ideas by further categorizing ingestion by the type, size, and consistency of food, while also describing behavioral adaptations that lead to ingestion.

Small Particle Ingestion

Numerous animals live exclusively on a diet of very small particles that include bacteria, algae, plankton, and detritus. Although most small-particle consumers are relatively small animals, they range from the tiniest animal-like organisms (protozoans) to the largest (whales). Many mechanisms have evolved to permit ingestion of small food particles. One common method is by endocytosis. During this process, the outer membrane of a cell surrounds a food particle and engulfs it within the cytoplasm, forming a food vacuole (a cellular organelle used for digestion). This mode of ingestion is best illustrated by protozoans. The amoeba, for example, uses pseudopodia (extensions of its cell membrane) to surround and then ingest prey. Paramecia use cilia (tiny hairlike processes on cell membranes that beat in a coordinated manner) to guide food particles into an oral region prior to ingestion by endocytosis.

Multicellular animals may also ingest small food particles by endocytosis. Sponges use flagella (motile, whiplike structures resembling long cilia) to aid in the gathering of small particles of food. The body cavity of sponges is lined with flagellated cells called choanocytes, or collar cells. The beating action of their flagella creates currents that move water through the body cavity, where food particles are removed and incorporated by the choanocytes.

Filter feeding is another strategy that is commonly used to obtain small bits of food. Most often cilia, mucus sheets, flagella, tentacles, and nets are used as filtering devices. Rotifers (small aquatic invertebrates), for example, use a special double-banded ciliary system to transport water and filter out suspended food particles, which are conducted to the mouth by a third set of cilia. In general, sessile (immobile) organisms (such as sponges, rotifers, and some oysters) are called filter feeders, because they must wait for food to come to them, then extract it from the surrounding medium.

Numerous free-moving animals also use filtering devices to obtain food. Sea cucumbers (animals related to starfish) live on the bottom of the seabed. By extending and periodically retracting sticky tentacles, they capture and ingest small food items. Clams, mussels, and some snails produce a sticky mucus that covers ciliated cells. The mucus traps fine suspended food particles, which are transported to the mouth by ciliary action. Mussels, for example, continuously pass water between their mucus-covered gill filaments for respiration, simultaneously trapping food particles. Similarly, herring and mackerel (fast-swimming fish) possess special structures called gill rakers, which act as sieves to catch plankton from water that continually passes over their gills for the process of respiration. Basking sharks and whale sharks also feed on plankton that is strained from water that enters their mouth and flows over their gills. Baleen whales use a filter consisting of a curtain of parallel filaments (called baleen) attached to the upper jaw to feed. These whales en-

Elephants use their trunks to bring food and water to their mouths. (Corbis) gulf a mouthful of water containing krill (small, shrimplike plankton) and use their tongue to force the water out, trapping krill in the hairlike edges of the baleen. The mouthful of krill is then swallowed. Flamingos feed in a similar manner. They use specially adapted beaks lined with filaments to strain plankton from the muddy bottoms of their aquatic habitat. Some fast-water caddis fly larvae spin tiny silk nets that are used to filter small food items. The nets are then periodically gleaned. Finally, spiders may be considered filter feeders because they use their webs to "filter" flying insects from their environment.

Large Item Ingestion

In contrast with small-particle consumers, numerous animals ingest large food items. Some of these organisms are saprovores, such as earthworms. These worms consume large masses of soil and dead leaves, from which they obtain usable organic matter. Some planarians (flatworms) extend a long extensible tube (called a pharynx) from their mouth to ingest decaying material. Other examples of saprovores include millipedes, wood-eating beetles, some sea cucumbers, many roundworms, and a few snails.

An extraordinary number of animals have adapted to eat plants. Eating plants requires special structures to free plant material for ingestion. Although invertebrates lack true teeth, they have other structures to obtain plants or plant parts. Snails have a unique structure in their mouth called a radula, which acts as a miniature rasping file that scrapes plant material from surfaces and rasps through vegetation. The freed plant material is then ingested. Sea urchins scrape algae by using a highly developed oral apparatus composed of five large pointed plates. Termites use strong jaws made of chitin, the hard structural component of their external skeleton, to cut tiny chunks of wood for ingestion.

Birds use horny beaks to obtain and ingest plant material. Cardinals and grosbeaks, for example, are well adapted to hull and then consume the nutritional portion of large seeds. Herbivorous mammals use specialized teeth to obtain and chew plant material. Rodents (such as beavers, porcupines, and mice), rabbits, and hares have chisel-like front teeth (called incisors) that are used to gnaw, slice, or pull off plant material. Other herbivorous mammals (including cows, sheep, deer, moose, elk, and giraffes) lack upper incisors and therefore use their lower incisors pressed against the roof of their mouth to pull off leaves. The ingested food is then chewed by grinding with premolars and molars.

In contrast to herbivores, many animals capture other animals and eat them. To be effective, these carnivorous predators must have appropriate behavioral adaptations to find and capture prey as well as specialized structures to seize and hold their victims. Jellyfish use tentacles that are equipped with stinging cells to grasp and subdue animals, whereas the tentacles of squid and octopuses have suction-cup-like structures to grasp and manipulate prey. The giant water bug is a carnivorous insect that hunts and captures small fish, relatively large prey for an insect. To do this, water bugs use their legs to seize and hold fish, and their piercing mouthparts to suck juices from their victims. Fish, amphibians, and reptiles have pointed teeth to seize and hold prey. It also is common for many of them to swallow their food whole. Snakes, for example, swallow whole items such as birds' eggs and small mammals. In addition, a snake's jaws are held together by elastic ligaments, permitting it to spread apart and ingest victims larger than its own head. Some large tropical snakes actually consume small pigs and deer. Chameleons and frogs swallow their prey whole, but in contrast to snakes, they use a long and sticky tongue that rapidly shoots out to capture insects. Some predatory carnivores (such as lions, tigers, bears, and dogs) have long, pointed, daggerlike teeth called canines to pierce and kill their prey. Carnivores also may have knifelike molars (called carnassials) that are used to slice flesh from bones. Carnivorous birds (such as hawks, eagles, and owls) use long, sharp talons to seize and kill small animals. Their beaks can be used to tear small pieces of food for ingestion. Further, many carnivorous animals possess specialized mechanisms for paralyzing victims. Jellyfishes, centipedes, spiders, scorpions, and some snakes possess structures that inject toxins that inhibit the nervous system of their prey. Finally, some electric eels may locate and stun their prey with electrical discharges.

Liquid Ingestion

Surprisingly, many animals live exclusively on a liquid diet. Herbivores such as bees, butterflies, moths, hummingbirds, and some bats derive nutrition by consuming plant nectar. As a consequence of their feeding, these animals help plants reproduce by dispersing pollen. Hummingbirds have specially adapted long, narrow beaks and long tongues to suck nectar from flowers. Nectar-consuming bats also have long narrow faces and tongues. Aphids, and many other insects that consume plant sap, have highly specialized mouthparts that pierce plants and act as miniature straws to suck sap.

A number of carnivores also are adapted to consume a liquid diet. As ghoulish as it might sound, ingesting blood is the most common mechanism of feeding for these animals. Mosquitoes, for example, are equipped with a syringelike mouthpart called a proboscis. Although the male sips nectar, the female mosquito uses her proboscis to pierce skin and suck blood. As with most bloodsucking animals, mosquitoes secrete an anticoagulant that prevents blood from clotting (and also makes people itch). Some flies use a similar mode of feeding, but the common housefly generally laps up food and sugary solutions. Leeches are also well adapted for bloodsucking: They have a suction-cup-like mouth that clings tenaciously to a host while their jaws make a Y-shaped cut in the skin. Further, leeches have a muscular pharynx (throat) that literally pumps blood from their host. Ticks, which are related to spiders and scorpions, have tiny heads that are designed to burrow into the skin of their host and suck blood. Unfortunately, they also are vectors for potentially serious diseases such as Lyme disease and Rocky Mountain spotted fever. Although vampire bats consume blood, they do not suck it. Instead, they lap blood with their tongue as it oozes from a shallow scrape in the skin made by their teeth.

Spiders also are adapted to live on a liquid diet; however, they prey on insects that have a tough external skeleton that is not easily ingested. To feed, they first pierce the insect's exoskeleton with hollow jaws and pump in strong digestive juices that liquefy the internal contents of their prey. Later, the spider sucks the insect empty. Some young birds, such as pigeons and emperor penguins, feed on a regurgitated milklike secretion (called crop milk) that is produced by their parents' crop. In addition, all mammals begin their life as fluid feeders, ingesting milk produced by their mother.

Finally, endoparasites comprise a group of animals that consume a liquid diet by living inside other organisms. Some eat host tissues, while others rely on their host to digest food for them and, as a result, lack a digestive system. Tapeworms, for example, have a specially adapted anterior end with hooks and suckers to maintain a fixed position in their hosts' gut while they consume predigested food. In contrast, hookworms (a type of roundworm) do have a digestive system, and they use their mouth opening and toothlike structures to draw and ingest blood from the inside of their host.

Studying Ingestion

Much of what has been learned about ingestion has come from simple observation of feeding behavior combined with careful note-taking. In fact, observation and data collection, along with analysis and interpretation, are the most fundamental of all scientific activities. Most people have seen a robin use its beak to pull an earthworm from the ground or a cat capture a mouse. By closely watching the lifestyle and daily activities of animals, biologists have discovered what food items are eaten and how they are ingested.

The naked eye is insufficient for observing very small animals, and for this activity microscopes aid biologists. These tools have permitted observation of endocytosis of paramecia and bacteria by the amoeba as well as other feeding mechanisms of protozoans. Microscopic, inert latex beads are used to study the direction and power of feeding currents generated by cilia and flagella and the formation of food vacuoles. For example, paramecia will direct beads into their oral region by ciliary action and then engulf them by endocytosis. Dyes are also commonly used to study the direction and action of feeding currents. This method has revealed that flagellated choanocytes of sponges move water in through small pores in the sides of the sponge and out a single larger opening at the top.

Videotape and photographic film are routinely used to supplement simple observation. These procedures not only provide a permanent record of the event but also permit additional analysis to be conducted at some future time. Further, feeding mechanisms that occur very quickly are difficult to analyze with the naked eye. These events can be recorded by high-speed cinematography and later played back at a slower speed for analysis. This method of study has been used to observe the lightning-fast movement of a chameleon's tongue and the way bats catch insects with their wing membranes while in flight. Alternatively, very slow feeding events, such as endocytosis or a snake swallowing a rat, can be recorded by time-lapse photography and later viewed at a faster speed for analysis.

Mechanisms of ingestion may also be inferred by carefully analyzing the body design of an animal. For example, birds possessing beaks that have an arrangement of tightly packed vertical filaments, as found in flamingos, feed by filtering. In contrast, birds with long, pointed beaks, such as woodpeckers, probe for food in narrow places. Finally, the contents of the stomach and fecal samples from animals may be analyzed to determine the type and size of the food items that were eaten.

The Necessity of Food

Animals have an absolute requirement for food. Animals must ingest food items because, unlike photosynthetic organisms, they cannot manufacture all the necessary nutrients they require from raw materials. Animals require food both as a fuel source to provide energy for locomotion and metabolism and as building blocks for growth, maintenance, and repair. Obtaining sufficient food is of paramount importance for survival. Therefore, the limited availability of food is selected by animals that have the most-successful feeding strategies and body designs for procurement and ingestion of nutrients. Because different sources of nutrition are utilized, the selection pressures for obtaining food may result in vastly different feeding mechanisms among closely related animals. For example, giant water bugs, termites, and aphids are all classified as insects. Yet, they rely on different diets and therefore possess divergent methods of feeding and structures for ingestion. In addition, and conversely, selection pressures for obtaining food may result in the development of similar body structures in distantly related species (convergent evolution). Baleen whales and flamingos, for example, are classified in different taxonomic groups (mammals and birds) but have similar feeding methods and therefore similar structures for ingestion. Thus, specific feeding behaviors and structures for ingestion are primarily shaped by the nature of the food items being utilized, and the vast diversity of feeding mechanisms reflects a similar diversity in food sources.

Ultimately, the source of energy to create food comes from the Sun. Photosynthetic organisms use light to synthesize energy-rich organic compounds, such as glucose, from energy-poor inorganic compounds, such as carbon dioxide and water. One exception to this scheme occurs in certain regions of the ocean floor, near the thermal vents. Far removed from sunlight and organic material derived by photosynthesis, the food chain of oceanic thermal vents is based upon certain bacteria that synthesize organic compounds from inorganic substances emitted by these undersea geysers.

Unfortunately, there is an unavoidable loss in usable material and energy between links in a food chain. This loss occurs because much of the energy stored in food is irreversibly lost when it is used by organisms for growth, repair, and maintenance. Therefore, it is more efficient to have a lower number of links in a food chain between its base (usually plants or plankton) and its end (typically large carnivores). With that in mind, it is interesting to note that some of the largest fish (whale sharks) and mammals (whales) in the world are filter feeders of tiny organisms. These huge animals, which require a large amount of energy, avoid extra links in their food chain by feeding on plankton instead of other large animals.

Bibliography

Childress, James J., Horst Felbeck, and George N. Somero. "Symbiosis in the Deep Sea." *Scientific American* 256 (May, 1987): 115-120. This article describes how a unique society of animals survives deep below the ocean surface totally devoid of sunlight and organic material derived from the Sun. Authors present the methods these animals utilize to gain energy from deep-sea hydrothermal vents and to obtain nutrition from certain bacteria. Illustrated with diagrams.

Eckert, Roger, David Randall, and George Augustine. *Animal Physiology: Mechanisms and Adaptations*. 4th ed. New York: W. H. Freeman, 1997. An intermediate college textbook that presents a comparative approach to animal physiology. Covers ingestion as well as related topics such as digestion and absorption. The text is written in a clear and concise manner, delineating different mechanisms or strategies of feeding. Well-constructed diagrams display a variety of feeding strategies in both invertebrates and vertebrates. Evolutionary correlations are also discussed.

Hickman, Cleveland, Jr., Larry S. Roberts, and Frances M. Hickman. *Integrated Principles of Zoology*. 11th ed. Boston: McGraw-Hill, 2001. A textbook for introductory college zoology. Discusses feeding mechanisms of animals as well as related topics such as nutrition, digestion, and regulation of food intake. Takes a comparative approach to ingestion, classifying animals on the basis of food type and consistency. Selected references are provided.

Pearse, Vicki, John Pearse, Mildred Buchsbaum, and Ralph Buchsbaum. *Living Invertebrates*. Rev. 4th ed. Cambridge, Mass.: Blackwell Scientific, 1992. Designed for the beginning college student, this text summarizes the biology of invertebrates. Without going into excessive detail, it describes the essential features of invertebrate biology, including feeding and ingestion. Supplemented with many excellent figures and photographs, including a series of color plates, that are easily interpreted.

Schmidt-Nielsen, Knut. *Animal Physiology: Adaptation and Environment*. 5th ed. New York: Cambridge University Press, 1998. Takes a comparative approach to animal ingestion and covers related topics such as nutrition, digestion, and noxious compounds used for defense by plants and animals. Although lacking in illustrations, the text is easily understood by the beginning college student. Classifies animal feeding by the nature of the ingested food and provides numerous biological examples. A long list of references is given.

Wessels, Norman K., and Janet L. Hopson. *Biology*. New York: Random House, 1988. Specifically designed for the college freshman biology student, this textbook has numerous learning aids, including key terms, summary statements, questions, and suggested readings. Presents animal ingestion by taking a taxonomic approach for the lower animals and then dividing the vertebrates into herbivores and carnivores. Clear figures and photographs supplement the text.

INSECT SOCIETIES

Type of animal science: Behavior
Fields of study: Ethology, invertebrate biology

Ants, termites, and many kinds of bees and wasps live in complex groups known as insect societies. Studies of such societies have enriched scientific knowledge about some of the most successful species on earth and have provided insights into the biological basis of social behavior in other animals.

Principal Terms

BROOD: all the immature insects within a colony; these include eggs, larvae, and, in the Hymenoptera, the pupal stage

CASTE: one of the recognizable types of individuals within a colony, usually physically and behaviorally adapted to perform specific tasks

EUSOCIAL: referring to any of the truly social species characterized by division of labor, with a sterile caste, overlapping generations, and cooperative brood care

HAPLODIPLOIDY: sex determination found in the Hymenoptera, where males arise from unfertilized eggs and females from fertilized eggs

METAMORPHOSIS (COMPLETE): a transformation that occurs during the development of higher insects, in which a grublike immature form enters a resting (pupal) stage for major tissue reorganization; after pupation, the adult, which bears no resemblance to the larval form, emerges

PHEROMONE: a chemical produced by one member of a species that influences the behavior or physiology of another member of the same species

TROPHALLAXIS: the exchange of bodily fluids between nestmates, either by regurgitation or by feeding on secreted or excreted material

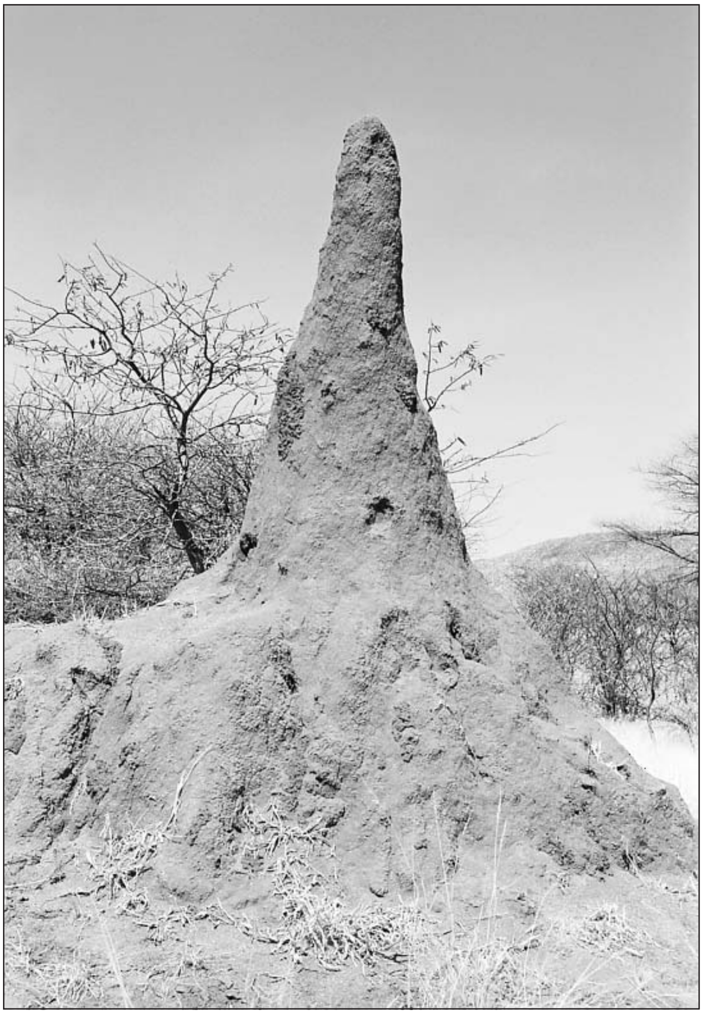
Many of the most robust, thriving species today owe their success in great part to benefits that they reap from living in organized groups or societies. Nowhere are the benefits of group living more clearly illustrated than among the social insects. Edward O. Wilson, one of the foremost authorities on insect societies, estimates that more than twelve thousand species of social insects exist in the world today. This number is equivalent to all the species of known birds and mammals combined. Although insect societies have reached their pinnacle in the bees, wasps, ants, and termites, many insects show intermediate degrees of social organization—providing insights regarding the probable paths of the evolution of sociality.

Ant, Wasp, and Bee Societies

Scientists estimate that eusociality has evolved at least twelve times: once in the Isoptera, or termites, and eleven separate times in the Hymenoptera, comprising ants, wasps, and bees. In addition, one group of aphids has been found which has a sterile soldier caste. Although the eusocial species represent diverse groups, they all show a high degree of social organization and possess numerous similarities, particularly with regard to division of labor, cooperative brood care, and communication among individuals. The organization of a typical ant colony is representative, with minor modifications, of all insect societies.

A newly mated queen, or reproductive female, will start a new ant colony. Alone, she digs the first nest chambers and lays the first batch of eggs. These give rise to grublike larvae, which are unable to care for themselves and must be nourished from the queen's own body reserves. When the larvae have reached full size, they undergo metamorphosis and emerge as the first generation of worker ants. These workers—all sterile females—take over all the colony maintenance duties, including foraging outside the nest for food, defending the nest, and cleaning and feeding both the new brood and the queen, which subsequently becomes essentially an egg-laying machine. For a number of generations, all eggs develop into workers and the colony grows. Often, several types of workers can be recognized. Besides the initial small workers, or minor workers, many ant species produce larger forms known as major workers, or soldiers. These are often highly modified, with large heads and jaws, well suited for defending the nest and foraging for large prey. Food may include small insects, sugary secretions of plants or sap-feeding insects, or other scavenged foods. After several years, when the colony is large enough, some of the eggs develop into larger larvae that will mature into new reproductive forms: queens and males. Males arise from unfertilized eggs, while new queens are produced in response to changes in larval nutrition and environmental factors. These sexual forms swarm out of the nest in a synchronized fashion to mate and found new colonies of their own.

With minor modifications, the same pattern occurs in bees and wasps. Workers of both bees and wasps are also always sterile females, but they differ from ants in that they normally possess functional wings and lack a fully differentiated soldier caste. Wasps, like ants, are primarily predators and scavengers; bees, however, have specialized on pollen and plant nectar as foods, transforming the latter into honey that is fed to both nestmates and brood. The bias toward females reflects a feature of the biology of the Hymenoptera that is believed to underlie their tendency to form complex societies. All ants, wasps, and bees have an unusual form of sex determination in which fertilized eggs give rise to females and unfertilized eggs develop into males. This type of sex determination, known as haplodiploidy, generates an asymmetry in the degree of relatedness among nestmates. As a consequence, sisters are more closely related to their sisters than they are to their own offspring or their brothers. Scientists believe that this provided an evolutionary predisposition for workers to give up their own personal reproduction in order to



Ant colonies can build huge mounds through their united efforts. (Corbis) raise sisters—a form of natural selection known as kin selection.

Termite Society

The termites, or Isoptera, differ from the social Hymenoptera in a number of ways. They derive from a much more primitive group of insects and have been described as little more than "social cockroaches." Instead of the strong female bias characteristic of the ants, bees, and wasps, termites have regular sex determination; thus, workers have a fifty-fifty sex ratio. Additionally, termite development lacks complete metamorphosis. Rather, the young termites resemble adults in form from their earliest stages. As a consequence of these differences, immature forms can function as workers from an early age, and—at least among the lower termites—they regularly do so.

Termites also differ from Hymenoptera in their major mode of feeding. Instead of feeding on insects or flowers, all termites feed on plant material rich in cellulose. Cellulose is a structural carbohydrate held together by chemical bonds that most animals lack enzymes to digest. Termites have formed intimate evolutionary relationships with specialized microorganisms—predominantly flagellate protozoans and some spirochete bacteria—that have the enzymes necessary to degrade cellulose and release its food energy. The microorganisms live in the gut of the termite. Because these symbionts are lost with each molt, immature termites are dependent upon gaining new ones from their nestmates. They do this by feeding on fluids excreted or regurgitated by other individuals, a process known as trophallaxis. This essential exchange of materials also includes, along with food, certain nonfood substances known as pheromones.

Insect Communication

Pheromones, by definition, are chemicals produced by one individual of a species that affect the behavior or development of other individuals of the same species that come in contact with them. Pheromones are well documented throughout the insect world, and they play a key role in communication between members of nonsocial or subsocial species. Moth mating attractants provide a well-studied example. Pheromones are nowhere better developed than among the social insects. They not only appear to influence caste development in the Hymenoptera and termites but also permit immediate communication among individuals. Among workers of the fire ant (*Solenopsis saevissima*), chemical signals have been implicated in controlling recognition of nestmates, grooming, clustering, digging, feeding, attraction or formation of aggregations, trail following, and alarm behavior. Nearly a dozen different glands have been identified which produce some chemical in the Hymenoptera, although the exact function of many of these chemicals remains unknown.

In addition to chemical communication, social insects may share information in at least three other ways: by tactile contact, such as stroking or grasping; by producing sounds, including buzzing of wings; and by employing visual cues. Through combinations of these senses, individuals can communicate complex information to nestmates. Indeed, social insects epitomize the development of nonhuman language. One such language, the "dance" language of bees, which was unraveled by Karl von Frisch and his students, provides one of the best-studied examples of animal behavior. In the waggle dance, a returning forager communicates the location of a food resource by dancing on the comb in the midst of its nestmates. It can accurately indicate the direction of the flower patch by incorporating the relative angles between the sun, the hive, and the food. Information about distance, or more precisely the energy expended to reach the food source, is communicated in the length of the run. Workers following the dance are able to leave the nest and fly directly to the food source, for distances in excess of one thousand meters.

Benefits of Cooperation

Living in cooperative groups has provided social insects with opportunities not available to their solitary counterparts. Not only can more individuals cooperate in performing a given task, but also several quite different tasks may be carried out simultaneously. The benefits from such cooperation are considerable. For example, group foraging allows social insects to increase the range of foods they can exploit. By acting as a unit, species such as army ants can capture large insects and even fledgling birds.

A second benefit of group living is in nest building. Shelter is a primary need for all animals. Most solitary species use naturally occurring shelters or, at best, build simple nests. By cooperating and sharing the effort, social insects are able to build nests that are quite elaborate, containing several kinds of chambers. Wasps and bees build combs, or rows of special cells, for rearing brood and storing food. Subterranean termites can construct mounds more than six meters high, while others build intricate covered nests in trees. Mound-building ants may cover their nests with a thatch that resembles, in both form and function, the thatched roofs of old European dwellings. Colonial nesting provides two additional benefits. First, it enhances defense. By literally putting all of their eggs in one basket, social insects can centralize and share the guard duties. The effectiveness of this approach is attested by one's hesitation to stir up a hornet's nest. Nest construction also provides the potential to maintain homeostasis, the ability to regulate the environment within a desirable range. Virtually all living creatures maintain homeostasis within their bodies, but very few animals have evolved the ability to maintain a constant external living environment. In this respect, insect societies are similar to human societies. Workers adjust their activities to maintain the living environment within optimal limits. Bees, for example, can closely regulate the internal temperature of a hive. When temperatures fall below 18 degrees Celsius, they begin to cluster together, forming a warm cover of living bees to protect the vulnerable brood stages. To cool the hive in hot weather, workers initially circulate air by beating their wings. If further cooling is needed, they resort to evaporative cooling by regurgitating water throughout the nest. This water evaporates with wing fanning and serves to cool the entire hive. Other social insects rely on different but equally effective methods. Some ants, and especially termites, build their nests as mounds in the ground, with different temperatures existing at different depths. The mound nests of the African termite, *Macrotermes natalensis*, are an impressive engineering feat. They are designed to regulate both temperature and air flow through complex passages and chambers, with the mound itself serving as a sophisticated cooling tower.

Finally, group living allows the coordination of the efforts of individuals to accomplish complex tasks normally restricted to the higher vertebrates. The similarities between insect societies and human society are striking. An insect society is often referred to as a superorganism, reflecting the remarkable degree of coordination between individual insects. Individual workers have been likened to cells in a body, and castes to tissues or organs that perform specialized functions. Insect societies are not immortal; however, they often persist in a single location for periods similar to the life spans of much larger animals. The social insects have one of the most highly developed symbolic languages outside human cultures. Further, social insects have evolved complex and often mutually beneficial interactions with other species to a degree unknown except among human beings. Bees are inseparably linked with the flowers they feed upon and pollinate. Ants have actually developed agriculture of a sort with their fungus gardens and herds of tended aphids. On a more sobering note, ants are the only nonhuman animals that are known to wage war. These striking similarities with human societies have led researchers to study social insects to learn about the biological basis of social behavior and have led to the development of a new branch of science known as sociobiology.

Studying Insect Society

Because of the diversity of questions that investigators have addressed regarding insect societies, many methods of scientific inquiry have been employed. In Karl von Frisch's experiments, for example, basic behavioral observations were cou-

Edward O. Wilson

Born: June 10, 1929; Birmingham, Alabama
Fields of study: Ecology, entomology, ethology, evolutionary science, genetics, zoology
Contribution: Wilson is recognized as the world's chief authority on social insects, particularly ants. He is also an expert on the genetic basis of the social behavior of all animals, including humans.

After his graduation from high school in Decatur, Alabama, Edward O. Wilson earned his bachelor's and master's degrees in biology at the University of Alabama at Tuscaloosa, concentrating his efforts on the study of ants. Continuing his educational pursuits at Harvard University, he earned his doctor's degree in zoology and received an appointment as a professor of zoology and curator of entomology at the Museum of Comparative Zoology at Harvard. Based on their study of insect societies, Wilson and W. L. Brown proposed the idea of character displacement: that after the populations of two closely related species come into contact, they undergo rapid evolutionary differentiation so as to minimize the chances of competition and hybridization between the two species.

Wilson's definitive work on ants and other social insects, *The Insect Societies* (1971), treats the societal behavior patterns of many species. It covers numerous aspects of insect societies, ranging from paleontology to formal genetics and from ethology to biochemistry. Providing an account of the natural history of social insects, with their great proliferation of genera, species, and behavioral types, Wilson incorporated concepts from the fields of modern genetics, selection theory, and biomathematics to explain the evolution of insect societies and their diversity in size and longevity. In *The Ants* (1990), Wilson and Bert Hölldobler published a comprehensive summary of current knowledge on ants.

Wilson's thorough study of insect societies led to his proposal that the biological principles governing animal societies extend to humans, which he explored in *Sociobiology: The New Synthesis* (1975). Wilson theorized that the preservation of the gene, versus the preservation of the individual, is the fundamental concept in evolutionary development. His argument was that social animals, including humans, behave according to rules written in their genes. Since this theory contradicts the belief in free will and suggests that some human groups may be biologically superior to others, it sparked much controversy among scientists and nonscientists alike. In *The Diversity of Life* (1992), Wilson further investigated how the world's living species became diverse, as well as the massive species extinctions produced by human activities in the twentieth century.

Wilson became the first and only person to receive both the highest award for science in the United States, the National Medal of Science, and the premier literary award, the Pulitzer Prize in literature. He received the latter award for his book *On Human Nature* (1978) in 1979. In 1990, he was awarded the prestigious Crafoord Prize by the Swedish Academy of Science for his work in ecology. In 1995, *Time* recognized Wilson as one of the twenty-five most influential people in America. An international poll in 1996 ranked him as one of the hundred most influential scientists of all time. His present research is focused on the concept of consilience, a controversial attempt to unify all knowledge by means of science so that explanations of differing kinds of phenomena are connected and consistent with each other.

—Alvin K. Benson

pled with simple but elegant experimental design to unravel the dance language of bees. The bees were raised in an observation colony. This was essentially a large hive housed between plates of glass so that an observer could watch the behavior of individual bees. Researchers followed specific workers by marking them with small numbers placed on the abdomen or thorax. Sometimes the entire observation hive was placed within a small, darkened shed to simulate more closely the conditions within a natural hive.

Bees learned to find an artificial "flower"—a glass dish filled with a sugar solution. Brightly colored backgrounds and odors such as peppermint oil were added to the sugars to provide specific cues for the bees to associate with the reward. Feeding stations were set up at fixed distances; observers could follow the exact movements of known individuals both at the feeder and at the hive. In this way, von Frisch was able to describe several types of dances (the round dance for near food sources, the waggle dance for feeding stations that were farther from the hive) and show that a returning bee could share information regarding the location and quality of a source with her nestmates. Scientists subsequently have developed robot bees that can be operated by remote control to perform different combinations of dance behaviors. This allows them to determine which parts of the dance actually convey the coded information.

The investigation of forms of chemical communication requires application of a variety of techniques. Chromatography is useful for identifying the minute amounts of chemical pheromones with which insects communicate. Chromatography (which literally means "writing with color") is particularly suitable for separating mixtures of similar materials. A solution of the mixture is allowed to flow over the surface of a porous solid material. Since each component of the mixture will flow at a slightly different rate, eventually they will become separated or spaced out on the solid material. Once the components of the pheromone have been separated and identified, their activity is assessed separately and in combination using living insects. Such bioassays allow researchers to determine exactly which fractions of the chemical generate the highest response.

Other biochemical techniques, such as electrophoresis, have been used to determine subtle behavioral differences, such as kin discrimination among hive mates. Each individual carries a complement of enzymes or proteins that catalyze biological reactions in the body. The structure of such enzymes is determined by the genetic makeup of the individual, and it varies among individuals. Because enzyme structure is inheritable, however, much as eye color is, the degree of similarities between the enzymes can be used as a measure of how closely related two individuals are. The amino acids composing the enzyme differ in their electrical charges, so different forms can be separated using the technique of electrophoresis. When a liquid containing their enzymes is subjected to an electrical field, the proteins with the highest negative charge will move farthest toward the positive pole. This provides a tool to distinguish close genetic relatives for use in conjunction with behavioral observations to test, for example, whether workers can discriminate full sisters from half-sisters, or relatives from nonrelatives, as kin selection theory would predict.

The Success of Social Insects

Social insects are among the most successful groups of animals throughout the world, especially in the tropics. Although the number of species is low when compared to all insects (twelve thousand out of more than a million species), their relative contribution to the community may be unduly large. In Peru, for example, ants may make up more than 50 percent of the individual insects collected at any site.

The study of social insects has provided scientists with new ways of looking at social behavior in all animals. Charles Darwin described the evolution of sterile workers in the social insects as the greatest obstacle to his theory of evolution by natural selection. In attempts to explain this seeming paradox, William D. Hamilton closely examined the social Hymenoptera, where sociality had evolved eleven separate times. Realizing that the haplodiploid form of sex determination led to sisters being more closely related to one another than they would be to their own young, Hamilton developed a far-reaching new theory of social evolution: kin selection, or selection acting on groups of closely related individuals. This theory, which provides insights into the evolution of many kinds of seemingly altruistic behaviors, arose primarily from his perceptions regarding the asymmetrical relatedness of nestmates in the social Hymenoptera. These insects, then, should be credited with providing the model system that has led to a subdiscipline of behavioral ecology known as sociobiology, the study of the biological basis of social behavior. Moreover, given their central roles in critical ecological processes such as nutrient cycling and pollination, it would be hard to imagine life without them.

Bibliography

Crozier, Ross H., and Pekka Pamilo. *Evolution of Social Insect Colonies: Sex Allocation and Kin Selection*. New York: Oxford University Press, 1996. Investigates the genetic basis for insect sociality.

Frisch, Karl von. *The Dance Language and Orientation of Bees*. Translated by L. E. Chadwick. Cambridge, Mass.: The Belknap Press of Harvard University Press, 1967. A detailed description of the research conducted by von Frisch and his students that provided the basis for scientists' knowledge of honeybee communication and orientation. Well illustrated with pictures and photographs, this book provides a particularly good section on the classical experimental methods used to study insect behavior in the field.

Gordon, Deborah M. *Ants at Work: How an Insect Society Is Organized*. New York: W. W. Norton, 1999. Summarizes fifteen years of research on red harvester ants for a general audience.

Hoelldobler, Bert, and Edward O. Wilson. *Journey to the Ants: A Story of Scientific Exploration*. Cambridge, Mass.: Belknap Press, 1994. Written for the nonspecialist, with many illustrations and color photographs. Investigates the reasons why ants are such a successful species, and also uses ants to illustrate concepts and research methods of sociobiology.

Ito, Yoshiaki. *Behavior and Social Evolution of Wasps: The Communal Aggregation Hypothesis*. New York: Oxford University Press, 1993. Uses wasps to argue that mutual defense rather than kin selection is the basis of insect sociality. Many illustrations, charts, and graphs, as well as extensive bibliography. Written for college level through professional readers.

Moffett, Mark W. "Samurai Aphids: Survival Under Siege." *National Geographic* 176 (September, 1989): 406-422. The discovery in 1972, by Aoki in Japan, of aphid species that possess a sterile soldier caste has added another insect group (the Homoptera) to those commonly considered eusocial. This article provides a popular discourse on this unusual group, with details of their life cycles and interactions with other species, including a mutually beneficial association with another social insect, a tiny ant. Excellent photographs and diagrams of the life cycle.

Prestwich, Glenn D. "The Chemical Defenses of Termites." *Scientific American* 249 (August, 1983): 78-87. Discusses the effective defenses of a specialized caste of termites known as nasutes. These highly modified soldiers have heads resembling nozzles, with which they squirt sticky toxic chemicals onto enemies. Striking electron micrographs show close-up details of the defensive apparatus.

Seeley, Thomas D. "How Honeybees Find a Home." *Scientific American* 247 (October, 1982): 158-168. Describes the behavior of honeybees searching for and choosing a new nest site, including how scouts assess the suitability of a new nest cavity and how they share that information with nestmates through a dance similar to the waggle dance. Good illustrations of the exploratory movements and dances of scouts, as well as a good photographic treatment of swarming.

Wilson, Edward O. *The Insect Societies*. Cambridge, Mass.: The Belknap Press of Harvard University Press, 1971. This is the most comprehensive treatment of social insects. Wilson covers every aspect known up to the writing in a lucid and well-organized fashion. This is the book for the expert wanting a summary of ant mimics and guests or wanting to learn more about the genetics of social evolution. Nevertheless, the material remains largely accessible to the nonexpert as well, in large part because of the wealth of excellent drawings and summary tables. The bibliography is extensive and covers many of the classic works as well as more modern treatments.

_______. *Sociobiology: The New Synthesis*. Cambridge, Mass.: The Belknap Press of Harvard University Press, 1975. A discussion of the evolution and structure of societies—both those of insects and those of higher animals. The format is very similar to that of Wilson's *The Insect Societies*, and the drawings and illustrations are of equal quality. The book is almost seven hundred pages long but is well indexed and suitable for browsing. An excellent source for anyone interested in comparing different social animals or in tracing ideas on the evolution of sociality.

_______. *Success and Dominance in Ecosystems: The Case of the Social Insects*. Oldendorf/Luhe, Federal Republic of Germany: Ecology Institute, 1990. Wilson argues that evolutionary longevity is a measure of a species' success, and ability to control biomass and energy in its ecosystem is a measure of its dominance. Includes an introduction by Otto Kinne.

INSECTS

Type of animal science: Classification
Fields of study: Anatomy, ecology, entomology, invertebrate biology

More than one million species of insects have been identified, and countless others await discovery. Insects provide many valuable products and services within ecosystems, but some cause damage by eating crops or spreading disease to plants, animals, and humans.

Principal Terms

APTEROUS: insects without wings, such as fleas

ECDYSIS: molting; the shedding of the exoskeleton that allows for insect growth

HEXAPOD: six-footed, a general term for an insect

OVIPOSITOR: egg-laying apparatus on the female abdomen, modified into a stinger in bees

PUPA: intermediate stage between the larval and adult stages of the life cycle

SPIRACLES: openings on the outside of the insect abdomen that lead to breathing tubes

VECTOR: transmits pathogens from one host to another

The history of insects dates back to the Devonian period, about 400 million years ago. Today numbering more than one million different species, insects are the most diverse class of animals on earth. Insects populate almost every habitat except the deep oceans and permanently frozen land masses. Insects are specialized to live underground, in live or rotting trees, in fast-flowing rivers, or stagnant puddles. Parasitic insects live attached to the outside (hair, skin) or inside (stomach lining, respiratory tract) of other animals. Crafty insects modify their habitat by building their own houses. Spittlebugs mix air into slimy anal secretions to form shelters. Bagworms spin silk to hold leaves together around them. Some African termites glue soil particles together with saliva into colossal nests measuring six meters high and nearly four meters across.

Insect Anatomy

Along the relatively straight digestive tract of an insect there are regions specialized for food storage, grinding, chemical breakdown, and nutrient absorption. Before undigested remains leave the insect, water and salts are reclaimed. Insect waste, termed frass, is thus very dry. This last step of water conservation is very important to insects because they lose water rapidly due to their small size.

The insect respiratory system is also adapted to save water. The tracheal system is a collection of tubes that allows for gas exchange from the outside environment directly with individual tissues. The openings in the body wall, spiracles, can be closed to conserve water between breathing cycles.

The circulatory fluid of insects, hemolymph, functions in keeping tissues moist and transporting nutrients and hormones. There are no red blood cells or other oxygen-carrying molecules because the insect respiratory system is totally separate from the circulatory system. The circulatory system is open. Hemolymph enters a series of chambers, collectively termed the heart, through holes called ostia. Muscular pumping of the heart propels the fluid through the aorta, toward the insect's brain. In the vicinity of the brain, the hemolymph flows out into the general body cavity, or hemocoel. Hemolymph directly bathes internal organs on its way to and from the legs and wings, starting the cycle again by entering the heart ostia. There are distinct veins in the wings. Insects take advantage of fluid circulation in the wings to transfer heat, warming themselves or cooling off when needed.

Insects are noted for their jointed exoskeletons. Chitin makes this armor especially strong. The exoskeleton functions much like the internal bones of vertebrates, serving to protect internal organs and as sites of muscle attachment. The exoskeleton puts limits on the overall size that insects can attain and makes growth energetically costly. The insect must shed its old exoskeleton and form a new one in order to increase in size. The old exoskeleton may be eaten to reclaim some of the nutrients within it. While a freshly molted insect is waiting for its new outer covering to harden, it is particularly vulnerable to attack from predators. Molting insects tend to be white; the exoskeleton will also develop color as it hardens.

The Insect Diet

Phytophagous insects feed on living plants. Caterpillars are famous leaf eaters. Other insects feed on plant roots, shoots, flowers, stems, or fruits. When a large group of phytophagous insects occurs in the same area, the crop or forest damage that they cause can be extensive. Yet there is quite another side to the relationship between insects and plants. Insect-pollinated plants have evolved odors, shapes, and ultraviolet color patterns to attract these important visitors. When the butterfly, bee, or other pollinator stops to drink the plant's rich nectar, pollen from the male part of the flower sticks to the insect's body. When it visits another flower of the same species, it deposits the pollen on the female floral organ. Without this interaction, beans, tomatoes, tea, cocoa, and many other plants could not reproduce.

Scavengers also serve an important purpose by recycling nutrients found in dead plant and animal matter. Termites are a nuisance when they infest a house but are invaluable at breaking down dead wood in nature. Dung beetles have the curious habit of forming animal feces into balls and rolling them away to feed their young. Carrion feeders assist in the decomposition of animal corpses. A succession of flies and beetles reduce a corpse to bones.

Predators hunt and kill to eat. Some predators use powerful mouthparts to tear apart their prey. Other predators inject digestive enzymes into their prey, digest them externally and suck out the liquefied tissues through a specialized beak. The first pair of legs of the praying mantis are striking

Insect Facts

Classification:
Kingdom: Anamalia
Subkingdom: Bilateria
Phylum: Arthropoda
Subphylum: Uniramia
Class: Insecta
Orders: Common orders include Coleoptera (beetles); Diptera (flies, mosquitoes); Hemiptera (true bugs); Homoptera (cicadas), Hymenoptera (ants, bees, wasps); Isoptera (termites); Lepidoptera (butterflies, moths); Odonata (dragonflies, damselflies); Orthoptera (crickets, grasshoppers)
Geographical location: Every continent except Antarctica
Habitat: Mainly terrestrial, some aquatic, primarily freshwater
Gestational period: Highly variable; some insects produce one, two, or several generations per year; conversely, relatively large insects may take more than one year for larval development
Life span: Highly variable; adult mayflies live less than one week, while queen termites have been known to live for more than twenty years
Special anatomy: Major regions include the head, featuring one pair of antennae, the thorax, with three pairs of legs and up to two pairs of wings, and the abdomen, housing spiracles and genitalia; in some insects, one or both pairs of wings are modified for functions other than flight, such as protection or balance

Image Not Available

examples of raptorial modifications for grasping and holding struggling prey.

Dragonfly nymphs, the young aquatic stage, have a diet of insects, crustaceans, tadpoles, and even small fish. Adult dragonflies eat bees, butterflies, and mosquitoes. Harmless insects such as dragonflies, which consume pest insects such as mosquitoes, are good candidates for biological control programs. Biological control is a method of pest control that takes advantage of natural predators of the pest. Ladybugs are commonly used by gardeners to control plant-damaging aphid populations.

On the other hand, a good parasite does not kill its food source, the host. Parasitic insects typically ingest host blood, mucus, or tissues, with minimal irritation or harm to the host. Trouble begins if there is a heavy parasitic burden (a large number of parasites per host), or if the parasitic insect transmits disease-causing organisms to the host. Ectoparasites live on the outside of their hosts. In this category, fleas and lice are adapted to avoid detection by the host and deter removal during normal grooming processes. Endoparasitic fly larvae live in the digestive or respiratory tract, mainly of livestock. Endoparasites of invertebrates do not follow the rules. Because there is little difference in size between this parasite and host pair, the host routinely perishes in this relationship. Species of endoparasitic wasps inject their eggs into caterpillars. When the larvae hatch, they tunnel farther into the host and feed off of its tissues. Upon completion of larval development, the wasps emerge from the caterpillar, killing it in the process.

Some parasites spend their lifetimes closely associated with the host, but others only briefly visit the host. On the time continuum, lice not only form a constant, more-or-less permanent association with a single host, but many generations of lice may inhabit the same host. However, these parasites are transferred from host to host during mating, nesting, or other close contact between individuals. Unlike lice, fleas leave the host frequently between bloodmeals. On the other end of the spectrum, mosquitoes normally require multiple hosts to complete a single bloodmeal; they are here and gone before they can be slapped by hand or tail.

Insect Behavior

Much of what insects do, they do by instinct, a genetically preprogrammed response to environmental stimuli, none the less amazing in its elegance and effectiveness. Antennae and setae, hairlike projections through the exoskeleton, serve as two of the many receptors of external stimuli. The necessity of keeping these sensory organs clean is evidenced by preening, commonly using mouthparts and legs. Major categories of environmental stimuli signal friend or foe.

Many insects locate opposite sex conspecifics, individuals of the same species, by sight. Color patterns, especially in the ultraviolet (UV) spectrum attract potential mates. Fireflies (Coleoptera) use visual recognition of patterns of light flashes. In some species, females use signaling to attract males. In other species the male and female signal to each other with the proper code and response. Females of the genus *Photuris* mimic the flashing patterns of other firefly species. When the male approaches, she makes a meal of him.

Sound production and reception are also used for mate location. The sound generated by a female mosquito's beating wings in flight is picked up by the male mosquito's antennae. Male homopterans and orthopterans produce songs of courtship. Cicadas use abdominal muscles and a resonating chamber for sound production. Grasshoppers and crickets rub their wings and or legs together. Sound receptors, "eardrums" of females in these orders, are found on their forelegs or first abdominal segments. Sound production and reception vary with temperature.

Pheromones, externally broadcast chemical signals, are another means of attracting mates. In moths, glands near the tip of the female's abdo-

Vector-Borne Disease

Insects are carriers of major human diseases. Interaction between disease-causing microorganisms and the insect vector is an interesting and vital component of the transmission cycle. The bubonic plague, for example, is endemic (naturally occurring) in populations of rodents. The plague bacteria, *Yersinia pestis*, is transmitted to humans primarily by *Xenopsylla cheopis*, the Oriental rat flea. When a flea ingests infected blood, the bacteria multiply in its gut and stick together, rapidly forming a plug. When a blocked flea attempts to feed, it regurgitates infected blood into its host. Still hungry, a blocked flea will repeatedly attempt to feed, increasing the chances of it infecting many hosts.

While there are still small geographic pockets where plague is present today, malaria rages as a widespread, tropical epidemic. Malaria is caused by species of protozoa in the genus *Plasmodium*, and carried by mosquitoes in the genus *Anopheles*. These mosquitoes not only transport the disease from host to host, they provide the only environment in which the protozoa can complete its life cycle. *Plasmodium* exhibits both asexual and sexual reproduction, but it reproduces sexually within the mosquito gut and nowhere else. After development in the gut, the protozoa migrate, through the mosquito, to the salivary glands. While feeding, the mosquito then spits *Plasmodium* into a new host.

Chagas' disease is also caused by a protozoan, *Trypanosoma cruzi*, but the vector and mode of transmission are radically different from that of malaria. Like *Plasmodium*, *T. cruzi* requires residence in the insect gut in order to develop into an infective stage. However, the insects that *T. cruzi* are associated with are true bugs (Hemiptera, Reduviidae). The protozoan remains in the bug's digestive tract until excretion within fecal material. Transmission of Chagas' disease relies on the host scratching infected feces into the itchy bite wound.

Forensic Entomology

Scientists and law enforcement agents capitalize upon the predictable sequence of insect development on human corpses to provide clues in homicide cases. Species of *Calliphora* (blowflies) lay eggs on the body almost immediately postmortem. The eggs hatch in a given amount of time, then the larvae go through distinct growth stages and pupate. During these first weeks, other species of flies also colonize and develop in this specialized microenvironment. After the flies have done their work, beetles arrive. Forensic entomologist M. Lee Goff has done many experiments with the decomposition of pig carcasses. Using his work, data tables have been established to aid scientists in interpreting the story of the insects present, and in turn provide clues regarding the fate of the deceased victim. The size of the larvae of each species is adjusted for temperature and this data is used to estimate the length of time that the person has been dead. Larval development is calculated at 72 degrees Fahrenheit. Time is subtracted for exposure to warmer environments since insect development speeds up at higher temperatures. At 80 degrees Fahrenheit, a larval fly would appear to be older than it really is. Insect evidence can assist investigators in determining whether the body has been moved and yield clues about poisons or drugs present in the body at the time of death.

men release pheromones that are received by the antennae of the male moths. Certain male butterflies and moths have specialized scent-producing glands on their wings. The notable pair of black patches, or androconia, on the hindwings of the male monarch secrete aphrodisiac pheromones that increase the female's receptivity to mating. Pheromones can also make already-mated females unattractive to subsequent suitors.

Members of the class Insecta display numerous protective behaviors and defense mechanisms when threatened. Walkingsticks are capable of losing part of a leg in the grasp of a predator. The amputated appendage continues to wiggle when severed, thus distracting the predator, while the walkingstick gets away. Some beetles play dead until the predator loses interest. Blister beetles are capable of reflex bleeding. They squeeze drops of hemolymph through joints in their exoskeleton. Their hemolymph contains cantharadine, which irritates and repels the predator. Bombardier beetles spray a noxious repellant from their anal glands for distances up to one meter.

Another means of defense is coloration. Insects blend into the surroundings by resembling a leaf, twig, pebble, or flower. Some insects use bright colors to hide in plain sight. Large eyespots on wings can startle would-be predators, or at least trick them into taking a bite out of the wing rather than from the head or body. Color patterns of orange and black seem to warn vertebrate predators that the insects would not make a good meal. Some of these insects derive chemicals from their diet that make them distasteful, even harmful, to predators. Without possessing such chemicals, mimics derive protection from their resemblance to the group that does.

Social insects exhibit the most complex behavior, approaching learning. Honeybees can communicate direction of a food source, and distance from the hive, to other bees through a multipart waggle dance. Some ants are farmers, planting and nurturing fungus gardens. Mound-building harvester ants ensure that the colony's young are kept at the optimal temperature through vertical migrations. The young are transported to top levels within the mound to warm up in the morning and evening. During the heat of the day, the young are carried to lower levels to cool off. Kidnapping of ants from other colonies to serve as workers in the home colony may not be considered a socially advanced behavior, but it is a complex one. The other major group of social insects, the termites, work together to build huge mounds, called termitaria, some reaching heights of 6 meters and diameters of over 3.5 meters. They engineer series of chimneys into the structure that can be opened and closed to regulate airflow and maintain constant temperature.

—*Sarah Vordtriede*

Maria Sibylla Merian

Born: April 2, 1647; Frankfurt am Main, Germany
Died: January 13, 1717; Amsterdam, Netherlands
Fields of study: Developmental biology, ecology, entomology
Contribution: Merian's paintings are significant as natural history illustrations in seventeenth century Western art. Her detailed observations, particularly of insect metamorphosis, also contributed to the development of entomology as a science.

Maria Sibylla Merian, the German-born Dutch naturalist, was the youngest of three children born into a family of artists. Her father, Matthaus Merian the Elder, a publisher, engraver, and botanical artist, died when Maria was just three years old. Her older brother, Matthaus Merian the Younger, became a famous portrait painter. Maria's own artistic talent was noticed early on by her stepfather, Jacob Marrell, himself a trained painter. Her curiosity and observation of the natural world was also established early in life. She kept a detailed journal of her observations from her teenage years until just before her death at the age of sixty-nine.

Deviating from other seventeenth century artists, Maria Sibylla Merian sketched, painted, and engraved insects from real-life observations rather than as still-life symbols. In this way, she was able to put their behavior and development into ecological context. She bred and raised silkworms and, at age thirteen, illustrated the egg, larva, pupa, and adult stages of these creatures, as well as many other butterflies. Merian is credited with being the first person to record such detailed observations on insect metamorphosis. Although she did not realize it at the time, she also documented parasitoid infection of some of the caterpillars. The organisms that she described as small black flies emerging from butterfly pupa were likely small wasps that complete their larval development within the pupal case of the butterfly host.

In 1699, funded by the city of Amsterdam, Merian and her youngest, teenaged daughter traveled to South America to study and paint insects, birds, and plants. They spent two years exploring the natural wonders of the cities, plantations and rainforests of the country of Suriname (formerly Dutch Guiana). Observational records from this excursion were published in 1705 under the title "De generatione et metamorphosibus insectorum surinamensium" ("of the reproduction and the transformation of insects in Suriname"). Both before and after her trip, she published several books of illustrations and observations of plants and the insects associated with them. Two of her paintings are featured on thirty-two cent U.S. postage stamps. In addition to her artwork, she traded in preserved insects, and instructed others according to the proper preservation of specimens.

Maria Sibylla Merian left quite a legacy. Her daughters continued research on insects after their mother's death, and Merian's artwork and keen scientific observations, meticulously recorded, are preserved for all to learn from and enjoy. Six plants, nine butterflies, and two beetles bear her name, which is ultimately fitting, since Carolus Linnaeus is said to have consulted her work while establishing his binomial nomenclature system for naming the living organisms of the earth.

INSTINCTS

Type of animal science: Behavior
Fields of study: Biochemistry, ethology, neurobiology

Instincts cover a range of inherited behaviors that are unlearned and are predictable for a species. Scientists are interested in locating the biochemical sources of instincts and analyzing the relationship between instincts and a species' biological success.

Principal Terms

ALTRUISM: a high degree of devotion to the interest of others that often includes self-sacrifice

ETHOLOGY: a branch of biology that studies behavior

FIXED ACTION PATTERN (FAP): a behavior whose timing and duration are invariable for all members of a species

INNATE: denotes an inherited and unalterable condition or ability in an organism

NEUROBIOLOGY: the study of the biology of the brain

NEUROETHOLOGY: the study of behavior as it relates to brain functions

PEPTIDE: a chemical combination of certain amino acids

SIGNAL: information transmitted through sound, such as bird calls, or through sight, such as body posture

STEREOTYPED BEHAVIOR: an unlearned and unchanging behavior pattern that is unique to a species

Instincts are patterns of behavior found in animals that are unlearned and that are inherited by successive generations of the species. Ethologists call these stereotyped behaviors fixed action patterns (FAPs). Over time, such patterns are shaped by evolution, but at any given moment, a species maintains a range of instincts that are unique to its members. A number of categories of stereotyped behavioral responses exist that apply to all organic forms. These include the basic drives such as reproduction, feeding, and protection from predators. The term "instinctive behavior," however, is generally reserved for animals and insects, while excluding plants, bacteria, and viruses. Simple forms of stereotyped responses include a variety of reflex actions in which sensory nerve cells are affected by conditions such as heat and light. The more complex forms of responses are studied in order to understand the sequence of responses and the process of evolution that selected these patterns.

The Study of Instincts

The study of instinctive behavior began in the nineteenth century with the development of clinical psychology. Scientists noticed a direct link between animal and human behavior, and since clinical experimentation of human subjects was not always possible or desirable, experiments were carried out on monkeys, mice, and guinea pigs. Experiments focused on the responses of test subjects to specific environmental conditions. An example of this type of experiment would be investigating the puzzle-solving ability of rats in a maze. The flexibility and nature of these responses were seen as part of a study of learning processes.

Meanwhile, the field of ethology began to formulate a different view of animal behavior. A European group including Konrad Lorenz, Nikolaas Tinbergen, and Karl von Frisch noticed that animals possess a specific innate capacity to perform complex activities in response to the environment. As a result, modern ethology shifted the study of animal behavior from learned responses to inherited patterns of behavior. From their beginning as "bird watchers," observing birds' courtship behavior, nest building, rearing of young, and territorial ownership, ethologists collected a body of scholarship that came to represent a respected field of study. A number of subfields have been created, ranging from neurology and genetics of behavior to ecology of species behavior. One element that links these diverse and distinctive fields of study is that of signals, language, and communications.

Charles Darwin gave the scientific world a theory of evolution, but he was also an avid observer of instinctive behavior. He observed domesticated pigeons and described how emotions are expressed by humans and animals. Other early pioneers in this field included Charles Whitman, who studied the family tree of a group of pigeons in Massachusetts, and Oskar Heinroth, who observed several species of waterfowls in Germany. Their observations led to the conclusion that members of a species not only share the same body functions and bone structures but also share behavior patterns.

The next step was to compare instinctive behavior across several closely related species. This work was accomplished between 1940 and 1960 by Lorenz and Tinbergen. Lorenz chose as his subject the courtship sequences of mallards, teals, and gadwalls. Recognition signals among ducks are a specific sequence of behaviors that include tail shaking, head flicking, and whistling. The exact sequence for different species is different, yet the components are the same. Through these studies, it is possible to conclude that courtship sequences originated in a single ancestral form, and crossbreeding between duck species produced variations in the pattern. Tinbergen arrived at a similar conclusion with his work on the calls, body postures, and movements of gulls. His study of the signaling behavior of more than fifteen species of gulls showed that their system of signals is similar. As a result of their work, Lorenz and Tinbergen provided a scientific basis both for the biological source of behavior and for an evolutionary source of instinctive reaction.

The Nature Versus Nurture Debate

Although few scientists of the time had objected to the notion that genetics contributed to instinctive behavior, there was an ongoing debate as to the extent of the genetic contribution. The scientific bias was on the side of learned behavior patterns in such areas as language, signals, and body postures. It seemed clear that higher animals learn how to transfer information among themselves. One example was that an isolated songbird, denied access to parental teaching, does not instinctively know the songs of its species. Consequently, the genetic component may play only a small part in the overall development of behavior. In this debate, the contribution of Karl von Frisch shifted the balance to the side of inheritance. Von Frisch showed that honeybees communicate both the direction and the

Nikolaas Tinbergen, one of the founders of the science of ethology and a Nobel laureate in 1973, conducted many experiments on the subject of instincts and behavior, especially in gulls. (Nobel Foundation) distance of a source of nectar through a sequence of dance patterns. A scouting bee returning to the hive can provide exact information to other bees. While it was argued that the larger brain sizes of higher animals contributed substantially to learning a system of communication, it was difficult to make the same argument for insects.

The debate on nature versus nurture produced extensive efforts to determine the extent to which instinctive behavior is shaped by inheritance or by learning. In the study of sea gull chicks, Jack Hailman created a series of experiments that added evidence to the side of learned behavior. The parent of a sea gull chick can elicit pecking from the chick either by pointing its bill downward or by swinging its bill from side to side. The chick will respond not only to a parent's action, however, but also to a model that has the shape of the parent. The initial feeding behavior of a newly hatched chick is a "hit and miss" affair. With growth, the chick responds more precisely to the figure of the parent and acquires greater coordination. Thus, the initial instinct is for the chick to peck at a variety of motions, but with maturity a learning component takes place to create greater discrimination.

Sequences of Behavior

During the 1950's and 1960's, researchers in instinctive behavior studied a number of animals and insects. Scientists began to understand that instincts are not a simple response to the environment but are a complex sequence of behavior. Scientists also began to find evidence suggesting that natural selection acts on behavior patterns as well as on an organism's biological makeup. The result of this research came to be categorized into three broad groups of instinctive behavior. One was the response of a simple instinct on the part of a single organ to some stimulus. An example is a nerve cell responding to light that triggers a reflex response. Other reflex reactions include locomotion and movement. Another type of stereotyped behavior was called fixed action patterns (FAPs). For example, the courting behavior of ducks can be classified as FAPs, wherein the pattern and timing of the responses are invariable for all members of the species. Similar FAPs are found in spiders, crabs, and a number of other insects and lower animals. A final group of instinctive behavior was described as modifiable action patterns (MAPs) and included fixed patterns that could be modified by the environment or by learning. For example, in species of birds, the core of nest-building behavior is fixed, but actual nest building depends on the availability of preferred building materials, which can be altered by location and setting.

With the deciphering of the genetic code during the 1950's, research in instinctive behavior shifted toward the genetic basis of innate behavior. Research has shown that one group of chemicals called neuropeptides are produced by specific genes. Within the brain, these peptides have the ability to govern stereotyped behavior. For example, a specific peptide (angiotensin II), when injected into vertebrates, causes spontaneous drinking activity. Research on neuroactive chemicals that influence behavior patterns is still in its infancy; research on brain functions and neuron pathways has only begun. In the future, biochemists expect to isolate the link between the genetic code and brain function.

There remains one area of stereotyped behavior that has puzzled scientists since the time of Darwin: the question of altruistic behavior. Scientists have wondered how to explain behaviors such as ants drowning themselves in a stream so that others can cross over them or a parent animal risking its life so that offspring can survive. W. D. Hamilton, among others, began to use probability models, which show that cooperative behavior, which may risk the lives of individuals, results in greater survival of the rest of the group. Altruistic behavior not only is "for the good of the species" but also provides the greater probability that large numbers of that group will reproduce and therefore gain an advantage.

The Fieldwork of Ethology

The early students of ethology were often called "bird-watchers" because they began their work by observing the behavior of birds. Fieldwork involves repeated observations of a subject over long periods of time. Eventually, a sequence of behavior emerges, and then it is possible to read the language of the behavior. For example, Lorenz observed that the courtship sequence of the mallard duck involved some ten segmented parts, such as bill-shake, head-flick, tail-shake, and grunt-whistle.

In certain instances, fieldwork with insects and lower animals offers the possibility of direct experimentation. In his attempt to translate the dancing motion of bees, von Frisch made the food source available. Consequently, he was able to vary the distance of the food source, change its location, and alter the quantity of food. Each change in the variables produced some variation in the dance—perhaps a new "phrase" added to the language. In other areas of research, the test subject can be modified for direct experimentation. When William Keeton attempted to explain how pigeons found their way home, he used contact lenses to cover the eyes of the pigeon to block out the position of the sun. He also created secondary magnetic fields around the pigeon to test the subject's sensitivity to the earth's magnetic field.

While all studies of stereotyped behavior begin with observation, either in the field or in controlled settings, further exploration usually requires laboratory research. In Jack Hailman's study of the learning component of sea gull chicks, he constructed models of gull parents and correlated pecking accuracy with growth. He also modified features of the model sea gull to study possible changes in responses from the chicks. As the search for the causes of instinctive behavior moves further into the organism, the methodology follows—into areas of brain function (neuroethology), the chemistry of innate behavior, and the genetic component of behavior. Investigating the source of egg-laying behavior of a species of a large marine snail (*Aplysia*), Richard Scheller and Richard Axel found three genes that produce a number of peptides that govern this behavior.

Instincts and Genes

Instincts are a part of all living organisms, and observable instinctive responses are only a small part of an intricate pattern. The genetic makeup of an organism dictates specific unlearned patterns of responses and variations that, in turn, determine a favorable selection of individuals within a species. Clearly, instincts in sexual selection, reproduction, food gathering, and other basic needs are critical for the survival of members of a species. In higher animals, instinctive activities are often overshadowed (and sometimes disguised) by learned patterns of responses. For example, in dogs, the pulling back of facial muscles and the showing of teeth is a response to fear and attack. In humans, laughter is a similar response to surprise, embarrassment, and uneasiness. Because of social adaptation, however, laughter takes on additional behavioral conventions.

Until the early part of the twentieth century, instincts were thought to be learned responses to specific situations. Consequently, if aggression were learned, then it could be modified, changed, and unlearned. With the establishment of a genetic and biochemical foundation for instincts, research in stereotyped behavior has become part of a heated debate. In 1975, Edward O. Wilson published *Sociobiology: The New Synthesis*. This highly technical work found a surprisingly large audience; in it, Wilson attempted to place all social behavior on a biological basis. Although the work emphasized animal behavior, Wilson implied that all human history was also part of evolutionary biology and that his work would synthesize all the social sciences with biology. Since instincts such as aggression, selection of sexual partners, and care of the young play a prominent part in cultural activities, Wilson seems to suggest that in the future, the study of society will be grounded in neurobiology and sociobiology.

A collection of essays focusing on description of behaviors in an attempt to explore the interaction of sameness and difference at the levels of individual, population, and species. Written for more advanced students of ethology.

Frisch, Karl von. "Dialects in the Language of Bees." *Scientific American* 130 (August, 1962): 2-8. The article describes a series of experiments undertaken to discover the "language" of honeybees. An excellent article for the reader with little technical background; highly recommended.

Goodall, Jane. *In the Shadow of Man*. Boston: Houghton Mifflin, 1971. An excellent view of fieldwork on primate behavior. Goodall gives a complete description of the difficulties and rewards of living and interacting with the subjects of her research. Highly recommended for the general reader.

Lorenz, Konrad Z. "The Evolution of Behavior." *Scientific American* 199 (December, 1959): 67-78. Lorenz suggests that instinctive behavior is inherited and that these traits are characteristic of a species. The article contains an excellent and brief summary of earlier scientific attitudes to instincts. Addressed to the general reader and highly recommended.

Scheller, Richard H., and Richard Axel. "How Genes Control an Innate Behavior." *Scientific American* 250 (March, 1984): 54-63. Describes how methods of recombinant DNA were used to find a set of genes that encode a neuropeptide and result in specific egg-laying behavior in a marine snail. Beyond the article's opening page, some background in college biochemistry and genetics is helpful.

Smith, John Maynard. "The Evolution of Behavior." *Scientific American* 239 (September, 1978): 176-192. Smith addresses the problem of how altruism can be favored by natural selection since the altruistic individual often does not survive. Some of the probability mathematics and game theory might prove difficult for the general reader, but the article is readable without the mathematics.

INTELLIGENCE

Types of animal science: Behavior, development
Fields of study: Developmental biology, ethology, evolutionary science

Animals are guided by more than instinct when interacting with their environment, yet the exact measurement of intelligence in various species remains problematic. While scientists devise numerous problem-solving tasks to assess intelligence, anthropomorphism leads to exaggerated claims of intelligence through anecdotal evidence.

Principal Terms

ANTHROPOMORPHISM: attributing human characteristics or states of mind to animals
COGNITION: transformation and elaboration of sensory input
COGNITIVE ETHOLOGY: scientific study of animal intelligence
LEXIGRAMS: symbols associated with objects or places in keyboard communication experiments with primates
PROTOGRAMMAR: word coined to signify the early foundation for grammar development found in primates
RECAPITULATION: stages of human development reappearing in different animal species

Both the general public and scientific community have long been intrigued with questions about how animals think and what are they thinking. Published reports of animal cognition increased dramatically in the last half of the twentieth century. Chimpanzees in the Ivory Coast have demonstrated extensive use of rocks as tools in cracking nuts. These primates have also been reported to hide undesirable expressions from their faces and act as if blind or deaf. Vervets have been found to use an elaborate system of alarm calls that seem to function as words. Parrots can demonstrate the ability to count, and birds exhibit the capacity to make and use tools to gather food. Dolphins apparently understand and follow simple commands. Primates have been trained to use signs in a symbolic fashion, communicating their needs, desires, and thoughts.

Theories of Cognitive Ethology

Cognitive ethology is a relatively new discipline that studies animal intelligence. Donald Griffin is considered to have founded this branch of study through the publication of *Animal Thinking* (1984) and *Animal Minds* (1992). Since the appearance of his books, numerous instances of animal intelligence have been gathered from observation and experimentation.

Traditionally, attitudes about animal intelligence can be sorted into those that place animals on a continuum with humans and those that see animals as distinct from humans. From the former perspective, animal behavior is readily interpreted as a definite sign of various cognitive skills and special abilities along a continuum of development. From a discontinuity perspective, only humans are considered to possess the higher cognitive skill of reasoning. The higher cognitive abilities are considered to be a uniquely human capacity that sets them apart from the lower animals, who are controlled by instinct.

Charles Darwin, in *The Descent of Man* (1871), defended the idea of the intelligence of animals existing on a continuum with humans. Since animals and humans have a common ancestry, animals would have the fundamental capacities for rational choice, reflection, and insight. Darwin concluded that the differences between the minds of humans and animals were of degree rather than of kind. Following Darwin's proclamation, a number of anecdotal studies concerning animal intelligence appeared that suggested extensive cognitive ability in animals. Unfortunately, many of the examples illustrated anthropomorphism. This is the process whereby humanlike characteristics are attributed to animal behavior.

Some interpretations of Darwin's statement created a distorted view about evolution that persisted long into the twentieth century. The idea that life on earth represents a chain of progress from inferior to superior forms began to influence the view of animal intelligence. The theory that ontogeny recapitulates phylogeny also became popular in the early years of the twentieth century. This theory, which does not have any scientific support, suggested that the advancement of life forms corresponded to the stages of development for humans. This stepladder approach to animal intelligence led to a ranking of animals compared to the developmental stages of human infants and children.

This approach to animal intelligence is flawed because it relies on the notion that some animals are more highly evolved than others are. Evolution does not have a single point of greatest evolution. The branches of the evolutionary tree have culminated with many different species occupying special niches. Thus, the "degree" of a species' evolution depends on the extent to which it successfully occupies its niche.

Animals Who Might Think

In addition to this tendency to attribute states of mind to animals that are found in humans, there were a number of cases of labeling trained behavior in animals as signs of reasoning skills. One of the most famous examples was the case of the horse, Clever Hans, in the early 1900's. Wilhelm von Osten owned a horse that demonstrated extensive arithmetic skills. When von Osten presented a written arithmetic problem to Hans, the horse would tap out the answer with his forefoot. Clever Hans also appeared adept at telling time, and answered questions about sociopolitical events by nodding or shaking his head yes or no. The horse's abilities suggested to many individuals the similarity between animal and human minds. Eventually, the Prussian Academy of Sciences discovered that Hans was not answering the

Measuring Arithmetic Skills in Primates

The chimpanzee Sheba was involved in a number of widely reported experiments that purported to demonstrate arithmetic ability in primates. Sheba was taught to associate a tray containing one, two, or three pieces of candy with cards containing the corresponding number of marks. If two candies were present on the tray, Sheba learned to pick the card with two marks. If the correct card was selected, Sheba would be rewarded by being allowed to eat the candy. In the next stage of the experiment, the marks on the cards were replaced by the numerals 1, 2, and 3. Then Sheba had to match the number of candy pieces with the correct number. After Sheba showed success in this phase of the experiment, the candy pieces were replaced with other inedible objects. If Sheba chose the number that matched the number of objects, she was rewarded with the corresponding number of candies. Eventually the numbers were expanded to include 0 and 4. Next Sheba was given the challenge of counting the total number of candies presented on a series of trays. Sheba demonstrated a rudimentary ability for addition showing correct responses 75 percent of the time. Initially the sums were restricted to one, two, or three. Sheba was eventually able to exhibit the skill to add numbers when the candies were replaced with the numerals 1, 2, and 3. Although Sheba was able to show mathematical ability, even the experimenter acknowledged some important limitations. Sheba required extensive training and "heroic" effort on the part of the trainer to accomplish the counting performances. A true mathematical ability should generalize to other situations, yet animals such as Sheba do not demonstrate easy or automatic transfer of numerical performance from one realm to another.

questions by means of any reasoning skills, but was an astute observer of the behavior of his owner and those around him. When questions were posed to Hans, cues were provided unconsciously to the horse about the correct answer. Since horses have evolved to ascertain subtle visual cues from others in their herd, Hans was able to form a number of cued associations which led to a reward. The owner of Clever Hans was not attempting to perpetrate fraud. He believed in the possibility that a horse could have reasoning ability, but von Osten was not sophisticated in how he tested for the skills. The inadvertent cueing of an animal to respond in a certain fashion is one of the major confounding factors found in the investigation of animal intelligence.

The case of Clever Hans illustrates two other problems that confound reports concerning the level of intelligence in animals. First is the problem of anthropomorphism. People develop an emotional bond with animals and interpret behavior in order to enhance the closeness they feel to them. The second problem concerns the methods used to measure intelligence. The classic case of Kohler's chimpanzees illustrates this problem.

In the early part of the twentieth century, Wolfgang Köhler assessed the reasoning ability of chimpanzees to obtain food outside of an enclosure. After a rake was left in the enclosure, food was placed out of reach of the caged chimpanzees. The chimpanzees were able to use the rake to bring food to the cage. Köhler concluded that the animals had insight into the nature of the problem and used reasoning to achieve a solution. A further study, requiring the fitting together of two sticks in order to reach the food, also supported Köhler's conclusions. However, later experimentation has revealed that chimpanzees without a history of playing with sticks could not solve the problem. Apparently, in order to solve the problem, the chimpanzees needed an extensive history of playing with sticks, which enabled them to learn how sticks could be used at a later time. In solving the problem, they were using an instinctual tendency to play with sticks and scraping them over the ground.

Primates and Sign Language

A contemporary example of the problem of measurement can be provided with the case of Washoe, the first chimpanzee to be taught sign language. Because of physical inability to vocalize human speech, chimpanzees were taught sign language as a mode of communication with humans. Soon Washoe and another signing chimpanzee, Nim Chimsky, were reported to have spontaneously created novel sentences through their signing. For example, Washoe was reported to have signed the combination water and bird after seeing a swan. Being a novel combination of signs, the trainers of Washoe explained the behavior as creative insight. Unfortunately, Washoe had also shown repeated signing of meaningless combinations, leading to the conclusion that a significant pairing of signs would eventually appear not because of the primate's cognitive reasoning but as a result of chance. Inevitably, these early attempts to demonstrate animal intelligence were widely discredited as exaggeration or self-delusion on the part of the animal's trainers, and this animal language research from the late 1970's fell into disrepute.

In order avoid the ambiguities of sign language, later researchers used keyboards that related symbols to a variety of objects, people, and places. Much of this research has taken place at the Language Research Center at Georgia State University in Atlanta under the guidance of Dr. Sue Savage-Rumbaugh. In the first experiments, two chimpanzees, Austin and Sherman, were familiarized with a system of symbols or lexigrams. Each was abstract and arbitrarily associated with an object, person, place, or situation. Eventually Austin and Sherman learned to communicate with symbols illustrated on a keyboard. For example, an experiment was devised where one chimpanzee was shown where food was being deposited in a certain container while the other had control of a tool to open the container. With the keyboard present, the chimpanzees were able to communicate with one another to use the tool on the correct container.

Soon a bonobo chimpanzee, Kanzi, became the star pupil of this technique and learned a vocabulary of two hundred symbols. Kanzi eventually showed the capacity to construct rudimentary sentences that were generated spontaneously. The chimpanzees trained using the keyboards appear to be exhibiting a protogrammar. This is a term to indicate the beginnings of grammar, roughly equivalent to the verbal skills seen in a human child about two to three years old.

In the late 1990's, another bonobo chimpanzee, Panbanisha, surpassed the capacities evidenced by Kanzi. Panbanisha has been reported to understand complex sentences and use the keyboard to communicate spontaneously with the outside world. Although the results have been impressive, critics of the Center's activities remain. The question remains whether the chimpanzees are demonstrating extremely effective training or some level of abstract reasoning.

INVERTEBRATES

Type of animal science: Classification
Fields of study: Anatomy, developmental biology, ecology, entomology, histology, invertebrate biology, marine biology, physiology

Over 98 percent of all known animal species are invertebrates, animals without backbones. At the base of many food webs, invertebrates provide nutrients to a wide range of other animals on land, underground, and in the seas. The diversity within the invertebrates is amazing, ranging from single-celled protozoans to cephalochordates possessing nerve cords, and claiming close relationship to vertebrates.

Principal Terms

COELOM: a true body cavity, lined by mesoderm

COLONY: a cluster of genetically identical individuals formed asexually from a single individual

CYST: a secreted covering that protects small invertebrates from environmental stress

GONOCHORISTIC: having separate sexes; an individual is either male or female

HYDROSTATIC SKELETON: a system in which fluid serves as the support by which muscles interact

MESODERM: a middle layer of embryonic tissue between the ectoderm and endoderm

With the exception of insects, which have extensively colonized terrestrial environments, most invertebrates are aquatic, many of those being marine. Even some of the land dwellers start life as aquatic larvae. Invertebrates follow one of three types of general body plan. Some marine sponges are asymmetrical, lacking an ordered pattern to their structure. Cylindrical organisms, such as sea anemones, are radially symmetric; any cut through the center of the organism divides it in equal halves. Asymmetrical and radially symmetric animals tend to stay in one place; thus their body plan helps them to collect environmental stimuli from every direction. Animals that exhibit bilateral symmetry have right and left halves that are mirror images of each other. They are mobile and usually have a distinct head end. This area of cephalization, concentrated nerve and sensory tissues, is directed forward in their travels, giving them new information about where they are going.

Invertebrate Feeding

Among the protozoans there are a variety of diets and feeding mechanisms. Organisms in the phylum Ciliophora have a cytostome, a cell mouth that can be found anteriorly, laterally, or ventrally, depending on species, on these single-celled creatures. Ciliates feed primarily on bacteria, algae, and other protozoans. Members of the phylum Amoebozoa have a similar diet to the ciliates but, in the absence of mouths, use pseudopodia to wrap around a food item, engulfing it. *Euglena* (phylum Euglenozoa), a flagellate protozoan commonly used in biology laboratories, is a self-feeder (autotroph). It contains chloroplasts and uses light energy to produce sugars, photosynthesized as in plants. It is interesting to note that some euglenids can and do ingest solid food if they are exposed to darkness for too long. Another group of interesting flagellates is the hypermastigotes. Species such as *Trichonympha campanula* live in the guts of termites. *T. campanula* breaks down the high cellulose content present in the termite diet of wood products, something that the termite cannot do for itself. In return these protozoans keep some of the nutrients for themselves.

Sponges, phylum Porifera, do not have any or-

Nematodes Are Everywhere

Members of the phylum Nematoda are typically one to two millimeters in length and tapered at both anterior and posterior ends. It is difficult to tell the head from the tail, externally. Except for the mouth and the genital pore, there are no obvious body openings to the outside. Nematodes do not have eyes, ears, or noses. However, they respond to temperature changes, light, mechanical stimulation, and chemical cues because they do possess special organs located in tiny pits that are sensitive to chemicals, and small papillae that are sensitive to touch. They breathe through their cuticle, skin, which is permeable to water and gases. With such a covering, desiccation (drying out) is a constant threat to their well-being. Thus, nematodes live in moist environments. There are some that are fully aquatic; those that are terrestrial surround themselves in a film of water; and those that are parasitic take advantage of the high moisture levels within the body of the host.

As far as numbers of individuals are concerned, nematodes are regarded as the most abundant multicellular animals alive today. There can be literally millions of these small worms per square meter of soil or shallow water sediment. Free-living nematodes are important for decomposition and nutrient cycling. Of the 40 percent of species that are parasitic, much of the toll of the resulting disease in the host is due to the concentration of individual worms competing with the host for nutrients and blocking vessels or entirely filling the heart. One ounce of undercooked pork can contain one hundred thousand worms, and each female can produce thousands of young in just a few days. Nematodes are prevalent in research labs as well. *Caenorhabidits elegans*, a soil nematode, is a model organism that has been studied to unlock many of the secrets of developmental biology and genetics of humans.

gans, but they do possess specialized cell types. Choanocytes, also termed collar cells, line the inside of the sponge and capture small food particles present in the circulating water. The phylum Cnidaria is well known for quite another specialty. Organisms in this phylum, such as jellyfish, have specialized stinging cells called nematoblasts. One of the functions of cnidae within the nematoblasts is secretion of toxins used to paralyze and kill prey. Cnidarians are patient hunters, lying in wait until their next meal contacts a tentacle or two, triggering the toxic sting.

Tapeworms (phylum Platyhelminthes, class Cestoda) have no mouth or digestive tract. They are highly adapted to a parasitic way of life. Swimming in nutrients that their host, usually a vertebrate, is in the process of digesting, tapeworms absorb nutrients through their outer surface, and return nothing besides waste products to their host.

Many rotifers (phylum Rotifera) are omnivores, meaning they eat anything that will fit into their mouth. After being ingested, prey passing into the muscular pharynx encounters grinding, crushing jaws called trophi. Rotifers have a one-way digestive tract. Wastes pass out the anus rather than being expelled through the mouth, unlike many of the animals discussed thus far.

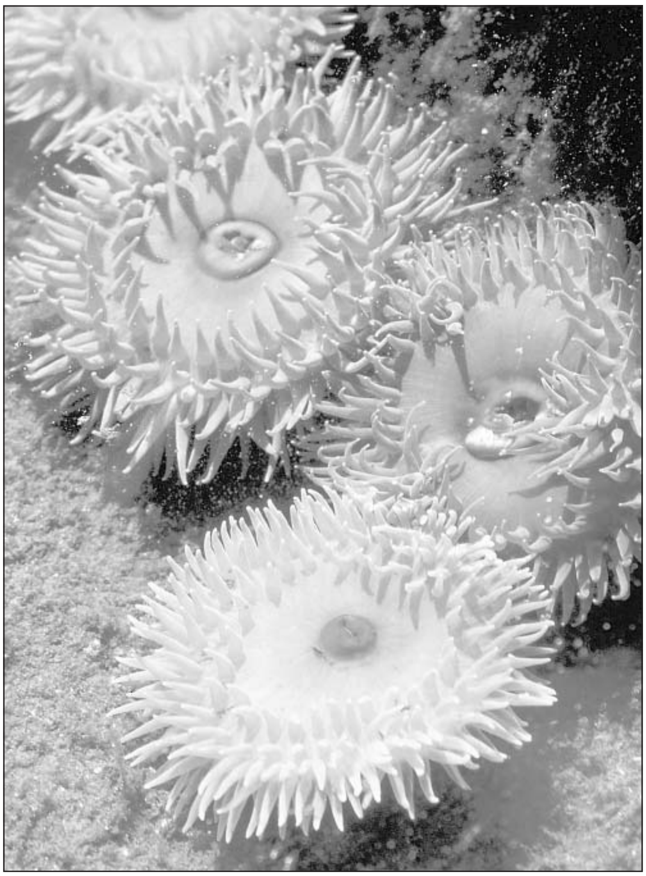
There is a wide range of feeding styles among the mollusks (phylum Mollusca). Some feed on plants; others feed on animals, and others feed on particles suspended in the water or mud that they themselves inhabit. There are also mollusks that are ectoparasites, living on the exterior of their host rather than inside it. An interesting molluscan feeding structure is the radula. The teeth on this tonguelike organ are replaced as they wear down or break.

The phylum Arthropoda is divided into two subphyla based on mouthpart structure. The Chelicerates, including horseshoe crabs, and arachnids (spiders, mites, ticks, and scorpions) have fanglike oral appendages used to grab and shred food items. Conversely, insects and crustaceans generally have mandibles, a pair of jaws for crushing food. This basic plan can be highly modified. The specialized coiled straw proboscis of a butterfly is such an example.

Starfish (phylum Echinodermata) prey on large invertebrates and small fish. These echinoderms have two stomachs and can protrude the cardiac stomach through the mouth and begin to digest prey externally. This is an especially useful maneuver when feeding on particularly large prey or when eating a clam through the small opening between its shells.

Respiration and Circulation

As single cells, protozoans have high body surface to volume ratio. They inhabit wet or at least moist environments and are able to take care of gas exchange through simple diffusion. Even though flatworms, phylum Platyhelminthes, are multicellular, they also posses a large external surface area relative to their internal volume, so they, too, rely on simple diffusion across their body surface area for gas exchange. A highly branched gastrovascular cavity allows most cells to be in contact with the digestive system, which means that nutrients do not have to circulate to remote parts of the body. Metabolic wastes generally diffuse out across the body surface.



Many invertebrates are radially symmetrical marine organisms, such as these sea anemones. (PhotoDisc)

Sponges rely on their body cavity (the spongocoel) for circulation and gas exchange. Seawater with dissolved oxygen is pulled into the spongocoel through pores in the body wall called ostia. Flagella in specialized collar cells lining the spongocoel set up an internal current to provide circulation. Water and waste products then pass out of a larger opening, called an osculum.

Cnidarians also lack specialized respiratory structures. They rely on epidermal and gastrodermal surfaces for gas exchange. The gastrodermis lines the gastrovascular, main body cavity. As its name suggests, the gastrovascular cavity functions in both gastric capacity of digestion and the vascular role of circulation.

Most aquatic mollusks have comblike gills that function in gas exchange and also in filter feeding in some. Both aquatic and terrestrial snails in the subclass Pulmonata have highly vascularized structures that function as modified lungs. Mollusks typically posses a heart or similar pump that circulates fluid through an open circulatory system. In an open circulatory system the conduits, or vessels, are limited, and most organs are bathed directly in the circulatory fluid. Cephalopods, such as squid and octopuses, are mollusks with closed circulatory systems. In a closed circulatory system, blood is contained in vessels. The squid actually has three hearts. The systemic heart receives oxygenated blood from the gills and sends it to the tissues. The two branchial hearts pump deoxygenated blood back to the gills.

Arthropods have open circulatory systems. The circulatory fluid, called hemo-

The Coral Reef Community

Coral reefs are colonies of small invertebrate animals (phylum Cnidaria, class Anthozoa). Some species of coral are solitary; the colonial reef builders are called hermatypic. The reef grows as new members of the colony take up residence on top of the calcium carbonate skeletons of previous generations. In this way, layer by layer, reefs can attain huge dimensions. Australia's Great Barrier Reef is over 2,000 kilometers long and 145 kilometers wide. Coral reefs are very diverse and fragile ecosystems. Reefs consisting of hundreds of species of corals, not to mention the countless species of other organisms, occur only in clear, shallow, tropical marine environments. Corals eat plankton but also rely on photosynthetic symbiotic algae for nutrient provision. Corals provide shelter and feeding grounds for many organisms: sponges, mollusks, echinoderms, tube dwelling worms, and fish, just to name a few reef inhabitants and visitors. Reefs also affect life on land by absorbing wave force, thus mitigating beach erosion.

There are four major types of reef formations. Fringing reefs border the shoreline. A lagoon separates a barrier reef from land. Atolls form on top of submerged volcanoes and platform reefs may form near atolls or be part of a larger barrier reef system. Stresses that threaten reef communities include wide fluctuations in water temperature, sedimentation, coral mining, blast fishing, and souvenir hunting. Natural disturbances, such as storms, can also disrupt life in the reef but may help propagate the reef. The breaking of coral branches during a storm is one way that coral asexually reproduces.

lymph, enters the heart through holes, called ostia. It is then pumped through short arteries and into the body cavity. There are a number of adaptations for gas exchange among the arthropods. Spiders have book lungs consisting of multiple stacked plates, like pages in a book. Insects have trachea, tubes that connect to the outside through holes (spiracles) in the exoskeleton. The trachea transport air directly between body tissues and the environment. Rounding out the arthropods, aquatic crustaceans respire using filamentous gills.

The water vascular system (WVS) is unique to the phylum Echinodermata. This system of canals services thousands of tube feet, in the starfish, for example. These feet extend through the body wall and have many other functions in addition to locomotion. Due to circulating fluid within the WVS, tube feet also are involved in gas exchange, waste excretion, chemoreception, and food collection. Another echinoderm, the sea cucumber, possesses internal rather than external respiratory structures. These respiratory trees attach to the cloaca, the common collection area for the exit of digestive and reproductive systems from the body. Gases are exchanged via the pumping of seawater in and out of the cloaca.

Reproduction and Development

Reproduction among the invertebrates is almost as varied as the animals themselves. Cnidarians and sponges are just two of the many phyla that reproduce asexually, offspring arising by breaking off from the parent organism. Groups such as rotifers and some arthropods alternate between asexual and sexual reproduction, depending upon environmental conditions. The term parthenogenesis is used to describe development of an egg in the absence of fertilization. Parthenogenesis tends to occur during stable, favorable conditions. Sexual reproduction, the mixing of genes from two parents through uniting of egg and sperm, produces individuals with new combinations of genes, which may adapt them for survival under stressful conditions.

There are variations in sexual reproduction as well. Some invertebrates are hermaphrodites. These animals, such as earthworms, possess both male and female reproductive systems. Some can fertilize themselves; others cannot. When hermaphrodites mate with other members of their species, each individual donates and receives sperm, resulting in twice as many offspring per mating. Gonochoristic species have separate sexes, an individual being either male or female. This is the case for most insects.

In marine invertebrates, fertilization may be external. This involves broadcasting sperm and eggs into the surrounding seawater and relying on the ocean currents to bring the two together. Internal fertilization is the rule for freshwater and terrestrial invertebrates. Sperm may be transferred directly into the female's reproductive tract through a copulatory organ such as a penis. An indirect method of sperm transfer involves a package called a spermatophore. This chemical packet commonly provides nutrients for the female and her resultant offspring.

Aquatic larvae are commonly the dispersal stage in the life history of the particular invertebrate. Many times the adults are sedentary or even sessile, anchoring themselves to the ocean floor or remaining in self-constructed burrows. The larvae, on the other hand, are planktonic, relying on the ocean currents for transportation. A similar scenario exists with spiders. The young spin silken parachutes and use the wind currents to disperse away from the web of the mother spider. However, for many terrestrial invertebrates, the young represent the feeding stage. Lepidopteran caterpillars eat voraciously, and some adults, such as the luna moth, do not eat at all, living strictly off food stores acquired as a larva. Especially with the winged insects, it is the adults who colonize new areas.

Bibliography

Barnes, Robert D. *Invertebrate Zoology*. 5th ed. Philadelphia: Saunders College Publishing, 1987. This detailed, morphologically oriented textbook is a classic. There are excellent drawings and black and white photographs.

Campbell, Neil A., Jane B. Reece, and Lawrence G. Mitchell. *Biology*. 5th ed. Menlo Park, Calif.: Benjamin/Cummings, 1999. This is a general biology text used in many universities and some high schools. The chapter on invertebrates is an excellent survey of the group. Clear text and an abundance of color figures and photographs help to communicate important concepts.

Knutson, Roger M. *Fearsome Fauna: A Field Guide to the Creatures That Live in You*. New York: W. H. Freeman, 1999. This little volume and its companion, *Furtive Fauna: A Field Guide to the Creatures Who Live on You* (1996), are humorous but factual depictions of the invertebrate parasites of humans.

Pechenik, Jan A. *Biology of the Invertebrates*. 4th ed. Boston: McGraw-Hill, 2000. This is a very accessible book for studying the diversity of the invertebrates. Highlights include research focus boxes within the chapters, and questions for discussion at the end of each chapter, complete with pertinent, introductory-level references from major journals.

Robertson, Matthew, ed. *The Big Book of Bugs*. New York: Welcome Enterprises, 1999. Complete with 3D glasses, this book is fun for everyone. Contrary to what the title suggests, the book deals with a wide range of invertebrates. There are fact boxes, activities, quizzes, and many pictures. It lacks a table of contents, which makes it difficult to look up specific items, but it is fun to flip through the pages.

ISOLATING MECHANISMS IN EVOLUTION

Type of animal science: Evolution
Fields of study: Ecology, evolutionary science, genetics, population biology, reproduction science, zoology

Isolating mechanisms act to prevent interbreeding and the exchange of genes between species. The establishment of isolating mechanisms between populations is a critical step in the formation of new species.

Principal Terms

ALLOZYME: one of two or more forms of an enzyme determined by different alleles of the same gene; usually analyzed by gel electrophoresis

CHLOROPLAST DEOXYRIBONUCLEIC ACID: a circular DNA molecule found in chloroplasts; chloroplasts are cytoplasmic organelles of green plants and some protists that carry out photosynthesis

FISSION: the division of an organism into two or more essentially identical organisms; an asexual process

HERMAPHRODITE: an individual with both male and female organs; functions as both male and female

HYBRID: a term that in the broad sense can apply to any offspring produced by parents that differ in one or more inheritable characteristics; used to denote offspring produced by a cross between different species

MITOCHONDRIAL DEOXYRIBONUCLEIC ACID (DNA): a circular molecule of DNA found in the mitochondria; mitochondria are cytoplasmic organelles that function in oxidative respiration

NUCLEAR RIBOSOMAL DEOXYRIBONUCLEIC ACID (DNA): nuclear DNA that codes for the ribosomal DNAs; ribosomes are small cytoplasmic particles that function in protein synthesis

Isolating mechanisms (reproductive isolating mechanisms) prevent interbreeding between species. The term, which was first used by Theodosius Dobzhansky in 1937 in his landmark book *Genetics and the Origin of Species*, refers to mechanisms that are genetically influenced and intrinsic. Geographic isolation can prevent interbreeding between populations, but it is an extrinsic factor and therefore does not qualify as an isolating mechanism. Isolating mechanisms function only between sexually reproducing species. They have no applicability to forms that reproduce only by asexual means, as by mitotic fission, stoloniferous or vegetative reproduction, or egg development without fertilization (parthenogenesis in animals). Obligatory self-fertilization in hermaphrodites (rare in animals) is a distortion of the sexual process that produces essentially the same results as asexual reproduction. Many lower animals and protists regularly employ both asexual and sexual means of reproduction, and the significance of isolating mechanisms in such forms is essentially the same as in normal sexual species.

Premating Mechanisms

Reproductive isolating mechanisms are usually classified into two main groups. Premating (prezygotic) mechanisms operate prior to mating, or the release of gametes, and, therefore, do not result in a wastage of the reproductive potential of the individual. Postmating (postzygotic) mechanisms come into play after mating, or the release of gametes, and could result in a loss of the genetic contribution of the individual to the next generation.

This distinction is also important in the theoretical sense in that natural selection should favor genes that promote premating isolation; those that do not presumably would be lost more often through mismatings (assuming that hybrids are not produced, or are sterile or inferior), and this could lead to a reinforcement of premating isolation.

Ethological (behavioral) isolation is the most important category of premating isolation in animals. The selection of a mate and the mating process depends upon the response of both partners to various sensory cues, any one of which may be species-specific. Although one kind of sensory stimulus may be emphasized, different cues may come into play at different stages of the pairing process. Visual signals provided by color, pattern, or method of display are often of particular importance in diurnal animals such as birds, many lizards, certain spiders, and fish. Sounds, as in male mating calls, are often important in nocturnal breeders such as crickets or frogs but are also important in birds. Mate discrimination based on chemical signals or odors (pheromones) is of fundamental importance in many different kinds of animals, especially those where visual cues or sound are not emphasized; chemical cues also are often important in aquatic animals with external fertilization. Tactile stimuli (touch) often play an important role in courtship once contact is established between the sexes. Even electrical signals appear to be utilized in some electrogenic fish.

Ecological (habitat) isolation often plays an important role. Different forms may be adapted to different habitats in the same general area and may meet only infrequently at the time of reproduction. One species of deer mouse, for example, may frequent woods, while another is found in old fields; one fish species spawns in riffles, while another spawns in still pools. This type of isolation, although frequent and widespread, is often incomplete as the different forms may come together in transitional habitats. The importance of ecological isolation, however, is attested by the fact that instances in which hybrid swarms are produced between forms that normally remain distinct have often been found to be the result of disruption of the environment, usually by humans. Mechanical isolation is a less-important type of premating isolation, but it can function in some combinations. Two related animal species, for example, may be mismatched because of differences in size, proportions, or structure of genitalia.

Finally, temporal differences often contribute to premating isolation. The commonest type of temporal isolation is seasonal isolation: Species may reproduce at different times of the year. A species of toad in the eastern United States, for example, breeds in the early spring, while a related species breeds in the late spring, with only a short period of overlap. Differences can also involve the time of day, whereby one species may mate at night and another during the day. Such differences, as in the case of ecological isolation, are often incomplete but may be an important component of premating isolation.

Postmating Mechanisms

If premating mechanisms fail, postmating mechanisms can come into play. If gametes are released, there still may be a failure of fertilization (intersterility). Spermatozoa may fail to penetrate the egg, or even with penetration there may be no fusion of the egg and sperm nucleus. Fertilization failure is almost universal between remotely related species (as from different families or above) and occasionally occurs even between closely related forms.

If fertilization does take place, other postmating mechanisms may operate. The hybrid may be inviable (F1 or zygotic inviability). Embryonic development may be abnormal, and the embryo may die at some stage, or the offspring may be defective. In other cases, development may be essentially normal, but the hybrid may be ill-adapted to survive in any available habitat or cannot compete for a mate (hybrid adaptive inferiority). Even if hybrids are produced, they may be partially to totally sterile (hybrid sterility). Hybrids between closely related forms are more likely to be fertile than those between more distantly related species, but the correlation is an inexact one. The causes for hybrid sterility are complex and can involve genetic factors, differences in gene arrangements on the chromosomes that disrupt normal chromosomal pairing and segregation at meiosis, and incompatibilities between cytoplasmic factors and the chromosomes. If the hybrids are fertile and interbreed or backcross to one of the parental forms, a more subtle phenomenon known as hybrid breakdown sometimes occurs. It takes the form of reduced fertility or reduced viability in the offspring. The basis for hybrid breakdown is poorly understood but may result from an imbalance of gene complexes contributed by the two species.

It should be emphasized that in most cases of reproductive isolation that have been carefully studied, more than one kind of isolating mechanism has been found to be present. Even though one type is clearly of paramount importance, it is usually supplemented by others, and should it fail, others may come into play. In this sense, reproductive isolation can be viewed as a fail-safe system. A striking difference in the overall pattern of reproductive isolation between animals and plants, however, is the much greater importance of premating isolation in animals and the emphasis on postmating mechanisms in plants. Ethological isolation, taken together with other premating mechanisms, is highly effective in animals, and postmating factors usually function only as a last resort.

Field Studies and Experimental Studies

Field studies have often been employed in the investigation of some types of premating isolating mechanisms. Differences in such things as breeding times, factors associated with onset of breeding activity, and differences in habitat distribution or selection of a breeding site are all subject to direct field observation. Comparative studies of courtship behavior in the field or laboratory often provide clues as to the types of sensory signals that may be important in the separation of related species.

Mating discrimination experiments carried on in the laboratory have often been employed to provide more precise information on the role played by different odors, colors, or patterns, courtship rituals, or sounds in mate selection. Certain pheromones, for example, which act as sexual attractants, have been shown to be highly species-specific in some insects. The presence or absence of certain colors or their presentation has been shown experimentally to be important in mate discrimination in vertebrates as diverse as fish, lizards, and birds. Call discrimination experiments, in which a receptive female is given a choice between recorded calls of males of her own and another species, have demonstrated the critical importance of mating call differences in reproductive isolation in frogs and toads. Synthetically generated calls have sometimes been used to pinpoint the precise call component responsible for the difference in response.

Studies on postmating isolating mechanisms have most often involved laboratory crosses in which the degree of intersterility, hybrid sterility, or hybrid inviability can be analyzed under controlled conditions. In instances in which artificial crosses are not feasible, natural hybrids sometimes occur and can be tested. The identification of natural backcross products can attest incomplete postmating, as well as premating isolation. Instances of extensive natural hybridization are of special interest and have often been subjected to particularly close scrutiny. Such cases often throw light on factors that can lead to a breakdown of reproductive isolation. Also, as natural hybridization more often occurs between marginally differentiated forms in earlier stages of speciation, new insights into the process of species formation can sometimes be obtained. Finally, such studies may yield information on the evolutionary role of hybridization, including introgressive hybridization, the leakage of genes from one species into another. Morphological analysis has long been used in such cases, and chromosomal studies are sometimes appropriate. In recent years, allozyme analysis by gel electrophoresis has become a routine tool in estimates of gene exchange, and molecular analysis of nuclear deoxyribonucleic acid (DNA), or mitochondrial DNA, have been useful. As mitochondria are normally passed on only maternally, their DNA can also be used to identify cases in which females of only one of the two species has been involved in the breakdown of reproductive isolation.

Investigations of the role of natural selection in the development and reinforcement of reproductive isolation have employed two different approaches. One has involved the measurement of geographic variation in the degree of difference in some signal character (call, color, or pattern, for example) thought to function in premating isolation between two species that have overlapping ranges. If the difference is consistently greater within the zone of overlap (reproductive character displacement), an argument can be made for the operation of reinforcement. Another approach has involved laboratory simulations, usually with the fruit fly *Drosophila*, in which some type of selective pressure is exerted against offspring produced by crosses between different stocks, and measurement is made of the frequency of mismatings through successive generations. The results of such studies to this time are contradictory, and the role of selection with regard to development of reproductive isolation requires further study.

Enhancing Reproductive Efficiency

The efficiency of reproduction in most animals is enhanced immeasurably by premating isolating mechanisms. Clearly, in animals a random testing of potential mates without regard to type is totally unacceptable for most species in terms of reproductive capacity and time and energy resources. Premating isolation in this sense is a major factor in promoting species diversity in animal communities.

Both premating and postmating isolating mechanisms are also critical to the maintenance of species diversity in that they act to protect the genetic integrity of each form: A species cannot maintain its identity without barriers that prevent the free exchange of genes with other species. Furthermore, a species functions as the primary unit of adaptation. Every species in a community has its own unique combination of adaptive features that enable it to exploit the resources of its environment and to coexist with other species with a minimum of competition. The diversity of different species that can coexist in the same area depends upon the unique "niche" that each occupies; adaptive features that determine that niche are based on the unique genetic constitution of each species, and this genetic constitution is protected through reproductive isolation.

The development of reproductive isolating mechanisms is also critical to the formation of new species (speciation), and ultimately to the development of new organic diversity. The most widely accepted, objective, and theoretically operational concept for a sexual species is the biological species concept. Such a species can be defined as population or group of populations, members of which are potentially capable of interbreeding but which are reproductively isolated from other species. The origin of new species, therefore, depends upon the development of reproductive isolating mechanisms between populations. A major focus of research in evolutionary biology and systematics has been, and continues to be, on the various factors that influence the development of reproductive isolating mechanisms.

Bibliography

Baker, Jeffrey J. W., and Garland E. Allen. *The Study of Biology*. 4th ed. Reading, Mass.: Addison-Wesley, 1982. Some of the more complete college-level biology texts provide a good overview of evolution and related topics for the beginner. Coverage in this text is particularly complete, including treatment of isolating mechanisms and speciation. A list of suggested readings should be helpful.

Dobzhansky, Theodosius. *Genetics of the Evolutionary Process*. New York: Columbia University Press, 1970. Dobzhansky's contributions over the years have had a major impact on genetics and evolutionary biology. The present book represents a revision and expansion of his *Genetics and the Origin of Species*, which first appeared in 1937. The book is directed at the advanced reader and presupposes a foundation in genetics. Much of chapter 10, however, which is devoted to an excellent review of reproductive isolation, can be understood by the more general reader. An extensive technical bibliography is provided.

Dobzhansky, Theodosius, Francisco J. Ayala, G. Ledyard Stebbins, and James W. Valentine. *Evolution*. San Francisco: W. H. Freeman, 1977. An excellent, if somewhat uneven textbook by four distinguished scientists. Although intended for advanced undergraduates and graduate students, the material is presented in such a way as to benefit those with a less complete background. Coverage of molecular techniques is particularly good but somewhat dated. Twelve pages are devoted to isolating mechanisms, and many references are given under literature cited.

Futuyma, Douglas J. *Evolutionary Biology*. 3d ed. Sunderland, Mass.: Sinauer Associates, 1998. This process-oriented textbook assumes some undergraduate training in biology, especially genetics, but most topics are prefaced with background information that should help the less prepared. Treatment of isolating mechanisms is brief, but the book provides one of the best introductions to current evolution theory presently available. Major references are given at the end of each chapter, and there is an extensive list of references under literature cited.

Mayr, Ernst. *Populations, Species, and Evolution*. Cambridge, Mass.: The Belknap Press of Harvard University Press, 1970. This text is essentially an abridgment of Mayr's *Animal Species and Evolution* (1963). Ernst Mayr has been a prime mover and shaker in the development of evolution theory over the past fifty years, and anyone with a serious interest in the subject should be exposed to some of his writings. This book, although directed toward the more advanced student, is lucidly written and can benefit those with a more limited background. Chapter 5 deals with isolating mechanisms, particularly in animals. A technical bibliography is provided.

JAGUARS

Type of animal science: Classification
Fields of study: Anatomy, physiology, wildlife ecology

Jaguars are the largest cats found in North or South America, originally occupying a wide diversity of habitats from the southwestern United States to Patagonia.

Principal Term

VIBRISSAE: stiff hairs, projecting as feelers from nose and head

Among big cats, jaguars, much larger than leopards, are exceeded in size only by lions and tigers. Males weigh from 125 to 250 pounds, are 6 to 9 feet long (including a tail up to 2.5 feet long), and stand twenty-four to thirty inches tall at the shoulder; females tend to be 20 percent smaller. Jaguar heads are massive and rounded; their bodies compact and heavily muscled. Individuals living in densely forested areas of the Amazon basin are significantly smaller than those inhabiting open terrain.

Tawny or yellow, with black rings and spots, jaguar coats resemble those of the leopard; however, jaguar coat rosettes are larger and usually contain black spots in their centers. Examples of melanism occur in Amazon regions, where jaguars are often called black panthers.

Behavior

Jaguar litters usually contain one to four cubs, which remain with their mother for eighteen months to two years while learning how to hunt. Other than during mating periods, adults live solitary lives, patrolling their own distinctly marked territories. Jaguar hunting ranges vary in size from five square miles, where prey is abundant, to two hundred square miles, where it is scarce. Male territories usually overlap the smaller ranges of several females.

Jaguars are crepuscular hunters, preferring dim light in which to stalk and surprise victims by leaping on their backs. The name jaguar comes from the Guarani word *yaguara*, meaning "wild beast that can kill its prey in a single bound." Large eyes and sensitive vibrissae permit jaguars to maneuver in the dark. They are opportunistic hunters, taking armadillos, peccaries, deer, capybaras, anteaters, caimans, turtles, and fish. Jaguars possess the most powerful bite among big cats; large canine teeth easily crush skulls and

Jaguar Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Eutheria
Order: Carnivora
Family: Felidae (cats)
Genus and species: Panthera onca
Geographical location: Originally ranged from the southwestern United States to southern Argentina
Habitat: Forests, jungles, and grassy plains
Gestational period: About fourteen weeks
Life span: Ten to twelve years in the wild, over twenty years in captivity
Special anatomy: Large eyes with excellent night vision; jaws adapted to seizing and gripping prey, teeth designed for tearing and slicing flesh

Image Not Available

penetrate armadillo armor or turtle shells. Sharp carnassial teeth and rasplike papillae soon clean their victims' bones.

Relations with Humans

Pre-Columbian Indian societies called the jaguar "Master of Animals," associating it with success in hunting and warfare, invoking it in religious rituals, and assigning it high social status. Jaguar thrones and jaguar skins were power symbols for rulers; hunters and warriors wore necklaces and bracelets of jaguar teeth or claws. Preferred foods of the elite were the meats that jaguars ate: venison, peccary, capybara, and armadillo.

European settlers viewed jaguars as dangerous competitors to be hunted and killed. When Europeans arrived, sixteen subspecies of jaguars inhabited a continuous area stretching from the southwestern United States to Patagonia in Argentina. Before the end of the twentieth century, all subspecies of jaguar were endangered, their territories reduced to a series of disconnected areas lying between southern Mexico and northeast Argentina. In North and Central America, the jaguar lost 67 percent of its range, in South America about 38 percent. Most of the estimated fifteen thousand jaguars remaining exist in a few relatively undisturbed jungle regions of Central America and the Amazon basin.

Hunting, destruction of habitat, and competition with ranchers and farmers all threaten the survival of the jaguar. In 1968, the United States imported 13,5l6 jaguar skins. The number of cats slain declined after the 1975 Convention on International Trade in Endangered Species banned traffic in jaguar pelts. However, illegal trade continues; it is profitable because the beautiful skins are as greatly prized by today's high-status women as they were by Inca monarchs.

Jaguars tend to avoid open areas such as pastures and villages, and rarely cross into fenced fields. However, when ranchers and farmers permit their animals to wander into jaguar hunting territory, they provide an easy meal. Such depredations, along with rare attacks on humans, create demands for the extirpation of the offenders.

Continued destruction of habitat, as forests and jungles are leveled for timber or for farm and ranch land, is the greatest threat to jaguar survival. As remaining territory becomes ever more discontinuous, populations becomes less dense, and reproductive success becomes problematic. Whether jaguars can survive in wild, free-ranging populations, or will be found only in zoos and carefully protected national parks, remains an unanswered question.

JELLYFISH

Type of animal science: Classification
Fields of study: Anatomy, invertebrate biology, marine biology, physiology

Over two hundred species of jellyfish are known; they are abundant, especially in shallow, warm, or subtropical waters. The jellyfish body plan is simple, but they possess unique stinging structures that are used for foraging and defense.

Principal Terms

CILIATED: bearing short, hairlike organelles on the surface of cells, used for motility

CNIDOBLASTS: specialized cells on the body or tentacles of jellyfish that contain nematocysts

MEDUSA: adult umbrella- or bell-shaped forms of jellyfish, with mouth facing downward

MESOGLEA: gelatinous material lying between the inner and outer layers of a jellyfish

NEMATOCYST: stinging structures containing barbs and/or poison

PLANULA: free-swimming, ciliated jellyfish larva

POLYP: immature cylindrical forms of jellyfish with mouth facing upward

The gelatinous jellyfish are widespread in marine environments, although they are most common in tropical and subtropical regions. These ancient animals first appeared on earth over 650 million years ago. The smallest jellyfish are difficult to see without a microscope, while the largest known jellyfish is 2.5 meters in diameter; some jellyfish may have tentacles over 100 feet in length. The body plan of jellyfish is relatively primitive and contains less than 5 percent solid organic matter, the remaining bulk coming from water. They completely lack internal organs. The bell-like jellyfish bodies are composed of an outer layer of epidermis and an inner layer of gastrodermis that lines the gut. The gut has a single oral opening. Between the two layers is the mesoglea, which contains few cells and has a low metabolic rate. Four to eight oral arms are located near the oral opening and are used to transport food that has been captured by the tentacles.

Jellyfish are able to exert minimal control over their movement, being largely at the mercy of ocean currents. Jellyfish do, however, have some regulation over vertical movement. They possess a ring of muscles embedded on the underside of the bell that pulses rhythmically, pushing water out of the hollow bell. Using this jet propulsion, jellyfish can change their position in the water column, moving in response to light and prey.

Feeding Strategy of Jellyfish

Jellyfish are simple but specialized carnivores. Although jellyfish have a low metabolic rate, they have the ability to capture large prey. These two characteristics allow jellyfish to survive in environments where prey are scarce. Jellyfish are equipped with a specialized apparatus, the cnidoblast, for defense and feeding. Cnidoblasts are found by the hundreds or thousands on the tentacles and sometimes on the body surface. Within each cnidoblast is a coiled harpoonlike nematocyst that is discharged by the presence of potential prey. The nematocyst injects poison into the prey as spines on the nematocyst anchor it to the prey. The trapped, paralyzed prey is pulled back by the tentacles and stuffed into the gastrovascular cavity to be digested. Jellyfish do not attack humans, but humans may receive stings if they encounter jellyfish. The effects of jellyfish poison on humans can range from a mild, itchy rash to death.

Jellyfish Facts

Classification:
Kingdom: Animalia
Subkingdom: Eumetazoa
Phylum: Cnidaria
Classes: Scyphozoa (jellyfish), Cubozoa (box jellyfish)
Orders: Stauromedusae (sessile cup-shaped forms), Coronatae (deep-dwelling jellyfish), Semaeostomae (disc jellyfish), Rhizostomae (tentacle-less jellyfish), Chirodropidae and Carybdeidae (box jellyfish)
Geographical location: All the Earth's oceans
Habitat: Almost entirely marine, although a few freshwater species are known
Gestational period: Not well studied, but many species appear to reproduce once a year
Life span: Polyps usually develop over a period lasting a few months but may live for several years producing clones; adult medusa forms live two to six months
Special anatomy: Umbrella-like body; no head or skeleton; composed of outer epithelial layer and inner gastrodermis layer with thick elastic jellylike substance between them; gastrovascular cavity; specialized ring of epitheliomuscular cells that pulses rhythmically to propel the animal through the water; four to eight oral arms; tentacles bearing cnidoblasts containing nematocysts

Jellyfish Reproduction

Most jellyfish proceed through several distinct stages in their life cycles. Male medusae produce sperm that are released from the oral opening into the oral opening of the female. The female then releases fertilized eggs which develop into slipper-shaped, solid masses of ciliated cells called planula which move through the water and even-

The tentacles of jellyfish contain cnidoblasts, organs that shoot harpoonlike, venomous nematocysts into prey; the paralyzed victim is then reeled back to the jellyfish and consumed. (PhotoDisc) tually settle onto a solid surface. From these settled planula develop polyps that have cylindrical stalks attached to the substrate, with tentacles surrounding their mouths. At this stage, the polyps resemble sea anemones. The polyps divide and bud into tiny young jellyfish (ephyra) which are often carried far from the parent polyp by ocean currents. The ephyra develop into mature medusae over several weeks. The medusae normally live three to six months.

Twig, George C. *Jellies: The Life of Jellyfish*. Brookfield, Conn.: Millbrook Press, 2000. Aimed at a young audience, this book describes the basic processes of life in jellyfish, accompanied by numerous color photographs.

KANGAROOS

Type of animal science: Classification
Fields of study: Anatomy, conservation biology, ethology, physiology, reproduction science, wildlife ecology

Kangaroos, comprising six species, are the largest marsupials. They evolved as the major grazing animals in Australia. Alone among large vertebrates, they hop as their preferred form of locomotion.

Principal Terms

DIAPAUSE: an interruption in embryonic development
HERBIVORE: animal solely dependent on plant material for its nutrition
QUADRUPED: animal with four feet

The ancestors of kangaroos differentiated from small, tree-dwelling, possumlike marsupials fifty million years before the present. About thirty million years ago, they came down from the trees of the rain forest that covered most of Australia at the time. Around five million years ago, the continent had started to dry out, and species closely related to modern kangaroos appeared. When the Aborigines first came to Australia forty thousand years ago, the continent included some larger marsupials. The latter apparently were not as fast and mobile as kangaroos, were easier prey, were overhunted, and as a result became extinct. The kangaroos were smaller and swifter, permitting them to survive. The six living species of true, large kangaroos differ in their habitats (temperate woodlands, tropical grasslands, arid outback) and size; the red kangaroo is the largest, with some males weighing two hundred pounds and standing six feet tall; the smallest, the black wallaroo, can weigh sixty pounds. Smaller relatives of kangaroos include wallabies (up to sixty pounds), pademelons (up to fifteen pounds), and rat kangaroos (less than one pound). While kangaroos are only found in Australia, some smaller relatives are also found in New Guinea, which was contiguous with Australia in the distant past.

Physical Characteristics of Kangaroos

Kangaroos stand on large rear legs, using their long tail for added support. They have small front legs, with handlike paws that lack an opposable thumb. Hopping is their most unusual characteristic. Besides kangaroos and their relatives, no vertebrate bigger than ten pounds hops. At slow speeds, kangaroos walk awkwardly and inefficiently, using their front legs and tail. However, at speeds over fifteen miles per hour, they hop upright in a graceful motion that can be more energetically efficient than running by quadrupeds, whose energy use is proportional to their speed. Kangaroos increase their speed by lengthening their stride, while keeping their hop frequency constant, at little increased energy expenditure. They propel themselves by virtue of highly elastic legs which move in unison and use their long tails to provide balance.

As marsupials, kangaroos nurse their young (called joeys) in a pouch. Female kangaroos, half the size of males, have one-month gestations, which can be interrupted if a young is still suckling in the pouch or under adverse nutritional conditions. In these cases, the embryo goes into diapause, a form of "suspended animation," until hormonal signals permit development to resume. The newborn is highly immature, pink and naked, resembles a slug, and weighs less than 0.03 ounces. Using its front legs and a good sense of smell, it crawls from the birth canal into the pouch

The kangaroo's strong tail assists it in maintaining an upright, bipedal posture. It is the only mammal with a weight over ten pounds that hops as its mode of locomotion. (Adobe)

and attaches itself to one of four teats of the mammary gland. Over the next three months, it remains permanently attached to that teat and becomes fully developed. Depending on the species, joeys leave the pouch for the first time at six to ten months, permanently leave the pouch at eight to eleven months, and are weaned at eleven to eighteen months. Females are sexually mature at eighteen months to two years, although some males do not become so until they are four years old.

Kangaroos are herbivores, and all six species are grazing animals. Their teeth are suited to grasses rather than shrubs and trees. They are also very efficient in their use of water, making them suitable for the arid regions of Australia. Some species consume less than 10 percent the water sheep do under the same conditions. When temperatures are moderate, they can get all of their water from the plants that they eat. They are inactive in the heat of the day and cool themselves by panting, sweating, and licking; the latter refers to the fact that they cover their front legs with saliva, which by evaporation cools not only their extremities but also their bodies via a dense network of blood vessels close to the surface. Kangaroos are among the most heat-tolerant of mammals. In addition, they have large, padded feet that compact the soil less than domesticated livestock.

Future of Kangaroos

Totaling over twenty million, the six species of large kangaroos are not presently endangered. This is in contrast with the risk to survival faced by some wallabies and smaller marsupials that are preyed upon by introduced wild animals, such as foxes, or by feral cats. The habitats of most kangaroos have been reduced by human activities, housing, industry, and agriculture, although the range of some of the less arid-tolerant species (eastern gray and western gray) has been increased when water is provided for livestock in remote regions. In addition, areas where sheep are protected from dingoes, as with the patrolled fence that stretches across Australia, have increased numbers of kangaroos. While they do compete with sheep and cattle for food and water, the extent of competition is limited, except during drought. Farming kangaroos for meat and hides remains a possibility but has not been developed. Some extensive preserves would be desirable not only to display these large animals in their natural environment but also to conserve their smaller, endangered relatives.

—James L. Robinson

Kangaroo Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Marsupialia
Family: Macropodidae (kangaroos and wallabies)
Genus and species: Macropus, with fourteen species including *M. giganteus* (eastern gray kangaroo), *M. fuliginosus* (western gray kangaroo), *M. rufus* (red kangaroo), *M. robustus* (wallaroo, four subspecies), *M. bernardus* (black wallaroo), *M. antilopinus* (antilopine kangaroo)
Geographical location: Australia
Habitat: Grasslands
Gestational period: One month, followed by six to eleven months in marsupium
Life span: Twelve to eighteen years in the wild; twenty-eight years in captivity
Special anatomy: Hops instead of running, by virtue of elastic legs and large tail for balance; gives birth to highly immature young that nurse and develop in a pouch

Dawson, Terence J. *Kangaroos: Biology of the Largest Marsupials*. Ithaca, N.Y.: Comstock Publishing, 1995. Written by an internationally recognized expert on kangaroos, this book details the natural history of all six species, including their habitat, nutrition, and reproduction. It also deals with conservation efforts and the potential of managing them as ranched animals.

McCullough, Dale, and Yvette McCullough. *Kangaroos of Outback Australia*. New York: Columbia University Press, 2000. This book documents a fifteen-month study of the ecology and behavior of the three largest kangaroos, the red, eastern gray, and western gray on a reserve where their ranges overlap.

Watts, Dave. *Kangaroos and Wallabies of Australia*. Sydney: New Holland, 1999. Written and photographed by one of Australia's leading wildlife photographers, this book describes and pictures kangaroos and their relatives, including wallabies, pandemelons, and rat kangaroos.

KIDNEYS AND OTHER EXCRETORY STRUCTURES

Type of animal science: Physiology
Fields of study: Anatomy, biochemistry, cell biology

All cells must live in a relatively constant environment. The kidney and other excretory organs play important roles in the regulation of the processes that maintain this necessary homeostasis. Although excretion is often assumed to be the only role of the kidney, it also regulates blood pressure, produces hormones, and affects the body's pH.

Principal Terms

ANTIDIURETIC HORMONE (ADH): a hormone produced in the hypothalamus that controls reabsorption of water in the loop of Henle

CONTRACTILE VACUOLE: the excretory organ of several one-celled organisms

FILTRATION: the process of diffusion of plasma from the blood to the glomerulus and nephron

GLOMERULUS (pl. GLOMERULI): a capsule fitting around capillary blood vessels that receives the filtrate from the blood and passes it into the tubule

LOOP OF HENLE: a slender hairpin turn in the tubule where most adjustment of the water balance of the body occurs

MALPHIGIAN TUBULE: the primitive excretory organ of insects

NEPHRIDIA: the primitive forms of kidneys found in worms and lower organisms

NEPHRON: the basic excretory unit of the kidney

TUBULE: the long, slender part of the nephron that is the location of almost all kidney function

UREA: a substance formed from by-products of protein metabolism and excreted by the kidney

All cells, from the single-celled animals to the highly diversified cells of higher mammals, must maintain a constant internal environment with regard to the kinds and amounts of specific ions, the pH of the protoplasm, the osmotic pressure, the water content of the cells, and the excretion of wastes. The kidney in vertebrates and the varied types of excretory organs found in lower animals perform this function. Although the excretory function is very important, an animal will die more quickly from a disturbance of the composition of the internal environment of the cell than it will from an accumulation of wastes. Fortunately, the kidney performs functions that keep both of these from happening.

Maintaining Fluid Homeostasis

All cells live in a watery environment, which is maintained constant through the processes of homeostasis. Maintaining homeostasis presents different problems for different organisms. For a primate, living in the air, water loss is a constant problem, and water must be conserved. A freshwater fish, on the other hand, takes in large quantities of water that has a lower concentration of salts than its body fluids, and it must excrete the excess. An ocean fish, living in water with a much greater concentration of salts than its body fluids, must obtain water from its environment and still avoid increasing the concentration of salts in the body fluids.

A kidney is able to perform all these functions, although in each of these cases it acts in a different way. The freshwater fish must excrete large quantities of very dilute fluid in order to maintain salt conservation, whereas the saltwater fish must excrete a high concentration of salt in a very concentrated solution. The primate must be able to regulate the output of fluid as a function of water intake. Evolution has adapted the kidney of each animal to its environment.

In addition, animals survive by metabolizing foodstuffs to provide the energy for movement. One of the major metabolic processes is the breakdown of protein to produce energy for the synthesis of other proteins and the rebuilding of body structures. In the breakdown of protein, nitrogen is freed from the organic molecule and must be excreted. One of the resultant nitrogen products is ammonia, which is toxic. The ammonia is converted into a less toxic material, urea (or uric acid, in some animals), before it is excreted by the kidney. In addition, the metabolism of the body usually results in the production of acids, particularly if fat is metabolized. The body functions well only within a narrow range of acidity, so unless the excess acid is removed, serious problems quickly arise. The kidney serves the function of maintaining the pH at a constant value.

The Excretory Organs

The organs of excretion have taken many forms. Simple single-celled organisms such as amoebas are able to form contractile vacuoles, or walled-off spaces within the cell, in which water can be stored and waste products deposited. These vacuoles are periodically transported through the cytoplasm and excreted through the external cell membrane. The size and number of vacuoles are determined by water intake and the organism's need to eliminate water as well as by the accumulation of waste materials.

As animals developed more cell types and the number of cells increased dramatically, the need to provide a constant internal environment around the cells arose. The excretory organs became, of necessity, more complex in nature. In addition to excreting waste products, they developed abilities to retain some ions and excrete others, to retain or excrete water, and to retain or excrete acids or bases to maintain a constant environment.

Many organisms have no obvious means of regulating water and salt balance, and they apparently accomplish this feat through the skin or the gut; others have rudimentary organs of excretion. Many lower animals have nephridia, primitive versions of the kidney that excrete water and wastes and regulate ion concentration. These are simple tubes into which body fluids pass; the fluids are excreted after chemical alteration. In animals such as worms, that have segments, a pair of nephridia may be located in each segment. Some of them open into the body cavity, while others are closed. In some animals, these are well differentiated and are called flame cells. These tubular structures serve to regulate the internal environment of the body. For example, if the sodium concentration in the coelom, or internal cavity, is high, the nephridia excrete sodium; if it is low, they reabsorb it. In the insect, the organ of excretion is the Malphigian tubule, which is able to regulate ion and water exchange. The accumulated fluid is flushed into the gut, where absorption of ions and water takes place.

The Kidney

In vertebrates, the kidney is the organ responsible for eliminating water and waste products. The kidney is a bean-shaped organ that receives a large blood supply from the heart. It has several auxiliary structures: the ureter, which collects fluid or urine from all the tubules; the bladder, which acts as a storage organ; and the urethra, which opens from the bladder to the outside of the body. The kidney consists of more than a million nephrons arranged symmetrically, with the lower part of each nephron pointing toward the hilus (the pole of the kidney where the ureter arises).

The kidney maintains homeostasis of the body through four basic mechanisms: filtration, reabsorption, secretion, and concentration. In filtration, a liquid portion of the blood is transferred to the tubule. There the cells proceed to reabsorb necessary materials, to secrete additional materials into the tubular liquid from the blood, and to concentrate the fluid in the tubule.

The nephron is the fundamental structure of the kidney. The nephron is a long, slender tube with different parts that are capable of secreting or reabsorbing ions, water, and other substances either to remove materials from the blood or to return materials to the blood, depending upon the needs of the body. One process it performs is the elimination of ammonia products and other waste materials.

The nephron consists of two major parts: a glomerulus and a tubule. The process of urine formation begins with filtration. The blood enters the kidney and then the glomeruli, under high pressure from the heart. The pressure forces fluid from the blood into the tubule. The amount is tremendous; in humans, every day some 180 liters (about 40 gallons of fluid) pass from the blood into the nephron. All the blood in the body passes through the nephron about thirty times per day. During this same period, seven hundred liters of blood pass through the kidneys, so only a small portion is actually filtered or transferred to the tubule. Most remarkable of all, only about 1.5 liters of urine are produced each day. The rest of this large volume is reabsorbed by the tubule.

As the fluid passes into the nephron, it enters a section of tubule at the beginning that reabsorbs much of the material needed by the body. Such things as the glucose needed for energy, amino acids for protein building, vitamins, and ions needed to maintain the correct concentration of the blood are removed and transported by the cells of the nephron back into the blood. At the same time, about 85 percent of the water of the filtrate is also transported back into the blood.

The cells of the nephron are able to secrete materials from the blood to the tubular fluid. This process is exactly the opposite of the reabsorption of substances. One of the most readily secreted substances is sodium. The cells of the body are high in potassium and low in sodium; since sodium is a constituent of every diet, the removal of excess sodium is necessary. Sodium is picked up from the blood that circulates around the nephron and is secreted into the tubule. The process of secretion also extends to other materials. The potent antibiotic penicillin was ineffective when it was first used to treat systemic infections, because it was rapidly secreted by the tubules. A high enough concentration could not be accumulated in the blood to destroy bacteria. It became useful only when a derivative that was not secreted could be found.

The Loop of Henle

The tubular fluid that has been adjusted in concentration, volume of fluid, and concentration of ions and other materials now passes into a hairpin-shaped portion of the tubule called the loop of Henle. The loop of Henle adjusts the volume of filtrate. A hormone is produced by the brain (in the hypothalamus) that is capable of altering the permeability of the cells of the loop of Henle to water. The substance, a protein hormone called antidiuretic hormone (ADH), causes the reabsorption of water from the loop. Cells of the hypothalamus respond to the concentration of particles in the blood (its osmotic pressure) and adjust the amount of water that is reabsorbed from the tubule by secreting more or less ADH as necessary to maintain a constant concentration in the blood. The range of adjustment is remarkable. The volume of urine produced can range from about 0.5 liter to more than 30 liters per day, depending upon the need. If water is administered or restricted, the water concentration of the body changes. This causes a change in the production of ADH, which in turn increases or decreases the excretion of water to return the level to normal.

Sweating also causes water loss and thus decreases urine flow. Intake of large amounts of fluid will dilute the body fluids and cause an increased urine output. There is a constant adjustment, because water is lost by breathing, through the skin, and through excretions, and the kidney must make the proper corrections. Losses have been reduced to a minimum in animals such as the kangaroo rat, which lives in the desert and must conserve water. All of its water intake is from seeds and other foods containing some water, and excretion is almost zero. The desert rat is able to concentrate urine to a level about five times that of the human.

As the urine passes from the loop of Henle, it enters upon a final adjustment in the latter portion of the tubule. Volume, concentration of material, and the like are adjusted to maintain homeostasis. Other alterations of the fluid are also made in the passage down the tubule. If the body becomes acidic, the cells of the tubule exchange sodium ions, which are neutral, for acid ions (H+), thus causing the body to lose acid. Conversely, if the body becomes basic (lacks acid or hydrogen ions), the reverse is true.

Studying Kidney Function

The kidney can be studied on many different levels. The output of the kidney, the urine, and the input, the blood, can be analyzed in order to determine function of both kidneys. In some animals, such as the frog, the individual nephrons are visible under a microscope. Through the use of the stop-flow technique, the behavior of an individual portion of the nephron can be studied. In this technique, a very small needle is introduced into one portion of the nephron, and a small drop of oil is injected. Another drop is injected in an adjacent section of the nephron, thus isolating a section between the two drops. The exchanges that occur in that portion of the nephron can then be measured by taking samples of the fluid at intervals.

The whole kidney can be studied by examination of the kidney in relation to a reference substance. For example, the chemical inulin goes through the nephron without any alteration, so its excretion can be compared with other substances: If more of another substance appears in the urine in proportion to the inulin, the substance must have been excreted from the blood into the urine and secreted. If less is present, some material must have been reabsorbed from the tubule into the blood. This is called the clearance technique, and it is widely used to predict kidney function in health and disease. For less sophisticated testing, substances—such as certain dyes—that can be taken orally and are excreted by the kidney can be used to measure the rate of excretion. Radioopaque substances, substances that will appear on X rays, can be used to detect overt kidney malfunction.

Bibliography

Brenner, Barry M., ed. *Brenner and Rector's the Kidney*. 6th ed. Philadelphia: W. B. Saunders, 1999. Authoritative coverage of the kidney, focusing on human anatomy. Covers normal renal function, fluid and electrolyte abnormalities, pathogenesis, pathophysiology, and management of renal failure. Written for medical students and professionals.

Hainsworth, F. Reed. *Animal Physiology*. Reading, Mass.: Addison-Wesley, 1981. This is an excellent book, with a wealth of examples of kidney function in various animals, focusing on the processes by which it adjusts pH, ion concentration, and the like. Excellent illustrations, bibliographies, and notes.

Smith, Homer. *From Fish to Philosopher*. Garden City, N.Y.: Doubleday, 1961. This book exists in many paperback editions. It is a classic work for the layman on the function of the kidney. Smith is a final authority on the kidney, and he is also an excellent writer, an essayist of note, and a raconteur. There are few references, as this is a series of essays.

Starr, Cecie, and Ralph Taggart. *Biology: The Unity and Diversity of Life*. 9th ed. Pacific Grove, Calif.: Brooks/Cole, 2001. An elementary biology text. It has good material on the kidney, dealing with all of its functions and using good examples of kidney performance. References are cited, and questions and examples are given.

Valtin, Heinz. *Renal Function*. 3d ed. Boston: Little, Brown, 1995. A more advanced book on the function of the kidney that is relatively easy to read. It is detailed and deals at length with the artificial kidney and with diseases of the kidney.

KOALAS

Type of animal science: Classification
Fields of study: Anatomy, physiology, zoology

Koalas are solitary animals existing on a low-energy diet of eucalyptus leaves. Since koalas are marsupials, the females have a pouch where their young develop. They are the sole member of the family Phascolarctidae.

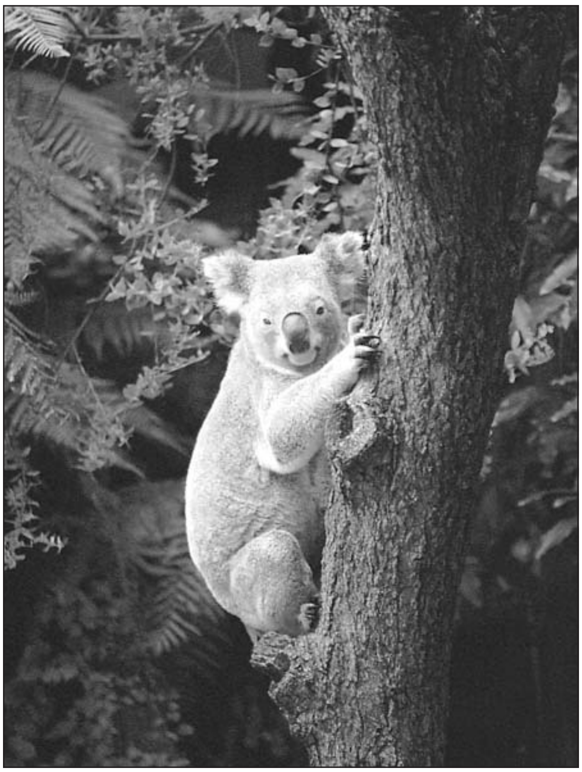
Principal Terms

ARBOREAL: living in trees
BELLOWING: guttural sound used in communication
CAECUM: structure in the digestive tract that aids in digestion and water retention
MARSUPIAL: animals whose young develop in a pouch
NOCTURNAL: active at night

Although they are commonly referred to as "koala bears" because of the resemblance to teddy bears, koalas are not bears. The koalas are marsupials. This is one of the oldest classes of animals, existing since over fifty thousand years ago. Koalas average about twenty-six pounds in weight and thirty-one inches in length. The coat of the koala is the thickest among the marsupials and has a gray to tawny color. White coloration appears on the chin, chest, and forelimbs. The fur is short, soft, densely packed, and springy to the touch. It is the most effective fur insulation among animals. The koalas do not rely on fat beneath the skin for insulation; rather, blood flow to the extremities can be reduced as a means to conserve heat. In the rain, water runs off the koala's fur. Only sick koalas will appear to be wet when it rains.

Koala Life

Koalas are nocturnal and highly arboreal, living solitary lives high up in eucalyptus trees. Koalas are known as phalangers, because they use their hands and hind feet to effectively grip tree trunks and branches when tree climbing and jumping from tree to tree. They walk with a clumsy gait in the following sequence: front right foot then back left foot, front left foot, back right foot. They have a very specialized diet, feeding almost exclusively on the leaves of a few species of eucalyptus. The leaves provide most of their water intake; in fact, the word "koala" means "no drink" in Aboriginal languages. For an average day, a koala will consume about a pound of leaves. They are very fussy



Koalas are extremely specialized feeders, eating primarily the leaves of the eucalyptus trees in which they live. (Digital Stock) eaters, typically being very careful in selecting which leaves from a bough to ingest. The koala uses a set of thirty teeth, comprising incisors, canines, premolars, and molars, to chew the eucalyptus leaves. Each day the koala spends approximately eighteen to twenty-one hours sleeping or resting.

In order to communicate, the koala uses a range of vocalizations. The male koala uses a deep, grunting bellow to communicate its physical and social position. The sound can resemble a far-off rumbling, like a motorcycle or pig snorting. During the mating season, the koala will use the bellowing as a means to locate and accurately pinpoint potential mates. The mating call is a deep, loud, guttural sound that can be heard for long distances. Female koalas do not show the same level of bellowing. Their calls communicate aggression and are part of the mating ritual. Both the male and female koalas share a similar call, sounding like a baby screaming. This is often accompanied by shaking and signals fear. Mother and cubs make soft squeaking noises to one another, as well as humming or murmuring.

Koala Facts

Classification:
Kingdom: Animal
Phylum: Vertibrata
Class: Mammalia
Subclass: Marsupialia
Order: Diprotodontia
Suborder: Vombatiformes
Infraorder: Phascolarctomorphia
Family: Phascolarctidae
Genus and species: Phascolarctos cinereus
Subspecies: P. c. victor (Victoria), *P. c. cinereus* (New South Wales), *P. c. adustus* (Queensland)

Geographical location: Two main groups living out in the wild are in eastern Australia in an area extending from Cooktown in northern Queensland to southwestern Victoria; have been introduced into western and southern Australia

Habitat: Wild eucalyptus forests and woodlands; they are found only in pockets with suitable vegetation of a relatively small number of eucalyptus species that they prefer to ingest

Gestational period: Thirty-five days

Life span: Thirteen to eighteen years

Special anatomy: Females have a pouch that faces the rear and has a drawstring type muscle which can be tightened to close the opening; mammary glands are located along the abdomen within the pouch; females have a duplicate reproductive system with two vaginas; males have dual-pronged, forked penises; each hand has two opposable thumbs, which are crucial for the ability to climb and cling to trees; digestive system includes a caecum, a structure used to digest eucalyptus leaves and assist in water extraction

Koala Reproduction

Females of the species have a pouch in which the young develop. The young are born in nearly embryonic form about the size of a human's little finger. After birth, the infant travels to the mother's pouch, where it attaches to teat. The teat then becomes engorged and forms a seal with the newborn. A single offspring is usually born. It is not until twenty-four weeks after birth that the young is covered with fur and develops teeth. The first six months of life are spent in the mother's pouch. The cub remains with the mother until about twelve months after birth. Mating is a brief event that takes place about once a year. Male koalas are nomadic and play virtually no part in the raising of the young. Extensive chlamydia infection has caused widespread infertility in female koalas and is a major contributing factor in their declining numbers.

LACTATION

Type of animal science: Reproduction
Fields of study: Biochemistry, developmental biology, embryology, physiology

Lactation is the process by which female mammals produce milk for the nourishment of their offspring. For all species except humans, successful lactation is essential for the survival of the young.

Principal Terms

ALVEOLI: the milk-producing areas within the mammary glands

COLOSTRUM: the precursor to milk that is formed in the mammary gland during pregnancy and immediately after birth of the young

DUCTS: the tubular structures that carry milk from the alveoli to the outside through the nipple or teat

LACTATION: the process of producing and delivering milk to the young; also, the time period during which milk is produced

MAMMARY GLANDS: the milk-producing glands found in all mammals; for example, the cow's udder contains the mammary glands

MILK EJECTION: also known as milk letdown, this is the reflex response of the mammary gland to suckling of the nipple; the hormone oxytocin mediates this reflex

MYOEPITHELIAL CELLS: the specialized cells within the mammary gland that surround the alveoli and contract to force milk into the ducts during milk ejection

NIPPLE: the raised area on the surface of the skin over the mammary gland that contains the duct openings

TEAT: an elongated form of nipple that contains one duct opening

Lactation is the process by which female mammals produce milk to feed their young. The ability to produce milk is one of the defining characteristics of the class Mammalia: All mammals, but no other animals, possess the highly specialized glands necessary for lactation. In evolutionary terms, the appearance of lactation coincides with the tendency of mammals to produce only a few offspring at a time; the provision of milk for these offspring helps to ensure their survival while removing competition between the adults and the young for food.

The Mammary Glands

The mammary glands are the milk-producing organs. The number varies among species from two to about twenty, with a rough correlation between the number of young born and the number of glands present. The glands are located on the ventral surface of the body, either in the thoracic (in humans, for example) or abdominal region (in horses and cows) or in two lines extending almost the length of the body (in dogs and rodents). Both male and female mammals have mammary glands, because in early mammalian development the basic body plan of male and female embryos is identical. The mammary glands of males are nonfunctional, however, since they lack the hormonal stimulation necessary for lactation.

Internally, the mammary glands of all mammals follow the same basic plan, consisting of alveoli that produce milk and ducts that carry the milk to openings on the surface of the skin. The alveoli are surrounded by myoepithelial cells that contract to squeeze the milk into the ducts during suckling by the young.

Externally, considerable variation exists among the mammals in the appearance of the mammary glands and their associated openings. In the spiny anteater and platypus, the many lobes of the mammary glands each open directly to the surface of the abdominal skin through individual ducts, and the young suck the hair-covered skin to obtain the milk. In other mammals, the mammary glands are more obvious as swellings beneath the skin, with a raised area, the nipple or teat, that contains the duct openings. In some four-legged animals (cows, horses, and goats) the mammary glands are located in a baglike structure called the udder, from which are suspended the elongated teats. In humans, the nipple, which contains the openings of fifteen to twenty-five ducts, is surrounded by pigmented skin, the areola. The areola contains glands (tubercles of Montgomery) that secrete a lubricating fluid.

Milk Production

Lactogenesis (milk production) does not begin until a female has produced young. During pregnancy, a complex of hormones prepares the mammary glands for milk production by promoting their growth and internal development. These hormones include prolactin from the mother's anterior pituitary gland, placental lactogen from the placenta within the uterus, and estrogen and progesterone, which are produced in the corpus luteum of the mother's ovary and in the placenta. Other hormones, including cortisol from the adrenal gland, thyroxine from the thyroid gland, and insulin from the pancreatic islets, may also be involved. Progesterone appears to participate in the induction of mammary development, but, paradoxically, it also prevents milk secretion during pregnancy.

Although true milk is not produced during pregnancy, a precursor to milk, colostrum, can be produced in small amounts by the mammary glands of most species. Colostrum is a sticky, yellowish, transparent liquid. Colostrum secretion continues in the first few days after birth of the young; there is then a gradual transition to production of true milk.

Milk contains water, proteins, fats, vitamins, minerals, and a unique sugar, lactose. The exact concentration of the various components varies greatly between species according to the nutritional demands of the young. The milk of seals is high in fat and other solids that contribute to rapid weight gain in the pups, a strategy that appears to be essential for their survival.

Noteworthy among the constituents of milk are antibodies produced by the mother. These antibodies help protect the newborn from disease in the period when the newborn's own immune system is immature and incapable of providing significant defense. The antibody concentration of colostrum is higher than that of true milk, and for this reason the first few days of nursing are considered the most important for immunological protection of the newborn.

The transition in production from colostrum to true milk is brought about by a change in the hormonal status of the mother. At the time of birth, the placenta is expelled from the mother's body, thus removing the source of progesterone, estrogen, placental lactogen, and other hormones. The decrease in progesterone levels is thought to be essential for the onset of lactogenesis. In addition, at the time of birth, there are changes in prolactin secretion that may play a role in initiating milk secretion.

Suckling

Once lactogenesis is established, a set of hormonal reflexes act to match milk production and delivery to the needs of the newborn. Suckling of the nipple involves motions similar to chewing as the infant takes the nipple between the tongue and the palate. This suckling motion stimulates nerve endings in the mother's nipple that relay signals about the stimulation back to the mother's brain. Within thirty to sixty seconds, these signals result in the release of prolactin from the mother's anterior pituitary gland and oxytocin from her posterior pituitary gland. Prolactin causes continued production of milk by the alveolar cells of the mammary glands. Oxytocin acts immediately on the myoepithelial cells of the mammary gland, causing them to contract and push milk from the alveoli into the ducts and thence through the nipple into the infant's mouth. Thus, the infant does not actually remove milk from the mammary gland by suction, but instead is responsible for promoting a hormonal reflex that results in active milk ejection, or letdown, from the mammary gland.

Because of the operation of the prolactin and oxytocin reflexes during suckling, lactation is a biological example of the principle of supply meeting demand. All that is necessary to increase milk production is to increase the suckling stimulus by nursing the young more often. Once established, lactation in some species can be sustained in this manner for years, assuming the nutritional needs of the mother are met. On the other hand, if the mother fails to nurse her offspring, the absence of the suckling stimulus will cause the mammary glands gradually to cease milk production.

The exact composition of the milk is altered as lactation continues to meet the changing nutritional needs of the growing offspring. The most extreme example of the ability of the mammary gland to change the composition of milk is seen in the kangaroo. In this animal, the newborn attaches to a teat in the mother's pouch shortly after birth and remains there for a month or more. A mother kangaroo may nurse offspring of different ages from separate teats, and each teat supplies a milk with the appropriate nutritional composition for that young.

Species vary in time spent suckling the young. The rabbit nurses her litter for only about five minutes once a day, while the rat nurses for about half an hour at a time, at intervals throughout the day. Lactation lasts about ten days in rodents, but it may persist for months in large species such as horses and cows. Continued lactation has a suppressive effect on ovulation that is thought to be attributable to interference by prolactin with the normal hormonal mechanisms that cause ovulation.

The Study of Lactation

Although it has always been clear that milk is expelled from the mammary glands, the realization

Image Not Available

that the glands themselves actually produce the milk is a relatively recent one. Early anatomists erroneously assumed that milk must be a product of the uterus, since the uterus is involved in support and nourishment of the fetus. Thus, much of the early anatomical work attempted to show some sort of connection between the uterus and the mammary glands. It was not until the late 1800's that the light microscope clearly demonstrated that milk is formed within the mammary glands. In the twentieth century, electron microscopy showed that during pregnancy the intracellular organization of the alveoli becomes increasingly more complex as the cells become capable of milk secretion.

Various techniques for labeling compounds with radioactive or fluorescent markers have been used in conjunction with electron microscopy to examine how milk is synthesized in the alveoli. The alveoli cells extract necessary precursors from blood flowing through the mammary gland, assemble the precursors into milk components, and then secrete the constituents of milk into the mammary gland ducts. Specific routes of secretion have been identified for the major components of milk.

More recently, researchers have used cell-free systems to study the biochemical pathways involved in milk synthesis. These systems use isolated fragments of deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and perhaps some cell organelles to examine the intermediate chemical steps in the synthesis of milk components. Using these techniques, researchers have been able to "watch" as complex milk proteins and constituents are assembled step by step. The knowledge of how the components of milk are assembled is leading to a fuller understanding of how the amounts of these substances in milk are hormonally regulated.

Knowledge of the hormones involved in inducing and maintaining lactation has come about through systematic assembly of information from several lines of research. Test animals can be treated with a specific hormone to determine if that hormone causes or suppresses lactation. The test animals may be males or immature females, with the goal being the duplication of the specific mix of hormones that cause lactation in the adult female. The opposite approach may also be taken: An endocrine gland can be removed from a lactating female to determine if the hormonal products of that gland are necessary for lactation. Another approach is to make careful measurements of the levels of hormones circulating in the blood as the lactational state changes; any hormone that shows a correlated change may be a good candidate for further investigation by treatment or removal from test animals. These methods have led to an understanding of the importance of prolactin, placental lactogen, oxytocin, estrogen, and progesterone in promoting lactation, but researchers still do not understand how the system is fine-tuned. For example, considerable variation exists in the volume and quality of milk produced by different individuals—or by the same individual at different times—but these differences cannot currently be explained by any known change in hormone levels. Research is focusing not only on describing changes in circulating levels of hormones but also on elucidating the exact effects of these hormones on the biosynthetic pathways within the mammary gland.

Bibliography

Larson, Bruce L., and Vearl R. Smith, eds. *Lactation: A Comprehensive Treatise*. 4 vols. New York: Academic Press, 1974. Every aspect of lactation is covered: development, structure, and diseases of the mammary gland; hormonal control; lactogenesis; milk components; and maintenance of lactation. Some of the chapters are specific to humans, and others cover domestic and laboratory animals.

Mepham, T. B., ed. *The Biochemistry of Lactation*. Amsterdam: Elsevier, 1985. Concentrates on ruminant lactation.

Peaker, M., R. G. Vernon, and C. H. Knight, eds. *Physiological Strategies in Lactation*. London: Academic Press, 1984. The purpose of this book is not only to explore mechanisms of lactation but also to analyze the impact of evolution on lactational patterns in different mammal species.

LAKES AND RIVERS

Types of animal science: Classification, ecology, reproduction
Fields of study: Anatomy, ecology, zoology

Lakes and rivers are large bodies of water produced by the hydrologic cycle. Lakes are stable bodies of water surrounded by land, while rivers are moving bodies of water flowing downhill toward oceans. They comprise important, animal-rich ecosystems.

Principal Terms

CARNIVORE: any animal that eats only the flesh of other animals

COURSE: the pathway of a river from its source to its entry into an ocean

ECOSYSTEM: an ecological community, which together with its environment is perceived as a unit

EROSION: the processes, including weathering, dissolution, and abrasion, by which earth or rock is removed from a part of earth's surface

ESTUARY: part of river's lower course, near entry to an ocean, where slow river flow and tidal action forms mud flats and sand banks

HYDROLOGIC CYCLE: earth's cycle of evaporation and condensation of water, which produces rain and maintains oceans, rivers, and lakes

LAKE: a large area of water surrounded by land

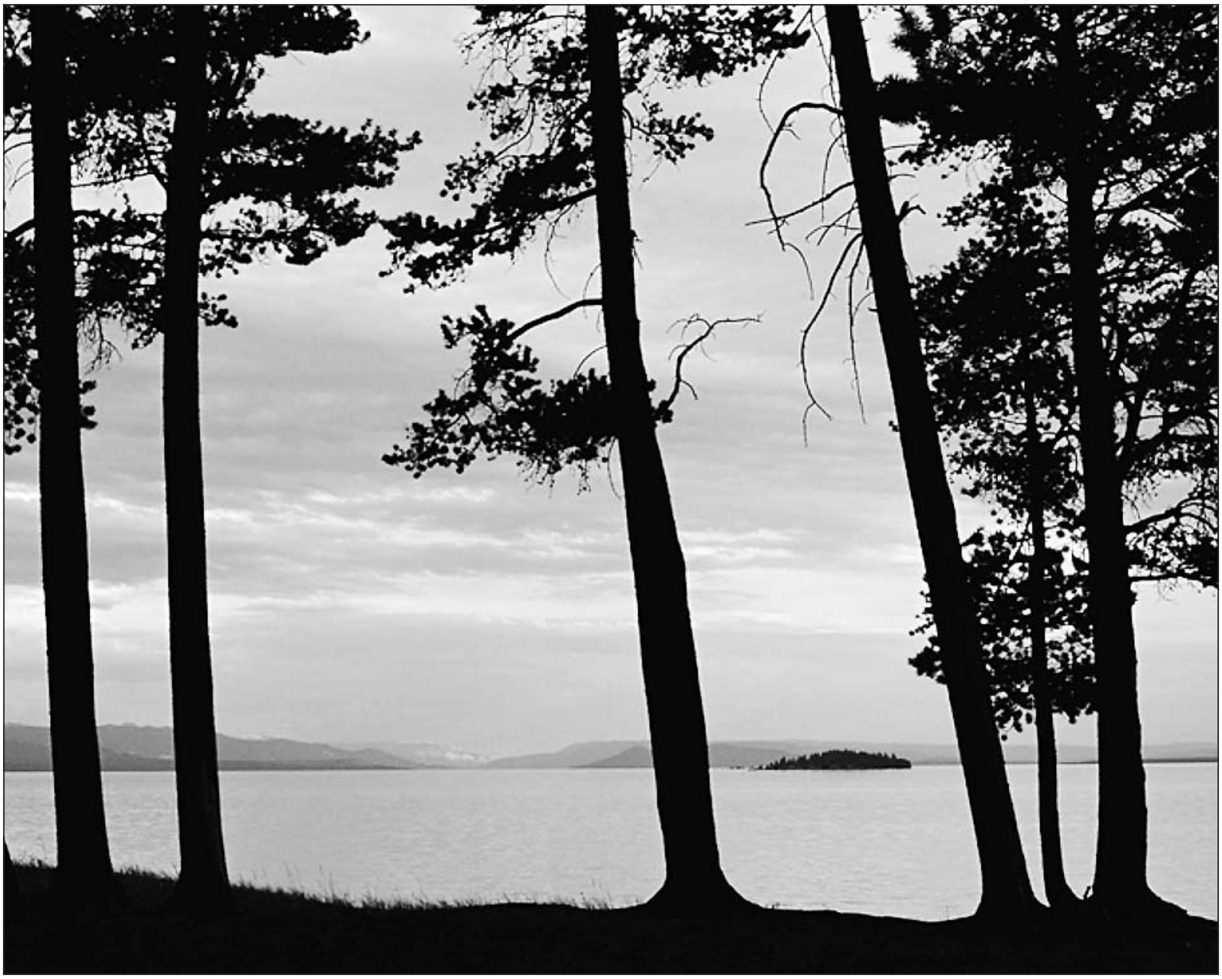
A lake is a large body of water surrounded by land. Lake waters move, partly due to rivers that enter and leave them. In addition, lake water circulates vertically, especially near its surface, where sunlight heats the water and lowers its density. Seasonal warming and cooling of water, evaporation, and other factors contribute to annual cycles of vertical lake water movement.

Most lakes form in hollows dug out of the ground by glaciers. Some huge lakes are really inland seas (such as the North American Great Lakes). Lake water is supplied by rivers and accumulated from rain draining off nearby land. River water contains minerals obtained by running over rocks, and rain holds airborne chemicals. Continued water flow through a lake keeps it fresh, enabling animal and plant survival. When water does not flow out of a lake, minerals are trapped and concentrated, as solar heat evaporates water. In time, salt accumulation turns such lakes into bodies of salt water (such as the Dead Sea, ten times saltier than the oceans) in which few organisms can live.

Animals Found in Lakes

Lakes provide rich habitats for many kinds of wildlife. They are also excellent examples of ecosystems, self-contained ecological units wherein all plants and animals present depend on each other for survival. Removing or damaging one plant or animal species can cause a chain of events that affect, even ruin the ecosystem.

Land beside a lake is usually marshy. Rushes, reeds, willow, and alder trees, as well as water lilies, grow in the shallows around a lake edge. The plant roots prevent lakeshore erosion. Farther from shore are submerged and floating plants which produce oxygen and provide food for small underwater animals such as insects, insect larvae, snails, shellfish, and worms. These small animals are eaten by fish, which are then eaten



Lakes offer rich habitats for complex ecosystems comprising organisms that live on both land and water. (Digital Stock)

by birds. Land mammals, such as martens and bears, also eat the fish. Overall, lake plants and animals make up a food chain that supports the lake ecosystem.

A great number of animals inhabits lakes and live around them. Animals present vary greatly depending on the lake's geographic location. For example, birds, which usually eat fish and aquatic insects, inhabit lakes throughout the world. Lake-dwelling bird species range from ducks, geese, and loons in Canada's cold lakes, to ducks, kingfishers, and herons throughout the United States, to the flamingos of the southern United States, Central and South America, and Africa. Marabou storks and other carrion eaters also inhabit African lakes.

Flamingos may be among the most dramatic of lake-dwelling birds. There are six species of these gorgeous water birds, which have long legs for wading, webbed feet, swanlike necks, and red, flame-colored, pink, or white feathers. Their bills bend abruptly in the middle and the upper mandible fits tightly into the lower one. Flamingos dip their heads upside down under water and scoop backward to feed. Their bill edges have ridges, and when the tongue pushes against the inner bill, the water runs out, leaving behind shellfish or other food. Flamingos live along lakes in nests made of mud, hollow on top, and able to hold one egg. The largest species, the greater flamingo, has two subspecies, one bright red, the other pale red. Males reach five feet tall. The smallest, most abundant species is the lesser flamingo.

Reptiles such as snakes and salamanders, amphibians such as frogs, and many turtle species are also present in lakes. Depending on size, they eat insects or each other, and are themselves eaten by birds. Many different fish species are also present, from minnow to sunfish to trout. They are parts of food chains, eating insects, plants, small reptiles, and each other, depending on size.

River Animals

Only animals adapted to cold, fast-flowing water survive in the upper courses of rivers, which are fine habitats, clean and full of oxygen. Some plants survive, but limpets, snails, and hardy water insects are preponderant. They become foods for the carnivorous fish, such as trout and salmon, found in rivers' upper courses.

The current slows along a river's middle course, and sediment settles to the river bed as earth and rock particles holding minerals on which plants thrive. These plants, from microscopic algae up, are used as food by wildlife inhabiting river banks, such as otters, martens, and raccoons, as well as fish and other animals which live in river waters. Small fish and insects, such as water striders, dragonflies, and aquatic beetles, are plentiful in the water. Reeds and trees are also homes and nests for birds of many kinds, as well as small to medium-sized mammals, such as rodents and skunks, snakes such as water moccasins, and other reptiles.

Depending on location, the size and danger associated with middle course river-animal life varies. However, food chains in rivers also assure continuation of the balance of nature, as small plants and animals are eaten by medium-sized animals and those creatures are, in turn, eaten by bigger animals. The largest, most dangerous river animals are found in the hot southwestern United States, Central and South America, Africa, and Asia.

Crocodiles, alligators, and caimans are among the most dangerous river animals. They are all crocodilians, differing in size, position of the fourth mandibular tooth, and snout shape. Crocodiles have lizardlike bodies up to twenty-five feet

Rivers

Roughly 70 percent of Earth's surface is covered with water. About 97 percent of this water is salt water in oceans, and 2 percent is freshwater in glaciers and groundwater. Only 1 percent is freshwater in rivers, lakes, and water vapor. Freshwater is recycled again and again by evaporation and condensation in a hydrologic cycle which creates and maintains rivers and lakes.

When water vapor condenses and falls as rain, it seeps into the ground, filling pores in soil and rocks. After all pores fill, excess water pools on the surface, flowing downhill due to gravity. Then it becomes streams that coalesce into rivers. Each river is a large body of water, regenerated over and over by the hydrologic cycle, flowing through low ground areas that become channels (river courses) and valleys. Because Earth's oceans are lower than the land, rivers flow down into them.

A river and the composition of its banks change as movement toward the ocean both creates and destroys land. A river's course has upper, middle, and lower parts. The upper course, near the river's source, flows downhill and carves deep valleys, as well as waterfalls wherever tough rock resists erosion. Next, the river flows onto plains in its middle course, and the gently sloping land slows it, leading to sideways erosion and snakelike bends. The last part of a river, its lower course, near entry to an ocean, is often an estuary. Here, the slow flow of the river across virtually flat land causes settling of sediment, forming mud flats and sandbanks.

long, with short limbs, long, thick tails that facilitate swimming, huge teeth, eyes atop their heads, and short, broad snouts in which the fourth mandibular teeth are visible. They are cold-blooded and inhabit salty, brackish, and fresh water in Africa, Australia, Asia, the Indies, and the Americas. They are carnivores, eating birds, amphibians, fish, mollusks, crustaceans, small mammals, and large mammals ambushed while drinking. Crocodiles mate in the water. After two-month gestation periods, females lay eggs on land. The eggs hatch in three months. Crocodiles can live for up to one hundred years.

Alligators, physically and reproductively similar to crocodiles, are only up to sixteen feet long. Their fourth mandibular teeth are hidden by their upper lips, they are more comfortable on land than crocodiles, and they have short, broad snouts. During the day, alligators sun themselves on river banks in the southeastern United States, China, and Central and South America. Caimans of Central and South America are small alligators, only up to eight feet long (although the black caiman can be twice as large). They inhabit rivers and swamps. Alligators and caimans live for forty-five to sixty-five years.

The largest river mammal is the herbivorous African hippopotamus, which can reach lengths of fifteen feet and body weights of four tons. All sorts of fish live in rivers, including minnows, catfish, sunfish, bass, trout, and river dolphins. Most such fish are not very dangerous to organisms other than their specific prey. However, the carnivorous piranha of South American rivers eat any animals that stray into their territory.

Many wild animals found in a river's middle course are even more plentiful downriver in its lower course, where the current is quite slow. However, in estuaries, which are salty due to the admixture of ocean water with the river's freshwater, few plants and animals can survive. There, worms, crustaceans, and gastropods such as snails inhabit mud banks and provide food for birds such as herons, gulls, and kingfishers.

River Ecosystems

Rivers contain series of ecosystems whose compositions vary with conditions in a given portion of the upper, middle, or lower course. In river ecosystems, like those in and around lakes, all plants and animals depend on each other for survival, and removing or harming one species can ruin the ecosystem. Beyond this, existence of multiple ecosystems on land and their connection to aquatic ecosystems points out that damage to any living organism or its local ecosystem will have ripple effects, which can spread out to damage much wider areas than at first perceived. Hence, reasonable actions of humans toward all other living organisms should be attempted and achieved.

LAMPREYS AND HAGFISH

Type of animal science: Classification
Fields of study: Anatomy, evolutionary science, physiology, systematics (taxonomy), zoology

Jawless vertebrates, or Agnatha, are represented today by the lamprey and hagfish. These organisms are of great interest as the survivors of a once-flourishing group of Paleozoic vertebrates that includes the earliest vertebrates in the fossil record.

Principal Terms

AGNATHA: a class of vertebrates that includes all forms in which jaws are not developed; the group to which the earliest vertebrates belong

AMMOCOETE: the larval form of lamprey, which lives in river silts

CLADISTICS: a method of determining relationships in which shared derived (advanced) characters exhibited by the organism are used

CYCLOSTOMES: the modern agnathans, comprising lampreys and hagfish

GNATHOSTOMATA: all vertebrates in which jaws are developed

NASOHYPOPHYSIAL OPENING: an opening in the head of modern agnathans leading to a sac that aids in olfaction

OSTRACODERMS: armored fossil agnathans that flourished during the Paleozoic

PALEOZOIC ERA: time period from 570 to 245 million years ago, which comprises the Cambrian, Ordovician, Silurian, Devonian, Carboniferous, and Permian periods

The vertebrates are normally divided into two groups based on the presence or absence of jaws. The vast majority possess jaws and are termed Gnathostomata; jawless forms are termed Agnatha. The Agnatha are represented today by the lampreys and hagfish, organisms of little economic importance but of great interest to biologists as the sole survivors of an extensive group of Paleozoic (245 to 570 million-year-old) agnathans, which includes the earliest known vertebrates. The extant forms are often referred to as the cyclostomes, the fossil forms as ostracoderms; however, these do not constitute monophyletic groups (groups including the common ancestor and all descendants), and some fossil Agnatha are closely related to cyclostomes.

The Physiology of Jawless Fishes

Lampreys and hagfish are similar in general appearance despite far-reaching differences in internal organization. Both are elongated fish, without paired fins, that swim with an eel-like motion and reach lengths of one meter and weights of up to one kilogram. They possess an entirely cartilaginous skeleton; however, the organization of the body conforms to the basic vertebrate pattern. The lamprey has more active life habits and, therefore, has a more developed median fin. The propulsive section of the tail is longer than that of the hagfish. The lamprey's mouth is surrounded by a sucker-like oral disc covered by small teeth on its internal surface. This rasping organ allows the lamprey to attach itself to prey, on which it feeds by rasping away surface tissues and ingesting blood. Above and behind the oral disc is the nasohypophysial opening, which leads into an olfactory pouch and ends blindly in a dilated sac above the anterior gill pouches. Lampreys have seven gill pouches opening through seven gill ports.

In hagfish, the mouth is ventral and overhung

Image Not Available

by a rostrum, and it contains a dental plate that can be rapidly retracted, enabling the animal to bite off fragments of tissue from the dead and decaying fish on which it feeds. The nasohypophysial duct passes backward below the brain to join the pharynx, and the respiratory current passes along it. Hagfish are quite variable in their number of gill pouches and openings. Pacific hagfish have twelve pouches with separate openings (this number may vary up to fifteen), while Atlantic hagfish have five pouches with one common opening. The eye is vestigial and covered by surface tissue, so it is not normally visible.

Lampreys

There are about thirty-five species of lampreys, and all breed in freshwater and spend the major part of their life cycle in a freshwater larval stage before transformation to an adult stage. The eggs develop into a blind larval form, the ammocoete, which burrows into silt banks and remains for several years filtering microscopic particles from the water. The ammocoete is very unlike the adult, as no suctorial disc is present; a ciliated groove on the floor of the pharynx, together with a tubular endostyle, forms the feeding apparatus. After metamorphosis, three different types of adult lamprey are known: nonparasitic brook lampreys; freshwater parasitic forms; and anadromous forms (living in marine conditions but ascending rivers to spawn). The nonparasitic forms, which constitute about half the known genera, have the mechanisms for parasitic feeding but do not use them. The gonads mature immediately after metamorphosis, the intestine atrophies, and the foregut remains as a solid rod. These nonparasitic forms remain dwarf as they cannot feed, and six to nine months after metamorphosis they reach sexual maturity, spawn, and die.

The parasitic freshwater forms live entirely in river systems, where they feed on fish. The anadromous forms move downstream to the estuary or sea after metamorphosis. There, they feed voraciously and grow rapidly, eventually returning to the river on an upstream spawning migration after one to three years. As in all lampreys, death follows shortly after spawning. In some cases, it appears that populations of originally anadromous lampreys may have become landlocked and are now entirely freshwater. That is what appears to have happened with the lampreys (*Petromyzon marinus*) that now inhabit the Great Lakes. They are capable of causing significant damage to fish populations and almost eradicated trout and whitefish from the Great Lakes between 1950 and 1960, when they peaked in that system, resulting in the collapse of a flourishing fishery.

Hagfish

Hagfish are purely marine fish, in contrast, and as they are benthonic (live on the bottom) and often inhabit deep water, little is known of their reproductive biology beyond the fact that eggs may be laid at any time of year and there appears to be no larval stage. They remain buried in mud during the day, emerging at night to feed. It appears that they normally attack only dead or dying fish, lacking the suction apparatus that makes the lamprey so successful in its attacks on living organisms; however, they will consume small invertebrates if they are available. When feeding, they may show "knotting behavior," during which the flexible body ties into a knot in order to gain a better purchase for the tearing off of food fragments. One characteristic of all twenty species of hagfish is the development of mucus pores along the body. If roughly handled or irritated, these pores produce copious quantities of mucus, resulting in the name "slime eels" for these animals. Neither hagfish nor lampreys are of more than local economic importance.

The Fossil Record

The fossil record of hagfish and lampreys is sparse, presumably because of the lack of an ossified endoskeleton. Both are known only from the Pennsylvanian period (280 million years ago) of Illinois and show close similarity to modern forms. These sediments also include two other agnathans of unknown affinities, indicating a wide diversity of forms of this type. There is, however, an extensive record of armored agnathans (ostracoderms) from rocks of Ordovician to Devonian age (360 to 470 million years old). These have been divided into two main groups, the Osteostraci and the Heterostraci, together with some smaller groups.

The Osteostraci were a group of fish that lived in the Silurian and Devonian periods (370 to 425 million years ago) and were characterized by the presence of an armored head-shield, the rest of the body being covered by large bony scales. The large eyes were dorsally placed, and between them were the pineal foramen (an opening for a light-sensitive organ) and the nasohypophysial opening. Located laterally on the head-shield were sensory fields that probably were sensitive to pressure waves in the surrounding water. The ventrally placed mouth and dorsoventrally flattened head indicate that the Osteostraci were benthonic fish, possibly feeding by sucking organic debris or small organisms into the mouth. Paired pectoral fins may have acted to move the animals by rhythmic undulations. Because the head-shield surrounded the brain, a considerable amount of detail of brain structure and cranial nerve pattern has been preserved. It has shown that the general pattern was very similar to that of the lamprey, implying a close relationship.

The Heterostraci were a long-ranging group whose earliest representatives occurred in the Middle Ordovician period (470 million years ago) and represent the first known record of vertebrates. Typical Heterostraci were armored over the anterior part of the body by variable numbers of bony plates and were further characterized by having only one pair of external gill openings. They were common in shallow marine and freshwater environments during the Upper Silurian and Devonian periods (360 to 425 million years ago) but became extinct at the end of the Devonian. They seem to have been adapted to a variety of modes of life, from benthonic detritus feeding to cropping algae and filter feeding. The Ordovician forms are known from rocks in North and South America and Australia and are united with later Heterostraci by the presence of the same type of acellular bone, aspidin, in the armor. Their exact position is uncertain, however, as they do not appear to have a series of branchial (gill) openings on each side.

Although it is clear that the Osteostraci were closely related to modern lampreys, no relationship has been determined yet between hagfish and any ostracoderm group. The relationship of the fossil and modern agnathans to gnathostomes is also still the subject of considerable debate, though in broad terms it is accepted that lampreys are the sister group of gnathostomes and hagfish the sister group of lampreys and gnathostomes. Much further information is needed before the details of their phylogeny can be elucidated, and continuing work on these organisms will aid understanding of both the origin of vertebrates and the early development of major vertebrate groups.

The Ichthyology of Jawless Fishes

Fish are generally excellent subjects for study and for the demonstration of anatomy, physiology, ecology, evolution, and other aspects of science. The detailed anatomy of the cyclostomes has been known for many years, and knowledge in this area is dependent on careful dissection of specimens. General knowledge of the life cycle, ecology, and feeding habits of the modern forms is based on observation either in the natural habitat or in aquariums. As lampreys spend most of their life cycle in freshwater, understanding of their development is fairly complete. Hagfish, however, are marine benthonic fish that move and feed mostly at night, and hence the ability to observe them is somewhat limited and understanding of their life cycle is incomplete. Sophisticated laboratory techniques now make it possible to analyze the biochemistry and physiology of these organisms and compare them to other chordates. Studies have also been made of their swimming methods, using high-speed cameras and electromyography, a technique that allows the tracing of the electrical changes that take place in muscles when they are active.

Fossil Agnatha cannot be studied as completely, because only the hard parts are preserved in the sediments. Techniques for studying these remains have changed very little in the past one hundred years. The bones are removed from the rock by chipping or dissolving the surrounding sediment away. Bone is composed of calcium phosphate and thus will resist some acids that can break down carbonate rocks. The acids most commonly used are acetic acid and formic acid, and the specimen to be dissolved out is often backed with plastic so that it does not disintegrate when the supporting matrix (surrounding sediment) is removed. The bone from these ancient agnathans is often so well preserved that thin ground sections can be made and viewed through a microscope using transmitted light.

The characters determined by these means are used to determine relationships. Studies on the relationships of the fossil and recent Agnatha have relied in recent years on the methodology termed "phylogenetic systematics," or "cladistics." Cladistics is distinguished from other taxonomic methods (taxonomy is the study of interrelationships) by the fact that it is a rigorous system in which only shared advanced characters are used to show relationships. These relationships are expressed as branching diagrams termed cladograms (from the Greek *klados*, "branch"), hence the name cladistics. Although studies using this methodology have improved understanding of the relationship between modern Agnatha and the gnathostomes, the relationships of the fossil forms are still poorly understood.

Modern Jawless Fishes

Modern Agnatha, or cyclostomes, are relatively rare and unimportant organisms, although they are representatives of a group that was important in the early history of vertebrate evolution. For example, hagfish can be a nuisance to fishermen, attacking and destroying bait and even the catch itself. Lampreys, because of their active parasitic mode of life, can be a serious menace to fisheries, as evidenced by the sea lamprey depredations in the Great Lakes. The construction of a canal bypassing Niagara Falls unfortunately allowed lampreys to enter the upper Great Lakes from Lake Ontario, where they had been established. Once in the upper lakes, they underwent a population explosion, probably as a result of the abundance of prey fishes, lack of predators, and suitability of the system for spawning and maintenance of larvae. The establishment of the lamprey resulted in a serious decline of a number of fish species and the collapse of a flourishing commercial fishery that has only been reversed by the establishment of control measures and the use of larvicides.

The fossil Agnatha, or ostracoderms, are generally poorly known as a result of their incomplete preservation. Yet they do throw some light on the earliest stages of vertebrate evolution, indicating that, as far back as 470 million years ago, humankind's earliest ancestors were small, rather tadpolelike fish with an external armor of bony plates. Although they appear in the fossil record before the earliest jawed vertebrates, or gnathostomes, it appears that the separation into jawed and jawless forms had already occurred. Many gaps remain, but it is to be hoped that further discoveries will enable humankind to develop a clearer picture of its earliest vertebrate ancestry.

LANGUAGE

Type of animal science: Behavior
Fields of study: Evolutionary science, human origins

The origins of human language and animals' communicative abilities help to achieve an understanding of humans' position in the natural order of evolution.

Principal Terms

CLOSED-CLASS VOCABULARY: typically including the structural and functional words, such as prepositions, determiners, quantifiers, and morphological markers, closed in the sense of resisting the introduction of new members

DISPLACEMENT: language's power to refer to or describe things and events beyond the constraints of the here and now

GRAMMAR: the structure of a language, consisting of systematic rules to specify word formation, such as inflection, derivation, and compound words (morphology), and systematic rules to specify how words should be ordered in combination to form phrases and sentences (syntax)

OPEN-CLASS VOCABULARY: content words such as nouns, verbs, and adjectives, open in the sense of its readiness to admit new members

PRODUCTIVITY OR GENERATIVITY: language's power to produce or generate an infinite number of understandable words and sentences from a finite number of symbols and rules

SEMANTICITY: meaning in language

SYMBOL: something that stands for something else, the connection between symbol and object being arbitrary in nature

One way to understand humans' position in the natural order of evolution is to locate the origins of language. Some scholars think that language is probably the product of the "mental mutation" of the large brain of *Homo sapiens*, because human language is the only animal communicative system that possesses all of the fundamental characteristics of arbitrary symbols, semanticity, grammar, productivity, duality of patterning, and displacement. Furthermore, human children are able to become effective users of such complex symbolic systems without formal teaching and within a fairly short period of time, in striking contrast to the limited expressions of animals, even after lengthy and extensive training. Linguist Noam Chomsky, for example, has proposed that human beings have a unique language forming capacity and human babies are innately equipped with a "Language Acquisition Device," which resides somewhere in the brain.

Many others, however, disagree with this discontinuity theory of the human language origins. Instead, they argue for an evolutionary ground (neuroanatomical, behavioral, cognitive, social, and cultural) to cultivate language formation. They believe that language is no exception from the governing of the law of evolution. For example, Philip Lieberman rejects the existence of linguistic genes or a language organ in the human brain. Rather, language had its first sprout at the intersection of the evolutionary products of neural mechanisms, communication, and cognition. These are the two main theories of language origins. The first line builds on the protolanguage theory, the second on the notion of behavior determinism in evolution.

Protolanguage Theory

"Protolanguage" means that utterances are not yet full language, although they serve symbolic referential and other communicative functions. The telegraphic speech of toddlers (such as "Mommy cookie!") has been used as an example. A "baby talk" was formed first, only to be shaped and refined later into a full language. It was hypothesized that modern speech could have been possible about 100,000 years ago, when the earliest *Homo sapiens* started to migrate from Africa to other places. John McCrone reasons that toolmaking and tool use, moving in troops to other regions, and collective hunting called for more group actions, which in turn promoted social interaction. These activities required joint attention and intentional communication. Using eye contact and gesture to direct attention as a means beyond reflexive behaviors to achieve joint attention might thus have been a major step toward human speech. The prolonged period for taking care of dependent human infants, a consequence of brain growth, afforded opportunities to cultivate the intimacy between mother and child. Meanwhile, social ties in a colony began to form. All these changes might have encouraged what could be called personalized noises. To meet their communicative needs, early *Homo* species were pressured to refine and stabilize their coarse communicative noises into protowords. These protowords were then passed down to the next generations. Practice of such vocalizations in turn further promoted vocal structure refinement.

The evolutionary principle of economy and efficiency was at work, so that concept categories (words) and combinatorial rules (grammar) were naturally selected, because words and grammar are far more cognitively economic and efficiently generative than mechanical one-to-one referential associations. Martin Nowak and David Krakauer, based on their mathematical and computational modeling using computer simulations, have contended that protolanguages can evolve in a nonlinguistic society. At first, signal-object associations were established, and later, combinations of sounds to form words and combinations of words to form sentences evolved into semantic and syntactic systems through natural selection to reduce mistakes in communication.

In addition to the supportive results of computer simulations, other empirical evidence came from studies involving primates and human children. In Leavens and Hopkins's study, 115 chimpanzees (*Pan troglodytes*) in captivity (aged three to fifty-six years), without any explicit training whatsoever, commonly employed gaze alterations and a pointing gesture in face-to-face communicative interactions with humans and among themselves. This demonstrated the presence of communicative intent and gestural precursors of language among humans' closest relatives, chimpanzees. The bonobo (*Pan paniscus*) Kanzi understands spoken English sentences and knows how to use human-designated lexigrams to announce his intention, all through laissez-faire learning without explicit teaching. The chimpanzee Washoe spontaneously taught her acquired American Sign Language (ASL) to her adopted son Loulis. Human babies are like chimpanzees in many ways. As McCrone describes it, human infants are born with the standard ape vocal plan—it is after six months that the voice box descends down into the throat. Human infants first play with vowels (coo) and then babble (combining vowels with consonants)—so vocalization comes before producing true words. They also employ gaze alterations and gestures to communicate before they say words. In the second year, they produce telegraphic speech, typically composed of two to three content words, which happens to be the mode of expression in the utterances of language-trained chimps (such as "Shirt hide" by Kanzi).

Behavior Determinism

William Noble and Iain Davidson do not think that a protolanguage existed in evolution. They have also cautioned people against accepting the performance of animals in captivity and human interaction experiences as evidence to back up evolutionary arguments, because these environments are drastically different from the ecologies of the *Homo* ancestors millions of years ago. These environments are not the same as those of the free-living primates, either. Language-trained animals' performance is like language emergence in human infants, who learn through interaction with other humans who already have language, a learning process quite different from the prehistoric origins of symbols and language from scratch.

Noble and Davidson agree that natural selection favored bipedalism, leading to neuroanatomical changes including larger brains. They do not believe, however, in biological determination of behaviors. Instead, they believe the opposite. The behavior of standing upright led to larger brains that needed to consume more energy. Meat as a good energy source had already been increased in the diet of *Homo erectus*. As meat-eaters, hominids had to run fast (either to catch prey or to escape predators). Running brought about better control of the breathing system (necessary for speaking) and adjustments to the thermoregulatory system (leading to the selection of the feature "hairlessness," which could have fostered face-to-face adult-infant interaction). In addition, hunting for meat facilitated coordinated group actions as well as tool creation. To expand food sources hominids began migrating, which further promoted groups and interaction. Thus the social context was present for the emergence of language.

In their discussion, Noble and Davidson have emphasized one important behavior responsible for the emergence of language: stone throwing. To be effective, manual control and timing control had to be achieved. As the timing control behaviors were bettered, the neuroanatomical structures improved too. These positive adjustments, together with other contextual changes, led hominids on an increasingly divergent behavioral path from their chimpanzee relatives. Better control of the forearm could develop into a pointing form. Hairlessness made it easy to carry an infant hominid in front, increasing the likelihood of adult-baby mutual observation and imitation. One such likely behavior could be arm extensions for referring. Later, better-controlled movements of forearms and fingers developed into a pointing form. Any vocalizations in company with manual gestures were first associated with the referred objects, and later became symbols, once it was realized that the sounds alone could stand for the targets themselves, even when they were out of sight.

There is consensus that the human vocal structure is a necessary condition for human speech. It has been noticed that animal vocalizations are graded in nature. A graded system contains only variations of vowel sounds but no consonants. Variations of vowels, although functional in communication, lack distinctive boundaries to mark different categories. Sue Savage-Rumbaugh and Roger Lewin have concluded that language is unlikely to emerge unless an organism can produce consonants, no matter how large its brain. How the human vocal tract acquired the ability to pronounce consonants unfortunately remains a mystery.

The evolution of language must have benefited the *Homo* species tremendously. Noble and Davidson have speculated how language could have contributed to human mentality. For example, colonization in different places would cause isolated groups to have trouble in understanding each other. Such failures and misunderstandings could contribute to the awareness of "us" vs. "them." This appreciation would lead to the realization of the possibility for a group to use their own symbolic system as a means for social control. Thus, human mentality, with language in use, is itself an evolving feature of the natural world. It is only logical that, with language available, mental representation of the world became possible, which eventually made abstract, imaginary, retrospective, hypothetical, and metacognitive thinking a reality. No wonder these modes of thinking reflect themselves in the characteristics of human language.

Animal Communication

Animals do communicate, at least in a broad sense. Animals use vocalizations, facial expressions, gestures, body postures and movements, and even odors, to warn peers, to attract attention, to find food, to care for the young, to mark territories, and to maintain social structures. However, animal communicative systems are typically not recognized as language because of they lack the key features of a true language. Many have argued that animal communication, even among chimpanzees, is in essence instinctive and reflexive. McCrone says that these behaviors are not under conscious control, and are triggered only by an event in the immediate environment, with both parties present. Hence, chimpanzees have no true arbitrary symbols or displacement. In addition, animal communicative systems are "closed," with no combinatorial rules to create new meanings; hence they lack duality of patterning, syntax, and productivity. Edward Kako has pointed out that no animals so far, including the language-trained ones, have demonstrated the ability to understand closed-class lexical items. Despite the criticisms, animals' language-learning achievements have been acknowledged.

Talking Animals

The most famous talking parrot is Alex, an African gray parrot (*Psittacus erithacus*) trained by Irene Pepperberg. Alex is able to speak many words and phrases referring to objects, materials, actions, colors, shapes, numbers, and locations. He can answer questions that require labeling objects, classifying objects (color and substance), comparing objects ("bigger than" or "same as/

American Sign Language Among Primates

Primates are members of the mammalian order Primates, which includes prosimians, or lower primates, and anthropoids (monkeys, apes, and humans). Apes are any primates of the subfamily Hominoidea, including the small apes and the great apes. The gorilla (*Gorilla gorilla*) is the largest of the great apes. Another great ape is the chimpanzee. The larger member of the chimpanzee family is the common chimpanzee (*Pan troglodytes*), and the smaller member is the bonobo (*Pan paniscus*) or the pygmy chimpanzee.

To obtain an understanding of their evolutionary roots, human beings have turned to the great apes, especially chimpanzees, because they are humans' closest living relatives, sharing as much as 98 percent of identical genetic material. Many attempts have been made to teach apes to learn language. Early attempts to raise apes along with human babies in the hope that these human-reared apes would learn to speak human language ended in failure, but researchers came to realize that apes do not have the vocal structure necessary for producing human speech sounds. Enlightened by the Braille system of writing for the blind and sign language for the deaf, researchers began to employ nonverbal symbolic systems, including plastic chips (David Premack's chimp Sarah), computer lexigrams (Duane Rumbaugh's chimp Lana), and American Sign Language (ASL). This line of research has yielded interesting results. Allen and Beatrice Gardner's chimp Washoe acquired ASL, and, moreover, she began to combine words and taught her adopted son, Loulis, to use ASL. Twelve percent of the ASL utterances produced by Herbert Terrace's chimp Nim were spontaneous. Francine Patterson's gorilla Koko mastered six hundred ASL words. Through natural observation and social interaction, Sue Savage-Rumbaugh's bonobo Kanzi understands spoken English and uses sign language and computer buttons in communication.

Language research with primates creates a path for humans to search for their links to animals. There are many potential research areas, such as body language, cultural transmission of learned language over generations, and the impact of language-trained chimpanzees living with naïve peers in their natural environment, just to mention a few. On the other hand, scientists are concerned about the well-being and the rights of the primates, especially in the areas of early separation from the mother, or lab controls. Many questions have no answers yet, but one thing is certain—scientific inquiry will go on, and it will be done with good ethical concerns.

—Ling-Yi Zhou

different from”), and counting (from one to six).

Two Hawaii bottle-nosed dolphins (*Tursiops truncatus*), trained by Louis Herman and his colleagues, are Phoenix, with an acoustic language, and Akekamai (Ake), with a gesture-based language. They can correctly carry out commands in varied word orders (syntax) with different meanings. They have further demonstrated their semantic and grammatical knowledge by either not executing grammatically incorrect and semantically nonexecutable orders or by extracting an executable segment from an anomalous string and then completing the task according to the meaning provided in that specific syntactic structure.

Sue Savage-Rumbaugh’s bonobo Kanzi is an exciting language star. Kanzi understands spoken English and uses hand signals as well as geometric symbols, and moreover, he has learned all that without explicit instruction but by mere social observation and interaction, just as a human baby learns a language. This natural learning process was successfully replicated with Kanzi’s sister, Mulika.

Comparative Language Research

Research methodology in the comparative language field has been improved greatly over the years. Designation of “language” takes into consideration the biological constraints of the species involved. Social interaction in a natural way is underscored. Possible experimenters’ and trainers’ biases are controlled through blind techniques such as blindfolding the eyes of the person who gives commands, using one-way mirrors and remote cameras, or separating the person who does recording and interpretation from the one who gives the command. Recent data are thus more scientifically sound than before. Yet some people are not happy with the fact that humans have imposed their dialogue on the animals. These people are now using the playback technique to decode the meaning of the signals in animals’ own communicative systems. Many species have been studied in their natural ecological niches, including vervet monkeys, tigers, humpback whales, orcas or killer whales, and elephants. These animals’ wild calls in nature are recorded, and then are played back to the animals to see their differentiated reactions, thus making the message decoding possible. The playback studies are very encouraging in confirming the symbolic nature of animals’ natural “languages” in the wild.

It is very important to study the animal’s own “language” for its own sake, for without such knowledge, commenting on nonhuman species’ linguistic abilities in the frame of human language is at least prejudiced. As primatologist and psychologist Roger Foutes put it: “The best approach to science is a humble one. We are humble enough to take the animals we are studying on their own terms and allow them to tell us about themselves. Too often science takes an arrogant approach.” According to him, “Someday we’ll realize that the human voice is not a lone violin but part of an orchestra. We’re not playing a solo; instead it’s a symphony.”

LEARNING

Type of animal science: Behavior
Fields of study: Ethology, neurobiology

Learning is any change or modification in behavior that involves the nervous system and cannot be attributed to the effects of development, maturation, or fatigue. Learning takes a number of forms, including habituation, sensitization, associative learning, perceptual learning, and insight.

Principal Terms

ADAPTATION: any heritable characteristic that increases the probability that an animal will survive and reproduce in its natural environment

CONDITIONING: the behavioral association that results from the reinforcement of a response with a stimulus

INNATE: any inborn characteristic or behavior that is determined and controlled largely by the genes

INSTINCT: any behavior that is completely functional the first time it is performed

NATURAL SELECTION: the process of differential survival and reproduction that leads to heritable characteristics that are best suited for a particular environment

STIMULUS: any environmental cue that is detected by a sensory receptor and can potentially modify an animal's behavior

Learning, as defined by ethologists, is simply any change or modification in behavior that is directed by previous experience and involves the nervous system but cannot be attributed to the effects of development, maturation, fatigue, or injury. These latter phenomena contribute to changes in behavior that generally do not constitute learning. Learning takes a number of forms, including habituation, sensitization, associative learning, perceptual or programmed learning, and insight. Each type has its own basic characteristics and adaptive significance. Habituation and sensitization are the simplest and most widespread forms of learning, and insight is the most complex and least understood form. Insight involves the ability to put two previous experiences together to solve an unrelated problem.

Habituation and Sensitization

Habituation and sensitization are considered the simplest forms of learning. Habituation involves a decrease in a behavioral response that results from repeated presentation of a stimulus. A young, naïve duck, for example, will exhibit an innate startle response when any hawk-shaped object is passed overhead. With repeated presentation of the hawk model, however, the intensity of the bird's reflex declines as the animal becomes habituated, or learns that the stimulus has no immediate significance. Habituation learning is common throughout the animal kingdom and has tremendous adaptive significance in that it prevents repeated response to irrelevant stimuli that could otherwise overwhelm the animal's senses and prevent it from accomplishing other critical tasks. One of the common characteristics of habituation is that after a short period, usually defined by the particular species and the stimulus in question, the animal will completely recover from the habituation experience and will again exhibit a full response to the stimulus. This, too, has important survival implications, especially for species that rely on stereotypic alarm responses for avoiding predation.

In contrast to habituation, sensitization is the increase in intensity of a response that results from the repeated presentation of a stimulus. A good example is the heightened sensitivity to even relatively soft sounds that results from the initial presentation of a loud, startling noise, such as a gunshot. Sensitization differs from habituation in important ways. First, the specific stimulus that elicits a sensitization response is different from the stimulus to which the animal becomes sensitized. Second, the underlying physiological mechanisms that control these two processes are fundamentally different.

The third and broadest category of learning is associative learning. In this type of learning, an animal makes a connection between some primary environmental stimulus (that involves either a reward or punishment) and a novel or neutral stimulus that is paired with the first stimulus.

Classical and Operant Conditioning

The simplest form of associative learning is classical conditioning, first studied by Ivan Pavlov. Pavlov observed that when a dog is presented with food, the dog will begin to salivate. He referred to the food in this case as an unconditioned stimulus (US), and to the salivation reflex as the unconditioned response (UCR). When the unconditioned response is effectively paired with a second, novel stimulus, such as a light or bell (called the conditioned stimulus, or CS), the dog will, after several trials, associate this second stimulus (CS) with the US and begin to salivate whenever the CS is presented. The salivation reflex that occurs following presentation of the CS is termed the conditioned response (CR).

Although classically conditioned learning is often associated with the controlled experiments of psychologists, it undoubtedly occurs throughout the animal kingdom, and it may be one of the most common ways by which animals learn about their immediate environment. A good example of this is the phenomenon of taste-aversion learning. Taste-aversion learning occurs when an animal associates a specific odor or visual stimulus with an unpleasant experience resulting from the consumption of an unpalatable or poisonous food item. After even a single experience with the distasteful food, the animal will subsequently avoid ingestion, even if it means starvation. Taste-aversion learning is especially important for nonspecialist feeders that forage on a variety of foods and must periodically sample unfamiliar food items. This learning phenomenon also serves as the basis for the evolution of many warning signals in animals.

Through natural selection, many distasteful prey have evolved distinctive marks, colorations, odors, or behavioral characteristics that serve as a reminder (a CS) to predators that it is distasteful or harmful. After one negative experience with this prey, the predator learns to associate these characteristics with the sight or smell of the animal. Such characteristics have obvious survival benefits for the prey. Taste-aversion learning differs from classical conditioning in that the critical time between the CS and the US is usually much longer and in that only one trial is necessary for the learning to occur. This latter effect has important implications for animals that rely on aversion learning to avoid poisoning. Many animals, such as blue jays and rats, wait a specific length of time after ingesting a novel food item to determine whether they will become ill.

A second major form of associative learning is operant, or instrumental, conditioning. Unlike classic conditioning, in which the animal is passively involved in the learning experience, in operant conditioning the animal learns by manipulating some part of its environment. In traditional operant learning experiments the animal, for example, presses a lever or rings a bell in order to receive some reward. Because this kind of learning usually improves with practice, it is often referred to as trial-and-error learning. This kind of learning has obvious adaptive significance under natural conditions. Perhaps the best example of this is the reinforced trial-and-error learning that is necessary for many young vertebrates to perfect their feeding techniques. The naïve young of many mammals and birds greatly enhance their feeding efficiency when repeatedly allowed to manipulate their food. Similarly, many animals, including insects, use this reinforced practice to learn their way around in their habitat, home range, or territory, much the way a rat learns its way around in a maze.

Programmed Learning

In addition to associative learning, there are a number of types of learning that seem to involve mechanisms more complex than simple association. The most common examples include song learning (in birds) and imprinting. Ethologists often refer to these types of learning as programmed learning, since they only take place at certain times and under very restricted circumstances.

Imprinting is the process whereby a young animal develops a behavioral attachment to some other animal or object. Animals have been observed to imprint naturally on their parents, individuals of the opposite sex, food items, preferred habitats, and home streams (in the case of salmon). All such types of imprinting have two general features in common. First, the imprinting must occur during some critical period. The most familiar type of critical period is that which occurs in parental imprinting, a specific imprinting routine whereby a newborn becomes behaviorally fixed on a parent. First described by Konrad Lorenz, this type of learning requires a critical period shortly after birth, in which the young learns to recognize and follow the parent. Outside this period the learning simply cannot occur. The second characteristic common to all types of imprinting is that the young animal must be actively involved in the learning process. In fact, the strength of the imprinting seems to depend largely on the degree of this involvement.

Song learning in birds is fundamentally quite similar to imprinting in that it too requires a specific learning period. White-crowned sparrows, for example, learn their song from their fathers, usually from one to six weeks after birth. During this critical period, these young birds learn to imitate the song that is specific to their species as well as the variations and dialect characteristic of their population. When young birds are raised in isolation and prevented from hearing their own species' song, they develop an abnormal vocalization. If given the opportunity to hear a recording of a normal adult song of its species during the critical learning period, the young bird will learn to sing normally. If, on the other hand, the animal is exposed to the song of some other closely related species, the animal will not develop a normal song. This suggests that birds are somehow innately programmed to learn their species-specific songs. Thus, it seems that both imprinting and song learning are in many ways quite similar and may be controlled by the same underlying mechanisms. The tendency to classify these as complex behaviors, however, may be attributable in part to ethologists' lack of understanding of these mechanisms.

Insight

Perhaps the most advanced and least understood form of learning is insight. Insight is said to differ from other forms of learning in that it is characterized by a modification in behavior that is not contingent on some particular recent experience. Instead, insight behavior involves the ability to put two independent ideas together to solve a third, unrelated, problem. Wolfgang Köhler's classic observations on learning in chimpanzees illustrate the phenomenon of insight. He observed that when a preferred food item (such as a banana) was placed out of reach of a caged chimpanzee, the animal quickly learned to use a pole as an extension of its arm to pull in the food; when the food was hung overhead, the animal would learn to stack boxes to reach the food. Examples of tool use by chimpanzees observed under natural field conditions include the use of sticks as probes for gathering insects and the use of small branches for warding off potential predators.

Although this type of problem-solving behavior seems fundamentally more complex than any other type of learning, it has been suggested that many of the specific behaviors cited as examples of insight may be nothing more than extensions of associative learning. Pigeons, for example, can be conditioned to perform certain activities that they use later in solving more complex problems. A pigeon conditioned at one time to push a box across its cage floor and at another time to climb on a box and peck at a food lever will later push and position a box under a lever so that it can peck at the lever and receive a reward. While this seems to reflect some type of problem-solving ability, it is interesting that birds that are not previously conditioned cannot solve the problem. Thus, insight may build on some form of associative learning.

Insight learning has also been invoked to explain the origin of many types of cultural learning. Cultural learning occurs when one animal in a group discovers a unique or novel behavior and the other members learn to copy the behavior through the process of observational learning. One of the classic examples of this kind of learning was observed in the blue tit, a small European bird that was observed to strip the caps off milk bottles in order to drink the cream that surfaced at the top. In relatively little time, the behavior spread and was exhibited by this species all across Western Europe. Although there is little doubt that such cultural transmission involves nothing more than the simple imitation of another animal's behavior, it is not clear whether the origin of such behaviors reflects some form of innovation.

Ethological and Psychological Approaches

The study of behavior and learning has long been characterized by two very different methodological and philosophical approaches: those of ethology and psychology.

Ethology, the study of animal behavior, is built on several very specific assumptions and principles that clearly distinguish it from the field of psychology. First, the study of ethology involves objective, nonanthropomorphic (that is, not biased by human expectations or interpretations) descriptions and experiments of the learning process within a natural context. Konrad Lorenz, one of the founders of the field, insisted that the only way to study behavior and learning was to make objective observations under completely natural field conditions. Building on Lorenz's purely descriptive approach, Nikolaas Tinbergen conducted rigorous field experiments, similar to those that now characterize modern ethology. The classic work of early ethologists helped demonstrate how an animal's sensory limitations and capabilities can shape its ability to learn. For example, in a series of classic learning experiments, Karl von Frisch convincingly documented the unusual visual capabilities of the honeybee. He first trained honeybees to forage at small glass dishes of sugar water and then, by attaching different visual cues to each dish, provided the animals with an opportunity to learn where to forage through the simple process of association. From these elegant (but simplistic) experiments, von Frisch found that bees locate and remember foraging sites by the use of specific colors, ultraviolet cues, and polarized light, a discovery that revolutionized how scientists view the sensory capabilities of animals.

A second important feature of ethology is that it is built on the assumption that learning depends not only on environmental experience but also on a variety of underlying physiological, developmental, and genetic factors. The work of countless neurobiologists, for example, clearly demonstrates how behavioral changes are linked to modifications in the function of nerves and neuronal pathways. By observing the response of individual nerves, neurobiologists can observe changes that occur in the nerves when an animal modifies its behavior in response to some stimulus. In a similar way, they can show how learning and behavior are affected when specific nerve fibers are experimentally cut or removed. Unfortunately, however, neurobiologists' understanding of the physiological control of learning is limited to simpler kinds of learning such as habituation and sensitization.

Like the neurobiologists, behavioral geneticists have shown that much of learning, and behavior in general, is intimately tied to internal mechanisms. The results of hybridization experiments and artificial breeding programs clearly demonstrate a strong genetic influence in learned behaviors. In fact, it has been well documented that many animals (including both invertebrates and vertebrates) are genetically programmed (or at least have a genetic predisposition) to learn only specific kinds of behaviors. Finally, the most important characteristic of ethology is that it places tremendous importance on the evolutionary history of an organism. It assumes that an animal's ability to learn is shaped largely by its evolutionary background, and it emphasizes the adaptive significance of the various types of learning.

In comparison with ethology, the field of psychology emphasizes the importance of rigorously controlled laboratory experiments in the study of learning. The most widely used methods in this field are those of classic and operant conditioning. The primary objective in these approaches is to eliminate and control as many variables as possible and thereby to remove any doubt as to the factors responsible for the behavioral changes. These approaches have met with considerable success at identifying specific external mechanisms responsible for learning. These techniques, however, tend to focus only on the input (stimulus) and output (response) of an experiment and, as a result, de-emphasize the importance of proximate mechanisms, such as physiology and genetics. In addition, these approaches generally ignore the evolutionary considerations that ethologists consider so fundamental to the study of behavior.

Understanding the Learning Process

Although the approaches used to study learning vary tremendously, nearly all such studies are directed at two goals: to understand the adaptive value of learning in the animal kingdom and to understand the physiological, genetic, and psychological mechanisms that control learning. For any animal, the adaptive advantages of learning result primarily from the increase in behavioral plasticity that learning provides. This plasticity (ability to be flexible) provides the animal with a greater repertoire of responses to a given stimulus and thereby increases the chances that the animal will survive, reproduce, and pass the genes that control the learning process on to the next generation. In comparison, the value of an innate behavior lies primarily in its ability to provide a nearly stereotypic response to a stimulus on the very first occasion on which it is encountered. Innate reflexes are especially important in situations in which there may not be a second chance for the animal to learn an appropriate response. The best examples are basic feeding responses (for example, the sucking reflex in newborn mammals) and predator-escape behaviors

Image Not Available

(alarm calls in young birds). It is a common misconception, however, that a learned behavior is attributable entirely to the animal's environment, whereas instinct is completely controlled by the genes. Many studies have demonstrated that numerous animals are genetically programmed to learn only certain behaviors. In contrast, it has been shown that instinct need not be completely fixed, but can be modified with experience. Thus, learning and instinct should not be considered two mutually exclusive events.

In addition to its evolutionary implications, the study of learning has provided considerable insight into the internal mechanisms that control and regulate behavior. These mechanisms are the cellular and physiological factors that provide the hardware necessary for learning to occur. As neurobiologists and geneticists learn more about these types of control, it is becoming increasingly evident that learning, at nearly all levels, may involve the same basic mechanisms and processes. In other words, the only difference between simple and complex behaviors may be the extent to which the learning is physically constrained by the biology of the animal. Thus, many invertebrates, by virtue of their simple body plan and specific sensory capabilities, are limited to simple learning experiences. Vertebrates, on the other hand, live longer and are not as rigorously programmed for specific kinds of behavior.

Bibliography

Alcock, John. *Animal Behavior: An Evolutionary Approach*. 6th ed. Sunderland, Mass.: Sinauer Associates, 1998. This is one of the most clearly written texts on the subject of animal behavior currently available. The chapter on the diversity of behavior describes different kinds of learning within an ethological and ecological context. One small section is devoted entirely to insight learning. It is well illustrated and is especially helpful at explaining the experimental evidence for various learning phenomena.

Bonner, John T. *The Evolution of Culture in Animals*. Princeton, N.J.: Princeton University Press, 1980. This small handbook provides a comprehensive but lucid survey of the process of cultural learning in the animal kingdom. Chapter 6 offers a solid introduction to the evolution of learning.

Donahoe, John W. *Learning and Complex Behavior*. Edited by Vivian Packard Dorsel. Boston: Allyn & Bacon, 1994. A biobehavioral approach to complex behavior in humans and animals, arguing that complex behavior is the product of selection. Requires some background in psychology.

Gould, James, L. *Ethology: The Mechanisms and Evolution of Behavior*. New York: W. W. Norton, 1982. This well-illustrated text provides an excellent introduction to the basic concepts of ethology. Three chapters are devoted specifically to the process of learning, and three additional chapters concentrate entirely on human ethology.

Grier, James W. *Biology of Animal Behavior*. 2d ed. St. Louis: Times Mirror/Mosby, 1992. This college-level text provides an excellent treatment of the study of animal behavior. It is clearly written and well illustrated; it should provide a good introduction for the layperson. The text integrates information from a variety of disciplines, including ethology, behavioral ecology, psychology, and neurobiology.

Hickman, Cleveland P., Jr., Larry S. Roberts, and Frances M. Hickman. *Integrated Principles of Zoology*. St. Louis: Times Mirror/Mosby, 1988. A general text on animal biology with an excellent introduction to the general concepts of ethology and animal behavior, with a specific emphasis on learning and instinct. A concise summary, additional references, and review questions appear at the end of each chapter.

McFarland, David, ed. *The Oxford Companion to Animal Behavior*. New York: Oxford University Press, 1987. Intended as a reference guide for both nonspecialists and people in the field, this comprehensive survey of the study of animal behavior was written by a team of internationally known biologists, psychologists, and neurobiologists, and it contains more than two hundred entries covering a variety of behavior topics. More than a dozen of the entries are specifically concerned with the process of learning, and a detailed index provides cross-references organized by both subject and species lists.

LEMURS

Types of animal science: Anatomy, behavior, classification, ecology, evolution
Fields of study: Conservation biology, ecology, ethology, zoology

Over fifty species of lemurs have been identified and classified in the superfamily Lermuroidea in the Primate order. They have evolved separately from East African and other primates for at least forty million years.

Principal Terms

DENTAL COMB: forward projecting lower incisors and canines that are used for grooming and feeding

DENTAL FORMULA: denotes the types of teeth in one quarter of the mouth: incisors, canines, premolars, molars

POLYGYNY: males compete for access to several females

PRIMITIVE: a feature that reflects an ancestral condition rather than those that represent more recent evolutionary changes (derived)

SEXUAL DIMORPHISM: behavioral and anatomical differences between the sexes

SUBLINGUA: fleshy plate under the tongue used to clean the dental comb

Lemurs are primitive monkeys that originally inhabited parts of North America, Eurasia, and Africa, but competition with monkeys and apes resulted in their present distribution, restricted to Madagascar. Humans arrived on Madagascar about two thousand years ago, contributing to extinctions of one third of the island's species through habitat destruction, hunting, climate change, and perhaps new diseases. Most lemurs are highly endangered.

Most lemurs are arboreal (tree-dwelling), although ring-tailed lemurs spend more time on the ground. Lemurs subsist primarily on three to four food species, consisting of a mix of leaves, fruit, buds, bark, and shoots, but favored foods can vary monthly or seasonally. The golden bamboo lemur tolerates high levels of cyanide in the bamboo shoots. The smaller, nocturnal lemurs and the aye-aye eat more insects. Several species are cathemeral (active during parts of day and night), and there are also diurnal (day-active) forms, such as ring-tailed lemurs or indris. The diurnal species may have a nocturnal past, because they share certain features with nocturnal lemurs, including seasonal breeding, female dominance, and reliance on scent for communication.

Unique Primates

Lemurs exhibit many types of social organization. They are solitary in smaller nocturnal forms, while larger diurnal or cathemeral forms live in pairs that sometimes congregate in larger groups, usually with 1:1 sex ratios. Lemurs lack sexual dimorphism, and if there is a difference, females are larger than males. In social species, females largely dominate males, to the extent that males signal submissiveness to all females independent of context. This unusual primate pattern may be due either to seasonally low food productivity and the resulting reproductive costs, or may be partly a function of extinctions of raptors that preyed on primates.

Lemurs range in size from the pygmy mouse lemur at thirty-one grams (about one ounce) to the indri at seven kilograms (sixteen pounds), although many extinct forms were larger. All lemurs have longer posterior than anterior limbs, and their anatomy reflects their ability to practice vertical clinging and leaping. This is most developed in the sifakas and indris, which generally position themselves vertically while in the trees, leap from tree to tree, and exhibit a leaping, kangaroo-like gait when on the ground.

Cheirogaleidae include the fat-tailed and greater dwarf lemurs, primates that hibernate for up to six months during the dry season. Many of the females in Cheirogaleidae, Megaladapidae, and Lemuridae carry offspring in their mouths and sometimes park them on branches when active.

The aye-aye has a high brain-to-body ratio and also has incisors that grow throughout its life (as in rodents) resulting in a dental formula of 1-0-0-3. The teeth are used to gnaw on dead wood during searches for grubs that are then removed with a lengthy third finger.

Lemur Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Primates
Suborders: Prosimians (lemurs, lorises, and tarsiers) or Strepsirhini (lemurs and lorises only)
Superfamily: Lemuroidea
Families: Lemuridae (brown, black, crowned, red-bellied lemurs, bamboo lemurs, ring-tailed lemurs, mongoose lemurs, ruffed lemurs); Megaladapidae (sportive lemurs); Cheirogaleidae (dwarf lemurs, mouse lemurs, fork-marked lemurs); Indriidae (avahi or woolly lemurs, indris, sifakas); Daubentoniidae (aye-ayes)

Geographical location: Madagascar and adjacent Comoro Islands

Habitat: Forests (primary or secondary, dry, humid, or rain forests, evergreen or bamboo forests); sometimes also bush, scrub, or savanna edges of humid forests, spiny deserts, and tree plantations

Gestational period: From 65 days in the dwarf lemur to 175 days in the larger sifaka, indri, and aye-aye

Life span: Ranges from about nine years in the greater dwarf lemur to twenty-five to thirty years in ring-tailed, brown, and black lemurs

Special anatomy: A long snout with a sensitive, moist pad (rhinarium); incompletely fused bony eye socket; reflecting retina (tapetum); ancestral dental formula of 2:1:3:3; dental comb in the lower jaw and sublingua; unfused lower jaw and frontal bone; multiple pairs of breasts; two-section uterus; grooming claw on second toe of foot

LEOPARDS

Type of animal science: Classification
Fields of study: Anatomy, physiology, wildlife ecology

Large cats widely distributed over Africa and Asia, leopards have the greatest geographic range of any wild cat, but face severe pressure from humans within many of their natural habitats.

Principal Terms

CANINES: four pointed, elongated teeth that grasp and kill prey
CARNASSIALS: pairs of large, cross-shearing teeth on each side of jaw
CREPUSCULAR: active at twilight or before sunset
MELANISTIC: having dark coloration of skin and hair
PAPILLAE: sharp, curved projections on tongue

Male leopards vary in length from five to eight feet, including a twenty-eight to thirty-seven inch tail. They stand eighteen to thirty-two inches high at the shoulder and weigh from fifty-five to two hundred pounds, depending on subspecies and geographic area. The largest leopards tend to inhabit mountainous terrain and colder regions. On average, females are 40 percent smaller than males. Leopard coats are short and sleek in the tropics and densely furred in colder areas. Their base color varies from yellow cream in desert areas, to golden yellow in grasslands, becoming deep gold in mountains and forests. All leopards are spotted, with black spots arranged in rosettes along the back and sides. Unlike jaguars, leopard rosettes do not have a spot in the center. Leopards in dark, moist tropical forests of Asia are often melanistic and are called black panthers; dark coats may be advantageous in areas of dim light.

The name leopard is also given to two other species: the snow leopard (*Panthera uncia*), displaying cream-colored fur and grayish rosettes, that inhabits mountainous Central Asia, and the clouded leopard (*Neofelis nebulosa*) of Southeast Asia, carrying grayish fur with cloudlike blotches on its sides. Both are endangered by overhunting for their beautiful fur.

Leopard Behavior

Leopard litters average two cubs; weaned at about three months, they soon begin to accompany their mother on hunts. Cubs remain with their mothers eighteen to twenty-four months before leaving to establish their own territories. Adult leopards are solitary hunters. Males sometimes hunt with females shortly after mating but play no role in raising the young.

Leopards are stealthy nocturnal or crepuscular hunters, preferring to stalk prey in the dark or half-light. They pursue a wide variety of targets as opportunity offers, including reptiles, rodents, birds, fish, and hoofed animals. Leopards kill by biting their victims' necks, strangling them, or severing their spinal cords with canine teeth. Scissoring carnassial teeth and rasplike papillae soon clean all bones of meat. Where their habitat abuts human settlements, leopards hunt close to houses, sometimes eating pets or livestock, but rarely attacking humans. Leopards are agile climbers; in areas where they face competition from lions or hyenas, leopards carry prey twice their body weight high into trees to discourage scavengers.

Relations with Humans

Leopard populations have been decimated by intensive hunting for their prized fur and through destruction of their habitat by expanding human populations. Originally, leopards had the widest east-west range and greatest habitat tolerance of any feline species. Their range included all of Africa outside the Sahara, as well as the Middle East, India, Indonesia, China, Korea, and eastern Siberia. Leopards are now endangered in much of Asia and virtually extinct in North Africa, the Middle East, China, and Korea. The 114 Amur leopards (*Panthera pardus orientalis*) currently held in zoos greatly exceed the estimated thirty or fewer still inhabiting the wild.

International traffic in leopard skins, though banned by the Convention on International Trade in Endangered Species, continues to be a problem, yet the leopard is showing greater survival success than its feline competitors in Africa, the lion and the cheetah. Leopards persist in substantial numbers in sub-Saharan Africa, where they are protected. Perhaps 100,000 or more roam the African plains, a number greater than the estimated total population of all other great cats—lions, tigers, jaguars, and mountain lions—combined. However, even where they are valued and guarded

Leopard Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Eutheria
Order: Carnivora
Family: Felidae (cats)
Genus and species: Panthera pardus
Geographical location: Found over most of Africa south of the Sahara, in the Middle East and India, north to central Asia, and south to Indonesia
Habitat: Grasslands, forests, mountains, and jungles
Gestational period: 3 to 3.5 months
Life span: About fifteen years in the wild, twenty to twenty-five years in captivity
Special anatomy: Large eyes with excellent night vision; jaws adapted to seizing and gripping prey, teeth designed for tearing and slicing flesh

Leopards are very agile climbers and usually haul their prey into trees to keep it away from scavengers. (Digital Stock) as tourist attractions in national parks, illegal hunters continue killing them and farmers on the edge of parks spread poison to protect their cattle and sheep from wandering predators.

Wherever human populations press on leopard habitat, often exaggerated stories of man-eaters arise. One such narrative describes the "Man-Eating Leopard of Rudyaprayag," who was accused of stalking and killing 115 pilgrims en route to a religious shrine in northern India, over a period of eight years, before being hunted down and killed.

LIFE SPANS

Types of animal science: Development, reproduction
Fields of study: Biochemistry, cell biology, developmental biology, genetics, population biology

An animal's life span, the time lapsing between its birth and death, differs greatly from species to species because of differing environmental pressures, chance variations in physical conditions, and heredity.

Principal Terms

LIFE CYCLE: the sequence of development beginning with a certain event in an organism's life (such as the fertilization of a gamete), and ending with the same event in the next generation

LIFE EXPECTANCY: the probable length of life remaining to an organism based upon the average life span of the population to which it belongs

LIFE SPAN: the maximum time between birth and death for the members of a species

METABOLISM: the biochemical action by which energy is stored and used in the body to maintain life

MORTALITY RATE: the percentage of a population dying in a year

Life span has two common meanings, often confused. Popularly, the term can refer to the longevity of an individual, but in biology it is more abstract, a characteristic of the entire species rather than individual members. In this sense, life span is the maximum time an individual can live, given its environment and heredity, and life expectancy is the amount of time remaining it at any point during its life span.

The great variety within the animal kingdom complicates the definition of life span. For some species, life span is essentially the same as its life cycle, the return to the same developmental stage from one generation to the next. Salmon, for instance, hatch from eggs in small streams, migrate to the sea where they reach maturity, then struggle up rivers to return to the site of their hatching in order to produce more eggs. After completing the reproduction cycle, both males and females die. For most animal species, however, an individual may produce several generations of offspring before dying. In the case of humans, individuals can live long after their fertility ends.

It is often difficult to measure the life span for specific species, and in fact, a time period is seldom definitive for all species members. Rather, scientists recognize that mortality, the percentage of individuals that die each year (or each day in some cases), increases for a population of organisms until at some age it reaches 100 percent, and all individuals in a generation are dead. Finding the life span of laboratory animals is fairly simple: A population is given the best possible living conditions, and observers wait for the last individual to die. That, presumably, is the optimal life span for the species. Much the same procedure can determine the life spans of pets and animals in zoos, except that the population to be observed is much smaller, sometimes only a single individual. Likewise, the records of thoroughbred domestic animals, born and raised in captivity, provide evidence for the maximum species life span. Most animals live in the wild, however, where investigations face a great variety of conditions and anecdotal evidence can be misleading. For example, biologists long thought that bowhead whales lived only about fifty or sixty years, but in the late 1990's, various new kinds of historical and biochemical evidence identified bowheads that lived well into their second century. Moreover, species

Image Not Available

whose members can, if need be, go into dormancy show a large variation in individuals' apparent longevity, even when all members pass through a single life cycle.

In general, however, the life span variation among species falls into a fairly narrow range of time. The shortest life spans, which last a single life cycle, can be a matter of days, while the longest last more than two hundred years. Humans enjoy the greatest longevity among primates; scientists estimate the theoretical maximum human life span to be from 130 to 150 years, more than double that of the species with the next greatest endurance, gorillas and chimpanzees. However, several kinds of invertebrates live more than two centuries.

Life Span Limiters and Extenders

While each species has a theoretical maximum life span, few if any individual animals reach it. Three general influences limit longevity: environmental pressures, variations in physiological processes, and heredity.

Most domesticated species have longer life spans, frequently two times longer, than their wild relatives, and wild animals in captivity often live longer than in their natural habitat. The gray squirrel, for example, lives for three to six years in the wild, but from fifteen to twenty years in a zoo. The reason is clearly the safer, healthier, less stressful environment. Predators are one of the biggest threats in the wild, as are fluctuations in climate that affect the availability of food and shelter. Natural calamities such as hurricanes, wild fires, and earthquakes also take their toll.

Disease and chance injury also kill off many organisms, but even if disease is absent, many physiological processes in the body appear to degenerate or stop with age. Biochemists find that individual cells age and die. Cross-connections among connective tissue, such as ligaments and cartilage, gradually reduce the body's flexibility and inhibit motion. Chemical plaques build up in brain tissue, hindering the electrochemical connection among neurons. Highly reactive oxidants, the ionized molecular byproducts of cellular metabolism, also build up with age and degrade the operation of cells' mitochondria, the generators of chemical energy, as well as other cellular organelles. Moreover, laboratory tests reveal that cells can divide only a certain number of times—about fifty for some human cells—and then they die, a limit called the Hayflick finite doubling potential phenomenon. In connection with this finding, geneticists discovered that the lengths of deoxyribonucleic acid (DNA) at the tips of chromosomes, called telomeres, shorten with age and appear to play a role in cell dysfunction and death.

Other genetic factors help determine the age limit of cells and the entire organism. Research in the late 1990's with mice and roundworms uncovered genes that regulate cell life, including one kind that causes cells to suicide if their DNA or internal structure is too damaged to function properly or if the cells turn cancerous. Loss of function by genes damaged during cell division (mitosis) or by environmental toxins can impair a cell's ability to maintain metabolism, or set loose functionless or even outrightly harmful proteins and enzymes into the blood stream and lymph system—all of which can bring on illness. Organisms that escape such effects still may face genetic disease. Most human populations, for instance, now have a longer life expectancy than ever before; because of it, neurodegenerative diseases (such as Alzheimer's disease), cardiovascular dysfunction, and immunological disorders, caused or made possible by genes, grow ever more common. Because many of these life-shortening maladies were rare or nonexistent before the twentieth century, natural selection has not had a chance to cull them from the human genome. Similar diseases crop up in domestic animals and wild animals in captivity.

Late twentieth century research also identified several ways to extend life. A sharply reduced diet extends the lives of mice and fruit flies beyond their normal life span (although for the brown trout, a richer diet is life-extending), and lower than normal temperature has the same effect on fruit flies, fish, and lizards. Discovery of the relation of telomere length to cell death and isolation of genes that order cells to suicide allowed scientists to bioengineer animals with cells whose DNA self-repaired the telomeres and genes that failed to trigger cell-suicide; the result was individuals that in some cases had life spans twice the normal length or more. However, the most pervasive life-extending method is the development of social life—colonies, herds, packs—in which individuals work together to protect, shelter, and feed themselves and rear their offspring. In the case of humans (and perhaps some whales), culture and intelligence permit the species to pass on recently acquired information from one generation to the next and even to alter the environment to lengthen collective and individual life spans.

Size and Life Span

Biologists noted long ago that large animals live longer than small animals, but why this should be true was a mystery. In 1883, Max Rubner proposed that the relation had to do with metabolism. Large animals have a smaller skin surface to body mass ratio than smaller animals; accordingly, large animals lose heat more slowly and so can maintain body functions with less energy burned per unit of mass; in other words, a slower metabolism. Scientists since found that individuals of different animal species all use about the same amount of chemical energy during their lives, twenty-five to forty million calories per pound per lifetime. (There are significant exceptions: Humans consume about eighty million calories per pound.) Because small animals must burn energy at a higher rate, the argument holds, they physically wear out faster.

In 1932, Max Kleiber derived a mathematical relationship for Rubner's proposal. According to Kleiber's law, also known as the quarter-power scaling law, as mass rises, pulse rate decreases by the one-fourth power. So elephants, which have 104 times the mass of chickens, have a pulse rate one tenth as fast. Scientists suggest that the relation results from the geometry of circulatory systems and point out that the quarter-power scaling law is pervasive in nature, but the underlying reason for it remains unknown. In any case, plenty of exceptions to the mass-life span correlation exist. With a life span of about one hundred years, box turtles outlive fellow reptiles, for example, and humans outlive all mammals (with the possible exception of some whale species) regardless of size. Exceptions also occur among domestic species living sheltered lives: Cats have longer life spans than dogs.

Theories of Life Span

A 1995 review of data from earlier animal studies suggested that heredity accounts for about 35 percent of the variation in life spans among invertebrates and mammals; 65 percent comes from unshared environmental influences. Nonetheless, theorists in the life sciences continue to debate the relative influence of genetic and other biochemical factors on the one hand and environment fac-

The Big, the Old, and the Immortal

In some species, the older an animal gets, the larger it grows. Big sharks are old sharks, as are big crocodiles and snakes. In 1912, a reticulated python was found that measured thirty-two feet, ten inches in length, the longest ever, but no one knows how old it was. The age record for snakes goes to Popeye, a boa constrictor at the Philadelphia Zoo that died in 1977 at the great age of forty years and three months. Even for reptiles, however, Popeye's life span was modest. One Madagascar radiated turtle lived 188 years.

Most species, including humans, grow to a maximum size and then stop. The longest attested life span for a person is 122 years, achieved by France's Jeanne Louise Calment, who died in 1997, followed by Japan's Shigechiyo Izumi, who died just short of 121 years in 1986. Despite theories relating large body mass to long life span, some big and small animals in the wild have about the same life expectancy at birth: fifty years for both golden eagles and most whales, for instance, or twenty-four years for rhesus monkeys compared with twenty-five years for lions.

There is some disagreement over which animal species has the longest life span. The tubeworms growing on the ocean floor near hydrocarbon-seep sites in the Gulf of Mexico are thought to be as much as 250 years old, and so have been called the longest-lived noncolonial animals without backbones. However, some mollusks of the class Lamellibranchia, such as quahogs, a variety of clam, have also been called the longest-lived animal. They, too, can lie snug in their ocean bed for 250 years.

Whether classified as animals or not, bacteria hold the record for life span. If they are not eaten by predators or killed by environmental change, these single-cell creatures are theoretically immortal. Furthermore, they do not get larger with age: They divide.

tors on the other hand. The debate derives from the premise that life spans are the product of the natural selection that ensured species' reproductive success. The proposals fall into three categories: random damage (stochastic) theory, programmed self-destruction theory, and ecological theory.

Random damage theories emphasize the wear and tear on the body that accumulates with metabolic action. It is the source of damage that differs from one theory to another. One holds that the buildup of metabolically produced antioxidants is the key factor, a spinoff of the long-standing conjecture that the faster an animal's metabolism is, the shorter its life span. A second theory focuses on proteins that change over time until their effect on the body alters for the worse, especially when the proteins are involved in cellular repair. There is, for example, the altered connective tissue that causes the cross-connections stiffening tendons and ligaments. Another such change is the glycosylation of proteins or nucleic acids, in which a carbohydrate is added. Glycosylation is involved in such age-related disorders as cataracts, vascular degeneration among diabetics, and possibly atherosclerosis A third theory points to the buildup of toxins inside cells, and a fourth concerns the potential problems that come from errors in metabolism or viral infection which slowly impair or kill cells. Fifth, the somatic mutations theory proposes that chance mutations accumulate in a person's nuclear or mitochondrial genome and induce cell death or produce proteins and enzymes that have aging effects.

Programmed death theories hold, as the name suggests, that a species' genetic heritage includes a built-in timer or damage sensor. Telomeres shorten as DNA ages until the genes at the end of chromosomes are unprotected and subject to deterioration during the splitting and gene crossover of mitosis. The genes then lose their ability to produce essential biochemicals, whose absence harms the body or leaves it defenseless against damage from infection or injury. Damage sensors can include the genes that instruct cancerous or malfunctioning cells to die. Although such genes clearly are a means to check the spread of disease, their cumulative effect may be harmful. Furthermore, scientists discovered genes that produce much more of, or less of, their metabolic products as cells age, which also contributes to the overall aging of the body.

The ecological theory draws conclusions about life span from a species' role in its environment. Small animals have faster metabolisms and live shorter lives, it is argued, because they are not likely to escape predators for very long. Therefore, they evolved to mature and reproduce rapidly. Large animals typically have more defenses against predators and can afford to take life slowly. Moreover, animals that evolve defensive armor, spines, or poison also avoid predation and live longer than related species that do not. Finally, species that evolve mechanisms to withstand environmental stress, as from extreme temperatures or food scarcity, also have long life spans.

The theories assume that the life span for individuals within a species serves the survival of the entire species. Yet even a species' days on earth are numbered. Environmental change can slowly squeeze them from their habitats, a catastrophe may wipe them out indiscriminately, or they may evolve into a new species. Scientists estimate that the average life span for a multicellular species lasts from one to fifteen million years. That average is stretched by several notable exceptions in the animal kingdom—such living fossils as crocodiles (140 million years old), horseshoe crabs (200 million), cockroaches (250 million), coelacanths (a type of fish, 400 million), and certain mollusks of the genus *Neopilina* (500 million).

The authors describe the age differences between closely related creatures of the same size to support their theory that environmental factors, such as predation, influence the evolution of life spans for species.

MacKenzie, Dana. "New Clues to Why Size Equals Destiny." *Science* 284, no. 5420 (April 6, 1999): 1607-1608. Discusses theories about the relation of size to life span in a style accessible to general readers.

Margulis, Lynn, and Karlene V. Schwartz. *The Five Kingdoms: An Illustrated Guide to the Phyla of Life on Earth*. 3d ed. New York: W. H. Freeman, 1998. A richly illustrated explanation of taxonomy with detailed information about the biology of the thirty-seven phyla in the kingdom Animalia, including discussion of life cycles and development.

Walford, Roy L. *Maximum Life Span*. New York: W. W. Norton, 1983. Delightfully written and lucid, this book, written by a pioneering researcher in aging, is somewhat out of date and focuses primarily upon human aging, but it still supplies solid information about the biological and ecological limits on animal life spans.

LIONS

Type of animal science: Classification
Fields of study: Anatomy, wildlife ecology

Lions, celebrated in myth as the King of Beasts, are the second largest of the big cats and the only members of the Felidae family to live and hunt in groups in the wild.

Principal Terms

CANINES: four elongated, pointed teeth that grasp and kill prey
CARNASSIALS: pairs of large, cross-shearing teeth on each side of jaw
CREPUSCULAR: active after sunset and in early morning
DIMORPHISM: existence of two distinct forms within a species
PAPILLAE: sharp, curved projections on tongue

Surpassed in size only by tigers, African male lions range in weight from 330 to 420 pounds, stand about forty-eight inches tall at the shoulder, and average 8 to 9.5 feet in length, including the tail. Females are smaller, weighing from 260 to 350 pounds, stand about forty inches tall, and average seven to eight feet in length. The Asian lion subspecies (*Panthera leo persica*) is similar in size, but somewhat shorter and stockier in build.

Among cats, lions are the only species to show sexual dimorphism—mature males display a distinctive mane encircling their head and shoulders; it darkens with age, giving the lion a majestic look. Coat color is normally tawny yellow to reddish brown in both sexes, with black accents on ears, tail tips, and manes. Cubs are born spotted, but by three months of age begin showing the uniform coat color of their parents.

Lion Behavior

Unlike other wild cat species, lions live and hunt in groups, called prides. (Domestic cats exhibit some similarities in group behavior.) The pride's core consists of two to twelve closely related lionesses, who assist each other in raising their cubs. Female offspring usually remain members of the group, but males are driven off before becoming sexually mature. Two to four unrelated males live with the pride, fathering the cubs, protecting the pride, and proclaiming their territory with scent marks and loud roars that can be heard for five miles. Males rarely control a pride more than three or four years before being replaced by younger, more powerful challengers.

Lions are crepuscular hunters, preferring to rest in the shade during the heat of the day; they emerge at sunset or in the early morning to pursue their prey. Lionesses do most of the killing, cooperating when stalking and ambushing victims. The preferred targets are medium to large hoofed animals such as antelopes, zebras, and wildebeests. Males rarely participate in chases unless their weight is needed to bring down large bull buffaloes; however, males claim first place at the pride's feasts. Lions are also opportunistic scavengers, stealing prey from leopards, cheetahs, and hyenas. Similar to other big cats, lions kill by biting their victims' necks, strangling them, or severing their spinal cords with sharp canine teeth. Scissoring carnassials and rasplike papillae leave little of their victims other than bones and skin.

Lions and Humans

Throughout history, lions have been called "King of Beasts" and used to symbolize royal authority. Rulers, often described as lions, wore lion skins to

Lionesses do most of the hunting for the pride. (Digital Stock)

impress subjects with their majesty and power. Hunters demonstrated bravery and prowess by killing lions. Lions have been celebrated in myth and legend from antiquity to the present; in astrology, Leo Major reigns as the fifth house of the Zodiac.

Originally, lions existed throughout southern Europe, all of Africa, the Near East, and from southwest Asia to India. As human population and agriculture expanded, hunting and habitat destruction greatly reduced lion numbers. By 100 C.E., lions had been eliminated from Europe, by the time of the Crusades they were extinct in the Near East, and before 1900 had vanished from North Africa and most of Asia. When the Nawab of Junagadh established the Gir Forest Lion Sanctuary in Gujarat, India, in 1965, less than 100 Asian lions remained in the world; a 1990 study estimated that the population had rebounded to about 250 individuals.

Estimates of the African lion population south of the Sahara Desert run as high as fifty thousand. The overwhelming majority live in national parks and reserves, where wild animals are protected as valuable national assets, attracting tourists and significant income. In the parks, lions have become so accustomed to humans that they sometimes rest in the shade of tour buses to avoid the afternoon sun. As human populations continue expanding, governments face pressure to reduce the preserves and permit agriculture and grazing to increase the food supply. However, most naturalists believe the monetary value of wild animals in producing foreign exchange will ensure the long-term survival of the African lion, even if reduced in numbers.

Lion Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Eutheria
Order: Carnivora
Family: Felidae (cats)
Genus and species: Panthera leo

Geographical location: Once common to many areas of Europe, Africa, and Asia; now found only within protected areas in Africa south of the Sahara and in one wildlife refuge in India

Habitat: Grassy plains, savannas, and open woodlands

Gestational period: 3 to 3.5 months

Life span: About twelve to fifteen years in the wild, twenty years or more in captivity

Special anatomy: Large eyes with excellent night vision; jaws adapted to seizing and gripping prey; teeth designed for tearing and slicing flesh

LIZARDS

Types of animal science: Behavior, classification, ecology, evolution, reproduction
Fields of study: Anatomy, conservation biology, herpetology, physiology, systematics (taxonomy), zoology

More than six thousand species of reptiles have been identified and named. They are classified in the order Squamata, of which slightly more than four thousand are lizards. The remainder are snakes. Technically, snakes comprise one group of limbless lizards. Squamata is the largest order of extant reptiles.

Principal Terms

ACTIVE OR WIDE FORAGING: moving about in search of prey

AUTOTOMY: loss of the tail by controlled muscle contractions resulting in breakage at intervertebral sutures

BEHAVIORAL THERMOREGULATION: maintaining relatively constant body temperature by shuttling between warm and cool microhabitats

ECDYSIS: sloughing off of old skin, which is replaced by new skin from underneath

LECITHOTROPHY: nutrition of developing offspring from yolk reserves within the egg

MATROTROPHY: nutrition of developing offspring directly from the mother; in the case of lizards, via a placenta

OVIPARITY: production of shelled eggs by females

PARTHENOGENESIS: reproduction in which unfertilized eggs develop into females genetically identical to their mothers

SIT-AND-WAIT FORAGING: sitting in one place, waiting, and attacking prey as they move

SPECTACLE: transparent scale covering the eye as a replacement for the eyelid; occurs in some lizards and all snakes

VIVIPARITY: production of live young by females

Lizards belong to the order Squamata, along with snakes. There are approximately four thousand lizard species.

Lizard Reproduction

Most lizards reproduce sexually, although some are parthenogenetic. Most lizards are polygynous, with males mating with more than a single female, although a few, such as Australian sleepy lizards (*Trachydosaurus rugosus*), are monogamous. Mating occurs after complex social behavior often involving prolonged courtship. Fertilization is internal. Males have paired intromittant organs called hemipenes, one of which is inserted in the female's cloaca during mating. Once eggs are fertilized, the female carries eggs or embryos for various periods of time. The weight of unborn offspring usually reduces the female's ability to run fast, thus affecting her ability to escape predators. Many females change their behavior while gravid to reduce the costs of reproduction. Costs of reproduction are not confined to increased predation risk; energy required for locomotion increases as well due to the added weight that females carry around while gravid.

Most lizards produce eggs (oviparity) but many produce live young (viviparity) following extended gestation periods. Females of oviparous species deposit eggs in places that are moist but not wet, such as inside rotted logs or in the ground, often under rocks. Most lizard eggs have pliable, leathery-shelled eggs, but a few, such as geckos, have hard, calcified eggshells. Lizard eggs

Lizard Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Vertebrata
Subphylum: Tetrapoda
Class: Reptilia
Subclass: Diapsida
Superorder: Lepidosauria
Order: Squamata
Suborders: Iguania (iguanids, chamaeleonids, and agamids); Scleroglossa (all other lizards and snakes); Gekkota (gekkonids, eublepharids, diplodactylids, and pygopodids); Autarchoglossa (teiids, gymnophthalmids, lacertids, xantusiids, dibamids, amphisbaenids, trogonophids, rhineurids, bipedids, scincids, gerrhosaurids, cordylids, anguids, xenosaurids, helodermatids, lanthanotids, varanids, and "snakes")
Geographical location: Every continent except Antarctica
Habitat: A vast majority live on land or in trees in all habitats (desert, savanna, temperate and tropical forest); a few are semiaquatic; one, the Galápagos iguana, dives into the ocean and feeds on algae
Gestational period: Highly variable; eggs of *Anolis* lizards hatch in several weeks, while embryos of some skinks (*Mabuya*) require a year
Life span: Variable; some small skinks and geckos live one year or less, whereas Gila monsters (*Heloderma*) and large monitors (*Varanus*) live thirty years or more
Special anatomy: All lizards have scales (like other reptiles), paired copulatory organs in males (hemipenes), and claws on their feet; most have four legs, an elongate tail, eyelids, and external ear openings; some lizards in several families have lost two or all four legs as adaptations for life underground, some have their ear openings completely covered by scales, some have short tails, and some have their eyes covered by a transparent scale (spectacle); some subterranean lizards, such as the strange worm lizards, have eyes reduced to an eyespot covered by scales

in the nest are vulnerable to predation by many animals because they cannot move. Eggs contain yolk, which is high in energy and thus a good food source for snakes, mammals, and even some other lizards. Consequently, mortality of lizard eggs in nests is high. A vast majority of oviparous lizards do not provide parental care to eggs, but females of a few, such as five-lined skinks and glass lizards, remain with the eggs, brooding them until they hatch. Hatchlings cut slices in their eggshells with a specialized scale on the front of their jaw, called the egg tooth. Parental care ends once offspring exit the eggs. Hatchlings are fully formed, resembling miniature adults. Females of viviparous species often provide some parental care to neonates (newborns). Most help neonates free themselves from embryonic membranes, often eating the membranes. A few, such as the large Australian sleepy lizard, engage in extended parental attention, but it does not involve feeding or grooming the young, as in birds and mammals.

A number of lizard species in several different families reproduce by parthenogenesis, a process in which females produce daughters that are genetically similar to their mothers without the involvement of males. In such species, potential population growth is extremely high because no energy is wasted on males and every individual produces offspring.

Although sex determination in most lizards is chromosomal, as in humans, some species of lizards lack sex chromosomes and have environmental sex determination. Eggs incubated at one set of temperatures produce all males, whereas eggs incubated at another set of temperatures produce all females.

The juvenile stage of most lizards is also a high mortality stage. Juvenile lizards are relatively small in body size, and, as a consequence, many predators can easily eat them. Because juveniles do not reproduce, all energy taken in is devoted to growth and maintenance. When lizards reach sexual maturity, growth slows and most energy is directed into reproduction and maintenance. Males use energy in reproductive related behaviors such as territorial defense and courtship, whereas females use energy for production of eggs.

Evolution of Sensing Systems

One of the most fascinating aspects of the natural history of lizards is the variation in relative importance of sensory systems and its consequences. Most lizards in the suborder Iguania are visually oriented, sit-and-wait predators. They capture prey by a process known as tongue prehension; basically, they stick their tongues out and carry insects into the mouth on their tongues. They are colored for camouflage, move very little, and attack moving prey from perches, to which they usually return. Their social systems usually involve territoriality, the defense of a specific area against intruders of the same species. In most instances, territorial behavior is directed toward other males.

Lizards in the suborder Scleroglossa use a combination of visual and chemical cues to locate and discriminate prey. They have well-developed vomeronasal systems; they pick up chemicals from the external environment with their tongues and bring them into the mouth, where they are passed over the vomeronasal organ (also called the Jacobson's organ) in the roof of their mouth. This organ transfers information directly to the lizard's brain, allowing it to discriminate prey on the basis of chemicals much like mammals' sense of smell. These lizards capture prey by grasping prey between their jaws. The tongue may be used to help manipulate prey within the mouth but is not used to capture prey. Most of these are active foragers; they travel around, searching for prey, many of which are not moving.

Venomous and Dangerous Lizards

Most lizards will bite in self-defense, and, because all lizards have teeth, some will break the skin. Only two lizard species in the world are venomous, the Gila monster and its close relative, the Mexican beaded lizard. Both have powerful jaws and are difficult to remove should they bite. They do not have fangs like poisonous snakes; rather, they have grooved teeth with venom glands located in the rear of the mouth. Venom moves along the grooved teeth as the lizards grind their jaws while biting. Bites are only rarely fatal. Large monitor lizards are nonvenomous, but their mouths contain high levels of bacteria, which can cause dangerous infections following bites. Some of the larger monitors, such as the Komodo dragon of the Lesser Sunda Islands, have sharp, serrated teeth and can bite completely through the

Iguanas are sit-and-wait predators that catch passing insects with their long tongues. (Digital Stock)

Some Types of Lizards

Anoles (genus *Anolis*) are highly diverse, with more than three hundred species, all in the New World. Most are arboreal, and females produce only a single egg in each clutch.

Chameleons (family Chamaeleonidae), restricted to the Old World, have prehensile tails and long protrusible tongues that they use to capture insects.

Chuckwallas (genus *Sauromalus*) are herbivorous lizards of the American Southwest desert that hide in rock crevices, where they inflate their bodies, making it very difficult to remove them.

Flying lizards (genus *Draco*) of Southeast Asia have large flaps of skin along the sides of their bodies that become parachutes when erected by their ribs, allowing them to glide through the air after jumping from tree surfaces.

Geckos (family Gekkonidae) include many species with adhesive toe pads, which allow them to climb smooth, vertical surfaces.

Glass lizards (genus *Ophisaurus*) have no legs and superficially resemble snakes. Their long tails are easily broken and often break into several pieces, each of which moves around violently, distracting predators while the lizard slowly escapes.

Iguanas (*Iguana iguana*) are large tropical lizards that feed exclusively on plants. They have microorganisms in their digestive tracts that break down cellulose, allowing them to digest leaves.

Monitors (genus *Varanus*) are large, intelligent lizards living in the Old World and Australia. The largest monitor is the Komodo dragon, which reaches nearly twelve feet in total length.

Night lizards (genus *Xantusia*) are secretive lizards that live in rock crevices and under branches of fallen Joshua trees in the desert southwest of North America. Even though they are very small in size, they are long-lived.

Tegu lizards (genus *Tupinambis*) live in open habitats in South America and reach more than 3.5 feet in total length.

Whiptail lizards (genus *Cnemidophorus*) are unusual New World lizards in that many species are parthenogenetic, reproducing without males and producing only female clones.

leg muscles of large vertebrates. As a result, their bites are potentially life-threatening even though they rarely attack humans.

LOCOMOTION

Type of animal science: Physiology
Fields of study: Anatomy, biochemistry, physiology, zoology

Locomotion, the ability to move from one place to another as needed, is widespread. It is seen in unicellular animals, which move via cilia, flagella, or like amoebas. The locomotion of multicellular animals includes crawling, walking and running, swimming, gliding, and flying.

Principal Terms

AIRFOIL: the wing of a flying animal or airplane that the provides lift and/or thrust needed for flight

ANGLE OF ATTACK: the angle at which an airfoil meets the air passing it

EUKARYOTE: a higher organism, whose cells have their genetic material in a membrane-bound nucleus and possess other membrane-bound organelles

LIFT: the force enabling flight; it occurs when an airfoil makes air passing it move so as to lower air pressure above the airfoil to values below that beneath the airfoil

LOCOMOTION: the ability of an organism to move from one place to another as needed

MITOCHONDRION: a subcellular organelle that converts foods to carbon dioxide, water, and energy

SESSILE: an organism that is not capable of moving from its point of origin

STRIATED MUSCLE: voluntary or skeletal muscle, capable of conscious enervation

Being a sessile animal, unable to move from place to place, makes life difficult for a wide variety of reasons. For example, if food is not available in a very limited area, death may come very quickly. As a result, a great many living animals, from unicellular microbes to the multicellular higher organisms, have developed the ability to move from one place to another as needed. This ability for self-directed movement is called locomotion.

Locomotion is under conscious (or voluntary) control. In essence, it serves to allow living creatures to move in chosen directions, toward food, away from danger, toward mates, and so on. Locomotion is essential for the optimization of the lives of animals. This can be seen in two ways: Most living animals are capable of locomotion; it is particularly well developed in large, higher organisms.

The Physiology of Locomotion

Many unicellular animals, such as protozoa, carry out locomotion via hairlike organelles called cilia and flagella, or by amoeba-like motion. Their movement is not complex. Multicellular animals, crawl, walk, run, swim, glide, or fly. The basis for these much more complex activities is cooperative operation of their skeletons and muscles, along with other processes needed to suit each organism to its environment. In addition, nerve impulse transmission coordinates locomotion.

The skeleton and the muscles act as the levers that can move to produce body motion in chosen directions and as the machines that produce the motive ability required for locomotion. Skeletons are of two types. The external, bony, jointed exoskeletons of arthropods (insects and crustaceans) surround them like medieval suits of armor. This design limits the dexterity of arthropods and the complexity of the motion possible for them. In contrast, the bony endoskeletons of vertebrates are much more complex and produce the ability for much more complicated and dexterous locomotion.

The muscle involved in locomotion can be exemplified by vertebrate striated skeletal muscle. This type of muscle is called striated because its fibers appear to be banded when viewed under light microscopes. Such muscle is under the conscious (voluntary) control of any higher organism containing it and wishing to move toward a desired place. Striated muscle is either red or white. Red striated muscle has a very good blood supply—the basis for its color—and obtains energy in the course of oxidizing foods into carbon dioxide and water. This occurs in its many mitochondria, subcellular organelles that carry out oxidative, energy-getting processes. White striated muscle has less of a blood supply and less mitochondria. It obtains most of its energy by converting food to lactic acid, without much use of oxidation or mitochondria.

All locomotion uses the contraction and relaxation of muscle or related systems, which can be thought of as muscle waves. In the unicellular eukaryotes (such as protozoa), cilia and flagella are used. These structures are cell organelles that are whiplike and identical in their makeup. However, their size and number per cell differ. One protozoan type may have on its surface hundreds of cilia, each ten to twenty microns long. Another species can have one or two flagella up to 250 microns long.

Both cilia and flagella cause movement by producing a wavelike motion transmitted all through the organelle, outward from its base. Their action uses organized protein microtubules in a network, interconnected by arms and spokes reminiscent of fibrils, and crosslinks of striated muscle. The mechanism of their action also uses a sliding mechanism initiated by a protein called dynein. Cilia and flagella are also found in multicellular eukaryotes, including humans. For example, flagella propel human sperm and are found in human lungs, where they mediate the removal of dust and dirt from the airways.

Amoeboid motion also occurs in protozoa. Here, their protoplasm flows in the direction of

Cheetahs are the fastest animals on earth, running at speeds of up to seventy miles per hour. They increase the distance covered in each step by leaping as well as running. (Corbis)

Muscle and Bone

Light microscopy of striated muscle fibers reveals a regular pattern of alternating light and dark bands that is repeated every few microns along the fibers. This banding pattern has been found to explain muscle contraction. The process operates due to the presence in the muscle of two kinds of filaments, thick filaments and thin filaments, which run lengthwise along each muscle fiber. Thick filaments are made mostly of a protein called myosin and have projecting cross-bridges. Thin filaments contain mostly the protein called actin and have no cross-bridges. When a muscle contracts, due to energy input, the cross-bridges of the thick filaments attach to the thin filaments surrounding them, pulling them so that they slide between thick filaments. This sliding action shortens the muscle fibers, and as the shortening proceeds, cross-bridges detach and reattach after walking to positions further along the thin filaments.

If a vertebrate animal is to walk, run, swim, or fly, a system of levers is required to turn its muscle contractions into locomotion. This is provided by its endoskeleton, which pulls the levers inside the body, joined to muscles. The skeletons of vertebrates are made of bones, which meet at joints that allow bending and twisting due to the action of muscles attached to the bones. A joint which only allows bending to occur (such as an elbow or knee) has flexor muscles to bend them and antagonistic extensor muscles to straighten them. Joints, such as those in the fingers, have the ability for much more freedom of movement. This is because they are moved by a larger number of muscles. Some muscles attach directly to the bones of the skeleton, but others join the bones via tendons.

desired motion, forming pseudopods, followed by forward locomotion of the cell. This type of locomotion seems to depend on cytoplasm transitioning between fluid endoplasm and gel-like ectoplasm. Pseudopod formation occurs due to the action of microfilaments of actin, one of the contractile proteins also found in striated muscle. Thus, the contraction mechanism may be similar to that in striated muscle.

The various forms of locomotion include crawling, walking and running, swimming, gliding, and flying. These locomotive processes all use muscle waves based on actin and myosin fibrils. However, the complete systems involved become more and more complex due to increases of the needs of locomotion, crawling on earth's surface, walking or running on land, swimming in lakes and oceans, and gliding or flying in the air. The increases in complexity are mostly due to the need for the involvement of more and more muscles.

Crawling, Walking, and Running

Crawling is movement on land without legs, produced by waves of muscular activity traveling along the crawler's body. Two crawling creatures are snakes and snails. When a snake crawls, it curves its body into bends around stones and ground irregularities. These bends travel backward along the snake's body in muscle waves. The waves push against the stones and irregularities and propel the snake forward. Snails, in contrast, usually crawl on a long foot covered with mucus, using waves of muscle contraction that travel along the foot. Snail locomotion depends on their interesting mucus, which resists gentle pressure as if it were a solid, but when pressed hard behaves like a liquid. The muscle waves of snail feet are designed so that foot portions moving forward exert pressure enough to liquefy the mucus, while parts that move backward do not.

All living organisms capable of walking or running have skeletons because the processes are intricate and require the use of a relatively large number of muscles in a complex fashion. Walking is locomotion at a slow pace, when there is no need for speedy movement. Running enables organisms to move much more quickly. It is done when predators threaten, or if there is an unthreatening reason to travel more quickly than usual, for instance, to obtain some choice food or a mate.

The complexity of walking and running is made clear by the coordination required. For example, when four-footed animals walk, at least one forefoot and one hind foot are kept on the ground at all times. In walking bipeds, at least one foot is on the ground at all times, and at intervals, both feet are on the ground. In running, there are times when both feet leave the ground simultaneously. Four-footed mammals walk slowly, but often attain higher speeds by trotting, cantering, or galloping. In each of these gaits, there are differences in the operation of the legs. For example, in a gallop, both forefeet are set down at one instant and both hind feet are set down at the next instant. This is not due to chance; rather, it allows the back muscles to contribute to the work done and spread the overall effort through the body.

Another aspect of the differences between walking and running is the interaction of the feet with the ground. Some animals, including humans, walk or run with the entire bottom of the foot on the ground; this is known as plantigrade locomotion. In contrast, most quadrupeds carry out these actions with only their toes on the ground, known as digitigrade locomotion. Such differences in ways in which vertebrates walk and run add to the complexity of the processes and the number of muscles used. The rate at which an animal moves also depends on its foot size. The larger the foot area that touches the ground while walking or running, the slower the animal. The complexity of running activity adds to total speed. For example, cheetahs can run at a speed of sixty-five to seventy miles per hour, partly by adding to their gait a series of leaps at chosen intervals. The added leaps help to produce the ability to move three times as fast as exceptional human athletes can run one hundred meter dashes.

Flying, Thrust, Drag, and Lift

Heavier-than-air craft, whether birds, bats, or airplanes, must conquer gravity to enter the air in controlled flight. In the case of animals who fly—as well as of airplanes—three different forces are involved. The first, called thrust, is empowered in animals by wing flapping. Thrust enables forward horizontal movement, as long it exceeds the second force, drag, caused by air viscosity.

The third aerodynamic force, lift, is the key to flight. It enables upward rise into the air, at a right angle to the direction of the forward motion. Lift in living creatures is supplied by the wings of flying animals. These wings (airfoils) are moved so the angle at which they meet air passing them (the angle of attack) makes the air flow much more rapidly past the upper airfoil surface than past its lower surface. This drops the air pressure above the airfoil to values below the air pressure under it and engenders lift needed to fly. In flying animals, the angle of attack (as in birds) is altered by wing motion adjustments.

The importance of the angle of attack of airfoils is clarified by its use and misuse by human pilots during flight. Angles of attack of up to fifteen degrees increase lift, enabling fast climbs but slowing airspeed. When the angle of attack is too steep, air currents atop airfoils decrease lift and cause aircraft to drop toward the ground in stalls. When pilot misjudgment produces a stall, the craft crashes unless the pilot quickly decreases the angle of attack. Birds do this instinctively, and so effortlessly that crashes due to bird stalls do not occur.

Swimming, Gliding, and Flying

Organisms that swim in water range from tiny ciliated or flagellate microbes to blue whales that are over one hundred feet long. Their locomotive operations are complex and use oarlike rowing, hydrofoil motion of propellers, body undulation, and jet propulsion. Oar and propeller actions have some similarities, but oars push in the direction of a desired movement, while propellers work at right angles to blade motion. Propeller action is due to lift, caused by hydrofoil action in the water. Propeller-mediated animal locomotion is more complex than walking or running, especially in the case of whale flukes. These hydrofoils, in addition to complex motion, must be tilted at angles which provide more lift than drag, under widely varying conditions.

In animals that swim by undulation, movements are made like the crawling of a snake. Here, the resistance to motion of poorly compressible water makes it easier for the swimmer to slide forward along its long axis than sideways along its short axis. The squid exemplifies those organisms that move by jet propulsion. A squid does this by drawing water into its mantle and squirting it out forcefully from an organ called a funnel. The squirt is aimed forward when a squid wants to swim backward, or backward when it seeks to swim forward.

One of the problems associated with locomotion by swimming is that most tissues in swimming organisms are more dense than water. Such organisms would sink, lacking ways to raise body buoyancy. These needs add to the complexity associated with swimming, compared with walking or running on land. Ways in which to counter sinking include swimming with all fins extended like airplane wings, as sharks do, to add buoyancy by increasing the surface area of the body. Also, swimming animals, such as the bony fish, adjust their densities to match that of the water via gas-filled swim bladders in their body cavities.

Only insects, birds, and bats are capable of locomotion by true flight. However, some other animals glide for short distances. Best known are flying squirrels, which glide from tree to tree. Also, flying fish use their large pectorals as wings of a sort. They leap out of the oceans with the fins spread and glide through the air for up to half a minute. As is the case with whale flukes in water, a glider supported by lift on its wings is slowed and pulled down by drag. Thus, most gliding organisms do not stay in the air for long Their time suspended aloft depends upon maintaining the appropriate angle of attack of their wings. They can adjust glide speed by changing these angles of attack. Increasing this angle slows them and decreasing it allows them to speed up.

Soaring, or gliding for long distances, is possible only for animals aloft in quickly rising air. Few animals other than birds and butterflies have wings capable of sustained gliding. The needed air currents are found mostly over hillsides or coastal cliffs and in thermals, which are currents of hot air rising from ground heated by the Sun. Vultures soaring to scan for carrion can travel for distances up to fifty miles. Butterflies, gulls, and albatrosses also soar for long distances. Long-distance soaring is very often used on migration trips, to conserve energy for other activities.

Ways to increase glide or soar distance include tilting the body to suit different angles of attack and moving wings forward or backward. These actions provide streamlining and move the center of gravity of the body. Gliding and soaring animals make turns by giving one wing a higher angle of attack than the other. Furthermore, gliding is usually done with legs retracted, to increase streamlining. The legs are lowered like the landing gear of airplanes when a braking effect is required. Clearly, locomotion in the air is even more difficult than swimming, involving much more complex interactions of the muscles and the skeleton.

Power, needed for most sustained flight, is obtained when flying animals flap their wings. There are two main animal flight types, high-speed flight and hovering flight. In the high-speed flight of birds, bats, and insects, the body moves forward at the same speed as the wings. The wings beat up and down as the animal moves forward through the air. Each down stroke produces lift and propels the flying animal forward and supports it in the air. The angle of attack of the upstroke is increased, so as to produce very little lift. This is because lift, acting upward at right angles to the wing's path, would slow high-speed flight.

In hovering flight, the body is stationary and the wings move very quickly, as when hummingbirds feed. Animals use two hovering techniques. Most often, their wings are kept horizontal and beat straight backward and straight forward. They turn upside down for each backstroke, adjusting the angle of attack so lift is obtained. The hum of hummingbirds is due to the frequencies with which their wings beat (twenty-five to fifty-five cycles per second). Insects buzz, whine, or drone, according to the sound produced by the higher frequencies at which their wings beat. In some cases, as in pigeons, hovering is accomplished when the wings clap together at the end of an upstroke. The clap enhances airflow into the space formed as they separate and so enhances lift. Initial wing-clap hovering in pigeons causes the sound first made when a flock flies away together.

LUNGFISH

Type of animal science: Classification
Fields of study: Anatomy, evolutionary science, paleontology, systematics (taxonomy)

Lungfish are freshwater members of the subclass Sarcopterygii, the fleshy- or lobed-finned fishes. As their name indicates, lungfish have lungs evolved from the swim bladder and can breathe air. Because they are among the fishes most closely related to the tetrapods, they play a crucial if controversial role in the study of vertebrate evolution.

Principal Terms

CONTINENTAL DRIFT: theory that the continents have moved slowly apart from an early landmass, explaining why many species appear to be closely related while separated by wide expanses of ocean

ESTIVATION: similar to hibernation; period of reduced activity or dormancy triggered by dry and/or hot environmental conditions

METAMORPHOSIS: pronounced developmental change in form or structure of an animal after birth or hatching, as in the transformation of tadpoles into frogs

SWIM BLADDER (AIR BLADDER): an internal organ evolved from the gut that allows a fish to regulate its vertical position in the water column (maintain its balance)

TETRAPODS: four-legged vertebrates (amphibians, reptiles, birds, and mammals)

Lungfish fossils first appear at the beginning of the Devonian period, about 400 million years ago. Once distributed around the world, lungfish now occur in only three areas (South America, Africa, and Australia) that were once adjacent but have since separated due to continental drift. South American and African lungfish are more closely related to one another. They have reduced gills and two lungs and are true air breathers, while Australian lungfish have one lung and rely mostly upon their gills for respiration, gulping air at the water surface to breathe only when dissolved oxygen is in short supply.

African and South American Lungfish

There are two related families in this order. The African family, Protopteridae, has one genus (*Protopterus*) and four species (*P. annectens*, *P. aethiopicus*, *P. dolloi*, and *P. amphibius*). They live in the rivers, lakes, and swamps of East and Central Africa and grow to 2 meters (6.5 feet) in length. The South American family, Lepidosirenidae, has only one species, *Lepidosiren paradoxa*. It lives in swampy areas of the Amazon and Paraná river basins and in the swamps of the Chaco region and grows to 1.2 meters (4 feet) in length.

During spawning season, males dig holes for the eggs and guard both eggs and young after they hatch. The South American male develops branched, gill-like structures on his pelvic fins that may supply extra oxygen to himself as he incubates and to his offspring. Juveniles hatch with adhering organs to attach to plants. They have external gills like salamander young and undergo metamorphosis. Adults live on crustaceans, mollusks, and small fishes. They survive the dry season by resting quietly in moist burrows dug in the mud. If it becomes too arid, they seal their burrows with mud, secrete a protective covering of mucus, and estivate, sometimes for several months. During estivation, metabolism slows down to conserve energy and air. Once the rainy season begins, water enters the burrow and awakens the estivating fish.

Australian Lungfish

The Australian lungfish was first discovered in 1870. This lungfish closely resembles fossil lungfishes except that its skull contains fewer, larger bones. It has remained unchanged for 100 million years or more, longer than any other vertebrate known. There is now only one living species of this order, *Neoceratodus forsteri*, and it occurs naturally in only two locations, the Burnett and Mary rivers in Queensland, Australia, although it is being introduced into other rivers in an effort to ensure its survival. During the summer, the rivers dry up, and the lungfish survive in small pools. They cannot estivate.

Spawning takes place after the rainy season starts. The eggs are laid in masses of fifty to one hundred on aquatic plants. The young breathe through the gills and skin. They do not have adhering organs or external gills and do not undergo metamorphosis. They develop pectoral fins at about fourteen days and pelvic fins at about ten weeks, gradually assuming the adult shape. They feed on algae, but adults feed on small fishes, mollusks, crustaceans, insect larvae, and some plants and grow to a size of about 1.8 meters (6 feet) and forty-five kilograms (one hundred pounds). They have broad, flat heads with the mouth underneath, small eyes, and pointed tails. The body is olive green or brown above and pinkish below.

Lungfish Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Superclass: Gnathostomata
Class: Osteichthyes
Subclass: Sarcopterygii
Order: Dipnomorpha or Dipnoi
Families: Lepidosirenidae (African and South American lungfish); Dipnorhynchidae, Dipteridae, Phaneropleuridae, Ctenodontidae, Conchopomidae, Sagenodontidae, Ceratodiae (Australian lungfish)

Geographical location: Africa, Australia, and South America

Habitat: Freshwater only (rivers, lakes, swamps, and marshes)

Gestational period: Australian lungfish, twenty-one to thirty days; African and South American lungfish, eleven to fifteen days

Life span: Unknown; larger fish may live to be many years old

Special anatomy: Elongated bodies, continuous rear fins composed of connected dorsal, caudal, and anal fins; Australian lungfish—laterally compressed body, large scales, two pairs of flipperlike pectoral and pelvic fins, one lung; African and South American lungfish—eel-like body with small scales, two pairs of long, thin pectoral and pelvic fins, paired lungs

LUNGS, GILLS, AND TRACHEAS

Type of animal science: Anatomy
Fields of study: Anatomy, histology

Gills, tracheas, and lungs are respiratory organs that are the primary sites of gas exchange in certain groups of animals. Gills are present in water-breathing animals, and tracheas and lungs are found in animals that breathe air. The structure and design of these organs are related to the particular manner of their function.

Principal Terms

BRONCHUS (pl. BRONCHI): an individual tube that is part of a lung and leads to one of the smaller lung parts

DIFFUSION: the passive movement of molecules from an area of high concentration (or pressure) to an area of lower concentration, often across a distance or a barrier

EPITHELIUM: a thin membrane that lines or coats a surface; in respiratory organs, the layer of cells that covers or lines the surface is called the respiratory epithelium

GILL: an extension or outpocketing of the body wall of an animal that creates a limblike structure, much as the fingers of a glove extend from the palm; gills are found almost exclusively in animals that breathe water

LAMELLA (pl. LAMELLAE): lamella means "platelike," and an individual lamella can be any one of several structures in the context of gas-exchange organs; these are usually found in gills

LUNG: a concave inpocketing of the body wall of an animal (in contrast to a gill); lungs occur in air-breathing animals

TRACHEA (pl. TRACHEAS): a tubular inpocketing of the body found mostly in insects and the spiders (arachnids), both of which are air breathers

The anatomy of a respiratory organ—gills, tracheas, or lungs—determines the way in which the organ functions. The design of the organ is specifically related to the way in which the animal functions in the world. Design refers to whether the structure is internal or external, large or small, and concerns some aspects of how it works. In order to understand the function of most organs and organ systems, it is necessary to know the structure.

The structure, or anatomy, can be considered from several different levels of organization. Gross structure is the size, shape, and position of the whole organ within the animal. Fine structure, on the other hand, refers to the microscopic level of organization. The microscopic structure includes the type and thickness of cells, the number of cells, and a description of the cell surface.

Common Features of Respiratory Organs

There are a few common features among gills, tracheas, and lungs in terms of both the gross structure and the fine structure. All three are organs of gas exchange and are therefore designed to permit oxygen and carbon dioxide gas to diffuse passively across this specific part of the body wall. Because one of the factors that directly affects diffusion is the total surface area, respiratory surfaces are greatly increased in order to maximize the movement of gas. Thus, the largest part of the total surface of an animal is the respiratory surface, no matter whether it is a lung, gill, or trachea. All three types of respiratory organs have openings to permit air or water to flow in (and out), tubes for conducting air or water to the exchange surface, the exchange surface itself, and the necessary support to hold the surface in place. The exceptions are those animals that have external gills with no enclosing cover.

The commonality of gas exchange function also imparts similar features to the microscopic level of structure. The epithelia of all three types of organs are thin and made of cells that are individually thin, providing less of a barrier to gas movement (although there is an exception to this in gill structure).

Gills

Gills are the most diverse and varied of all respiratory organs. Gills are found in aquatic animals, both vertebrate (animals with internal skeletons) and invertebrate (animals with external skeletons or no hard skeleton). With few exceptions, all animals with gills live in and breathe water, even if the volume of water is small and only one life stage of the animal breathes water. Most people are familiar with several types of animals that breathe water and use gills: fish, crabs, lobster, shrimp, crayfish, clams, aquatic insects, many worms (but not all), and numerous other animals. The form and function of gills have been variously modified in different animals through the process of natural selection.

The gills of many marine worms and of the marine sea hare and sea slug (both are related to snails) are thin, blind-ending tubules representing extensions of the body wall that form an elaborate treelike structure. For the most part, these are not complicated either in the pattern of blood flowing through them on the inside or in the way water is passed over them on the outside. Worms and sea slugs usually extend the gills into the water above and let the water's own movement bring the oxygen-filled water to the gills. Sea hares, however, cover the gills with a flap of skin, an extension of the body wall, and pump water over the gills by the beating action of numerous tiny cilia.

The gills of crabs are formed from a central structure, called an arch, and platelike extensions of the gill arch, called lamellae. Each lamella has a thin layer of epithelium, but because it is formed as an extension of the outside layer of the body, the epithelium is covered with a very thin layer of shell, called chitin. This is true of crabs, lobster, shrimp, and all the crustaceans. Nevertheless, the layer still permits the exchange of gases between the blood on the inside and water on the outside.

Each lamella is exposed to the water on both sides and has numerous supporting cells on the inside that keep the two sides apart so that blood may flow between. These support cells are called pillar cells, and if an observer could look down between the sides, the inside would look something like a forest. Blood comes into each lamella from a single channel, an artery, located at the top, and flows out through a vein located at the bottom of the lamella.

Not all lamella are alike even in the same crab, much less in crabs from habitats as different as the deep ocean and a tropical forest. One of the major differences is that some epithelia are specialized to transport salts actively across the gill in much the same way as the kidney does in a mammal. These gill lamella are thicker, with cells that are modified to transport sodium and chloride. Blue crabs, land crabs, and crayfish (which have podia instead of lamellae) are examples of animals with this type of specialization.

Not all crustaceans have gills that are lamellar in form; the crayfish and lobster have fingerlike projections of the gill arch. These projections are called podia and are more like the blind-ending tubules found in some worms than they are like the lamellae of crabs. The inside of the podia is divided, however, so that blood flows to the tip of the tube on one side and back to the animal on the other side of the podia.

Fish gills are not unlike those of a crab in many ways, but those of fish are more complex. Both are composed of flattened extensions of a trunklike support structure that contains the blood vessels. Gills of most teleost fish (bony fish, such as perch and bass) have further, or secondary, extensions from these, which are oriented perpendicular to the main lamella. The result is that the primary lamellae form a flat surface in a horizontal plane, and the secondary lamellae form the largest surface area, extending in a vertical plane. Some primitive fish, or those with adaptations to special conditions, have reduced secondary lamellae.

Some of the major differences between vertebrate and invertebrate gills are that fish gills are thinner, so that the layer separating the blood from the water is not as thick in fish. Fish-gill epithelia are usually about 20 percent as thick as those of the invertebrates described. Many fish have two different types of lamellae on the gill arch: primary and secondary lamellae. Many fish gills also contain specialized cells to transport salts across the border between the animal and the water, as happens in blue crabs.

Tracheas

Tracheas, found in insects, spiders, and related invertebrates, are long, thin tubes that extend from the outside of an animal to the inside, similar to the way a trachea leads to the lung in humans. The tracheal system, however, is made up entirely of branching tubules, each somewhat smaller than the one leading to it. The major tubes are called tracheas and the smaller ones are tracheoles; the smallest ones are as thin as hairs and reach within a very short distance of the cells inside the body. The outside opening to each trachea is controlled by a special structure, a spiracle, that can open and close the trachea.

Lungs

Lungs are actually the simplest type of respiratory system to describe in terms of animal type, distribution, and variations on the common form. Lungs are found only in air-breathing vertebrates, are always internalized, and have a single opening through which air flows both in and out. A single tube, the trachea, is the conducting passage for inspired and expired air. This tube branches into two smaller tubes, the bronchi, that lead to each of the individual sides, or lobes, of the lung. Tracheas and bronchi are usually, if not always, reinforced with cartilage rings for structural support to prevent collapse. Thus, animals with lungs actually have two, one on each side.

Tracheas and bronchi are not designed for gas exchange but are conducting tubes that also serve to "condition" the air before it reaches the lungs. Both tubes are lined with special cells that have hairlike projections called cilia on the surface. The cilia continually sweep small particles (such as dust) toward the outside to protect the lungs. Other cells in tracheas and bronchi secrete mucus to keep the surface moist and maintain high humidity so that air will be 100 percent humid when it reaches the alveoli.

At the end of the tubes of the lungs are the sac structures that form the gas-exchange surface. These very thin structures are the alveoli and are the site of gas movement into and out of the body. On the inside of each alveolus is an entire network of tiny blood vessels, capillaries, that supply the blood which is the source of the carbon dioxide that is exhaled and is the sink for the oxygen taken up at the alveoli.

Studying Respiratory Organs

The anatomy of gas-exchange organs is studied in whole living animals, in preserved specimens, and in sections prepared for microscopic examination. Both light microscopy and electron microscopy are used to study these organs. Light microscopy is simply the use of a microscope that requires standard lighting with the type of lens systems that have been used for decades; there are also some much more sophisticated systems that use specialized optics and lighting techniques. Electron microscopy uses beams of electrons to enable magnification of more than 100,000 times and the visualization of cells and their component parts. In some cases, miniaturized laser optics are used to examine the relatively large organs, such as lungs, while they are functioning. This application is often used in health-related studies and diagnosis of disease.

Studying the gross morphology of gills, tracheas, and lungs involves the dissection of a whole animal, either preserved or freshly deceased. Each option offers advantages, and both methods will be employed in a complete examination. Part of the dissection will be to determine qualitative features such as attachment points, spatial relations, and general appearance. A thorough study of the anatomy of an organ also includes measurements of features such as surface areas, number of parts, distances, and volumes. These are the quantitative measures, and they are applicable to all the organs. These numerical values are absolutely necessary in order to quantify the functions.

In the case of small animals, including shrews, insects, and fish the size of minnows, a dissection of the whole animal may have to be carried out with additional magnification, using a microscope designed for such work. These microscopes are called dissection microscopes and have enough distance between the lens and the object to allow dissection with small instruments by hand. In a few cases, the material is so small that microdissecting techniques developed by neurobiologists must be used. Traditional histological examination of respiratory organs has also revealed much about the design and nature of these structures. Histological examination (examining tissue structure, usually under a microscope) reveals the thickness of the epithelium, the number of layers, and some information about the nature of the material in the layers.

One of the purposes for studying the anatomy of all respiratory structures, and lungs in particular, is to improve medical applications. In veterinary medicine, knowledge of the general structure of lungs is crucial in treating diseased lungs and other respiratory problems. The use of animals in research has always been a controversial topic, but if such research is to be conducted properly, then accurate knowledge of the anatomy of the experimental animals is necessary. In this way, the animals can be kept healthy and monitored properly so that the intended purpose of the research may be realized.

Comparing Respiratory Structures

Evolutionary and taxonomic relationships are revealed in comparisons of respiratory structures in some groups of animals. Other relationships are evident in making comparisons between very different groups. There are only subtle differences in lung structure among the air-breathing vertebrates with lungs: amphibians, reptiles, and mammals. These differences occur more in the gross structure than at the cellular level, indicating how evolutionary pressures create successful adaptations.

The differences in the gill structures of crabs, worms, and fish from various habitats give valuable insight into evolutionary changes. Land crabs and air-breathing fish have fewer gills, fewer lamellae with thicker surfaces, and special structures to hold them in position. These latter are needed in air because without the support offered by water the gill lamellae would otherwise adhere to one another and not function. Similarly, some fish that live in water that contains too little oxygen must depend on air breathing and show these same adaptations.

One of the most widely studied aspects of comparing respiratory structures in different animals is the evolutionary transition from breathing water to breathing air. The transition from water to land has always interested scientists, and this level of anatomy is part of that interest. Biologists have examined the differences between air and water breathers in many groups of animals generally, and in groups that have both, such as the crabs and the amphibians, in particular. The features of interest include the surface area, thickness, position in the body, and pattern of circulation.

Few groups of animals display such a clear example of the evolution of structure and function in the tracheal system as do insects. Insects have a respiratory system, the tracheas, that reaches nearly to the cells themselves, bringing them oxygen-laden air and removing the carbon dioxide produced by the cells. It would seem, then, that there would be little need for a circulatory system to serve that function, and indeed there is but a rudimentary one in insects.

Anatomy of respiratory structures is also studied in relation to other functions and organ systems. The circulatory system provides the blood that exchanges gases with the water or air on the outside of the animal. Thus, the anatomy of the blood vessels is an important part of the anatomy. Similarly, the control of the flow of blood to the lungs or gills is critical for respiratory system function.

The fine structure of several types of respiratory systems, but primarily gills, is part of the study of other, nonrespiratory functions. The gills of some aquatic animals play an important role in regulating the animal's salt balance. In these animals, the fine structure of the gills shows where this process takes place and what special modifications are needed.

Bibliography

Barnes, Robert D. *Invertebrate Zoology*. 6th ed. Philadelphia: Saunders College Publishing, 1994. This invertebrate zoology text complements the Romer and Parsons vertebrate zoology text. Barnes's book for advanced high school or college level is considered by many to be the best, and it contains excellent illustrations and a rather complete bibliography. The reader must get the information for each group from the appropriate chapter, but the index is sufficiently detailed so that this is not a problem. Most of the phyla have gills or trachea, so the reader must look carefully.

Comroe, J. H. "The Lung." *Scientific American* 214 (February, 1966): 56-68. This magazine only features a subject once, so the story on the lung is dated, but it still gives an accurate description of basic lung anatomy and includes information on function.

Klystra, J. A. "Experiments in Water Breathing." *Scientific American* 219 (August, 1968): 66-74. Somewhat dated, but the illustrations effectively compare lungs and gills; there are accompanying explanations of the function of each.

Raven, Peter H., and George B. Johnson. *Biology*. 6th ed. St. Louis: Times Mirror/Mosby, 2001. A text for college freshmen; includes much more than only the anatomy of the three respiratory systems. It does a better than average job of explaining gills, tracheas, and lung structure, and it includes some material on function, evolution, and related matters. The illustrations are clear, and there is a glossary.

Romer, Alfred S., and Thomas S. Parsons. *The Vertebrate Body*. 6th ed. Philadelphia: W. B. Saunders, 1986. This is one of the best texts dealing with comparative anatomy of vertebrates. Written for college students, this is certainly the most comparative survey and gives an excellent evolutionary perspective. The figures are good; the glossary is extensive but succinct.

Storer, Tracy I., Robert L. Usinger, Robert C. Stebbins, and James W. Nybakken. *General Zoology*. New York: McGraw-Hill, 1979. The authors are four of the finest zoologists of the past several decades, each with his own specialization to bring to the book. Every part is written by a specialist in the field, a feature of which few general textbooks can boast. Unlike most texts, the material is covered by function and by animal group. The respiratory structures are described in the section on that topic and for each group as presented. College level with illustrations.

MAMMALIAN SOCIAL SYSTEMS

Type of animal science: Behavior
Fields of study: Anthropology, ecology, ethology, zoology

Social organization in mammals ranges from solitary species, which come together only to breed, to large and intricately organized societies. Understanding the social systems of mammals is essential for effective conservation of species.

Principal Terms

BROWSER: an organism that feeds primarily on leaves and twigs of trees and shrubs rather than on grasses

CARNIVORE: a member of the meat-eating order Carnivora, which includes dogs, cats, weasels, bears, and their relatives

EUSOCIAL: a social system with a single breeding female; other members of the colony are organized into specialized classes (exemplified by bees, ants, and termites)

GRAZER: an organism that feeds primarily on grasses

PRIMATES: members of the order Primates—monkeys, apes, and their relatives

RODENT: a member of the order Rodentia—squirrels, rats, mice, and their relatives

SAVANNA: a grassland with scattered trees; some ecologists restrict the term to tropical regions

TERRITORY: an area that an animal defends against other members of the species and that often contains food, shelter, and other requirements for the individual or group

UNGULATE: a hoofed mammal from the order Artiodactyla (pigs, cattle, antelope, and their relatives) or from the order Perissodactyla (horses, rhinoceroses, tapirs, and their relatives)

All levels of social organization occur in mammals. There are solitary species, such as the mountain lion (*Felis concolor*), in which the male and female adults come together only to mate, and the female remains with her young only until they are capable of living independently. At the other numerical extreme are some of the hoofed mammals, which form herds of thousands of individuals. Other extremes might be considered in terms of specialization for social life. The most socially specialized mammal is probably the naked mole rat (*Heterocephalus glaber*) of Africa, which has a eusocial colony structure similar to that of ants, bees, and termites. Between these extremes, there are many variations. No current theory accounts for the diversity of mammalian social systems, but two broad generalizations are consistently employed to explain mammalian species' social organization. These are the environmental context in which the species exists and the mammalian mode of reproduction.

More than any other group of animals, mammals are required to form groups for at least part of their lives. Although in all sexually reproducing animals the sexes must come together to mate, mammals have an additional required association between mother and young: All species of mammal feed their young with milk from the mother's mammary glands. This group, a female and her young, is the basis for the development of mammalian social groups. In some species, the social group includes several females and their young and may involve one or more males as well.

The particular social organization adopted by a mammalian species is a response to the environmental conditions under which the species lives. The species' food supply and the distribution of that food supply are often the predominant determinants, but predators on the species are also important in determining the form of its social organization. The best way to see the effects of these factors on mammalian social structure is by example.

Primate Social Organization

The primates are the most social group of mammals. Monkeys demonstrate the importance of food supply and its distribution in determining social structure. The olive baboon (*Papio anubis*) occupies savannas, where it exists in large groups of several adult males, several adult females, and their young. Finding fifty or more animals in a group is not uncommon. Individual males do not guard or try to control specific females except when the females are sexually receptive. The group's food supply is in scattered patches, but each patch contains an abundance of food. The advantage of having many individuals searching for the scattered food is obvious: If any member finds a food-rich patch, there is plenty for all.

Predation probably also plays a role in the olive baboon's social organization. The savannas they roam have many predators and few refuges for escape. A large group is one defense against predators if hiding or climbing out of reach is not practical. Having many observers increases the chance of early detection, giving the prey time to elude

Primates, such as these chacma baboons, are the most social of mammal orders. Social structures offer increased safety from predators, efficient use of food resources, and a wider range of learning opportunities for the young. (Corbis) the predator. A large group can also mount a more effective defense against a predator. Large groups of baboons use both of these tactics.

The hamadryas baboon (*Papio hamadryas*), on the other hand, lives in deserts in which the food supply is not only scattered but also often found in small patches. The hamadryas baboon's social structure contrasts with that of the olive baboon, perhaps because the small patches do not supply enough food to support large groups. A single adult male, one or a few adult females, and their young make up the basic group of fewer than twenty individuals. Several of these family groups travel together under certain conditions, forming a band of up to sixty animals. Within the band, however, the family groups remain intact. The male of each group herds his females, punishing them if they do not follow him. The bands are probably formed in defense against predators. They break up into family units if predators are absent. At night, hamadryas baboons sleep on cliffs, where they are less accessible to predators. Because suitable cliffs are limited, many family groups gather at these sites. Hundreds of animals may be in the sleeping troop, probably affording further protection against predators.

Though there are exceptions, forest primates consistently live in smaller groups. In many species, fewer than twenty individuals make up the social group at all times. These consist of one or a few mature males, one or a few mature females, and their offspring. The groups are more evenly distributed throughout their habitat than are groups of savanna or desert primates. In forests, the food supply is more abundant and more evenly distributed. Escape from predators is also more readily accomplished—by climbing trees or hiding in the dense cover. Under these conditions, the advantages of large groups are minimal and their disadvantages become apparent. For example, in small groups the competition for mates and food is less.

Ungulate Social Organization

The ungulates have all levels of social organization. African antelope demonstrate social organizations that, in some ways, parallel those of the primates. Forest antelope such as the dik-dik (*Madoqua*) and duiker (*Cephalophus*) are solitary or form small family groups, and they are evenly spaced through their environment. Many hold permanent territories containing the needs of the individual or group. They escape predators by hiding and are browsers, feeding on the leaves and twigs of trees.

Many grassland and savanna antelope, such as wildebeest (*Connochaetes*), on the other hand, occur in large herds. They outrun or present a group defense to predators and are grazers, eating the abundant grasses of their habitat. In many cases, they are also migratory, following the rains about the grasslands to find sufficient food. The social unit is a group of related females and their young. Males leave the group of females and young as they mature. They join a bachelor herd until fully mature, at which time they become solitary, and some establish territories. The large migratory herds are composed of many female/young groups, bachelor herds, and mature males. The social units are maintained in the herd. Though it may seem strange to speak of solitary males in a herd of thousands, that is their social condition. The male territories are permanent in areas that have a reliable food supply year-round, but they cannot be in regions in which the species is migratory. Under these conditions, the males set up temporary breeding territories wherever the herd is located during the breeding season.

There are parallels with primate social patterns. Large groups are formed in grasslands, and these roam widely in search of suitable food. The groups are effective as protection against predators in habitats with few hiding places. Smaller groups are found in forests, where food is more evenly dispersed and places to hide from predators are more readily found.

Rodent Social Organization

Rodents also have all kinds of social organizations. The best known, and one of the most complex, is the social system of the black-tailed prairie dog (*Cynomys ludovicianus*). The coterie is the family unit in this case, and it consists of an adult male, several adult females, and their young. Members maintain a group territory defended against members of other coteries. Coterie members maintain and share a burrow system. Elaborate greeting rituals have developed to allow the prairie dogs of a coterie to recognize one another. Hundreds of these coteries occur together in a town. The members of these towns keep the vegetation clipped—as a result, predators can be seen from a distance. Prairie dogs warn one another with a "bark" when they observe a predator, and the burrow system affords a refuge from most predators.

The only vertebrate known to be eusocial is the naked mole rat. It occurs in hot, dry regions of Africa. The colony has a single reproductive female, a group of workers, and a group of males whose only function is to breed with the reproductive female. The workers cooperate in an energetically efficient burrowing chain when enlarging the burrow system. In this way, they are able to extend the burrow system quickly during the brief wet season. Digging is very difficult at other times of the year. The entire social system is thought to be an adaptation to a harsh environment and a sparse food supply.

Carnivore Social Organization

Most carnivores are not particularly social, but some do have elaborate social organizations. Many of these are based on the efficiency of group hunting in the pursuit of large prey or on the ability of a group to defend a large food supply from scavengers. The gray wolf (*Canis lupus*) and African hunting dog (*Lycaon pictus*) are examples. In both cases, the social group, or pack, consists of a male and female pair and their offspring of several years. There are exceptions, solitary carnivores and carnivores that form temporary family units during the breeding season, such as the red fox (*Vulpes vulpes*), which hunt prey smaller than themselves. The coyote (*Canis latrans*) can switch social systems to use the food available most efficiently. It forms packs similar to those of the gray wolf when its main prey is large or when it can scavenge large animals and is solitary when the primary available prey is small.

These examples and many others show that the social groups of mammals are based on the family group. The particular social organization employed by a species is determined by the ecological situation in which it occurs. The specific aspects of the environment that seem to be most important include food abundance, food distribution, food type, and protection from predators.

Fieldwork and Laboratory Studies

Observation has been a very important method of studying mammal societies. One of the reasons that primate and ungulate societies are so well known is that they are large and active during the day, and so are easily observable. The observer must take great pains to be inconspicuous or, in some cases, to become a part of the subject's environment. Small mammals (and sometimes larger mammals) have been kept in enclosures and observed to learn more about their social lives. The observer maps movements, records activities and interactions, and analyzes the data that result.

Simple observation is enhanced by manipulating the subjects in various ways. Individual animals can be marked, or in some cases they can be identified by natural color patterns, scars, or other marks. These marked individuals can be followed, and their behavior and interactions with other individuals observed. Radios and radioactive tracer elements are sometimes implanted in individuals, and these individuals are followed in the field. Much can be learned about a species' social behavior by following the locations of such tagged animals. In addition, they are more readily locatable for direct observation.

Small mammal species that are not readily observable are trapped live, marked, released, and recaptured. Mutually exclusive use of certain areas, areas used in common, and patterns of multiple captures in individual traps are some types of information from trapping that can be interpreted in terms of social behavior. Experiments are sometimes carried out in the natural context. A group or a specific individual is presented with an artificial situation, and any reactions to it are recorded, often on film or videotape.

Laboratory studies are also used to supplement the field observations. Psychological and physiological capabilities of organisms can best be studied in the controlled confines of a laboratory experiment. These data, however, must always be put back in the context of the field observations to make a meaningful contribution to the understanding of the species' social behavior.

Computer simulations and mathematical models have been used to explore the possible reactions of social systems to various environmental pressures. As with laboratory results, it is important to test predictions generated in these ways against the social system in nature before assuming their validity. Comparative studies of all the above types are of great importance. Related species, or different populations of the same species, that occur in different regions are studied and compared; these studies are tantamount to reading the data from a natural experiment.

Social Organization and Food

Mammalian societies are always organized around one or more females and their offspring. Males may also be part of the group, or they may form separate groups. The size and structure of the group are determined by the ecological setting in which it evolves. The particular ecological factors that seem to be of greatest importance in this determination are food supply, the distribution of the food, and predation (including the hiding places and escape routes available in the habitat).

Large groups occur when food is scattered in a patchy distribution. These groups are largest when the patches contain abundant food. Many organisms are more likely to find the scattered patches than is a single individual. As long as the patches have enough food for all members of the group, it is to each member's advantage to search with the group. On the other hand, if food is evenly dispersed in small units throughout the environment, the advantage of a group search is lost. Each individual will be better off searching for itself, and some strategy involving a very small social group or even solitary existence would be advantageous.

A somewhat similar argument follows for predators. If large prey are taken, a group of predators should be able to subdue the prey and protect its remains from scavengers more efficiently. If small prey are taken, solitary predators have the advantage, since the prey is easily dispatched and the predator will have it to itself. Many other factors are involved in determining the final form of a species' social organization, but the family unit and environmental context are fundamental in determination of all mammalian social structures.

Conservation of the mammal species that still exist on the earth requires knowledge of their social organization. Understanding that mammalian social organizations are responses to the environmental context in which they have evolved emphasizes the need to conserve entire ecosystems, not only the individual species that exist within them.

MAMMALS

Type of animal science: Classification
Fields of study: Anatomy, systematics (taxonomy), zoology

Mammals are four-legged animals with backbones; they have a number of unique characteristics, including hair, constant warm body temperatures, mammary glands, and specialized teeth that are replaced only once. Mammals originated more than two hundred million years ago from mammal-like reptiles, and they eventually evolved into tree-dwelling, flying, burrowing, and aquatic forms.

Principal Terms

GENUS (pl. GENERA): a group of closely related species; for example, *Felis* is the genus of cats, and it includes the species *Felis catus* (the domestic cat) and *Felis couguar* (the cougar or mountain lion)

MAMMARY GLANDS: the milk glands that female mammals use to nurse their young

MARSUPIAL: a mammal that gives birth to a premature embryo and then lets it finish its development in a pouch

MONOTREME: a primitive mammal, such as the platypus and spiny anteater, which lays eggs and has other archaic features

ORDER: a group of closely related genera; in mammals, orders are the well-recognized major groups, such as the rodents, bats, whales, and carnivores

PLACENTALS: mammals that carry the embryo in the mother until it is born in a well-developed state; it is nourished in the womb by a membrane (the placenta)

VERTEBRATE: an animal with a backbone; this includes fish, amphibians, reptiles, birds, and mammals

Mammals are a group of vertebrates (animals with backbones) that have been the dominant animals on land and in the sea since the dinosaurs died 65 million years ago. Indeed, this period of time, the Cenozoic era, is often called "the age of mammals." About 4,170 species of mammals are alive today, but at least five times that many are now extinct. About 1,010 genera of mammals are living, but according to a 1945 tabulation, there were an additional two thousand extinct genera, and that number has greatly increased since 1945 as taxonomical research has progressed. Mammals have been very successful in occupying a great variety of terrestrial and aquatic ecological niches. These mammals include terrestrial meat-eaters and plant-eaters, tree-dwellers, burrowing forms, and aquatic forms. The largest mammals today are elephants, but the extinct hornless rhinoceros Paraceratherium was much larger, reaching six meters at the shoulder and weighing about twenty thousand kilograms. The largest mammals, however, are whales, which can weigh up to 150,000 kilograms in the case of the blue whale. That is larger than even the largest dinosaurs.

The Features of Mammals

Living mammals are easily distinguished from all other vertebrates by a number of unique evolutionary specializations. Unlike other vertebrates, mammals all have hair, have mammary glands to nurse their young, and bear live young (except for the most primitive egg-laying mammals, the platypus and the spiny anteater). Mammals maintain a constant, relatively high body temperature. They have a four-chambered heart and a very efficient digestive and respiratory system. Mammals grow rapidly as juveniles and then stop growing when they reach adult size, unlike other animals, which grow continuously throughout their lives.

In addition to these features, mammals have a number of features in their skeletons that make them easy to distinguish from birds or reptiles. Their limbs are designed for efficient walking or running and so are aligned straight under the body (rather than sprawling, as in reptiles). Their ribs are locked into a solid rib cage, so they do not use rib muscles to pump their lungs; instead, they have a diaphragm in the chest cavity to aid in breathing. Their skulls are highly modified, with fewer bones than in birds or reptiles. Some of these modifications include a single nasal opening, a bony palate that separates the breathing passages from the mouth, a large opening on the side of the skull for jaw muscles, and a pair of joints around the spinal column to hold up the head. They have only a single bone in their jaw, and the bones that form extra jaw bones in the reptile have been modified to form the three sound-conducting bones of the ear: the hammer, anvil, and stirrup. Finally, unlike the simple, peglike teeth of reptiles, mammal teeth are highly specialized: There are nipping incisors in front, big stabbing canines for grasping prey, and grinding teeth (molars and premolars) in the back of the jaw for processing food. These teeth are replaced only once (baby teeth are replaced by adult teeth), unlike the continuous replacement found in other animals.

Monotreme and Marsupial Mammals

Living mammals can be divided into three major groups, based on their mode of reproduction. These are the monotremes (egg-laying mammals), marsupials (pouched mammals), and placentals (mammals that carry their young to full term). The monotremes include the platypus and the spiny anteater of Australia and New Guinea. They lay a leathery egg much like that of reptiles, although the young is born after ten days and is then carried in a pouch. The females have mammary glands but no nipples, so the young must lap up the milk as it oozes from their skin. Monotremes have a number of other primitive reptilian features, such as a variable body temperature and a venomous claw in male platypuses. The platypus has a flexible, ducklike "bill," webbed feet, and a beaverlike tail, which it uses to swim in streams and catch freshwater insects and crayfish. The spiny anteater is covered with thick spines and lives on ants and termites, which it catches with its long, sticky tongue.

The more advanced mammals bear live young. One group, the pouched mammals, or marsupials, give birth to a premature, partially developed embryo. The embryo then climbs into the mother's pouch and fastens onto a nipple, where it finishes its development. Although this sequence makes the young more vulnerable than a placental embryo, which is always carried in the mother, there are advantages. If conditions are bad, a marsupial mother can abort the baby without losing her own life and survive to breed again. A female marsupial can also carry one baby in the pouch and become pregnant with another, allowing a higher rate of reproduction.

The most familiar marsupials are the kangaroo, koala, Tasmanian devil, and opossum, although there have been many other types of marsupials in the past, and many are still alive today in Australia and South America. Where marsupials lived in isolation with no competition from placental mammals, they evolved into many different body forms, which converge on the body forms of their ecological equivalents in the placentals. In Australia today, there are marsupial equivalents of cats, wolves, mice, flying squirrels, rabbits, moles, tapirs, and monkeys. Among extinct marsupials of South America, there were the equivalents of lions and of saber-toothed cats. As similar as these animals look to their placental equivalents in their external body form, they are not related to true cats, wolves, or the rest, since they are all pouched mammals.

Placental Mammals

Unlike marsupials, placentals must carry the embryo in their womb through their full development. To allow this, the embryo is nourished by an extra membrane surrounding it in the womb. This membrane, the placenta, is shed when the baby is born and is part of the "afterbirth." This mode of

Mammals come in many shapes, colors, and sizes. (PhotoDisc)

reproduction makes the placental embryo less vulnerable than a marsupial, but it means that the mother is more vulnerable, since she must carry a larger embryo for a longer time.

After the extinction of the dinosaurs, about 65 million years ago, the earth was open for a new group of large animals to evolve and take over the vacant ecological niches. Placental mammals underwent a tremendous diversification, until they occupied many ecological niches, and some reached the size of sheep. Most, however, were no larger than a cat. The placentals soon diversified into the edentates (anteaters, sloths, armadillos, and their relatives) and the rest of the mammalian orders (groups of genera). Like marsupials, edentates had their greatest success in isolation in South America, although the armadillo is successfully spreading northward. Edentates have a very primitive womb and a slow, variable metabolism compared to other placentals. Although the name "edentate" means toothless, only the anteaters are actually toothless; sloths and armadillos have simple, peglike teeth. Anteaters and armadillos eat ants and termites, and sloths hang upside down from branches, slowly munching leaves.

The rest of the placental mammals have occupied a variety of niches. One group, the insectivores, includes the shrews, moles, and hedgehogs. All these animals are small in size and have sharp teeth for eating insects and worms. The smallest shrews are only three centimeters long and weigh only two grams. They must eat almost continuously in order to make up for their small body size and rapid heat loss. They are so active and aggressive that they will attack animals many times their size. Moles live exclusively underground; they are nearly blind and have well-developed digging claws. Hedgehogs are covered with thick spines and roll up in a ball when they are threatened.

Carnivores and Archontans

In addition to the insectivores, the primary mammalian predators are the carnivorans. They include the feliforms (cats, hyenas, and mongoose) and the caniforms (dogs, bears, seals, sea lions, walruses, pandas, raccoons, weasels, and their relatives). Carnivora (except the panda) all live by killing prey and eating the meat. For this purpose, they have sharp cutting and slicing teeth and enlarged front canine teeth for stabbing. Most have sharp claws, and cats have claws that are retractable. Some carnivora, such as bears, eat fruit, berries, insects, fish, and almost anything else that is available. The pinnipeds, another group of carnivorans related to the bears, have become secondarily aquatic. These include the seals, sea lions, and walruses. Their aquatic specializations include a streamlined body for swimming, with hands and feet developed into flippers.

Another group of placentals, the archontans, have taken to the trees and the air. These include the primates (lemurs, monkeys, apes, and humans), the bats, the elephant shrews, and the colugos, or “flying lemurs.” Primates developed front-facing eyes with binocular color vision and agile, grasping hands and feet (with nails rather than claws) for life in the trees. Most have long tails, and New World monkeys can grasp with their tails. Apes and humans, however, have lost their tails. Most primates eat fruit, leaves, or seeds, and they have complex social behavior and well-developed brains.

Bats, on the other hand, have developed a membrane between their fingers that allows them to become excellent fliers. Most bats catch insects in flight by means of their sonar, and they fly at night, sleeping in caves during the day. Fruit bats, however, are much bigger, living in trees and eating fruit during the day.

Glires and Ungulates

The most successful group of mammals is certainly the Glires, or rodents and rabbits. There are more than 1,700 species of rodents alone, or about 40 percent of the mammals, and in numbers and rate of reproduction, they also are far more abundant than any other group of mammals. Rodents (including rats, mice, hamsters, gophers, squirrels, chipmunks, beavers, porcupines, guinea pigs, chinchillas, capybaras, and hundreds of less familiar forms) have developed chisellike incisors (front teeth), which are used for gnawing. They have adapted to a tremendous variety of ecological niches, including sheep-sized browsers (capybaras), terrestrial fruit-, seed-, and insect-eaters, tree-dwellers, and a variety of burrowing forms (such as gophers, ground squirrels, prairie dogs, and mole rats). The rabbits, hares, and pikas form another group that is distantly related to the rodents. Like rodents, they have chisel-like gnawing incisors, but there are two pairs instead of the single pair found in rodents.

Most of the large, plant-eating mammals are ungulates, or hoofed mammals. These include the even-toed artiodactyls (pigs, hippos, camels, deer, antelope, goats, sheep, and cattle), the odd-toed perissodactyls (horses, rhinos, tapirs, hyraxes, and their extinct relatives), the tethytheres (elephants, manatees, and sea cows), and the whales, along with a number of extinct archaic groups. Most ungulates have developed hooves, or hard protection on their toes for better running, and many have elongate limbs for fast running. Since they are nearly all herbivorous, most ungulates have developed a complex stomach system to digest large quantities of low-quality, relatively indigestible plant material. Ungulates have also modified their teeth, so that they have larger grinding teeth, which grow almost continuously. That allows them to chew tough, gritty vegetation without becoming toothless. Whales, dolphins, and porpoises are completely aquatic, having lost their hind limbs and developed flippers for front feet. Although they do not look like other hoofed mammals, they had terrestrial ancestors that looked like large bears and were similar to the most primitive ungulates.

Field and Laboratory Studies

Mammalogists use a wide variety of techniques. Traditionally, most studies of the behavior of mammals require going into the wild and observing their ecology. These are the types of studies that are most familiar from nature programs on television. Individual mammals can be studied in detail; in addition, scientists can observe and film their behavior. Often, they are trapped, labeled with a radiocollar or some permanent marking, and freed to be followed or recaptured later. To learn more, however, scientists must collect specimens and study them in the laboratory. There, the anatomy of the specimen can be studied in detail, or the specimen can be kept alive and its behavior and physiology examined much better than in the wild. Mammalogists also have begun to study the details of the biochemistry and molecular biology of mammals. Such studies allow the analysis of the genetic diversity, the evolutionary relationships, and the detailed molecular basis for many of the properties of mammals that were poorly understood before.

MAMMOTHS

Type of animal science: Classification
Fields of study: Anatomy, genetics, paleontology, zoology

Mammoths were prehistoric herbivorous mammals that became extinct approximately 10,000 to 3,800 years ago.

Principal Terms

IVORY: a white or honey-colored, bony substance

PATHOGENS: bacterium or viruses which cause diseases

PERMAFROST: soil layer below the earth's surface which never thaws

PLEISTOCENE: epoch occurring from 1.7 million to 10,000 years ago

TUNDRA: vast, mostly treeless area coated by ice and snow

Mammoths lived during the Ice Ages of the Pleistocene epoch. The oldest recovered mammoth fossils, found in Africa, are four million years old. Mammoths migrated from Africa, and several species of varying sizes and appearances evolved on other continents. Some mammoths crossed the Bering land bridge. Most mammoths favored tundra habitats formed when Ice Age glaciers covered parts of the northern hemisphere.

Anatomy

Most mammoths were large mammals, standing 3.5 to 4.3 meters (12 to 14 feet) tall when measured from the ground to the top of their shoulders. They weighed an average of seven metric tons (eight tons). Other mammoths were dwarves that only stood 1.8 meters (6 feet) tall. These small mammoths lived on islands, including Siberia's Wrangel Island and California's Channel Islands.

Woolly mammoths grew long, thick brown fur over a short undercoat, which protected them in cold climates. Fat layers, which were 7.5 centimeters (3 inches) thick, underneath their skin and in their shoulder hump and prominent brow, insulated their bodies. Each mammoth had two ivory tusks, which extended from their upper jaw. Mammoths' tusks were as long as five meters (sixteen feet) and curved toward and crossed over their trunk. During their lifespan, they had a total of twenty-four molars, which they shed. Because of their cold habitat, mammoths' ears were small, to retain heat.

Life Cycle

Mammoths roamed in herds, sometimes covering great distances in their search for vegetation, such as sedge and Arctic sagebrush, to eat. They spent an average of twenty hours a day finding and eating food. Chewing plants smoothed their teeth. When frozen land inhibited plant growth, the mammoths' stored fat provided essential nutrients and vitamins necessary to live.

Mammoths acted protectively toward immature, elderly, and infirm herd members. Males often fought over females during breeding seasons. Gestation lasted twenty-two months. Females usually produced one calf. Mammoths were unique because their mammary glands were near their front legs, unlike other mammals. Young mammoths remained with their mothers for several years, gradually becoming independent. Mammoths reached maturity by the age of twelve years.

Because of their size, adult mammoths had few predators. They moved slowly, which made them more vulnerable. The saber-tooth tiger killed mammoths for their flesh, and prehistoric humans hunted mammoths for their meat, hides, bones, and tusks. Human hunters devised strategies to capture mammoths in traps that confined their legs. Prehistoric people used mammoth tusks and

Image Not Available

bones to build shelters. Many mammoths died when they fell into naturally occurring sinkholes or were mired by quicksand and tarpits. Sometimes, male mammoths' tusks became entangled while fighting, and they starved to death.

Although mammoths were abundant during the Ice Ages, they became extinct in the period between 13,000 and 2000 B.C.E. Paleontologists estimate that the last mammoths died circa 1800 B.C.E. Researchers hypothesize that mammoths' extinction occurred because they were unable to adapt to the altered environment, specifically the warmer climate and different edible plants that existed after the final Ice Age, or that humans hunted them into extinction. Evidence exists for both theories. Mammoths migrated north as glaciers began to recede. When the final Ice Age glaciers disappeared about 9500 B.C.E., many placental mammals became extinct. Fossils suggest that some mammoths survived on an isolated Siberian Arctic island until 1500 B.C.E.

Recovering Specimens

Humans have found mammoth fossils on land and in bodies of water, such as the North Sea, which used to be dry land where mammoths roamed. The Siberian permafrost has preserved carcasses that have not decomposed or become too dry for examination. A baby mammoth that scientists called Dima was located in 1977 and had intact red blood cells. Many mammoth fossils have been located during the digging of the Eastside Reservoir, near Los Angeles, California, including a female found in April, 1999, which is considered to be the best preserved mammoth specimen.

Mammoth Facts

Classification:
Kingdom: Animalia
Subkingdom: Metazoa
Phylum: Vertebrata
Class: Mammalia
Subclass: Eutheria
Order: Proboscidea
Suborder: Elephantoidea (elephant-like)
Family: Elephantidae
Genus and species: Mammathus africanavus (North African), *M. columbi* (Columbian), *M. exilis* (dwarf), *M. imperator* (North American), *M. jeffersonii* (southern North America), *M. meridionalis* (European), *M. primigenius* (wooly), *M. subplanifrons* (southeast Africa), *M. trogontherii* (steppe mammoth)
Geographical location: Africa, Northern Europe, North America, Eurasia, Siberia
Habitat: Tundra, grasslands
Gestational period: Twenty-two months
Life span: Sixty years
Special anatomy: Curved tusks, fatty hump, protruding brow

In 2000, paleontologists recovered what they believed to be the first completely frozen mammoth on Siberia's Taimyr Peninsula. Named the Jarkov mammoth, it was airlifted to a cold cave research facility, encased in a block of permafrost that included plants, insects, and pathogens, which scientists hoped would provide insights to mammoths' environments. They planned to test a hypothesis that mammoths became extinct due to an epidemic. Initially, scientists hoped to secure enough DNA to clone the mammoth, but it turned out that radar readings had incorrectly shown more of the carcass remaining than actually existed.

MANATEES

Type of animal science: Classification
Fields of study: Conservation biology, ethology, evolutionary science, marine biology, physiology, population biology, wildlife ecology, zoology

Manatees are aquatic, herbivorous animals of the order Sirenia that inhabit warm, shallow waterways. Decreasing habitat and other challenges from humans have caused all four of its species to be threatened or endangered.

Principal Terms

METAZOA: organisms which are multicellular
MOLARS: flat, stout teeth used for grinding food
NOTOCHORD: longitudinal, flexible rod located between the gut and nerve cord
PLACENTA: structure that connects a fetus to the mother's womb; indicative of internal gestation of young
SIRENIAN: refers to animals in the family Sirenia, the only completely aquatic herbivorous mammals; the two families, those of the dugongs and manatees, contain four species
VIBRISSAE: whiskers or bristles, used to provide positional information to an animal

The Florida manatee (*Trichechus manatus latirostris*) is found primarily in the Florida peninsula, but can occasionally be sighted as far north as Virginia and west to Mississippi. The Antillean manatee (*Trichechus manatus manatus*) shows a patchy distribution, including northeastern South America, southern Texas, Mexico, and the Caribbean. *Trichechus senegalensis*, the West African manatee, can be found on the west coast of Africa from Senegal to Angola. The Amazonian manatee, *Trichechus inunguis*, is found throughout the Amazon river drainage basin.

The species are distinguished by their geographical distributions, and while they are physically very much alike, some differences exist. Manatees all exhibit a streamlined body, full around the middle with no visible neck, tapering to a paddle-shaped tail used for propulsion. They have two small pectoral flippers on their upper bodies that are used for steering and bringing food to the mouth. The lips are long and flexible, and help in funneling plants into their mouths. Manatees are grayish-brown in color and have sparse, bristly hair scattered thinly over their torsos. They have molars at the back of their mouths, and unlike most other mammals, as the front molars wear down they are continually replaced by new teeth from the back of the mouths. Adult West Indian and West African manatees average about ten feet in length and weigh approximately 800 to 1200 pounds. Amazonian manatees are smaller, shorter, and more slender, averaging about eight feet in length and less than eight hundred pounds.

Adapted for the Aquatic Life

Streamlined bodies and flippers are ideal for the aquatic life of a manatee. They are agile and typically cruise in search of food at speeds of two to six miles per hour, but can swim as fast as fifteen miles per hour. While they have been sighted diving to depths of about thirty-three feet, they primarily forage for food no deeper than ten feet. Manatees can stay underwater for up to twenty minutes, but typically surface every two to three minutes for air.

Manatees spend most of their day foraging for aquatic plants and will consume between 4 and 9 percent of their body weight in wet vegetation daily. The animals are nonaggressive and non-

Manatees have streamlined bodies with no visible neck, which increases their efficiency in swimming. (Digital Stock)

territorial and spend the rest of their time traveling, investigating objects, and socializing. Manatees are considered semisocial, and the typical social unit is a female and her calf; however, congregations of up to two hundred individuals can be found near warm water sources such as power plant outfalls and hot springs, especially during winter months.

Male manatees are sexually mature at about nine to ten years of age, and females at about seven to eight years. Mating takes place in the water, and the female is accompanied by, and mates with, several males. Gestation takes about twelve months; the newborn calf measures about four feet and weighs sixty to seventy pounds. Calves remain close to their mothers for up to two years. The calf is dependent on its mother for nutrition, and for learning about feeding and resting areas, migratory routes, and warm water refuges. It is believed that manatees can live to sixty years in the wild; however, habitat destruction and injury by boats and fishing lines are seriously endangering manatees worldwide.

Manatee Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebra
Class: Mammalia
Subclass: Eutheria
Order: Sirenia
Family: Trichechidae (manatees)
Genus and species: Trichechus manatus (West Indian manatee, with subspecies *latirostris*, the Florida manatee, and *manatus*, the Antillean manatee); *T. senegalensis* (West African manatee); *T. inunguis* (Amazonian manatee)
Geographical location: Florida, Caribbean, and northern South America; West Africa; Amazon River basin
Habitat: Warm tropical and subtropical water, including shallow coastal waters, estuaries, and rivers
Gestational period: Approximately twelve months
Life span: Twenty-eight years in the wild; fifty to sixty years in captivity
Special anatomy: Flat, paddle-shaped tail; two pectoral flippers; nasal openings at the top of the snout; large, flexible upper lip equipped with vibrissae attached separately to nerve endings and each with its own blood supply

MARINE ANIMALS

Type of animal science: Ecology
Fields of study: Behavior, marine biology, oceanography, physiology

The world's oceans contain the largest and most varied array of life forms on earth. The marine environment is divided into coastal, open water, deep-sea, and bottom zones, and the lives of animals living in each of these regions are dictated by the physical conditions present in these zones. Due to the inaccessibility and hostility to human life of most of the ocean environment, much remains to be learned about the biology and ecology of most of the animals living in the marine world.

Principal Terms

BENTHOS: organisms living upon, or below, the surface of the substrate that forms the ocean floor

ESTUARY: the region where freshwater rivers empty into and mix with the marine environment of oceans or seas

INTERTIDAL ZONE: the portion of the marine environment located between low and high tide marks

NEKTON: larger marine animals that have sufficient powers of locomotion to move independently of water currents

NERITIC ZONE: the shallow water areas that extend over the continental shelves up to the low tide mark

PELAGIC ZONE: portions of the marine environment that are located away from the shorelines; the open ocean environment

PLANKTON: small animals and plants that drift with the water currents in the marine environment

Approximately 71 percent of earth's surface is covered by salt water, and the marine environments contained therein constitute the largest and most diverse array of life on the planet. Life originated in the oceans, and the salt water that comprises the largest constituent of the tissues of all living organisms is a vestigial reminder of the aquatic origins of life.

Marine Zones

The marine environment can be divided broadly into different zones, each of which supports numerous habitats. The coastal area between the high and low tide boundaries is known as the intertidal zone; beyond this is the neritic zone, relatively shallow water that extends over the continental shelves. The much deeper water that extends past the boundaries of the continental shelves is known as the oceanic zone. Open water of any depth away from the coastline is also known as the pelagic zone. The benthic zone is composed of the sediments occurring at the sea floor. Areas in which freshwater rivers empty into the saltwater oceans produce a continually mixed brackish water region known as an estuary. Estuarine zones often also include extensive wetland areas such as mud flats or salt marshes.

Zones in the marine environment are distributed vertically as well as horizontally. Life in the ocean, as on land, is ultimately supported by sunlight in most cases, used by photosynthetic plants as an energy source. Sunlight can only penetrate water to a limited depth, generally between one hundred and two hundred meters; this region is known as the photic or epipelagic zone. Below two hundred meters, there may be sufficient sunlight penetrating to permit vision, but not enough to support photosynthesis; this transitional region may extend to depths of one thousand meters and is known as the disphotic or mesopelagic zone. Below this depth, in the aphotic zone, sunlight cannot penetrate and the environment is perpetually dark, with the exception of small amounts of light produced by photoluminescent invertebrate and vertebrate animals. This aphotic zone is typically divided into the bathypelagic zone, between seven hundred and one thousand meters as the upper range and two thousand to four thousand meters as the lower range, where the water temperature is between 4 and 10 degrees Celsius. Beneath the bathypelagic zone, overlying the great plains of the ocean basins, is the abyssalpelagic zone, with a lower boundary of approximately six thousand meters. Finally, the deepest waters of the oceanic trenches, which extend to depths of ten thousand meters, constitute the hadalpelagic zone. In each of these zones, the nature and variety of marine life present is dictated by the physical characteristics of the zone. However, these zones are not absolute, but rather merge gradually into each other, and organisms may move back and forth between zones.

Plankton

Marine life can be divided broadly into three major categories. Those small organisms that are either free-floating or weakly swimming and which thus drift with oceanic currents are referred to as plankton. Plankton can be further divided into phytoplankton, which are plantlike and capable of photosynthesis; zooplankton, which are animal-like; and bacterioplankton, which are bacteria and blue-green algae suspended in the water column. Larger organisms that can swim more powerfully and which can thus move independently of water movements are known collectively as the nekton. Finally, organisms that are restricted to living on or in the sediments of the seafloor bottom are referred to as the benthos.

The phytoplankton, which are necessarily restricted to the photic zone, are by far the largest contributors to photosynthesis in the oceans. The phytoplankton are therefore responsible for trapping most of the solar energy obtained by the ocean (the primary productivity), which can then be transferred to other organisms when the phytoplankton are themselves ingested. The phytoplankton are composed of numerous different types of photosynthetic organisms, including diatoms, which are each encased in a unique "pillbox" shell of transparent silica, and dinoflagellates. The very rapid growth of some species of dinoflagellates in some areas results in massive concentrations or blooms that are sometimes referred to as red tides. Chemicals that are produced by red tide dinoflagellates often prove toxic to other marine organisms and can result in massive die-offs of marine life. Smaller photosynthetic plankton forms comprise the nanoplankton and also play an important role in the photosynthetic harnessing of energy in the oceans.

The zooplankton are an extremely diverse group of small animal organisms. Unlike the phytoplankton, which can make their own complex organic compounds via photosynthesis, the phytoplankton must ingest or absorb organic compounds produced by other organisms. This is accomplished by either preying upon other planktonic organisms or by feeding on the decaying remains of dead organisms. A number of zooplankton species also exist as parasites during some portion of their life cycles, living in or upon the bodies of nekton species. The largest group of zooplankton are members of the subphylum Crustacea, especially the copepods. These organisms typically possess a jointed exoskeleton, or shell, made of chitin, large antennae, and a number of jointed appendages. Space precludes a definitive listing of all of the zooplanktonic organisms; however, virtually all of the other groups of aquatic invertebrates are represented in the bewildering variety of the zooplankton, either in larval or adult forms. Even fishes, normally a part of the nekton, contribute to the zooplankton, both as eggs and as larval forms.

The bacterioplankton are found in all of the world's oceans. Some of these, the blue-green algae (cyanobacteria), play an important role in the photosynthetic productivity of the ocean. Bacterioplankton are usually found in greatest concentrations in surface waters, often in association with organic fragments known as particulate organic carbon, or marine snow. Bacterioplankton play an important role in renewing nutrients in the photic zones of the ocean; such renewal is important in maintaining the photosynthetic activity of the phytoplankton, upon which the rest of marine life is in turn dependent.

One of the principal problems facing plankton is maintaining their position in the water column. Since these organisms are slightly denser than the surrounding seawater, they tend to sink. Clearly this is a disadvantage, particularly since plankton typically have very limited mobility. This is especially true for the photosynthetic phytoplankton, which must remain within the photic zone in order to carry on photosynthesis. A number of strategies have evolved among planktonic species to oppose this tendency to sink. Long, spindly extensions of the body provide resistance to the flow of water. Inclusions of oils or fats (which are less dense than water) within the body provide positive buoyancy by decreasing the overall density of the plankton. Finally, some species, such as the Portuguese man-o'-war, generate balloonlike gas bladders, which provide enough buoyancy to keep them at the very surface of the epipelagic zone.

Nekton

The nekton is composed of those larger animals that have developed locomotion to a sufficient degree that they can move independently of the ocean's water movements. Whereas the plankton are principally invertebrates, most of the nekton are vertebrates. The majority of the nekton are fishes, although reptile, bird, and mammalian species are also constituent parts. The oceanic nekton are those species which are found in the epipelagic zone of the open ocean. These include a wide variety of sharks, rays, bony fishes, sea birds, marine mammals, and a few species of reptiles. Some members of the oceanic nekton, such as blue sharks, oceanic whitetip sharks, tuna, flying fish, and swordfish, spend their entire lives in the pelagic environment; these are said to be holoepipelagic. Others, the meroepipelagic nek-

The nekton is made up of animals with independent locomotion, such as fish. (Digital Stock)

Hydrothermal Vents

One of the most exciting discoveries made by deep-sea biologists occurred as recently as 1977. Scientists aboard the deep submersible *Alvin* happened upon a previously unknown hydrothermal vent community while studying the Galápagos Rift Zone, 2,700 meters below the sea surface. These communities were composed of high densities of organisms never before seen by humans, in an otherwise barren landscape of sparse benthic life. Since their discovery, over four hundred species have been recovered from hydrothermal vents, including one new class, three new orders, and twenty-two new families of animals. Among the more notable animals are giant clams, mussels, and vestimentiferan tubeworms. Vestimentiferan tube worms are about two meters long and lack a digestive tract.

These dark ecosystems obviously cannot be supported by photosynthetic organisms, but instead, chemoautotrophic bacteria that derive energy from sulfide are the primary producers that feed this unique food web. Vestimentiferan tube worms have these chemoautotrophic bacteria living symbiotically within their tissues. These bacteria directly provide the tube worms with the fixed carbon they need to survive, which is why the worms do not have digestive tracts. They do not need to eat. Since the discovery of hydrothermal vent communities in the Galápagos rift, similar communities have been discovered along rifts in the Atlantic, Indian, and western Pacific Oceans.

ton, only spend a portion of their lives in the epipelagic zone, returning to coastal areas to mate, as with herring and dolphins, or returning to freshwater, as with salmon and sturgeon. Sea birds are a special case: Although they spend much of their time flying over the epipelagic zone and nest on land, they feed in the epipelagic zone and some species may dive as deep as one hundred meters in search of prey. Some members of the nekton enter the epipelagic only at certain times in their life cycle. Eels of the family Anguillidae spend most of their lives in freshwater but return to the epipelagic zone to spawn. Additionally, at night many species of deep-water fishes migrate up into the epipelagic to feed before returning to deeper waters during the daylight hours.

The pelagic environment, unlike the terrestrial one, is profoundly three-dimensional. Nektonic animals can move both horizontally and vertically within the water column. Furthermore, since most of the pelagic environment is essentially bottomless, since there is no apparent or visible ground or substrate, the environment is basically uniform and featureless. These characteristics play an important role in the evolution of the behavior of nektonic animals. Fishes suspended in an essentially transparent and featureless medium have no shelter in which to hide from predators, nor are there any apparent landmarks to serve as directional cues for animals moving horizontally from place to place. Life in the open ocean has therefore favored adaptations for great mobility and speed with which to move across large distances and escape from predators, as well as camouflage and cryptic coloration designed to deceive potential predators or prey.

As is the case for plankton, most nektonic animals are denser than the surrounding seawater, and maintaining position in the water column is of the first importance. Most fishes possess a swim bladder, a gas-filled membranous sac within their body that opposes the tendency to sink and provides the fish with neutral buoyancy. Sharks and rays lack a swim bladder, but accumulate large concentrations of fats and oils in their liver, which also help counter the tendency to sink. Large, fast-swimming species of shark, tuna, and many billfish also rely on the generation of hydrodynamic lift to maintain vertical position in the water column. The tail and body of these fishes generate forward thrust, moving the animal through the water, and the fins, notably the pectoral fins, generate lift from the water flowing over them in a manner similar to that of an airplane's wing. Thus these animals fly through the water, but are in turn required to move continuously in order to generate lift.

All members of the nekton are carnivores, feeding on other nektonic species or upon plankton, particularly the larger zooplankton. In general, the size of the prey consumed by nekton is directly related to the size of the predator, with larger species consuming larger prey. However, the organisms that feed upon plankton, the planktivores, include a wide variety of fish species such as herring, salmon, and the whale shark, the largest extant fish species. They also include the largest marine animals of all, the baleen whales. The case of large animals feeding upon very small plankton directly addresses the need of all animals to meet their energy requirements. For all animals, the amount of energy obtained from food consumed must necessarily exceed the energy expended in acquiring the prey. Very large animals, such as whales and whale sharks, require a great deal of energy to move their bodies through the aquatic environment, but because of their great size they are necessarily less agile than smaller forms. The amount of energy required to chase and catch these smaller animals would generally exceed the energy derived from ingesting them. Plankton, however, are relatively easy to obtain due to their very limited mobility. However, because of their small size, vast quantities of plankton must be ingested in order to meet the metabolic requirements of large marine animals. Some very large species that are not planktivores solve the energy problem by evolving behaviors for acquiring specialized diets that yield higher energy. White sharks, for example, feed on fish when young, but as they age and increase in size, marine mammals, notably seals and sea lions (pinnipeds), become a major part of their diet. Marine mammals all possess blubber, an energy-rich substance that yields much more energy than fish. Similarly, sperm whales, the largest hunting carnivores on the planet, have a diet that consists in large part of giant squid, which are hunted in the ocean depths largely using the whale's acoustic echolocation sense. Orcas (killer whales) effectively use pack hunting techniques to hunt larger whales and other marine mammals.

The deeper regions of the ocean are dominated by different types of nekton. However, we know even less about their ecology due to their relative inaccessibility. The disphotic or mesopelagic zone contains many animal species that migrate vertically into surface waters at night to feed upon the plankton there. Many of these organisms possess large, well-developed eyes and also possess light organs containing symbiotic luminescent bacteria. The majority of the fish species in this group are colored black and the invertebrates are largely red (red light penetrates water less effectively than do longer wavelengths, and these animals appear dark-colored at depth). Beneath this zone, in the bathypelagic and abyssalpelagic zones, there are many fewer organisms and much less diversity than in the shallower levels. Animals in this region are typically colorless and possess small eyes and luminescent organs. Because organisms in these deep regions are few and far between, many species have become specialized in order to maximize their advantages. Thus, deep-sea fish are characterized by large teeth and remarkably hinged jaws that allow them to consume prey much larger than might be expected from their size. Similarly, since encounters with potential mates are presumably scarce, a number of unique reproductive strategies have evolved. In the anglerfish (Ceratius), all of the large individuals are female and the comparatively tiny males are parasitic, permanently attaching themselves to the female. Much, however, still remains to be learned of the ecology of these deep-sea organisms.

Benthos

The benthos of the world's oceans consists of animals that live on the solid substrate of the water column, the ocean floor. Scientists typically divide benthic organisms into two categories, the epifauna, which live on the surface of the bottom at the sediment-water interface, and the infauna, those organisms living within the sediments. In shallow water benthic communities, members of virtually every major animal group are represented. Ecologists generally differentiate between soft bottom benthic communities (sand, silt, and mud, which comprise the majority of the benthic zone) and rocky bottom communities, which are less common proportionately. Soft bottom communities have an extensive diversity of burrowing infauna, such as polychaete worms, and mollusks, such as clams. Rocky bottom communities possess a larger proportion of epifauna, such as crustaceans and echinoderms (starfish, sea urchins, and brittle stars), living on the surface of what is essentially a two-dimensional environment. Vertical faces of the hard bottom environment, such as canyon walls or coral reefs, are often home to a wide variety of animals occupying various crannies and caves. In some parts of the world, kelp plants that are anchored to the substrate and which extend to the water surface dominate the rocky bottom substrate. In these kelp forests, large kelp plants (actually a species of brown algae) form a forestlike canopy that plays host to a wide and complex array of animals extending throughout the water column. On the deep ocean floor, the benthos is composed of representatives of virtually every major animal group: crustaceans such as amphipods, segmented polychaete worms, sea cucumbers, and brittle stars. Less common are starfish, sea lilies, anemones, and sea fans. The fishes of the deep benthos include rat tails and a number of eel species.

Estuaries, where freshwater rivers empty into marine environments, are typified by large, cyclic changes in temperature and salinity. Although estuaries have played an important role in human history as the sites of major ports, the variety and number of estuarine species tend to show less diversity of animal species due to the difficulty in adapting to the large swings in environmental conditions.

Animal life in the sea, like that on land, shows an astonishing variety of forms and behaviors, the result of natural selection. The inaccessibility and hostility of much of the world's oceans to human exploration and observation leaves much yet to be learned about the biology of marine life. Much remains to be achieved in order to obtain a useful body of knowledge concerning life in the sea.

MARINE BIOLOGY

Type of animal science: Fields of study
Fields of study: Conservation biology, ecology, environmental science, invertebrate biology, marine biology, oceanography, zoology

Marine biology is the study of the plants, animals, fungi, protists, and microbes that live in the oceans. Because humans are not well adapted to marine environments, it is difficult to observe and study marine organisms in their natural surroundings. However, with modern technology such as scuba, submarines, and remote cameras, marine biologists are gaining considerable information about marine organisms.

Principal Terms

AUTOTROPHS: primary producers; organisms that are self-feeding; includes photosynthetic and chemoautotrophic organisms

BENTHIC: the area of the ocean floor; organisms associated with the sea bottom

EPIFAUNA: animals that live on the sea floor

HETEROTROPH: consumers; organisms that must acquire energy by consuming organic material

INFAUNA: animals that live in the sea floor

INVERTEBRATES: animals that lack backbones

LITTORAL: the area in the intertidal zone; organisms that live in the intertidal

NEKTON: organisms that are strong swimmers and can move against ocean currents

PELAGIC: the area of open water in the oceans; organisms that occur in the water column

PLANKTON: organisms that drift in the ocean currents because they have limited power of locomotion

The earliest known life forms were marine. The oceans cover 71 percent of earth's surface and have an average depth of 3,800 meters, which means that they represent 99 percent of the living space on the planet. Marine biology is the study of all the organisms that occupy this space. Despite having 99 percent of the planet's living space at their disposal, only 250,000 of approximately 1.8 million described living species (14 percent) are marine. While the oceans may lack diversity at the level of species, they are home to members of thirty-one of thirty-four animal phyla, about twice the number of phyla that are found on land or in freshwater.

Because of its vastness and humans' inability to easily visit deep waters, the oceans remain the least studied habitats on earth. For example, scientists know that giant squid eighteen meters in length, larger than any other invertebrate, exist because they have been found in the stomachs of sperm whales and washed up on beaches. However, no human has ever seen one of these creatures living in their natural habitats. If this sheet of paper represented the area of the ocean, the area directly observed by people would be smaller than the period at the end of this sentence. Despite the small amount of study in marine biology, research in these systems has contributed greatly to the understanding of living systems.

Oceanographers divide the ocean into zones that have distinct physical characteristics. These physical conditions, in turn, select for different organisms that are adapted to the set of conditions. The benthic realm refers to the sea floor and extends from the high intertidal zone, where ocean meets terrestrial land, to depths of eleven kilometers at oceanic trenches, the deepest parts of the ocean where the ocean floor slowly sinks back in to the interior of the earth. Organisms that live in, on, or near the ocean floor are appropriately called benthic organisms, and represent 98 percent of all marine creatures. The pelagic realm of the ocean refers to the open ocean, basically the space between the benthos and the sea surface. Pelagic organisms, representing the remaining 2 percent of marine species, live in the water column. The pelagic zone can be divided into the photic and aphotic zones, a distinction that is especially important for photosynthetic organisms. The photic zone is the shallow part of the ocean that receives enough sunlight to support photosynthesis, which is about two hundred meters deep in the clearest waters, and as shallow as three meters in turbid coastal waters. The aphotic zone is where there is not enough light to support photosynthesis, and extends from the bottom of the photic zone to the ocean floor.

Organisms of the Open Ocean

Pelagic creatures can be further categorized into plankton, which drift around in the ocean currents, and nekton, which are capable of swimming against currents. Photosynthetic plankton live in the photic zone and are called phytoplankton. These algae form the base of the food web in the open ocean and are eaten by zooplankton (heterotrophic plankton including protists and small crustaceans such as copepods). Zooplankton are eaten by small fishes, which are eaten by larger fishes, which are eaten by sharks, birds of prey, and people. The open ocean food web is one of the longest food webs known, partly because it starts with the smallest photosynthetic organisms.

The largest animal migrations on earth occur every day in the open oceans, in a process called diel vertical migration. Zooplankton, midwater fish, squid, and krill migrate to shallow waters at night and then return to the dark depths during the day. The main reason for this daily migration is probably to feed, and to avoid being eaten. Food densities are highest in the shallow productive waters, so these predators move to the shallows to feed at night. Because they would be susceptible to their own visually oriented predators in the well-lit shallows, they return to the dark depths during the day to avoid being eaten.

In the aphotic zone, there are only heterotrophic organisms that are supported mostly by organic material that rains down from the lit environments above. These animals live in darkness, with the exception of light produced by the animals themselves, called bioluminescence. It is common for sea creatures (especially ones at intermediate depths) to house luminescent bacteria within their tissues, which are able to produce light for communication, as a lure to attract prey, or to light their bottom surface to conceal their silhouette against the dimly lit background from above. Anglerfish are deep-sea predators that attract prey near their mouths by dangling a bioluminescent lure in front of their head.

The density of organisms in the deep sea is low. Because of this low density, a long period of time can pass between meals, or between encounters with the opposite sex. To deal with the problem of infrequent meals, deep-sea creatures are often gigantic compared to shallow-water relatives. Large size allows for storage of food reserves that sustain the animals between meals. Predatory fish also have large mouths and stomachs that allow them to take full advantage of any meal, regardless of size. To overcome the problem of rare mates, the miniature males of some anglerfish have the unusual adaptation of attaching themselves to the female, where they live the rest of their lives as parasitic sperm producers.

Organisms of the Bottom

Most marine species are found at the ocean floor. They occur in such familiar marine habitats as mud flats, sand flats, beaches, coral reefs, kelp forests, and the rocky intertidal. The main primary producers in benthic habitats are macroscopic seaweeds that grow attached to the bottom or microscopic algae that grow within the tissues of animals such as corals, sponges, and bryozoans. Benthic animals include mobile creatures such as fish, crabs, shrimp, snails, urchins, sea stars, and slugs. Additionally, there are numerous animals that, unlike familiar terrestrial animals, never move around as adults. These sessile animals include

Oases on the Deep Ocean Floor

Although animal life exists on the ocean floor, much of that zone is barren, with relatively few animals distributed at large intervals. One of the most exciting discoveries in marine biology during the last quarter of the twentieth century occurred in 1977 with the discovery of abundant animal life in the regions immediately surrounding four hot water geysers on the ocean floor. These hydrothermal vents, located in the eastern Pacific Ocean at a depth of approximately 2,700 meters, boasted a spectacular variety of species all located within a few meters of the vent. The geyser is caused when water is heated by Earth's mantle and rises rapidly through the cooler waters above. Water in the geyser reaches temperatures of 8 to 16 degrees Celsius, as opposed to the surrounding water, which is about 2 degrees Celsius. This warm water is also rich in dissolved hydrogen sulfide gas, which serves as a source of energy for bacteria at the vent. The bacteria, in turn, act as food for the various animal species in the area of the vent. Similar hydrothermal vents, each with a population of animals surrounding it, have since been discovered at other sites in the Atlantic and Pacific Oceans.

The largest animals located at these vents include large clams and mussels and several species of tube (vestimentiferan) worms. Other species include crabs, snails, segmented worms and spaghetti worms, so called because of their appearance. Many of these species had not been previously observed or described. All vent communities appear to have similar types of organisms in association, but not always the same species. Current estimates indicate that the life span of the vents is quite short (probably in the tens of years) and that when the vent dies, so do the animal communities surrounding it. How these vents are located and colonized by organisms living on the deep ocean floor is just one of many interesting questions concerning these deep-sea oases that remain to be answered.

barnacles, sponges, oysters, mussels, corals, gorgonians, chrinoids, hydroids, and bryozoans.

The commonness of sessile animals in the marine benthos suggests that it is a successful way of life. These animals' lifestyle combines facets of plant and animal lifestyles. Sessile invertebrates are plantlike in that they obtain some of their energy from sunlight (the animals themselves do not photosynthesize, but they house photosynthetic symbionts), they are anchored in place, and they grow in a modular fashion just as the branches of a tree do. They are animal-like in that they capture and digest prey and they undergo embryonic development, often involving metamorphosis. In fact, nearly all benthic animals start life in the pelagic realm, drifting around as planktonic larva, dispersing to new habitats as they develop and feed. After a few hours to weeks of pelagic living, they sink to the ocean floor to complete life as adults.

Being stuck in one place presents special challenges for sessile animals, including food acquisition, predator avoidance, and mating. Sessile animals feed by having symbiotic algae and by filtering organic particles from passing water currents. Like plants, sessile animals use structural and chemical defenses against predators, and have tremendous regenerative abilities to recover from partial predation events. Most benthic animals mate via external fertilization: Sperm and eggs are spawned into the water column and fertilization occurs outside the body of the female. Amazingly, sessile barnacles must copulate to achieve internal fertilization. These animals increase their reproductive success by being hermaphroditic, thus assuring that any neighbor is a potential mate; being gregarious to assure a high density of mates; and by having a penis long enough to deliver sperm to an individual seven shell lengths away.

Trophic Cascades and Keystone Predators

Marine organisms live in environments that are foreign to humans, and they have lifestyles that are unique to them and different from terrestrial creatures. However, the study of marine organisms has led to advances in ecological theory that have proven to be useful in understanding terrestrial communities as well. The concept of keystone species, where a relatively rare species has a disproportionately large effect on the community structure, was discovered from research conducted on rocky intertidal habitats. Professor Robert Paine removed starfish from rocks off the coast of Washington state and observed that mussels soon crowded out seaweeds and barnacles, resulting in about a 50 percent reduction in species richness. He concluded that starfish are keystone predators because their predation prevented mussels from excluding less-competitive species from the habitat.

Not far offshore from the rocky intertidal in kelp forests, another keystone species was shown to influence the community by a trophic cascade (where the effects from a top predator "cascade" down to lower trophic levels). Sea otters, by preying on sea urchins, protect the kelps that make kelp forests, an important habitat that many marine species rely on. In the 1800's, hunters greatly reduced the number of otters by harvesting their thick furs. As a result, sea urchin populations exploded because they were relieved from predation, resulting in a decimation of kelps by the herbivorous urchins. Once otters received government protection, their numbers increased, urchins decreased, and kelp forests returned, at least in some areas. Interestingly, Aleutian killer whales began preying on otters in the 1980's, causing kelp forests to begin disappearing again. The reason orcas began eating otters is probably due to concurrent declines in seal and sea lion numbers, the normal prey of these killer whales. The ultimate causes of these altered food webs is uncertain, but it almost certainly is the result of human activity. Even though humans are poorly adapted for a marine existence, the evidence is mounting that humans are altering marine ecosystems in complex, novel, and unpredictable ways. The science of marine ecology is best equipped to study these effects and offer information to protect and manage ocean life.

The interrelationship between orcas (pictured), seals, sea otters, and kelp forests can cause a trophic cascade when one element of the food chain is disturbed. (Corbis)

The Problem of Ocean Navigation

The epipelagic environment is essentially a featureless one, without many of the landmarks or other indicators that might serve as directional indicators for migratory ocean species. Yet many animal species are known to make long and highly accurate migrations through the apparently trackless regions of the world's oceans.

The best-known example of oceanic migration is probably in salmon, which as young animals move from the freshwater streams in which they hatched out to the open ocean in which they mature. Upon reaching sexual maturity, the salmon return to their natal freshwater streams, where they spawn and die. The later portions of this return migration, when the animals are moving up the river system and locating the precise stream in which they were born, has been the most intensely studied, and the sense of smell appears to play an important role. However, the salmon are also faced with the difficult navigational task of locating the mouth of their home river from the vast expanse of the open ocean. How they accomplish this task is completely unknown.

Other astonishing examples of animals making precise migratory movements are known. Green sea turtles (*Chelonia mydas*) from the Caribbean and North and South America are known to accurately navigate to Ascension Island in the middle of the Atlantic Ocean to lay their eggs. American and European eels leave their freshwater homes in streams and ponds upon reaching sexual maturity and migrate out to sea. Upon reaching the marine environment, these animals transform from freshwater eels to marine deep-sea eels of strikingly different appearance, and navigate to a region in the North Atlantic known as the Sargasso Sea, where they spawn and die.

The cues that are used by these animals in their migrations are unknown. Although it is tempting to call this instinctive behavior, instinct is merely a label for mechanisms that are unlearned and innate. These animals are clearly making choices of which direction to proceed in order to reach their goal, but the manner in which those choices are made remain mysterious and fascinating.

Bibliography

Cousteau, Jacques-Yves. *The Ocean World*. New York: Abradale Press, 1985. Virtually an encyclopedia of the undersea world, this comprehensive volume covers several aspects of marine biology by the famous explorer who first strapped on a scuba cylinder to enter the aquatic world. It contains over four hundred photographs, maps, and diagrams.

Earle, Sylvia A. *Sea Change: A Message of the Oceans*. New York: G. P. Putnam's Sons, 1995. A fascinating autobiographical book by an accomplished marine biologist and deep-sea explorer who shares a passion for exploration of the sea and warns of looming dangers to these vast systems.

National Geographic Society. *Ocean Drifters*. Washington, D.C.: Author, 1993. This videotape follows a loggerhead sea turtle into the open ocean and examines the wonderful creatures it encounters. Incredible cinematography.

Nybakken, James Willard. *Marine Biology: An Ecological Approach*. 5th ed. San Francisco: Benjamin/Cummings, 2001. An undergraduate textbook that covers marine organisms, their oceanic environment, and their interactions with their biotic and abiotic environment.

MARK, RELEASE, AND RECAPTURE METHODS

Type of animal science: Ecology
Fields of study: Conservation biology, genetics, population biology, wildlife ecology

The number of animals present within an area can be determined by the ratio of marked to unmarked animals. Knowledge of these numbers provides the biologist with information on the impact of environmental events. It is often necessary to know animal abundance to prevent exploitation, allow effective management of the population, and project future animal numbers.

Principal Terms

DENSITY: the number of animals present per unit of area being sampled

EMIGRATION: the movement of animals out of an area; one-way movement from a habitat type

HABITAT: the physical environment, usually that of soil and vegetation as well as space, in which an animal lives

HOME RANGE: the space or area that an animal uses in its life activities

IMMIGRATION: the movement of animals into an area; a one-way movement into a habitat type

MARKED: an individual animal that is identifiable by marks that may be either human-made, such as metal bands or tags, or natural, such as the pattern of a giraffe

N: a standard abbreviation for the size of an actual population; if capped with a ^ ($\hat{n}$) it is an estimated value

POPULATION: a group of animals of the same species occupying the same physical space at the same time

RECAPTURED: a previously marked animal that is either seen, trapped, or collected again after its initial marking

SAMPLING: the process of collecting data, usually in such a manner that a statistically valid set of data can be acquired

There are four different ways to determine the number of animals within a habitat or population: counting the total number of animals present, sampling part of the area (a quadrat) and extrapolating to find a total, sampling along a line-transect and measuring the distance and angle to where the animal being counted was first seen, and using the mark-recapture approach. Different types of animals require different techniques for population estimation. The mark-recapture approach is often used for groups of animals whose populations are too large or too secretive for other methods. These are usually vertebrates, although mark-recapture procedures have also been used for invertebrates, such as grasshoppers.

All mark-recapture calculations are based on how many individual animals are marked (denoted M) in the population being studied, how many animals are captured during sampling (n), and how many of the captured animals have been previously marked (m). The estimated population is commonly indicated $\hat{n}$. The basic mathematical relationship of these data is $\hat{n}/M = n/m$, when $\hat{n} = Mn/m$. An estimate of population density can be obtained by dividing the area being sampled by the estimate of N.

Marking

Animals may be either temporarily or permanently marked. Temporary marking may be daubing paint on an animal's body, clipping some hair off a mouse's back, or pulling off a few scales from a snake's belly. If each animal is given a unique mark, such as a number or symbol, then it is possible to determine how long the particular animal lives, its home range, and patterns of movement, such as immigration and emigration rates. Some mark-recapture calculations require that the number of times an individual animal is captured be known; "recaptured" must be separated individually for these calculations.

There are pitfalls in this census method that should not be overlooked. Several conditions must hold if mark-recapture population estimates are to be valid. The marked animals must neither lose nor gain marks. Care must be taken if natural marks, such as missing toes on a mouse, are used; additional mice losing toes would lead to an error in population estimation. Marked animals must be as subject to sampling as unmarked ones. Because of the excitement of being captured, many animals will not return to a live-trap a second time, leading to an overestimation of animal abundance. If an animal becomes easily caught and returns frequently to the trap, such as kangaroo rats often do in the desert, then this trap-happy animal produces an underestimate of population size. The marked animals must also suffer the same natural mortality as unmarked ones, and the stress of being captured and marked may cause a higher mortality rate in the animals that are marked. If this occurs, the population estimate will be too high.

The marked animals must become randomly

Image Not Available

mixed with the unmarked ones in the population, or the distribution of sampling effort must be proportional to the number of animals in different parts of the habitat being studied. If the animals are "clumped," population estimates will be either too high or too low, depending on whether the clumps of marked animals are included in the sample. Marked animals must be recognized and reported on recovery. Technicians working with the animals must be able to recognize marked animals and/or read the individual numbers per animal correctly. If marked animals are not recognized, population estimates are too high. There can only be a negligible amount of recruitment or loss to the population being sampled during the sampling period; emigration, if occurring, should be balanced by immigration. A short time between marking the animals and collecting the additional samples for the population estimate is necessary, or the ratio of N to M changes from that existing when n:m was established.

Even under the ideal conditions above, it is apparent, according to the laws of chance, that the ratio of marked to unmarked animals in the sample will not always be the same as that of marked to unmarked animals in the population; in fact, the two ratios may seldom be the same. Possibilities for sampling error can be decreased by enlarging the size of the sample. As the sample size approaches the population in size, chances for error become smaller. When the point is reached where the sample includes the entire population, there can be no error in estimation. In general, at least 50 percent of the population should be marked, and the number of marked animals in the sample should be 1.5 times the number of unmarked animals in the sample. In actual practice, it is difficult (if not impossible) to meet all these requirements. Consequently, it is often best that mark-recapture population estimates be used as measures of trends in major population fluctuations from year to year.

Applications of the Method

There are many different formulas for utilizing the mark-recapture data to produce estimates of population size for any animals that can be marked and recaptured or observed later. The first use of the ratio of marked to unmarked animals for population estimation was for fish and ducks; the technique is usually called the Lincoln-Petersen method or index. Its formula is $N = Mn/m$, where N is the total estimated population, n is the number of animals sampled or captured, M represents the number of animals marked in the population before sample size n is drawn, and m equals the number of previously marked animals recovered in sample size n.

An example of how the calculations for the Lincoln-Petersen index would be made is shown by the following information. If 375 quail were banded and later, in a sample of 545, there were 85 previously banded birds recovered, therefore $N = Mn/m$, or 375 × 545/85 = 2,404 quail estimated to be present in the population being sampled.

When, as is the case with ring-necked pheasants, there is a variation in the capture of the sexes, caused perhaps by capturing technique, the formula can be applied to both sexes, or even to age classes, to arrive at a better estimate of the total population. For example, if 500 males and 750 females were banded before hunting season and then 360 males and 150 females were recovered after the harvest, with 150 banded males found in the 360 males checked and 50 banded females recovered in the 150 females checked, a population estimate can be made. The estimate would be 500 × 360/150, equaling 1,200 males in the population. The female population estimate would be 750 × 150/50, equaling 2,250 females in the population. The total population of pheasants would be estimated to be 1,200 males and 2,250 females, equaling a total of 3,450 pheasants.

The Lincoln-Petersen index differs from other mark-recapture calculations in that only two periods, the initial period when animals are marked and the second period when the sample (n) is collected, are used. If several capture periods are used, sequential formulas, such as the Schnabel method, must be utilized. In each sample taken, all unmarked animals are marked and returned to the population; marking and recapture are done concurrently. The sequential approach makes allowances for the increasing number of marked animals in the population (M). M usually increases with time, but it may decrease with known mortality or removal of marked animals from the population. All the assumptions for the Lincoln-Petersen index should also be met for the Schnabel method to produce accurate population estimates.

The Schnabel method formula for multiple sampling periods is $N = \Sigma(C_T M_T)/R_T$. Each line of the Schnabel method calculation corresponds to a line in the Lincoln-Petersen index calculation. C represents the number captured during sampling time one, M is the total marked, and R is the number of recaptures. The subscript T is the sample time.

An example of the Schnabel calculation can be demonstrated with the following data. For four days of trapping, the following data were obtained: day one, five animals captured, no recaptures; day two, ten animals captured, five previously marked animals in the population at the start of the second day of trapping, three previously marked animals in the day two sample; day three, fifteen animals captured, fifteen previously marked animals in the population at the start of day three of trapping, three previously marked animals in day three of trapping; day four, ten animals captured, twenty previously marked animals in the population at the start of day four, and four previously marked animals among the animals captured on day four. For the four days of trapping, then, ten animals were recaptured. From these data, the Schnabel method estimate of population density would be $N = (5 \times 0) + (10 \times 5) + (15 \times 15) + (10 \times 20)/(0 + 3 + 3 + 4)$ with $N = 50.5$.

Another approach to the estimation of animal numbers has been developed that differs from the usual approach to mark-recapture population estimation calculations. The Eberhardt method is based not on the ratio of marked to unmarked animals but on the number of times an individual is recaptured during the recovery operations; the assumption is that this recapture frequency is related to the total population size. The relationship is believed to be a hypergeometric one. Eberhardt's formula is $N = n/1 - (n/t)$, where n = number of individuals handled in recovery operations and t = the total number of captures of individuals. In this tally, t will always be greater than n unless all animals are captured only once. To use these modified mark-recapture data, individual animals must be recognizable. This calculation has been used for a number of mice studies. For example, if twenty different kangaroo rats in the Mojave Desert were captured thirty-five times, the estimated population would be $N = 20/1 - (20/35)$; $N = 46.67$ animals.

These represent only a few of the mark-recapture formulas available for the estimation of population size and animal density. Many other, more complicated, formulas for calculation of population estimates based on mark-recapture ratios (such as the Schumacher-Eschymeyer, DeLury, and Jolly procedures) exist, but the simplest formulas often provide the best, most usable estimates of animal numbers.

Uses of the Method

The use of mark-recapture procedures allows the biologist to determine numbers of animals present in a given area. Without these numbers, the future of these animals cannot be predicted. This knowledge allows appropriate management strategies to be developed, either protecting them or providing needed control activities, such as spraying insecticides on agricultural crops before severe economic damage to the crops results. Information about animal populations is essential for determining the effects of environmental changes or human activities, such as construction, on animal communities.

The populations of different areas may be compared; population numbers between seasons or years may also be studied. The fact that certain areas have high numbers of individuals implies that these areas have good conditions for them. Wildlife managers need to know why these areas have higher numbers so that they can improve the relevant conditions in other areas. Learning this would not be possible without knowing population sizes on these respective sites. The success of management work can be judged by changes in population size.

Mark and recapture techniques are applicable to more population situations than are the other options for population estimation. The wide variety of methods available for marking animals often allows previously marked animals to be identified without actually being handled. This minimizes the stress on the marked animal by reducing human contact.

If information on how long an animal lives in the wild is needed, individual marking from population work can also serve this purpose. From their recapture points, the area used by individuals on a daily, seasonal, and yearly basis, known as the home range, can be determined. The degree of movement of individuals within the population can also be estimated. These data are economical to obtain, because the marking and capture of the animals for the population estimate also funds the cost of obtaining home range, movement, and longevity data. The rate of exploitation of the population and the rate of recruitment of new members into it can also be calculated from the ratio of marked to unmarked animals collected during the population studies. The biology of organisms in the wild cannot be adequately studied without accurate estimates of their population levels and fluctuations being known. Mark and recapture procedures are among the important scientific tools for the collection of this information.

MARSUPIALS

Types of animal science: Anatomy, classification, ecology, evolution, geography, reproduction
Fields of study: Anatomy, ecology, physiology, zoology

Marsupials are a primitive group of mammals that separated early from the dominant group of mammals today, the placentals. Their present strongholds are in Australia, New Guinea, Tasmania, Mexico, Central America, and most of South America.

Principal Terms

ADAPTIVE RADIATION: the rapid evolution of new animal forms to fill unoccupied ecological niches

CONVERGENT EVOLUTION: the process by which unrelated animals tend to resemble one another as a result of adaptations to similar environments

MARSUPIUM: the abdominal pouch possessed by most marsupials, in which immature young attach to nipples to complete their development

MONOTREME: the egg-laying mammals, including the platypus and spiny anteaters

OMNIVOROUS: description of a diet utilizing a great variety of food material

Marsupials are pouched animals that form a distinctive group within the class Mammalia. They possess the diagnostic features of typical mammals, including high and stable body temperature, furry pelt, simple lower jaw, and mammary glands. However, there are other features that distinguish them from what are considered to be typical mammalian features.

The kangaroo is the most commonly known marsupial, but a vast array of marsupials exist. Most marsupials are crepuscular or nocturnal, so most zoo visitors are unable to observe them. Most marsupials are found in Australia and New Zealand. Outside of Australia, it is rare to see marsupials in zoos. Australian authorities impose strict export sanctions to protect their numerous endangered species. The only naturally occurring marsupial found in the United States is the opossum, *Didelphis marsupialis*. The opossums of North and South America are the most diverse of three families of extant marsupials outside of Australia.

There are three families of marsupials, Didelphidae, Microbiotheriidae, and Caenolestidae, that inhabit South and Central America. One species of didelphid, the Virginia opossum, extends across North America and beyond the Canadian border. The American marsupials alive today are mostly small, ranging from mouse to rabbit size. These are generally either carnivorous or omnivorous, living in forests and feeding on insects.

Marsupial Development

Marsupials are an example of adaptive radiation. This adaptation to their varied habitats has led to their enormous diversity of forms and niches. They are also an example of convergent evolution, as indicated by the similarities between marsupials and placentals in the rest of the world. The marsupial gliders resemble the flying squirrels and lemurs, the Tasmanian tiger or thylacine was doglike, and marsupial moles resemble eutherian moles. There are many physiological similarities as well. Wombats process grasses and sedges as horses do and numbats feed on termites as anteaters do.

With few exceptions, marsupials are not conspicuous in coloration or any external physical attributes. The greatest majority of them are small, ranging in size between that of a mouse and of a small rabbit. They developed from small carnivores into herbivores the size of hippopotamuses. The larger marsupials died out only several thousand years ago.

For the most part, marsupials have remained curiosities for the general public. Humans have not traditionally exploited marsupials. They have never been kept as pets, the meat of larger kangaroos is mostly used for dog and cat food, and the furs of only a few marsupials have commercial value.

Marsupials include 18 families, 76 genera, and over 266 species, but these divisions and categorizations are currently being debated. Marsupials are the only order in the subclass Metatheria. There is no other group within the higher mammals that contains such a diversity of higher species, genera, and families as the marsupials.

There are marsupials that spring about on their hind legs, as well as climb, glide, burrow and even swim, and they range in adult size from 147 pounds to only 0.1 ounce. They are found in habitats as diverse as freshwater, alpine areas, hot deserts, and tropical rain forests. Their diet ranges from purely insects to vertebrates, fungi, underground plant roots, bulbs, rhizomes and tubers, plant exudates such as saps and gums, seeds, pollen, terrestrial grasses, herbs and shrubs, and tree foliage. Because of this vast diversity it is impossible to categorize marsupials with a simple description. Instead, the physiology of marsupials must be used to categorize them.

Physiology

There are three types of reproductive patterns in mammals. There are monotremes, which are egg-laying mammals, such as the duck-billed platypus. There are placentals, whose embryo develops inside the uterus, and the placenta formed in the uterus provides nutrients to the developing embryo. In placentals, the offspring are born completely developed, as in humans. Finally, there are marsupials, which functionally fall in between monotremes and placentals.

Marsupial Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Theria
Infraclass: Metatheria
Order: Marsupialia
Suborders: Polyprotodonta and Diprotodonta
Families: Didelphidae (American opossums, eleven genera, seventy-five species); Microbiotheriidae (Monito del montes); Caenolestidae (shrew or rat opossums, three genera, seven species); Dasyuridae (quolls, dunnarts, and marsupial mice, eighteen genera, fifty-two species); Myrmecodoiidae (numbats); Thylacinidae (thylacines); Notoryctidae (marsupial mole); Peramelidae (bandicoots, seven genera, seventeen species); Phalangeridae (cuscuses and brishtails, three genera, fourteen species); Burramyidae (pygmy opossums, four genera, seven species); Pseudocheiridae (ringtail opossums, two genera, sixteen species); Petauridae (gliders, three genera, seven species); Macropodidae (kangaroos and wallabies, eleven genera, fifty species); Potoridae (rat kangaroos, five genera, ten species); Phascolarctidae (koalas); Vombatidae (wombats, two genera, three species); Tarsipedidae (honeypossums)

Geographical location: Australian region; North, Central, and South America

Habitat: Varied depending on species, but includes major terrestrial habitats and some arboreal habitats

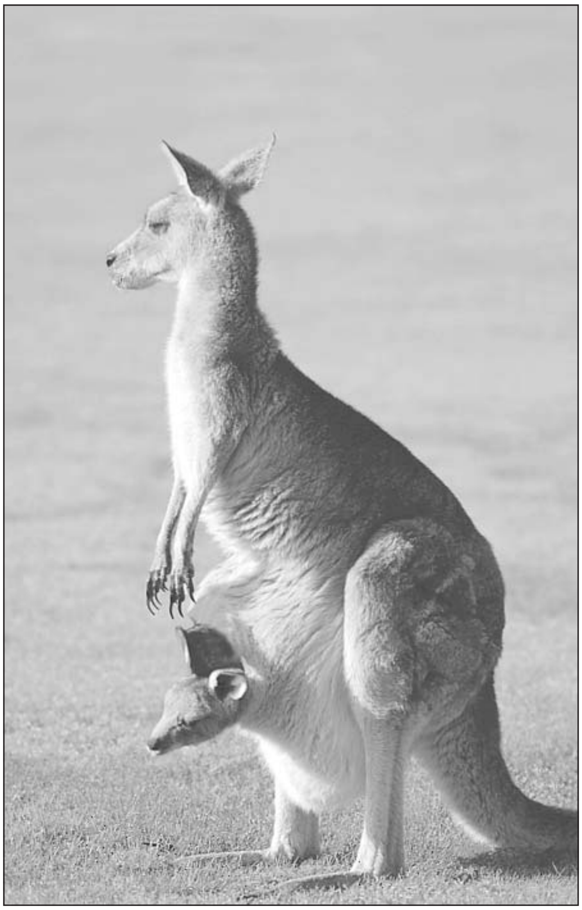
Gestational period: Characteristically short, as the newborn completes its development attached to a nipple inside the marsupium

Life span: Varies by species

Special anatomy: The marsupium, or abdominal pouch, is characteristic, although some forms, such as the murine opossum of Central and South America, lack one

Marsupials are often thought of as pouched mammals. Their embryo develops inside the uterus but, unlike placental mammals, the marsupial is born very early in its development. It completes its embryonic development outside the mother's body, attached to teats of abdominal mammary glands, which are often but not always enclosed in a pouch called the marsupium. The helpless embryonic form has forelimbs that are strong enough to climb from the birth canal to the mother's nipples, where it grabs on and nurses for weeks or months depending on the species.

When the young are born, their eyes and ears are closed, hind limbs and tails are stumps, and they are completely hairless. Their olfactory senses are greatly developed, as are their tactile senses, allowing them to navigate their way to the marsupium.



Kangaroos are the archetypal marsupials, carrying their young in an abdominal pouch, or marsupium, for up to eleven months. (Digital Stock)

The marsupium is formed in diverse ways, ranging from the "primal pouch" (the annular skin creasing around each teat), to common marsupial walls surrounding all teats, and finally to a closed marsupium, which can be opened to the front or to the rear. Marsupials are usually woolly, with shortened forelimbs and elongated hind limbs. In kangaroos, these physical features allow locomotion in a hopping movement only. However, at an equivalent speed, allowing for the differences in weight, a hopping kangaroo uses less energy than a running horse or dog.

In several families, second and third toes of the hind foot function as grooming claws and the first toe is always clawless, except in the shrew opossum. Vision is usually poorly developed and olfactory, tactile, and auditory senses are well developed.

The gestation period is eight to forty-two days, after which the young is carried in the marsupium for between thirty days and seven months. Litter sizes range from one to twelve per birth. The young are weaned anywhere between six weeks and one year. The relationship between mother and offspring is long lasting in many species. Sexual maturity is reached between ten months and four years, depending on the species. The longer range is associated with the male koala.

Behavior

Marsupials range from pure carnivores to pure herbivores, with all the intermediate stages in between. They are usually nocturnal and crepuscular. Some species are solitary, while others live in family groups.

In all mammals, because of the milk produced by the mother, male assistance in feeding the young is less important than in birds, for example. In many marsupials, the role of the male is further reduced because the pouch takes over the functions of carrying and protecting the young and keeping it warm. A female's need for assistance in rearing young does not appear to be an important

The Tasmanian Tiger

One unique marsupial is the Tasmanian tiger, or thylacine, a carnivorous marsupial now believed to be extinct. This mammal has attracted special attention because of its striking similarity to the dog. Also unique to this animal is its tigerlike dorsal stripes, thirteen to nineteen dark, transverse stripes that were distinct over the light gray to yellow brown coat. Reports of size vary, but it was similar in size to the American wolf. Reliable biological and behavioral information on this animal is very rare.

With the arrival of sheep ranchers, the Tasmanian tiger's numbers declined rapidly. Due to a government bounty program, between 1888 and 1905 more than two thousand Tasmanian tigers were officially killed, with the actual numbers likely much higher. What was believed to be the last wild Tasmanian tiger was shot in 1930. Tasmanian tigers never reproduced in captivity. Ironically, the Tasmanian tiger embellishes the Tasmanian coat of arms, designated by King George of England in 1917.

factor promoting the formation of long-lasting male-female pairs or larger social groups. The majority of marsupial species mate promiscuously. There are few examples of long-lasting bonds and they do not live in groups. Some species form monogamous pairs and harems. It is hypothesized that the lack of frequent examples of this sort is due to the lack of external pressures.

Evolution

Marsupial evolutionary development is not yet clearly understood. Fossil records suggest that they may have evolved simultaneously with the placental animals about 100 million years ago, in the Cretaceous period. The oldest geological finds come from the recent Upper Cretaceous of North America, about seventy-five million years ago. Although there was some development of marsupials in North America, they later declined as placentals increased in diversity. In contrast, South America has a considerable diversity of marsupial fossil forms, indicating their persistence for more than sixty million years. Seven families of living and fossil marsupials are known from South America. About two to five million years ago, a land connection between the two Americas was established again, and more placental animals reached South America, including carnivores such as the jaguar. In the face of such competition, the large carnivorous marsupials disappeared, but the small omnivores have persisted successfully to the present day. Some of them moved north to colonize in North America.

The earliest marsupials found in Australia are dated from twenty-three million years ago. Most modern families and forms were clearly established by that time. There is no clear evidence to establish whether marsupials originated in North America, South America, or Australia. The lack of fossil records of marsupials in Asia or Africa makes the most likely route of migration from South America to Australia via Antarctica. At that time, all three southern continents were united in the land mass known as Gondwanaland. This mass of land began breaking up 135 million years ago, with South America and Antarctica still being connected until about 30 million years ago. One land mammal fossil has been found in Antarctica which is a marsupial dated to be forty million years old. The Australian plate then gradually drifted northward for another thirty million years before reaching its current latitude. This long isolation allowed the extensive development of the marsupials in Australia in the absence of competition from other placentals.

As marsupials evolved in Australia, so did the placentals in the rest of the world, filling the same ecological niches. In many cases, they adopted similar morphological solutions to ecological problems. One example is the convergent evolution of the carnivorous Tasmanian devil, a marsupial, and placental wolves of other continents. The marsupial mole is very similar in form to the placental mole. The marsupial sugar glider and the two flying squirrels of North America are also very similar.

Habitat

The arrival of European settlers and the influx of new species—sheep, cattle, rabbits, foxes, cats, dogs, donkeys, and camels—have caused a large-scale modification of the marsupial's habitat in Australia. The first major change was in the late Pleistocene, with the extinction of whole families of large terrestrial marsupials. Included in this extinction was Diprotodon, the largest browsing kangaroo. It is likely that the climatic fluctuations increased aridity and reduced the available favorable habitat. Many of the species were already under stress when man arrived.

Approximately nine species have become extinct in Australia and fifteen to twenty have suffered gross reduction in range. The most affected have been small kangaroos, bandicoots, and large carnivores such as the thylacine and native cats.

Not all the environmental changes have been unfavorable for marsupials. Many of the larger herbivores have fared well with the advent of ranching and available grazing land and watering holes already set up for stock animals. As these marsupials become competition for sheep and cattle, Australian authorities have developed programs to keep their population controlled by allowing a certain number to be shot. Most species of marsupials have little or no importance as pests and their continued existence depends largely on the maintenance of sufficient habitat to support secure populations. The control of feral foxes and cats is very important to keep predation limited.

Marsupials outside Australia appear to have suffered no ill effects due to the destruction of habitat in North and South America.

MATING

Type of animal science: Behavior
Fields of study: Ethology, invertebrate biology, zoology

Mating is the process by which individuals of a species accomplish the fertilization of ova, or eggs. Mating systems vary widely in the animal kingdom, but every system must bring together two animals, usually of different sexes of the same species.

Principal Terms

ASEXUAL REPRODUCTION: reproduction without the union of male and female sex cells

DIOECIOUS: having two separate sexes, namely male and female

ESTRUS: the period of the sexual cycle during which a female is sexually receptive

GAMETE: a sex cell, either male or female

HERMAPHRODITE: an animal with both male and female sex organs

MONOGAMY: a mating system in which one male and one female comprise the main breeding unit

POLYGAMY: a mating system in which a single adult of one sex mates with several members of the opposite sex.

As one observes the diverse and elaborate movements and behaviors seen in courtship displayed by all types of animals, it is easy to lose sight of what courtship is meant to accomplish. Whether it is relatively simple or highly complex, the ultimate goal of courtship is to bring together two animals of different sexes of the same species to bring about successful mating and reproduction. Although they may not always be as obvious, mating patterns among animals also are quite diverse.

Reproduction, one of nature's most fundamental and essential functions, is the process by which all living organisms produce offspring. The need to propagate is a cardinal necessity for the preservation of the species. Each living organism has its own unique way of accomplishing this requirement. The higher the animal, the more intricate the process. In one-celled organisms reproduction is usually asexual, where only one living entity is required for procreation. The one-celled animal simply splits in two, losing its original identity and thereby creating two new organisms that are characteristically exact duplicates of the parent. The process is known as fission. Some single-celled entities reproduce sexually, where two similar organisms fuse, exchange nuclear materials, and then break apart, after which each organism reproduces by fission. This form of unicellular reproduction is known as conjugation. Sometimes after conjugation, the participating organisms do not reproduce. It appears that the process is merely to revitalize the organisms. This is the most primitive method of sexual reproduction. The new organisms that are produced are from two distinct parents, having definite genetic characteristics of their own.

The procreation process in most multicellular animals involves a more complex form of sexual reproduction. Here, unique and differentiated male and female reproductive cells called gametes unite to form a single cell known as the zygote. The zygote undergoes successive divisions to form a new multicellular organism, where half the genes in the zygote come from one parent and half from the other, creating a singularly different living creature.

Since most species of animals have sexual reproduction, it must offer some advantages. Sexual reproduction results in maintaining high levels of genetic variability within a population. Genetic variability produces variability in behavior, structure, and physiology and provides a species with greater flexibility in meeting changing environmental conditions. There must also be some long-term evolutionary advantages.

A dictionary definition of mating encompasses the idea of individuals coming together to form a pair, with the implication of doing so to produce offspring. If an emphasis is placed on the latter part of the definition, then it is seen that mating may involve all degrees and types of relationships and interactions among animals. In animals that have sexual reproduction, the union of male and female sperm and eggs, also known as gametes or sex cells, may be accomplished by either external or internal fertilization. Simple or elaborate courtship rituals ready animals for mating and fertilization. Several factors may influence reproduction. Most animals have a distinct time of the year, the breeding season, when reproduction is possible. Depending on the species, the breeding season may be the spring, summer, fall, or winter. In other species, including the human and some primates, breeding may occur throughout the year. The breeding season starts with the onset of courtship and is finished when the last offspring are weaned. The same species may have different breeding seasons depending on where they live. In temperate regions of the world, there may be much variation in the breeding in different years. Any factor that affects the health of animals may modify their breeding season, including food availability, temperature, light, and population density. In general, the breeding season usually is coordinated to maximize the likelihood of survival of the young.

Mating Systems

The means by which males and females are brought together in courtship and, ultimately, copulation is achieved is by some type of mating

Sexual reproduction, the form of mating that involves the mixture of genetic material from a male and a female organism, increases a species' genetic flexibility in coping with environmental changes. (Corbis)

Sexual Reproduction—With and Without Copulation

When one thinks of mating and sexual reproduction, one usually thinks of the act of copulation and the physical coupling of the male and female. However, sexual reproduction does not always involve actual copulation and there is much variation among animals. Sexual reproduction which involves the union of male and female sex cells may be achieved by means of internal or external fertilization. In most animals, the male and female sex cells are of unequal size, and typically, a small gamete fertilizes a large gamete. In certain flagellates, however, the two gametes are identical but still function to produce a new individual.

External fertilization is accomplished in a number of invertebrates as well as in some vertebrates. Among many aquatic animals, large numbers of sperm and eggs may be simply expelled into the water, and although the system is inefficient, the large number of sex cells assures that some fertilization will be effected. Among the vertebrates, fertilization is internal in some fishes and external in others. Most frogs and toads have external fertilization: As eggs are released by the female, they are fertilized by the males.

Even in those vertebrates that have internal fertilization, the copulatory organ may not necessarily be a penis. Among fishes, there are modified fins and claspers which serve to transfer sperm for internal fertilization. In most species of birds there is no penis, and during copulation sperm from the male is transferred from his cloaca (a common cavity into which the reproduction, urinary, and intestinal canals open) to the female's cloaca by direct contact, in what biologists refer to as a "cloacal kiss." All mammalian males have a copulatory organ, although there is much variation in the size and structure of the penis. In the egg-laying mammals, the penis is attached to the wall of the cloaca and its canals are used only for the transfer of sperm to the cloaca of the female.

In many mammals, but not all, the penis contains a bone, the os penis or baculum. A baculum is found in most carnivores and aquatic mammals, as well as in some rodents and a variety of other mammals. Other interesting structural variations in the penis include the corkscrew-shaped penis of the pig and the forked tip of the penis of the opossum.

Regardless of the way in which sexual reproduction is accomplished, it succeeds in producing new genetic combinations, and this increased genetic variability appears to be a major advantage to species.

system or pattern. Systems vary widely throughout the animal kingdom, but there are several general groupings. (A reading of the literature in cultural anthropology shows that virtually all of these mating systems can be found in different human cultures, as well.) Mating systems typically are classified under three headings: promiscuity, monogamy and polygamy. It also is useful to delineate subcategories within some of these.

Promiscuity, as it defines a mating system, means that no pair bond is formed between individuals. A technical term for this system is polybranchygamy. which literally means "many brief matings." In this system, any male may mate with any female and no one individual has exclusive rights over any individuals of the opposite sex. Males and females may copulate with from one to many of the opposite sex. Promiscuity is found more often in males than in females, and this observation is probably related to the fact that in such species males have a far lesser investment in offspring than do females. The system is found in a small percentage of bird species and many species of mammals. Promiscuity is demonstrated well in those species that form leks. A lek is an area or territory used for communal courtship displays and mating by certain species. Leks have been observed among grouse, some African antelope, a species of bat, and some insects. Leks are used solely for mating. Females are attracted to the leks by elaborate courtship displays by the males, and mate with one or a small number of the males. Usually, only a select few of the males perform most of the matings. In one study of grouse, less than 10 percent of the males carried out more than 75 percent of all copulations. The African antelope, the Uganda kob, is an example of a mammal that utilizes a lek. Here, also, a small percentage of males breed most of the adult females. The system is very effective, as nearly all of the females produce offspring.

A second major type of mating system is monogamy. It is a system in which a pair-bond is formed between one female and one male. The pair-bond may exist for only one breeding season (annual monogamy) or it may persist for one or more breeding seasons (perennial monogamy). Monogamy is very common in birds, with a large majority of species showing it. Swans and eagles are examples of species showing perennial monogamy, and sparrows and warblers are examples of species showing annual monogamy. Although it has been thought that many birds practice true monogamy, evidence has accumulated that in monogamous birds there are frequent matings of the males with females outside of the primary pair-bond relationship. These matings are known as extra-pair-bond copulations, and offer advantages to the males if they result in successful fertilization of additional eggs. Monogamy seems to occur when both the male and female have nearly identical roles in the rearing of the young.

Monogamy is far less common in mammals than it is in birds, but there are some good examples. If monogamy is likely to occur where there is equal parental investment by both males and females, it might be predicted there is less need for male mammals to practice monogamy, since only the females nourish the young with milk. Among mammals, monogamy can be observed in gibbons, foxes, wolves, beaver, red fox, and even among some small rodents. Why should there be monogamy among any mammals? It would be advantageous for males to be monogamous if by doing so they increased the likelihood of survival of their offspring. Males could do so if they helped to feed the young and helped to defend the territory against predators. Monogamy can also be looked at from the perspective of the female, a so-called female-enforced monogamy, which may take place if females can gain sole benefit from the male's efforts without having to share them with other females.

The third major type of mating system is polygamy. In polygamy, an individual of one sex forms a pair-bond with several members of the opposite sex. The two major subtypes of polygamy are polyandry, where one female mates with more than one male, and polygyny, where one male mates with more than one female. Within both polygyny and polyandry there may be either a serial type or a simultaneous type. In the former case, one male or one female bonds with several members of the opposite sex but only one at a time. In the latter case, one male or one female bonds with several individuals of the opposite sex at the some time. Simultaneous polygyny is often referred to as harem polygyny. Although it appears to resemble promiscuity, it differs from promiscuity in that a pair-bond is formed even though it may be temporary. In altricial birds, in which the young are born in a helpless state, it is often observed that polygyny is present in habitats where food is unevenly distributed and one male is able to provide food for more than one female. Polygyny also may result in cases where there is a lack of availability of suitable territories for breeding and where there may be a pressure of heavy predation.

Hermaphroditism

Although most species of animals are dioecious, meaning that they have two separate sexes, male and female, some individuals and even whole species are monoecious and have both sexes in one individual. Monoecious individuals are also called hermaphrodites. Although hermaphroditism is unusual in humans and most mammals, in some species it is the rule. There are many invertebrates in which the same individual produces both eggs and sperm. Some examples of hermaphroditic species include garden snails, free-living flatworms, the common earthworm, and some fish. It might seem that the hermaphroditic condition is a beneficial and efficient one, since any single individual is capable of producing and delivering both eggs and sperm. However, there is at least one major drawback to the system, the possibility of self-fertilization. Self-fertilization does not lead to as much genetic variability in the offspring compared to what might be expected if there was cross-fertilization. In species in which hermaphroditism is the rule, there are a number of processes at work which make self-fertilization unlikely, if not impossible. Some animals produce eggs at one time and sperm at a different time, making it impossible to self-fertilize. In animals in which the sex organs mature at different times, a condition known as protandry, an individual alternates between being different sexes, functioning as a female or male first and then becoming the other sex at a later time. In some species, including the earthworm, two individuals come together to engage in a mutual copulation. The two worms are held together by a secretion produced by both of them. The togetherness allows sufficient time for sperm from one worm to travel to the other worm and fertilize that worm's eggs and vice versa. Although in most animals the act of copulation is quite short, in the earthworm it may last three hours.

It would be remiss not to mention briefly an example of parthenogenesis in invertebrates. There are a few species of fish and lizards in which only females are known and in which the offspring are produced from eggs without fertilization by sperm. The Amazon moly, a fish, goes through the acts of courtship and mating with a male, but it is with males of other species, and sperm do not fertilize any of her eggs. The eggs develop parthenogenetically and produce another generation, apparently only of females.

Even a brief discussion of mating in animals reveals the complex and diverse methods that are used to produce another generation of the rich diversity of animal life on earth.

MEERKATS

Type of animal science: Classification
Fields of study: Ethology, population biology, wildlife ecology, zoology

Meerkats are close relatives of mongooses and are particularly noted for their close, cooperative societies.

Principal Terms

CARNASSIAL TEETH: teeth designed to sheer flesh; the characteristic that unites all members of the order Carnivora
DENTITION: referring to the teeth
DIURNAL: active during the day
METAZOA: organisms which are multicellular
NOTOCHORD: longitudinal, flexible rod located between the gut and nerve cord
PLACENTA: structure that connects a fetus to the mother's womb; indicative of internal gestation of young

Meerkats, also called suricates, have the long body and short legs characteristic of most mongooses. The body length is from ten to thirteen inches, and the tail adds an additional seven to nine inches in length. The short fur of the meerkat is grayish-brown to light gray in color, featuring dark stripes across the back. The eyes and nose are dark and form a contrast with the light-colored head and throat. The belly fur of the meerkat is rather thin, which helps to regulate the animal's body temperature. To warm up, the animal will bask in the sun while sitting up or lie belly-down on warm earth, and to relieve itself from the hot desert sun, a meerkat will lie belly-down in a cool, shaded area or inside its burrow.

Meerkats are desert creatures, primarily inhabiting the Kalahari and Namib deserts and other dry, open areas of southern Africa. One of the most notable characteristics of meerkats is their extreme gregariousness. They typically live in family units of up to thirty individuals. The colony of animals occupies a home territory, and digs several systems of burrows with multiple entrances connected by tunnels and a number of distinct chambers. The colony moves several times during a year as food becomes depleted, and establishes a new system of burrows or occupies those left from a previous occupation by the group.

Group Life

Because life in the open desert is harsh and predators, such as jackals, hyenas, and birds of prey, are plentiful, the meerkat group social structure ensures that there are many individuals to act as sentries while the group is foraging for food. The sentry takes its place on a raised area such as a sandbank, bush, or tree, and constantly scans the sky and the horizon for potential predators. The keen eyes and ears of meerkats aid in their constant vigil against danger. Should a predator be spotted, the sentry barks a warning and all members rush to the protection of the burrows. When larger animals, such as hyenas, have threatened the safety of the meerkats inside the burrow, the entire meerkat colony has been seen to band together, stand on their hind legs, and confront the intruder with barking threats, successfully repelling the threatening advances of the much larger animal.

The diet of meerkats consists largely of whatever is available in the harsh desert habitat. Insects, spiders, centipedes, scorpions, lizards, snakes, small mammals, birds and their eggs, roots, tubers, and other plant matter are all staples of the meerkat diet. Each individual takes its turn

The meerkat's distinctive upright pose allows it to search the environment for possible predators. (Digital Stock)

Meerkat Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebra
Class: Mammalia
Subclass: Eutheria
Order: Carnivora
Family: Viverridae
Genus and species: Suricata suricatta (gray meerkat)
Geographical location: Southwestern Angola to southern Africa
Habitat: Desert, open country, savanna, and bush
Gestational period: Approximately eleven weeks
Life span: About ten years in the wild, up to seventeen in captivity
Special anatomy: Long, stiff tails that are used to stand upright; keen eyes located at the front of their heads provide good depth of vision

at sentry duty while the others forage, and the sentry is changed about every thirty minutes. Meerkats are diurnal creatures, spending much of their time foraging for food during daylight hours, except for the hottest portion of the day when they rest in the shade.

Mating generally occurs between October and April, and females give birth to two to five young after a gestational period of about seventy-seven days. Mothers give birth in a specific chamber in the burrow and young are born blind, but their eyes open in twelve to fourteen days. Meerkat young begin eating solid food at about three or four weeks of age but typically nurse for eight to twelve weeks. In meerkat society, there are many individuals who "babysit" young while the mothers forage for food. Meerkat young are sexually mature about one year after birth.

METABOLIC RATES

Type of animal science: Physiology
Field of study: Biochemistry

Metabolic rate is a measure of the amount of energy used by an organism in a period of time (calories per hour). By studying factors that affect metabolic rates, scientists can calculate food requirements for animals in particular conditions and explain energy adaptations to different habitats.

Principal Terms

ADENOSINE TRIPHOSPHATE (ATP): the primary energy storage molecule in cells; links energy-producing reactions with energy-requiring reactions

ANABOLISM: a series of chemical reactions that builds complex molecules from simpler molecules using energy from ATP

BASAL METABOLIC RATE (BMR): the rate of metabolism measured when the animal is resting and has had no meals for twelve hours; used to compare different species

CATABOLISM: a series of chemical reactions that break down complex molecules into simple components, usually yielding energy

ELECTRON TRANSPORT CHAIN: a series of electron carrier molecules found in the membrane of mitochondria; oxygen is used and ATP is made at this site

HORMONE: a chemical messenger molecule within organisms; acts as a regulator of cell activities

MITOCHONDRION (pl. MITOCHONDRIA): a cell organelle found in plants, fungi, animals, and protists; the site of most aerobic metabolism

SPECIFIC METABOLIC RATE: the rate of metabolism per unit body mass (calories per gram per hour)

All living things require energy to sustain life as well as to carry out normal activities, develop, and grow. All the chemical reactions that allow energy acquisition and use are collectively called metabolism. Animals usually obtain energy by breaking down food in the presence of oxygen, so the amount of oxygen they use can be considered a measure of their rate of metabolism. Oxygen consumption is not always a good indicator of rate of energy conversion and use. Some organisms, such as fish, that live in oxygen-poor environments gain energy without using oxygen through anaerobic metabolism. Since all energy used by living things is eventually converted to heat, metabolic rate can be defined as the total amount of heat produced by an organism in a certain time period.

Rates of metabolism measured on whole organisms can be used to study the effects of factors such as temperature, size, age, and sex on rates of energy use. Studies of metabolic rates of different species of organisms are used to determine food requirements and energy adaptations in different environments. Metabolic rate can also be measured on isolated tissues, cells, or cell organelles in order to study the different biochemical reactions that occur in tissues and cells.

Factors Affecting Metabolic Rate

One of the most important factors that affects metabolic rate is the temperature of the organism, since within limits all chemical reactions of metabolism proceed faster at higher temperatures. The internal temperature of most invertebrate animals, fish, and amphibians is the same as the temperature of the environment in which they live. Such organisms are called poikilotherms. In poikilothermic organisms, metabolic rate increases as the environmental temperature increases. Such organisms move slowly and grow slowly when the temperature is cold, since their metabolic rate is very low at cold temperatures. To compare the metabolic rates of different poikilotherms, one must measure their rate of metabolism under standard conditions. Standard metabolism is usually defined as the rate of energy use when the animal is resting quietly, twelve hours after the last meal, and is at a temperature of 30 degrees Celsius; however, for small invertebrates, protists, and bacteria, only temperature is usually controlled. Most reptiles, birds, and mammals can maintain their body temperature at a constant level even when the environmental temperature changes greatly. Such organisms are called homeotherms. Birds and mammals can maintain their body temperature through internal heat production (endothermic homeothermy), while reptiles must acquire the necessary heat from their environment by changing their behavior, body posture, or coloration (ectothermic homeothermy). Most endotherms can maintain a constant body temperature over a range of temperatures (thermal neutral zone) without affecting their rate of metabolism. At temperatures outside the thermal neutral zone, metabolic rate increases to maintain constant body temperature. At colder temperatures, increased muscular activity and shivering require increased metabolic rate. Sweating and panting can increase the rate of metabolism at high temperatures. To compare the metabolic rates of endothermic homeotherms, scientists measure the basal metabolic rate (BMR), which is also referred to as the energy cost of living.

Body size (mass in grams or kilograms) is another major factor that affects basal or standard metabolic rate. A 3,800-kilogram elephant has a metabolic rate of about 1,340 kilocalories per hour, while a 2.5-kilogram cat has a rate of 8.5 kilocalories per hour, which means an elephant needs about 150 times as much food as a cat each day. A different picture emerges if one looks at energy use per kilogram of mass. For each kilogram of mass, the cat actually uses ten times the energy of a kilogram of elephant. Metabolism per unit of mass (specific metabolism) decreases as body size increases for all organisms. Since small organisms or cells have a larger surface area relative to their total volume than large ones, they can lose more heat from the surface. For two organisms of the same mass, the taller or thinner organism will have a larger surface area and higher BMR than a shorter, fatter one. More oxygen, food, and waste products can diffuse across the larger surface area; thus cell size in single-celled organisms and in different types of cells in multicellular organisms is limited by rate of energy metabolism. Small animals move faster, breathe faster, and their hearts pump faster. A mouse has a heart rate of six hundred beats per minute, while an elephant's heart rate is thirty beats per minute. Even the length of life appears to be related to the faster metabolic rate of these small creatures. Mice live only two to three years, while an elephant can live sixty years or longer.

Age and sex also influence basal metabolism. Young animals that are growing rapidly have a higher BMR than adults. As adults age, the proportion of skeletal muscle decreases and the BMR declines. Muscle tissue is metabolically very active even at rest, contributing to the higher BMR in males as opposed to females, since males have a higher proportion of body mass that is muscle. Physical or emotional stress can increase metabolic rates by increasing the catabolism of fats through the action of the hormones epinephrine and norepinephrine.

Skeletal muscle activity causes rapid short-term increases in metabolic rate. In humans, for example, a few minutes of vigorous exercise causes a twentyfold increase in the rate of metabolism, and the metabolic rate remains high for several hours. Walking, swimming, running, and flying require more energy than sitting still; however, each of these activities influences metabolic rate differently. Water is denser and has higher viscosity and resistance to movement compared to air, so more energy must be expended to swim than to walk at a given speed. Running also increases energy use, and the faster one runs, the more energy is required. Large animals, however, increase their rate of metabolism less per kilogram of mass than do small animals, so there is a metabolic advantage to large body size. Intriguingly, for the same size animal, flying is less energy-expensive than running.

Measuring Metabolism

Rate of metabolism can be measured as the amount of heat produced by an organism in a time period. The traditional unit of heat is the calorie; a kilocalorie is one thousand calories. The two terms are frequently confused in popular literature. In the international system of units, heat is measured in joules, and 1 calorie is equal to 4.184 joules.

Metabolic rate can be determined from the energy budget of an animal. If the total energy excreted in urine and feces is subtracted from the total energy in food eaten during a period of time, the result would be a measure of metabolic rate. The energy content of food and waste products can be determined by burning these materials in a calorimeter. The amount of heat produced is used to raise the temperature of a known amount of water. This method assumes that the organism is not growing or changing the amount of fat stored during the measurement period. It is also difficult to control metabolic activity of gut microorganisms. Although this technique is cumbersome, it may be the best way to assess energy metabolism in a normally active state for animals in their natural habitat.

More controlled measures of basal and standard metabolism can be made by isolating the animal in a calorimeter and directly measuring heat produced. This method is more accurate than the energy budget approach but still assumes that no new molecules are being produced and no activity or work is being performed. This technique is most useful for birds and small mammals that have relatively high rates of metabolism. Normal behavior and function may be altered by the confined conditions.

Indirect calorimetry is the most often used method in assessing metabolic rate in whole organisms, isolated cells, and cell components. Some factor related to energy use, such as oxygen consumed or carbon dioxide produced, is measured as an index of energy use. For aerobic metabolism, the amount of heat produced is related to oxygen use by the organism. Respirometry is the method used to monitor the oxygen used and carbon dioxide produced by an organism in a closed chamber. Oxygen consumption can be measured by absorbing carbon dioxide with soda lime and measuring the change in gas pressure in the closed system by a manometer. Oxygen electrodes can also be used to measure the decrease in oxygen concentration in water within the chamber if the animal is a water-dweller. For air-breathing animals, oxygen in the gas phase can be measured by a mass spectrometer. Carbon dioxide can also be measured by an infrared unit. In such closed systems, the gases can be monitored in the air as it enters and leaves the chamber. Respirometry can also be accomplished in open systems if the animals are fitted with breathing masks and the respired air is collected and analyzed. Oxygen consumption is a good index of metabolic rate for most animals at rest, since most of their metabolism is aerobic. Animals that live in oxygen-poor environments, such as internal parasites and mud-dwelling invertebrates, and all animals under extreme exercise often metabolize anaerobically.

To translate the amount of oxygen used into heat produced, one must know the proportion of fat, carbohydrate, and protein in the diet, since the amount of heat produced for each liter of oxygen consumed differs. In practice, it is usually assumed that only carbohydrates are being used.

Assimilating and digesting food cause large increases in metabolic rate. This increase reaches a maximum about three hours after a meal and remains above basal level for several hours in birds and mammals and up to several days in poikilotherms. Foods differ in the amount of increase in metabolic rate. Proteins, for example, cause about three times the increase in rate compared to carbohydrates or fats. The increase partially results from increased activity in cells of the digestive tract and partly from higher activity of liver and muscle cells preparing these foods for storage. Basal metabolism must then be measured after a twelve-hour fast to minimize this effect.

Since body temperature, body size, and activity affect metabolic rate of organisms, one can see that available food supplies, oxygen levels, and environmental temperatures limit the physiology of energy metabolism in different habitats. Scientists study metabolic rates in whole organisms to explain their food habits and their distributions in different habitats and to calculate energy requirements for raising animals under different conditions.

METAMORPHOSIS

Types of animal science: Development, physiology
Fields of study: Biochemistry, entomology, invertebrate biology, zoology

Metamorphosis is the major change in body form that occurs after embryonic development is complete in many types of animals, including insects.

Principal Terms

- CORPORA ALLATA: a gland in insects that synthesizes and secretes juvenile hormone (JH)
- ECDYSONE: a hormone that triggers both molting and metamorphosis in insects as well as in many other species of animals
- IMAGINAL DISK: flat sheets of cells within an insect larva; these cells will change shape during metamorphosis and form the external structures of the adult
- JUVENILE HORMONE (JH): a species-specific hormone which controls whether a molt will produce a larger larva or initiate metamorphosis
- LARVA: the reproductively immature feeding stage in the development of many species of animals, including those insects which undergo complete metamorphosis
- NYMPH: the sexually immature feeding stage in the development of those insects which undergo incomplete metamorphosis
- PROTHORACIC GLAND: the gland where ecdysone is made in insects
- PROTHORACICOTROPIC HORMONE (PTTH): a hormone made in the brain of insects which stimulates the prothoracic gland to make ecdysone
- PUPA: the stage of insect development during which metamorphosis occurs

Unlike mammals, most animals become adults by first going through a distinctly different immature, or larval, stage of development. Larvae look nothing like the adults they will form. They are specialized primarily for growth and feeding and are unable to reproduce. At a certain time in their growth, often in response to signals from hormones or the environment, the larva undergoes a second spurt of development called metamorphosis.

The word “metamorphosis” comes from the Greek word for transformation and is today defined as a major change in body form that occurs after embryonic development is completed. Metamorphosis is very widespread in the animal kingdom but it has been studied most thoroughly in three different groups of organisms: the arthropods (crabs, lobsters, and insects), the amphibians (frogs and salamanders), and the echinoderms (sea urchins and starfish).

Metamorphosis affects the ways animals eat, breathe, and move; it can also change the nature of the environment in which they live. In echinoderms, the larval stage is microscopic and free swimming, while the adults are large and move very little if at all. The changes in body form thus coincide with significantly different ways of feeding and moving.

Amphibian Metamorphosis

In amphibians, metamorphosis prepares the organism for its transition from living in water to living on land. Internally, the digestive system changes to accommodate the new diet as the animal switches from consuming plants to animals. Sense organs like the eyes and ears also change to adapt to functioning predominantly in air. Finally, many of the chemical reactions which occur in the individual cells of the frog also change at this time.

Metamorphosis in amphibians is controlled by a pair of hormones. Prolactin, a protein secreted by the anterior pituitary gland, controls the rate of growth of the tadpole and suppresses metamorphosis. Thyroxine is a modified amino acid made in the thyroid gland of the tadpole and causes metamorphosis to begin. After the tadpole has grown to a certain minimal size, the thyroid gland is stimulated by environmental conditions to produce large quantities of thyroxine, which reverses the suppression exerted by prolactin and begins metamorphosis. The hormones pass through the tadpole's circulation and instruct different tissues to activate and deactivate different sets of genes that cause some tissues to degenerate, others to change, and others to grow.

These same hormones, prolactin and thyroxine, are produced by other vertebrates; nature often uses the same molecules to produce very different results in different animals. In humans, thyroxine regulates the rate of metabolism, while prolactin is crucial for milk production in nursing women. In fish, however, prolactin is crucial for keeping the cell's content of salt in balance.

Insect Metamorphosis

The hormonal control of metamorphosis in one group of animals, the insects, has yielded basic information about how genes and hormones interact to guide development in all animals. This process is understood in greater detail in insects than in any other group of animals.

Insects, like all arthropods, have a rigid exoskeleton, called a cuticle, that supports their body mass and allows the attachment of muscles for movement. Because it is external and fixed in size, however, the cuticle must be shed periodically for growth to occur. The process of insects shedding their cuticle and producing a new, larger one is called molting, and the number of molts normally occurring is regulated by the insect's genes. Many insects have developed complex behaviors to ensure that they molt in a secluded location and avoid predation. Without their hard, external covering, they are relatively defenseless.

About 10 percent of all insect species, such as the grasshoppers and true bugs, go through a process of incomplete metamorphosis. Here, the egg hatches into a juvenile form called a nymph that resembles the adult but is much smaller and is not capable of reproduction. At each molt, the nymph sheds its cuticle and grows before the newly produced cuticle hardens. When the signal for metamorphosis arrives, the molt produces an adult, often with wings, but, more important, fully capable of reproduction. Male and female adults can then mate and lay a new generation of eggs.

Complete metamorphosis, on the other hand, is a very different process that is undergone by 90 percent of all species of insects, including the ants, bees, flies, butterflies, and moths. Here, the larval form looks nothing like the adult. For example, the larval form of a butterfly is a caterpillar and the larval form of a fly is a wormlike maggot. Each

When an insect nymph undergoes metamorphosis within a chrysalis, its tissues completely break down into a kind of sludge, which is reformed under the directions of cellular imaginal discs. (Digital Stock) larva undergoes a series of molts so as to be able to grow. The larva of the cecropia moth increases in mass by five thousand times during its larval development. When the trigger for metamorphosis occurs, the insect undergoes a radical change. The larva stops feeding and moving, anchors itself to a twig, leaf, or rock, and either spins a cocoon or encloses itself in its own hardened cuticle.

Silkworm Metamorphosis

The silkworm, *Bombyx mori*, undergoes complete metamorphosis, and its development begins when the egg hatches and includes five distinct larval stages. Each stage is larger than the one preceding as the larva eats, voraciously consuming several times its own body weight in food each day. At the end of the fifth larval stage, the molting event that follows is very different from the previous larval molts as the caterpillar spins a cocoon made out of silk (which is the commercially valuable product of this organism) and becomes a pupa. The next molt occurs within the pupal case when metamorphosis begins. When the adult has formed, the cocoon breaks open and the adult emerges to begin reproduction.

Metamorphosis involves the complete replacement of one body form with another. Inside the pupal case, the larval tissues break down and their molecules are reutilized in the construction of the cells and tissues of a very different looking animal, the adult. Certain groups of cells, called imaginal disks, along with the larval brain are generally the only tissues that are not broken down in this process. Opening a cocoon at this time shows that it is filled with a white, milky sap and little else as the caterpillar has been completely broken down.

The imaginal disks, round, flat sheets of cells, begin to evert or "telescope" and form the external structures characteristic of the adult cuticle. There is an imaginal disk for each eye, for each antenna, for the two or four wings, and for each of the six legs. These structures attach and the adult insect is constructed. In the well-studied fruit fly, *Drosophila*, this process takes about a week, while it can take months for other insects.

Hormonal Regulation of Metamorphosis

In insects, three very different hormones combine to regulate the timing of both molting and metamorphosis. Each of these three hormones is produced in a different tissue, and each has a different chemical structure and mode of function. The signal to molt originates in a small group of cells within the caterpillar's brain in response to neural or environmental signals. The hormone produced there, prothoracicotropic hormone (PTTH), is a small protein that passes through the insect's hemolymph (blood) to all parts of the body. As is true of all hormones, only certain target tissues are genetically programmed to respond to the production of this hormone. In this case, the prothoracic gland responds by producing a second hormone called ecdysone, the molting hormone. Ecdysone is a steroid, a chemical derivative of the cholesterol that the insect requires in its diet. Ecdysone is not actually the molting hormone itself, but must first undergo some minor chemical changes before it becomes active. More important, ecdysone and its derivatives are the molting hormone not only for all insects, but for all arthropods and many other animals. This chemical signal thus evolved before divergence of these organisms from a common ancestor.

Different tissues respond differently to ecdysone, but the hormone's major effect is to trigger molting by causing the hardening of the cuticle and the separation of the living cells beneath the cuticle from it. The cuticle then dries and cracks and the larva can then emerge from its old skin and grow. If PTTH production stops, the amount of ecdysone released from the prothoracic gland also falls. This happens normally in the period between molts, but can also occur during a molt. In cecropia moths, the level of PTTH drops during the pupal stage and the subsequent drop in ecdysone production causes diapause, a programmed pause in development. The pupa will remain in diapause until an environmental signal, consisting of a minimum of two weeks in the cold followed by a normal spring warming, triggers the resumption of PTTH secretion and the completion of metamorphosis.

Ecdysone acts specifically on certain groups of insect genes and not others. Many genes required for larval functions are turned off in response to ecdysone, while those genes required for molting and metamorphosis are turned on. This effect can be seen when imaginal disks are placed in a culture dish along with physiological levels of ecdysone. The disks stop growing and begin metamorphosis. Such development can even produce normal-looking legs floating free in a culture dish. The changes in shape of the disk cells can be directly attributed to the function of genes turned on by ecdysone.

The hormone ecdysone therefore not only causes metamorphosis, but also triggers certain simple molts. The third hormone involved in the control of metamorphosis is responsible for this choice, the choice to molt and grow or to undergo metamorphosis to the adult form. This compound is called juvenile hormone (JH). JH is produced in a gland called the corpora allata, and the hormone has yet a third chemical structure, a derivative of a class of molecules called terpenes. Unlike ecdysone, however, the JH of each species has a different chemical structure.

When a molt is triggered by the production of ecdysone, the type of molt that occurs will be determined by the level of JH present. During larval development, the amount of JH in the hemolymph is high and the tissues respond to ecdysone by undergoing a molt to become a larger larva. Later in development, the corpora allata stops producing JH and any new molt triggered by ecdysone causes the organism to proceed to the pupal stage and begin metamorphosis. The interaction of ecdysone and JH thus governs which type of molt will occur.

Although these hormones are crucial for controlling molting and metamorphosis, they play other roles as well. For example, adult female insects produce large quantities of ecdysone and adult males do not because ecdysone is important to egg production.

Laboratory Studies of Metamorphosis

Various parts of the elaborate interplay of the three hormones that regulate metamorphosis in insects were discovered in a number of laboratories. The role of ecdysone was discovered first by Carroll Williams and Vincent Wigglesworth, who found that the prothoracic gland of the larva was responsible for producing a substance that triggered metamorphosis. They tied a fine string around the middle of a cecropia larva and observed that only the front half underwent metamorphosis. The signal was thus produced somewhere in the front half and could not reach the rear of the insect. The prothoracic glands were later discovered to be the source of the molting signal when glands transplanted to the rear half of a ligated larva caused metamorphosis to occur there as well.

Ecdysone was painstakingly purified and chemically identified by Peter Karlson's group in Germany. In a monumental effort, they extracted twenty-five milligrams of pure ecdysone from a ton of silkworms. Much of the difficulty encountered in this isolation stemmed from the lack of an easy method for identifying the presence of ecdysone in the extract they were producing.

A tedious and relatively insensitive bioassay was used. In this assay, the extract to be tested during the isolation was dissolved in an organic solvent and painted on the cuticle of an insect. If the extract contained ecdysone, the larva would begin to molt. Although time-consuming and not very reproducible, the bioassay allowed the purification of ecdysone from insects.

The role of the corpora allata and JH was found by a similar set of experiments. Wigglesworth found that if he decapitated a fourth-stage Rhodnius nymph and sealed the body with wax to that of a decapitated fifth-stage nymph, the insects could survive for a long period of time. This technique is called parabiosis. The mature nymph never underwent metamorphosis but rather molted in response to its own ecdysone or to ecdysone painted on its cuticle to form a larger nymph. Once again, tissue transplantation experiments showed that the hormone coming from the immature nymph that prevented metamorphosis was produced by the corpora allata. Removing the corpora allata from a larva or nymph caused either death or premature metamorphosis to the adult stage.

The role played by PTTH was also elucidated by a similar set of surgical experiments. Removing the brain of a larva prevented the production of ecdysone from the prothoracic gland so long as the removal occurred before the brain released the PTTH. After the PTTH signal was released, removing the brain had no effect on the subsequent production of ecdysone for that molt.

Today, the presence and amount of the three hormones are measured by easy, sensitive, and highly reproducible immunological techniques. In these procedures, antibodies, proteins having the chemical ability to bind tightly to a specific insect hormone, are produced. If an extract contains one of these hormones, adding its specific antibody will cause the hormone to bind to the antibody, and the amount of bound antibody can be accurately measured in a number of different ways.

These immunological procedures have allowed researchers to monitor the changing levels of the three hormones during the development of any insect and to correlate these changes with the progress of metamorphosis. Coupled with new information about the ability of hormones to turn genes on and off directly, these procedures have advanced the understanding of the mechanisms of control of metamorphosis at the molecular level.

Raven, Peter H., and George B. Johnson. *Biology.* 6th ed. St. Louis: Times Mirror/Mosby, 2001. A good, introductory college-level text that is also suitable for high school students. Metamorphosis in insects and other animals is clearly discussed with very good diagrams (pages 836-838) that show insect development and the roles played by insect hormones. Glossary.

MICE AND RATS

Types of animal science: Behavior, classification, ecology
Fields of study: Ecology, physiology

House mice and Norway rats are found worldwide and almost always are found related to humans and human activities. No other mammals are greater pests than are mice and rats.

Principal Terms

ALTRICIAL: born in a helpless state and completely dependent on the parent(s)
COMMENSAL: living in close association with humans; the word means "sharing the table"
OMNIVOROUS: eating all kinds of food, both plant and animal
RODENTS: the gnawing mammals characterized by specialization of the incisor teeth into gnawing teeth

Although there are many types of mouse and rat, the words most often are used to refer to the house mouse, *Mus musculus*, and the Norway rat, *Rattus norvegicus*. These two species belong to a family of rodents known as the Muridae, the Old World mice and rats, and there are over 450 species within this group. Both species underwent their early evolution in the wilds of Asia. As humans appeared and began to settle in farms and villages, mice and rats became associated with them. As humans migrated to other parts of the world and as commercial exchanges took place around the world, mice and rats went along for the ride and became established in the Old World and the New World, and today may be found almost any place on earth where humans are found.

At birth, mice and rats are unimposing animals, as the pups are born in an altricial state and are naked, sightless, and helpless. They develop rapidly, however, and by three weeks of age are weaned from their mother. By 1.5 to 2 months of age for the mouse, and 2 to 3 months of age for the rat, they are sexually mature. Their powers of reproduction are phenomenal and many litters, some containing more than a dozen young, can be produced in a single year. A single female mouse may produce over one hundred young in one year.

As adults, mice and rats still are not imposing. They have a long, scaly, scantily haired tail, and are a grayish brown color, which is somewhat paler in the belly. Although they have poor sight, their senses of smell, hearing, and taste are all excellent.

The Good and Bad of Mice and Rats

All of the other mammalian species combined, as well as all other animals, do not cause as much damage and destruction to humans as do mice and rats. The two species have been able to adjust to living with and near humans and their habitations. Their diets are omnivorous and include all types of foods, grains, and grain products. They can climb, burrow, and swim, and can invade nearly all buildings, houses, barns, warehouses, and other structures. As a result, they cause billions of damage each year around the world. Human food is eaten or destroyed by contamination with urine and feces. The urine may contain bacteria, causing diseases such as leptospeosis. Food poisoning may be caused by salmonellosis in their feces. Many children and some adults are bitten each year by rats, especially in rundown urban areas. Even those mice and rats that live under semi-wild conditions may affect humans in their effect on other wildlife. Ground-nesting birds and the young of other animals are susceptible to predation by mice and rats. The costs of these pests to humans is tremendous.

Some consolation for having to deal with the extensive bad side of mice and rats may be found in their beneficial use as laboratory animals. Both species are used widely in medical and genetic research. The mouse has been used to elucidate many basic principles of genetics, and today, its many genetic variants serve as models for many human disorders, including genetic diseases and cancer. As studies define the human genome, similar studies are defining the mouse and rat genomes. The laboratory rat, although not as

Mouse and Rat Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Theria
Infraclass: Eutheria
Order: Rodentia
Suborder: Myomorpha
Family: Muridae, with fifteen subfamilies, 241 genera, and 1,082 species

Geographical location: Worldwide, through introduction by humans

Habitat: Occurs in highly varied habitats, usually in association with humans

Gestational period: Nineteen to twenty-two days, although this may be lengthened in nursing females due to delayed implantation

Life span: Around one year in the wild; laboratory rats and mice may live three to four years or longer

Special anatomy: The scantily haired tail helps to distinguish house mice and Norway rats from most other types of mice and rats

Image Not Available

genetically well known as the mouse, has been used extensively in physiological and psychological research.

It is unlikely that humans will ever be able to eliminate completely mice and rats and control their destruction, but it also is unlikely that their importance to both basic and applied science will ever be diminished, at least in the foreseeable future.

MIGRATION

Type of animal science: Behavior
Fields of study: Biophysics, ethology, neurobiology, marine biology, ornithology

Migration is an important ecological process that results in the redistribution of animal populations from one habitat to another. Adaptive habitat changes are fundamentally important aspects of the life histories of many species.

Principal Terms

BIOLOGICAL CLOCK: an inherent sense of timing regulating certain types of behavioral activity such as migration

CLOCK SENSE: an inherent awareness of time or time intervals used, for example, to compensate for celestial movements in navigation

DISPERSAL: the spreading apart of individuals away from one another and away from a place; includes a directional component when passive animals are moved by winds or currents

HABITAT: a specific, recognizable geographical region in which a particular kind of organism lives

MIGRANT: a group or species of animal that moves from one habitat or geographical region to another

NAVIGATION: to follow or control the course of movement from the place of origin to a specific destination

NOMADS: migrants without a specific habitat; wanderers

ORIENTATION: an inherent sense of geographical location or place in time

POPULATION: a group of individuals of the same species geographically located in a given habitat at the same time

Migration is a general term employed by ecologists and ethologists to describe the nearly simultaneous movement of many individuals or entire populations of animals to or between different habitats. As defined, migrations do not include local excursions made by individuals or small groups of animals in search of food, to mark territorial boundaries, or to explore surrounding environments.

Nomads are migrants whose populations follow those of their primary food sources. Such animals (the American bison, for example) do not have fixed home ranges and wander in search of suitable forage. Some scientists view nomadic movements as a form of extended foraging behavior rather than as a special case of migration. In either context, the important point is that populations change habitats in response to changing conditions.

In contrast to migrations made by populations and excursions made by individuals, the spreading or movement of animals away from others is known as dispersal. Examples of dispersal include the drift of plankton in currents and the departure of subadult animals from the home range of their parents. In numerous species (sea turtles, rattlesnakes, and salmon, for example), dispersed members of a population may return to the place of origin after a variable interval of time.

Means and Reasons

Some migratory species can orient themselves—that is, they know where they are in time and space. Many birds and mammals, for example, have an inherent sense of the direction, distance, and location of distant habitats. Orientation and travel along unfamiliar routes from one place or habitat to another is called navigation. Navigators use environmental and sensory information to reach distant geographical locations, and many of them do so with a remarkably accurate sense of timing. Homing pigeons are perhaps the best-studied animal navigators. These birds are able not only to discover where they are when released but also to return to their home loft from distant geographical locations.

Much has been learned about how animals successfully navigate over long distances from the pioneering studies of Archie Carr. Carr proposed that green sea turtles successfully find their widely separated nesting and feeding beaches by means of an inherent clock sense, map sense, and compass sense. His investigations and those of many others continue to stimulate great interest in the physiology and ecology of navigating species and in the environmental cues to which they respond. Sensory biologists, biophysicists, and engineers have incorporated knowledge of how animals detect and use environmental information to develop new and more accurate navigational systems for human use.

Animals use a variety of cues to locate their positions and appropriate travel paths. Most species have been found to use more than one type of information (sequentially, alternatively, or simultaneously) to navigate. Among the animals known to navigate are birds (the best-studied group), lobsters, bees, tortoises, bats, marine and terrestrial mammals, fish, brittle starfishes, newts, toads, and insects. Included among the orientation guideposts that one or more of these groups may use are the positions of the sun and stars, magnetic fields, ultraviolet light, tidal fluctuations caused by the changing positions of the moon and sun, atmospheric pressure variations, infrasounds (very low frequency sounds), polarized light (on overcast days), environmental odors, shoreline configurations, water currents, and visual landmarks. Celestial cues also require a time sense, or an internal clock, to compensate for movements of the animal relative to changing positions of celestial objects in the sky. In addition to an absolute dependence on environmental cues, young or inexperienced members of some species may learn navigational routes from experienced individuals, such as their parents, or other experienced individuals in the population. Visual mapping remembered from exploratory excursions may also play a role in enhancing the navigational abilities of some birds, fish, mammals, and other animals.

The different categories of animal movements, however, are perhaps not so important as the reasons animals migrate and the important biological consequences of the phenomenon. As a general principle, migrations are adaptive behavioral responses to changes in ecological conditions. Populations benefit in some way by regularly or episodically moving from one habitat to another.

An example of the adaptive value of migratory behavior is illustrated by movement of a population from a habitat where food, water, space, nesting materials, or other resources have become scarce (often a seasonal phenomenon) to an area where resources are more abundant. Relocation to a new habitat (or to the same type of habitat in a different geographical area) may reduce intraspecific or interspecific competition, may reduce death rates, and may increase overall fitness in the population. These benefits may result in an increase in reproduction in the population. Reproductive success, then, is the significant benefit and the only biological criterion used to evaluate population fitness.

Programmed and Episodic Movements

While many factors are believed to initiate migratory events, most fall into one of two general categories. The first and largest category may be called programmed movements. Such migrations usually occur at predictable intervals and are important characteristics of a species' lifestyle or life cycle. Programmed migrations are not, in general, density-dependent. Movements are not caused by overcrowding or other stresses resulting from an excessive number of individuals in the population.

The lifestyle of a majority of drifting animals whose entire lives are spent in the water column, for example, includes a vertical migration from deep water during the day to surface waters at

Bird migrations are among the most noticeable animal migrations, with huge flocks passing through the skies on their way to a seasonal home. (Corbis)

night. Thus, plankton exhibit a circadian rhythm (activity occurring during twenty-four-hour intervals) in their movements. An abundance of food at or near the surface, and escape from deep-water predators, are among the possible reasons for these migrations. Daily vertical movements of plankton are probably initiated by changes in light intensity at depth, and the animals follow light levels as they move toward the surface with the sinking sun. It is interesting to note that zooplankters living in polar waters during the winter-long night do not migrate.

Monarch butterflies and many large, vertebrate animals, such as herring, albatross, wildebeests, and temperate-latitude bats, migrate from one foraging area to another, or from breeding to foraging habitats, on a seasonal or annual basis. Annual migrations usually coincide with seasonal variation. Changes in day length, temperature, or the abundance of preferred food items associated with seasonal change may stimulate mass movements directly, or indirectly, through hormonal or other physiological changes that are correlated with seasonal environmental change. The onset of migration in many vertebrates is evidenced by an increase in restlessness that seems, in human terms, to be anticipatory.

In addition to their daily vertical migrations (lifestyle movements), the life cycles of marine zooplankton involve migrations, and it is convenient to use them as examples. As discussed, most adult animal plankters are found at depth during the day and near the surface at night. In contrast, zooplankton eggs and larvae remain in surface waters both day and night. As the young stages grow, molt, and change their shapes and food sources, they begin to migrate vertically. The extent of vertical migrations gradually increases throughout the developmental period, and as adults, these animals assume the migratory patterns of their parents. Patterns of movement that change during growth and development are examples of ontogenetic, or life-cycle, migrations.

The second large category of migratory behavior includes episodic, density-dependent population movement. Such migrations are often associated with, or caused by, adverse environmental changes (effect) that may be caused by overlarge populations (cause). Local resources are adequate to support a limited number of individuals (called the “carrying capacity” of the environment), but once that number has been exceeded, the population must either move or perish. Unfortunately, migration to escape unfavorable conditions may be unsuccessful, as another suitable habitat may not be encountered. Migrations caused by overpopulation or environmental degradation are common. Pollution and habitat destruction by humankind’s activities are increasingly the cause of degraded environments, and in such cases, it is reasonable to conclude that humans have reduced the carrying capacity of many animal habitats. Familiar examples of density-dependent migrations are those of lemmings, locusts, and humans.

Studying Migration

Methods used by scientists to study the mass movements of animals are quite varied and depend on the investigator's research interests and on the kinds of organisms being investigated. Environmental or physiological factors that initiate migrations may be of interest to sensory biologists and physiological ecologists; knowledge of variation in population distributions is important to biogeographers and wildlife biologists; and migrations in predator-prey relationships, competition, pollution, and life-history strategies are important aspects of classical ecological studies.

In addition to the specific aspect of migration being studied, the particular group of animals under investigation (moths, eels, elephants, snails) requires that different methods be used. Some of the approaches used in migration-related research illustrate how information and answers are obtained by scientists.

Arctic terns migrate from their breeding grounds in the Arctic to the Antarctic pack ice each year. The knowledge that these birds make a twenty-thousand-mile annual round-trip comes from the simplest and most practical method: direct observation of the birds (or their absence) at either end of the trip. Direct observation by ornithologists of the birds in flight can establish what route they take and whether they pause to rest or feed en route. Many birds have also been tracked using radar or by observations of their silhouettes passing in front of the moon at night. Birds are often banded (a loose ring containing coded information is placed on one leg) to determine the frequency of migration and how many round-trips an average individual makes during its lifetime. From this information, estimates of longevity, survivorship rates, and nesting or feeding site preferences can be made.

Factors that initiate migratory behavior in terns and in other birds can often be determined by ecologists able to relate environmental conditions (changes in temperature, day length, and the like) to the timing of migrations. Physiological ecologists study hormonal or other physiological changes that co-occur with environmental changes. Elevated testosterone levels, for example, may signal the onset of migratory behavior.

How Arctic terns orient and navigate along their migratory routes is usually studied by means of laboratory-conducted behavioral experiments. Birds are exposed to various combinations of stimuli (magnetic fields, planetarium-like celestial fields, light levels), and their orientation, activity levels, and physiological states are measured. Experiments involving surgical or chemical manipulation of known sensory systems are sometimes conducted to compare behavioral reactions to experimental stimuli. In such experiments, the birds (or other test animals) are rarely harmed.

Tags of several types are used to study migrations in a wide variety of animals, including birds, bees, starfishes, reptiles, mammals, fish, snails, and many others. Tags may be transmitting collars (located by direction-finding radio receivers); plastic or metal devices attached to ears, fins, or flippers; or even numbers, painted on the hard exoskeleton of bees and other insects. Additional types of tagging (or identifying) include radioactive implants and microchips that can be read by computerized digitizers; the use of brands and tattoos; and, of great interest, the use of biological tags. Parasites known to occur in only one population of migrants (nematode parasites of herring, for example) provide an interesting illustration of how the distribution of one species can be used to provide information about another.

The Importance of Migration

The causes, frequency, and extent of animal migration are so diverse that several definitions for the phenomenon have been proposed. None of these has been accepted by all scientists who study animal movements, however, and it is sometimes difficult to interpret what is meant when the term "migration" is used. Most researchers have adopted a broad compromise to include all but trivial population movements that involve some degree of habitat change.

It is important to recognize that few populations of animals are static; even sessile animals (such as oysters and barnacles) undergo developmental habitat changes, which are referred to as ontogenetic migrations. Aside from certain tropical and evergreen forest areas where migrations are relatively uncommon, a significant number of both aquatic and terrestrial species move from one habitat to another at some time during their lives. In the face of environmental change, including natural events such as seasonal variation and changes caused by resource limitations and environmental degradation, animals must either move, perish, or escape by means of drastic population reduction or by becoming inactive until conditions become more favorable (hibernation, arrested development and dormancy, and diapause in insects are examples of behavioral-ecological inactivity). Migration is the most common behavioral reaction to unfavorable environmental change exhibited by animals.

One cannot understand the biology of migrators until their distribution and habitats throughout life are known. The patterns of animal movements are fascinating, and it is useful to summarize some of the major differences between them. First, many species travel repeatedly during their lives between two habitats, on a daily basis (as plankton and chimney swifts do) or on an annual basis (as frogs and elks do). Second, some species migrate from one habitat (usually suitable for young stages) to another (usually the adult habitat) only once during their lives (for example, salmon, eels, damselflies, and most zooplankton, which live on the bottom as adults). Third, some species (many butterflies, for example) are born and mature in one geographical area (England, for example), migrate as adults to a distant geographical area (Spain, for example), and produce offspring that mature in the second area. These migrations take place between generations. In a fourth pattern, one may include the seasonal swarming of social arthropods such as termites, fire ants, and bees. A fifth but ill-defined pattern is discernible, exemplified by locust "plagues," irruptive emigration in lemmings and certain other rodents, and some mass migrations by humankind, as caused by war, famine, fear, politics, or disease. These are episodic and often, if not primarily, caused by severe population stress or catastrophic environmental change.

Bibliography

Able, Kenneth P., ed. *Gatherings of Angels: Migrating Birds and Their Ecology.* Ithaca, N.Y.: Comstock, 1999. A collection of essays by avian biologists on many aspects of a wide variety of bird migrations in the western hemisphere. Illustrations.

Aidley, David, ed. *Animal Migration.* New York: Cambridge University Press, 1981. An exceptionally well-written reference book covering all important aspects of animal migration. Contributing authors discuss major concepts in the ecology of migrations, as well as mechanisms of orientation and navigation in a variety of different animal groups. Emphasis is placed on birds, whales, fish, insects, and terrestrial mammals. Each chapter includes technical and general references. Suitable for college students and the general reader.

Begon, Michael, John Harper, and Colin Townsend. *Ecology: Individuals, Populations, and Communities.* 3d ed. Sunderland, Mass.: Sinauer Associates, 1996. One of the best modern textbooks in ecology. Presents a comprehensive overview of patterns of migrations using both familiar and exotic examples of different animal groups. Subject and taxonomic indexes, many references, outstanding illustrations. College or advanced high school level.

Dingle, Hugh. *Migration: The Biology of Life on the Move.* New York: Oxford University Press, 1996. Discusses a wide variety of animal movements, focusing on birds and insects. A good general reference. Numerous illustrations.

Eisner, Thomas, and Edward Wilson, eds. *Animal Behavior: Readings from "Scientific American."* San Francisco: W. H. Freeman, 1975. A collection of articles originally published in *Scientific American*. Includes many classic papers on ecological, physiological, and behavioral aspects of migration. Section 1 includes chapters on moths and ultrasound, the flight-control systems of locusts, and annual biological clocks. Habitat selection and homing behavior in pigeons and salmon are discussed in section 2. Clearly illustrated, very informative, and well written. Includes illustrations, a bibliography, and an index. College or general audience.

Newberry, Andrew, ed. *Life in the Sea: Readings from "Scientific American."* San Francisco: W. H. Freeman, 1982. A collection of articles published in *Scientific American*. Migrations of oceanic plankton are discussed in chapter 2. Chapter 16 focuses on migrations of the shad; biological clocks of the tidal zone are discussed with respect to migrations in chapter 19. As with all special-topic collections from *Scientific American*, each chapter is very informative and well illustrated. Includes a bibliography and an index. College or general audience.

Pyle, Robert Michael. *Chasing Monarchs: Migrating with Butterflies of Passage.* Boston: Houghton Mifflin, 1999. A well-known lepidopterist literally follows the migration of monarch butterflies from northern Washington state and Canada, south to their winter roosts in the mountains of Michoacan, in southwestern Mexico.

Rankin, Mary, ed. *Migration: Mechanisms and Adaptive Significance.* Port Aransas, Tex.: Marine Science Institute, University of Texas at Austin, 1985. A collection of scientific contributions presented at an international symposium on the subject of migrations. It is one of the most important and comprehensive monographs on the subject. Experimental and field approaches to the study of an extremely wide range of organisms are described, as are the evolutionary and ecological consequences and mechanisms of migration. The book was written by experts for other experts, but the book's organization and style make it an excellent source of further reading for high school and college students of biology. Includes many graphic illustrations, a general index, and topic bibliographies.

Reader's Digest Association. *The Wildlife Year.* Pleasantville, N.Y.: Author, 1993. Organized by month, covers stages in the yearly life cycles of 288 plants and animals, including seasonal migrations. Over four hundred photographs.

Schone, Hermann. *Spatial Orientation: The Spatial Control of Behavior in Animals and Man.* Translated by Camilla Strausfeld. Princeton, N.J.: Princeton University Press, 1984. Schone describes first the relationship between orientation, behavior, and ecology to provide the background for detailed discussions of types of orientation movements, sensory physiology, and the kinds of environmental information perceived and used by animals to direct their movements. An exhaustive treatment of the subject is presented, and the format is technical, but it should be understandable to advanced high school and college students with some background in biology.

MIMICRY

Types of animal science: Development, ecology, evolution
Fields of study: Ecology, evolution science, genetics, population biology

Mimicry is the process whereby one organism resembles another and, because of this resemblance, obtains an evolutionary advantage.

Principal Terms

ADAPTATION: a phenotype that allows those organisms that have it a competitive advantage over those that do not have it

CAMOUFLAGE: patterns, colors, and/or shapes that make it difficult to differentiate an organism from its surroundings

WARNING COLORATION: the bright colors seen on many dangerous and unpalatable organisms that warn predators to stay away

The broadest description of mimicry is when one organism, called the operator or dupe, cannot distinguish a second organism, called the mimic, from a third organism or a part of the environment, called the model. There are many different types of mimicry. Some mimics look like another organism; some smell like another organism; some may even feel like another organism. There are many ways that mimicking another organism could be helpful. Mimicry may help to hide an organism in plain sight or protect a harmless organism from predation when it mimics a harmful organism. It can even help predators sneak up on prey species when the predator mimics a harmless organism.

In the case of hiding in plain sight, the line between camouflage and mimicry is not sharply defined. Spots or stripes that help an organism blend with the surroundings are classified as camouflage, since those patterns allow the organism to remain hidden in many areas that have mixtures of sunlight and shadow, and the organism does not look like any particular model. As an organism's appearance begins to mimic another organism more and more closely, rather than being just a general pattern, it moves toward mimicry. As in all other areas of biology, there are arguments about where camouflage ends and mimicry begins. The stripes of a tiger and the spots on a fawn are certainly camouflage. The appearance of a stick insect is more ambiguous. Its body is very thin and elongated and is colored in shades of brown and gray. Is this mimicry of a twig or just very good camouflage? Many biologists disagree. The shapes and colors of many tropical insects, especially mantids, also fall into this gray area of either extremely good camouflage or simple mimicry.

Batesian and Müllerian Mimicry

In contrast to camouflage, which hides its bearers, many species of dangerous or unpalatable animals are brightly colored. This type of color pattern, which stands out against the background, is called warning coloration. Some examples are the black and white stripes of the skunk, the yellow and black stripes of bees and wasps, red, black, and yellow stripes of the coral snake, and the bright orange of the monarch butterfly. Several species of harmless insects have the same yellow and black pattern that is seen on wasps. In addition to mimicking the coloration of the more dangerous insects, some harmless flies even mimic the wasps' flying patterns or their buzzing sound. In each case, animals that have been stung by wasps or bees avoid both the stinging insects and their mimics. This mimicry of warning coloration

Image Not Available

is called Batesian mimicry. Batesian mimicry is also seen in the mimicry of the bright red color of the unpalatable red eft stage of newts by palatable salamanders. Sometimes two or more dangerous or unpalatable organisms look very much alike. In this case, both are acting as models and as mimics. This mimicry is called Müllerian mimicry. Müllerian mimicry is seen in monarch and viceroy butterflies. Both butterflies have in their bodies many of the chemicals found in the plants they ate as larvae. These include many unpalatable chemicals and even toxic chemicals that cause birds to vomit. If a bird eats either a monarch or a viceroy that has these chemicals, the bird usually remembers and avoids preying on either species again—a classic Müllerian mimicry. Interestingly, not all monarchs or viceroys are unpalatable. It depends on the types and concentrations of chemicals in the particular plants on which they fed as larvae. Birds that have eaten the palatable monarchs or viceroys do not reject either monarchs or viceroys when offered them as food, but birds that have eaten an unpalatable monarch or an unpalatable viceroy avoid both palatable and unpalatable members of both species. This represents both Batesian and Müllerian mimicry at work.

Aggressive Mimicry

Mimicry by predators is called aggressive mimicry. The reef fish, called the sea swallow, is a cleaner fish, and larger fish enter the sea swallow's territory to be cleaned of parasites. The saber-toothed blenny mimics the cleaner in both appearance and precleaning behavior, but when fish come to be cleaned, the blenny instead bites off a piece of their flesh to eat. Anglerfish have small extensions on their heads that resemble worms. They use the mimic worms to lure their prey close enough to be eaten. The alligator snapping turtle's tongue and the tips of the tails of moccasins, copperheads, and other pit vipers are also wormlike and are used as lures. Certain predatory female fireflies respond to the light flashes of males of a different species with the appropriate response of the female of that species. This lures the male closer, and when the unsuspecting male is close enough to mate, the female devours him. This mimicry is quite complex, because the predatory females are able to mimic the response signals of several different species.

There are many other instances of mimicry, but the world champion mimics may be octopuses. As predators, these animals show unbelievable aggressive mimicry of other reef organisms. Octopuses can take on the color, shape, and even texture of corals, algae, and other colonial reef dwellers. As a prey species, the octopus can use the same type of mimicry for camouflage, but can also be a Batesian mimic, taking on the color and shape of many of the reef's venomous denizens.

Since in each case, being a mimic helped the organism in some way, it is not hard to understand how mimicry may have evolved. In a population where some organisms were protected by being mimics, the protected mimics were the ones most likely to mate and leave their genes for the next generation while the unprotected organisms were less likely to breed.

—Richard W. Cheney, Jr.

MOLES

Types of animal science: Anatomy, classification, reproduction
Fields of study: Anatomy, reproduction, zoology

Moles spend most of their time in underground burrows, digging for food with specialized front paws. They perform a service to farmers by destroying grubs, caterpillars, and insects.

Principal Terms

BOLTRUN: mole burrow tunnel used as an emergency exit
GESTATION: time in which mammalian offspring develop in the uterus
MARSUPIAL: nonplacental mammal having a marsupium
MARSUPIUM: abdominal pouch containing mammary glands and sheltering offspring until they are fully developed

Moles inhabit Africa, Europe, Asia, North America, and Australia. They are voracious, continually burrowing in the ground for food, for a mole must eat its weight in food daily. This is accomplished by digging approximately twenty-five feet of burrow per hour. Mole burrows are close to ground surfaces and can cause surface ridges. A mole's home is also recognized by its large, central mound of earth. This mole hill is created from the earth dug up in the mole's search for food. There are twelve mole genera worldwide, five of which inhabit the United States.

Types of Moles

Moles have pointy snouts, rudimentary eyes, velvety fur, short legs, and powerful digging nails on their front legs. Moles are nearly or totally blind; however, their hearing is acute and they detect sounds from great distances. Common garden moles are six inches long with furless tails, and have huge forelegs whose broad, thick nails gouge out earth. The largest species in the United States, *Scapanus townsendii*, is nine inches long. Shrew moles, the smallest, are 3.5 inches long.

European moles inhabit grasslands and pastures in the British Isles, continental Europe, and Asia. They dig elaborate burrows that hold central chambers with round connected galleries. Passageways radiate in all directions from galleries (for example, there will be a boltrun exit in case of danger). Each burrow has a warmly lined nest

Mole Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Insectivora
Family: Talpidae, with twelve genera and twenty-nine species, including *Scalopus aquaticus* (common garden mole), *Scapanus townsendii* (largest U.S. mole), *Neurotrichus gobbsi* (shrew mole), *Talpa europaea* (European mole), *Condylura cristata* (star-nosed mole), *Notoryctes typhlops* (marsupial mole)
Geographical location: Europe, Asia, North America, and Australia
Habitat: Most inhabit grasslands and pastures, though some live in freshwater
Gestational period: Two to six weeks
Life span: Three to six years
Special anatomy: Huge forelegs with broad nails; leathery pads or tentacle rings covering nasal passages

Image Not Available

for the mole. Tunnels run from just below ground level to 2.5 feet deep and may be 170 feet long. European moles eat worms, beetle and fly larvae, and slugs. They are active day and night, alternating every four hours between digging or eating and resting, and they live alone except when mating.

Golden moles inhabit grassy forests, riverbanks, mountains, and semidesert areas of Africa. The smallest species is Grant's golden mole, 2.5 inches long, and the largest species is the giant golden mole, 9 inches long. Their golden fur repels water, keeping them dry while digging. When burrowing, leathery pads cover their noses, keeping dirt out. Burrowing allows foraging for insects, larvae, earthworms, crickets, slugs, snails, and spiders. Golden moles cannot see well and find food by touch. Sometimes they come to the surface (for mating, as an example). They live alone and defend their homes when other moles—even others of their own species—intrude.

Star-nosed moles, of eastern Canada and the northeastern United States, are black-furred, five inches long (excluding the tail) and weigh three ounces. They live near water, swim well, and dig in soil along shorelines. They burrow day and night, foraging for earthworms, aquatic insects, fish, and mollusks. Their nose tips hold a twenty-two-tentacle, touch-sensitive star which is their main sense organ. Star-nosed moles are solitary.

The Australian central desert holds the only species of marsupial mole. Their bodies range from 2.5 to 8.5 inches long, and they weigh from 0.3 to 6 ounces. Like other moles, they have short legs and front paws holding digging claws. A bare patch of skin atop each mole's nose pushes aside dirt as it digs. They have yellow fur, small nose slits, and no functioning eyes.

Marsupial moles burrow in soil near rivers and grasslands in Australian desert. While burrowing, they eat moths and beetle larvae. They do not dig permanent burrows but travel widely, sleeping in temporary burrows. They are solitary and their females have marsupiums, to carry young.

Life Cycles of Moles

Life cycles are best known for the star-nosed, European, and golden moles. Male and female star-nosed moles mate between February and April. The female builds a nest of leaves and moss in her burrow and has two to seven furless, blind, helpless young after a six-week gestation. They develop quickly, leave the nest in three weeks, and can mate after ten months.

Male European moles enter the tunnels of females to mate. After a five-week gestation, three to seven blind, hairless young are born. The young grow fur, open their eyes, and leave the nest in five weeks. European moles live for three years.

Male golden moles wishing to mate can attract mates at any time of the year. Litters contain two to three hairless young. They are two inches long, blind, and weigh less than one ounce. After nursing, when they weigh about 1.5 ounces, the young leave the nest for good.

Moles are considered to be pests by farmers and home gardeners, who think they eat plant roots and kill crops. However, moles never eat plants and perform a real service by killing grubs, caterpillars, and insects. Nonetheless, farmers, gardeners, and people with lawns consider them nuisances and poison them or set traps in their tunnels because they "spoil gardens and fields."

MOLLUSKS

Type of animal science: Classification
Fields of study: Anatomy, invertebrate biology, physiology

Mollusks, the phylum Mollusca, have soft, boneless bodies. Most also have shells. There are fifty thousand species of mollusks, including snails, oysters, and clams.

Principal Terms

FOOT: bottom portion of gastropods, on which they walk; it subdivides into tentacles in cephalopods

HERMAPHRODITE: an organism having both male and female reproductive systems

MANTLE: the outermost living tissue of mollusks; it makes shells, mother-of-pearl, and pearls

RADULA: a tonguelike, toothed organ used to grind food or drill holes in shells of prey

SESSILE: an organism incapable of moving from its point of origin

Mollusks first appeared in early Cambrian times, 650 million years ago. They are the second largest animal phylum, Mollusca (from Latin *mollis*, "soft"). The only larger animal phylum is Arthropoda. According to current estimates, there are approximately 49,000 mollusk species. All mollusks have soft, boneless bodies. Most have shells, though some shells are poorly developed and are even absent in some cases. Mollusk shells are like coats of armor.

Mollusks form seven classes. Best known are gastropods, including approximately 38,000 species of snails and slugs; bivalves or pelecypods, approximately 8,000 species of clams and scallops; cephalopods, approximately 600 species of squid and octopuses; and polyplacophora, approximately 600 species of chitons. The other classes contain under 1 percent of mollusk species and are not discussed.

Mollusks are present in all of earth's habitats. However, most of them, comprising the greatest species diversity, are in the oceans. There, the largest number are various species of gastropods (snails). All gastropods are univalves, possessing one shell. Many other mollusks are the familiar pelecypod—bivalve—mollusks (clams), which have two shells. Mollusk bodies look undeveloped and many lack apparent heads. However, all have well-developed nervous, circulatory, respiratory, and sensory systems. Except for cephalopods, mollusks are slow-moving, sluggish, or immobile (sessile). In many cases they spend their adult lives attached to rocks or dug into sand or mud, awaiting the approach of prey.

Some mollusks, mostly gastropods, occur in freshwater and on land. For example, snails and slugs are seen at the bottoms of ponds, rivers, and lakes, or under fallen trees and decaying logs. Some land snails even live in tree branches. Characteristic features of gastropods are a true head, a creeping surface (or foot), eyes, and tactile feelers. The foot gives gastropods their name, which means "foot on belly" in Latin. Most gastropods have a univalve shell, but some species have no shell. Others, such as garden slugs, have tiny, internal shells.

Physical Characteristics of Mollusks

The largest mollusk is the giant squid, which is also the largest invertebrate. It can be fifty-five feet long and weigh several tons. Most mollusks, however, range from 0.5 to 10 inches in length and only weigh up to a few pounds. One exception to the size rule is the tropical giant clam, maximum diameter 4.5 feet, maximum weight five hundred pounds.

Mollusk Facts

Classification:
Kingdom: Animalia
Phylum: Mollusca (soft-bodied)
Classes: Bivalva (two-shelled, no distinct head); Cephalopoda (no shell or internal shell, very mobile, tentacled, has head and eyes); Gastropoda (univalve shell, moves slowly, tentacled, has head); Polyplacophora (simple crawling mollusks or chitons); Scaphopoda (elongated, open-ended tusk shells, tentacled, but no head)
Orders: Protobranchia, Septibranchia, Filibranchia (mussels and oysters), Eulamellibranchia (clams), Tetrabranchia (Nautilids), Dibranchia (octopuses, squid, cuttlefish)
Geographical location: Every ocean and many bodies of freshwater on every continent except Antarctica
Habitat: Mostly salt water, although many live in freshwater and on the land
Life span: Some live for under a year, others for one to five years; giant squid and giant clams may live for twenty-five years or longer
Special anatomy: Foot (for locomotion), siphons (for jet propulsion), a shell of calcium carbonate and protein, gills or lungs, a tonguelike radula for drilling or grinding food

Mollusk shells thus function protectively, like the rib cages and pelvic bones of vertebrates. The shells of bivalves are divided into two valves, which are opened or tightly closed by strong muscles. These muscles must be cut in order to open the shell for examination. The gastropods possess one asymmetrical shell, often of spiral shape, into which they retreat from the world. In cephalopods the shell is internalized, but still yields organ protection.

The organs and their positions in mollusks, especially gastropods, are as follows. At the anus end of the body are two or more gills (lungs in land forms) for breathing. At the front end of the body are jaws and a tonguelike, toothed radula. It grinds food or procures it by drilling into shells of prey or ship timbers (in shipworm snails).

There are many mollusk variations. However, some features can be generalized in mollusk bodies, based on gastropods and bivalves. In motile forms, locomotion is due to crawling on flat, muscular, snail-like feet, though jet propulsion occurs in cephalopods. Also, the mollusk body has a head at one end and an anus at the other. Furthermore, much of the body is covered by a shell (internalized in cephalopods) of calcium carbonate and protein. Shells are made by mantle tissue. Inside a shell is a large part of the body, fragile parts of cardiovascular, digestive and excretory, nervous, reproductive, and respiratory systems.

Most mollusks, such as this swimming scallop, are distinguished by their calcified, bivalve shells, which provide armorlike protection for their soft, boneless bodies. (Digital Stock)

Around the jaws are tentacles, used for sensation in gastropods. Cephalopod tentacles are used to capture prey. Between the radula and the anus are the stomach and the gut. A heart, near the hind end of the body, receives blood and sends it into the body cavity. The mollusk nervous system—comparable to that in fish—is composed of nerves that surround the gut, a brain, and sense organs. Mollusks also have kidneys and gonads.

Many mollusks are herbivores, grazing on underwater plants. Some terrestrial gastropods, such as slugs, eat cultivated plants and are serious garden and agricultural pests. Scaphopoda feed on organic matter deposited on ocean and lake bottoms. Bivalves filter protozoa, eggs of sea animals, and diatoms out of the water in which they live. Many gastropods are hunter carnivores, eating slower-moving or sessile animals, such as other mollusks. Cephalopods are very active predators and prey on animals such as crabs.

The Life Cycles and Senses of Mollusks

Most mollusks have separate sexes and a few exhibit courtship behavior. With or without courtship, mollusks usually spawn sperm and many thousands of eggs into waters around them. There, fertilization and development of offspring occur. When eggs hatch, offspring undergo a larval stage. Larvae of most mollusk species are, at first, free-swimming, using for locomotion a ring of cilia. Most settle to lake, ocean, or stream bottoms as crawlers who mature into adults.

Many mature mollusks, such as oysters and mussels, are sessile, permanently affixed to rocks. Gastropods are capable of slow crawling on a muscular foot. Cephalopods, such as squid and octopuses, are an exception to the mobility rule for mollusks. They are very mobile at all stages of their lives. Adult cephalopods move very quickly by expelling jets of water from mantle cavities, using an organ called a siphon. Jets are expelled in the direction opposite to movement. Jet propulsion makes cephalopods the fastest-moving mollusks. It also suits them to a life of vigorous predation. In cephalopods, the foot differentiates to ten arms (squid) or eight arms (octopuses) that seize prey.

In some cases, fertilization in mollusks is internal, with protective coverings secreted around eggs. In others, fertilization and development are internal in females and offspring are delivered alive, as with live-bearing snails. Slow-moving snails and related mollusks are often hermaphro-

Oysters, Beds, and Pearls

Edible oysters, such as *Ostrea virginica*, are plentiful on European and North American coasts. Oysters were a major food of coastal Native American peoples. Colonists ate them too, and natural oyster supplies were severely depleted by the late 1800's. Cultivated oyster beds were then developed to enhance nature's yield. In the twenty-first century, many food oysters come from cultivated beds.

The beds begin with the millions of eggs spawned yearly by every female oyster. They are started by finding places holding many newly hatched oyster larvae. Bricks, flowerpots, old shells, and other objects are placed on shallow sea bottoms beneath them. Then, a week after hatching, larvae produce tiny shells and, weighed down, drop to the sea bed. They attach to the objects and remain attached for the rest of their lives. After attachment, oyster-laden objects are dredged up and moved to the new beds.

Some oysters are invaded by foreign bodies that lodge between mantle and shell. These irritants cause the mollusks to produce mother-of-pearl to seal them off. In time, an irritant encased inside many layers of mother-of-pearl becomes a pearl. Most pearls are irregularly shaped and much less valuable than a few perfectly spherical pearls used in pearl necklaces. Pearl color depends on oyster diet and bed temperature. The pearls sought most are white, rose, steel blue, or black. They arise naturally in small numbers, or are cultured by the insertion of mother-of-pearl beads into oysters.

dites (both male and female). This doubles the number of mates available to each such organism, and often self-fertilization occurs. Both options have great survival value. A few species reproduce by parthenogenesis, without fertilization. Also, mother mollusks may protect developing eggs, and some oysters raise their offspring within the mantle cavity.

The mollusks live for periods ranging from under a year to two years for many small to medium-sized varieties and four to five years for some snails and shellfish. Giant squid and giant clams reportedly can live for over twenty-five years. Such life spans occur only when organisms reach old age, an uncommon situation for wild animals.

Sensory ability varies in mollusks. Most mollusks see poorly or not at all. However, the cephalopods have eyes like vertebrates, complete with lenses and retinas. Squid eyes reportedly lack eyelids but otherwise look very much like those of humans. Although it is not ubiquitous in mollusks, some gastropods have well-developed abilities to smell and find food at considerable distances. Predators are often detected in this way, too. Conclusive studies of intelligence have not been carried out in mollusks. However, ability to learn from experience has been claimed for cephalopods.

Beneficial and Destructive Mollusks

Mollusks are very abundant. On the benefit side, they are important foods for bottom-feeding fish and whales. Numerous mollusks are also valuable foods for humans. Especially widely eaten are clams, mussels, oysters, octopuses, and scallops. More exotic food mollusks include land snails. Mollusks (especially oysters) also produce pearls, the only gems made by living organisms.

On the debit side, gastropod and cephalopod carnivores do serious damage. Gastropods prey on slow-moving or sessile organisms, wreaking havoc on clam and oyster beds that provide shellfish for human consumption. Also, cephalopods are active predators, diminishing the sea's yield of meats sought by humans.

Another mollusk problem is foreign invasion, exemplified by zebra mussels (*Dreissna polymorpha*). These pistachio-nut-sized European saltwater mussel invaders were released into the Great Lakes from the hulls of ocean-going vessels in the late 1980's. They flourish in the Arkansas, Hudson, Mississippi, Ohio, and Saint Lawrence rivers. Superabundant reproduction (a female lays a million eggs per year) yields myriad larvae that, as adults, clog power plant and factory water intakes, requiring costly cleanup. More problematically, they eat microbes in the water, damaging the lifestyles of indigenous wildlife that also use this food. It is estimated that the mussels cost industry and consumers over $500 million per year.

MOLTING AND SHEDDING

Type of animal science: Development
Fields of study: Developmental biology, invertebrate biology, physiology

Molting or shedding is a hormonally regulated process during which animals lose and then replace either their entire body surface covering or structures associated with the body surface such as hair or feathers.

Principal Terms

ARTHROPODS: animals with jointed exoskeletons, including insects, crayfish, and spiders

EXOSKELETON: a skeleton made up of proteins and minerals, found on the outer surface of an animal

HORMONES: chemical messengers produced by specialized organs and cells either in the endocrine system or the nervous system; they have specific effects on different cells of the body

INVERTEBRATE: animal without an internal skeleton made up of individual bones or vertebrae

METAMORPHOSIS: a change in the physical state of an animal, such as the transformation of a tadpole into a frog or the development of a moth from a caterpillar

STEROID HORMONE: a hormone that is made from cholesterol

As a normal part of growth and development, some species of invertebrate and vertebrate animals undergo a process commonly called molting or shedding. Scientists term this process ecdysis, which is derived from a Greek word meaning "to escape or slip out." It is common for animals to molt more frequently as larvae or juveniles and less often as they mature and become adults. Molting is also an integral part of metamorphosis. Immediately after a molt, animals may not be fully protected from the environment, and they may be more vulnerable to predators. For example, the new exoskeleton of arthropods may not be fully hardened, or some birds may lose flight feathers. During a molt, animals may shed and replace their entire body covering or structures associated with the body surface. Molting may involve the replacement of the skin, an exoskeleton, or a cuticle in its entirety. In temperate regions, it is not unusual in the summertime to see the old exoskeleton of a cicada still clinging to a tree. Feathers, fur, or hair, which are derived from skin cells, are often shed in a cyclic fashion rather than all at once. Animals may also lose body structures during a molt. Adult male deer shed their antlers at the end of the mating season and lemmings replace their claws. In most animals the interval between molts is called the intermolt, except insects, where it is referred to as an instar.

The Molting Process

Environmental factors such as stress, temperature, and light cycle can serve as stimuli to molting in different species of animals, but the actual sequence of events leading up to shedding and replacement is strongly influenced by hormones and by specific interactions between the nervous system and the endocrine system. Hormone production is the primary function of the endocrine system. However, regions of the brain also produce hormones, which in this case are called neurohormones. One class of hormones in particular, steroid hormones, is actively involved in the regulation of molting.

Before an animal molts, a new skin or exoskeleton will have formed beneath the old one. Often

Life Cycles and Molting

Animals in the phylum Arthropoda and class Insecta undergo many molts and possibly several metamorphoses as a normal part of their life cycle. By responding to appropriate environmental stimuli, the arthropod brain controls the processes of molting and metamorphosis. It does so by regulating the release of specific hormones. The amount of one hormone, commonly referred to as ecdysone, controls molting and growth. This hormone also stimulates the digestion and reabsorption of the old exoskeleton. Another, called juvenile hormone, controls metamorphosis. Some insects such as grasshoppers have a nymph stage where the juvenile undergoes considerable growth in body size as the nymph makes the transition to an adult. When an exoskeleton is shed, the new one will not immediately harden. This allows time for the skeleton to expand to the new body size. Greater than 80 percent of insects including moths and butterflies have a caterpillar or larval stage during which active growth occurs. The overlying cuticle, the exoskeleton, acts like a jacket to confine the caterpillar to a maximum size and therefore limit growth at each stage of development. Thus, the exoskeleton needs to be periodically shed. Animals often swallow air as one way to rupture the old skeleton and to resize the new one. After several molts in the caterpillar stage, the amount of juvenile hormone is decreased and the caterpillar transforms to a pupa. Finally, in the absence of juvenile hormone, a final molt will occur and the pupa undergoes metamorphosis into an adult. Once they become adults, insects no longer molt. However, the adults of other arthropods, such as crayfish and lobsters, continue to have periodic molts their entire life.

the old exoskeleton splits along the midline of the posterior surface and the animal then crawls out. Different animals have specific ways to stretch the new exoskeleton before it hardens. The best way to stretch the skeleton is by increasing body size. This might be accomplished by a growth stage or by artificially increasing size. A lobster, for example, might absorb enough water to increase body size by 20 percent, while other animals take up air.

Molting in Amphibians and Reptiles

Molting of an entire body surface such as the skin or exoskeleton requires the separation of the layer being shed from the underlying tissue that will become the new outer surface. The chemical and physical processes leading up to the separation will vary slightly between animal groups. Amphibians such as frogs, toads, and salamanders periodically shed the outermost surface layer of their skin. Prior to molting, mucus is secreted beneath this layer of cells. Since the mucus is secreted between the old and new surface layer, it may assist in the separation by creating a space between them. The mucus may also act as a lubricant and aid the animal in removal of the old skin. Frogs are also known to bloat themselves and increase movement to break out of the old skin. Animals will often eat the skin they have shed as a way to recycle nutrients.

Reptiles show a good deal of variability in the replacement of their scales. In fact, snakes may shed their skin several times a year. In the time immediately preceding ecdysis in snakes, a fragile zone develops. Old skin will now separate from the underlying, newly developed scales. During the molt the snake's eyes will appear cloudy, because the outer part of the eye, which is a part of the skin, is also detaching. The rattlesnake's rattle is formed from the part of the skin that remains attached to the tail at the end of each shedding cycle. Snakes shed their skin in one piece, but lizards do not. Turtles are different from both snakes and lizards. First, their scales do not overlap to form sheets and second, most turtles add new growth to existing scales and do not molt. The molting pattern in crocodiles and alligators, which shed and replace individual scales, more closely reflects events in birds than other reptiles.

Molting in Birds

Birds shed their feathers each year and it is not unusual for some species to molt several times during the year. During the molting season, a bird's behavior may be affected in several ways, including events associated with reproduction. Molting will be influenced by the time of year and the mating season. Many female chickens often stop laying eggs when they are molting. New feathers will develop in the same area of the skin as the old ones. As the new feathers grow from the follicle they may push the old feathers out of the skin or they may be pulled out. The primary purpose of molting is to replace worn feathers with new ones, and often a pattern of feather loss will be noted. Wing feathers closest to the body are lost first and the molt progresses outward along the wings.

It is common for male birds to molt so that they can replace their duller plumage with more colorful feathers associated with attracting a mate. This is called a prenuptial molt and generally occurs in late winter or early spring. A postnuptial molt is common in both males and females. The chicks will lose their original feathers (down) when they undergo a postnatal molt to juvenile feathers. If it is a species of bird where the males have a coloration pattern different from the females, the early juvenile coloration more closely resembles the female. As the juveniles mature they will undergo successive molts to adult plumage. The time frame for maturation can vary considerably. Eagles can take up to five years before a final molt into full adult feathers. Mature birds that depend upon flight as a method of escaping predation will not molt all of their feathers at one time. A complete molt would result in the loss of flight feathers on the wings as well as tail feathers which assist in stability and guidance during flight. Flight is less adversely affected if there is a symmetrical loss of feathers on the wings and if tail feathers are

Image Not Available

shed in groups. Birds such as ducks and geese, which are able to spend extended periods of time in the water, are able to avoid most predators by swimming or hiding in tall grass. These birds do molt all of their flight feathers at one time. Male ducks are also somewhat unusual because, during the summer months, they molt from mating colors to plumage similar in color to females. This change is called an eclipse and makes it more difficult to tell males from females.

Molting in Mammals

When they lose hair, mammals, including humans, are molting. Like feathers, a hair grows outward from a follicle in the skin and, as new hairs grow, old hairs will be lost. Under normal conditions in humans, hair loss will be a gradual process over an individual's lifetime and it does not occur all at once. Molting in many mammals is directly influenced by length of day and interactions between the endocrine system and the nervous system. The number of molts per year varies, and many mammals molt twice a year, once in the spring and once in the fall. Foxes, however, molt once a year in the summer, and the snowshoe hare molts three times: summer, autumn, and winter. In general, it is common for the summer coat of mammals to be thinner than the winter one, and it is not unusual for the two coats to be different colors. Changing hair color provides one method of camouflage. White fur lacks pigment and blends well with snow and light surroundings. In contrast, darker shades blend better in the summer and fall. In mammals, like other animals, the transition from juvenile into adult can be associated with a molt. Deer fawns, for example, have very pronounced white spots, but when they become further developed they molt into the solid coloration of adults.

MONKEYS

Type of animal science: Classification
Fields of study: Anatomy, wildlife ecology, zoology

Monkeys are a favorite in zoos around the world. Representing more than 140 species spread throughout the tropics, the term "monkey" is often misused as a synonym for any primate.

Principal Terms

ARBOREAL: living completely or primarily in the trees
OPPOSABLE: a thumb which can be turned so that its pad makes contact with the pad of each of the fingers (as in the human)
PREHENSILE: capable of grasping
QUADRUPEDAL: walking on all four feet
SEXUAL DIMORPHISM: the occurrence of anatomic or physiologic differences that distinguish males from females of a particular species

The term "monkey" is used to denote any higher primate (suborder Anthropoidea) that is not an ape. Thus, it includes both members of the New World monkeys (infraorder Platyrrhini) as well as the Old World monkeys (infraorder Catarrhini, superfamily Cercopithecoidea). Monkeys have little in common with each other except for the fact that most are quadrupedal, but this does not eliminate all other primates. It is unclear where the name "monkey" originated, although a common interpretation is that it relates to the medieval term "moneke," meaning manikin.

Old World (Catarrhine) Monkeys

The Old World monkeys are the largest and most diverse family of primates, covering about ninety-five species and ranging over most of Africa, Asia, and Indonesia. The name Catarrhine means "downward-nosed," referring to the fact that the nostrils are close together and point forward and down. Catarrhine monkeys include macaques, mangabeys, baboons, mandrills, velvet monkeys, guenons, colobuses, proboscis monkeys, and langurs. There are two subfamilies: the leaf-eating, arboreal Colobinae (examples include the colobus and the langur), and the omnivorous, often ground-dwelling Cercopithecinae (including the baboons, mandrills, macaques, and guenons). The Colobinae have a rather complex stomach and digestive system, whereas the Cercopithecinae have a simple stomach combined with cheek pouches in which food can be stored.

The macaques are the greatest in number among the Old World species, as well as the most widespread. The most northerly is the Japanese macaque, which can live in cold, snowy climates. Other macaques live in dry, almost desertlike conditions in the tropics.

Old World species are generally larger than New World species, and there is considerable sexual dimorphism. Most have bare buttock pads, which may be brightly colored. Their tails are seldom fully prehensile, and may be significantly reduced in size. Almost all are active during the day, with excellent vision, hearing, and sense of smell. They communicate almost entirely by sight and sound, displaying a wide range of calls. Many display a range of facial expressions, used for communication with their own species as well as with other species nearby. Most are fully arboreal, but baboons are ground feeders, and macaques live both on the ground and in the trees.

When more than one species of monkey dwells in the same locality, the various species generally occupy different vegetation levels in order to avoid competition. This behavior is known as arboreal stratification. Most authors recognize four layers of vegetation in the tropics: the ground layer, lower canopy, middle canopy, and upper canopy. For instance, in the African guenons (*Cercopithecus* spp.), DeBrazza's monkey lives at the ground level, the red-tailed monkey sleeps in the middle canopy but spends the day on the ground, the blue guenon lives in the upper canopy but forages in the middle, and the Diana monkey lives solely in the upper canopy.

New World (Platyrrhine) Monkeys

The New World monkeys are a highly successful and diversified group colonizing Central and South America. The term usually refers to the infraorder Platyrrhini, meaning "flat-nosed." As compared with the Catarrhine monkeys, the nostrils of the Platyrrhines are broadly separated and usually point to the sides. Members of the Platyrrhines include capuchins, howler monkeys, sakis, woolly monkeys, squirrel monkeys, and uakaris, a total of about forty-five species.

New World monkeys have long, thin fingers on each hand, with flattened or curved nails. Although their thumbs are not opposable, as they are in the human, the big toe can be opposed against the other toes for gripping branches tightly. New World monkeys are excellent runners and jumpers, swinging and leaping through their densely wooded habitats. Their tails are fully prehensile; they can grasp objects at the tip and curl around a branch and support the full body weight of the animal. In almost all cases, the tail is at least as long as the head and body, and it acts as a balancing organ, often being held in a curled pattern.

None of the New World monkeys are ground dwellers, unlike the baboons and other Old World monkeys. None of them have cheek pouches, and sexual dimorphism is rarely seen. New World monkeys are gregarious and live in family-based

Most monkeys live in social groups that range over a defined territory in search of food. (PhotoDisc)

Monkey Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Primate
Suborder: Anthropoidea
Families: Cercopithecidae (Old World monkeys, eight genera, forty-five species); Cebidae (New World, capuchin-like monkeys, eleven genera, and thirty species)
Geographical location: Africa and Asia (Catarrhines), Central and South America (Platyrrhines)
Habitat: Mostly forests, some grasslands
Gestational period: Old World monkeys, 5 to 6 months; New World monkeys, 4 to 7.5 months
Life span: Old World monkeys, twenty to thirty-one years; New World monkeys, twelve to twenty-five years
Special anatomy: Opposable thumbs, forward-facing eyes for binocular vision, large brain case

groups with much vocal and visual communication. They have highly developed olfactory organs that may also be used for communication. Males of many species contain a glandular patch on the sternum (breastbone) which they rub against tree branches to act as scent markers. Marking by means of urine and feces is also common. For instance, night monkeys coat their hands and feet with urine so that they leave a telltale scent wherever they go.

Families are well developed in most species of monkeys, although females do most of the caring for their offspring. Mothers usually carry their young on their backs until they are ready to move through the canopy on their own. Group size seems to depend primarily on the productivity and abundance of the foods typically eaten by the species. Species that live in small groups tend to feed on small, scattered, or scarce resources such as insects, small vine fruit, or newly emerged leaves of bamboo. Species that form large groups use abundant or clumped resources, such as fruits on large fig trees. Small family groups are typically one to three animals, while large groups may involve seven to twenty members.

MONOTREMES

Types of animal science: Reproduction, development
Fields of study: Biochemistry, cell biology, developmental biology, embryology, physiology, reproductive science

Monotremes represent an ancient developmental line of mammals. They retain many reptilian characteristics, including the laying of eggs. Monotremes are found primarily in Australia.

Principal Terms

BROOD POUCH: a temporary external pouch created by folding the skin of the abdomen together; used to carry young as they continue to develop

CLOACA: a bodily opening at the end of the gut into which both the waste disposal and reproductive systems open

ECHIDNA: a long-snouted, insect eating, egg-laying mammal; also known as the spiny anteater

MONOTREME: reptilelike mammals, distinguished from other mammals by the fact that they lay eggs and have a cloaca

PLATYPUS: web-footed, duck-billed, semi-aquatic, egg-laying mammal

The monotreme order of mammals is comprised of two families, Ornithorhinchidae and Tachyglossidae. The first family contains just one genus and species, that of the duck-billed platypus, while the second contains two genuses and two living species of echidnas (short-nosed and long-nosed). These animals have much of the conventional appearance of mammals, but they are also quite different in some respects from the rest of the mammals. Both the platypus and the echidnas lay eggs which are incubated and hatched outside the body of the mother.

Monotreme Anatomy

The monotremes are more closely related in evolution to the reptiles than are any other recent mammals. They are not the ancestors of the marsupials or the placental mammals, but rather they represent a distinct line of mammalian evolution. They possess certain mammalian features, such as hair and mammary glands, and they are warm-blooded. On the abdomens of the females, milk oozes from paired areas of tubular glands (they possess no teats for suckling) and is lapped up by the young. They have a four-chambered heart and skeletal features associated with mammals. Other features, such as the presence of a cloaca, along with features of the vertebrae and ribs, are very reptilian.

In male monotremes, the penis is attached to the ventral wall of the cloaca, and is divided at the tip into paired canals used only for the passage of sperm. In female monotremes, the oviducts, which carry the eggs from the ovary, open separately into the cloaca. In the oviducts, the eggs are fertilized and then covered with albumen (a protein like that found in chicken egg whites) and a flexible, sticky, leatherlike shell. This reptilian feature of a shell-covered egg is found in no other order of mammals.

Both living animals and fossil records indicate a range for the monotremes that includes only Australia, Tasmania, and New Guinea.

Duck-Billed Platypus

W. H. Caldwell, in 1884, first demonstrated that platypuses lay eggs, unlike other mammals. There are still many unknowns regarding platypus reproduction and development, especially in terms of biochemistry and endocrinology. Copulation generally takes place during the spring months of

August and September, and usually occurs in water. The female then withdraws to a rather complicated nesting burrow dug into the side of a streambed. Inside the burrow is a nesting chamber consisting of a bed of grass, reeds, and leaves. Generally, two sticky eggs are laid here. There is no pouch for the eggs to incubate in, and the exact mechanism of incubation remains unclear. It is likely that the female curls around the eggs and protects them with her body heat. Incubation is seven to ten days, after which the hatchlings use an egg tooth (much like reptiles) to emerge from the egg. At birth the hatchlings are about 17 millimeters (0.65 inches) long. They feed on ill-defined milk patches hidden under dense fur on the ventral side of the mother. Hatchlings have very large, strong forelimbs that are used for holding on to the fur over the milk patches. Because they are so well protected in the dense fur, hatchlings are nearly impossible to detect by looking at the mother.

As the young grow, the mother's mammary glands also grow. These mammary glands are very similar to those seen in other mammals, and the chemical composition of the milk is also similar. Until they emerge from the burrow, hatchlings feed on only the milk from their mother. Young platypuses emerge from the burrow for the first time in December or January, generally being thirty to thirty-five centimeters (twelve to fourteen inches) long. They will eventually grow to forty to forty-five centimeters as adult females, or fifty to fifty-five centimeters as adult males.

Echidnas

Previously known as spiny anteaters, echidnas have compact, rounded bodies covered with short, thick spines. They have elongated, slender snouts and strong limbs, and are powerful diggers. They have no teeth and, like other ant- and termite-eating mammals, have a long sticky tongue that reaches well beyond the snout. Termites, ants, and other small arthropods are swept into the mouth by its action.

Adult echidnas are solitary animals, except when it is time to mate. During the breeding season (late June to September), males will follow females for several weeks at a time before being allowed to mate. Often several males will be seen in single file following a female, this being referred to as an echidna train. It is not known exactly how males find breeding females, although it is likely that females secrete a scent that can be detected several miles away.

Females develop a brood pouch during breeding season. Following mating, a single fertilized egg is transferred from the cloaca to the pouch, although the actual mechanism for this transfer is not clear. The leathery-shelled eggs average 14-17 millimeters (0.55-0.65 inches) in length. The egg is incubated for ten days in the pouch before the hatchling appears. The young echidna (who is about 1.2-1.3 centimeters, or 0.5 inches, in length when it is born) remains in the brood pouch for an additional eight weeks until its spines develop. During this time it feeds on milk flowing from the mammary ducts onto tufts of hair within the pouch.

When the youngster emerges from the pouch, it is hidden by its mother in a protected spot. It appears that the young echidna then begins a short period of hibernation, during which continued development occurs. Echidnas are reproductively mature at one year of age.

MOOSE

Types of animal science: Anatomy, classification, reproduction
Fields of study: Anatomy, systematics (taxonomy), zoology

Moose, the largest species of deer, are herbivorous ruminants. Once hunted almost to extinction, they are now a protected species.

Principal Terms

ARTIODACTYLS: hoofed mammals, including cattle, pigs, goats, giraffes, deer, and antelope
GESTATION: the term of pregnancy
HERBIVORE: an animal that eats only plants
KERATIN: a tough, fibrous protein which is a major component of hair, nails, hooves, and the outer covering of true horns
RUMINANT: a herbivore that chews and swallows plants, which enter its stomach for partial digestion, are regurgitated, chewed again, and reenter the stomach for more digestion

Moose are artiodactyls of the family Cervidae (deer). Almost all artiodactyls walk on two toes. Their ancestors had five, but evolution removed the first toe, and the second and fifth toes are vestigial. Each support toe—the third and fourth toes—ends in a hoof. Artiodactyls are herbivores and many, especially the Cervidae, are ruminants. This means that they chew and swallow vegetation, which enters the stomach for partial digestion, is regurgitated, chewed again, and reenters the stomach for additional digestion. This maximizes nutrient uptake from food.

Moose are the largest of deer. Like all cervids, male moose have solid, bony, branched antlers, which are shed and regrown each year. Moose live in northern Europe, eastern Siberia, Mongolia, Manchuria, Canada, Alaska, Wyoming, and the northeastern United States.

Physical Characteristics of Moose

Moose—called elk in Europe—have long, solid bodies. Males can be eight feet tall at the shoulder, ten feet long from muzzle tip to rump, and weigh up to 1,800 pounds. Females are 25 percent smaller overall. Moose heads, antlered in males, are angular, long, and have large muzzles. Their large eyes, as in other deer, are set back on their faces and on the sides of their heads. This optimizes their vision. Moose also have thick necks, humped shoulders, and long, strong legs that allow running speeds of up to forty miles per hour. Moose

Moose Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Artiodactyla
Family: Cervidae (deer)
Genus and species: Alces alces
Geographical location: Northern Europe, eastern Siberia, Mongolia, Manchuria, Canada, Alaska, Wyoming, and northeastern United States
Habitat: Mountains, forests, and near lakes or marshes
Gestational period: Seven to eight months
Life span: Fourteen years, but some live up to twenty years
Special anatomy: Antlers

Moose have palmate antlers, shaped like a fingered hand, rather than the spiky antlers of most other cervids. (Digital Stock)

fur is brownish-black, fading to grayish-brown on the belly.

Moose antlers are large and palmate, holding up to twenty branched points, which look like fingers on a hand. Antlers are important during mating, when a male lacking them would lose fights for mates and a chance for offspring. Antlers differ from true horns, which are pointed, permanent, bony structures often seen on heads of male ruminants. Horns have bone cores which are extensions of the skull's frontal bone. Atop the core is a skin layer, rich in a tough, fibrous protein, keratin. The high keratin content in this skin makes it tough and durable. Horns range from straight spikes to elaborately curved varieties. Animals having horns keep them for life Antlers are horns that are shed yearly and regrown. Like true horns, antlers grow out of skull bones. They arise from permanent frontal bone structures called pedicles. At first antlers have soft, velvetlike skin coverings. Instead of hardening, as in horns, the covering dies off and is rubbed away by the animal. Antlers function like horns, serving for self-protection and allowing males to develop ascendancy.

Moose are often found on mountains, in forests, and near lakes and marshes. They are herbivores lacking upper incisor and canine teeth, but having pads in their upper jaws to help lower teeth grind vegetable food. Adults eat up to fifty pounds of vegetation per day, including water plants, branches, twigs, and leaves from aspen, willow and birch trees, berries, and bark. A moose often stands up against young trees and bends them over to reach leaves at their tops. In winter, moose dig through snow to find grass, twigs, and other vegetation. Moose eat during the daylight hours and at night.

The Life Cycle of Moose

Male moose are solitary animals during spring and summer. In September and October, they fight for mates. A successful male may lead several females and babies all winter. In the spring, the male leaves his harem, returning to a solitary life. Moose gestation, seven to eight months, yields one or two offspring which nurse for four months and stay with the mother until she is ready to give birth again. A moose can mate when it is two years old. The life spans of moose can be up to twenty years.

Moose are so large and strong that they have few enemies. Bears and wolves may prey on them. However, they usually attack young, old, or sick moose and males weakened by hunger or mating battles. Human hunters are the greatest threat to moose. For example, during the moose mating season, male moose seek females. Moose hunters lure moose into shooting range by imitating the love call of a cow through a horn or cupped hands. At one time, hunters killed off almost all moose in the eastern United States. Currently, they are protected by law in the United States and Canada.

MORPHOGENESIS

Type of animal science: Development
Fields of study: Cell biology, embryology, genetics

Morphogenesis is the process, operating during the development of the organism and appearing through evolutionary history, by which patterns of form come into being in genetically controlled systems. By studying this multifaceted process, it is possible to understand underlying factors that regulate the appearance of patterns of structure in living organisms.

Principal Terms

BIFURCATION: the division of a Y-shaped and connected mesenchymal structure into a single proximal chondrogenic focus and two distal chondrogenic foci; this can lead to the formation of separate chondrification centers in a developing digit

CHONDRIFICATION: the process by which undifferentiated connective cells transform into chondrocytes (cells that make cartilage) and begin forming extracellular matrix

EPITHELIUM: the tissue that covers and lines all exposed surfaces of an organism, including internal body cavities such as the viscera and blood vessels

LIMB BUD: thickened epithelial cells along the lateral body fold that are underlain by mesoderm, creating a paddle-shaped extension from the trunk

SEGMENTATION: the division of a structure into linearly arranged segments; it can lead to the formation of somites, or it can lead to the formation of separate chondrification centers in a developing digit

ZONE OF POLARIZING ACTIVITY (ZPA): a region at the posterior base of the limb bud that seems to influence the distal development of pattern in a developing limb

Morphogenesis is the process that leads to the appearance of form in specific patterns, through the differential reproduction, growth, and movement of cells and tissues and interactions between tissues. Such movements are controlled by a variety of factors, including cell adhesion molecules (CAMs), the nature of the extracellular matrix (ECM), and the size of the cells themselves.

Most multicellular organisms begin their lives as fertilized eggs. Although this seemingly simple cell is really quite highly organized, it is still relatively uncomplicated when compared to the structural complexity of the parent. As each egg cell divides, the daughter cells become structurally and functionally distinct. This is the beginning of the process of cell differentiation, which can lead to complex multicellular organisms. As new cells appear, grow, mature, and divide, there is a point at which the eventual fate of these cells is determined. That is, at some point the eventual location, structure, and function of the descendants of such cells are fixed. This fate determination frequently takes place very early in the development of an organism. After a particular fate is determined, it is the process of morphogenesis that allows the potential fate to be realized. Also through the process of morphogenesis, patterns of form develop that increase the structural and functional complexity of an organism.

The Rules of Morphogenesis

Fate determination, morphogenesis, and pattern formation are not haphazard. In fact, these events are highly constrained, extremely stereotyped, and very predictable—so much so that models of morphogenesis have been formulated that rely on rules of development to establish the probabilities of particular forms developing. These rules take into account two types of conditions—initial and boundary conditions—that work together to produce pattern formation in a cascading process. Initial conditions are simply the cellular conditions that prevail in a certain part of an organism, such as cell size and number and the chemical makeup of cell membranes. Boundary conditions are the conditions that exist at boundaries of different types of tissue.

Only a few phenomena are responsible for setting the initial and boundary conditions within which a morphogenetic system operates. A variety of cellular phenomena are involved, including cell migration, cell division (producing new cell lineages), the rate of cell division, cell number, cell density, the orientation of daughter cells relative to parent cells, and even the places in which cell death occurs. Tissue-level phenomena also have an important impact on morphogenesis. In these cases, specific tissues possess certain properties and a limited ability to respond differently within the constraints allowed by those properties. For example, sheets of epithelial cells can become folded, but they seldom form a solid mass of cells. Finally, there are interactions that take place between different tissues. Among these interactions is induction, wherein one tissue will induce a specific response in an adjacent tissue. Examples of such induction are numerous and well known; they include the mesenchymal induction of dental epithelium during the formation of teeth.

Limb Morphogenesis

Although far from completely understood, one of the most thoroughly studied morphogenetic systems is the development of the tetrapod limb. (A tetrapod is a vertebrate with two pairs of limbs.) Because amphibians (such as frogs and salamanders) and chickens have large, easily obtainable eggs, they have been studied most. It will be useful to summarize the course of limb development, since it exemplifies many of the common features of morphogenesis and pattern formation.

Early in the formation of the limbs, a ridge forms along the flank of the embryo. Along this ridge, the apical ectodermal ridge (AER) develops as a thickened layer of epithelial cells. Undifferentiated connective tissue cells, called mesenchyme cells, accumulate underneath the AER and form the limb bud. These mesenchymal cells are derived from mesoderm that migrates into the limb bud following pathways of the ECM that are laced with CAMs, especially fibronectin. The AER is responsible for the formation of pattern in the proximodistal axis, which is a line from the base of a limb (the proximal end) to the outer end of the limb (the distal end).

Another focus of pattern formation also appears quite early in limb development; it is called the zone of polarizing activity (ZPA) and has influence over the anteroposterior axis of limb development. Together, the AER and the ZPA regulate a pattern of form that is shared by all tetrapods.

Under the influence of these pattern-generating centers, three types of mesenchymal chondrogenic foci will form: de novo condensations (which are unconnected), bifurcations, and segmentations. Segmentations and bifurcations both show recognizable connections, and they appear in a consistent and stereotyped fashion. Linear series of mesenchymal condensations showing connections with one another are called segmentations; a Y-shaped condensation with a single proximal focus connected to two distal foci is called a bifurcation.

In all tetrapods, a bifurcation leads to the formation of two skeletal elements in the region between the proximal bone in the arm (or leg) and the hand (or foot). In frogs and amniotes, the condensations at the base of the putative fourth digit, showing connection to the bone in the forearm (or lower leg), are the first to appear as the result of a bifurcation event. Each subsequent proximal digit condensation appears as a bifurcation. All distal condensations, after the proximal digital element forms, appear as the result of segmentation events. Thus, the development of limb elements is asymmetric and always emanates from the axis of the first digit to form chondrogenic foci.

The morphogenetic control of this pattern, which has been conserved throughout the long evolutionary history of tetrapods, is both simple and complex. It is simple in that only a few morphogenetic processes are responsible for generating the complex pattern of limb structure, so different in all the various tetrapods. It is complex in that so many phenomena can influence the ultimate structure of any particular limb. For example, the number of somites that contribute mesoderm to the limb bud mesenchyme can dictate the number of limb elements that will eventually form.

Studying Morphogenesis

There are two general methods for studying morphogenesis. In the older—but still widely used—approach, tissues are removed from an organism in order to be examined under a microscope. Tissues are often stained (a variety of staining materials may be used) to make them more readily visible, and they are usually cut into thin slices called sections. The purpose is to determine the position of individual tissues. If carefully staged materials have been used, it is possible to get some ideas about whether cells have moved and, if so, approximately how far they have moved. There are problems with studying morphogenesis in this way: Details can be missed, or, more worrisome, preconceived notions can bias observations. For example, a small set of sections may support a theory, but, because thin sections of tissue can vary greatly, many sections of the material under study may contravene a pet theory of development. One could simply reject the many conflicting sections, claiming them to be poorly prepared or somehow damaged material. Indeed, many sections are so rejected. With the advent of transmission electron microscopy (TEM) and scanning electron microscopy (SEM), more detailed observations could be made. New problems, however, accompany these methods. In TEM, the thinner sections which must be used increase the occurrence of variation, also increasing the chances of biased observations. SEM allows for the magnification of surfaces and a great increase in the depth of field, but it requires that materials be very carefully staged. In none of these methods is it possible actually to see individual cells move.

A second approach seeks to document cellular movements. Understanding such movements requires that individual cells be "marked." Marked cells are then grafted onto an unmarked host organism and followed. Both natural and artificial markers can be used. Pigment granules such as melanin and stained glycogen are examples of natural markers. These markers, however, can be affected by cellular activities, making it hard to follow the cells. Fortunately, there are other natural markers not so affected. For example, chick and quail cells stain differently, so the cells of one can be followed when they are transplanted into the other. One of the more frequently used artificial markers is tritiated thymidine. When it is introduced, this radioactive substance is permanently incorporated into the deoxyribonucleic acid (DNA) of the selected cells. Tritiated thymidine has several advantages: It works in any cell, it follows along with the cells, and it will be in all the offspring of the cell to which it was originally introduced. Unfortunately, as cells continue to divide, the concentrations of tritiated thymidine eventually approach undetectable levels.

Many systems have been studied using these methods, including the development of the tetrapod limb and vertebrate head, somite differentiation, and the appearance of the primary germ layers that eventually yield all other tissues.

Morphogenesis is the reflection of all the interactions that take place during the formation of a living organism and of the patterns of structure that characterize this organism. The study of morphogenesis is motivated by the desire to understand the appearance of patterns of structure. Such patterns are often conserved through evolutionary history. It is hoped that a clear picture of how these patterns are formed and regulated will show how the origin of novel morphologies is constrained. Thus, it will be possible to understand both the origin of novel forms and the maintenance of unchanging form.

Bibliography

Bard, Jonathan. *Morphogenesis: The Cellular and Molecular Processes of Developmental Anatomy.* New York: Cambridge University Press, 1990. A critical review of the physical mechanisms of morphogenesis. An appendix outlines three dozen areas where future research is needed. Clearly written, requiring only a minimal understanding of embryology. Extensive bibliography.

Bonner, John Tyler. *On Development: The Biology of Form.* Cambridge, Mass.: Harvard University Press, 1974. Updated from Bonner's earlier (1952) text on morphogenesis, this volume is also intended for the college-level student. Illustrations are rarely included. Endnotes and index.

De la Cruz, María Victoria, and Roger R. Markham. *Living Morphogenesis of the Heart.* Boston: Birkhäuser, 1998. An encyclopedic survey of the developmental anatomy of the heart, focusing on chicken embryos, with comparisons to other mammalian hearts. Written for medical professionals.

Edelman, Gerald M., and Jean-Paul Thiery, eds. *The Cell in Contact: Adhesions and Junctions as Morphogenetic Determinants.* New York: John Wiley & Sons, 1985. The subject of this book, intended for specialists, is the nature of the contacts that cells make and how they determine the fate of morphogenesis. Articles are contributed by researchers in this area and are grouped into five sections: membrane structure, determinants of animal form, cell adhesion molecules, extracellular matrix/cell-substrate adhesion, and specialized junctions. Most contributions are illustrated. Each article is followed by a literature cited section. The book ends with a subject index. Wessells (1977) is a more accessible college-level treatment of some of the same issues.

Hinchliffe, J. R., and D. R. Johnson. *The Development of the Vertebrate Limb: An Approach Through Experiment, Genetics, and Evolution.* Oxford, England: Clarendon Press, 1980. This volume is intended for specialists, but it can be understood by college-level students. It is a detailed and extensive treatment of limb development, divided into seven sections: the origin of the vertebrate limb, adaptation/diversity, descriptive and experimental embryology, regeneration, pattern, and mutants and the process of evolution. The well-illustrated text is followed by a long bibliography, an index, and plates.

Thomson, Keith S. *Morphogenesis and Evolution.* New York: Oxford University Press, 1988. This well-written, very short volume is intended for evolutionary biologists with a budding interest in development. Most of the examples chosen for discussion come from vertebrates. Nine chapters cover very broad topics including theories, the difference between pattern and process, pattern formation (both early and late), and the general properties of morphogenetic systems. The infrequent illustrations are all line drawings; the text is followed by references and a short index.

Trinkaus, John Philip. *Cells into Organs: The Forces That Shape the Embryo.* Englewood Cliffs, N.J.: Prentice-Hall, 1984. This exceptional book is intended as an upper-division college text that specialists might also find indispensable. It is an expanded version of an earlier edition of the same title. Fifteen chapters, illustrated by photographs and line drawings, extensively cover topics including cell movements, the structure of cell surfaces, cell adhesion, the environmental control of cell motility, mechanisms of morphogenetic movement, and the spread of cancer cells. Selected references follow each chapter. The author provides criticisms, suggests many avenues for future research, and notes many unsolved developmental problems.

Webster, Gerry, and Brian Goodwin. *Form and Transformation: Generative and Relational Principles in Biology.* New York: Cambridge University Press, 1996. Argues that the theory of Darwinian selection must be supplemented by a theory of biological form, based on a generative theory of organisms as developing and transforming entities of a distinctive type.

Wessells, Norman K. *Tissue Interactions and Development.* Menlo Park, Calif.: Benjamin/Cummings, 1977. This brief but detailed text is intended for undergraduate college students. Eighteen chapters cover the main processes of development, including morphogenesis. Emphasis is on how tissues interact to bring about morphogenesis. The text is well illustrated with line drawings and numerous photographs. Each chapter closes with a brief "Concepts" section that outlines important points, followed by a references-cited section. The last chapter is a handy summation of the major points discussed. Glossary and index.

MOSQUITOES

Type of animal science: Classification
Fields of study: Anatomy, ecology, entomology, invertebrate biology, physiology, zoology

There are about 3,500 known species of mosquitoes, all of which are placed in the family Cuicidae of the insect order Diptera. The importance of mosquitoes to humans lies with their ability to feed on vertebrate blood and transmit organisms that cause disease.

Principal Terms

LABIUM: the sheath that contains the slender stylet-like mouthparts of the mosquito, including the mandibles, maxillae, and hypopharynx

SALIVA: the liquid containing enzymes secreted by the salivary glands that is injected into the host when the adult mosquito feeds

SIPHON TUBE: tube that extends from the rear of the larval abdomen at the air-water interface and allows the larva to breathe air

Although mosquitoes are found all over the world, as far north as the Arctic Circle, the vast majority of them live in the tropics and subtropics. The adults have wings and are able to fly, but the immature stages, or larvae, are wormlike and are confined to small bodies of water. Adult male mosquitoes do not have mouthparts that are capable of penetrating skin, so they feed primarily on nectar from flowers. However, adult females have piercing mouthparts that easily pass through the skin of larger animals so they can feed on their blood. About 200 million years ago they probably evolved from other insects that used their mouthparts to feed on plants.

The Life Cycle of Mosquitoes

Female mosquitoes lay their eggs in water or in areas that will be flooded with water after rainfall accumulates or the snow melts. The eggs hatch after a few hours of being submerged, and this is the reason for the usually large numbers of mosquitoes in the wet spring months. The larvae that hatch from the egg must remain in the water to develop, but they are only able to breathe when they come to the water's surface. At the end of the larval abdomen is a strawlike siphon tube that allows air to enter. By hanging with its head down and its siphon tube at the surface, the larva can continue to feed underwater and breathe at the same time. The larvae feed by filtering out small particles of food from the water and grow by periodically producing a new skin and molting the old skin. After three larval molts over the course of about one week, the larva changes into a comma-shaped pupa that does not feed but is transformed into the adult. The pupa comes to the water surface when its development is complete and the adult mosquito escapes from the pupal skin and flies from the water surface.

Adult mosquitoes often mate shortly after they emerge. The males of many mosquito species form swarms over trees and bushes into which the female enters. When she enters the swarm of males, her wingbeats produce a tone that attracts the male. Most females only mate once during their lives and store the sperm in a special sac that is used to fertilize the eggs just before they are laid. Males live only about two weeks and feed on sugars from plants. Female mosquitoes live for about a month. Unlike the males, they have needlelike mouthparts consisting of two elongated maxillae, two long mandibles, a labium, and a hypopharynx

Image Not Available

that has a hollow tube running its length. When the mosquito feeds, the sheathlike labium that encloses the other mouthparts folds away and the six needlelike mouthparts then penetrate the skin. The tube within the hypopharynx is connected to the salivary glands and allows saliva to be injected into the animal being fed upon. The saliva prevents the blood from clotting in the mouthparts and may also lessen the pain so the mosquito can feed without being detected. The saliva that is injected also produces the common symptoms of itching and redness that usually follow the mosquito bite. Feeding on blood is necessary if the female is to develop her eggs. By using the protein contained in the blood, she is able to mature about one hundred eggs within two days of feeding. She can take another blood meal and develop another egg batch every two days. Feeding behavior usually occurs at dusk or during the evening hours, when its hosts are asleep and less likely to defend themselves. A few mosquito species do not feed on blood at all and acquire the protein they need to develop eggs from the larval stage.

Adult female mosquitoes have special sensory receptors on their antennae that can detect the odors of potential hosts. The carbon dioxide that animals give off as they breathe is one of the major signals the female uses to locate a host for a blood meal, but other chemicals produced by the skin are also important. The female mosquito may also use body heat and the visual image of the host to locate it. Darker colors are generally more attractive than are lighter colors. Common mosquito repellents are believed to act as chemical masks that disrupt the pattern of host stimuli so the female no longer recognizes the host.

Mosquitoes and Disease

Mosquitoes are not just nuisances when they feed on humans. Female mosquitoes are able to acquire parasites, such as viruses and protozoa, when they feed on an animal that already has an infection in its blood. Some of these parasites are able to infect the tissues of the mosquito and then invade its salivary glands. Once the salivary glands contain the parasites, they can be transmitted to an uninfected host the next time the mosquito injects its saliva and feeds. Many diseases of humans and other animals are transmitted by mosquitoes when they feed on blood. Malaria is the most important of these, causing over one million human deaths each year. Other important mosquito-transmitted diseases include dengue, yellow fever, and viral encephalitis, all caused by viruses. Heartworm is an important disease of dogs that is caused by a nematode worm transmitted by mosquitoes. Filariasis is a similar disease in humans that produces grossly enlarged limbs.

The best way to control mosquitoes is to limit the places larvae can breed. This involves preventing water from collecting in small containers and channeling water runoff so it does not accumulate in puddles that might last long enough for the larvae to develop into adults.

MOUNTAIN LIONS

Type of animal science: Classification
Fields of study: Anatomy, wildlife ecology

Large animals, usually classified in the small cat Felis *genus, mountain lions once ranged across the New World. However, human predation and habitat destruction have greatly reduced or eliminated many regional subspecies.*

Principal Terms

CARNASSIALS: pairs of large, cross-shearing teeth on each side of jaw
CREPUSCULAR: active at twilight or before sunset
EPIHYAL: presence or absence of this hyoid bone determines if a cat generally purrs or roars
HYOID BONES: series of connected bones at base of tongue
PAPILLAE: sharp, curved projections on tongue

Mountain lions, also known as American lions, catamounts, cougars, deer tigers, Florida panthers, and pumas, are classified in the genus *Felis* with small cats because they share a solid epihyal bone that restricts their ability to roar. Mountain lions purr and during mating emit harsh, frightening screams.

Among American felines they are second in size only to the jaguar. Adult male mountain lions weigh from eighty to over two hundred pounds, and are often nine feet long from nose to tip of tail, and up to thirty inches high at the shoulder. Females are about a third less in size. Cats in the equatorial regions are smaller and have thinner coats than those in the extreme north and south of the mountain lion range.

Mountain lion coats are uniform in color, varying from reddish bronze to brownish yellow or gray, with black markings around the mouth and eyes and on the tip of the tail. Kittens are born spotted, but these marks soon fade. Thirty subspecies of mountain lions, varying slightly in head shape, coat color, and size, occupy separate geographic regions.

Behavior

Kittens remain with their mothers for eighteen months to two years. Otherwise, mountain lions live solitary lives. Each female has a distinct hunting range; where such areas intersect, cats avoid each other. Males hunt over much larger tracts, sometimes covering hundreds of square miles. Each territory overlaps several female ranges, which the males check frequently for breeding opportunities. Older males face challenges from younger cats seeking to establish their own territories.

Mountain lions are nocturnal or crepuscular hunters; they are almost invisible when silently stalking their victims in dim light. Except for mothers and kittens, there are few reports of cats aiding each other during hunting. Deer are the major prey in North America, capybara and peccary the preferred quarry in equatorial America. When larger animals are unavailable, mountain lions eat rodents, rabbits, and beaver. Blending into their surroundings, cats creep slowly toward intended prey, closing with a furious forty-five mile per hour rush, sometimes leaping as much as forty feet to surprise their target. Sharp claws hold victims, as canine teeth sever their spinal column or windpipe. Powerful jaws, containing scissorslike carnassials and tongues with rasplike papillae, permit cats to harvest every speck of meat from their prize.

Relations with Humans

Native Americans, carrying carved cat images as fetishes, revered the mountain lion as the greatest of all hunters. Native rituals used lion skins and paws to ensure hunting success. Europeans were less respectful, treating big cats as dangerous vermin to be destroyed. From the seventeenth century through much of the twentieth century, governments offered bounties for lion skins. Humans were the only species consistently preying upon adult mountain lions. Hunters set iron traps, dug pits, and used dogs to chase and tree the cats.

As expanding human settlement made wild prey scarce, mountain lions found cattle, sheep, and horses irresistible. The cats tended to avoid humans, but rare attacks and killings frightened people and led to calls for the cats' extermination. John James

Mountain Lion Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Eutheria
Order: Carnivora
Family: Felidae (cats)
Genus and species: Felis concolor
Subspecies: F. c. cougar (eastern cougar), *F. c. coryi* (Florida cougar)

Geographical location: Original range was southern British Columbia to the Straits of Magellan and from the Atlantic Ocean to the Pacific Ocean

Habitat: Mountains, forests, deserts, and jungles

Gestational period: About three months

Life span: Up to twelve years in the wild, twenty or more years in captivity

Special anatomy: Large eyes with excellent night vision; jaws adapted to seizing and gripping prey, teeth designed for tearing and slicing flesh

Mountain lions prefer to stalk their prey during the twilight or early morning hours. (Corbis)

Audubon noted that by the 1840's, man had nearly eliminated mountain lions east of the Mississippi. By 1900, few mountain lions existed in North America east of the Rocky Mountain states.

Attitudes toward mountain lions began changing in the last decades of the twentieth century. Laws in western states banned or strictly limited hunting. However, as human intrusion into the mountain lion's habitat increased, cats occasionally attacked solitary hikers, joggers, and skiers, stimulating calls for removal of the predators. With great effort and expense, conservationists maintain a relict population of some seventy Florida panthers (*Felis concolor coryi*) in southwest Florida—a subspecies originally ranging from Louisiana to Florida. In Central and South America, where significant populations of mountain lions remain, destruction of habitat by expanding settlement has greatly reduced surviving numbers. Outside Florida, mountain lions are not technically an endangered species, but their long-term future remains precarious.

MOUNTAINS

Types of animal science: Ecology, geography
Fields of study: Conservation biology, ecology, environmental science, wildlife ecology, zoology

Mountains cover one fifth of the earth's terrestrial surface, and are one of the most extreme environments in the global ecosystem. They are globally significant landforms that function as storehouses for irreplaceable resources such as clean air and water, and biological and cultural diversity, as well as timber and mineral resources.

Principal Terms

ASTHENOSPHERE: the region below the lithosphere where rock is less rigid than that above and below it

BIOCLIMATIC ZONE: a zone of transition between differing yet adjacent ecological systems

ENDEMISM: the occurrence of species only within narrow environmental ranges

LOCAL RELIEF: the elevation difference between the lowest and highest points in an area

SUCCESSION: directional change in communities of vegetation or animals

TECTONIC PLATE: tectonic plate theory suggests that the earth's surface is composed of a number of oceanic and continental plates which have the ability to move slowly across the earth's asthenosphere

Mountains are the most conspicuous landforms on earth. They are found on every continent, and have been defined simply as elevated landforms of high local relief, with much of the surface in steep slopes, displaying distinct variations in climate and vegetation zones from the base to the summit. The earth's mountain ranges have been created by the collision of tectonic plates. Associated with many of these mountain ranges are volcanoes. If the solidified magma of a volcano builds up, it can become a mountain; likewise, if the collision involves two oceanic plates, a string of volcanic mountains, called an island arc, can form on the ocean floor.

Mountain Habitat

Mountains are globally significant reservoirs of biodiversity. They contain rich assemblages of species and ecosystems. Because of the rapid changes in altitude and temperature along a mountain slope, multiple ecological zones are stacked upon one another, sometimes ranging from dense tropical jungles to glacial ice within a few kilometers. Many plant and animal species are found only on mountains, having evolved over centuries of isolation to inhabit these specialized environments. Mountains can also function as biological corridors, connecting isolated habitats or protected areas and allowing species to migrate between them. These extraordinary ecological conditions, coupled with many bioclimatic zones, have resulted in an extremely high number of ecological niches available for habituation in mountain ecosystems.

Mountain Fauna

Because of the great diversity in habitats within mountainous regions, with each region showing a different combination of environmental factors, total mountain fauna is relatively rich and the variety of small communities very great, in spite of the general severity of the mountain environment as a whole. Likewise, this diversity has resulted in a wide range of endemic species that have evolved over centuries of isolation from other genetic material. Rocky Mountain National Park typifies this diversity as a home to 900 species of plants, 250 species of birds, and 60 species of mammals. Some are easily seen and others are elusive, but all are part of the ecosystem in the park. On a global scale, mountain fauna diversity includes many species of ungulates, including elk, bighorn sheep, moose, and deer. Also included in mountain communities are many species of rodents. Rodent species may include beaver, marmots, squirrels, and chipmunks. Other mammalian animal life includes bear, canids, including coyote and wolf, and many species of felids, such as mountain lions and bobcats. Mountain avian fauna includes many families of hummingbirds, bluebirds, hawks, falcons, eagles, and many more.

Major Mountain Ranges of the World

Africa: Atlas, Eastern African Highlands, Ethiopian Highlands
Asia: Hindu Kush, Himalayas, Taurus, Elburz, Japanese Mountains
Australia: MacDonnell Mountains
Europe: Pyrenees, Alps, Carpathians, Apennines, Urals, Balkan Mountains
North America: Appalachians, Sierra Nevada, Rocky Mountains, Laurentides
South America: Andes, Brazilian Highlands

Mountain meadows provide habitats for many animal and bird species. (PhotoDisc)

Threats to Mountains

Mountains are threatened in a variety of ways. There are constant threats from human activities, such as camping, hiking, and other recreational activities. Hikers create tracks in the soil that form erosion gullies. Likewise, hikers may trample on vegetation that has taken many years to grow. Commercial harvesting of trees in the lower forest zones of mountains is having an increasingly detrimental effect on biodiversity. Many countries have replanted indigenous trees with fast-growing coniferous trees, in an ill-fated effort to supply a growing human population with wood products. These hybrid forests are not nearly as beautiful as the native forests, but more to the point, they do not offer an environment conducive to the ecosystem that the native species supported. This problem creates a loss of wildlife, which becomes even more rare in these forests because of the decline of native vegetation. Global warming is another threat to mountain ecosystems. Snowlines are receding, and eventually, continued melting of glaciers and polar ice caps could lead to drying of major river systems which feed from them. Without question, human settlement and activities constitute the biggest threat to the mountain ecosystem.

MULTICELLULARITY

Type of animal science: Evolution
Fields of study: Cell biology, evolutionary science, paleontology

By studying the fossil record, scientists have found that the first multicellular life appeared on the earth about 1 billion years ago. Before that time, only single-celled organisms existed. The appearance of multicellularity paved the way for the evolution of all higher organisms.

Principal Terms

Ediacarian (Ediacaran) fauna: a diverse assemblage of fossils of soft-bodied animals that represents the oldest record of multicellular animal life on the earth

eukaryotic cell: a cell that has a nucleus with chromosomes and other complex internal structures; this is the type of cell which makes up all organisms except bacteria

fossils: the remains of ancient life preserved in sediment or rock

multicellular organisms: organisms consisting of more than one cell; there are diverse types of cells, specialized for different functions and generally organized into tissues and organs

Precambrian eon: the earliest chapter of the earth's history, covering the time interval between the formation of the earth, about 4.6 billion years ago, and the beginning of the Cambrian period, about 570 million years ago

prokaryotic cell: a primitive cell that lacks a nucleus, chromosomes, and other well-defined internal cellular structures; only members of the kingdom Monera (such as bacteria) are prokaryotic cells—all higher organisms have eukaryotic cells

Multicellular organisms are those consisting of more than one cell. Three of the five kingdoms of living organisms are multicellular: the plants (Plantae), the animals (Animalia), and the fungi (Fungi). The other two kingdoms consist of single-celled organisms: the bacteria (Monera), which have primitive prokaryotic cells, and the protists (Protista), which have complex eukaryotic cells. Prokaryotic cells lack a nucleus and other internal cell structures and are found today only among the bacteria. Eukaryotic cells, on the other hand, contain a nucleus, other complex internal cell structures called organelles (such as mitochondria, which perform respiratory functions), and sometimes chloroplasts (which contain chlorophyll and perform photosynthesis). All multicellular organisms are composed of eukaryotic cells, so the eukaryotic cell must have evolved before multicellular organisms could develop. It is generally accepted that simpler types of organisms evolved first, followed by more complex organisms.

The Multicellular Kingdoms

Plants are multicellular organisms that have chlorophyll (a green pigment used for photosynthesis), plastids (internal structures on the cell that contain chlorophyll), and a cell wall that contains cellulose. Plants are sometimes called "primary producers" because they can manufacture their own food from carbon dioxide and water through a process called photosynthesis, using sunlight for energy and producing oxygen and organic matter (carbohydrates) as by-products.

Animals are multicellular organisms that cannot produce their own food and must feed on other organisms. They are "consumers." Metazoans have many types of cells, which are organized into tissues, and groups of tissues, which form organs. There are two primary embryonic tissue layers present in all metazoans (except the sponges). These are the ectoderm (outer layer) and the endoderm (inner layer). More advanced metazoans also have a third embryonic cell layer, the mesoderm, which lies between the other two layers.

Fungi (mushrooms and their relatives) possess cell walls like plants, but unlike plants, they lack chlorophyll. Although fungi appear plantlike, they cannot produce their own food because of the absence of chlorophyll, so they must feed by ingesting organic material and therefore are consumers. Because they are neither plants nor animals, the fungi are placed in a separate kingdom (Fungi).

Advantages and Origins of Multicellularity

Multicellularity probably evolved because it gave organisms some sort of advantage, assuring them of a greater chance of survival. Multicellularity allows organisms to become larger (which helps them to outcompete other organisms and provides a greater internal physiological stability), to have a longer life (because individual cells are replaceable), to produce more offspring (because many cells can be dedicated to reproduction), and to have a variety of body plans (which permits adaptation to various modes of life or environmental conditions). Specialization of cells for particular functions allows organisms to become more efficient.

Evidence for the origin of multicellularity comes from the fossil record, studies of the organization and biochemistry of living cells and organisms, and from studies of the embryonic and larval stages of animals. During the Archean eon (between 3.8 and 2.5 billion years ago), only single-celled, prokaryotic life (bacteria-like organisms) existed on the earth. Some of the prokaryotes were photosynthetic, including the cyanobacteria (or so-called blue-green algae). Some of these prokaryotes were colonial, with cells organized into structures such as chains, or filaments, or algal mats. These colonies differ from true multicellular organisms because they generally consist of only one type of cell rather than many types of cells. Colonies of blue-green algae formed moundlike structures called stromatolites, which were quite common during the Precambrian but are present only in a few areas today. Stromatolites appeared about 3 billion years ago but did not become abundant until about 2.3 billion years ago.

The Rise of Eukaryotic Organisms

Eukaryotic organisms appeared during the Proterozoic era. The eukaryotic cell probably evolved from prokaryotic ancestors some time before about 1.4 billion years ago. The oldest convincing fossils of eukaryotic cells are generally considered to be those from the 1.3 billion-year-old Beck Spring dolomite of California. Eukaryotic fossil cells have also been found in chert from the approximately 850 million-year-old Bitter Springs formation of Australia. The earliest eukaryotes were animal-like protozoans. This evolution occurred when photosynthetic prokaryotic cyanobacteria were ingested by protozoans and then developed a symbiotic (mutually beneficial) relationship with them. The evolution of the plantlike eukaryotes probably occurred by at least 1.4 billion years ago. (This date has been suggested because primitive multicellular algae fossils are present in rocks 1.3 billion years old.)

The eukaryotic cell was a prerequisite for the development of multicellular organisms. The plantlike eukaryotes are considered to be ancestral to the multicellular algae and higher plants. The protozoans are considered to be the ancestors of the metazoans (animals). The first multicellular organisms may have been algae. Fossils that appear to be primitive multicellular algae are known from the 1.3 billion-year-old sedimentary rocks of the Belt supergroup of Montana, and the 800 million- to 900 million-year-old Little Dal group of northwestern Canada. Multicellular algae can be found living today in both freshwater and marine environments.

Fossil fungi first appear in the fossil record in the 790 million- to 1,370 million-year-old Bitter Springs formation cherts of Australia. The fossil record of fungi is poor and not well known.

The Rise of Multicellular Animals

Multicellular animals evolved independently of the multicellular plants, probably arising from protozoan ancestors. The oldest evidence of metazoans (multicellular animals) in the geologic record is in the form of trace fossils. Trace fossils are imprints such as tracks, trails, or burrows made in sediment by moving animals. Over time, the sediment hardened into sedimentary rock as a result of compaction and cementation. The earliest trace fossils consist of simple trails and tubelike burrows. In some places, there is a succession of types of trace fossils from simple tubelike burrows in older rocks to more complex structures in younger rocks. This change suggests that the evolution and diversification of increasingly complex burrowing organisms occurred during the latter part of the Precambrian. The oldest trace fossils are less than one billion years old, and many scientists believe that it is unlikely that any trace fossils exist in rocks much older than about 700 million years old. The trace fossils appear in the geologic record just before the first appearance of soft-bodied metazoan fossils. Structures that resemble trace fossils, however, have been reported from much older rocks. Among these questionable traces are the one-billion-year-old Brooksella, which resembles a jellyfish. In addition, tubelike structures from the upper Medicine Peak quartzite in Wyoming have been dated at 2 billion to 2.5 billion years, at least 1 billion years older than the oldest known metazoans. The origin of these older traces is uncertain and may be a result of inorganic processes (such as dewatering of sediment), rather than of organisms.

One possible fossil metazoan that appears to be more than 850 million years old has been reported from the Tindir group of Alaska. This fossil is less than one millimeter long and appears to be a flatworm (phylum Platyhelminthes). Both the age and identification of this fossil have been disputed, but if valid, it is a very important find because some biologists theorize that the earliest metazoans would have been primitive flatworms.

The oldest unquestioned metazoan fossils are the imprints of a diverse assemblage of relatively well-developed, soft-bodied marine animals. More than half of the organisms appear to be some type of cnidarian or coelenterate (related to jellyfishes), about 25 percent appear to be segmented worms (related to annelids), and a small percentage appear to be arthropods (related to insects, crabs, and lobsters). Trace fossils are also present. This assemblage of soft-bodied fossils is called the Ediacaran fauna. It was discovered in 1946 in sandstones of the Pound subgroup in the Ediacara Hills of the Flinders Range in South Australia. The exact age of the Ediacaran fauna is uncertain because there are no nearby rocks of the proper type for radiometric dating. The Ediacaran fauna is clearly Precambrian, however, judging from its position in the geologic sequence. The soft-bodied Ediacaran fossils are separated from the younger fossil shells of the Cambrian (570 million years old) by a thick section of unfossiliferous rock (up to several hundred meters thick). Since the 1950's, fossils similar to the Ediacaran fauna have been found in rocks of approximately the same age on virtually every continent on the earth (with the possible exception of Antarctica). In some of these other areas, it is possible to date radiometrically the rocks associated with the fauna. These radiometric dates indicate that the early metazoan soft-bodied fossils range from about 620 million to 700 million years old. It is likely that the metazoans evolved some time prior to 700 million years ago because these fossils represent well-developed, complex animals.

Skeletonized faunas (animals with shells or other hard parts) did not appear until approximately 580 million years ago. The skeletonized faunas are represented by microscopic scraps, cones, tubes, and plates made of calcium phosphate or a hard organic material called chitin. It is not known exactly what types of organisms produced these skeletal remains, but the tiny fossils are so diverse and complex that it is assumed that the organisms must have had a long history of evolution during the Precambrian. The origin of skeletons was advantageous to marine organisms because hard parts provide protection against predators as well as the mechanical functions of support and muscle attachment.

Theories of the Origin of Multicellular Life

There are a number of theories to explain the origin of multicellular life. Most of the theories are derived from studies of various types of cells and living organisms, including advanced protozoans, early developmental stages (embryos), and larval stages. Four types of cells are central to these theories, and they are grouped into two categories: motile (capable of movement) and nonmotile (not capable of movement). The motile protists include flagellate cells (those with a whiplike "tail," or flagellum) and amoeboid cells (those such as Amoeba, which move by pseudopodia, or fingerlike extensions of the cell membrane). The nonmotile stages include coccine cells (those with many nuclei, sometimes called multinucleate cells) and sporine cells (those that divide and stick together to form multicellular aggregates).

There are many theories that have been proposed to explain the origin of plants, fungi, and metazoans (animals). Formerly, it was thought that plants evolved from prokaryotic algae (cyanobacteria, or blue-green algae), but it is more likely that plants arose from a eukaryotic ancestor, such as a flagellate cell. Flagellate algae are similar to flagellate protozoans, but it is not certain whether the algae evolved from the protozoan or vice versa. The presence of plastids (such as the chloroplasts that contain chlorophyll used for photosynthesis) may be the key feature separating plants from protozoans, fungi, and animals. According to a theory proposed by Lynn Margulis, plastids evolved from prokaryotic blue-green algae that were captured by eukaryotic cells. The sporine cell is another possible ancestor of the plants. Sporine cells appear to have had the capacity to evolve beyond the colony level and to produce complex tissue-level green algae and higher plants.

Fungi used to be considered as plants that had lost (or never evolved) chlorophyll. The discovery of a single-celled stage with flagellae among the more primitive fungi, however, suggests that fungi probably evolved from protozoans.

The ancestral multicellular organisms, which gave rise to all the more-complex living animals, are all extinct. The simplest multicellular animal living today is the sponge (phylum Porifera). The sponges are not considered to be ancestors of the more complex animals because their body organization and developmental history are very different. Sponges have no tissues, mouth, or internal organs. Instead, they consist of an aggregate of flagellate and amoeboid cells (and a few other types) roughly arranged in layers. The sponges may have evolved independently from the other metazoans. Sponges are classified as a distinct side branch of the animal kingdom (Parazoa), with a primitive multicellular grade of organization (no tissues). The remaining multicellular animals are grouped into the Eumetazoa.

Theories of Metazoan Origin

Several theories have been proposed to explain the origin of the metazoans. These theories can be placed into the following categories: evolution from single-celled protozoans; evolution from colonial protozoans; evolution from multinucleate coccine cells as a result of development of internal cell boundaries; and evolution from sporine cells. There are several versions of each of these theories, and there is no general agreement on which theory is best. Some researchers promote the colonial theory as the most widely accepted theory, whereas others claim no longer to take it seriously. Most experts agree that evolution of metazoans from colonial protozoans would seem to be easier than evolution directly from a single cell. Multicellularity may have arisen independently several times, in several different ways.

The colonial theory suggests that the metazoans evolved from flagellate or amoeboid protozoans that lived together in colonies, much like the modern green alga Volvox, which is shaped like a hollow sphere. From an original hollow spherical form, the shape of the ancestral metazoan changed as an indentation or invagination formed in the side. The indentation became larger, producing a double-walled "cup" (envision pushing one's thumb into the side of a deflated ball until that side becomes nested into the other side of the ball, forming a cuplike shape). The double-walled cup shape is referred to as a diploblastic body plan, meaning two layers of body tissue. These two layers are the ectoderm (outer layer) and the endoderm (inner layer). This process of indentation to produce a diploblastic (double-walled) form occurs in the embryos of many animals. The jellyfishes are a good example of animals with a diploblastic body plan. Nearly all groups of animals have ectoderm and endoderm (except the sponges), suggesting that nearly all groups of animals are related. Because the jellyfishes (phylum Cnidaria) have the simplest body plan, they are believed to be the most primitive. The diploblastic ancestral form has been called a gastrea. Ernst H. Haeckel, a prominent nineteenth century German biologist who studied animal embryos, believed that all bilaterally symmetrical animals evolved from a gastrea.

A second theory for the origin of metazoans suggests that the ancestral form was a bilaterally symmetrical animal resembling a flatworm. Some scientists believe that the complex organs and organ systems of metazoans are beyond the evolutionary potential of flagellate and amoeboid cells. The flatworm may have evolved from "cellularization" of a multinucleate coccine cell (formation of cell membranes around each of the nuclei) or from clumping of sporine cells. Most of the cells in the metazoans are sporine cells that stick together to form multicellular aggregates. Sporine protozoans do not exist, so it is hypothesized that sporine ancestors of the metazoans must have evolved from "preprotozoans." These hypothetical ancestors may have been solid balls of cells resembling the early stages of many embryos. At some point, the exterior cells may have developed (or redeveloped) flagellae and become specialized for locomotion, and the interior cells may have become specialized for digestion and reproduction. Such colonies of cells would have resembled the larval (immature) form of cnidarians, called a planula larva, and, hence, they are called planuloids. Planuloids are believed to have given rise to two groups of metazoans, the cnidarians (jellyfishes and their kin) and the flatworms. The primitive flatworms are believed to have been ancestral to all other bilaterally symmetrical metazoans.

Evidence from Rocks

Theories to explain the origin of multicellular life have been developed by biologists as a result of studies of various types of cells and living organisms, including advanced protozoans, early developmental stages (embryos), and larval stages.

Geologists (scientists who study rocks) and paleontologists (scientists who study fossils) have a variety of techniques that they use to search for the evidence of life in Precambrian rocks (older than 570 million years). These include searching for fossil remains and chemical analysis of organic residues that are probably the breakdown products of once-living organisms.

The first step in the search for Precambrian life is to locate rocks of the proper age. Geologic maps exist for virtually all parts of the world. From an examination of these maps, it is possible to identify areas that contain rocks of the proper age. (The age of a rock is determined by radiometric dating.) Age, however, is not the only consideration. For fossil remains to be preserved, the rocks must also remain little altered from the way they were originally deposited. Metamorphism (geologic alteration caused by heat and/or pressure) has deformed many Precambrian rocks to the extent that any fossils that may have been present can no longer be recognized.

Assuming that undeformed rocks of the proper age can be located, the search begins for fossil remains. Unfortunately, most Precambrian rocks are not fossiliferous. Precambrian multicellular fossils are found in only a few places in the world. In Australia, soft-bodied Precambrian metazoan fossils are restricted to a few thin layers of sandstone in a sequence of Precambrian rock more than one thousand meters thick. In most places in the world, however, there is a thick section of unfossiliferous rock separating the Precambrian metazoan fossils from the shelly faunas in the Cambrian rocks. This unfossiliferous sequence of rock is an interval for which there is little or no information on the types of life that existed.

Before multicellular organisms appeared (prior to perhaps one billion years ago), only microscopic, single-celled organisms existed on the earth. Microscopic fossils of single-celled organisms are found by careful examination of fine-grained, dark-colored rocks such as black cherts. The black color of the rocks commonly indicates the presence of carbon, which is present in all living organisms and which may be preserved in some fossils. Very thin slices of rock are prepared and mounted on glass slides so that the organic matter can be studied. These slices of rock, called thin sections, are so thin that light can pass through them, and they are examined with a microscope. Much of the carbon in these rocks is present as amorphous (indistinct or shapeless) patches, but in some places, microscopic structures are present that appear to be the fossilized remains of single-celled organisms. Pieces of rock can also be prepared for examination using a scanning electron microscope. The search for microfossils is difficult and painstaking. Among the problems involved are the possibility of contamination by modern-day organic matter in the laboratory and the possibility that the microscopic structures may really be inorganic in origin.

Chemical tests are used to search for the products of biological activity, which may be preserved in rocks. In principle, rocks that have been influenced by biological activity should contain certain characteristic isotopic ratios. There are a number of problems inherent in searching for organic residues. Organic material may have been preserved in the rock, but it could easily have been altered subsequently by heat and pressure or by circulating fluids. In addition, circulating fluids can contaminate the rocks by introducing organic material from much younger rocks.

Multicellularity in the Evolutionary Process

Studying the origin of multicellularity helps one to understand the conditions that led to the evolution of plant and animal life on the earth. As one begins to understand how multicellular life evolved, one may begin to wonder about why it was such a slow process. It is known that the earth formed about 4.6 billion years ago and that the first cells appeared about 3.5 billion years ago, but that the first multicellular life did not appear until approximately 1 billion years ago. In other words, it took more than 3.5 billion years for multicellular life to develop. More than three quarters of the earth's history had passed before multicellular life ever appeared.

One may also begin to wonder about the conditions that promoted the origin of multicellular life. Of all the planets in the solar system, the earth seems uniquely suited to life. Two of the most important factors involved are the presence of liquid water (which requires a specific temperature range) and the presence of an oxygen-rich atmosphere. None of the other planets in this solar system has either of these two characteristics. Interestingly enough, the earth originally did not have liquid water or an oxygenated atmosphere. Geologic evidence suggests that the earth's early atmosphere was the result of volcanic outgassing and that it consisted of gases such as carbon dioxide, carbon monoxide, ammonia, methane, hydrogen sulfide, nitrogen, and water vapor. As the planet cooled from its original molten state, the water vapor in the atmosphere condensed to form liquid water, which fell to the earth as rain and accumulated to form the oceans, rivers, and lakes. There is abundant geologic evidence that the earth's early atmosphere lacked the free oxygen that is breathed today. In the absence of free oxygen, chemical evolution in the oceans or lakes led to the formation of organic compounds, or what has been called the "primordial soup." The first living cells, the prokaryotes, evolved in this organics-rich water. As time passed, some of the early prokaryotic cells became photosynthetic, which allowed them not only to produce their own food from water and carbon dioxide but also to produce oxygen as a waste product. Oxygen was toxic to these early organisms. In order to survive, the cells had to develop a mechanism to adapt to the presence of increasing levels of oxygen. The buildup of oxygen led to the development of the ozone layer in the atmosphere and to the appearance of the eukaryotic cell. As the percentage of oxygen in the atmosphere increased, it is believed that some threshold level was reached, and it became possible for the environment to support multicellular organisms. That allowed a rapid diversification of life on the earth.

Hence, it appears that multicellular life on the earth appeared as a result of some prehistoric accident that resulted in global atmospheric change—the buildup of a toxic waste product (oxygen) as a result of photosynthesis by early life-forms. One might also speculate on the possible global effects of the increasing waste products that humans are now producing. The thinning of the atmospheric ozone layer is but one manifestation of the way that life is presently changing the earth's fragile environment. Knowing that the formation of the ozone layer was probably essential to the appearance of multicellular life on the earth, it is alarming to speculate on the consequences of its destruction. Life as humans know it depends on an earth with environmental conditions in a precarious balance.

Bibliography

Ayala, Francisco J., and James W. Valentine. *Evolving: The Theory and Processes of Organic Evolution.* Menlo Park, Calif.: Benjamin/Cummings, 1979. This book covers the basic principles of evolution and contains a section on the geologic record, which is extremely important in studies of the origin of early life-forms. It is designed for a college-level audience but is clearly written and easy to read.

Bittar, E. Edward, and Neville Bittar, eds. *Evolutionary Biology.* Greenwich, Conn.: JAI Press, 1994. A collection of essays on the structure and dynamics of DNA, RNA, and protein, and more general topics on the origin and cellular basis of life.

Boardman, Richard S., Alan H. Cheetham, and Albert J. Rowell, eds. *Fossil Invertebrates.* London: Blackwell Scientific Publications, 1987. A textbook that is designed for use in college courses in invertebrate paleontology. It begins with a number of chapters on basic principles (such as ecology, paleoecology, evolution, classification, and fossil preservation), followed by a run-through of kingdom Protista and twelve invertebrate phyla of kingdom Animalia that are commonly preserved as fossils. Well illustrated with photographs and line drawings. Will be most useful for those who have had courses in high school biology and historical geology.

Cloud, Preston. *Oasis in Space: Earth History from the Beginning.* New York: W. W. Norton, 1988. This book is part of a series designed to make science more accessible to the general public. It is clearly written, well illustrated, easily understood, and up-to-date. Unfamiliar scientific terms are explained on first mention in the text, and the reader can easily locate definitions by using the index at the back of the book. A two-page time chart indicating major events in geologic history is in the front of the book. Earth history is clearly covered, in addition to many of the basic principles of geology that contribute to the interpretations.

Futuyma, Douglas J. *Evolutionary Biology.* 3d ed. Sunderland, Mass.: Sinauer Associates, 1998. A textbook aimed at advanced undergraduates and graduate students, emphasizing the history of life and microevolutionary processes. Comprehensive glossary, index, bibliography, abundant illustrations.

Minkoff, Eli C. *Evolutionary Biology.* Reading, Mass.: Addison-Wesley, 1983. A college textbook that deals with evolution in an interdisciplinary way. It is a good reference book that will be most useful to those who have had an introductory course in college-level biology, but it can also be understood by beginners because it clearly explains new terms and has a good index and a glossary.

Selander, Robert K., Andrew G. Clark, and Thomas S. Whittam, eds. *Evolution at the Molecular Level.* Sunderland, Mass.: Sinauer Associates, 1991. A collection of essays focused on four themes: bacteria and viruses, organelles, "selfish" genes, and nuclear multigene families.

Stanley, Steven M. *Earth and Life Through Time.* 2d ed. New York: W. H. Freeman, 1989. A textbook for introductory college historical geology classes that can be readily understood by those without previous training in geology. It clearly covers the origin of life and rise of multicellular organisms during the Precambrian. It also presents a clear picture of the interrelationship between the physical and biological history of the earth. It is amply illustrated and has a glossary, comprehensive index, and summary of the classification of major fossil groups in the back.

MUSCLES IN INVERTEBRATES

Type of animal science: Anatomy
Fields of study: Histology, invertebrate biology

Invertebrates, animals whose name means "without a backbone," make up more than 95 percent of all animal species. The internal organization of each of the invertebrate phyla differs drastically from one to another and from the vertebrate body plan. Variables such as skeletal elements and lifestyle affect the activity and survival of the group, but all invertebrates use muscles built on the same plan as those of vertebrates.

Principal Terms

ACTIN: one of the two major types of contractile proteins; it forms the thin myofibrils of the sarcomere

FAST MUSCLE: muscle cells that respond quickly to nervous impulses; in invertebrates, these muscle fibers have short sarcomeres and a low ratio of thin to thick myofibrils

MYOSIN: one of the two major contractile proteins making up the thick myofibrils

PARAMYOSIN: a structural protein associated with myosin myofibrils and thought to support them

SLOW MUSCLE: muscle cells that respond slowly to nervous impulses; in invertebrates, these muscle fibers have long sarcomeres and a high ratio of thin to thick myofibrils

TROPOMYOSIN: a double-stranded protein that lies in the grooves of actin myofibrils, blocking actin from attachment to myosin

TROPONIN: a globular protein composed of three subunits; one subunit binds calcium ions, and another draws tropomyosin away from actin, which allows myosin to form crossbridges constituting the third subunit

The most obvious characteristic of animals may be movement. Movement requires a mechanism. The mechanism allowing multicellular animals of all kinds to change position or posture is a muscle cell.

The Mechanism of Movement

A muscle cell, also called a muscle fiber, is specialized for contraction. Muscle is composed of many muscle fibers, and each muscle cell contains contractile molecules permitting the cell to shorten and thereby change its shape. Each muscle fiber moves by drawing its ends together or by contracting.

The contractile molecules are common to muscles of invertebrates and vertebrates. There are several kinds. Actin and myosin are the most prominent contractile molecules. Each actin molecule is rounded and forms myofibrils by assembling repetitive monomers to form a helix, a springlike shape. Two of these helices are coiled around each other like two intertwined strings of pearls.

Myosin is a more complex myofibril. Each myosin molecule is composed of a head and a tail. The tails of two myosin molecules are wound around each other helically, while the heads project from the same end but in different directions. In the presence of calcium ions, each head can swivel. If an actin molecule is exposed, the myosin head can attach to it, forming a crossbridge. Since they lie parallel to each other in the cell, when the myosin

Image Not Available

returns to its original position, it pulls the actin myofibril. The ends of the contractile unit move closer to each other, shortening the muscle cell.

Myosin tails lie parallel to each other, but at the opposite ends of the myosin myofibrils, the heads project in opposite directions. The heads lie close to the two end walls that attach the actin myofibrils. There is a small central area where only the oppositely facing tails of the myosin myofibrils are found.

A contractile unit is called a sarcomere. A sarcomere is a repeated unit within a muscle cell consisting of overlapping thick myofibrils (myosin) and thin myofibrils (actin). Since there are areas in which there is no actin and areas in which there is no myosin, some light stripes are seen crossing the myofibrils in a microscopic preparation of certain muscle fibers. Actin myofibrils connect to thick walls that mark the ends of a sarcomere. The myosin myofibrils are connected across the center of the sarcomere. During relaxation, actin is absent from the center, producing a light band. The regular pattern of light and dark areas along the length of the muscle fiber is characteristic of striated or skeletal vertebrate muscle. This vertebrate muscle type is the most studied in physiology and, therefore, is the best known.

The Specifics of Invertebrate Muscles

Invertebrate muscles have similar components, but the arrangement is less regular, the alignment of sarcomeres often being oblique. Actin and myosin myofibril arrangement is not readily delineated, but similar structures exist. A sarcoplasmic reticulum, similar to the endoplasmic reticulum of ordinary cells, is characteristic of vertebrate and invertebrate muscle fibers. It is arranged in a series of flattened sacs over a sarcomere's myofibrils. The sarcoplasmic reticulum can quickly absorb calcium ions, keeping their concentration around the sarcomere low. Without calcium ions, the myosin heads cannot be cocked.

Transverse, or T, tubules extend along the thick end wall of each sarcomere. They conduct the nerve impulse throughout the sarcomere to initiate contraction rapidly and simultaneously. When the impulse reaches the sarcoplasmic reticulum, stored calcium ions are released. This release begins contraction. Contraction ceases only if adenosine triphosphate (ATP) is present. Because they no longer make ATP, dead animals' contracted muscles do not relax; the muscles become stiff (exhibit rigor mortis).

Other molecules are also typically found in muscle cells. Tropomyosin is a strand of molecules that lies in a groove of the helically wound actin myofibrils. It blocks the attachment of myosin heads to actin molecules. Troponin is a three-part molecule that rests along the actin myofibril. One subunit attaches calcium ions. This changes troponin's conformation so that another subunit attracts the tropomyosin molecule, unblocking the actin myofibril so that the cocked head of myosin molecules can attach to the actin.

Paramyosin is a molecule similar to myosin found in invertebrates. It seems to act as a "filler" for myosin, keeping the myosin myofibrils aligned so that they can interact with the actin. It may be the contractile protein of some invertebrate muscle types. It is prominent in the "catch" muscles of mollusks.

Muscle Response Rates

Muscles may vary in their response rates even though they look the same. "Fast" muscle fibers contract rapidly in response to a nerve impulse. "Slow" muscle fibers contract several times more slowly. Although both types use the same contractile machinery, the slow muscle cells have less sarcoplasmic reticulum. This means that the calcium ions necessary to initiate contraction are not released as quickly everywhere along the contractile fibrils and are not pumped away from them as quickly as they are in the fast muscle cells.

Most invertebrate muscles are synchronous. This means that each contraction is initiated by a nerve impulse. The rate of contraction of synchronous muscles is determined by the rate of passage of nerve impulses. Even in flight, these muscles usually contract only about thirty-five times per second. Synchronous flight muscles are connected directly to the wings and are found in insects such as grasshoppers, moths, butterflies, and dragonflies.

True flies and bees, as well as beetles and true bugs, have a specialized kind of flight muscle called an asynchronous muscle. In asynchronous muscles, every contraction is not initiated by a nerve impulse. The contraction rates, up to one thousand times per second, are so rapid that nerve impulses could not be received and acted on quickly enough to produce that contraction rate. In these muscles, contraction is initiated by a nerve impulse received and transmitted by the T tubules, but there is no sarcoplasmic reticulum. Even fibrils removed from the cell and placed in a solution containing calcium ions and ATP contract and relax in an oscillatory fashion. The rates seem to be regulated by the myofibrils rather than by the calcium concentration. The T tubules seem to signal the contraction to begin and later turn off the cycling behavior of the myofibrils.

Asynchronous muscles are not directly attached to the wings of the insect. Elevator muscles are attached to the roof of the thorax. Their contraction pulls the roof of the thorax down and elevates the wings. Contraction of the wing depressor muscles pulls down the wings, but this stretches the wing elevators, stimulating them to contract and allowing the thorax roof to "pop up." Raising the thorax shortens the wing depressor muscles and terminates the active state of the depressors. They relax until stretched again by the elevation of the wings. The elevator and depressor muscle contractions follow the same sequence of stretch → contraction → shortening → relaxation → stretch, but are out of phase with each other. The frequency of wing beats depends upon the mechanical properties of the thorax and wings and not upon the frequency of nerve impulses.

Unlike vertebrate animals, there is a correlation between sarcomere length and speed of contraction. Rapidly contracting arthropod muscle fibers have short sarcomeres and relatively low ratios of thin to thick fibrils. Slowly contracting muscle fibers have long sarcomeres and high ratios of thin to thick fibrils. Intermediate types of fibers can exist within the same muscle.

Variations of Invertebrate Muscle Types

Because invertebrates are so varied, there is no generalization to which an exception cannot be found. For example, lobsters and crayfish have two separate muscle fiber types in their tail musculature. The tails are important in swimming and, particularly, in escape maneuvers. They must flex and extend rapidly to evade predators or aggressors. The bulk of the tail muscles consist of short sarcomere, rapidly contracting flexors and extensors. Thin sheets of long sarcomere—slowly contracting flexors and extensors—lie near the carapace. They are used for postural adjustments and for slow movements.

Flexors and extensors are good examples of another principle of muscle action. Muscles contract and they shorten. This shortening moves a body part. Relaxation allows the muscle fibers to lengthen. The force needed to lengthen the relaxed muscle comes from the contraction of its antagonist, a muscle that produces movement in the opposite direction from that of the first muscle. For example, flexing the tail of a lobster or crayfish is performed by the tail flexors. Relaxation does not return the tail to its extended position. Contraction of the extensor muscles moves the tail away from the body and extends the tail again. Relaxation of the extensors may allow the tail to be less rigid in its extension, but the tail will not flex until the flexor muscles are contracted. Muscles work in antagonistic groups to produce opposite movements (flexion and extension) and to produce postural changes that allow a lobster or crayfish to maintain its position when the current changes direction or speed.

Studying Invertebrate Muscles

Numerous methods are used to study the muscles of the invertebrates. Initially, the contraction patterns of whole muscles were studied by electrically stimulating muscles and their nerves. As in all biology, however, work is being done on the molecular level.

Glycerinated muscle is a preparation used to study the molecular elements necessary for contraction. Soaking muscle cells in glycerin removes the cell membrane and sarcoplasmic reticulum, but leaves the contractile fibrils intact. These can be used to determine the effect of presence or absence of ATP, calcium, magnesium, or other factors that might influence the working of the fibrils. They are used much the same as a whole muscle preparation. The ends of the fibrils are attached to one point that does not move and to another that does move when the muscle fibrils contract and relax. The movement can be recorded on paper or on an oscilloscope screen. The tension generated, or the length of shortening, can be calculated.

Microscopic analysis of the structural organization of invertebrate fibers also adds to the store of knowledge. Most invertebrate muscles do not have the striated appearance of vertebrate skeletal muscles. The myofibrils vary in their arrangements and are often difficult to discern. Microscopic analysis shows that rapidly contracting fibers have low ratios of thin to thick fibrils and slowly contracting fibers have larger ratios of thin to thick fibrils.

Muscles do not function without the coordination of the nervous system. Its contribution is different from that in vertebrates. Invertebrate muscle fibers do not exhibit the all-or-none response characteristic of vertebrates. Invertebrate muscle fibers receive innervation from several nerve fibers. A single nerve may serve many muscle fibers. Any muscle fiber is served by more than one nerve. The contraction strength of invertebrate muscle fibers depends upon the number and types of nerves sending impulses to that muscle cell at any time.

The study of the biochemical composition of myofibrils is also important. Actin and myosin are similar in all species. Vertebrate myosin occurs in two forms. One form has a higher intrinsic ATPase activity and responds quickly; the other has a slower intrinsic ATPase activity and twitches slowly. Invertebrate muscle fibrils have no such differences between myosin molecules. Paramyosin is a molecule peculiar to invertebrates. It is thought to be part of a supporting structure for the myosin tails. Some invertebrate muscles have been found not to have troponin and to have different forms of tropomyosin.

Electrophysiological studies have shown that invertebrate muscle fibers receive excitatory and inhibitory nerve fibers. Excitatory nerve fibers secrete acetylcholine and cause contraction. Inhibitory nerve fibers secrete serotonin and dopamine. The relaxation produced by these fibers is thought to be mediated by cyclic adenosine monophosphate (cAMP), a derivate of ATP. The relaxation may be a result of the breaking of crossbridges stabilized by paramyosin.

Simple and Complex Arrangements

Invertebrate neuromuscular systems are organized along the same general principles as in vertebrates: They coordinate body movements. All muscle cells shorten after receiving a stimulus, but the shortening will produce motion only if there is a skeleton, a structure to which the muscle fiber is anchored and another part to which force can be applied.

Sedentary sea anemones are relatively simple coelenterates that escape from threats by withdrawing their soft tentacles and contracting toward the substrate protected by thick body walls. Their body wall is a cylinder composed of two layers of cells separated by mesoglea, a jellylike material that allows diffusion of nutrients, wastes, and gases. Two groups of muscles are embedded in the body wall. In the outer body wall, longitudinal muscles parallel the long axis of the body. Their contraction shortens the body wall and draws it downward toward its base; its attachment is to the substrate. The circular muscles ring the inside layer of the body wall. Their contraction lengthens the body by squeezing the contents inward and narrowing the cylinder like a Chinese finger puzzle.

More complex invertebrates have more complex arrangements of muscles and skeletal parts. Their movements become more complex also. The best-known examples come from the larger and more numerous invertebrate phyla, the annelids, mollusks, and arthropods.

Annelids and Mollusks

Annelids have a hydrostatic skeleton like that of the sea anemone. Their bodies are divided into discrete segments, each with a fluid-filled cavity. Circular muscles of a segment contract, pressing against the fluid in the cavity extending it. This contraction of the circular muscles stretches the longitudinal muscles and sets the tiny bristles along the side of each segment into the substrate. The contraction of the longitudinal muscles squeezes the fluid into a shorter segment which stretches the circular muscles and widens the segment. The body is pulled forward by the bristles that had been set in the substrate.

One of the few examples of the use of hydrostatic pressure in place of muscles occurs in some spiders. The hind legs of jumping spiders have flexor muscles that bring the legs toward the body. They have no extensor muscles. Rapidly increased body fluid pressure straightens the legs, causing the spider to jump forward.

Mollusks include bivalves—sedentary clams, mussels, and oysters; gastropods—the slowly moving snails and slugs; and cephalopods—some of the quickest, most intelligent, and largest invertebrates, the octopods and squid. The muscular systems of these animals are as varied as their lifestyles.

The bivalves settle as adults in one place. They are unable to move about. Whenever a predator threatens them or environmental conditions change (for example, if the tide goes out), they must close their shells to shield their delicate body tissues. “Catch” muscles protect them by closing tightly without using much energy. These obliquely striated adductor muscles can maintain their contracted state for a long period. A short train of nerve impulses initiates a contraction that may last hours or days with no further nerve impulses. The catch muscle does not stretch readily, so prolonged pressure by a predator, such as a starfish, does not lengthen the muscle. The catch muscle remains contracted until a relaxation mechanism is activated by neural impulses in separate neurons. These catch muscles contain paramyosin surrounded by myosin molecules.

Arthropods

The arthropods are characterized by an exoskeleton, the joints of which allow movement. The skeleton is outside the body. It is composed of the cuticle, a hardened covering of chitin, with a thin, pliable hinge in the joints. Muscles cross the gap covered by the hinge. In arthropods, muscle tension is controlled largely or entirely by gradation of contraction within a motor unit. The degree of depolarization of these muscle fibers depends upon the frequency of impulses transmitted in motor neurons. Each fiber is a part of several motor units. In addition, inhibitory factors to arthropod muscles can prevent depolarization and, hence, contraction of the muscle (unlike vertebrate muscles). The neurons fire in short bursts to produce rapid movements.

Most rapidly contracting, short-sarcomere fibers are innervated by a phasic axon capable of producing rapid movements. The slowest, long-sarcomere muscle fibers are supplied only by the tonic axon that is active most of the time. These fibers provide for slow movements and postural adjustment. Muscle fibers with intermediate contraction times are innervated by both phasic and tonic axons. A muscle can, therefore, contract over a range of speeds and durations. An extreme example of this is the crustacean claw-opener muscle and the stretcher (extensor) of the proximal leg segment, which are both innervated by a single excitatory neuron. Separate inhibitory neurons supply each muscle so that they can be controlled independently.

In lobsters, the differentiation of the claws into a large crusher and a small cutter is correlated with muscular and neural activity. In their younger states, juvenile lobster claws have the same shape. Either claw can develop into the crusher. In the cutter claw, all the muscle fibers transform to fast fibers. In the crusher claw, all the muscle fibers become slow fibers. The change in shape and muscle type depends upon the presence of a manipulable environment and on the animal having unequal neuromuscular feedback to the central nervous system. The presence of a crusher on one side prevents the development of a crusher on the opposite side. Few generalizations describe invertebrates. Their muscles exhibit the same variety as the organisms that make up this diverse assemblage.

MUSCLES IN VERTEBRATES

Type of animal science: Anatomy
Fields of study: Histology, zoology

Vertebrate muscle tissue provides for many vital bodily functions. For these purposes, there are three major types of vertebrate muscle tissue: skeletal, cardiac, and smooth.

Principal Terms

INVOLUNTARY: functioning automatically; not under conscious control

MOTOR NEURON: a nerve cell that transmits impulses from the central nervous system to an effector such as a muscle cell

MOTOR UNIT: a motor neuron together with the muscle cells it stimulates

TISSUE: a group of similar cells that executes a specialized function

TWITCH: a rapid muscular contraction followed by relaxation that occurs in response to a single stimulus

VOLUNTARY: capable of being consciously controlled

The ability of vertebrates to move their bodies and many of the contents of their bodies is a feature of major importance for their survival. The movements result from the contractions and relaxations of tissues specialized for the active generation of force: the muscles. Although initially it may seem sufficient to have only one type of muscle tissue, reflection on the functional requirements makes it clear that more than one type of muscular tissue is probably necessary. For example, the movement of the limbs should be under the conscious, voluntary activation and control of the animal. Otherwise, unwanted and uncoordinated random limb movements would result, or desired and possibly vital movements would not be forthcoming. In addition, the control of the limb movements should be precise, with as wide a range as possible for the forces which can be generated.

On the other hand, consider the movement of the blood through the circulatory system. This job must be continuously performed every minute of the animal's life. It would obviously be better to have this function run automatically, without the need for conscious, voluntary activation and control. The need for precise control of the forces generated here is also not as great as for the limb movements, nor is the need for a wide range of forces as great. The flow of blood to the various organs can be much better regulated by varying the diameter of the blood vessels at or near their entrance to the organs, thereby varying the flow into the organs, while the pumping forces generated to propel the blood remain relatively constant.

For the functions of controlling blood flow into organs and the mixing and passage of food through the digestive tract, it is again most reasonable to have automatic operation of the muscles involved, without the need for conscious, voluntary activation and control. To control the huge number of such muscles consciously is an impossible task in any case. Also, these muscles need to be able to change their lengths greatly, and sometimes, to maintain a maximal contraction for very extended periods; however, very rapid actions are not as important.

The preceding considerations make it appear necessary to have three fundamentally different types of muscle tissue. In fact, vertebrates do have three types of muscle tissue, whose different characteristics match these three sets of operational requirements: skeletal muscle tissue, cardiac muscle tissue, and smooth muscle tissue.

Skeletal Muscle

The skeletal muscle tissue occurs in the form of muscles that are usually attached to bones and cause movements of the skeleton. Some skeletal muscles are attached to the skin or to other skeletal muscles. They are under the animal's conscious, voluntary control. Skeletal muscle cells are long, cylindrically shaped cells with rounded ends and, when viewed under a microscope, are seen to have thousands of alternating light and dark bands oriented perpendicular to their long axis. Because of this appearance, skeletal muscle cells are said to be striated. The cells of a muscle are arranged in a parallel fashion, with their long forms mostly following the long axis of the parent muscle.

When a nerve signal stimulates a skeletal muscle cell, the muscle cell contracts relatively quickly and then, just about as quickly, relaxes (a muscle twitch). The contraction results in a shortening and thickening of the cell, which pulls the two ends of the cell, and whatever is attached to them, toward each other. The duration of a skeletal muscle twitch varies from muscle to muscle. For example, a muscle cell from one of the muscles controlling eye movements may complete a twitch in about ten milliseconds, while a cell from the soleus muscle (found in the calf of the leg) will complete a twitch about ten times more slowly.

The strength of the overall contraction of a skeletal muscle depends on two factors: the number of individual muscle cells in the muscle which become stimulated and therefore contract (called multiple motor unit summation, or recruitment); and the frequency at which the stimulations, and therefore the contractions, occur (called temporal summation). Since most skeletal muscles are composed of hundreds of individual muscle cells, and since each of the nerve cells (motor neurons) which can stimulate the muscle makes contact with only a relatively limited number of the muscle cells (each motor neuron and the muscle cells it contacts forming a motor unit), it is possible to regulate the strength and precision of the muscle's contractions, voluntarily, over a very wide range. This is accomplished by varying the summations—multiple motor unit (number of motor units activated) and temporal (the frequency of motor unit activation)—to meet the demands of a particular situation.

When two muscle twitches occur in rapid succession, it is possible for the muscle to begin the second twitch before it has completely relaxed from the first twitch. In this case, the contraction of the second twitch adds its strength to the force developed as a result of the first contraction; therefore, the second contraction develops more force than the first contraction. The result of continuing the frequency of such twitch-evoking stimuli is a somewhat jerky, oscillating contraction called incomplete tetanus. At high frequencies of stimulation (for example, about fifty twitches per second), there is no evidence of the muscle relaxing from any one twitch before the following twitch takes place, and the muscle makes a very smooth and sustained contraction called complete tetanus. If, following an initial single twitch-evoking stimulus of a skeletal muscle cell, a second stimulus is applied too quickly, there will be no further contraction of the muscle cell, regardless of how strong the second stimulus may be. The cell's ability to respond to this second stimulus is absent until enough time has passed to allow the cell to recover its excitability. The period during which the cell's excitability is absent is referred to as its refractory period. The refractory period of skeletal muscle cells is quite short (about five milliseconds). Skeletal muscles are responsible for the movements of the skeleton (skull, limbs, fingers, toes, and trunk) and for the variety of facial expressions that humans can produce. They also permit speaking, eye movements, breathing, chewing, and swallowing.

Cardiac Muscle

The second type of muscle tissue found in vertebrates is called cardiac muscle. It is the muscle tissue found in the heart. Microscopic examination of cardiac muscle cells reveals them also to possess striations similar to skeletal muscle; however, cardiac muscle is not under voluntary control. Hence, cardiac muscle is referred to as involuntary striated muscle. Cardiac muscle cells also differ from skeletal muscle in that the cardiac fibers branch and form interconnections with one another, forming a network of cells. The individual members of a network are joined by special types of cellular junctions called intercalated disks. The intercalated disks permit the excitation of a single cell, which must occur for the muscle cell to contract, to spread throughout the entire network of cardiac cells; therefore, the contraction of any one cardiac cell will result in the contraction of the entire network of cardiac cells. Thus, the heart's muscle tissue network operates as a functional unit, which is very important for the efficient development of the pressures necessary to push blood through the body's circulatory system. Another very important characteristic of cardiac muscle is its ability to contract in a spontaneous, rhythmical fashion without the need for neural or hormonal stimuli (although both nerves and hormones are present and function as modulators of cardiac activity, also at a subconscious level). This property is termed autorhythmicity, and it accounts for the involuntary nature of cardiac muscle. Cardiac muscle twitches are about ten to fifteen times longer than those of skeletal muscle, and the refractory period (about three hundred milliseconds) is about sixty times longer than that of skeletal muscle. The consequences of these traits are important. The long twitch maintains muscular pressure on the blood contents of the heart until most of it has been pumped out of the heart's chambers. The long refractory period prevents the development of tetanus, and allows the heart to relax between beats so that it can be refilled with blood.

Smooth Muscle

The third type of vertebrate muscle is called smooth muscle because of its lack of striations when viewed microscopically. Its basic and most important functions relate to the maintenance of stable internal conditions within vertebrate bodies. Examples of this are the regulation of blood flow to the various organs to supply them with the proper amounts of oxygen and nutrients, the maintenance of blood pressure during postural changes (such as from reclining to standing), the mixing and movement of ingested food within the digestive tract, and the directing of blood flow through or away from the skin to aid in body temperature regulation. Smooth muscle is also usually involuntary and often displays automaticity. Automaticity refers to the fact that smooth muscle often is stimulated to contract simply by being stretched, as, for example, occurs in the stomach following a meal, without the necessity of neural or hormonal stimulation. Nevertheless, involuntary nerves and hormones are both involved in regulating the actions of smooth muscle cells. The functions of smooth muscle are almost always such that contraction is the appropriate response to stretch of the organ containing the smooth muscle (as in the stomach example just mentioned).

Smooth muscle cells are very small: only about eight micrometers in diameter and between thirty and two hundred micrometers long. They are spindle-shaped, tapering toward each end. Although very small, these cells are able to contract to a length which is a much smaller fraction of their resting length than can either cardiac or skeletal muscle cells. Smooth muscle can also remain fully contracted for long time periods and consume very little energy. The speed of contraction of smooth muscle, however, is the slowest of all three muscle types.

Many smooth muscle cells are arranged as functional units which have the individual cells connected to each other by gap junctions. Gap junctions permit the passage of contraction signals from one cell to the next in the network in much the same way as it occurs in cardiac muscle. The result is that when one cell within the network begins to contract, a wave of contraction spreads throughout the entire network of smooth muscle cells.

Studying Vertebrate Muscle

Light and electron microscopes are frequently used to study muscle tissue. In particular, the electron microscope has made it possible to visualize the intricate and highly specialized internal structures of muscle cells, most of which are impossible to view with a light microscope, given their very small dimensions.

Many studies of muscle cells are actually studies of isolated parts of muscle cells. It is possible to break apart muscle cells and to separate many of their components from one another by the use of centrifugation. Centrifugation is the use of centrifugal force to separate objects by size and/or density. A centrifuge is a device in which samples of objects (in this case, muscle-cell structural components) that are to be separated are subjected to high centrifugal force generated by spinning the samples at great speed. The centrifugal force is the force that tends to impel an object outward from the center of rotation.

Once the various subcellular components are isolated, they can be subjected to a wide variety of biochemical tests to determine what type of molecules they contain (such as proteins, lipids, or carbohydrates), how much of each type they contain, and the exact chemical composition of these molecules (such as the amino acid sequence of a protein). In the case of muscle cells, much of the interest has centered on the large quantities of the proteins actin and myosin which they have been found to contain. Using isolated actin and myosin, scientists have learned much about their functions in muscle cells. In particular, it is now known that these two proteins are the molecules which generate the contractile forces which muscle cells are capable of producing. The precise molecular mechanisms are still unknown, but great progress has been made in discovering how actin and myosin accomplish the generation of contractile forces.

Studies of the electrical properties of muscle cells are performed using very sensitive amplifiers connected to fine glass pipette microelectrodes. These electrodes are formed from thin glass tubes which have been heated and pulled apart to produce a tapering of the wall of the tube. The final tip of the tapered tube is much smaller than a muscle cell. This makes it possible to insert the tip into the cell without killing it. When the electrodes are filled with a solution capable of conducting electrical signals, they can record the electrical activity that takes place in living, contracting, and relaxing muscle cells: their electrophysiological properties. These studies have revealed that all muscle cells possess an electrical voltage difference between their interior region and the surrounding environment. Just before a muscle cell begins to contract, this voltage difference decreases toward a zero value extremely rapidly. Combining such electrophysiological studies of muscle cells with simultaneous biochemical studies can be very rewarding.

Other techniques used in the study of muscle tissue include the observation of the relationships that various muscles have with other muscles, with nerves, and with bones, and the use of strain gauges to measure the strength of muscles when different experimental conditions occur (such as temperature changes, blood-flow variations, and pharmacological treatments). Even high speed X-ray motion pictures have been applied to the study of muscle tissue.

The Importance of Muscle

Vertebrate muscle tissue is involved in almost every bodily function. In particular, any function requiring the movement of some body part or parts needs to have a source of motive power. For this purpose, evolution has resulted in the development of the specialized muscle tissues found in all vertebrates, which account for up to 50 percent of their total body weight.

Because of the muscle-tissue characteristics of excitability (the ability to respond to stimuli), extensibility (the ability to be stretched), contractility (the ability to shorten actively and thereby generate force for the production of work), and elasticity (the ability to return to original length following extension or contraction), vertebrates have a wide range of important capabilities available which assist them in their survival.

For the muscular system, disease states or disorders resulting from improper nutrition, injury, or toxic substances are very often life-threatening conditions. This is most obvious for disturbances of the respiratory muscles or of the muscles involved in eating and swallowing; however, muscular disorders involving the heart, the circulatory system, the digestive tract, or any major group of skeletal muscles may also prove to be life-threatening.

The most common heart problems are caused by reduction or blockage of the blood supply to the heart muscle. Reduced blood supply usually is the cause of a reduced oxygen supply. The insufficient oxygen supply weakens the heart-muscle cells, causing the condition of ischemia. Complete interruption of the blood supply to an area of cardiac muscle tissue usually results in necrosis (death) of the affected muscle cells; the condition is referred to as myocardial infarction. The dead muscle cells do not regenerate but are replaced by scar tissue, which is not contractile. This results in decreased pumping efficiency by the heart. Depending on the size and location of the dead area, the result may range from barely noticeable to sudden death.

As a consequence of some bacterial infections, it is possible for the lining of the heart muscle to become inflamed. This can then result in abnormal irritation of some of the heart-muscle cells. These cells can then disrupt the normal autorhythmicity of the heart. Irregular heartbeats and/or uncoordinated contractions among the heart-muscle cells ensues. These conditions are very serious and can lead to death.

Bibliography

Hildebrand, Milton. *Analysis of Vertebrate Structure.* 5th ed. New York: John Wiley & Sons, 2001. This college-level text describes muscle tissue, concentrating on skeletal muscles and presenting their anatomy, physiology, and evolution, as well as cardiac muscle. Smooth muscles are discussed in a variety of places throughout the text. The index is very complete; the glossary is adequate. The references for each chapter are good, but some are of an advanced nature.

Kardong, Kenneth V. *Vertebrates: Comparative Anatomy, Function, Evolution.* 2d ed. Dubuque, Iowa: Wm. C. Brown, 1998. A textbook written for upper-level undergraduates, with solid coverage of the muscular systems in different vertebrates.

Keynes, R. D. *Nerve and Muscle.* 3d ed. New York: Cambridge University Press, 2001. Covers all aspects of the nerve and muscle systems and their interrelations.

Netter, Frank H. *Musculoskeletal System: Anatomy, Physiology, and Metabolic Disorders.* Summit, N.J.: CIBA-GEIGY, 1987. Probably one of the best scientific illustrators, Netter has created stunning and extremely informative diagrams to help both the general reader and specialist in their study of the musculoskeletal system. High school readers may find the text somewhat difficult, but the illustrations alone make this book worth consulting. Highly recommended.

Tortora, Gerard J., and Nicholas P. Anagnostakos. *Principles of Anatomy and Physiology.* 9th ed. New York: John Wiley & Sons, 2000. Chapters 10 and 11 cover muscles and muscle tissue with good illustrations, excellent photographs, and well-written discussion. This college-level text has a very good glossary, an index, and a short list of titles for further reading.

MUTATIONS

Types of animal science: Development, evolution
Fields of study: Biochemistry, cell biology, developmental biology, embryology, evolutionary science, genetics

Mutations have been used to work out metabolic pathways, define genes and their controlling sites, understand how multicellular organisms develop, and study how organisms evolve.

Principal Terms

- ALLELE: one of many possible sequences of a gene
- CONTROLLING SITE: a sequence of nucleotides generally fifteen to sixty nucleotides long, to which a transcriptional activator or repressor binds
- GENE: a sequence of one thousand to ten thousand nucleotides, which usually specifies a protein
- MUTATION: a change in the nucleotide sequence of a gene or of a controlling site; changes in genes alter the protein, whereas changes in controlling sites determine where and how much of a protein is produced

In all living organisms, the hereditary information consists of two complementary strands of deoxyribonucleic acid, known as DNA. DNA strands are constructed of subunits called nucleotides that consist of a nitrogenous base, a deoxyribose sugar, and a phosphate. Generally, DNA strands consist of millions of nucleotides attached to each other like the rings of a chain. There are four different nucleotides. The two complementary strands are held together by hydrogen bonds between the bases. If there is an adenine (A) in one strand, it hydrogen bonds to a thymine (T) in the complementary strand. Similarly, if there is a guanine (G) in one strand, it hydrogen bonds to a cytosine (C) in the other strand. Thus, the amount of A is equal to T and the amount of G is equal to C. The order of nucleotides in a strand specifies the order of amino acids in proteins.

Genetics is the study of how the information in DNA molecules is expressed and how DNA molecules account for the heredity of an organism. Changes in the sequence of nucleotides in DNA may alter an organism's proteins, which in turn may change one or more of an organism's traits. DNA changes are called mutations, and the organisms that harbor mutations are known as mutants. The commonly encountered trait or organism is referred to as the wild-type. The characterization of mutations and mutants has been and still is one of the best ways of discovering the function of genes and determining how organisms maintain themselves, evolve, and develop. A study of mutations and mutants also has shed light on numerous genetic diseases.

Heat: The Cause of Most Spontaneous Mutations

Most mutations are caused by the instability of the nucleotide bases. Sometimes bases hit by rapidly moving water molecules briefly alter their chemistry. These chemical changes are known as tautomeric shifts. Tautomeric shifts alter the distribution of electrons and protons in the bases so that bases in the complementary strands no longer pair normally. The redistribution of electrons and protons in the bases causes abnormal pairings to occur. For example, an abnormal adenine (A*) pairs with C and an abnormal guanine (G*) pairs with T.

When a DNA molecule is being replicated, spontaneous tautomer shifts can result in permanent mutations. Spontaneous mutations occur, for example, when an A in the template strand undergoes a tautomer shift (A→A*) just as the DNA polymerase reaches it. A cytosine pairs with the A* and becomes part of the new strand being synthesized by the DNA polymerase. When this new strand, with a C in it instead of a T, functions as a template, the complementary strand will have a G in it rather than an A. This type of tautomeric shift during DNA replication converts what normally would have been an A = T base pair in "granddaughter" DNA to a G = C base pair.

Chemicals That Cause Mutations

Mutations are induced by many chemical and physical agents that are called mutagens. Many chemicals act as mutagens. Nitrous acid, for example, diffuses into cells and removes amino groups from DNA bases. These chemically altered bases no longer base pair normally. When DNA is replicated or repaired, incorrect nucleotides are inserted opposite the chemically altered bases. Nitrous acid changes adenine to hypoxanthine, which pairs with cytosine. It also changes guanine to xanthine, which pairs with T.

Base analogues are molecules that closely resemble normal nucleotides and consequently are incorporated into DNA that is being repaired or replicated. A base analogue to thymine, such as 5-bromouracil (5BU), is efficiently incorporated into DNA. 5BU spontaneously undergoes tautomeric shifts at a high rate. The abnormal form of 5BU pairs with G rather than A. Thus, 5BU introduces many base pair transitions in newly synthesized DNA molecules.

The most potent mutagens are alkylating agents, such as nitrosamines, methyl bromide, and ethylene oxide. These mutagens attach methyl or ethyl groups (alkyl groups) to A and G. This causes A and G to undergo tautomeric shifts at a higher than normal rate.

High-Energy Electromagnetic Radiation and Particles

Ultraviolet (UV) light is a powerful mutagen. It generally penetrates cells but is readily absorbed by thymine and cytosine bases in DNA. When two thymines or two cytosines next to each other in a strand absorb UV light, they often react chemically with each other to form thymine dimers or cytosine dimers that distort the DNA. These distorted regions stimulate a repair system that cuts out the

The Use of a Mutation to Determine a Catabolic Pathway

Sir Archibald Garrod (1857-1936) was an English physician who studied the effects of a mutation in humans and discovered a catabolic pathway. Garrod's research into the cause of alkaptonuria, a condition where the urine turns black upon exposure to the air, led to the idea that alkaptonuria occurred in persons with two defective genes for the enzyme that eliminates homogentisic acid in the urine. Homogentisic acid turns black when oxidized by oxygen.

In a paper published in 1902, Garrod analyzed a number of families where alkaptonuria occurred, establishing that the trait was recessive and followed simple Mendelian genetics. This was the first account of recessive inheritance in humans. When Garrod fed alkaptonuric patients homogentisic acid, their urine blackened upon exposure to air and contained nearly the same amount of homogentisic acid that they consumed. Normal individuals given homogentisic acid contained no detectable homogentisic acid in their urine. By feeding alkaptonuric patients various compounds that might give rise to homogentisic acid, Garrod discovered the metabolic pathway that led from the amino acids phenylalanine and tyrosine to homogentisic acid.

In his book published in 1908, *Inborn Errors of Metabolism*, Garrod concluded that alkaptonuria is caused by a block in the catabolic pathway that eliminates homogentisic acid. He reasoned that the catabolic block was caused by the lack of a specific enzyme. The fact that the trait followed Mendelian genetics suggested that a functional gene normally specified the enzyme involved in the breakdown of homogentisic acid. This was the beginning of the idea that genes specify enzymes.

Mutations Used to Determine an Anabolic Pathway

Between 1937 and 1941, George W. Beadle and Edward L. Tatum isolated fungal mutants that were unable to synthesize various vitamins and amino acids. They isolated these mutants to try to understand how genes control specific reactions in various metabolic (synthetic) pathways. The mutants would not grow on a simple medium unless supplied with the nutrient they were unable to synthesize. Beadle and Tatum induced large numbers of mutations in the fungus they were studying and isolated hundreds of mutants. Seven mutants were isolated, each carrying a defective form of a gene involved in the synthesis of the amino acid arginine. Using these mutants, Beadle and Tatum were able to order the chemical reactions by feeding the fungal mutants different metabolic intermediates. If the fungal mutants grew when a particular metabolic intermediate was provided, then the gene mutation affected a step leading to the synthesis of the intermediate. If the mutant did not grow, however, then the gene mutation affected a step that converted the intermediate into arginine. They concluded from their experiments that each gene controlled a different chemical reaction. They confirmed that a specific chemical reaction fails to take place in diploid organisms if both representatives of a given gene were defective. Beadle and Tatum's research strengthened the idea that genes specify enzymes. Their idea became known as the "one gene-one enzyme" hypothesis.

dimers and some DNA on either side and replaces the DNA with normal nucleotides. Excessive repair leads to an increased occurrence of spontaneous mutations. Sometimes a distortion in the template allows the DNA polymerase to add or to leave out nucleotides as it moves along the template during strand synthesis. This may explain how some additions and some deletions occur.

Very energetic electromagnetic radiation, such as X rays and gamma rays, as well as high-energy particles released from radioactive atoms, also induce mutations. These energetic mutagens easily penetrate cells and chemically alter many molecules in their path by stripping away electrons. Ions and radicals formed by these mutagens react with the DNA, causing bases to be released and DNA to break. DNA deletions, DNA transpositions, and DNA inversions may be promoted by DNA breakage.

When a gene is mutated, the protein the gene specifies generally becomes nonfunctional. In bacteria that have only one copy of each gene, traits are immediately altered by a mutation. On the other hand, in animals and plants that may have more than one copy of a gene, a mutation in only one gene may not produce a new trait because the wild-type (normal) gene often provides enough of the essential protein. When developing animals and plants are missing both genes, however, they may fail to develop or they may develop, but in a different way.

A few mutations are beneficial to the organism that acquires them and may make the organism better adapted to its environment. These beneficial mutations may make a protein work a little better or in a different way. Some mutations are also beneficial because they create diversity in a population. Diversity promotes the survival of a population by ensuring that some organisms survive if the environment drastically changes. A population that is too well adapted to a particular environment will not survive if there are significant changes in the environment. There have been at least five major mass extinctions during the history of life on earth, in some cases eliminating more than 85 percent of all species. The organisms that survived these mass extinctions were much less specialized than the organisms that did not.

Usefulness of Mutations

Mutations have been extremely useful in the study of organisms. Mutations allow scientists to understand what a particular gene and its product do. If the mutation eliminates the gene (and prod-

Mutations Used to Determine How Genes Are Regulated

In 1963, François Jacob and Jacques Monod published a classic paper in which they presented a model for how genes might be regulated. They used wild-type and mutant bacteria to demonstrate that certain enzymes are not produced when the genes that specified the enzymes are blocked by a repressor protein. Wild-type bacteria contain a repressor gene (R). A repressor specified by the repressor gene blocks DNA transcription (the synthesis of mitochondrial ribonucleic acid, mRNA) by binding to a controlling site (operator site, O) on the DNA that partially overlaps the ribonucleic acid (RNA) polymerase binding site (promoter site, P). If RNA polymerases are prevented from binding DNA, transcription is blocked. When transcription of a gene is inhibited, no enzyme can be synthesized. Jacob and Monod demonstrated that certain mutations (O) in the operator site could block repressor binding to the DNA. These controlling site mutations result in the continuous synthesis of mRNA and the enzymes the mRNA specified. These operator constitutive mutations (O) were shown to prevent repressor binding. Certain mutations in the repressor gene (R-) would eliminate the repressor and result in continuous synthesis of the enzymes regulated by the repressor. Other mutations in the repressor gene would create a super repressor (R) that failed to disengage from the operator site. This blocked the synthesis of the enzymes regulated by wild-type operators (O). Super repressors do not respond to the organic ligand that may bind to them and causes them to disengage from operator sites. Nevertheless, super repressors are unable to bind to constitutive operator sites. Researchers have discovered that many genes are also regulated by protein activators. Some promoter site mutations (P) increase the level of transcription, whereas other promoter site mutations (P-) abolish transcription.

Controlling sites, such as O and P, can be differentiated from genes, such as R, since controlling sites only affect genes on the DNA molecule where they are located (*cis* effect). Genes specifying repressors and activators affect genes both on the DNA molecule where the regulatory genes are located (*cis* effect) and also on other DNA molecules (*trans* effect). This is how genes became known as cistrons.

uct), scientists can guess what the gene does by looking at the affected organism. For example, if a mutation changes eye color (red to white), the affected gene most likely has something to do with pigment synthesis or deposition of the pigment in the eye.

The study of mutations and mutant organisms has helped scientists unravel anabolic (synthetic) and catabolic (degrading) pathways, determine how parental genes combine to produce new characteristics in progeny, clarify what genes are and what they do, establish how genes are regulated, and even decipher how multicellular organisms develop and evolve.

Mutations in Development and Evolution

The study of mutations and mutant organisms at the end of the twentieth century led to an understanding of how multicellular organisms develop and evolve. One of the most useful organisms in unraveling the development problem has been the small fruit fly *Drosophila*. Thousands of mutations that affect development of this organism have been characterized. Scientist found that a hierarchy of genes are involved in development. First, maternal genes are expressed. These genes activate gap genes and these, in turn, activate pair-rule genes. All of these gene catagories are known to be involved in regulating the expression of homeotic genes. Maternal, gap, pair-rule, and homeotic gene products all function as transcriptional activators and repressors. For example, the maternal gene product called bicoid stimulates its own synthesis, whereas it inhibits the synthesis of another maternal gene product called nanos.

Maternal Genes→Gap Genes→Pair Rule Genes→Homeotic Genes

This gene hierarchy is responsible for the anterior-posterior segmentation seen in *Drosophila*. Edward B. Lewis, Christiane Nüsslein-Volhard, and Eric Wieschaus shared the 1995 Nobel Prize in Physiology or Medicine for their studies of the genes that control *Drosophila* development.

Thomas Hunt Morgan

Born: September 25, 1866; Lexington, Kentucky
Died: December 4, 1945; Pasadena, California
Fields of study: Genetics
Contribution: Morgan's studies popularized the use of the fruit fly *Drosophila* for the study of animal genetics. He is credited with discovering the first sex-linked trait in *Drosophila* and with demonstrating how new characteristics could be passed on to successive generations. Morgan and his students showed that chromosomes exchanged genes, a process known as crossing over. In 1933, Morgan was awarded the Nobel Prize for Physiology or Medicine for his work on *Drosophila* genetics.

In his classic paper of 1910, Thomas Hunt Morgan described very rare white-eyed flies that appeared spontaneously in a red-eyed population. Because these mutants were always males, Morgan suspected that the gene controlling eye color was linked to the X chromosome that influenced the development of sex. The observation that white-eyed females could be produced from certain matings, however, indicated that the white-eyed trait was not limited to males.

Morgan's experiments demonstrated for the first time that a gene controlling eye color was linked (or limited) to the X chromosome. Red and white eyes are caused by different alleles of the same gene. These alleles on the X chromosome are represented in the following manner: X and X. Any gene linked to the X chromosome is called a sex-linked gene. In *Drosophila*, two X chromosomes generally result in a female fly, whereas one X chromosome results in a male. Morgan found that the R allele inducing red eyes is dominant over the r allele that allows white eyes to develop when it is the only allele a fly has.

The Y chromosome that pairs with the X chromosome in males (XY) lacks sex-linked genes. Thus, mating red-eyed females (XX) to white-eyed males (XY) results in all first filial (F1) generation flies, XX females and XY males, having red eyes. Matings between the F1 flies demonstrated that the red-eye-inducing allele and the white-eye-promoting allele always remained associated with the X chromosome. This suggested that the alleles were linked to the X chromosome.

In 1913, A. H. Sturtevant, working in Morgan's laboratory, reported on mutations linked together on a fruit fly's X chromosome. Sturtevant demonstrated that recombination between two X chromosomes could separate genes controlling different traits. In addition to using the alleles that determined eye color, Sturtevant used alleles that influenced wing formation. A normal wing forms under the influence of the L gene, but a miniature wing is associated with the l allele of the L gene. Genes linked on the X chromosome may be shown as follows: XL. Sturtevant observed recombination when he characterized the offspring from certain crosses. A female fly with red eyes and normal wings, XlXL, usually produces two types of eggs. One type of egg has the Xl chromosome, whereas the other type of egg has the XL chromosome. Very infrequently, when there is a crossover between the X chromosomes, rare eggs are produced with recombinant X chromosomes, one type of egg has the Xl chromosome, whereas the other type of egg has the XL chromosome. When these recombinant eggs fuse with a sperm carrying only a Y chromosome, recombinant male flies result, those that have normal eyes and normal wings (XLY) and those that have white eyes and miniature wings (XlY). By using various mutant flies, Morgan and Sturtevant discovered that they could both order a number of different genes on the X chromosome and determine how far they were from each other. The farther a gene is from another gene, the greater the number of recombinant offspring. The pattern of offspring was used to determine the sequence of genes on the X chromosome. Finding flies with mutations in different genes was essential for determining the sequence of genes and the distances between them.

—Jaime Stanley Colomé

Thomas Hunt Morgan popularized the use of the fruit fly Drosophila melanogaster *for the study of genetic mutations.* (Library of Congress)

Homeotic genes are found in all multicellular organisms. Homeotic genes similar to those found in *Drosophila* control the development of segments most visibly exemplified by the vertebrae and the bones in animals' appendages. Mutations in homeotic genes or their controlling sites affect the development of segments. Segments can be eliminated or modified by homeotic gene controlling site mutations.

One well-studied homeotic gene in *Drosophila* is the gene antennapedia, *antp*. Certain mutations in the controlling sites for the antennapedia gene result in legs developing rather than head antennae. Another homeotic gene is ultrabithorax, *ubx*. Some mutations in the controlling sites for ultrabithorax gene result in a second pair of wings developing where the pair of halteres normally develop. Halteres are tiny, winglike appendages that all flies have, which promote stable flight. Other mutations in the controlling sites for *ubx* produce a second pair of winglike structures that are half haltere (anterior portion), half wing (posterior portion). By studying mutations and the altered traits, scientists have discovered that controlling site mutations change when and where proteins are synthesized. For example, if a protein is to be produced in seven segments along the anterior-posterior axis of an animal, there must be at least seven different controlling sites that can respond to the different activators and repressors produced in each segment.

Numerous studies suggest that antennapedia and ultrabithorax are transcriptional repressor-activators that not only repress the development of legs and wings, but also stimulate the development of antennae and halteres, respectively. The study of *Drosophila* mutants is beginning to clarify how antennae and mouth parts evolved from leglike appendages and how halteres evolved from wings. The study of genes and controlling sites has led to the understanding of their role in the maintenance, development, and evolution of every organism.

NATURAL SELECTION

Type of animal science: Evolution
Fields of study: Ecology, evolutionary science, genetics

Natural selection is the process of differential survival and reproduction of individuals resulting in long-term changes in the characteristics of species. This process is central to evolution.

Principal Terms

ADAPTATION: the process of becoming better able to live and reproduce in a given set of environments

EVOLUTION: any cumulative change in the characteristics of organisms or populations over many generations

FITNESS: the relative ability of individuals to pass on genes to subsequent generations

HERITABILITY: the extent to which variation in some trait among individuals in a population is a result of genetic differences

POPULATION: a group of individuals that occupy a common area and share a common gene pool

SPECIES: the group of all individuals or populations that interbreed or potentially interbreed with one another under natural conditions

Natural selection is a three part process. First, there must exist differences among individuals in some trait. Second, the trait differences must lead to differences in survival and reproduction. Third, the trait differences must have a genetic basis. Natural selection results in long-term changes in the characteristics of the population.

As one of the central processes responsible for evolution, natural selection results in both fine-tuning adaptations of populations and species to their environments and creating differences among species. The importance of natural selection was first recognized by Charles Darwin, who provided the first widely accepted mechanism for evolutionary change. Natural selection is one of several processes responsible for changing the characteristics of populations and leading to an increase in adaptiveness. Other processes include genetic drift and migration. These processes interact with the processes responsible for producing variation (mutation and development) and those responsible for determining the rate and direction of evolution (mating system, population size, and long-term ecological changes) to establish the path of evolution of a species.

The Process of Natural Selection

Natural selection occurs through the interaction of three factors: variation among individuals in a population in some trait, fitness differences among individuals as a result of that trait, and heritable variation in that trait. If those three conditions are met, then the characteristics of the population with respect to that trait will change from one generation to the next until equilibrium with other processes is reached. An example that demonstrates this process involves the peppered moth. It has two forms in the United Kingdom, a light-colored form and a dark-colored form; there is variation in color among individuals. Genetic analysis has shown that this difference in color is caused by a single gene; the variation has a heritable basis. The moth is eaten by birds that find their food by sight. The light-colored form cannot be seen when sitting on lichen-covered trees, while the dark-colored form can be seen easily. Air pollution kills the lichen, however, and turns the trees dark in color. Then, the dark-colored form is hidden and the light-colored form visible. Thus, differences in color lead to fitness differences. In the early nineteenth century, the dark-colored form was very rare. In the last half of the nineteenth century, however, air pollution increased, and the dark-colored form became much more frequent as a result of natural selection.

The characteristics of a population can be changed by natural selection in several ways. If individuals in a population with an extreme value for a trait have the greatest fitness on average, then the mean value of the trait will change in a consistent direction, which is called directional selection. For example, the soil in the vicinity of mines contains heavy metals that are toxic to plants. Individuals with the greatest resistance to heavy metals have the highest survivorship. Evolution leads to an increase in resistance. If individuals in a population with intermediate values for a trait have the greatest fitness on average, then the variation in the trait will be reduced, which is called stabilizing selection. For example, in many species of birds, individuals with intermediate numbers of offspring have the greatest fitness. If an individual has a small number of offspring, that parent has reduced reproduction and a low fitness. If the number of offspring is large, the parent will not be able to provide enough food for all the young, and most, or all, will starve, again resulting in reduced reproduction and a low fitness. Evolution leads to all birds producing the same, intermediate number of offspring. If individuals in a population with different values for a trait have the greatest fitnesses on average and intermediates have low fitness, then the variation in the trait will be increased. This is called disruptive selection. For example, for Darwin's finches, individuals with long, thin bills are able to probe into rotting cactus to find insects. Individuals with short, thick bills are able to crack hard seeds. Individuals with intermediate-shaped bills are not able to do either well and have reduced fitness relative to the more extreme types. Evolution leads to two different species of finch with different bills.

A Slow and Holistic Process

Natural selection is a slow process. The rate of evolution—that is, response to selection—is determined by the magnitude of fitness differences among individuals and the heritability of traits. Fitness differences tend to be small so that more fit individuals on average may have only a few more offspring than less fit individuals. Heritabilities of most traits are low to intermediate, meaning that most differences among individuals are not a result of genetic differences. So, even if one individual has many offspring and another has few offspring, they may not differ genetically and no change will occur. For example, if all the beetles in a population were between one and two centimeters in length and there was selection for larger beetles, it could take five hundred generations before all beetles were larger than two centimeters. Also, the direction of selection may change from one generation to the next, so that no net change occurs.

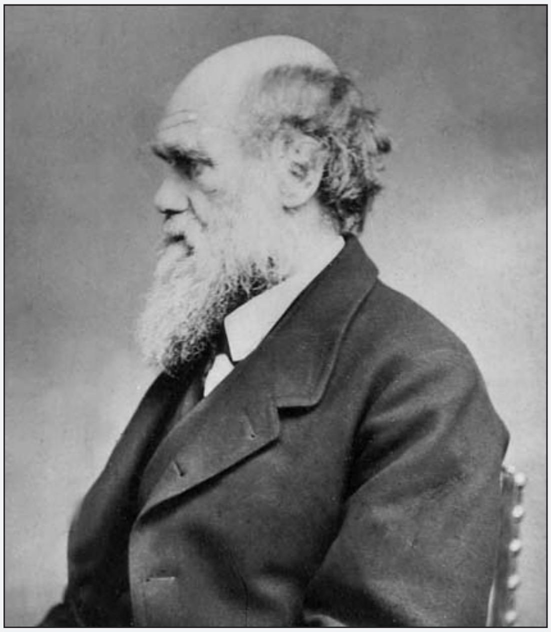
Natural selection does not act on traits in isolation. How a trait affects fitness in combination with other traits, called correlational selection, is important. For example, fruit flies lay their eggs in rotting fruit. Considered in isolation, a female should always lay as many eggs as possible. One fruit is not big enough for all the eggs she might lay, however, so she must fly from fruit to fruit. Flying requires energy, and the more energy that is used in flight the less that can be used to make eggs. So natural selection results in the division of energy between eggs and flight that yields the greatest overall number of offspring. This example demonstrates that the result of natural selection is often a trade-off among different traits.

By acting differently on males and females, natural selection results in sexual selection. This form of selection can explain differences in the forms of males and females of a species. In general, because male gametes, sperm, are much smaller and "cheaper" to produce than female gametes, eggs, more sperm than eggs are produced. As a result, it is possible for one male to fertilize many eggs, while other males fertilize few or no eggs. For example, a lion pride usually consists of

Charles Darwin

Born: February 12, 1809; Shrewsbury, England
Died: April 19, 1882; Downe, England
Fields of study: Entomology, evolutionary science, human origins, invertebrate biology
Contribution: Darwin was not the first philosopher or scientist to posit a theory of evolution, but his theories of natural and sexual selection provided much of the foundation for later scientific evolutionary theory.

Charles Robert Darwin had briefly studied medicine at the University of Edinburgh and attended Cambridge University, intending to prepare for the ministry, when he was offered a chance to sail on the HMS *Beagle* as a naturalist and companion to Captain Robert FitzRoy. The fifty-seven month voyage, from December 7, 1831, to October 2, 1836, allowed Darwin unique opportunities to explore fossils, fish and sea mammals, and coral reefs. Lengthy land excursions allowed him to examine land animals and fossils, primarily in South America.



Charles Darwin's theory of evolution through natural selection revolutionized not only the scientific view of the world but popular understanding as well. (National Archives)

Returning to England, he first published his findings as *Journal and Remarks*, volume 3 in the series *Narrative of the Surveying Voyages of H.M.S. "Adventure" and "Beagle" Between 1826 and 1836* (1839). This work was revised and published the same year as *Journal of Researches into the Geology and Natural History of the Various Counties Visited by H.M.S. "Beagle"* (1839). His findings caused him to question generally accepted assumptions about animal creation and to posit evolutionary change as occurring mainly through natural selection. In later works, he increasingly stressed the importance of sexual selection. Challenged by peers to examine individual species before generalizing about life as a whole, he began lengthy examinations of such life-forms as beetles and barnacles, which he published.

By the 1850's, despite his aversion to public controversy, he accepted the need to publish his general theories. They appeared in 1859 as *On the Origin of Species by Means of Natural Selection: Or, The Preservation of Favoured Races in the Struggle for Life*. Although he avoided discussion of human origin in this work, the controversy he dreaded was forthcoming. His ideas, however, were adopted by young scientists, most notably Thomas Henry Huxley, who sought to establish the natural sciences as disciplines separate from the natural theology that then prevailed in universities. These scientists became his spokespersons, as he continued his experiments at his estate; his theories gained widespread acceptance. In 1871, he dealt directly with the origin of human life in *The Descent of Man*; he followed this, in 1872, with *The Expression of Emotions in Man and Animals*. These works clearly placed man within the animal kingdom, not the product of a separate creation.

Darwin also published on narrower topics involving animal life and fossils, and extensively revised *On the Origin of Species*, ultimately producing six revised editions in the quarter-century after its initial publication. He wrote a brief autobiography, published posthumously in 1887. He was awarded numerous honors in England and on the Continent. At his death, his work was so widely respected that, despite his religious skepticism, England honored him with burial in Westminster Abbey.

—Betty Richardson

one or a few males and many females. Other males are excluded, and they live separately; larger males are able to chase away smaller males. The thick mane on male lions helps to protect their throats when they fight other males. Thus, larger males with thicker manes father more cubs than other males, leading to selection on these traits. Only males are under natural selection since all females, regardless of size, will mate. The result is that males are larger than females and have manes.

Group Selection

Natural selection can occur not only among individuals but also among groups. This process is generally known as group selection; when the groups are composed of related individuals, it is called kin selection. Group selection operates the same way as individual selection. The same three conditions are necessary: variation among groups in some trait, fitness differences among groups because of that trait, and a heritable basis for that trait. For example, in Australia, rabbits introduced from Europe in 1859 spread rapidly during the next sixty years. In order to control the rabbits, a virus was introduced in 1950. At first, the virus was very virulent, killing almost all infected animals within a few days. After ten years, however, the virus had evolved to become more benign, with infected rabbits living longer or not becoming sick at all. Virulent strains of the virus grow and reproduce faster than benign strains. So, within a single rabbit, virulent strains have a higher fitness than benign strains. The longer a rabbit lives, however, the more opportunity there is for the virus to be passed to other rabbits. Thus, a group of benign viruses infecting a rabbit are more likely to be passed on than a group of virulent viruses. In this example, group selection among rabbits resulted in evolution opposite to individual selection within rabbits; however, group selection and individual selection can result in evolution in the same direction. In general, natural selection can act at many levels: the gene, the chromosome, the individual, a group of individuals, the population, or the species.

Natural selection is the primary process leading to adaptation of individuals. It involves many traits acting together, differences among males and females, and differences among levels. The interaction of all these processes of natural selection determines the path of evolution.

Measuring Natural Selection

Natural selection is investigated in two ways: by use of indirect measurements and direct measurements. The indirect methods involve observing the outcome of natural selection and inferring its presence. The direct methods involve measuring the three parts of the process and following the course of evolution. Although the direct methods are preferred, as they provide direct proof of natural selection, in most instances, only indirect methods can be used.

Indirect methods involve three kinds of observations. First, comparisons are made of trait similarities or differences among populations or species living in the same or different areas. For example, many species of animals living in colder climates have larger bodies than those living in warmer climates. It is inferred, therefore, that colder climates result in natural selection for larger bodies. Second, long-term studies are done of traits, in particular changes in a group in the fossil record. For example, during the evolution of horses, their food, grasses, became tougher and horses' teeth became thicker. It is inferred, therefore, that tough grass resulted in natural selection for thicker teeth. Third, comparisons are made of gene frequencies of natural populations, with predictions from mathematical models. Gene frequencies are measured using various techniques, including scoring differences in appearance, as with light-colored and dark-colored moths; using electrophoresis to observe differences in proteins; and determining the sequence of base pairs of deoxyribonucleic acid (DNA). The models make predictions about expected frequencies in the presence or absence of selection. Indirect methods are best at revealing long-term responses to evolution and general processes of natural selection that affect many species. The indirect methods suffer from the problem that often many processes will result in similar patterns. So, it must be assumed that other processes were not operating, or other predictions must be made to separate the processes.

Direct methods involve two kinds of observation. First, there is observation of changes in a population following some change in the environment. There are many types of environmental changes, including man-made changes, natural disasters, seasonal changes, and introductions of species into new environments. For example, from the changes in the peppered moth following a change in pollution levels, one can measure the effects of natural selection. The second type of observation is the direct measurement of fitness differences among individuals with trait differences. For example, individual animals are tagged at an early age and survival and reproduction are monitored. Then, statistical techniques are used to find a relationship between fitness and variation among individuals in some trait. Alternatively, comparisons of traits are made between groups of individuals, such as breeding and nonbreeding, adults and juveniles, or live and dead individuals, again using statistical techniques. For example, lions that breed are larger than lions that do not breed. Direct methods are best at revealing the relative importance to natural selection of the three factors (variation, fitness differences, and heritability). The direct methods suffer from two limitations. It takes a long time for evolution to occur. So, although one can measure natural selection, it is often not known if it results in evolution. Also, for many species, it is impossible or impractical to mark individuals and follow them through their lives.

Many methods can be used to study natural selection and evolution. Each method provides information about different parts of the process. Only through the integration of these methods can the entire process of evolution be revealed.

Adaptation and Evolution

Natural selection is the central process in adaptation and evolution. By understanding how the process operates and where its limits lie, scientists hope to determine why evolution has proceeded in the fashion that it has. Historically, it was only after Darwin presented his theory of natural selection that the idea of evolution became widely accepted in the nineteenth century. In the twentieth century, much of the work of evolutionary biologists during the 1930's, 1940's, and 1950's was to integrate the fields of genetics, ecology, paleontology, and systematics, using natural selection and evolution as the unifying concepts.

Knowledge of natural selection is still growing; many questions proposed by Darwin and others are yet to be answered. It is still not known to what extent organisms are well adapted to their environments or whether the evolution of the parts of the chromosome that are not translated into proteins are a result of processes that do not involve natural selection. Of the many theories of how natural selection works, it is still unknown which ones are the most important in nature and to what extent evolution is caused by natural selection at the level of the individual, the group, and the species.

Genetic engineering requires knowledge of natural selection. The addition of a new gene into an organism will result in natural selection on that gene and change selection on other genes. Efficiency will be gained if successful and unsuccessful outcomes can be predicted beforehand. If genetically engineered organisms are to be released into nature, scientists need to be able to forecast their fates, such as whether the organism will remain benign or will become a pest. Genes added to one organism could possibly spread to other, native species. The solutions to these dilemmas involve predictions of the outcome of natural selection.

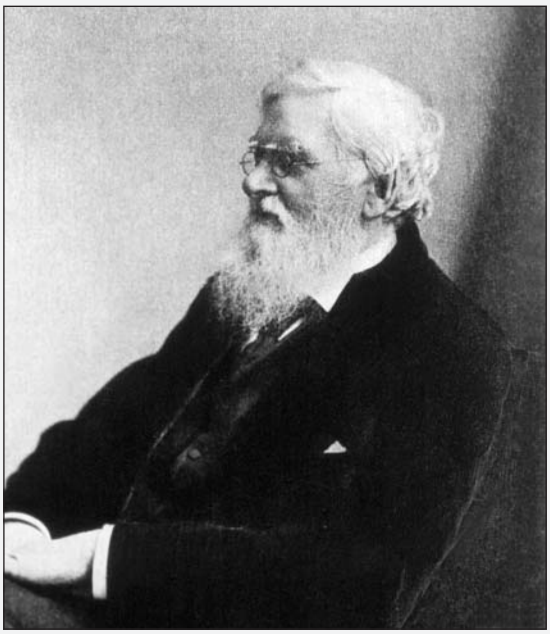
An understanding of natural selection is critical for conservation biology. During the twentieth century, the rate at which natural areas are being destroyed and species are becoming extinct has accelerated tremendously. Conservation biology attempts to stop that destruction and preserve species diversity. For extinction of endangered species to be halted, it must be understood how

Alfred Russel Wallace

Born: January 8, 1823; Usk, Monmouthshire, Wales
Died: November 7, 1913; Broadstone, Dorset, England
Fields of study: Entomology, evolutionary science, population biology, zoology
Contribution: Wallace, a pioneer of the science of zoogeography, proposed a theory of evolution by natural selection in 1855 that predated and stimulated the publication of Charles Darwin's *On the Origin of Species* (1859).

Alfred Russel Wallace grew up in rural Wales and then in Hertford, England. His formal education was limited to six years at the Hertford Grammar School. From 1837 to 1844 Wallace worked in his brother William's surveying business. In 1844, Wallace taught at the Collegiate School in Leicester, England.

In 1848, Wallace and the entomologist Henry Walter Bates embarked on an expedition to Brazil. Wallace and Bates planned to collect and identify biological specimens and then pay for their trip by selling their collections. Wallace spent a total of four years exploring the Amazon River basin, collecting birds, butterflies and other insects.



Alfred Russel Wallace independently proposed a theory of evolution very similar to that of Darwin. (National Library of Medicine)

Unfortunately, on the return voyage Wallace lost his precious collections when his ship caught fire and sank. Nevertheless, the expedition led to the publication of several articles and two books (*Palm Trees of the Amazon and Their Uses* and *Narrative of Travels on the Amazon and Rio Negro,* 1853). These reports attracted the attention of the Royal Geographical Society, which helped to fund his next expedition. For eight years (1854-1862) Wallace continued his research in the Malay Archipelago (Indonesia). Wallace's research on the geographic distribution of animals among the islands of the Malay Archipelago provided crucial evidence for his evolutionary theories and led him to devise what became known as Wallace's Line, the boundary that separates the fauna of Australia from that of Asia. By the time Wallace returned to England in 1862 he had collected over 125,000 animal specimens.

During an attack of a tropical fever, Wallace experienced a flash of insight in which he realized that natural selection could serve as the mechanism of evolution. Within a few days he completed his essay "On the Tendency of Varieties to Depart Indefinitely from the Original Type" and sent it to Charles Darwin for review and possible publication. Darwin was shocked to find that Wallace had developed a theory of evolution identical to that outlined in his own unpublished 1842 essay. Darwin's friends Charles Lyell and Joseph Hooker arranged for a joint presentation of the papers written by Wallace and Darwin and simultaneous publication in the August, 1858, *Proceedings of the Linnean Society.*

Graciously allowing Darwin to claim priority for the discovery of evolution by means of natural selection, Wallace continued to publish works on natural history and travel, including *The Malay Archipelago* (1869), *Contributions to the Theory of Natural Selection* (1870), *Geographical Distribution of Animals* (1876), and *Island Life* (1880). It was Wallace who called evolution by means of natural selection "Darwinism" in order to distinguish this theory from its predecessors. Unlike Darwin, however, Wallace continued to believe that natural selection could not account for the higher faculties of human beings.

—Lois N. Magner

natural selection will affect these species given massive environmental changes. By discovering how evolution is occurring under natural conditions, researchers will learn how to design nature preserves to maintain species.

Bibliography

Avers, Charlotte J. *Process and Pattern in Evolution*. New York: Oxford University Press, 1989. An intermediate-level college text that lays out the evidence for evolution and the processes that cause it. Chapters 6 and 7 present natural selection and its mechanisms and are a good introduction to the mathematical theories.

Bell, Graham. *Selection: The Mechanism of Evolution*. New York: Chapman and Hall, 1997. Clearly explains the processes of natural selection and explores its possible consequences. Offers many examples and gives an extensive review of the literature. Written for nonspecialists with some science background.

Brandon, Robert N. *Adaptation and Environment*. Princeton, N.J.: Princeton University Press, 1990. Explores the varying roles of environment at different levels of natural selection, the external, ecological, and selective environments.

Darwin, Charles. *On the Origin of Species by Means of Natural Selection*. London: J. Murray, 1859. The most important book written on natural selection. The basic premises are laid out, and data from natural and domestic species are presented. The ideas presented here are still being explored and tested.

Endler, John A. *Natural Selection in the Wild*. Princeton, N.J.: Princeton University Press, 1986. This book, although a somewhat more technical presentation, presents the best summary of the process of natural selection. Chapters 1 and 2 are a nontechnical description of the process and a discussion of the relationship between natural selection and evolution.

Futuyma, Douglas J. *Evolutionary Biology*. 3d ed. Sunderland, Mass.: Sinauer Associates, 1998. A textbook for an intermediate-level college course in evolution. Chapters 6 and 7 provide an overview of natural selection, its mechanisms, and its consequences. It is well illustrated and contains many examples.

Gould, Stephen J. *The Panda's Thumb*. New York: W. W. Norton, 1980. A compilation of columns from *Natural History* magazine, this book provides a very entertaining and accessible view of evolution and natural selection. This and Gould's other books are the nonscientist's best introduction to the subject.

Provine, William B. *Sewall Wright and Evolutionary Biology*. Chicago: University of Chicago Press, 1986. Sewall Wright was one of the most important figures in the development of evolutionary biology in the twentieth century. Besides describing his life, this book places his work within the context of the development of evolutionary theory. Chapters 7, 8, and 9 present an excellent overview of theories of evolution and natural selection and are understandable by a general audience.

Suzuki, David T., Antony Griffiths, Jeffrey Miller, and Richard Lewontin. *An Introduction to Genetic Analysis*. 4th ed. New York: W. H. Freeman, 1989. An intermediate-level college text that presents the experimental basis of the understanding of genetic processes. Chapter 23 focuses on natural selection and evolution and is useful for gaining a more mathematical understanding of the phenomenon.

NEANDERTHALS

Types of animal science: Anatomy, classification, evolution
Fields of study: Anthropology, archaeology, evolutionary science, human origins, physiology, systematics (taxonomy)

Neanderthals are the best-known extinct members of the human lineage. It is generally agreed that they were close relatives of modern humans, but the nature of the relationship is vigorously debated. They have been assumed to be a direct ancestor, a diseased member of the species, or an extinct side branch of the family tree.

Principal Terms

DEOXYRIBONUCLEIC ACID (DNA): the chemical that carries the instructions for all living things; closely related organisms have very similar DNA

GENUS: the first part of the scientific name of an organism; members of the same genus but different species are closely related, but cannot mate and produce fertile offspring

MITOCHONDRIA: subcellular structures containing DNA used to estimate the relationships between groups of organisms; the more similar the DNA, the more closely related the groups

SPECIES: the second part of the scientific name of an organism; members of the same species can mate and produce fertile offspring

SUBSPECIES: the third part of a scientific trinomial, assigned to one of two groups that can mate and produce fertile offspring, but that have some strikingly different characteristics

TAXONOMY: the science of classifying and naming living and fossil organisms, or the classification and scientific name of a living or fossil group

The fossil that gave the Neanderthals their name was found in a cave being quarried for limestone in Germany's Neander Valley in 1856. At least two Neanderthal fossils were discovered before the Neander Valley individual; however, neither was recognized as a member of an extinct human group until after the name "Neanderthal" was assigned. Many similar fossils have been found in scattered locations all over Europe and the Middle East since the Neander Valley discovery. Dates assigned to the various fossils indicate that the Neanderthals originated late in the Ice Age and became extinct a few thousand years before the last glacial retreat (from about 200,000 years ago to about 30,000 years ago). Thus the Neander Valley specimen lent its name to a fossil relative of modern humans that occupied Europe and the Middle East late in the Ice Age.

Though the Neanderthals were very similar to modern humans, they had several distinctive characteristics. Neanderthals were short and exceptionally stout-bodied with broad supportive bones and joints. This body form suggests a life filled with intense physical effort. Perhaps the compact body also helped them cope with cold stress under Ice Age conditions. Their brains were somewhat larger than modern human brains. That size may have compensated for the more massive total body size of the Neanderthals, since large-bodied organisms generally have larger brains. Their foreheads sloped up from their exceptionally heavy eyebrow ridges, their jaws extended forward beyond the plane of the face, and their chins were weakly developed. These and several other characteristics are used to define a fossil find as a Neanderthal.

Structure and Behavior

Rudolph Virchow's initial interpretation of the Neander Valley fossil as a diseased human was popular for a time. Virchow held that the fossil was a modern human whose unique features were the result of disease. However, as more fossils with the same characteristics were discovered all around Europe and the Middle East, this explanation became untenable. Later, misinterpretation of the characteristics of Neanderthal fossils led Marcellin Boule and others to interpret Neanderthals as stooped, bent-kneed, apelike subhumans with an animal nature to match.

Additional fossil discoveries, including evidence for toolmaking and burials, sometimes with flowers placed in the grave, caused anthropologists to rethink the presumed animal nature of the Neanderthals. Although the evidence for flowers has been challenged, the evidence for burials, presumably accompanied by mourning, is accepted by many anthropologists. In addition, fossils showed that some Neanderthals lived much of their lives with deformed limbs and other disabilities, which would have made it difficult or impossible for them to fend for themselves. Yet they apparently lived many years in that condition, suggesting the support of other members of a social group. Such behavior was not in keeping with Boule's picture of the Neanderthals as nonhuman animals.

Reinterpretation of the anatomic evidence also suggested that, instead of a bent-kneed, stooped posture, the Neanderthals walked on two rather straight legs and had hands capable of manipulating materials and making tools, much as modern humans do. All this indicated that the Neanderthals were more like modern humans than Boule's interpretation, and they came to be thought of in that light.

Taxonomic Relationship to Modern Humans

Neanderthals have always been recognized as close relatives of modern humans, but the specific taxonomy of the relationship is still a point of contention. They are placed in the same genus (*Homo*) as modern humans by almost all anthropologists, but researchers debate whether they were members of our species, *Homo sapiens* or belonged in their own species, *Homo neanderthalensis*. The discussion of the structure and behavior of Neanderthals bears directly on this question. If the Neanderthal characteristics were the result of disfigurement caused by disease, Neanderthals were simply aberrant humans and not especially interesting from the perspective of human evolution. However, if they were stooped, bent-kneed, and animal-like in behavior, they were probably a separate species, perhaps ancestral to modern humans, and therefore more interesting from the evolutionary perspective. On the other hand, if they were upright in stature, were skilled toolmakers, were supportive of their handicapped and elderly, and buried their dead with mementos such as flowers, they might earn the designation *Homo sapiens* and take on an even greater interest to the more modern members of that species.

Such arguments are part of the practical taxonomy of the Neanderthals, but the real key to species identification and species separation is (at least theoretically) interbreeding. If the members of two groups can mate with each other and produce fertile offspring, and if these offspring can produce fertile offspring, the two groups are generally considered to be members of the same species. Therefore, the real taxonomic question becomes: Could Neanderthals and early modern humans interbreed?

Because it is difficult to determine whether fossil groups interbred with one another, Neanderthal taxonomy has been primarily determined by anatomic and presumed behavioral characteristics, such as those already discussed. That taxonomy has vacillated with changing interpretations of those characteristics. Neanderthals have been placed in their own species (*Homo neanderthalensis*) for much of their history, but they have been identified as a human subspecies (*Homo sapiens neanderthalensis*) at other times. The latter designation implies that the Neanderthals and modern humans (*Homo sapiens sapiens*) were members of the same species and therefore could interbreed.

Determination of the Neanderthals' taxonomic position is an integral part of arguments over the mechanism of the origin of modern humans. There are two main hypotheses for that origin: the replacement hypothesis of Christopher Stringer and the multiregional hypothesis vigorously supported by Milford Wolpoff. The replacement hypothesis is also designated "out-of-Africa" because it assumes that a population of African origin expanded throughout Africa, Europe, and Asia and rapidly replaced the more primitive humanlike species living there, including the Neanderthals. Whether this replacement was by competition or by more direct and violent means is undetermined. The multiregional hypothesis suggests that the widespread, more primitive humanlike populations evolved into modern humans rather than being replaced by new immigrants. Both hypotheses hold that the more primitive populations also originated in Africa and spread to Europe and Asia at a much earlier date.

Because the Neanderthals are the best known and best understood early human group, an understanding of the Neanderthal relationship is critical to an understanding of the evolutionary history of humanity. A Neanderthal contribution to modern human ancestry would support the multiregional hypothesis, and the lack of such a contribution would be consistent with the replacement hypothesis.

Advances of the Late Twentieth Century

By the 1990's, the Neanderthals were well established as a group related to modern humans, but the questions remained: How close was the relationship? Did the two groups interbreed? Were Neanderthals a part of the evolutionary heritage of modern humans? During the 1990's, improved techniques and additional fossil discoveries led to greater understanding of the Neanderthals but little consensus on these questions. A few examples will illustrate the situation.

In a 1996 study, Jean-Jacques Hublin and several coworkers determined that Neanderthals found at an archeological site in France made bone tools and wore decorative emblems on their bodies, behaviors not uncovered with older Neanderthal fossils. They concluded that the Neanderthals were influenced by early modern humans who lived in the same area at the same time and that a reasonably elaborate cultural exchange must have occurred between the two groups. However, based on the strikingly different anatomy of the two groups' inner ears, they also concluded that the Neanderthals and modern humans did not interbreed. The investigators reasoned that if interbreeding had occurred, the two groups would have shared a common ear structure.

In 1997, Matthias Krings, Svante Paabo, and their colleagues isolated and engineered deoxyribonucleic acid (DNA) from the mitochondria of Neanderthal bones and compared it to DNA from modern human mitochondria. They found the Neanderthal DNA to be quite different from that of modern humans and concluded not only that the two groups were different species but also that Neanderthals were not ancestral to modern humans.

In 1998, Daniel Lieberman proposed that a reduction in the length of the sphenoid bone during embryology can explain most differences between the two groups' skulls. The sphenoid is a bone in the skull of both Neanderthals and modern humans, and Lieberman showed it to be shortened in modern humans but not in Neanderthals. He hypothesized that the impact of shortening the sphenoid resulted in the modern human skull characteristics, while the longer sphenoid resulted in the Neanderthal skull. Based on the fundamental nature of the change, he concluded that Neanderthals do not belong to the same species as modern humans and were probably not ancestral to modern humans.

In 1999, Cidàlia Duarte, Erik Trinkaus, and several colleagues discovered the buried remains of a four-year-old child in southern Spain. The skeleton was estimated to be about 24,500 years old, and they interpreted its anatomy to be a mixture of modern human and Neanderthal characteristics. Most anthropologists agree that southern Spain supported Neanderthal populations longer than other parts of the world, perhaps as late as 27,000 years ago, and that modern humans and Neanderthals coexisted in the region. Duarte, Trinkaus, and their group suggested that the skeleton they found demonstrated that the two groups did interbreed and that Neanderthals were part of the ancestry of *Homo sapiens*.

Significance

Consideration of this short list of studies in the 1990's demonstrates the state of knowledge about the Neanderthals' place in human evolution. Viewed alone, each study seems to clinch the position of its authors. In fact, the first three reinforce one another so well that Neanderthals would seem to be eliminated from direct participation in the evolution of modern humans. However, Duarte and Trinkaus's study would seem to clinch the opposite position, that Neanderthals were direct participants in the evolution of modern humans. This situation symbolizes the absence of consensus in the field. There are also established scientists with alternative viewpoints for each of these studies. Lieberman himself is a coauthor of a letter that criticizes his own conclusions about the sphenoid and points to the need for a better understanding of the development of primate skulls to help clarify the situation.

A number of anthropologists have pointed out that Krings and Paabo's conclusions are extrapolated from a single, short segment of the mitochondrial DNA and that more extensive studies, including studies of DNA from the nucleus, are necessary before definitive conclusions can be drawn. In fact, nuclear DNA studies of modern humans have suggested that modern human DNA comes from a number of sources rather than a single African source as in the out-of-Africa hypothesis. Clearly, extensive DNA comparisons would be helpful; however, DNA from fossils is difficult to find and difficult to work with, so an extensive collection of such studies is not likely to accumulate.

Ian Tattersall, who rejects the Neanderthals as direct contributors to modern human evolution, has criticized Duarte and Trinkaus's data and their interpretation of the data. The verbal exchange has been bitter, not an unusual circumstance for disagreements in this field.

Although anthropologists have learned an enormous amount about the Neanderthals, their relationship to modern humans continues to escape consensus. This is, without question, a result of the difficulty of the problem and the tentative nature of the evidence. Most agree that the Neanderthals were a successful group closely related to modern humans. Everyone's hope is that more fossils, improved technology, and fresh insight will clarify the question because understanding the Neanderthals is likely to contribute to an understanding of humanity.

This commentary is a reply to the paper by Duarte, Trinkaus, and their colleagues (pages 7604-7609 of this same issue) in which they report the description of a 24,500-year-old fossil with characteristics of both Neanderthals and early modern humans. The two positions are clearly laid out in the article and the commentary.

Trinkaus, Erik, and Pat Shipman. *The Neanderthals: Changing the Image of Mankind*. New York: Alfred A. Knopf, 1992. An interesting and well-written account of the Neanderthals and the scientists who study them.

NERVOUS SYSTEMS OF VERTEBRATES

Type of animal science: Anatomy
Fields of study: Developmental biology, evolutionary science, neurobiology, physiology

The anatomy of vertebrate nervous systems determines many of the behaviors and adaptative capabilities of animals. Its study is a prerequisite to understanding how it functions.

Principal Terms

AXON: an extension of a neuron's cell membrane that conducts nerve impulses from the neuron to the point or points of axon termination

GRAY MATTER: the part of the central nervous system primarily containing neuron cell bodies and unmyelinated axons

INTERNEURON: a central nervous system neuron that does not extend into the peripheral nervous system and is interposed between other neurons

MYELINATED AXON: an axon surrounded by a glistening sheath formed when a supporting cell has grown around the axon

NEURAL INTEGRATION: continuous summation of the incoming signals acting on a neuron

NEURONS: complete nerve cells that respond to specific internal or external environmental stimuli, integrate incoming signals, and sometimes send signals to other cells

NUCLEUS (pl. NUCLEI): cluster of neuron cell bodies within the central nervous system

TRACT: a cordlike bundle of parallel axons within the central nervous system

WHITE MATTER: the part of the central nervous system primarily containing myelinated axon tracts

Animals must be able to coordinate their behaviors and to maintain a relatively constant internal environment, despite fluctuations in the external environment, in order to survive and reproduce. To do so, animals must monitor their external and internal environments, integrate this sensory information, and then generate appropriate responses. The evolution of the vertebrate nervous system has provided for the efficient performance of these tasks.

The Pattern of the Vertebrate Nervous System

Although the various vertebrates show differences in the organization of their respective nervous systems, they all follow a similar anatomical pattern. The nervous system can be partitioned conveniently into two major divisions: the peripheral nervous system (PNS) and the central nervous system (CNS). These divisions are determined by their location and function. The CNS consists of the spinal cord and the brain. The PNS, that part of the nervous system outside the CNS, connects the CNS with the various sense organs, glands, and muscles of the body.

The PNS joins the CNS in the form of nerves, which are cordlike bundles of hundreds to thousands of individual, parallel nerve-cell (neuron) axons (long tubular extensions of the neurons) extending from the brain and spinal cord. The nerves extending from the spine are called spinal nerves, while those from the brain are called cranial nerves. The elements of the PNS include sensory neurons (for example, those in the eyes and in the tongue) and motor neurons (which activate muscles and glands, thereby causing some sort of action or change to occur). Most nerves contain both sensory and motor axons.

Thus, the PNS can be divided into two major subdivisions: sensory (or afferent) neurons and motor (or efferent) neurons. There is very little information-processing accomplished in the PNS. Instead, it relays both environmental information to the CNS (sensory function) and the CNS responses to the body's muscles and glands (motor function). Sensory neurons of the PNS are classified as somatic afferents if they carry signals from the skin, skeletal muscles, or joints of the body. Sensory neurons from the visceral organs (internal organs of the body) are called visceral afferents.

The PNS motor subdivision also has two parts. One is the somatic efferent nervous system, which carries neuron impulses from the CNS to skeletal muscles. The other is the autonomic nervous system (ANS), which carries signals from the CNS to regulate the body's internal environment by controlling the smooth muscles, the glands, and the heart. The ANS itself is subdivided into the sympathetic and parasympathetic nervous systems. These are generally both connected to any given target and cause approximately opposite effects to each other on that target (for example, slowing or increasing the heart rate).

The CNS, where essentially all information-processing occurs, has two major subdivisions: the spinal cord and the brain. Virtually all vertebrates have similarly organized spinal cords, with two distinct regions of nervous tissue: gray and white matter. Gray matter is centrally located and consists of neuron cell bodies and unmyelinated axons (bare axons without the glistening sheaths called myelin, created by supporting cells wrapping around the axons). White matter contains mostly bundles of myelinated axons (white because they have glistening myelin sheaths around them). Bundles of axons in the CNS are called nerve tracts. Within the spinal cord, these are either sensory tracts carrying impulses toward the brain, or they are motor tracts transmitting information in the opposite direction.

Interneurons are neurons positioned between two or more other neurons. They accept and integrate signals from some of the cells and then influence the others in turn. Interneurons are particularly numerous within the gray matter. In the spinal cord, they permit communication up, down, and laterally. Most axons in the cord's tracts belong to interneurons.

The Vertebrate Brain

The brain of vertebrates is actually a continuation of the spinal cord, which undergoes regional expansions during embryonic development. The subdivisions of the brain show more variety among vertebrate species than does the spinal cord. The brain has three regions: the hindbrain, the midbrain, and the forebrain. Their structures are complex, and various systems of subdividing them exist. The major components forming the brain regions are the hindbrain's medulla oblongata, pons, and cerebellum; the midbrain's inferior and superior colliculi, tegmentum, and substantia nigra; and the forebrain's hypothalamus, thalamus, limbic system, basal ganglia, and cerebral cortex.

The hindbrain begins as a continuation of the spinal cord called the medulla oblongata. Most sensory fiber tracts of the spinal cord continue into the medulla, but it also contains clusters of neurons called nuclei. The posterior cranial nerves extend from the medulla, with most of their nuclei located there.

Also in the medulla, and extending beyond it through the pons and midbrain, is the complexly organized reticular formation. This mixture of gray and white matter is found in the central part of the brain stem but has indistinct boundaries. Essentially all sensory systems and parts of the body send impulses into the reticular formation. There are also various nuclei within its structure. Impulses from the reticular formation go to widely distributed areas of the CNS. This activity is important for maintaining a conscious state and for regulating muscle tone.

Prominent on the anterior (front) surface of the mammalian medulla oblongata are the pyramids: tracts of motor fibers originating in the forebrain and passing without interruption into the spinal cord to control muscle contraction. These tracts cross to the opposite side of the medulla before entering the spinal cord, which results in each side of the forebrain controlling muscle contraction in the opposite side of the body.

Many sensory fibers from the spinal cord terminate in two paired nuclei at the lower end of the medulla, the gracile and cuneate nuclei. Axons leaving these nuclei cross to the opposite side of the medulla and then continue as large tracts (the medial lemnisci) into the forebrain. Thus, each side of the brain gets sensory stimuli mostly from the opposite side of the body.

Immediately above the medulla is the pons. It contains major fiber pathways carrying signals through the brain stem, and a number of nuclei, including several for cranial nerves. Some pontine nuclei get impulses from the forebrain and send axons into the cerebellum, again with a majority crossing to the opposite side of the brain stem before entering the cerebellum.

On the dorsal (back) side of the medulla and pons is the cerebellum, an ancient part of the brain that varies in size among vertebrate species. The cerebellum forms a very important part of the control system for body movements, but it is not the source of motor signals. Its gray matter forms a thin layer near its surface called the cerebellar cortex and surrounds central white matter.

Vertebrates with well-developed muscular systems (for example, birds and mammals) have a large cerebellum, with several lobes and convex folding of its cortex. It is attached to the brain stem by three pairs of fiber tracts called cerebellar penduncles, which transmit signals between the left and right sides of the cerebellum and between the cerebellum and motor areas of the spinal cord, brain stem, midbrain, and forebrain. The cerebellum times the order of muscle contractions to coordinate rapid body movements.

The Midbrain and the Forebrain

The midbrain is the second major region of the brain. The midbrain's dorsal aspect, called the tectum, is a target for some of the auditory and visual information that an animal receives. The paired inferior colliculi form the lower half of the tectum. They help to coordinate auditory reflexes to relay acoustic signals to the cerebrum. The two superior colliculi, the other half of the tectum, assist the localization in space of visual stimuli by causing appropriate eye and trunk movements. In lower vertebrates, the superior colliculi actually form the major brain target for visual signals. Connecting fiber pathways (commissures) link the individual lobes of each pair of colliculi.

The midbrain's tegmentum contains several fiber tracts carrying sensory information to the forebrain and carrying impulses among various brain-stem nuclei and the forebrain. Two cranial nerve nuclei concerned with the control of eye movements are also in the tegmentum. The reticular formation extends through the tegmentum and regulates the level of arousal. It also helps to control various stereotyped body movements, especially those involving the trunk and neck muscles. Finally, the tegmentum contains the red nucleus, which, in conjunction with the cerebellum and basal ganglia, serves to coordinate body movements. The substantia nigra functions as part of the basal ganglia to permit subconscious muscle control.

The forebrain, the final major area of the brain, differs from the lower areas in the more highly evolved functions it controls. It has a small but extremely important collection of about a dozen pairs of nuclei called the hypothalamus. These control many of the body's internal functions (such as temperature, blood pressure, water balance, and appetite) and drives (such as sexual behavior and emotions). Immediately above the hypothalamus lies the thalamus, another collection of more than thirty paired nuclei. The two thalami are the largest anterior brain-stem structures. Their ventral (front) parts relay motor signals to lower parts of the brain. The dorsal (back) parts transmit impulses from every sensory system (except olfaction, the sense of smell) to the cerebrum.

The limbic system is organized from a number of forebrain structures mostly surrounding the hypothalamus and thalamus. It determines arousal levels, emotional and sexual behavior, feeding behavior, memory formation, learning, and motivation. In general, the limbic system exchanges information with the hypothalamus and thalamus, and receives impulses from auditory, visual, and olfactory areas of the brain.

The basal ganglia function with the midbrain's tegmentum and substantia nigra, the cerebral cortex, the thalamus, and the cerebellum. These paired structures' functions are unclear, but it is known that they are important for adjusting the body's background motor activities, such as gross positioning of the trunk and limbs, before the cerebral cortex superimposes the precise final movements.

The cerebral cortex, like the cerebellum, is an ancient brain structure; however, it shows even more variation among vertebrate species than the cerebellum. It is formed into two hemispheres, which have olfactory bulbs projecting from their anterior (front) ends. The olfactory bulbs receive impulses from olfactory nerves for the sense of smell. The gray matter of the cerebral cortex is at the surface, enclosing the white matter (fiber tracts) beneath. The white matter connects various parts of the gray matter of one hemisphere with others within the same hemisphere and with corresponding parts in the opposite hemisphere. It also connects the cortical gray matter with lower brain structures. The ultimate control of voluntary motor activity resides in the motor areas of the cortex, although this control is heavily influenced by all the previously mentioned motor-control areas of the CNS.

Corresponding to each of the major senses (touch, vision, audition), there are primary sensory areas. These areas get the most direct input from their sensory organs by way of the corresponding sensory thalamic nuclei. Surrounding each primary area are association areas that receive a less direct sensory input but also more inputs from other sensory cortical areas. In general, the more intelligent an animal is, the larger are its association areas.

Studying the Nervous System

Many methods are used in studying vertebrate nervous systems. The level of description desired often determines the methods employed. For example, the gross structure visible to the unaided eye is usually investigated using the entire brain or spinal cord of the animal under study. It will then be photographed or drawn, sliced at various points either parallel to its long axis or across its long axis, and again photographed or drawn, until a complete series of such "sections" has been assembled.

To see finer structural details requires microscopes and very thin slices of nervous tissue (less than a millimeter in thickness). Preparation of such thin slices of this soft tissue requires that it first be either frozen or embedded in a block of paraffin wax. A special slicing device called a microtome is then used to produce the thin sections. For easy observation of different structural details (such as nuclei and fiber tracts), various chemical stains can be applied to the slices of tissue. These stains specifically color particular structural features green, blue, or some other color, thereby making them more visible.

Nervous tissue can be selectively and painlessly destroyed in an anesthetized animal by cutting a nerve trunk, inserting a fine wire electrode into the CNS and destroying tissue with electricity, or inserting a fine needle and then either injecting a chemical agent that kills nervous tissue or using a suction device to remove areas of tissue. The precision and reproducibility of wire or needle placement within the CNS is possible with a device called a stereotaxic frame. This instrument positions the animal's head and brain in an exact standard position. Then, wires or needles are inserted a certain distance away from (for example, behind, below, or to one side of) common landmarks on the skull. Stereotaxic atlases are books published by investigators for specific animals, with the exact coordinates in three-dimensional space for most CNS structures.

Following such procedures, the animal may be immediately and painlessly sacrificed, its brain or spinal cord removed, and the previously described thin slices prepared and stained. It may be necessary to allow the animal to recover from its surgical treatment, since several days or weeks must sometimes pass for the severed fiber tracts to degenerate. Then, following a painless lethal injection, the nervous tissue is prepared as above using special staining techniques, which reveal the pathways of degenerating nerve fibers in the tissue sections studied later under the microscope.

Although new techniques are constantly being developed, the preceding methods have revealed that the hundred billion neurons of the vertebrate nervous system form the most complexly organized structure known. Through this knowledge of the structure of the nervous system, it has become possible to study intelligently its functions, to diagnose its diseases, and to devise methods of treatment when it becomes damaged or diseased.

A Complex Structure

The vertebrate nervous system is the most complex structure known to humankind. The human nervous system, for example, has more than a hundred billion cellular elements, and perhaps a hundred trillion points of information exchange between these elements. It is impossible to understand the details of such a structure in the same way that one can understand the structure of a radio; however, the general organizational plan can be discovered through the application of modern neuroanatomical techniques.

It is a widely accepted tenet of physiology that in order to comprehend the functioning of an organ or an organ system, it is necessary to have a critical understanding of its structure. In fact, physiology and anatomy are inseparable because function (physiology) always reflects structure (anatomy): It is impossible for an organ to perform in any other way than its architecture permits.

The nervous system is the ultimate control and communication system in the vertebrate body. Its complexity allows the vast range of vertebrate behaviors, as well as the rapid and precise regulation of the body's internal environment. The most complex vertebrate nervous systems display self-consciousness, reasoning, and language capabilities.

There are many reasons for studying the organization of vertebrate nervous systems, ranging from purely theoretical (such as determining the mechanisms of memory recall or clarifying the evolutionary relationships among vertebrate species) to very practical (such as treatments for mental illnesses, precisely defining brain death, or designing better computers).

For many, the ultimate goal is to obtain a better understanding of the relationship between the brain and the mind. It has been proposed that the mind and mental processes are emergent properties that appear when a certain degree of organizational complexity within the nervous system has been reached. The individual elements of the nervous system (the neurons) are not the constituents that think or possess consciousness. These unique capabilities are achieved as a result of the specific connections between neurons and sensory organs, and among neurons themselves.

It does not matter whether one performs an analysis of a machine or of a nervous system; it can never be expected to reveal its soul or its consciousness—if they exist. All that can be done is to admire the intelligence of its designer or the wisdom of nature.

Bibliography

Butler, Ann B., and William Hodos. *Comparative Vertebrate Neuroanatomy: Evolution and Adaptation*. New York: Wiley-Liss, 1996. Focuses on the nervous systems of nonmammalian vertebrates.

Hildebrand, Milton. *Analysis of Vertebrate Structure*. 5th ed. New York: John Wiley & Sons, 2001. This classic textbook is for college-level readers. Several chapters present material relevant to the vertebrate nervous system. The index is very complete, while the glossary is only adequate. The list of references for each chapter is good, but some are of an advanced nature.

Keynes, R. D. *Nerve and Muscle*. 3d ed. New York: Cambridge University Press, 2001. Covers all aspects of the nervous and muscular systems, and their interactions.

Simmons, Peter J., and David Young. *Nerve Cells and Animal Behavior*. 2d ed. New York: Cambridge University Press, 1999. A college-level text explaining the link between the nervous system and behavior. Extensive use of case studies in the functions of nerve cells, sense organs, sensory filters, motor systems, startle behavior, intraspecific signals, and hunting, hearing and echolocation.

NESTING

Types of animal science: Behavior, ecology
Fields of study: Conservation biology, ecology, environmental science, ornithology, wildlife ecology

Many animals build structures to house their eggs and their young. Egg-laying animals, such as birds, amphibians, reptiles, and fish, build temporary nests for each year's young, while social insects, such as bees, build nests, or hives, as permanent homes. The nests of mammals may be permanent or temporary, depending on species.

Principal Terms

INSECTIVORE: any animal that feeds on insects
MALLARD: a species of wild duck
ORNITHOLOGY: the scientific study of birds
PHEROMONES: chemicals excreted by animals into their immediate environments to identify their territorial influence to other organisms
TERRITORIAL BEHAVIOR: the combination of methods and actions through which an animal or group of animals protects its territory from invasion by other species
TERRITORY: any area defended by an organism or a group of organisms for purposes such as mating, nesting, roosting or feeding

Many animals build structures to house and protect themselves, their eggs, and their young. Nest sites include grasses, shrubs, and trees, but also cracks in trees, holes in the ground and banks, crevices in rocks, under the surface of the ground, within the nests of other larger animals, or even near wasp nests. The nests of birds are the most obvious and well known, but many amphibians, reptiles, fishes, social insects, and mammals also build nests of varying degrees of complexity and permanence.

Bird and Insect Nests

Larger bird nests are constructed of various kinds of material, such as mud, bark, roots, twigs, hair, feathers, grass, plant fibers, shed snake skin, spider webs, lichens, or even prey remains and human-made material such as shiny, light, metallic ornaments. Many nests are cup-shaped and open, while fewer are oval, round or ball-shaped, closed, with an entrance at the side or the roof. An example of the latter is the nest of the South American ovenbird (*Furnarius*), which is often built with mud on top of a fence or another exposed surface. Others build a domed, oven-shaped nest out of plant material (the North American ovenbird) or huge nests suspended from the ends of tree branches (thorn birds). Some oceanic gulls (*Rissa tridactyla*) nest on narrow cliff ledges. Grassland and tundra owls nest on the ground or on an elevated hummock.

Some birds utilize amazing skill to construct their nests. The weavers are capable of tying knots with strips of grass or palm leaves and can prepare an exceptionally tight and compact nest. Birds of the genus *Orthotomus* are known as tailorbirds due to their ability to manufacture nests that are built in a pocket made by sewing together the edges of one or more leaves, using plant fibers. Some others (the family Contingidae) prepare very primitive and weak nests in an apparent effort to avoid the attention of predators, since they are attended minimally by the parents. Finally, woodcreepers nest in holes, while vireos weave a cup between the arms of a forked branch.

Most bird species in an area construct a unique nest in a unique location but use specific construction materials transferred from a distance. Generally, female geese and robins build their own nests, but among several other species the nest is built only by the male, who may use it as a sexual attractant in courtship. In these species, the female chooses a nest and indicates her choice by adding the nest lining.

Woodpeckers create cavities in trees, thus supplying safe nesting sites for a large number of birds. These include owls, parrots, parids, and flycatchers. In some areas, forest managers protect pileated woodpecker cavity trees and employ strategies to encourage continued production of new cavity trees where even smaller woodpecker species may find a haven for nesting.

Bird nests are most often made of plant material such as grasses, providing temporary homes for eggs and hatchlings. (NOAA Central Library)

Some insects, such as termites and carpenter bees, excavate a tunnel through solid wood. When termite colonies accidentally separate from an original nest they may migrate or march to a new nesting site and develop supplementary reproductives.

Mammal Nests

Most rodents build underground residences with a central chamber, where they sleep, raise their young, and hibernate, and other chambers that serve as food storage quarters. Moles build the most complex shelters among all insectivores. The shelters have an underground nest chamber that is surrounded by concentric rings of tunnels that are interconnected by radiating ones. The presence of shallow surface tunnels allows the marking of their course and the accumulation of a large amount of earth indicates the location of the deep tunnel system. The mole uses its forefeet like a shovel to dig in a type of body movement that resembles that of a breaststroke swimmer. Shrews dig surface nests, but they also use the runs of other animals, such as rodents, and line them with plant material on which they place their offspring. Hedgehogs and solenodons construct nest chambers, usually during their breeding season, which warm them during low-temperature periods. Tree shrews build their nests of leaves and other vegetation among tree roots or in cavities of fallen timber, but they immediately desert them when they feel that their residence has been stalked or even detected by a predator.

Ground squirrels and kangaroo rats transport enough seeds and other food in their cheek pouches to last them for a whole season. Excavation of one rat den where a single five-ounce kangaroo rat resided produced nine underground storage chambers with a total of thirty-five quarts of seeds. Kangaroo rats also dig one-cubic-inch storage pits that they stuff with seeds. In one case, an area of fifty-five square feet adjacent to a den had close to nine hundred such pits. This can have a devastating effect on local crops, so-called rodent plagues. On the other hand, such underground activity tends to germinate seeds for wild grass in the arid steppe regions of Central Asia. Squirrels carry acorns and nuts to hollow trees and barns, as well as to holes in the ground. They also have an amazing memory of where the food is stored, which keeps them alive during the harsh winter. Finally, the North American pack rat or trade rat is attracted by bright, shining objects (like the magpie) and carries them home to its nest, where it stores them together with tree sticks and grass.

Cooperative breeding appears to exist in the form of communal nesting among several mammal species. Tree squirrels (*Sciuridae sciurini*), fox squirrels (*Sciurus niger*) and gray squirrels (*Sciurus carolinensis*) form kin clusters among unrelated members of their own species during all seasons, especially in winter. Gray squirrels have shown an intense female-female bond in the formation of groups.

Territorial Behavior and Nesting

Animals appear to have a distinct notion of nesting and territory. The dog's persistent trend to leave its own scent during its evening walk is an example of territorial behavior, whereby an animal or group of animals, including insects, vertebrates, and other invertebrates, protects its territory from the invasion of other organisms. The boundaries may be clearly defined by the animal through sounds, such as a bird song, or scents, created by pheromones, which are secreted by specialized glands. The animal is often fierce in claiming its territory and may even fight and chase intruders to discourage them. Generally, the closer the requirements different species have of their territory, the less likely it is that they can coexist in the same area. Thus, species with similar requirements can sometimes live in the same area only if they differ in behavioral ways, such as in feeding and nesting patterns, as well as activity periods. However, should the food resources be limited in areas, such as the desert, direct competition may lead to violent confrontations. Invaders may attack eggs or young offspring to suppress their hunger.

Territorial behavior secures the ability for an animal to mate uninterrupted, raise its young in a less harmful area and keep other animals from devouring the food intended for the young. Often territories are temporary, as in the case of birds or mammals that protect the immediate feeding area until the young become old enough to be self-sufficient. That territory may even be identified as the nest itself, a phenomenon common with most birds. Territorial claims are often successful since the inhabitants of neighboring or overlapping territories may avoid each other, especially during the nonmating seasons.

Artificial Nesting

Humans living in suburban and rural areas can provide the appropriate housing for cavity nesting birds, and people do have the ability to become backyard bird specialists. Artificial structures have been used extensively in the United States and Canada to increase waterfowl production, although the users of the artificial materials are not always the animals for which they were intended. During a study conducted in 1995, in which artificial nesting structures were intended for mallard use, redheads were found to be using them for normal nesting. It is believed that a combination of elevated water surfaces and subsequent limited nesting in the emergent vegetation may have made these nesting sites attractive to the redheads, which has thus provided a new alternative for nesting redheads.

Another study on the excavation and use of artificial polystyrene snags by woodpeckers was performed in Eastern Texas over a period of five years in the early 1990's. Only half of the monitored downy woodpeckers (*Picoides pubescens*) appeared to use the artificial snags for cavity excavation and later for nocturnal roosting, but not for nesting. None of the other six woodpecker species in the area excavated cavities in the artificial snags. Other animals, however, used these excavated cavities in the artificial snags. These include Carolina chickadees (*Parus carolinensis*), prothonotary warblers (*Protonotaria citrea*), southern flying squirrels (*Glaucomys volans*) and red wasps (*Polistes* sp.).

The human factor may affect, directly or indirectly, the breeding success of animals. Possible biological effects of electromagnetic fields attributed to high-voltage transmission lines are suspected to reduce the reproductive success of birds whose nests are nearby, as in the case of tree swallows. Similar effects have been postulated for the terns, gulls, and other birds that live in areas such as the Gulf Coast, where oil tankers, commercial fishing vessels, yachts, and other pleasure boats have degraded the environment. A debate and controversy occurred in the 1990's in the Pacific Northwest of the United States, where environmentalists lobbied for the preservation of the nesting habitat of the spotted owl to the detriment of the local logging industry.

This book discusses cooperative breeding that occurs among fifty different bird species and has an extensive bibliography and description of its evolution, kin selection, and demography.

NEUTRAL MUTATIONS AND EVOLUTIONARY CLOCKS

Type of animal science: Evolution
Fields of study: Ethology, genetics

A neutral mutation is a change in the nucleotide sequence of a gene that causes no change in the function of the protein coded by that gene. If most molecular mutations are neutral, as has been hypothesized, then they can be used as "clocks," because the number of changes in the gene (or gene product) is positively correlated with elapsed time.

Principal Terms

ALLELE: one of two or more alternate gene forms of a single gene locus

AMINO ACID: an organic molecule with an attached nitrogen group that is the building block of polypeptides

ELECTROPHORESIS: a technique for separating molecules when they are placed in an electrical field; the separation is usually based on their charge and weight

GENETIC CODE: the three-nucleotide base sequences (codons) that specify each of the twenty types of amino acids; there can be more than one codon for a particular amino acid

NUCLEIC ACID: an organic acid chain or sequence of nucleotides, such as DNA or RNA

PHYLOGENY: the evolutionary history of taxa, such as species or groups of species; order of descent and the relationships among the groups are depicted

POLYMORPHIC: a genotype or phenotype that occurs in more than one form in a population

The hypothesis has been advanced, primarily by Motoo Kimura of the National Institute of Genetics of Japan and Masatoshi Nei of the University of Texas, that the vast majority of polymorphisms that occur at the molecular level are selectively neutral. Two major categories of polymorphisms are involved. The first is attributable to changes in the nucleotide sequences of deoxyribonucleic acid (DNA). The second is isozymic variation, detectable by protein electrophoresis. Isozymic variation is usually caused by changes in the amino acid composition of the protein. Since amino acids are determined by the genetic code, this type of variation also ultimately depends on changes in DNA. The proponents of the neutral theory admit that most of the evolution that occurs on the nonmolecular level, such as changes in morphological and behavioral traits, is attributable to natural selection. On the molecular level, however, they believe that most of the changes are caused by chance.

Selection Versus Chance

Extensive variability has been found for both DNA sequences and isozymes within the majority of natural populations. Isozymic polymorphism, in which two or more variants of an enzyme occur within the same species, ranges from approximately 15 percent in mammals to approximately 40 percent in invertebrates. Isozymic variation, even within the same individual, ranges from about 4 percent in mammals to 14 percent in some insects. Variability in DNA sequences among individuals of the same species is even higher than those found for isozymes. Proponents of the neutral hypothesis hold that these levels of variability are too high to be attributable to selection, but instead, most variability at the molecular level is attributable to chance. The result, they say, has been a large amount of enzyme and DNA variability that is selectively neutral. They are neutral in the sense that their contributions to an organism's fitness are so small that their occurrence is attributable more to chance than to natural selection. Neutralists do not believe that most molecular mutations are neutral; they assume that most are harmful and are eliminated by natural selection. Rather, they believe that those that currently exist are adaptively equivalent. Proponents of the neutrality theory believe that changes in DNA and amino acid sequences are for the most part neutral, consisting primarily of the gradual random replacement of functionally equivalent alleles.

Although the neutral theory is able to explain much about molecular evolution, there are some issues that remain subjects of intense debate. It is known that some protein and gene variation is not neutral but, instead, under certain conditions, conveys selective advantages or disadvantages. In some organisms (for example, the Japanese macaque), there also appear to be more rare alleles than would be predicted by the neutrality hypothesis.

The Hypothesis of a Molecular "Clock"

If the neutrality theory of molecular evolution is correct, then changes in base sequences of DNA could act as evolutionary "clocks." This theory holds that because mutations change the DNA in all lineages of organisms at fairly steady rates over long periods of time, a clocklike relationship can be established between mutation and elapsed time. The number of base substitutions in the DNA is directly proportional to the length of time since evolutionary divergence between two or more species. The idea of molecular evolutionary clocks was forwarded in the early 1960's by Linus Pauling and Emile Zuckerkandl.

The molecular clock postulated by the neutrality hypothesis is not like an ordinary timepiece, which measures time in exact intervals. Rather, molecular changes occur as a stochastic clock, such as occurs during radioactive decay. Although there is some variability for this type of clock (it is slower or faster during some periods than others), it would be expected to keep relatively accurate time over millions of years. A potential problem arises, however, because the rate of "ticking" for the molecular clock is not the same at every position along the DNA molecule. The rate has been shown to be slow for DNA sequences that directly affect the function of a protein (for example, those at an enzyme's active site), while the rate of change has been faster for positions on the DNA that are selectively neutral, that is, where they have little or no affect on the protein's function.

In a molecular clock, the number of changes in a DNA or protein molecule are the "ticks" of the clock. The number of "ticks," in turn, estimates the extent of genetic differences between two species. With this knowledge, scientists can reconstruct phylogenies. The phylogenies are usually depicted as branching patterns, which are based upon differences in DNA base-pair sequences or amino acid sequences. They depict not only the order of descent but also the degree of relatedness.

When choosing alternative phylogenetic hypotheses, biologists usually follow the principle of Occam's razor—the simplest theory is chosen over more complex ones. Thus, the phylogenetic tree that requires the fewest mutations is preferred over those that require more mutations. By "calibrating" the molecular clock with other, independent, events, such as those obtained from the fossil record, the actual chronological times of divergence can be estimated.

For example, humans and horses differ by eighteen amino acids in the alpha chain of the blood protein hemoglobin. It has been estimated from the fossil record that humans and horses diverged from a common ancestor approximately ninety million years ago. Other evidence suggests that half the substitutions took place since the time of divergence. Since nine amino acids have changed over a ninety-million-year period, the rate of amino acid substitution would equal approximately one every ninety million years.

Since mutation rates are known to be different for different genes, the ticking rate for different genes or proteins would not necessarily be the same. For example, the rate of substitution for the genes coding for the protein histone H4 is lower than that for the genes coding for the protein gamma interferon. Yet when nucleotide substitution rates are averaged for a number of different proteins, there does appear to be a marked uniformity in the rate of molecular change over time; the ticking of a number of clocks can be averaged, leading to more accurate estimates for divergence times.

Advantages and Disadvantages of the Theory

Much of the early work was done on sequence changes in proteins; however, there is a drawback to protein clocks. Their usefulness is limited because the genetic material itself is not being examined but, rather, a product coded by genes. This means that some of the changes in the genetic material may not be detected. For example, because of the redundancy of the genetic code, there could be a number of changes that occur in the nucleotide sequence of DNA that would not result in changes in the amino acid composition in a protein. Consequently, there has been great interest in directly examining the DNA itself.

Because of the advent of recombinant DNA techniques, molecular clocks can be based on changes in the genetic material. DNA-DNA hybridization also involves the comparison of DNA sequences, although on a broader scale. The DNA-DNA hybridization technique is attractive because it effectively compares very large numbers of nucleotide sites, each of which is effectively a single data point. One of the criticisms of molecular clocks is that most genes have not been found to "tick" with perfect regularity over long periods of time. During some periods, the rate of change (primarily because of mutation) may be fast, while at other periods it may be significantly slower. By comparing very large numbers of nucleotides, which represent many genes, DNA-DNA hybridization measures the average rates of change, which will produce more uniform estimates.

The concept of a molecular clock has been criticized on a number of grounds. First, it assumes that evolution in macromolecules proceeds at an approximately regular pace, whereas morphological evolution is usually recognized as occurring irregularly. It is also clear that the clock can tick at different rates among different macromolecules, whether they be proteins or DNA. Another problem is that the rate of the molecular clock varies among taxonomic groups. For example, the insulin gene has evolved much more rapidly in the evolutionary line leading to the guinea pig than in some other evolutionary lines. There are also notable differences among different parts of molecules. This variability was evident when sequences were compared among the first molecules examined in the light of the molecular clock hypothesis, notably hemoglobin molecules and cytochrome c. Another criticism is that a number of processes, known collectively as molecular drive, perturb the clock.

Recent data, however, suggest that nucleotide substitution rates in organisms as different as bacteria, flowering plants, and vertebrates are remarkably similar. For example, the average rate of substitution at "silent sites" (those at which mutation in the DNA produces no change in the amino acid encoded) is 0.7 percent per million years in bacteria, 0.9 percent for mammals, and 1 percent for plants. This relatively equal substitution rate across broad taxonomic categories would support the concept of the constancy of molecular clocks.

Testing the Hypothesis

A number of types of molecular clocks have been hypothesized. In the first group are techniques that directly estimate differences in the sequences of nucleic acids that make up DNA or in amino acid sequences (which are determined by DNA). Other methods are less direct, such as DNA-DNA hybridizations and immunological techniques. All the techniques ultimately assay genetic differences caused by base pair changes in DNA. Sequence comparisons and DNA-DNA hybridization techniques are now used more extensively.

In sequence comparisons, nucleic acid replacement in DNA or amino acid replacement in proteins are compared between species. Nucleic acid substitutions can be assayed by using restriction enzymes that only recognize specific base sequences or by direct sequencing. Amino acid substitutions can be assayed by traditional biochemical techniques, through automated sequencers, or by mass spectrometers. In both types of sequence analysis, the assumption is made that the greater the number of substitutions, the greater the evolutionary distance between the species. In DNA-DNA hybridization, DNA molecules from individuals from two species are separated into individual strands at high temperatures. The strands are then mixed at a lower temperature. This promotes joining of the strands from the different organisms. The extent of rejoining (how tightly they bond together) will be dependent on the degree of nucleotide pairing that occurs. If the nucleotide sequences between the two species are very similar, the DNA strands will bond very tightly; if there is little similarity, the bonds will be weak. The extent of bonding is measured by the temperature at which the new DNA duplex dissociates, or "melts." The higher the melting temperature, the greater the nucleotide similarity between the DNA strands from different species. The nucleotide similarity is presumed to be related to the evolutionary distance between the species.

Uses of the Theory

The use of molecules as clocks, in spite of their imperfect nature, has proven to be a valuable tool for inferring phylogenetic relationships among species and in estimating their times of divergence. Molecular data can be used independent of morphological and behavioral data for establishing evolutionary relationships. Similarly, divergence times estimated from the fossil record can be clarified through the use of molecular clock data. Molecular clocks have had a significant impact on evolutionary studies of organisms ranging from bacteria to humans, and molecular data have been instrumental in changing some long-held phylogenetic views. For example, the data obtained from DNA-DNA hybridizations in birds have forced a major revision in bird taxonomy. Molecular clocks have been used to assign time scales to a large number of phylogenies. Some of the phylogenies are wide-ranging; approximate times of evolutionary divergence have been assigned to vertebrate species as diverse as sharks, newts, kangaroos, and humans. Others are more specific. Some of the best-known (and most controversial) work has been done on primates. In one set of experiments, the amino acid differences of serum albumin (a blood protein) were measured among different species of primates. By comparing the albumins of species whose divergence times were known from fossil evidence, researchers were able to "calibrate," or calculate, the mean rate of change for serum albumin. Previously, most anthropologists believed that humans and apes had diverged approximately twenty-five million years ago; the DNA-DNA hybridization data suggest a much more recent date of approximately five million years. Subsequent DNA studies have confirmed the latter estimate. This had led to a reevaluation of the primate fossil record and of the way in which primates have evolved, including humans.

Another group of researchers has used DNA-DNA hybridization data to calculate the divergence dates among different primate species. After calibrating the molecular clock with dates previously established from the fossil record, they estimated the following approximate divergence dates: Old World monkeys, 30 million years ago; gibbons, 20 million; orangutans, 15 million; gorillas, 7.7 to 11 million; and chimpanzees and humans, 5.5 to 7.7 million years ago. In contrast to earlier work, they concluded that humans and chimpanzees are genetically closer to each other than either are to gorillas. As with the serum albumin data, these new estimates of times and order of divergence led to a reexamination of primate evolution.

NOCTURNAL ANIMALS

Type of animal science: Behavior
Fields of study: Anatomy, behavior, physiology, zoology

Nocturnal animals are those active during the night. They are specially adapted to living where there is little or no light. Often, such creatures find their way, locate food, and detect danger in nearly total darkness.

Principal Terms

AUDITORY: pertaining to hearing
DIURNAL: awake and functional during the daylight hours
ECHOLOCATION: sonarlike determination, from sound echoes, of the positions of unseen objects
PINNA (pl. PINNAE): a term indicating the external ear of an animal
PIT VIPER: a poisonous snake, such as a rattlesnake, which detects its prey via paired heat-sensing pits in its head
TYMPANIC MEMBRANE: the eardrum

At nightfall, many animals are just beginning to waken and to function. All of these night creatures are called nocturnal animals. Folklore often brands them as evil, inimical creatures. This is not so; they are merely different from diurnal animals, which are active during the day. Their activity during the hours of darkness is usually due to a combination of factors. First, the nocturnal animals may make use at night, without having undue competition, of food sources and habitats also used by diurnal animals. Second, they may be safe from many predators who would hunt them during the daylight hours. Finally, nocturnal animals may be predators which, at night, have much less competition for prey, or have a better chance to capture it, than in daylight.

Most nocturnal creatures are highly adapted to living under conditions in which there is little or no light. These adaptations enable nocturnal animals to find their way through the world, locate food, and detect danger in almost total darkness. Although the diurnal species outnumber the nocturnal creatures, almost every type of creature living on earth has a nocturnal version.

More on Bat Echolocation

An echolocating bat, needing to find prey or to navigate, emits ultrasonic waves of frequencies between twenty-five and eighty kilocycles per second. These sound waves bounce back from nearby objects. The patterns of the returning waves give a bat an accurate estimation of the size, shape, texture, and location of all objects scanned in this way. The process is very sensitive. Bats using echolocation can detect items one to two millimeters thick, located six to seven feet away.

Several adaptations of the auditory systems of bats optimize the effectiveness of its echolocation. One of them is the huge size—sometimes nearly as large as the bat's skull—and very complex folding of each of the bat's external ears (pinnae). This size, folding, and great pinna mobility collect returning sound echoes quite well and help the bat to pinpoint their sources.

Another feature of bat echolocation has to do with the muscles of the bat's inner ear, which contract briefly as the ultrasound emissions occur. The contraction is essential to counter the great intensity of the emitted ultrasound. If these muscles did not contract upon sound emission, the bat would deafen itself with its echolocation calls. Another aspect of the bat ear that aids echolocation is the light weight of the tympanic membranes and bones of the bat's middle ear. These auditory modifications, away from the norm in other rodents, allow faint echoes returning to the ear to cause vibrations that can be sensed and used.

Regular Senses and Special Senses

Diurnal animals survive as long as they have a combination of senses that enables them to fit, successfully, into a daylight ecological niche. This usually includes ability to see adequately, to hear well, and to have a useful sense of smell. The ability to see, hear, and smell falls within a fairly broad range among earth's many successful diurnal animals. Furthermore, weaknesses in one sense, such as the nearsightedness of the rhinoceros, may be compensated for by enhancement of one or more of the other senses. In rhinos, both the ability to hear and to smell are very well developed.

Nocturnal animals live under conditions that are skewed far away from the normal visual range of diurnal organisms. They must operate under conditions where there is either very little light or even no light at all. For this reason, all animals that are nocturnal have at least one sense, sight, hearing, smell, taste, or touch, that is very highly developed, compared to those who are diurnal. These powerful sense adaptations enable them to survive well in the dark hours. The extent of such special sensory development varies, depending upon the organism, its needs, whether it also functions during the day, and the extent to which it is subject to predation by other organisms. In some cases, senses not seen among diurnal animals operate in nocturnal animals.

The large, carnivorous felines, such as lions, tigers, or leopards, are not threatened by many other organisms. They survive well by using a combination of keen eyesight and hearing, as well as an excellent sense of smell. To further aid these big cats, their eyes face forward, allowing very accurate judgment of distances when they hunt. They also rely quite heavily upon very acute reflexes, great strength, and the ability to run down most prey hunted.

An extreme in visual development is seen in owls, which are the ultimate nocturnal avian raptors and which function and hunt almost exclusively at night. These birds are gifted with superb vision, fine hearing, and a very wide visual and aural range. For example, the night vision of many owl species is one hundred times more sensitive than that seen in humans. In addition, owl hearing is very acute, aided in some cases by the possession of asymmetric skulls with the two ears at different places, further enhancing their hearing. Another adaptation that optimizes owl vision and hearing is the ability to turn the neck through 270 degrees. This gives owls the widest aural and visual range of all birds. It is therefore unsurprising that owls hear even the tiniest squeak or rustle made by their prey on the ground below them, and then very efficiently locate the prey by vision.

Bats function only after the sun sets, most often feeding on insects captured while in flight. They have good hearing. However, their eyes are small and they possess relatively poor vision. Perhaps this is why they have developed a special sense, sonarlike echolocation, to pinpoint insect prey in the dark night skies and to navigate. In bat echolocation, sounds (often clicks) are emitted from the larynx or nose of the bat, depending upon species. These sounds then strike insects (and rocks or trees), and echoes bounce back to the bat's ears. The bat then uses the echoes to find its prey. Many bats have developed means to direct the sounds they make for echolocation. For example, bats with skin flaps on the nose often use them to direct sounds in the nasal passages. The excellent hearing found in bats is aided by their large, mobile, external ears. Bats are not "blind as bats." For example, they can use vision to navigate their way home, and often do. Some nocturnal birds, such as the nightjar, also use echolocation to capture their prey.

Rattlesnakes and many other snakes locate their prey in total darkness in another way that involves special sense organs. This process is most sensitive in poisonous snakes called pit vipers. These snakes have two heat-sensitive pits located on the sides of their heads. The pits help them to detect small animals which are their prey, such as rodents or birds. The detection is possible because the prey sought are warmer than their surroundings. The pit viper heat sensors are large groups of nerve endings so sensitive that they can detect the body heat of a rodent over a foot away. The heat discrimination of the pit nerve endings is huge and they can identify a temperature difference of less than one hundredth of a degree.

Nocturnal Animal Habitats

People generally think of nocturnal animals as living in the wild. However, many live cheek-by-

Nocturnal Animals

Bats sleep in caves or trees by day and seek food soon after sunset. Most eat insects, which they capture while in flight, via echolocation. Here, sound is emitted in flight, strikes insects, and then echoes bounce back. The bat uses the echoes to find its prey.

Gerbils, Jerboas, and other rodents burrow in the ground for safety from predators and to escape the heat of their desert environment. They come out at night to eat insects and plants. Their large eyes give them good night vision and their huge ears pick up very faint sounds.

Leopards and other big cats stalk herbivore prey in the dark. They depend on their ability to stalk prey silently or to ambush them, very acute hearing, good night vision, and their capacity for quick movement.

Nightjars are nocturnal insect-hunting birds. They fly with mouths open and eat bugs in their paths. They, like bats, use echolocation to find food.

Owls of woods, forests, and barns roost during the day. At night they hunt mice, voles, and small birds. First, an owl listens for tiny squeaks or rustling sounds from the ground. When these signals occur, the owl attacks silently. Its predation is aided by night vision one hundred times more light-sensitive than in humans, and a wide field of vision.

Scorpions and some Spiders are nocturnal, sleeping in burrows by day. At night they catch prey in similar ways. Scorpions await the close approach of insect prey. Then they move quickly, catch prey in their pincers, paralyze, and kill them. Trapdoor spiders speed out of partly open, sand-covered, silk burrow doors, seize, and kill insects that come close.

Tarsiers are small nocturnal primates. They sleep by day, and at night eat leaves, bugs, and frogs. Nocturnal existence protects them from predation. Large, sensitive, forward-facing eyes and very acute hearing via large, mobile ears help them to obtain food and to move effortlessly in dark trees.

jowl with humans in parks, gardens, and empty lots in urban and suburban areas. Just a few examples are badgers, raccoons, deer, and foxes. People often see them and view them as pests or problems because they raid gardens and garbage cans, and some kill pets. Another problem associated with nocturnal animals is that they can carry severe, contagious diseases (for example, foxes and raccoons may carry rabies) which can be fatal to people. Finally, many nocturnal species are on the verge of extinction. These range from insects to the big cats. A few nocturnal species, such as tigers, are finally being covered by international conservation agreements, perhaps just in time. The others should be helped to survive, too.

Popper, Arthur N., and Richard R. Fay, eds. *Hearing by Bats*. New York: Springer-Verlag, 1995. This specialized, edited text has a lot of information on bat hearing and echolocation. It also speaks to mammal hearing in general and has an excellent bibliography.

NONRANDOM MATING, GENETIC DRIFT, AND MUTATION

Type of animal science: Evolution
Fields of study: Ecology, ethology, genetics, population biology

Nonrandom mating, genetic drift, and mutation are three mechanisms, besides natural selection and migration, that can change the genetic structure of a population.

Principal Terms

ALLELE: alternative forms of a gene for a particular trait

ASSORTATIVE MATING: a type of nonrandom mating that occurs when individuals of certain phenotypes are more likely to mate with individuals of certain other phenotypes than would be expected by chance

GAMETE: a haploid sex cell that contains one allele for each gene; sperm and egg cells are gametes that fuse to form a diploid zygote

GENETIC VARIATION OR DIVERSITY: the total number and distribution of alleles and genotypes in a population

GENOTYPE: the complete genetic makeup of an organism, regardless of whether these genes are expressed

HETEROZYGOTE: a diploid organism that has two different alleles for a particular trait

HOMOZYGOTE: a diploid organism that has two identical alleles for a particular trait

INBREEDING: mating between relatives, an extreme form of positive assortative mating

PHENOTYPE: the expressed genetic traits of an organism

Evolution is a process in which the gene frequencies of a population change over time, and nonrandom mating, genetic drift, and mutation are all mechanisms of genetic change in populations. These mechanisms violate the assumptions of the Hardy-Weinberg model of genetic equilibrium by increasing or decreasing the frequency of heterozygote genotypes in the population.

Nonrandom mating occurs in a population whenever every individual does not have an equal chance of mating with any other member of the population. While many organisms do tend to mate randomly, there are some common patterns of nonrandom mating. Often, individuals tend to mate with others nearby, or they may choose mates that are most like themselves. When individuals choose mates that are phenotypically similar, positive assortative mating has occurred. If mates look physically different, then it is negative assortative mating. Population geneticists use the term "assortative" because it means "to separate into groups," usually in a pattern that is not random. The terms "positive" and "negative" refer to the probability that mated pairs have the same phenotype more or less often than expected by chance. Two color varieties of snow geese (*Chen hyperborea*), blue and white, are commonly found breeding in Canada, and they show positive assortative mating patterns based on color. The geese tend to mate only with birds of the same color; blue mate with blue and white with white. Since a bird's color (phenotype) is determined by the presence of a dominant blue color allele, matings between similar phenotypes are also matings between similar genotypes. Matings between similar genotypes cause the frequency of individuals that are homozygous for the blue or the white allele to be greater, and the frequency of heterozygotes to be less than if mating were random and in Hardy-Weinberg equilibrium. Negative assortative mating increases the frequency of heterozygote genotypes in the population and decreases homozygote frequency. Assortative mating does not change the frequency of the blue or white alleles in the goose population; it simply reorganizes the genetic variation and shifts the frequency of heterozygotes away from Hardy-Weinberg equilibrium frequencies.

Inbreeding is the mating of relatives and is similar to positive assortative mating because like genotypes mate and result in a high frequency of homozygotes in the population. In assortative mating, only those genes that influence mate choice become homozygous, but inbreeding increases the homozygosity of all the genes. High homozygosity means that many of the recessive alleles that were masked by the dominant allele in heterozygotes will be expressed in the phenotype. Deleterious or harmful alleles can remain hidden from selection in the heterozygote, but after one generation of inbreeding, these deleterious alleles are expressed in a homozygous condition and can substantially reduce viability below normal levels. Low viability resulting from mating of like genotypes is called inbreeding depression.

Genetic Drift and Mutation

Genetic drift, like positive assortative mating, reduces the frequency of heterozygotes in a population, but with genetic drift, the frequency of alleles in a population changes. Nonrandom mating does not change allele frequency. Genetic drift is sometimes called random genetic drift because the mechanism of genetic change is random and attributable to chance events in small populations, such that allele frequencies tend to wander or drift. Statisticians use the term "sampling effect" to describe observed fluctuations from expected values when only a few samples are chosen, and it is easy to observe by tossing a coin. A fair coin flipped a hundred times would be expected to produce approximately fifty heads and fifty tails, plus or minus a few heads or tails. Yet, if the coin is flipped only four times, it is not too surprising to get four heads or four tails. The probability of getting either all heads or all tails on four consecutive flips is one out of eight, but the probability of getting all heads or all tails decreases to much less than one in a billion as the sample size increases from four to a hundred tosses. Similarly, it is much easier for nonrandom events to occur in small populations than in large populations. If a population has two alleles with equal frequency for a particular trait, then the result of random mating can be simulated by tossing a coin. The frequency of each allele in the next generation would be determined by flipping the coin twice for each individual, since sexually reproducing organisms have two alleles for each trait, and counting the number of heads and tails. In a small population, only a few gametes, each containing one allele for the trait, will fuse to form zygotes. Chance events can cause the frequencies of alleles in a small population to drift randomly from generation to generation; often one allele is lost from the population.

In small populations with fewer than fifty mating pairs, alleles may be eliminated in fewer than twenty generations by random genetic drift, leaving only one allele for a particular trait in the population. Thus, all individuals would be homozygous for the remaining allele and genetically identical. Theoretically, in any finite population random genetic drift will occur, but it is usually negligible if the population size is greater than a hundred. Sometimes, disasters or disease may drastically reduce the population size, causing a bottleneck effect. The bottleneck in population size reduces genetic variability in a population because there are only a few alleles and results in random genetic drift. Many islands and new populations are established by a small group of founders that constitute a nonrandom genetic sample because they have only a fraction of the alleles from the original large population. Founder effects and bottleneck effects are phenomena that result in a loss of heterozygosity and decreased genetic variability because of the chance drift in allele frequency away from Hardy-Weinberg equilibrium values in small populations.

Mutations are any changes in the genetic material that can be passed on to offspring. Some mutations are changes at a single point in the chromosome, while at other times, pieces of the chromosome are removed, extra pieces are added, or pieces are exchanged with other chromosomes. All these changes could result in the formation of new alleles or could change one allele into a different allele. The random mistakes in the chromosomes occur at the molecular level, and only later are the changes in information or alleles translated into phenotypic differences. Thus, mutation is the ultimate source of genetic variability and is random with respect to the needs of the organism. Most mutations are lethal and are never expressed, but nonlethal mutations provide the necessary variation for natural selection. Even though mutations are very important for evolution, they have only a small effect on allele and genotype frequencies in populations because mutation rates are relatively low. If an allele makes up 50 percent of the gene pool and mutates to another allele once for every hundred thousand gametes, it would take two thousand generations to reduce the frequency of the allele by 2 percent. The net effect of mutations is to increase genetic variability, but at a very slow rate.

Studying Genetic Variability

Population geneticists use a wide variety of laboratory, field, and natural experiments to investigate genetic variability. Natural experiments are situations that have developed without a scientist intentionally designing an experiment, but conditions are such that scientists can test a theory. Researchers have used known pedigrees or ancestral histories of zoo animals and have found that mortality rates of inbred young are often two to three times higher than for noninbred young. Population geneticists use pedigrees to calculate the probability that two alleles are identical by descent; this research provides an index of the amount of inbreeding in a population.

The study of random genetic drift is usually carried out in the laboratory. Scientists often use small organisms that reproduce quickly, such as fruit flies (*Drosophila melanogaster*), to conserve space and save time. In a 1956 study of eye color conducted by Peter Buri, after only eighteen generations and sixteen fruit flies per population, more than half of the 107 populations started had only one of the two alleles for eye color.

Mutations are so rare that even fruit flies reproduce too slowly for scientists to study the effects of mutations on populations, even though much is known about the mechanism of mutation by studying *Drosophila*. Small bacterial growth chambers can hold many millions of bacterial cells, and, since they reproduce quickly, even mutations that occur in only one in a million cells can be detected. In 1955, it was found that mutation rates were very low in bacteria until caffeine was added to the growth chamber, whereupon mutation rates increased tenfold. Any chemical or type of radiation that can cause mutations is called a mutagen. Electrophoresis has also been a useful tool for the study of nonrandom mating, genetic drift, and mutations, because allele and genotype frequencies can be determined from samples of the population and unique alleles can be identified.

The Dangers of Inbreeding

Most governments and religions forbid marriages between close relatives because matings between first cousins result in a 20 percent decrease in heterozygosity; for those between brothers and sisters, there is an 80 percent decrease in heterozygosity. The decrease in heterozygosity and genetic variation and increase in homozygote frequency often result in inbreeding depression because deleterious recessive alleles are expressed. All inbreeding is not undesirable; many of the prizewinning bulls and pigs at state fairs have some inbreeding in their pedigrees. Most breeds of dogs were produced by breeding close relatives so that the offspring would have particular traits.

Zookeepers and others that breed and protect rare and endangered species must continually be concerned about the negative effects of both inbreeding and genetic drift. Most zoos are lucky if they have two or three pairs of breeding adults, and total population sizes are usually very small compared to those of natural populations. These conditions mean that inbreeding may reduce the vigor of the population and genetic drift will reduce the diversity of alleles in the population, thus reducing the chances of survival for the captive species. There is hope for rare and endangered species if independent inbred lines are crossed, thus reducing the effects of inbreeding depression, and if breeding adults from other zoos or populations are traded occasionally, thus increasing the effective population size.

Mutations are the ultimate source of genetic variation and so are very important in the study of evolution, but the population-level effects of one mutation are difficult to study because of the low frequency of natural mutations. Certain nonlethal mutations may have little evolutionary impact but may be important medically because spontaneous mutations result in hemophilia or dwarfism (achondroplasia) in more than 3 out of 100,000 cases. As exposure to background radiation and chemical levels increases, mutation rates are likely to increase, as well as the incidence of mutation-related diseases.

Bibliography

Ayala, Francisco J. *Population and Evolutionary Genetics: A Primer*. Menlo Park, Calif.: Benjamin/Cummings, 1982. This book introduces required basic genetics and mathematics in the process of explaining the concepts and theories of evolution at the genetic level. Ayala's writing style is very clear and he uses only high school algebra throughout the text. An excellent section on probability and statistics.

Crow, J. F. *Basic Concepts in Population, Quantitative, and Evolutionary Genetics*. New York: W. H. Freeman, 1986. A college-level text that emphasizes the theory of genetics, with plenty of examples from the empirical literature that enhance the text. The reader should have an understanding of basic genetics and calculus. Classical and molecular genetics are also discussed.

Fisher, R. A. *The Genetical Theory of Natural Selection*. New York: Dover, 1958. Fisher's terse writing style makes this important book difficult to read, but it provides one of the best descriptions of the effects of mutation and natural selection on genetic variability.

Hartl, Daniel L. *A Primer of Population Genetics*. 3d ed. Sunderland, Mass.: Sinauer Associates, 2000. This introductory-level text for college students is written so that only basic algebra skills are required. Most of the problems are illustrated with numerical examples that are often based on actual data. Chapters on genetic variation and causes of evolution provide a good introduction to basic population genetics. There is also a section on molecular genetics.

Mettler, L. E., T. G. Gregg, and H. E. Schaffer. *Population Genetics and Evolution*. 2d ed. Englewood Cliffs, N.J.: Prentice-Hall, 1988. A well-written college text for courses in population genetics. Parts require some basic math, genetics, and chemistry. Most of the modern theories and hypotheses are given a historical perspective with a brief chronology of important papers on the topic.

Real, Leslie A., ed. *Ecological Genetics*. Princeton, N.J.: Princeton University Press, 1994. A collection of papers by five different writers based on a symposium series, offering a balance of comprehensive review of an aspect of the field of population genetics and ecology, and specific reviews of the author's own case studies.

Wilson, E. O., and W. H. Bossert. *A Primer of Population Biology*. Sunderland, Mass.: Sinauer Associates, 1971. Uses simple mathematical models to present advanced topics in a self-teaching format. Chapter 2 provides the basics of population genetics with a number of problems dealing with mutation and genetic drift.

NOSES

Types of animal science: Anatomy, behavior, development, evolution
Fields of study: Anatomy, biochemistry, biophysics, cell biology, developmental biology, genetics, herpetology, histology, immunology, neurobiology, ornithology, pathology, physiology, zoology

The nose is the major access channel for the sense of smell. The nose signals danger by detecting the smell of spoiled food, smoke, or natural gas. The nose also warms and humidifies the air as it moves onto lungs. It filters out particles and bacteria found in the inspired air and so prevents these particles from entering the lungs.

Principal Terms

MUCUS: the watery material covering the internal nasal structures that aids in humidification, warming, and particle filtration
OLFACTION: the sense of smell
SEPTUM: the bony structure that divides the nose into two sections
TURBINATES: bony structures that define the internal nasal anatomy

In vertebrates, the back of the throat is connected to the outside air through a passageway called the nose. The outside opening of the nose is referred to as the external naris, whereas the opening from the nose to the back of the throat is called the internal naris. In reptiles and amphibians, air drawn into the lungs passes through the external naris and into a tubelike structure which is the simplest form of a nose. In animals like the salamander, the nasal air passageway is a straight tube. Air exits this tube via the internal naris where it proceeds into the back of the throat. In some amphibians, such as the bullfrog, the channel between the external and internal naris has a bony bump on the floor of the nasal passageway. This bump, called the ementia, apparently functions like a baffle plate, so that the incoming air stream is deflected. As a result of this deflection, air moving through the nose is turbulent. This turbulence likely increases the ability to detect smells as well as improves the efficiency of the other nasal functions.

In mammals, the internal anatomy of the nose is defined by bony structures called turbinates. These turbinates produce multiple and convoluted air flow paths for the inspired air. As in the frog, these convoluted flow paths facilitate the various nasal functions.

In mammals the nose is divided into two halves along the midline by a bony structure called the nasal septum. In some mammals, such as the rat, the septum is incomplete, and so there is some mixing in the nose of air that comes into the left and right nostrils.

Air entering the nose travels in the airspace between the turbinates and the nasal septum. The surface of these nasal structures has a very rich blood supply, and so blood flow to these areas can be quickly changed. By changing the amount of blood flow to the nasal structure, the diameter of the nasal airspace itself can be quickly changed. Because of the speed and amount of diameter change that can occur in these areas they are called nasal "swell spaces."

Heat, Humidity, and Purification

When cold air enters the nose, it causes the blood flow to the swell spaces to increase dramatically. This causes a swelling of the nasal tissue and so reduces the size of the airspace through which the incoming air must travel. Because the air passageways are now more narrow, more heat can be transferred from the blood stream to the incoming air. Thus, the cold air is effectively warmed before

All canids, including wolves, have exceptionally keen senses of smell. (PhotoDisc)

it enters the lungs. When air that is warmer than the body temperature enters the nose the reverse happens, and the nasal air passageways are made wider.

The material covering the turbinates and nasal septum is called the mucus. This mucus layer is mostly composed of water and serves to humidify the incoming air. When the air is dry, water is evaporated from the mucus into the inspired air. When the air is dry, a considerable quantity of water can be lost through the nose. For animals living in dry, desert conditions, the nasal humidification process is critical because it is necessary to save every drop of water while still humidifying the incoming air. When these animals take air into the lungs, the inspired air passes through the extensive turbinate structures of the nose where it is humidified by the evaporation of water from the nasal mucus. As evaporation takes place, the surface of the mucus is cooled. When it is time to discharge the air from the lungs, the expired air passes over the cooled surface of the mucus. As a result, water in the inspired air is now picked up by the cooled surface and so it is not lost in the expired air. This type of water conservation method has been seen in kangaroo rats living in the deserts of Australia and in certain birds, such as the cactus wren, which inhabit warm, dry areas.

In addition to supplying water for humidification purposes, the nasal mucus serves as a trap for particulate matter. Smoke and dust particles and even airborne bacteria are trapped in the mucus of the nose. Beneath the nasal mucus is a layer of cells that contain hairlike protrusions called cilia. As the cilia of these cells beat, they create a wavelike action in the mucus. The mucus is thus moved through the nose and to the back of the throat. Once in the throat the mucus is swallowed and the particles and bacteria are dealt with in the stomach. The movement of the nasal mucus is an ongoing process and so trapped particles are continually being removed from the nose. There are also white blood cells and enzymes found in the mucus that destroy bacteria.

When particles (and sometimes even air) touch parts of the nose a sneeze occurs. In this case, breathing is stopped and air is forcibly expelled from the lungs at a high flow rate. The sneeze is an attempt to expel the particles from inside the nose.

However, when the odorant is very foul or stings the nose, breathing may be temporarily stopped. This protects the lungs from potentially damaging chemicals. The detection of potentially harmful chemicals occurs both through the smell receptors as well as through pain receptors that are found in the nose.

NUTRIENT REQUIREMENTS

Type of animal science: Physiology
Fields of study: Biochemistry, physiology

All animals depend on external sources of nutritional raw materials for energy, growth, maintenance, and functioning.

Principal Terms

CARBOHYDRATE: an organic molecule containing only carbon, hydrogen, and oxygen in a 1:2:1 ratio; often defined as a simple sugar or any substance yielding a simple sugar upon hydrolysis

LIPID: an organic molecule, such as a fat or oil, composed of carbon, hydrogen, oxygen, and sometimes phosphorus, that is nonpolar and insoluble in water

MINERAL: one of the many inorganic elements other than carbon, hydrogen, oxygen, and nitrogen that an organism requires for proper body function

PROTEIN: an organic molecule containing carbon, hydrogen, oxygen, nitrogen, and sulfur and composed of large polypeptides in which over a hundred amino acids are linked together

VITAMIN: an organic nutrient that an organism requires in very small amounts and which generally functions as a coenzyme

Food, used to provide material for production of new tissue and the repair of old tissue as well as used as an energy source, is obtained from a variety of plant, animal, and inorganic sources. Regardless of the source, food must provide its consumer with a sufficient amount of the essential nutrients. A nutrient is any substance that serves as a source of metabolic energy, raw material for growth and repair of tissues, or general maintenance of body functions.

General Nutritional Requirements

Animals differ widely in their specific nutritional needs, depending on the species. Within any given species, those needs may vary according to variations in body size and composition, age, sex, activity, genetic makeup, and reproductive functions. A small animal requires more food for energy per gram of body weight than does a larger animal, because the metabolic rate per unit of body weight is higher in the smaller animal. Likewise, an animal with a cool body temperature will have less energy needs and require less food than an animal with a high body temperature. An egg-producing or pregnant female will require more nutrients than a male. In order for an animal to be in a balanced nutritional state, it must consume food that will supply enough energy to supply power to all body processes, sufficient protein and amino acids to maintain a positive nitrogen balance and avoid a net loss of body protein, enough water and minerals to compensate for losses or incorporation, and those essential vitamins that are not synthesized within the body.

Activities such as walking, swimming, digesting food, or any other activity performed by an animal require fuel in the form of chemical energy. Adenosine triphosphate (ATP), the body's energy currency, is produced by the cellular oxidation of small molecules, such as sugars obtained from food. Cells usually metabolize carbohydrates or fats as fuel sources; however, when these carbon sources are in short supply, cells will utilize proteins. The energy content of food is usually measured in kilocalories, and it should be noted that the term "calories" listed on food labels is actually kilocalories (1 kilocalorie = 1000 calories). Cellular metabolism must continually produce energy to maintain the processes required for an animal to remain alive. Processes such as the circulation of blood, breathing, removing waste products from the blood, and in birds and mammals, the maintenance of body temperature, all require energy. The calories required to fuel these essential processes for a given amount of time in an animal at rest is called the basal metabolic rate (BMR). For a resting human adult, the BMR averages from thirteen hundred to eighteen hundred kilocalories per day. As physical activity increases, the BMR increases.

Energy balance requires that the number of calories consumed for body maintenance and repair and for work (metabolic and otherwise) plus the production of body heat in birds and mammals be equal to the caloric intake over a period of time. An insufficient intake of calories can be temporarily balanced by the utilization of storage fats, carbohydrates, or even protein, and will result in a loss of body weight. On the other hand, an excessive intake of calories can lead to the storage of energy sources. Animals normally store glycogen, but when the glycogen stores are full, food molecules, such as carbohydrates and protein, will be converted to fats.

Nutrient Molecules

Proteins are composed of long chains of amino acids and serve a number of important functions in all living organisms, but they are primarily used as structural components of soft tissues and as enzymes. Proteins can also be utilized as energy sources if they are broken down into amino acids. Animal tissues are composed of about twenty different amino acids. The ability to synthesize amino acids from other carbon sources, such as carbohydrates, varies among species, but few, if any, animal species can synthesize all twenty required amino acids. Those amino acids that cannot be synthesized by an animal, but are required for the synthesis of essential amino acids, are the so-called essential amino acids, and must be included in the diet. Humans, for example, require nine essential amino acids. Both plant and animal tissues can serve as protein sources, but animal protein generally contains larger quantities of the essential amino acids.

Carbohydrates are primarily used as immediate sources of chemical energy, but they can also be converted to metabolic intermediates or fats. Some carbohydrates are also structural components of larger molecules. For example, the nucleic acids deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) contain the sugars deoxyribose and ribose, respectively, as an integral component of their structure. Most animals can also convert proteins and fats into carbohy-

Feeding Mechanisms

Since most animals cannot absorb nutrients directly from their environments, they must exert energy in order to obtain food. Although animals show tremendous diversity in their methods of obtaining food, most feeding habits can be classified in one of three different types. Many animals, particularly those living in aquatic environments, feed on particulate matter, the free-floating material made up of plankton, microscopic aquatic life-forms, and organic remains of dead and decaying plants and animals. Some of the animals utilize a technique referred to as suspension feeding, in which the food material is drawn into the digestive tract by currents created by external structures, such as cilia or setae. Other particulate feeders feed on deposits of detritus (decaying organic matter) that accumulate at the bottom of lakes or oceans.

A second feeding method involves the consumption of food masses. Most of these animals utilize specialized adaptions that allow them to capture and manipulate solid food. Herbivores have special adaptions for cutting and crushing or grinding plant tissues, while carnivores such as predators must have the ability to capture, hold, and either swallow the prey whole or shred it into smaller pieces. Feeding on liquids is a third type of feeding habit. This method, which involves the sucking of fluids from a host plant or animal, is utilized primarily by parasites, but it can also be observed in certain insects.

drates. The principle sources of carbohydrates are the sugars, starches, and cellulose in plants and the glycogen stored in animal tissue.

Lipids are an important and essential component of all biological membranes. In addition, several animal hormones, such as the sex hormones, are lipoidal in nature. Fats and lipids are also especially suitable as concentrated energy reserves, because each gram of fat supplies twice as much energy as a gram of carbohydrate or protein and does not have to be dissolved in water. Hence, animals commonly store fat for times of caloric deficit when energy expenditure exceeds energy uptake. Some animals, such as migratory birds and hibernating mammals, store large quantities of fat to offset the times that they are not actively feeding. Lipid molecules include fatty acids, monoglycerides, triglycerides, sterols, and phospholipids.

All animals require an adequate supply of essential inorganic minerals. Carbonate salts of the metals calcium, potassium, sodium, and magnesium as well as some chloride, sulfate, and phosphate are important constituents of intra- and extracellular fluids. Calcium phosphate is present as hydroxyapatite, a crystalline material that gives hardness and rigidity to the bones of vertebrates and the shells of mollusks. Certain metals, such as copper and iron, are required for oxidation-reduction reactions and for oxygen binding and transport. The catalytic function of many enzymes requires the presence of certain metal atoms. Animals require moderate amounts of some minerals and only trace quantities of others.

Animals require a variety of vitamins, diverse and chemically unrelated organic substances. Vitamins primarily function as coenzymes for the proper catalytic activity of essential enzymes. As with amino acids, the ability to synthesize differ-

Functions of Essential Minerals and Vitamins

Minerals

Calcium: nerve and muscle function, blood clotting, bone and tooth formation

Chlorine: acid-base balance, gastric juice

Chromium: associated with glucose and energy metabolism

Cobalt: component of Vitamin B_{12}

Fluorine: maintenance of tooth structure

Iodine: component of thyroxine, a thyroid hormone

Iron: component of essential enzymes and electron carriers in energy metabolism

Phosphorus: transfer of chemical energy, bone and tooth formation, nucleic acid synthesis

Potassium: proper nerve function, acid-base balance, water balance

Selenium: component of essential enzymes and functions in association with vitamin E

Sodium: proper nerve function, water balance, acid-base balance

Sulfur: component of certain amino acids

Copper, Magnesium, Manganese, Molybdenum, Zinc: components of essential enzymes

Vitamins

Vitamin A (Carotene): formation of visual pigments, maintenance of certain membranes

Vitamin B_1 (Thiamine), Vitamin B_2 (Riboflavin), Niacin: coenzymes for certain enzymes in energy metabolism

Vitamin B_6 (Pyridoxine): coenzyme for amino acid synthesis and fatty acid metabolism

Vitamin B_{12} (Cyanocobalamin): required for nucleoprotein synthesis

Vitamin C (Ascorbic acid): vital to collagen formation, serves as an important antioxidant

Vitamin D (Calciferol): increases calcium absorption from gut, bone and tooth formation

Vitamin E (Tocopherol): maintains pregnancy in mammals; serves as an important antioxidant

Vitamin K (Naphthoquinone): required for synthesis of a protein necessary for blood clotting

Biotin: coenzyme for enzymes associated with protein synthesis

Folic acid: required for nucleoprotein synthesis and formation of red blood cells

Pantothenic acid: forms part of coenzyme A associated with energy metabolism ent vitamins from other carbon sources varies among species. Those essential vitamins that cannot be synthesized by the animal itself must be obtained from other sources, primarily from plants but also from dietary animal flesh or from intestinal microoganisms. Vitamin C (ascorbic acid) can be synthesized by many animals, but not by humans. Vitamins K and B are produced by intestinal bacteria in humans. Vitamins such as A, D, E, and K are fat soluble and can be stored in fat deposits within the body; however, water soluble vitamins such as vitamin C are not stored and are excreted through the urine. Hence, the water soluble vitamins must be consumed or produced continually in order to maintain adequate levels.

Although not commonly thought of as a nutrient, water is tremendously important and comprises up to 95 percent or more of the weight of some animal tissue. Water is replaced in most animals by drinking, ingestion with food, and to some extent, by the metabolism of carbohydrates and lipids.

OCTOPUSES AND SQUID

Type of animal science: Classification
Fields of study: Marine biology, zoology

Octopuses and squid belong to the order Octopoda, members of which have eight tentacles covered with sucker pads. They have two eyes and a well-developed nervous system and are considered among the most intelligent of all invertebrates.

> **Principal Terms**
>
> INVERTEBRATES: animals without backbones
> TENTACLES: a long flexible arm or projection

Octopuses and squid belong to the order Octopoda, which is in the class Cephalopods, phylum Mollusca, which includes snails and clams. They are related to other mollusks but have no internal or external shell. There are more than one thousand species of octopuses and squid alive today. They have two eyes and eight (octopuses) to ten (some squid) tentacles that are attached directly to the head. The tentacles are covered with sucker pads that help the animal move along the ocean floor, its normal place of residence. They have the most complex brain of the invertebrates, and also have long- and short-term memories, much like vertebrates.

The genus *Octopus* contains several different species, which vary greatly in size. The smallest is *Octopus arborescens*, a species that averages two inches in length. The largest species, *Octopus dofleini*, commonly known as the giant Pacific octopus, can grow to sixteen feet in length and weigh up to three hundred pounds, with a tentacle span of thirty feet. The best known and most widely distributed species is *Octopus vulgaris*, a medium-sized octopus found in every ocean. This species is from two to three feet in length and lives in holes on the ocean floor. It feeds mainly on crabs, lobsters, and other crustaceans. It is very intelligent: One Japanese scientist taught an octopus how to open a sealed jar in order to get at its contents, a spiny lobster.

An octopus can change its skin color quickly when it is frightened or threatened. Its changed color provides camouflage to help it blend in with the background so that the octopus becomes almost invisible to predators. Scientists have discovered that octopuses change colors not only for defense, but also to reveal their moods and emotions. Angry members of the species turn a deep red in color, while during mating season, both males and females display stripes and colors that reflect their inner excitement. Some species squirt out clouds of a dark inky substance, which hangs in the water for several seconds. This inkblot has the same size and shape as the octopus, and while it draws the attention of the predator, the octopus escapes. When an enemy, such as a moray eel, attacks an octopus, it may lose one of its eight arms in the fight, and while the eel watches the twitching arm the injured octopus can swim away. The tentacle grows back very quickly.

Squid are cephalopods and belong to the order Teuthoidea (ten-armed), which has many species. They are found in every ocean and range in size from less than one inch to more than sixty-five feet in length. Adult squid of some species can race through the water at speeds of up to twenty-five miles per hour. They are aggressive hunters, equipped with two more tentacles than octopus. The squid use these extra arms to catch their food. Some squid hunt in packs and use their ability to change color to lure their prey. They are also bioluminescent, which means they can light up.

Cephalopod Facts

Classification:
Kingdom: Animalia
Subkingdom: Eumetazoa
Phylum: Mollusca
Class: Cephalopoda
Subclass: Nautiloidea (chambered nautilus), Coleoidea (octopuses and squid)
Orders: Sepioidea (cuttlefishes), Teuthoidea (squid), Octopoda (octopuses)
Suborder: Three suborders of Octopoda—Palaeoctopoda (finned), Cirrata (webbed), Incirrata (round bodied)
Geographical location: Every ocean, but mainly the Indian Ocean and the South Pacific
Habitat: The ocean floor
Gestational period: Varies by species from forty days to one year
Life span: One to three years for octopuses; five years for squid; fifteen to twenty years for chambered nautilus
Special anatomy: Eight to ten tentacles, usually with suction cups at the end; round, sacklike bodies for octopuses

Actually, bacteria living under their skin produce the light in squid that live close to the surface. Deep-water squid, on the other hand, living thousands of feet below the surface, make their own light. These species have light-producing organs called photophores that make two chemicals: a protein called luciferin and an enzyme known as luciferase. When the two chemicals are mixed, the enzyme breaks down the protein, releasing a pale, blue-green light. This is the same process used by fireflies. Some squid species can squirt out clouds of glowing bacteria when they are endangered. This light show distracts the predator and helps the squid escape.

Squid, Cuttlefish, and Nautilus

The giant squid, *Architeuthi*, is the largest invertebrate on the earth, having eyes the size of automobile headlights and weighing up to one thousand pounds. Despite their size, no one has ever seen one of these animals in its natural environment. Although these monsters of the deep have been found in the nets of commercial fishermen, in the stomachs of sperm whales, and washed ashore in Australia, no scientific information has been gathered on the species by direct observation. Perhaps the major reason so little is known about giant squid is that they live so deep in the ocean. Another reason is their enormous speed and rapid acceleration. Because of this speed they can easily evade their major predators, tuna and sharks. Some apparently even have the ability to leave the water for short periods and glide through the air like flying fish to escape their enemies.

The cuttlefish, genus *Sepia*, is a cephalopod that can eject clouds of ink to confuse enemies and can swim almost as rapidly as squid. It most remarkable characteristic, however, is its ability to change color, which biologists believe is used by the species as a method of communication. Cuttlefish can display thirty different color patterns that range from very light to very dark. They can also exhibit zebralike stripes and patterns that look like a pair of dice. They can change colors quickly to escape predators by blending into the background. Color changes are also used to attract mates and outshine rivals during courtship. Cuttlefish have ten arms or tentacles, with two longer than the other eight. Most of the time the two longer arms are tucked under their bodies, but if supper swims by they shoot out to grab the shrimp or fish and drag it to their mouths.

Next to the octopus, the cuttlefish is probably the most intelligent invertebrate in the sea. In experiments, cuttlefish have been taught to recognize which colored disks signal food and which do not. Baby cuttlefish know from the moment of birth how and when to bury themselves in the sand, how to squirt an inky substance to confuse predators, and how to get away quickly when they encounter larger animals. The ink of the cuttlefish, which is called sepia (the genus name) was the original dark pigment used in India ink. This ink was used in quill pens in England and France in the 1600's and is still used today by artists for drawing and lettering.

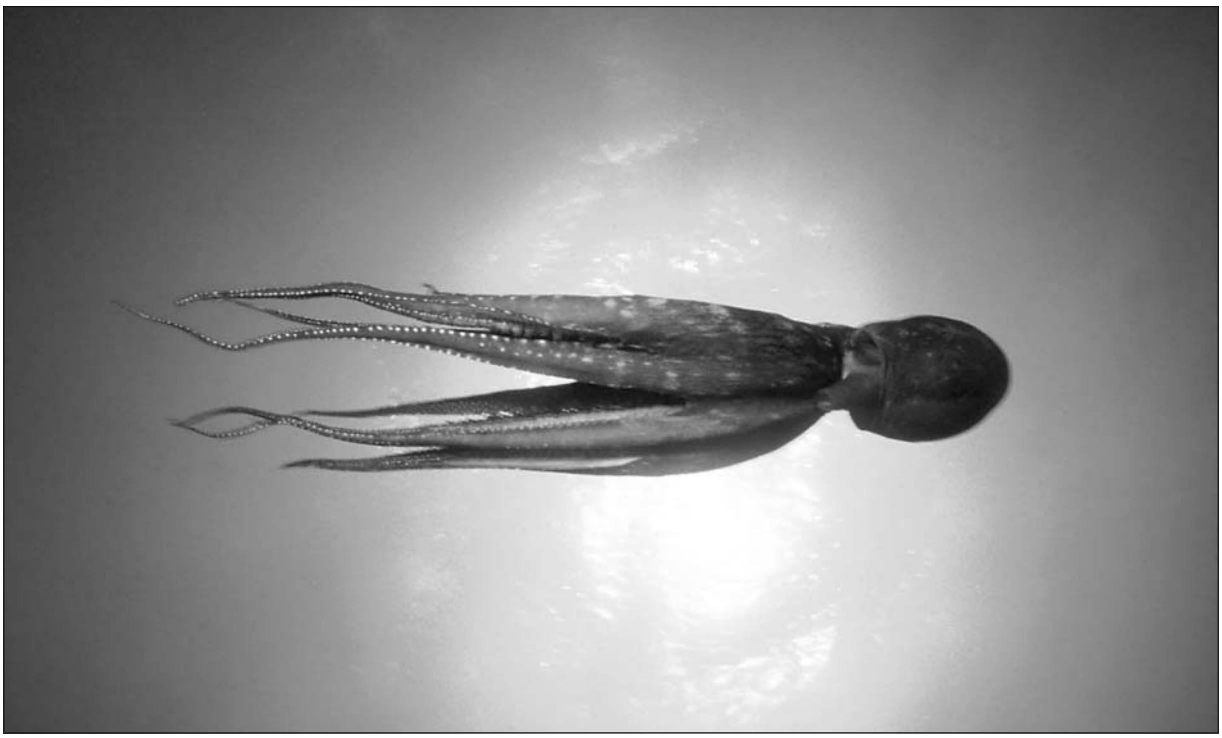
The chambered nautilus is one of five species in the genus *Nautilus*. It is a living fossil. The surviving species are found only 60 to 1,500 feet below the surface of the Indian and Pacific oceans. Five hundred million years ago, nautiloids were the masters of the sea. At that time there were more than 2,500 species, some with straight shells and others with coiled shells like the modern nautilus. They are nocturnal feeders, coming to the surface only on moonless nights to feast on small fish and shrimp. They are the only members of the class Cephalopoda to still have an external shell. They have eighty to one hundred arms surrounding their heads. Each arm can touch and taste food. The nautilus gets its name from the thirty to thirty-eight walled chambers that are found inside its shell. The animal lives in the outermost chamber and uses the others to float in the water.

The nautilus is an endangered species, mainly because of the beauty of its shell. Philippine Island fishermen catch about five thousand living animals every year to sell to shell collectors. They are also hunted extensively off the coasts of India and Indonesia.

Growth and Reproduction

Most cephalopods, including the giant squid, grow quickly and die after a short life. The great Pacific octopus, for example, which is only one-twentieth the size of the giant squid, lives just two to three years. It is estimated that the giant squid lives for no more than five years. This means that its growth to adulthood is extremely fast. When it is a baby, it is less than an inch long, but within three years it has reached almost sixty feet in length. Growing at such a rapid rate requires huge amounts of food. Giant squid eat enormous quantities of fish and other squid, which they catch with the suckers on their tentacles and crush in their massive mouths.

Octopuses and squid have separate sexes and reproduce internally. In some species, modified



The tentacles of an octopus are attached directly to its head, leading to the name "cephalopod," meaning "head-foot." (Digital Stock) sucker discs at the tip of one of its tentacles distinguish the male. This arm is used to remove a packet of sperm from within his body cavity and insert it into the cavity of the female. Within two months after mating, the female attaches strands of clustered eggs to the ceiling of her dwelling under the sand. The number of eggs laid varies greatly from species to species, with the common octopus laying anywhere from 200,000 to 400,000 very tiny eggs. Other species lay as few as 150 eggs. Once the eggs are laid, the mother gently caresses the eggs with her suckers to keep algae and bacteria from growing on them. She also squirts them with streams of water to keep them clean. As the baby inside the egg matures, the mother's gentle caresses become more violent to help the developing octopus break away from its egg house. Most mothers do not eat after laying their eggs and die shortly after their eggs have hatched. Baby octopuses in species like *Octopus vulgaris* are carried about in water currents for about a month before they settle to the bottom, where they start to feed. Babies in other species look just like a miniature adult and immediately sink to the bottom where they start living. On average, the survival rate for a baby octopus is extremely tiny. Only about one or two out of 200,000 eggs will survive to become an adult.

The chambered nautilus cements its eggs to rocks or coral on the seafloor. They take almost a year to hatch. A baby nautilus is only about an inch long when it hatches from its egg case but grows into an adult quickly. It is the longest-living cephalopod, with some adults living fifteen to twenty years. Unlike the octopus, the chambered nautilus does not die immediately after reproduction.

Cephalopods make up a large part of the diet of whales, seals, fishes, and seabirds.

Cephalopod Evolution

The earliest ancestors of octopuses and squid were mollusks with thick shells that protected them from their enemies. Of the estimated one thousand species of cephalopods still living, only the chambered nautilus and cuttlefish have remnants of an internal shell. Cephalopods began losing their shells in the Triassic period, 245 to 208 million years ago. The earliest squid appeared in the Jurassic period, 208 to 144 million years ago. The oldest known octopod, *Palaeoctopus newboldi*, now extinct, comes from the Cretaceous period and is at least 140 million years old.

OFFSPRING CARE

Types of animal science: Behavior, reproduction
Fields of study: Ethology, ornithology, reproduction science

In most species, one parent alone or neither parent cares for the offspring. In some species, however, both parents jointly care for their offspring. In a few species, several adults share parenting duties or take turns "babysitting."

Principal Terms

ALLOPARENTING: performance of parenting duties by an individual not the parent of the offspring (though usually a relative)
ALTRICIAL: the condition of being weak and relatively undeveloped at birth (or hatching) and thus dependent upon parental care for a prolonged period
CUCKOLD: a partnered male who is helping his mate to raise offspring which are not genetically his own
NEST-PARASITE: also called brood-parasite; an individual (or species) that lays its eggs in the nest of another individual (or species) and does no parenting at all
PRECOCIAL: the condition of being strong and relatively well developed at birth (or hatching) and thus not particularly dependent upon parental care
SEX-ROLE REVERSAL: generally used to refer to species in which the male does most of the parenting
VIVIPAROUS: characterized by live birth (as opposed to egg-laying)

In the animal kingdom, there are species in which neither parent cares for offspring, species in which one parent cares for offspring, species in which both parents care for offspring, and species in which individuals other than parents help care for offspring. Patterns of caring for offspring relate to several key factors.

Precocial Species Versus Altricial Species

The most important factor determining the number of caretakers, as well as the quality and duration of parental care, is simply how much care the offspring need. In species in which young are born well developed and capable of surviving on their own, there is little reason for parents to provide help. Hatchling fish and baby turtles, for example, are born or hatched looking just like miniature adults, and are fully capable of moving about and feeding themselves. Young of such species are referred to as precocial, and usually get no parental care at all. Young of most invertebrate species as well are capable of surviving without help, and so are typically left to fend for themselves.

On the other hand, in species in which young are born or hatched quite helpless with no chance of surviving on their own, it should not be surprising that one or both parents are likely to stay around. Young of such species are referred to as altricial. Dogs and cats are excellent examples of species with altricial offspring; so are humans. Generally speaking, mammals are more altricial than most groups of animals, and all mammalian young initially depend upon their mother for food (milk), delivered by means of lactation.

Compared to other animals, birds, too, are relatively altricial—especially raptors (birds of prey) and songbirds. When altricial birds first hatch they are featherless and unable to regulate their own body temperature; one or both parents must regularly warm the hatchlings just as they earlier warmed the eggs. Furthermore, altricial birds hatch with their eyes closed and they are not strong enough or coordinated enough to leave the nest to feed or to flee from danger. Because baby birds need tremendous amounts of food and there are usually quite a few offspring, in most species of birds, both parents provide care.

Prey Species Versus Predatory Species

Although the young of birds and mammals are quite helpless compared to the young of animals in other taxonomic groups, there are variations. As a rule, prey species tend to be more precocial than predatory species and, therefore, to require less parental care.

Young of species which are herbivorous (vegetarian) but are in constant danger of being eaten by carnivorous (meat-eating) species cannot afford to be completely helpless even if they are dependent upon their mother for food. Grazing mammals, such as zebra and deer, are vulnerable to lions and wolves, so young of these species must be able to stand up and run just a few minutes after birth: they are born with open eyes, well-developed muscles, and a full coat of hair. Although mammalian young need to nurse from their mother, they are able to start grazing fairly quickly, so typically it is only the mother who provides support, and her care is not exceptionally prolonged.

Among birds the same pattern is found: Herbivorous species, such as ducks and chickens, that are preyed upon by mammalian, avian, or reptilian predators, hatch with open eyes, the ability to walk, run, or swim, and a coat of downy feathers so that even though they cannot yet fly, they can leave the nest without need of further incubation. Offspring of these species can usually eat on their own almost immediately after hatching, and therefore can often get by with only one parent to show them what to eat and to protect them until they can fly.

Compared to young of prey species, young of predatory species tend to be born in a much more altricial state, and therefore, to need more parenting. Lion cubs and wolf pups do not have open eyes or the strength and coordination to leave their nest, den, or lair until a few weeks after birth. Even after they can move about and are weaned from mothers' milk, they are still too uncoordinated to hunt successfully and must be fed by one or both parents. In fact, species such as lions and wolves, which not only have altricial young, but frequently have large litters, often re-

"Noncooperative" Breeding

In Australia, birds called choughs (pronounced "chuffs") live in extended family groups that cooperate to defend territories and raise young that may need provisioning for as long as two years. Some of the youngest helpers are not much older than their younger siblings, and when provisioning their charges, often cheat. If no older adult is looking, a young helper may pretend to feed its sibling, but at the last minute, swallow the food itself.

In the southwestern United States live acorn woodpeckers, a communal species in which a group of up to a dozen birds shares common nest-holes and food repositories for storage of acorns. Despite their seeming cooperation, when more than one female lays eggs in the same nest-hole, they initially take turns destroying or removing one another's eggs from the hole and placing them in the food repository for later consumption. Over a third of eggs laid get destroyed in this fashion.

Some birds lay their eggs in another bird's nest and do not do any parenting at all. Facultative or opportunistic nest-parasites (also called brood-parasites) are species such as ducks, which usually make their own nest and raise their own young, but which, in a good season, may lay extra eggs in a neighbor's nest or, in a bad season, may forego nesting but lay a few eggs elsewhere on the chance that another parent will manage better. Obligate nest-parasites are species such as the Australian and European cuckoos, which never make a nest and never raise their own offspring, but which lay their eggs in the nest of birds of a different species.

cruit other adults to help raise their offspring. Amongst African (but not American) lions, related females form groups called prides that hunt together and help take care of one another's offspring. Wolves form hunting packs, and all members (both male and female) help to feed the young. This behavior is called aunting when it is done by a female relative, or more generally, alloparenting. Alloparenting is also seen among some rodents and primate species.

As with mammals, carnivorous and insectivorous birds come into the world in a more altricial state than their vegetarian brethren, and therefore need more care. In the majority of bird species, both parents cooperate to raise young and, as with some of the most altricial mammalian species, if there is a large brood, parents of some species recruit helpers. In birds, helpers are usually the parents' offspring from a previous brood or season, and are thus siblings or half-siblings of the young they are helping to raise. Species that use this extended family system are referred to as cooperative breeders—although some are less cooperative than others.

Quantity Versus Quality Parenting

A third factor relevant to parenting is the number of offspring, either sequentially or in litters, that an individual produces. All individuals have a limited life span and a limited amount of energy, and during that life span they can allocate that energy either to producing a large number of offspring or to providing intensive care for a smaller number of offspring. Thus, while animals with altricial young that require intensive care do not have an option of producing huge numbers of offspring, species with precocial young do.

Most invertebrates and many vertebrates (other than birds and mammals) take the "quantity" strategy: They produce large numbers of offspring and provide no parental care at all. A large majority of the offspring of these species die before reaching adulthood, but a small percentage survive and reproduce. Extreme examples of taking a "quantity" strategy are the semelparous species, species that can only reproduce once in their lifetime. Salmon are well-known for this form of reproduction. Many spiders and insects, too, die before their only batch of young are even hatched.

At the other extreme is the strategy of having a small number of well-cared-for offspring, each of which has a high probability of survival. All altricial species are constrained to the "quality" strategy, but some precocial species opt for "quality" as well. Alligators and crocodiles are excellent mothers, protecting their eggs before they hatch, then transporting and protecting the young afterward. Some species of amphibians, fish, and even insects are devoted parents.

Maternal Care Versus Paternal Care

In mammals, if only one parent is necessary, it is always the mother who is committed to caretaking because she is the one who must provide the offspring with their first food through nursing. No other animals, however, nurse their young, so in other species, if only one parent is necessary, it does not necessarily have to be the mother who becomes the caretaker.

In single-parent species, whether it is the mother or father who becomes the caretaking parent depends, to a great extent, on parental certainty. In viviparous species (species that give birth to live young rather than lay eggs) the parent that gives birth is, for certain, one of the two genetic parents, and is therefore the parent most likely to care for the young if they need it. With rare exception, that means that mothers become the caretaking parent in viviparous species. In egg-laying (oviparous) species, parental certainty depends on whether fertilization was internal (as in birds and many invertebrates) or external (as in most fishes and amphibians). If fertilization is internal, then again, it is only the mother who is certain to be a genetic parent of the eggs she lays, and who is therefore most likely to take on the role of caretaker when only a single caretaker is needed. If, on the other hand, fertilization is external, then both parents are equally likely to be the genetic parent of any young that later hatch from eggs at the breeding site, and if parenting is needed, male and female are equally likely

Fathers Extraordinaire

Because mothers are the single parent in most single-parent species, those species in which the father does most of the parenting are referred to as sex-role-reversed. Typical of role-reversed species is a cluster of sex differences that are reversed in many ways other than just parenting: Females tend to be larger, more aggressive, and more flashy than the males, and they may be the more "promiscuous" sex, mating with a series of stay-at-home fathers in a mating system called polygyny.

Polygyny and exclusive paternal care have been best studied in birds. Other types of animals, however, also provide examples of exclusive paternal care. In several species of invertebrates, fish, and amphibians, females lay their eggs and leave, while males remain to guard the eggs after they have been fertilized, protecting them against the vagaries of weather, water currents, and predation. Even after the eggs hatch the male may continue to guard the young or to transport them: Some tiny Amazonian frogs carry their tadpole offspring on their back if the small pool of water where they hatched starts to dry up. In other species, males carry fertilized eggs on their back, in their mouth, or in a specialized pouch. In the case of pipefish, seahorses, and some frogs, the male's tissue actually provides nutrients to the developing embryos. In these rare creatures, one could truly say that it is the male that becomes pregnant.

to become the caretaker. The result is that while most species that have external fertilization do not remain with their eggs or provide any parental care at all, in those that do, factors other than parental certainty determine which sex becomes the guardian.

In species with internal fertilization, the probability that a particular male is the father (or one of the fathers) of a particular set of offspring depends upon how many males the female mated with and when. In the few species that have been closely studied, if a mother needs help to raise her offspring, males seem to expend effort in proportion to the probability that they are actually the genetic father. This is because males that are parenting or otherwise providing resources for offspring that are not genetically their own are wasting their effort in terms of reproduction.

A male that is caring for another males' offspring is sometimes referred to as a cuckold. In some human cultures, to call a man a cuckold (or the equivalent) is a huge insult. However, in humans and other animals, when a male provides care for a female's offspring even though they are not genetically his, he is sending her a signal that he is a good provider, and perhaps he is making it more likely that she will mate with him in the future.

The Spectrum of Parental Behavior

Most parents are good to most of their offspring most of the time. Parents provide food and sometimes shelter; they protect their offspring from danger and chase away predators; they may place their offspring in safe refuges; they may even teach their offspring necessary information or skills such as how to hunt, the location of productive feeding sites, or traditional migration routes.

At some point, however, there may be conflict between parents and offspring; conflict is especially common over how much care the parents provide versus how independent the offspring have become. Avian parents, for example, may displace their offspring from the nest to make way for a new brood; mammalian mothers may resort to force to wean their maturing offspring and so be able to nurse a new infant or litter. Alternatively, offspring may be sexually mature and ready to leave, but are manipulated by their parents to remain in the family acting as helpers.

The most extreme forms of parental manipulation involve neglect and what is called tolerated siblicide. In particularly bad times when resources are scarce, parents may provide care for only one or a few offspring, allowing the others to die. Even in good times, parents with very large broods or litters may neglect the smallest and weakest young. Parents of some species allow older siblings to kill, and perhaps eat, their younger siblings; in fact, this behavior is the norm in some species.

Humans tend to equate parenting with moral goodness; among other animals it equates simply to survival and reproduction. Different species provide parental care—or not—as it is needed, in order to maximize the probability that at least a few offspring will survive to maturity. In some vertebrate species parenting may be associated with intense emotions and bonding, as it is in humans, but across the animal kingdom there is no one right way to parent; what works is what works.

OMNIVORES

Types of animal science: Anatomy, classification
Fields of study: Anatomy, entomology, ornithology, marine biology, zoology

Omnivores are animals that eat both plants and animals. They are found in all types of animals, including arthropods, fish, birds, and mammals. Omnivore diets may vary seasonally.

Principal Terms

CARNIVORE: a flesh-eating animal
CARRION: dead animals
DIURNAL: active during the day
HERBIVORE: an animal that eats only plants
HERMAPHRODITE: an organism having male and female reproductive systems
RADULA: a tonguelike, toothed organ for grinding food

Many animals are either herbivores, who eat only plant food, or carnivores, who eat only the flesh of other animals. The preference for one type of food or the other depends largely on the type of digestive system that the animal has, and the resources it can put into its "energy budget." Meat is generally easier to digest and requires a less complex digestive system and a relatively short intestinal tract. However, in order to get meat, carnivores have to invest a lot of time hunting their prey, and the outcome of a hunt is always uncertain. The food of herbivores is much easier to obtain, since plants do not move and all the herbivore has to do is graze on the grasses, leaves, or algae readily available around it. However, the cellulose that plants are made of is very tough to digest, and thus herbivores must have a much more complex and lengthy digestive tract than carnivores. Many herbivores are ruminants, with multipart stomachs, who have to chew and digest their food more than once in order to get adequate nutrition from it.

Carnivores and herbivores are also vulnerable to a loss of their food source. Herbivores whose digestive systems are specialized to process only one type of food will starve if that food becomes scarce due to drought or some other climatic change. Carnivores often have specialized hunting patterns that cannot be changed if the prey (usually herbivores) become scarce due to loss of their own food source.

Omnivores maximize their ability to obtain food by having digestive tracts capable of processing both plant and animal food, although they are usually not capable of digesting the very tough plant material, such as grasses and leaves, that many large herbivores eat. Omnivores may also be scavengers, eating whatever carrion they may come across. Omnivores often lack the specialized food-gathering ability characteristic of pure carnivores and herbivores. Many animals often thought of as carnivores are actually omnivores, eating both plants and animals.

Types of Omnivores

Omnivores can be found among all types of animals, living on land and in water. They include fishes, mollusks, arthropods, birds, and mammals.

Most insects are either herbivores, such as grasshoppers, or carnivores such as mantises. However some, such as yellow jacket wasps, are omnivores, eating other insects, fruit, and nectar. Omnivorous snails and slugs eat algae, leaves, lichens, insects, and decaying plant and animal matter. Their main organ for eating is called a radula, a tonguelike, toothed organ that is drawn along rocks, leaves, or plants to scrape off food; it

Raccoons eat everything they can get their paws on, including fish, insects, birds, plants, crustaceans, and carrion. (PhotoDisc)

is also used to bore holes through shells of other mollusks, to get to their flesh.

Omnivorous fish include the common carp, goldfish, catfish, eels, and minnows. Since a fish's food is often suspended in the medium through which the fish swims—water—being able to gulp up whatever comes into its mouth is an efficient way for a fish to eat. Similarly, bottom-feeders (fish that suck up material from the floor of whatever body of water they inhabit) also benefit from not needing to sort through the material before they ingest it.

Many birds are omnivores, such as robins, ostriches, and flamingos. The pink or red color of flamingos occurs because they eat blue-green algae and higher plants which contain the same substances that make tomatoes red. They also eat shrimp and small mollusks.

Mammal omnivores include bears, members of the weasel family, such as skunks, the raccoon family (raccoons and coatimundis), monkeys, apes, and humans. Raccoons and coatis, found only in the Americas, eat insects, crayfish, crabs, fishes, amphibians, birds, small mammals, nuts, fruits, roots, and plants. Like other omnivores, they also eat carrion. Bears eat grass, roots, fruits, insects, fishes, small or large mammals, and carrion.

OPOSSUMS

Type of animal science: Classification
Fields of study: Anatomy, zoology

Opossums are omnivorous mammals which are the only native marsupial in North America.

Principal Terms

ARBOREAL: living in trees
CARRION: rotting carcasses
MARSUPIUM: pouch
OPPOSABLE: positioned opposite of other objects
PREHENSILE: wrapping

Opossums represent the oldest surviving mammal family. Ancestors resembling modern opossums lived on earth at the same time as the dinosaurs. Scientists have located seventy-million-year-old opossum fossils. The Virginia opossums are found in the United States and Canada, while relatives representing seventy species of the Didelphidae family live in Central and South America.

Anatomy

The Virginia opossum is the largest species of the Didelphidae family. They are about the size of a domestic cat and measure from 0.3 to 0.8 meters (1 to 2 feet) in length, with a 22 to 50 centimeter (9 to 20 inch) long tail. Their weight varies from 2 to 5.5 kilograms (4 to 12 pounds). Other opossums are much smaller, averaging 7.5 centimeters (3 inches) in length with a 5 to 10 centimeter (2 to 4 inch) long tail.

Opossums have varying lengths and thicknesses of fur, in shades of white, gray, brown, and black. Some opossums have stripes. Opossum eyes are black, and their ears are usually hairless. Their faces have a mask or are white. They have a pink nose at the end of a long, pointed, whiskered snout which has fifty sharp teeth. Their four feet and tail are also pink and hairless. Each forefoot has five toes with claws. Opossums have an opposable, thumblike toe on their hind feet that can grasp objects and cling to branches. They are arboreal animals and agile climbers. Their prehensile tails are used for balance.

Life Cycle

Male opossums attain maturity at eight months, and females are sexually mature between six and nine months. Female opossums can produce two litters annually. As many as fifty-six offspring

Opossums have prehensile tails that allow them to hang from branches and other objects. (Corbis) may be in a litter, but, because female opossums can only nurse twelve to fifteen newborns in their marsupium, most newborn opossums die.

Born blind, each newborn opossum, which is almost embryonic and as small as a bean, crawls from the birth canal near their mother's tail and across her stomach to her pouch. They attach to nipples inside the pouch, where they nurse for two to three months. This nursing period provides them with immunities to diseases. The babies stay inside the pouch when the mother leaves the den to forage. As they grow and the pouch becomes full, the young opossums sometimes briefly leave the pouch, then return for nourishment. From the age of three to five months, the babies ride on their mother's back. While traveling this way, the young opossums gain scavenging and survival skills.

Opossum Facts

Classification:
Kingdom: Animalia
Subkingdom: Metazoa
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Eutheria
Order: Marsupialia
Suborder: Didelphoidea
Family: Didelphidae
Genera: Didelphis (opossums, with three species); *Marmosa* (mouse opossums, with forty-seven species); *Monodelphus* (short-tailed opossums, with fourteen species); six other genera

Geographical location: North, Central, and South America

Habitat: Forests, grasslands, mountains, and swamps

Gestational period: Twelve to fourteen days

Life span: From one to three years in the wild, up to ten years in captivity

Special anatomy: Opposable thumblike toe on the hind foot, prehensile tail, pouch

Behavior

Opossums tend to be solitary, nomadic animals that can range over 30 to 96 acres (0.5 to 1.5 square miles) daily. They nest in hollow trees and other animals' burrows. Opossums are nocturnal, foraging at night. Because they are adaptable, opossums can live in a variety of habitats and are frequently found in urban areas which formerly were wooded. They adjust their scavenging and living habits to find food and shelter whether they are in a rural setting or in the middle of a city. Extremely cold weather is the primary environmental condition that deters opossums from otherwise suitable habitats. Opossums are hardy and immune to most diseases. They are the mammal most resistant to rabies.

Opossums are omnivorous and eat a variety of insects, especially crickets, beetles, and cockroaches. They also consume snails, slugs, snakes, worms, birds, and rodents in addition to carrion and eggs. Berries, fruit, and vegetables appeal to opossums, particularly when overripe. Opossums have keen senses of smell, vision, and hearing to locate sustenance and clean up organic wastes in their territories.

The life expectancy of opossums is one to three years in the wild and as many as ten years when kept in captivity. In addition to being preyed upon by wildlife and domesticated animals, opossums are killed by humans for sport, fur, and meat, or by accident with vehicles. Baby opossums often survive automobile impacts which kill their mothers. Opossums show a variety of defense mechanisms: They move more slowly than their predators and often spray a foul-smelling secretion to thwart attacks. Virginia opossums feign death by becoming limp when frightened and unable to escape. They sometimes hiss or growl, exposing their teeth. Opossums occasionally fight and bite. Opossums hide in brush-covered areas that are difficult for predators to access. They can make sounds, including screeches, but are usually quiet. Scientists have gauged opossums' ability to learn and distinguish objects as greater than that of dogs and almost equivalent to pigs.

The National Opossum Society (http://www.opossum.org) offers information about how people can rehabilitate injured opossums and raise orphans. The group also addresses the controversial use of opossums as laboratory research specimens.

ORANGUTANS

Type of animal science: Classification
Fields of study: Anatomy, conservation biology, wildlife ecology, zoology

Orangutans are large apes with orange to reddish-brown shaggy hair. They have very long arms and no tail. They survive solely in the jungles of Borneo and Sumatra, where their habitat has been destroyed to the point that they are listed as a threatened species.

Principal Terms

ARBOREAL: living completely or primarily in the trees
BIPEDAL: walking on only two feet, as humans do
QUADRUPEDAL: walking on all four feet
SEXUAL DIMORPHISM: the occurrence of anatomic and physiologic differences that distinguish males from females of a particular species

The name "orang-utan," commonly written in the hyphenated form, comes from two Malay words: *orang* meaning "person," and *hutan* meaning "forest or jungle." Thus, Malaysian *orang-utan* means "persons of the jungle." Since these animals are very humanlike and live secretive lives in the dense jungle, the origin of the name makes sense. Orangutans are considered to be a threatened species. Less than twenty thousand are believed left in the wild.

Orangutans are the second largest of the apes, and show marked sexual dimorphism. Males may grow to be 220 pounds (100 kilograms) and females about half that. The arms of a full-grown male may reach a span of 7 to 8 feet (2.1 to 2.4 meters), and their hands are longer than any other primate. These arms and hands are ideally adapted for the arboreal life. Comparatively, the legs are short and weak; there is no external tail. While adult males with arms extended (swinging through the jungle) may appear to be enormous, when standing erect on the ground they rarely exceed 4.5 feet (1.3 meters) in height. Females, by contrast, reach only 3.5 feet (1.1 meters).

Habitat

Two to three million years ago, orangutans lived as far north as China and as far south as Java. As land bridges formed during the Ice Age, orangutans moved south in search of a warmer climate. Today they can only be found on the Indonesian islands of Borneo and Sumatra.

Orangutans are the only truly arboreal apes, spending most of their life in forest trees. Their anatomy is well suited for this lifestyle. They walk

Orangutan Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Primate
Family: Hominidae
Genus and species: Pongo pygmaeus
Geographical location: Sumatra and Borneo
Habitat: Dense rain forests, particularly lowland forests
Gestational period: Eight to nine months
Life span: Thirty-five years in the wild, fifty years in captivity
Special anatomy: Orange to red-brown hair; arm length exceeds torso length

up trunks using irregularities in the bark to give a grip to fingers and toes, and proceed silently through the middle stories of the forest. These middle stories are especially well suited for horizontal travel, where densely growing trees poke up into the canopy. Often vines are used for quickly moving up and down to get to the next horizontal branches. Orangutans do not jump; they climb and walk the branches on all four legs. They may also sit, recline, or hang in a variety of positions, including suspended from both feet or from one foot and one hand.

On the ground, orangutans are normally quadrupedal, although they occasionally walk in the bipedal position. Their weight is borne by clenched fists with the palm touching the ground (unlike gorillas and chimpanzees). Their walk is similar to that of a dog, with diagonally opposed limbs moving forward together.

Orangutans are very shy primates that spend virtually all of their lives in trees. (PhotoDisc)

Orangutans live alone, in pairs, or in small family groupings. They build nests in the trees from groups of small branches, bent or broken and laid across one another, then lined with smaller branches that are patted down into a circle of approximately three feet in diameter. Nests are placed ten to one hundred feet above the ground and are difficult to spot. Nests may be built new each night when animals are moving about, but may remain intact for several months after being built.

While moving and at rest in trees, the orangutan grasps vegetable and animal matter within its reach, testing each one as food. It prefers a variety of jungle fruits as its principal diet, but also eats or chews an infinite variety of buds and leaves, flowers, bark, epiphytes, canes and roots, honey, and even fungi. It forages and eats at leisure, picking fruits with cupped hands and spitting seeds and shells back out of its mouth.

Orangutans satisfy most of their need for water by taking it in with their moist food. When on the ground they drink from a stream or lake by bending over from a standing position. They have also been seen to squat down and use their hands to spoon the water into their mouths.

Reproduction and Development

Orangutans reach maturity at about ten years of age, and can begin breeding at any time thereafter. Mating begins with a male singing a song, a low hum that increases to a deep roar before decreasing again. Often playful wrestling, touching, and other acts precede mating. Mating occurs in trees, face to face, usually in a hanging position. Mating may occur repeatedly over a period of several weeks. The pair then separates and each goes its own way. Males play no role in parenting.

Female orangutans have a menstrual cycle similar to that of a human female. It lasts twenty-nine days, with a slight flow of blood for three to four days. Pregnancy lasts nearly nine months, and newborns generally weigh 2.25 to 3.25

Biruté Galdikas

Born: May 10, 1946; Weisbaden, West Germany
Fields of study: Conservation biology, systematics (taxonomy), wildlife ecology, zoology
Contribution: Galdikas has devoted her life to studying the endangered orangutan and preserving its rain-forest habitat. She is the world's leading authority on these mysterious apes, whom she has studied for nearly thirty years in the jungles of Borneo.

Biruté Galdikas was born in West Germany not long after the end of World War II. Her parents met at a refugee camp after fleeing their Lithuanian homeland during the war. Two years after her birth, her father moved the family to Canada so he could work in the copper mines. Galdikas grew up in Toronto and enjoyed visiting the zoo. She became particularly fascinated by the primates, and noted that the behavior and expressions of the orangutans reminded her of humans. She hoped that one day she could learn more about them.

Her family moved to Vancouver, and then to Los Angeles. Galdikas entered UCLA to study psychology and anthropology. She received her B.A. degree in 1966 and entered graduate school to study anthropology. It was while she was a student there in 1969 that she met the renowned paleontologist Louis Leakey. It did not take long for her to convince him to support her efforts to study the wild orangutans (Dr. Leakey already supported the work of Jane Goodall with chimpanzees and Dian Fossey with gorillas). With Dr. Leakey's support for her project, Galdikas set out for Borneo in 1971, and set up a jungle camp that she called Camp Leakey.

From Camp Leakey and various jungle outposts, Galdikas has studied the orangutan in its natural environment for thirty years. She has rescued many babies that were taken illegally from the jungle, restored them to health, and has released more than two hundred back to the wild. She has marveled at the mysteries surrounding orangutan social life, and has studied their behavior, speech, reproduction, and life cycle in the wild. She has collected enough data to radically update our understanding of the forces that shape the lives of orangutans in the wild. Galdikas and her colleagues have even taught sign language to orangutans in the hope of being able to learn what was important to them. By hiring many local people to help with her work at Camp Leakey, she has also helped the government and the peoples of Borneo to gain a greater respect for the orangutan and the need to preserve its habitat.

Amidst her studies in the jungles of Borneo, Galdikas wrote about her observations and prepared her doctoral thesis. In 1978, she received a Ph.D. in anthropology from UCLA. When not engaged in field work in Indonesia, she teaches at Simon Fraser University in British Columbia and at Indonesia's Universitas Nasional.

Biruté Galdikas formed and continues to run the nonprofit Orangutan Foundation International. Its purpose is to prevent the extinction of orangutans and their rain-forest habitat by raising money to fund research, conservation, and educational programs. She continues her scientific work to learn more about these solitary primates.

—Kerry L. Cheesman

pounds (1.1 to 1.6 kilograms). The infant clings to the mother's fur and the mother holds the infant with one arm, usually over the hip. This leaves three limbs for traveling and feeding. The youngster nurses for two to three years, with solid food (chewed up fruit) being added periodically. By the end of the first year the youngster begins to explore away from its mother, but remains within eyesight at all times.

By age four, a youngster is pretty much on its own, feeding itself and roaming freely. At that point, the mother is able to mate again. Offspring have only about a 50 to 60 percent survival rate in the jungle, with accidents and disease striking many young orangutans.

Orangutans are shy animals that have only one natural enemy: humans. Currently, orangutans are protected by law in all of their territory, but poaching and illegal logging continue to threaten the survival of the species. Unless large areas of undisturbed jungle are set aside as sanctuaries, the orangutan may have a hard time surviving in the future.

—Kerry L. Cheesman

OSMOREGULATION

Type of animal science: Physiology
Fields of study: Biophysics, cell biology

Osmoregulation is the ability an organism must have to adjust its internal concentrations of solutes and of water so that it can maintain an osmotic pressure appropriate to its functioning.

Principal Terms

EURYHALINE: the ability of an organism to tolerate wide ranges of salinity

HYPEROSMOTIC: describes a solution with a higher osmotic pressure, one containing more osmotically active particles relative to the same volume, than the solution to which it is being compared

HYPOOSMOTIC: a solution with a lower osmotic pressure, fewer osmotically active particles relative to the same volume, than the solution to which it is being compared

ISOSMOTIC: a solution having the same osmotic pressure, the same number of osmotically active particles relative to the same volume, as the solution to which it is being compared

OSMOCONFORMER: an organism whose internal osmotic pressure approximates the osmotic pressure of its environment; such an organism is also referred to as "poikilosmotic"

OSMOREGULATOR: an organism that maintains its internal osmotic pressure despite changes in environmental osmotic pressure; such an organism is also referred to as "euryosmotic"

STENOHALINE: the inability of an organism to tolerate wide ranges of salinity

Osmotic pressure of a solution is the measure of the tendency of water to enter a solution from pure water. Osmoregulation, the regulation of osmotic pressure, is vital to every organism. The phenomenon collectively is called "osmosis." It is the difference of hydrostatic pressure that must be created between that solution and pure water to prevent any net osmotic movement of particles in the water when the solution and pure water are separated by a semipermeable membrane. Hydrostatic pressure is a measuring device: It is a means of assessing the tendency of a solution to take on water osmotically.

Only dissolved solutes contribute to osmotic pressure. The number of individual particles determines the strength of osmotic pressure. Each particle makes a roughly equal contribution to osmotic pressure. The same number of molecules of a substance such as sodium chloride (table salt), which ionizes in water to release two ions (one sodium ion and one chlorine ion) display twice as much osmotic pressure as the same number of molecules of glucose, which retains its molecular form in water. Cells and other suspended materials do not contribute to osmotic pressure.

Several characteristics of solutions depend upon the number of particles in the solution. These are called "colligative properties." Increasing the number of particles of solute impairs the ability of the solvent to change state. The colligative properties are the freezing point, the boiling point, the osmotic pressure, and the vapor pressure. Only freezing point depression and vapor pressure are used to determine osmotic pressure.

Osmoticity refers to the osmotic pressure of solutions. Isosmotic solutions have equal osmotic pressures. A hypoosmotic solution has an osmotic pressure lower than the solution to which it is being compared; a hyperosmotic solution is one with a greater osmotic pressure than the solution to which it is being compared. These solutions can be body fluids, environmental liquids, or laboratory solutions.

The terms used to describe the changes in volume of cells exposed to solutions of differing concentrations are often confused with those comparing osmotic pressure. Changes of cell volume are described by the term "tonicity." Solutions isotonic to a cell cause no change in cell volume. Hypotonic solutions will cause the cell to swell as water diffuses into the cell; the cell may even burst. Hypertonic solutions will cause a cell to shrink as water diffuses across the cell membrane into the solution.

The Challenges of Osmoregulation

This discussion reveals some of the problems that an organism encounters in the environment as concentrations of water and salts vary. Most organisms attempt to regulate both their volume and their ion content. If volume is not regulated, the chemicals within the cell will become too dilute to react or too concentrated to interact. If ions are not regulated, chemical reactions will be affected by inappropriate levels of ions, which may change the electrochemical properties of the cellular solution. Thus, there are independent challenges to volume regulation, to ion regulation, and to osmotic regulation. The homeostatic physiological responses to all three types of challenges are interconnected but distinct.

Osmoregulation is the regulation of the ratio between all dissolved particles, regardless of their chemical nature as ions or molecules, and water. All organisms are exposed to osmotic stress. Any organism incurs obligatory water losses. These occur during respiration, urination, and defecation. The organs most often thought of as participating in osmoregulation are the kidneys. They are intimately concerned with the elimination or conservation of water. Some salts are also found in urine. The proportions of the salts excreted in urine may be different from those in the body fluids because the kidney can retain required ions while eliminating less desirable ones.

Freshwater organisms are in danger of dilution, and they excrete great quantities of dilute urine. Saltwater organisms usually produce small quantities of isosmotic urine, which preferentially excretes divalent ions such as magnesium and sulfate. Other surfaces lose water, causing desiccation. The composition of the diet also influences the need for excretion of urine. Nitrogenous wastes from protein metabolism must be eliminated in urine, often as urea, which requires water for its excretion.

Carbon dioxide released during metabolism of carbohydrates and fats is eliminated by the respiratory organs. In terrestrial organisms, air leaving the lungs is usually saturated and some water is lost on expiration. The respiratory organs of aquatic organisms are gills. Their surfaces must be permeable to water. Freshwater organisms gain water through them and hypoosmotic marine organisms lose water through them.

The metabolism of carbohydrates produces what is known as metabolic water, which can be used to prevent desiccation. Metabolic water produced from the metabolism of fats is lost because of the higher rate of respiration required to supply the oxygen needed in fat oxidation.

Salt Loss

Preformed water is present in any food. Even the driest seeds contain a small amount of water. The nutrients also always include salts. The presence of great quantities of salts may require urinary loss of water in excess of the preformed water found in the food.

Although feces may appear to be solid, they contain some water that was not absorbed in the gut. The presence of salts and other solutes in the digesta may also draw water from the hypoosmotic body fluids into the gut. One of the reasons that humans cannot drink seawater, in fact, is that the magnesium ions in ocean water increase the permeability of the gut and increase water loss, because the seawater is hyperosmotic to body fluids. More water is lost than can be gained.

Salts can be lost from the body by means other than urine formation and defecation. Marine reptiles and birds have salt glands located on the head. Since neither can produce hyperosmotic urine, these glands allow the elimination of salt with a minimum loss of water as the secretion may be four to five times as concentrated as body fluids. The cloaca of birds and the rectal glands of sharks also have the capacity to excrete salts.

One of the most fascinating mechanisms of osmoregulation is found in elasmobranch fish—the sharks, skates, and rays. Their body fluids are hyperosmotic but hypoionic to seawater. Blood salt concentrations are below those of seawater. Excess osmotic pressure is supplied by two molecules: urea and trimethylaminoxide (TMAO). Urea is toxic to most organs, but some organs resist its deleterious effects. Others would be harmed but are apparently protected by the TMAO. Retention of both urea and TMAO minimizes enzymatic disturbances by urea and allows the elasmobranchs to avoid the salt gain associated with hypoosmotic body fluids.

Organisms exposed to environmental variations have two choices: they can maintain internal constancy or homeostasis at the expense of metabolic energy, or they can allow their internal conditions to follow that of the environment. Organisms that maintain their internal osmotic pressure despite changes in external osmotic pressure are called osmoregulators. These euryosmotic organisms are protected from environmental changes. Their metabolism can continue to function, but much of the energy will be used to maintain their body fluids at the appropriate osmotic pressure.

Organisms that allow their osmotic pressure to follow that of the environment are called osmoconformers. These poikilosmotic organisms often have a limited tolerance for such changes. They are stenohaline. They may be less vigorous at salinities other than their optimal levels. The adults of such groups (for example, mollusks such as oysters and mussels) may be found in salinity extremes not tolerated by their young. These populations must be maintained by immigration of young spawned in more favorable salinity conditions.

Hormonal Regulation of Osmotic Pressure

The internal osmotic pressure is affected by the hormones present in the body fluids. In invertebrates such as annelids, mollusks, and arthropods, neuroendocrine changes are seen upon changing the osmotic pressure of the environment. These changes indicate that nervous and endocrine systems are at work regulating the osmotic pressure of the organism. In most invertebrates, the biochemical nature of these hormones is unknown. Some freshwater pulmonate snails, however, produce an antidiuretic hormone and a neurosecretory factor associated with electrolyte balance. Depending upon the demands placed on them, insects such as grasshoppers and cockroaches can synthesize diuretic or antidiuretic hormones.

The best-known hormonal factors in ion regulation are studied in vertebrates. The pituitary gland produces antidiuretic hormone (ADH), which promotes water retention in terrestrial vertebrates. In fish and amphibians, ADH may induce urine formation and increase water loss through diuresis.

The adrenal gland also produces hormones that influence ion retention. In mammals, aldosterone increases reabsorption of sodium in the kidney and promotes the excretion of potassium. In nonmammalian vertebrates, extrarenal glands maintain salt and water balance by affecting the gills and intestines of fishes, the urinary bladder and skin of amphibians, and the salt glands of elasmobranchs, reptiles, and birds.

Measuring Osmoregulation

Osmoregulation involves the balancing of water and solutes in the body so that the animal can continue to function. Because the presence of particles influences certain physical characteristics of the solution, these colligative properties can be used to determine osmotic pressure of solutions. Colligative properties change with increasing numbers of particles in solution: The osmotic pressure increases; the boiling point increases; the freezing point decreases; the vapor pressure decreases.

Freezing point depression and vapor pressure can be used to measure a solution's osmotic pressure. Freezing point is used most often. It works for the same reason that salt is spread on ice on sidewalks in winter. The salt lowers the freezing temperature of the water. Body fluids are much more dilute than the salt and water mixtures that melt ice, but the salinity of the ocean (approximately thirty-five parts salt for each thousand parts of solution) causes it to freeze as much as 1.6 degrees Celsius lower than pure water. Only marine organisms have body fluid osmotic pressures in that range. Terrestrial organisms have much less salt and therefore much lower osmotic pressures in their body fluids. Because most body fluids are so dilute, a large sample may be required to determine freezing point depression. When only small volumes of body fluid exist, the determination becomes more difficult.

Vapor pressure determinations are also used in osmometry. Usually, a small amount of the fluid being studied is tested in a capillary tube. In one ingenious method, the capillary tube is placed in a solution more concentrated than the experimental fluid. The higher osmotic pressure of the reference solution pushes a meniscus up the tube. The rate of movement of the meniscus depends upon the difference in concentrations between the experimental and the reference solutions.

Another ingenious method of using vapor pressure to determine the osmotic pressure of an experimental solution requires enough fluid to fill a depression. A glass plate with capillary tubes filled with reference solutions of known osmotic concentrations is mounted over the experimental fluid. The reference tube that exhibits no movement is at equilibrium with the experimental fluid. One of the rigors of this method is that all movement must stop.

Another method involves capturing a precise volume of experimental fluid in a capillary tube. The shape of drops of the same volume of reference solutions is compared to that of the experimental solution. Those of the same concentration will have the same shape because their vapor pressures are exerting equal force on the drop. Thermocouples are also used in vapor pressure determinations. This procedure is delicate and costly and is used infrequently. All these procedures are difficult and require patience. Now, electronic instruments analyze the constituents of solutions and allow easier calculation of the osmotic pressures of solutions than ever before.

Freshwater Versus Saltwater Environments

All organisms experience osmotic stress. There is no environment in which the osmotic pressure and the ion composition exactly match the requirements of the cells. Every organism must expend metabolic energy to maintain appropriate water and ion concentrations.

Freshwater organisms are hyperosmotic to their environment. They risk losing scarce ions through their permeable gills and in their urine and also tend to take up water through their gills or other surfaces and in their food. They face the problem of dilution of their body fluids by the environment.

Marine organisms are often isosmotic to the salt water they inhabit. They must change the concentrations of some ions, however, in order to attain this state. Magnesium is present in greater amounts in seawater than is desirable in their body fluids and must be eliminated. These organisms ion regulate even though they are not in danger of volume changes.

Marine organisms that evolved from freshwater or terrestrial ancestors are often hypoosmotic to seawater. They are in danger of desiccation as water from body fluids diffuses into the hyperosmotic ocean water. They also must regulate the types of ions that are retained and eliminated from their bodies.

Marine organisms may also be exposed to freshwater when they enter rivers, which dilute the salt content of the incoming tidal water. Under these conditions, the water is brackish—not as salty as the sea, but not as pure as freshwater. The criticality of this situation depends upon whether the organism is tolerant or intolerant of salinity changes. Organisms that can live in only a narrow range of salinities are called stenohaline. Organisms that are tolerant of wide ranges of salinities are called euryhaline.

Terrestrial organisms are always hyperosmotic to their environment, so they continually face desiccation in the air. They also must adjust the ion composition of their body fluids, because the foods that they eat may not have inorganic ions in the desired ratios and because some ions are always lost in urine.

One example of the influence of these effects concerns the interaction of oysters and the protistan parasite known as MSX. (MSX stands for "multinucleate sphere unknown," which refers to the protista *Haplosporidium nelsoni*.) The MSX organism survives in osmotic pressures greater than 0.4 osmolar. Oysters are osmoconformers which grow in saline, brackish, and nearly fresh water. At osmotic concentrations less than 0.4 osmole, oysters can survive and are unaffected by MSX. When rainfall is abnormally low, however, the salinity of brackish water increases, and oysters which were protected in low-salinity water are exposed to higher-salinity water, which allows the MSX organism to infect them.

Organisms exposed to tides may protect themselves from exposure to variations in osmotic pressure by sealing themselves off, the way snails and bivalve mollusks do. Others may move offshore to more saline waters or onshore, away from the increasing salinity. Worms that burrow in the sediments of salt water are protected from transient changes in salinity because there is little exchange of solutes with the overlying salt water.

The vertebrates adapted to their various environments by using hormones to regulate salt and water balance. Because of the differing demands of aquatic and terrestrial environments, in different groups, the same hormone may have opposite effects, but that effect is always to maintain the optimal osmotic pressure to ensure survival.

OSTRICHES AND RELATED BIRDS

Type of animal science: Classification
Fields of study: Anatomy, ornithology, physiology, population biology

The ostrich and its relatives are famous for their exotic appearance and for being flightless birds. They are the oldest type of bird alive today, dating back eighty million years to the age of dinosaurs.

Principal Terms

MOLT: to shed old feathers and grow new ones
MONOGAMOUS: having only one mate
NOMADIC: travels distances in search of food
OMNIVOROUS: eating both animal and plant foods
POLYGAMOUS: having more than one mate
PRECOCIAL: in birds, those that are down-covered, fully developed, and active at birth

Ostriches belong to a striking group of flightless birds known as ratites, that also includes emus, cassowaries, rheas, and kiwis. Ratites have flat, smooth breastbones that lack a keel to which flight muscles could attach. They are thus unable to fly, and have weak wing muscles. They do use their wings, spreading them out to help them cool off, and also to splash water when bathing. Ratite feathers are different from those of flying birds. The individual strands are not interlocked, and thus they are soft and billowy and air passes right through them. Their plumes have long been admired by humans and used for decoration and adornment. As with other birds, their feathers function as protection from the elements, and ratites preen, spreading waterproofing oil to their feathers with their beaks. They also molt once a year. Ratites have heavy, strong bones and powerful leg muscles, and are able to run swiftly. They are omnivores, feeding on a variety of grasses, plants, seeds, fruit, insects, and small animals. There are many farms in the United States that raise ostriches, emus, and rheas for their feathers, hide, meat, and oil. In their native countries, ratites are hunted or raised for their feathers and as food. Ostriches have also been tamed for riding and for pulling carts.

Ostrich Characteristics

Ostriches have long necks and legs and are the largest living birds. Males stand eight feet tall, and weigh three hundred pounds. The ostrich can take strides of twenty-five feet and outrun pursuers at speeds of forty miles per hour. If cornered, the ostrich has a powerful kick that can maim an enemy. It has two toes on each foot, and a razor-sharp toenail that both grips the ground while running and can slash the flesh of its enemy.

Male ostriches are black with white plumes on their tail and wings. Females are grayish-brown. The head and legs are featherless. The neck is covered with down and is red or grayish. The ostrich has huge eyes with long protective lashes and has keen eyesight for spotting danger a long way off. It can make loud hissing and roaring noises.

Ostriches are native to Africa; they are nomadic and graze on open savanna. They often follow herds of zebras or antelope, catching insects and small animals stirred up by their hooves. They swallow sand and stones to help grind up their food. Contrary to popular belief, they require a regular water supply.

When mating, male ostriches make a booming call and perform a courtship dance for the females. They are polygamous, taking three or more

Ratite Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Subphylum: Vertebrata
Class: Aves
Orders: Struthioniformes (ostriches); Casuariiformes (emus, cassowaries); Rheiformes (rheas); Apterygiformes (kiwis)
Families: Struthionidae (ostriches, one genus, six species); Dromaiidae (emus, one genus, three species); Casuariidae (cassowaries, one genus, four species); Rheidae (rheas, two genera, nine species); Apterygidae (kiwis, one genus, seven species)
Geographical location: Southern Hemisphere—Africa (ostrich), Australia (emu and cassowary), New Guinea (cassowary), South America (rhea), New Zealand (kiwi)
Habitat: Semidesert and open plains (ostrich, emu, rhea); forests (cassowary, kiwi)
Gestational period: One breeding cycle per year; incubation varies from forty days (ostrich) to eighty days (kiwi)
Life span: Ostriches average forty years in the wild, up to eighty years in captivity; others average ten to twenty years
Special anatomy: Unkeeled breastbone, tiny wings, unbarbed feathers, solid bones, strong muscular legs

hens as mates. The male scratches a shallow pit into which each female lays up to a dozen eggs, for a total clutch size of up to thirty eggs. This communal nesting behavior is unusual among birds. The male shares incubation with one dominant female. The male sits at night and the female during the day. Ostriches lay the largest eggs of all living birds, seven inches long and three pounds. The eggshell is very tough and hard for predators to crack open. The parent will sometimes lay with its neck outstretched on the ground when danger threatens, giving rise to the legend that they bury their heads in the sand. They may also feign injury to lure predators away from the nest. Newborn chicks are precocial and instinctively know how to search for food. They are full adults by three years of age.

Ostrich Relatives

Rheas live in flocks on grasslands in South America. They are similar to ostriches in behavior and appearance, although they have three toes on their feet, as do most of the other ratites. They are brownish in color and can be five feet tall. They are polygamous, but only the male incubates the eggs.

Emus live on plains in the Australian outback, and flock nomadically according to rainfall patterns and the resulting food supply. The emu is the second largest flightless bird, nearly six feet tall and eighty-five pounds. It has brown feathers and a loose, moplike tail. Emus are monogamous.

Cassowaries live in the rain forests of New Zealand and northeastern Australia. They are solitary and territorial, pairing only to mate. They feed primarily on fruit fallen from trees. Cassowaries have black, loosely hanging feathers, and the wings are composed only of quills. They have bright blue heads and colorful wattles. A distinctive bony crown on the head called a casque helps them push through the dense forest, and is also used to turn over litter in search of food.

Kiwis are elusive, nocturnal birds that live in the forests of New Zealand. They are the smallest ratites, about the size of a chicken. They have round, brown-feathered bodies, short legs, four toes, and run by placing one foot directly in front of the other. Their long, slender beaks have nostrils at the very tip, and are used to probe the ground to locate worms, beetles, spiders and larvae by smell. Males have a shrill, whistling mating call. Females lay only one or two eggs that are enormous in proportion to their body size.

Ostriches are one of the few species of flightless birds, but they can run very fast on their long legs. (Corbis)

OTTERS

Types of animal science: Behavior, classification, ecology
Fields of study: Ecology, wildlife ecology, zoology

Otters are found in many parts of the world where there is clean, flowing water. Otters are large members of the weasel family, the Mustelidae, which includes mink, skunks, and badgers.

Principal Terms

CARNIVORE: an animal that feeds on other animals for its diet

DELAYED IMPLANTATION: a process of delaying the implantation in the uterine wall of the fertilized egg

DORSAL: the back portion of an animal

NOTOCHORD: a dorsal, flexible, rodlike structure extending the length of a vertebrate's body; serves as an axis for muscle attachment

PELAGE: a mammal's fur coat

PREDATOR: an animal that preys on other animals for its food

Playful and proud, river otters are born to have fun. At least, it appears that river otters are having fun, because of their playful antics with each other, as well as their facial and body expressions. By any measure, otters are extremely curious and intelligent mammals.

River Otters

Adult river otters reach a length of about 127 centimeters, including their tails, which are nearly one third of that length. Adults weigh between five and fourteen kilograms. Females are slightly smaller than males.

River otters have a dense, short fur with great water resistance. Air is trapped beneath their dense furry coats and acts as insulation against the cold water, where these mostly aquatic mammals feed. Otters roll and rub themselves on sand, rocks, old logs, and even snow in their coat grooming activities. These carnivorous mammals mostly feed on fish. Crayfish also serve as diet items when abundant. Researchers have found that river otters feed directly on fish proportion-

Otters are playful, intelligent, and very curious. They spend much of their lives in and near water. (Corbis) ally to their availability and inversely to the fish's swimming ability.

Shelters that have been abandoned by other animals are frequently used by river otters, such as old beaver dens or riverbank excavations. On occasion, river otters use rock piles and log jams as dens. Some investigators have discovered nests along river and stream banks which river otters had constructed of aquatic vegetation.

Mating activity usually occurs in the water, although there are reports of mating on land. The breeding season is usually late winter to spring. Litter size is between one and six cubs. The newborn otters have full pelage, but their eyes are not open and they have no erupted teeth. Females wean their young at about three months of age.

Several predators, including bobcats, foxes, and alligators, have been observed dining on river otters. Humans also have made their impact on otter populations in at least three ways: habitat destruction, water pollution, and overtrapping.

Otter Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Class: Mammalia
Order: Carnivora
Family: Mustelidae
Subfamily: Lutrinae
Genus and species: Lutra canadensis (North American river otter), *L. lutra* (European river otter), *L. felina* (marine otter), *L. provocax* (southern river otter), *L. longicaudis* (neotropical river otter), *L. umatrana* (hairy nosed otter); *Hydrictis maculicollis* (spot-necked otter); *Lutrogale perspicillata* (Indian smoothed-coated otter); *Aonyx cinera* (oriental short-clawed otter), *A. capensis* (Cape clawless otter); *Pteronura brasiliensis* (giant otter); *Enhyda lutris* (sea otter)

Geographical location: Until the eighteenth century, North American river otters were found in all major water courses in the United States and Canada; presently, river otters are scattered in several river systems across the United States and Canada, and many river otters have been reintroduced into river systems where they once flourished

Habitat: Exclusively aquatic, adaptable to many nonpolluted aquatic environments

Gestational period: 288 to 375 days, with delayed implantation

Life span: Ten years, with a maximum of twenty-three years

Special anatomy: Webbed feet

Sea Otters

Another interesting otter is the sea otter. These seafaring mammals are confined to the northern Pacific Ocean. Being the largest in the family Mustelidae, sea otters weigh between twenty-seven and thirty-eight kilograms and attain a length of about 148 centimeters. Unlike seals and whales, which have a fat layer (blubber) for insulation, sea otters rely on air trapped beneath their densely packed pelage. Some researchers have estimated the number of hairs in a sea otter's coat to be 800 million.

Sea otters, just as their freshwater cousins, have delayed embryo implantation. Females usually produce one pup in a litter. The pup is unable to swim or dive until it is two to three weeks old.

Food preferences of sea otters include abalones, sea urchins, clams, and crabs. It is a common practice of sea otters to eat while floating on their backs. Furthermore, sea otters use rocks to open the shells of their diet items, making them a member of a small group of animal tool users.

Unlike other members of the Mustelidae, sea otters lack functioning anal scent glands. Also, unlike most carnivores, sea otter teeth are adapted to crushing their prey, rather than tearing.

OWLS

Type of animal science: Classification
Fields of study: Anatomy, ornithology, physiology, zoology

Any of the Strigiformes, a group of birds with highly specialized characteristics for nocturnal activity, including soft feathers and enhanced hearing and eyesight.

Principal Terms

ASYMMETRICAL EARS: in some species of owls, the ears are of unequal size and located unequally on the sides of the head

ASYNCHRONOUS: an uneven event; in hawks and owls, the staggered hatching of eggs that results in a nest of different-aged young

FACIAL DISK: the distinctive concentric circles of feathers that encircle the eyes of owls, helping direct sound toward the ears

OWL PELLETS: compacted packets of undigested prey that is regurgitated. Owl pellets may be used to determine food habits

OWLS: any of the strigiformes, a group of birds with highly specialized characteristics for nocturnal activity, including soft feathers and enhanced hearing and eyesight

NEST BOX PROGRAMS: construction and placement of nest boxes in suitable habitat to provide nesting platforms for specific birds of prey

PAIR BOND: close relationship between a male and female for breeding purposes

With their rounded facial disk encircling their large, forward-looking eyes, owls are the most recognizable of birds. Their unique traits also include superb auditory abilities and soft feathers for silent flight. Sharp talons for catching and killing prey and powerful bills for tearing flesh complete their basic characteristics. Most owls are colored in drab shades of brown, buff, and gray, either spotted or streaked, which helps conceal them during daylight hours. Woodland owls tend to be darker, while those of open country are lighter and paler. Thus, the eastern North American race of great horned owl (*Bubo virginianus virginianus*) is much darker than the pale northern race (*B. v. lagophonus*) of interior Alaska and the Yukon. A few smaller owls have rounded, eyelike disks on the back of their head to deter predators. Although once thought to be the nocturnal kin of hawks and eagles, owls are actually most closely related to the frogmouths and nightjars. The similarities between hawks and owls result from the evolutionary convergence of morphological features that facilitate their roles as avian hunters of live animals.

The 205 species of owls are a widespread and successful group that occupies virtually all habitats on all continents, from tundra to tropics, and are even found on most oceanic islands. They range in size from the forty-gram sparrow-sized elf owl (*Micrathene whitneyi*) of the Southwest desert to the formidable eagle owl (*Bubo bubo*) of Eurasia, which may reach 0.6 meter in length and weigh forty kilograms.

All the owls are placed in a single order, the Strigiformes, in which two owl families are recognized. The family Tytonidae includes sixteen species of barn (*Tyto* sp.), grass, and bay owls (*Phodilus* sp.), defined by small, dark eyes set in a narrow skull with a heart-shaped facial disk. The other 189 species are loosely grouped in the family

Strigidae, all of which have rounded skulls and large, wide-set eyes in a concentric facial disk. Owls of both families are named for their plumage colors or patterns (the tawny owl, *Strix aluco*, the black-and-white owl, *Strix nigrolineata*, the spectacled owl, *Pulsatrix perspicillata*, and the spotted owl, *Strix occidentalis*), habitats (the barn owl, *Tyto alba*, and jungle owllet, *Glaucidium radiatum*), size (great gray owl, *Strix nebulosa*, and little owl, *Athene noctua*), power and strength (eagle owls, *Bubo* sp.), presence of ear tufts (great horned, long-eared, *Asio otus*, and short-eared owls, *Asio flammeus*), or for their distinctive songs (screech owls, *Otus* spp., saw-whet owls, *Aegolius* sp., and barking owl, *Ninox connivens*).

Throughout history, owls have been alternately revered and feared. To the ancient Greeks, the solemn owl was the bird of wisdom and a companion of their warrior goddess, Athena. The Romans attached more ominous signs and portents to the ghostly cries of owls in the night. During the Middle Ages, owls were thought to be the companions of witches and the harbingers of evil and death. Many Native American tribes placed owls on a higher footing. The Arikara Plains Indians had secret owl societies, in which initiates were adorned with facial masks of owl feathers, while the Pimi Indians believed spirits of departed warriors assumed the shape of owls. Thanks to enlightened conservation efforts, owls are at long last recognized as important, interesting, and beneficial birds and all are protected by law.

Hunting and Food

All owls are predators, hunting a variety of animals commensurate with their size and strength. Woodland owls mostly hunt by the perch-and-pounce method, but hawk owls (*Surnia ulula*), short-eared owls, and other open country species may forage, harrier-like, over fields and meadows in search of prey. Burrowing owls (*Speotyto cunicularia*) are more terrestrial than most, spending a good deal of time running across the ground pursuing insects and small mammals. Most owls have broad wings—shorter in woodland species that maneuver in vertically complex habitats, longer and more hawklike in species that hunt open

The owl's soft, fluffy feathers allow it to fly in complete silence through the night. (Corbis) country or are migratory. Bird-chasing owls, such as pygmy owls (*Glaucidium* sp.) and brown owls (*Ninox* sp.) have longer wings and tails for agile flight.

Owls use their combination of large eyes, superb hearing, and silent flight to hunt and catch prey. Their relatively large wings and small bodies give owls a low wing loading which, combined with soft, fluffy feathers, enables the quiet flight that makes owls such efficient nocturnal hunters. The large eyes of owls are densely packed with light-gathering rods for seeing in very low light, while the overlapping fields of their binocular vision enable precise parallax judgment of distance to prey. Head bobbing movements seen in many owls also help estimate distance and angle to prey.

If light is absent or nearly so, owls can continue to hunt, substituting ears for eyes. Studies by ornithologist Roger Payne have shown that barn owls, for example, can locate prey in total darkness entirely by sound. When an owl hears rustlings of prey, it turns its head toward the sound, using the facial disk of flattened feathers to direct and amplify faint sounds toward the ears set on either side of the wide, flat face to pinpoint the location of the source. The asymmetrical ears of some species—the right ear is larger and higher on the skull than the left—permits determination of vertical and horizontal direction to the sound. If the sound reaches the higher right ear first, then the source is from above; if it reaches both ears at the same time, the source lies straight ahead. By turning its head, the owl can determine the precise distance and angle of the flight path to the prey to within 1.5 degrees. When flying toward prey, the head is forward of the body to detect prey movements and make minor adjustments. Once within striking range, the owl extends its legs and spreads the talons in a wide oval to snare prey. Most prey are killed by the powerful, slashing talons, but larger animals may be dispatched by a bite to the back of the neck.

Owls tend to be opportunistic in their food habits, hunting a wide variety of mammals, birds, and other vertebrates. Rabbits, rats, and mice are staples of many of the large and medium-sized owls, but birds, lizards, snakes, insects, fish, and occasionally carrion are also consumed when available. The smallest owls, such as the elf owl, tropical screech owls, and boobook owls (*Ninox boobook*) are mostly insectivorous, while the larger and more powerful owls take hares, rabbits, and other medium-sized mammals and birds. The Eurasian eagle owl is a champion hunter, fully capable of killing chamois and foxes. With their long, bare shanks, the fishing owls (*Ketupa* sp.) of Africa and Southeast Asia spear fish from woodland streams or wade in the shallows to search for frogs, crabs, and crayfish.

Although some owls have a reputation for taking chickens and other poultry, most owls help keep injurious rodent populations in check. This awareness has led to the establishment of barn owl nest box programs in some inner cities to pro-

Owl Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Subphylum: Vertebrata
Class: Aves
Order: Strigiformes
Families: Tytonidae (barn owls); Strigidae (owls), with subfamilies Buboninae (true owls, eighteen genera, eighty-three species), Striginae (long-eared and dish-eyed owls, six genera, twenty-six species)

Geographical location: All continents except Antarctica

Habitat: Virtually all habitats

Gestational period: Around thirty days, depending on species

Life span: Depending on species, three to ten years

Special anatomy: Rounded facial disk that directs sounds toward the ears; soft feathers for soundless flight; sharp talons and beak; large eyes with densely packed rods to enhance night vision; ability to turn the head up to 270 degrees; some species have asymmetrically spaced ears to assist in locating prey by sound vide nest sites for an urban owl population to control rodents.

Small prey is swallowed whole but larger prey is broken into pieces. Prey is digested to a semiliquid consistency and then passed on to the intestinal tract. The undigested remains, mostly fur, feathers, bones, teeth, and other indigestible substances, are compacted into a small ball which is regurgitated in a reflexive, choking motion that casts the pellet out. The process takes several hours, so that today's pellet contents represent yesterday's meal. Owl biologists collect and analyze the pellets to determine food habits and impact of owl hunting on different species.

Owl Seasons

Tropical owls may breed at any time of year, but temperate owls commence breeding activity in late winter or early spring. Males claim a territory with territorial and courtship songs and postures. Songs of almost all owls consist of a series of hoots or wailing cries that echo ghostly through the night skies. Many owl species pair for life. Courtship may involve alternate duetting, billing and cooing, and mutual preening. Males of many species present food offerings, both as a courtship gift and to display their hunting ability.

Following courtship the female selects a suitable nest site. Although snowy owls (*Nyctea scandiaca*) of the Arctic select a spot beneath a clump of tundra sedge, most owls choose secluded tree hollows, cavities in cliffs, rock outcrops, or caves. Some species may also appropriate hawk or squirrel nests. Nest improvement usually consists of scraping a shallow hole or lining the nest with a few breast feathers. The oval or nearly oval eggs are usually laid at two-day intervals, but incubation begins with the first egg, resulting in a nest of different-aged young. The female incubates the eggs and the male brings food to the female or to a delivery site near the nest. The male may replace the female on the nest for short periods while she hunts, but his role in incubation is unclear.

Recently hatched young are typically fed pieces of food by the female. Later the adults simply deposit food at the nest and allow the young to pick and tear at it. Nest defense is weak or nonexistent during the early stages of nesting, but intensifies when young are in the nest. Defense varies from alarm calls and vigorous bill clacking in smaller species to aggressive and determined attacks by great horned owls and other large species. The female is usually most active in nest defense.

The fledged young typically remain in company of the adults for a few weeks before dispersing in search of new territories, usually in late summer or early fall. This is the most dangerous period of their lives, as they must perfect their hunting skills while avoiding enemies.

Longevity varies greatly; great horned owls and other large species may live ten or more years but the life span of smaller owls is usually only a few years. Other than humans, owls have few enemies. Larger owls prey on smaller owls while ravens and crows steal an occasional egg. Humans continue to be the main threat to owl populations. About thirty-five species are currently listed as threatened or endangered. Pollutants, disturbance, and collisions with vehicles and structures all take their toll of owls, but habitat loss factors most heavily. Several island races have disappeared following habitat alteration or introduction of exotics, and island populations continue to be at risk.

Bibliography

Bent, Arthur C. *Owls*. Part 2 in *Life Histories of North American Birds of Prey*. 1938. Reprint. New York: Dover, 1961. Bent exhaustively summarized all of the available reports of ecology, behavior, and food of North American owls. Still an important reference.

Burton, James A., ed. *Owls of the World: Their Evolution, Structure, and Ecology*. Rev. ed. London: Peter Lowe, 1992. An entertaining but still very informative book written for a more general audience. Contains excellent summaries of the natural history of the world's owls.

Clark, Richard J., Dwight G. Smith, and Leon Kelso. *Working Bibliography of Owls of the World*. Washington, D.C.: National Wildlife Federation, 1978. All the books, papers, articles, and news about owls ever published (to 1978) is presented in this bibliography, which also includes summaries of owl taxonomy and distributional status across the globe.

Del Hoyo, Josep, Andrew Elliott, and Jordi Sargatal, eds. *Barn-Owls to Hummingbirds*. Vol. 5 in *Handbook of the Birds of the World*. Barcelona, Spain: Lynx Edicions, 1999. A stunningly illustrated tour de force of all of the world's owls. Photos and plates make this massive, oversized volume a must-see for anyone even remotely interested in owls. Lengthy and learned introductory chapters precede the section on barn and bay owls of the world and another equally impressive chapter introduces the typical owls. What makes this volume exceptional is that each species account is by noted field researchers, most of whom have actually conducted research on the particular species.

Johnsgard, Paul A. *North American Owls: Biology and Natural History*. Washington, D.C.: Smithsonian Institution Press, 1988. Detailed accounts of all species of North American owls written in an authoritative and entertaining manner. Natural history and ecology is emphasized throughout.

Konig, Claus, Friedhelm Weick, and Jan-Hendrik Becking. *Owls: A Guide to the Owls of the World*. New Haven, Conn.: Yale University Press, 1999. An authoritative treatment of all of the world's owls. The book includes an overview describing why owls are really owls and detailed accounts of every recognized owl species. Each account succinctly describes identification, vocalizations, distribution, habitat, measurements and weight, habits, food, and breeding, status and conservation, and lists recent references. There are also chapters on evolution of owls, how to study owls, and owl conservation. Excellent color plates of owls are a highlight of the book.

PACKS

Types of animal science: Behavior, ecology
Fields of study: Ecology, ethology, population biology, wildlife ecology, zoology

Packs are social groups of carnivores, consisting of one or more families. They are generally highly cooperative for the purposes of rearing young and capturing food, particularly prey that is larger than any one member of the pack. These social packs are often called prides, clans, troops, schools, or packs.

Principal Terms

ANTIPREDATOR BENEFITS: benefits that come from actions that protect individuals from being killed
CARNIVORES: animals that eat the flesh of other animals
DOMINANCE HIERARCHIES: ranks of individuals within a group

Packs occur whenever animals group together in highly organized social systems for traveling, hunting, feeding, and sleeping, usually with bonds of attachment between all members. These social units tend to be fairly stable in composition, in comparison to most herds. This stability results in a social hierarchy, commonly called a dominance hierarchy, in which individuals are ranked in order of the number of other animals below them. Dominance hierarchies are maintained by dominant animals threatening subordinates, but fights are rare. Generally, subordinates engage in appeasement behaviors or avoid the dominant individual(s) altogether.

Dominance characteristics can be linked to body size, age, or weaponry. However, in some packs, dominance is inherited. This is common in baboon and macaque monkey troops, and in hyena clans, and is dependent upon the mother's rank. Females can move up in status every time a younger sister is born; however, several subordinates can form a coalition to challenge an individual above them in status.

Advantages to dominant animals are many. Greater access to food is one common benefit, and in some packs only the dominant pair breeds while the subordinates help to rear their young. Costs to dominants are that they are frequently challenged and run a greater risk of being killed or injured.

Packs and Predation

Predatory methods differ among species that form packs. Lions, who do not display endurance running, rely on stalking their prey and then rushing. During the rushing phase, lions will target any individual that appears to be slower or weaker than others in the prey herd. This tactic, also used by wolves, requires the predator to approach the prey very closely prior to rushing. In contrast, African wild dogs are known as coursers, chasing their prey for many miles until they can either drive it into other pack members or exhaust it. Hunting success in these dogs is very high. Hyenas vary their hunting tactics based on prey species. For attacks on wildebeest, they rush the herd, run for a while, stop to choose a target, and then resume the chase. As the chase continues, more and more hyenas join, and they generally take down their prey when it turns or runs into a lake or stream. They rely upon sheer numbers to overwhelm their target.

Theoretically, the formation of packs allows individuals within the group to exploit more food resources than they would be able to do on their own. In some pack species, this is the case: Cooperative hunts of lions are more successful than those by solitary lions, and there is some evidence to suggest the same for African wild dogs and hyenas. However, the cooperation does not necessarily increase the amount of food available for each member of the pack; in some cases, the nutritional intake per individual decreases with an increase in the size of the pack. Nonetheless, packs may be more able to protect their kills from predators and thus may be more capable of consuming prey completely than could one individual. Packs may also be more successful at driving other packs off from a kill; lions are known for relying on the kills of hyenas for up to half of their food. Hyenas form clans of up to sixty individuals, but these clans break up when food is scarce. Similarly, lions may form larger prides when food is common, but may split into pairs or threesomes as food becomes scarce.

Packs and Rearing of Young

If food per individual is not increased with increasing pack size, then other reasons must be present for the establishment and continuation of a pack. Suggested benefits include better defense of cubs against infanticide by outside coalitions of males that take over the pack (common in lion prides), higher reproductive success because all pack members share in feeding the offspring, and providing food for young while they grow to maturity, thereby ensuring that offspring will survive.

Rearing young in a group can benefit the young because of opportunities to learn from more than

Wolf Packs

Wolves are one of the best-known examples of animals that form packs for cooperative hunting and rearing of cubs. Most packs consist of fewer than eight members, although two or more packs can temporarily come together. When this happens, a pack may accept one member of another pack, while rejecting and chasing other members away. The packs always include a breeding pair of adults, some pups, subadults, and other adults, some of which may be allowed to breed in addition to the dominant pair. Packs can produce up to six cubs per year, and more than one female can reproduce, but often the dominant female will interfere with the care of the subdominant female's cubs.

Wolves prey on deer, moose, buffalo, sheep, caribou, and elk. The stimulus for beginning a hunt is apparently the completion of consumption of a previous kill. Wolves typically pursue prey by direct tracking, although they can occasionally come upon prey by chance encounter. Once they have located their prey, which usually occur in herds (except moose), they begin stalking until they get within feet of their targets. They then rush the target and chase it. Chases can last for less than a mile or for long distances over several days. They focus on the weakest targets: young, old, and sick prey. The wolves can injure a prey animal and then leave it alone for several days, resuming harassment until the prey can no longer rise and run. The pack then attacks from all sides to kill.

Wolves have been described as hunting in an extremely cooperative manner. However, what is more generally observed is that wolves in a pack attack the rear quarters of their prey, and the weight of many wolves biting and slashing on this area helps to bring the prey down. Wolves apparently have a low hunting success rate, which means that they must hunt frequently and test many individuals within a herd before finding one that displays some characteristic likely to be disadvantageous. While many have postulated that wolves form packs to facilitate food capture and that an increase in the pack size will help to increase the amount of food captured per individual, there is, in fact, a negative relationship between pack size and food available per wolf. Packing behavior may instead be more dependent on cooperation between kin where adults can more efficiently share their food with offspring, and young can obtain more food by remaining with their parents than they could by hunting on their own.

Baboon Troops

Hamadryas baboons form groups consisting of a dominant male, one to four females and their offspring, and some accessory males. A number of groups can come together to form bands of forty to fifty individuals. At night, these bands can coalesce to form troops of one hundred to over seven hundred individuals. Groups seem to form for mating purposes and care of the young. Bands are distinct feeding units and troops seem to avoid protection against nocturnal predators. A troop may range over an area comprising three to six square miles, and baboons move in troops to cover this vast area, gathering food, and congregating at water holes. While on the move, the subordinate males take the lead, followed by older juveniles and nonreproductive females. Females with infants and the most dominant males take up the middle positions, and other subdominant males bring up the rear. If a predator approaches the troops from any direction, it must encounter males. Many observers have reported that leopards, cheetahs, lions, and dogs can be run off by the males. Antipredator benefits seem to be one of the major benefits of this species' sociality, but adoption of infants and protection of juveniles from harassment also are known. In contrast to hamadryas baboons, gelada baboons have a social organization that is more similar to that of herding ungulates in that it varies with food availability and consists of distinct types of herds: harem herds, bachelor herds, and juvenile herds. Antipredator benefits dominate.

In both hamadryas and gelada baboons, play behavior by infants and juveniles serves to teach them all the important skills that must be learned and practiced. Thus, in addition to providing protection against predators, grouping in baboons serves to facilitate learning in offspring. Finally, grouping provides advantages because these species' food sources are clumped, and safe sleeping areas are limited.

one adult. It can also provide the young with practice in certain tasks that later prove important when the offspring are on their own. Cooperative hunting can provide young with the opportunity to learn hunting skills from their elders. Generally, this benefit occurs in longer lived species that produce only a few young per year per female.

The formation of packs tends to occur in groups where kin form the nucleus of the association. Dominance hierarchies are common in such packs and serve to stabilize the relationships among group members. Benefits are then realized in terms of hunting larger prey, spreading food resources between the older and younger generation, help in rearing young from all or most members of the pack, and dissemination of skill learning from adults. In a few packs, associations can serve an antipredatory function or can allow the defense of resources that would otherwise be taken by some other species or group.

PAIR-BONDING

Type of animal science: Behavior
Fields of study: Anthropology, ethology, ornithology, zoology

Pair-bonding is the formation of attachments or relationships of various durations for purposes of reproduction and care of the young, relationships that may appear analogous to marriage and family in humans.

Principal Terms

BOND, BONDING: the tie or relationship between opposite-sex partners in a pair bond

BONDING BEHAVIORS: behavior patterns that establish, maintain, or strengthen the pair bond

CONSORT PAIR, CONSORTSHIP: a temporarily bonded pair within a polygamous group

LONG-TERM PAIR BOND: pair bonding that continues beyond a single reproductive period

MONOGAMY: exclusive pair-bonding between one male and one female

PAIR, PAIRING: may refer to mating, sexual coupling (or copulation) or to formation of a pair bond, depending upon the context

POLYGAMY: a mating system in which one male mates with several females (polygyny) or one female mates with several males (polyandry)

PROMISCUITY: a mating system in which sexual partners do not form lasting pair bonds, where their relationship does not persist beyond the time needed for copulation and its preliminaries

In the animal world, there is a great variety of ways in which males and females pair or associate for reproductive purposes (called mating systems). While some animals pair with more than one member of the opposite sex (polygamy), others pair exclusively with only one mate (monogamy). While some animals associate only long enough to copulate (promiscuity), other animals form pair bonds that last for varying lengths of time, from one reproductive period (until young leave the nest) to a lifetime. While some pair-bonding has been observed in all vertebrate classes, and even in some invertebrates (some crabs and insects), it is particularly common in birds, while infrequent in fish and mammals.

Pair-Bonding in Birds

Most bird species are monogamous, although some are polygamous, and a few may be promiscuous. In some birds, such as prairie chickens, male and female pair only for copulation, after which the female is on her own to nest and parent. However, most birds pair bond, remain with their mates, and cooperate in some way until their young can leave the nest and survive independently. Some birds, such as song birds, pair bond for only a single breeding season, while others, such as swans, geese, penguins, and albatrosses, exhibit pair-bonding for more than one season, sometimes for life.

The American robin, for example, is mostly monogamous while it pair-bonds and shares parenting for one breeding season. Typically, in the spring, male robins are the first to migrate north. When the females arrive about a week later, the males have already selected territories and call or carol as though advertising for a mate. Courtship, involving three types of songs (only the males sing) and feeding, leads to mating and pair-bonding. The female builds a nest and lays her clutch of usually three or four eggs. While the female incubates the eggs, the male stands guard nearby, though he may help with the incubation as well. After the eggs hatch, both parents forage and feed the young. When the young leave the nest, they still need approximately two weeks of feeding and parental care before they are mature enough to survive independently. While the father provides this care, the mother repairs the nest and lays another clutch of eggs. American robins typically have two or three broods per year. In this case, the pair bond usually endures for the breeding season, but not through migration south for the winter and the nonbreeding season.

Birds are the most likely of all animals to pair-bond for life. (Adobe)

Pair-Bonding in Fish

Most fish do not form lasting pair bonds. An interesting exception, however, is the seahorse. At the beginning of the seahorse breeding season, males and females court for several days. The female produces eggs, and when they reach maturity, she deposits them into an egg pouch on the male seahorse's trunk. Then she swims away. Male seahorses typically remain in a habitat of approximately one square meter, while females range over an area that may be a hundred times as large. During the male's pregnancy, the female returns every day for a short, five- to ten-minute morning visit. During this visit, the seahorse pair exhibit social interaction and bonding behaviors reminiscent of courtship. Afterward, the female swims away until the next day, when she returns for another visit. After two to three weeks of pregnancy, the male gives birth to a few dozen or more baby seahorses during the night. When his mate returns in the morning for their daily visit, the male is ready for courtship, and the mating and reproductive cycle starts over again. Females have been observed to refuse to mate with other males during their mate's pregnancy, and so appear to be monogamous for the breeding season. In laboratory experiments, where mates were separated during pregnancy and the female interacted with another male, the original pair bond was broken. Thus, the social interaction and bonding behaviors that occur during the seahorse couple's short daily visits appear to be important factors in maintenance and longevity of pair-bonding.

Pair-Bonding in Mammals

Polygamy is the most common mating system among mammals. Within polygamous (or promiscuous) groups, such as baboons and chimpanzees, a male and female may pair temporarily and separate themselves somewhat from the group, while engaging in social grooming and sexual activity. Temporary pairings that do not endure to the end of a reproductive cycle are referred to as consort pairs or consortships in the primate literature. When pair-bonds in a polygamous system are more lasting, the social structure is sometimes called a harem.

Only a small minority (3 to 5 percent) of mammals exhibit monogamous pair-bonding. Gibbons, the smallest of the apes, are particularly interesting because they are the exceptional case, and exhibit not only long-term monogamous pair-bonding but a social organization somewhat analogous to the human nuclear family. Gibbons pair at eight to ten years of age, and have five to six offspring, spaced about three years apart, over their ten- to twenty-year reproductive lifetime. Gibbon offspring remain with their family groups until they approach or reach sexual maturity, when they may leave voluntarily or be evicted by the same-sex parent. Gibbons are territorial, and family members cooperate as needed to defend both territory and mate or family. Just prior to sunrise every morning, mated males sing solo songs that can be heard up to a kilometer away, seemingly identifying their territory as occupied. Later in the morning mated females sing their own songs, and join their mates in singing duets, which appear to publicize both territory and pair-bonding.

Pair-Bond Formation and Maintenance

Formation of a pair-bond usually involves the behavior patterns of courtship and mating. Usually, the male initiates pair formation, while the female decides whether a bond is formed or not. How long a pair-bond endures depends upon various factors. Many animal pairs maintain and strengthen their relationship by continuing the bonding behaviors that were initially used in courtship. Some animals maintain close physical proximity, groom each other, communicate with movement (display) or with vocalizations (call or song), or share food, nests, and territory. Reproductive success and dependency of young also appear to maintain pair-bonding.

PALEOECOLOGY

Type of animal science: Ecology
Fields of study: Evolutionary science, paleontology, zoology

Paleoecology is the study of ancient organisms and their relationships to one another and to their environments. The characteristics of ancient environments may be determined by examining rock and fossil features.

Principal Terms

CATASTROPHISM: a belief that the earth and its features are the result of sudden, violent upheavals that occurred in the relatively recent past

DENDROCLIMATOLOGY: the study of tree-ring growth as an indicator of past climates

FOSSIL: any trace of the presence of an ancient organism, whether track, imprint, or preserved remains

PALYNOLOGY: the study of pollen and spores; also called paleopalynology

RADIOCHRONOMETRY: the determination of the age of an object using radioactive isotope decay rates

TAPHONOMY: the series of events between the death of an organism and its preservation as a potential fossil; also, the study of such events

THANATOCOENOSIS: an assemblage of fossil species from a particular environment; a fossilized community; compare to biocoenosis, an assemblage of living species

UNIFORMITARIANISM: the belief that the earth and its features are the result of gradual biological and geological processes similar to the processes that exist today

Paleoecology is the study of ancient environments. As a field of science, it is most closely related to paleontology, the study of fossils. It is also related to paleoclimatology, paleogeography, and a number of other areas of study dealing with the distant past. All these disciplines have a handicap in common: Because they deal with the past, scientists are unable to apply the usual scientific criteria of direct observation and measurement of phenomena. When ecologists study present environments, direct measurements of environmental variables such as temperature, wind speed, current, soil moisture, and biological interactions can be taken. The organisms may be observed in their habitats—nesting, competing, eating, and being eaten. In order to make any conclusions about the past, scientists must assume at least one statement to be true without direct observation: The processes that exist in the modern universe and on the modern earth existed in the past.

Although one cannot observe any ancient falling objects, one assumes that the law of gravity existed in the past and that objects fell down; since rainfall occurs today, it must have occurred in the past. Similarly, paleontologists must assume that ancient plants and animals had tolerances to temperature, moisture, and other environmental parameters similar to those of modern organisms. This belief that “the present is the key to the past” is called uniformitarianism. It has been a key concept of the biological and earth sciences for almost two hundred years. Uniformitarianism does not include the belief that the ancient earth was like the modern earth in its life-forms or geography. During the early part of the nineteenth century, another worldview dominated: catastrophism, the belief that the earth is relatively young and was formed by violent upheavals, floods, and other catastrophes at an intensity unlike those of modern earth. Many catastrophists explained the presence of fossils at high elevations by the biblical Flood of Noah. The uniformitarian viewpoint prevailed and, although admitting that local catastrophes may be important, their long-term, earthwide importance was denied. It is interesting to note that catastrophism was revived in the 1980's to explain certain important events. The rapid extinction of the large dinosaurs at the close of the Mesozoic era has been attributed to the climatic changes associated with an alleged encounter between the earth and a comet—certainly a catastrophic event.

Types of Evidence About the Past

One of the most intensively investigated paleoecological problems has been the changing environments associated with the ice ages of the past million years. Analysis of pollen from bogs in many parts of the world indicates that there have been at least four advances and retreats of glaciers during that period. Evidence for this is the changing proportions of pollen from tree species found at the various depths of bogs. In North America, for example, spruces (indicators of cool climate) formerly lived much farther south than they do now. They were largely replaced almost eight thousand years ago by other tree species, such as oaks, which are indicative of warmer climates. This warming trend was a result of the latest glacial retreat.

Tree ring analysis not only enables paleoecologists to date past events such as forest fires and droughts, but also allows them to study longer-term cycles of weather and climate, especially those of precipitation and temperature. In addition, trees serve as accumulators of past mineral levels in the atmosphere and soil. Lead levels in tree wood showed a sharp increase as the automobile became common in the first half of the twentieth century because of lead additives in gasoline. Tree rings formed since the 1970's have shown a decrease in lead because of the decline in use of leaded fuels. Tree-ring analysis has also been a valuable tool for archaeologists' study of climatic changes responsible for shifting patterns of population and agriculture among native Americans of the southwestern United States.

Fossil evidence is the chief source of paleoecological information. A fossil bed of intact clam shells with both valves (halves) present in most individuals usually indicates that the clams were preserved in the site in which they lived (autochthonous deposition). Had they been transported by currents or tides to another site of deposition (allochthonous deposition), the valves would have been separated, broken, and worn. Similarly, many coal beds have yielded plant fossils that indicate that their ancient environments were low-lying swamp forests with sluggish drainage periodically flooded by water carrying a heavy load of sand. The resulting fossils may include buried tree stumps and trunks with roots still embedded in their original substrate and numerous fragments of twigs, leaves, and bark within the sediment.

Certain dome- or mushroom-shaped structures called stromatolites are found in some of the most ancient of earth's sedimentary rocks. These structures may be several meters in diameter and consist of layers of material trapped by blue-green algae (cyanobacteria). Such structures are currently being formed in shallow, warm waters. Uniformitarian interpretation of the three-billion-year-old stromatolites is that they were formed under similar conditions. Their frequent association with mud cracks and other shallow- and above-water features leads to the interpretation that they were formed in shallow inshore environments subject to frequent exposure to the air.

Relative oceanic temperature can be estimated by observing the direction in which the shells of certain planktonic organisms coil. The shell of *Globigerina pachyderma* coils to the left in cool water and to the right in warmer water. *Globigerina menardii* shells coil in an opposite fashion—to the right in cool water and to the left in warmer water. Uniformitarian theory leads one to believe that ancient *Globigerina* populations responded to water temperature in a similar manner. Sea-bottom core samples showing fossils with left- or right-coiling shells may be used to determine the relative water temperature at certain periods. Eighteen-thousand-year-old sediments taken from the Atlantic Ocean show a high frequency of left-handed *pachyderma* and right-handed *menardii* shells. Such observations indicate that colder water was much farther south about eighteen thousand years ago, a date that corresponds to the maximum development of the last Ice Age.

Fossil Shape and Content

Fossil arrangement and position can be a clue to the environments in which the organisms lived or in which they were preserved. Sea-floor currents can align objects such as small fish and shells. Not only can the existence of the current be inferred, but also its direction and velocity. Currents and tides can create other features in sediments which are sometimes indicators of environment. If a mixture of gravel, sand, silt, and clay is transported by a moving body of water such as a stream, tide, or current, the sediments are often sorted by the current and deposited as conglomerates—sandstones, siltstones, and shales. Such graded bedding can be used to determine the direction and velocity of currents. Larger particles, such as gravel, would tend to be deposited nearer the sediment source than smaller particles such as clay. Similarly, preserved ripple marks indicate current direction. Mud cracks in a rock layer indicate that the original muddy sediment was exposed to the atmosphere at least for a time after its deposition.

Certain minerals within fossil beds or within the fossil remains themselves can sometimes be used to interpret the paleoenvironment. The presence of pyrite in a sediment almost always indicates that the sedimentary environment was deficient in oxygen, and this, in turn, often indicates deep, still water. Such conditions exist today in the Black Sea and even in some deep lakes, with great accumulations of dead organic matter.

The method of preservation of the remains of the fossilized organism can be an indication of the environment in which the creature lived (or died). Amber, a fossilized resin, frequently contains the embedded bodies of ancient insects trapped in the resin like flies on flypaper. This ancient environment probably contained resin-bearing plants (mostly conifers), and broken limbs and stumps that oozed resin to trap these insects. Mummified remains in desert areas and frozen carcasses in the northern tundra indicate the environments in which the remains were preserved thousands of years ago.

Marks made on fossil parts by other organisms offer indirect evidence of the presence and activity of other species that might not have left fossil remains. Predators and scavengers can leave such marks on bones and shells by boring, scratching, and gnawing. One of the most controversial taphonomic problems in paleoecology is distinguishing between tooth marks left by animal scavengers and predators on bones and those marks left by the stone and bone tools of early human ancestors.

Studying Paleoecology

Fossils, especially fossil assemblages (thanatocoenoses), are the most commonly used indicators of ancient environments. The use of any fossil in interpreting the past must be subject to several qualifications. The fossil record is sparse for most groups of organisms because fossilization itself is a relatively rare event. Rapid burial of the remains and the presence of hard body parts (wood, shells, bones, and teeth) are only two of several fossilization prerequisites that must usually be met. This means that terrestrial organisms and soft-bodied organisms are seldom fossilized. Events leading to fossilization after the death of an organism (taphonomy) usually destroy the soft tissues through decay and scavenging and often disrupt and distort the remaining hard parts through transportation and weathering. An additional taphonomic problem is encountered when clumps or clusters of fossil remains are located. Without careful study, it is difficult to determine whether these assemblages are truly representative of the groupings of the organisms in life or if they are simply coincidental aggregations of such items as shells and limbs that were swept together by currents or wind and thus not indicative of the living situation and environment. Because of limitations on the interpretation of ancient environments by the use of fossilized body parts, trace fossils are often more reliable indicators of environmental conditions. Trace fossils are preserved tracks, burrows, trails, and other indirect indications of the presence of an organism. The presence of marine worm burrows, for example, can indicate environmental factors such as salinity and depth. Such traces are not transported from one site to another because transportation results in their destruction. Whenever these imprints are found, therefore, paleoecologists are able to make some inferences about the environment in which they were formed.

One of the most important methods to be mastered by paleoecologists is stratigraphy—the science of correlating and determining the age of rock layers with those of the fossils contained within these layers or formations. Rock layers or strata are not usually connected over large regions. While they might have been deposited as sediments at the same time and under the same conditions, subsequent erosion has usually made the layers discontinuous. Stratigraphers attempt to correlate discontinuous rock strata by measuring and describing them and by noting the presence of unique fossils called index fossils. If two strata are correlated, then they were probably deposited during approximately the same period, although there may be a gradation of conditions. For example, there may be a layer of sediment deposited at the same time, but under nearshore conditions at one spot and under offshore conditions at another. Relative ages are determined by using the law of superposition: Older rocks lie beneath younger rocks. One can say that a certain stratum is older than, the same age as, or younger than another layer, depending upon their relative positions. Absolute ages (estimated age in years before the present) are determined by measuring the amounts of certain radioactive elements within igneous rocks. Such radiometric age determinations are of less value for sedimentary rocks since they give the age of the minerals of the rock, not the age of the rock itself.

Uses of Paleoecological Research

Paleoecological data are applicable to other, related paleo-fields of the earth and life sciences. The study of fossils, paleontology, is enhanced by the inclusion of information about the fossil organisms' environments and relationships with other organisms. Paleontologists should attempt to reconstruct ancient environments because organisms did not exist alone or in vacuums: They lived in dynamic biological communities. Paleogeography relies heavily on paleoecological information to discern the locations, directions, and time intervals of glaciation, deposition of sediments, temperature, and other environmental variables. This information has been used to determine the past positions of continents and has been a valuable contribution to scientists' knowledge of continental drift.

Paleoclimatologists, who study ancient regional and planetwide conditions, must make use of local bits of paleoecological information to see the big picture of climate. One of the major concerns of paleoclimatology is the recognition of planetary climatic cycles and associated environmental and biological cycles. If there is a repeated recurrence of global environmental change, then predictions about future climatic change become more accurate and probable.

PALEONTOLOGY

Types of science: Anatomy, classification, ecology, evolution
Fields of study: Anatomy, anthropology, evolutionary science, human origins

Paleontology is the branch of geology that deals with prehistoric forms of life through the study of fossil animals, plants, and microorganisms. Many bursts of evolution and many extinction events have been uncovered by this field.

Principal Terms

- EVOLUTION: the science that studies the changes in astronomical bodies, the earth, and living organisms and creates explanations of how changes occur and how things are related.
- FOSSILS: the hardened, petrified (rocklike) impressions of animal, plant, and microbial remains
- GEOLOGICAL PERIODS: the twelve divisions in successive layers of sedimentary and volcanic rocks, which are differentiated by the distinctive fossils present within each division
- MASS EXTINCTIONS: five events in the history of life that resulted in the disappearance of more than 75 percent of all species
- PALEONTOLOGY: the branch of geology that deals with prehistoric forms of life through the study of fossil animals, plants, and microorganisms
- PLATE TECTONICS: the branch of geology that studies the fragmentation of the earth's crust into plates (crust fragments), the movement of plates, and the subduction or uplifting of plates
- RADIOISOTOPES: unstable elements that decay into stable forms at a constant rate, which are used to determine how long ago volcanic rocks solidified

When organisms die, their soft parts usually decompose into their constituent elements, leaving no trace. The harder parts, such as wood, exoskeletons, bones, teeth, and shells, may survive many years, but eventually even they decompose. Sometimes, however, organisms are buried in an avalanche, are covered by volcanic ash, or sink into mud. If the burial inhibits decomposing microorganisms and prevents the rapid replacement of the buried tissue with inorganic material, a fossil is likely to form.

There are a number of different ways in which fossils form. Most fossils form through a process of mineralization. In this type of fossilization, buried material is slowly replaced by minerals such as calcium carbonate ($CaCO_3$), silicate (SiO_2), pyrite (FeS_2), sulfate ($Ca [SO_4] - H_2O$), and iron-phosphate ($Fe_3[PO_4] - H_2O$). These mineralized remains can be separated from the surrounding sediment and may superficially appear to be the actual remains. Sometimes fossils can form when the remains completely decompose. Organisms encased in a highly compacted sediment or covered by volcanic ash that quickly hardens, imprint into the covering a replica of their surfaces. When the organisms degrade, the space fills with minerals that harden. This is how surface replicas of organisms form. Mineralization and replication are responsible for most fossils. In some cases, organisms crawling through or stepping in sediment leave imprints of their passing, called trace fossils. Imprinted sediment explains some fossils.

Microorganisms, plants, and animals often get caught in tree sap (resin) that ages over millions of years, first into copal and then into amber. Amber

The Leakey Family

Louis Leakey
Born: August 7, 1903; Kabete, Kenya
Died: October 1, 1972; London, England
Fields of study: Anthropology, evolutionary science, human origins, paleontology
Contribution: African paleontologist-anthropologist whose most notable works were the characterization of a nearly complete 1.8-million-year-old skull of *Australopithecus boisei* and the piecing together of a 1.8-million-year-old skull of *Homo habilis*.

Mary Leakey
Born: February 6, 1913; London, England
Died: December 9, 1996; Nairobi, Kenya
Fields of study: Anthropology, evolutionary science, human origins, paleontology
Contribution: African paleontologist-anthropologist whose most notable works include the discovery of 3.6-million-year-old humanlike foot prints made by *Australopithecus afarensis*, the piecing together of the 1.8-million-year-old skull of *Australopithecus boisei*, and the characterization of the nearly complete 1.5-million-year-old *Homo erectus* fossil known as Turkana boy.

Richard Leakey
Born: December 19, 1944; Nairobi, Kenya
Fields of study: Anthropology, evolutionary science, human origins, paleontology
Contribution: African paleontologist-anthropologist, son of Louis and Mary, whose most notable works include the piecing together of a 1.9-million-year-old skull of *Homo habilis*, the reconstruction of a 1.8-million-year-old skull of *Homo rudolfensis*, and the unearthing and characterization of Turkana boy.

Maeve Leakey
Born: 1948
Fields of study: Anthropology, evolutionary science, human origins, paleontology, zoology
Contribution: African zoologist-paleontologist, wife of Richard, whose most notable works include her reconstruction of 1.8-million-year-old *Homo rudolfensis* and her characterization of 4.1-million-year-old *Australopithecus anamensis*. In early 2001, her announcement of the discovery of a new 3.5-million-year-old fossil hominid, *Kenyanthropus platyops*, threw the previous understanding of human evolution into confusion.

Louis Seymour Bazett Leakey was born in Kenya to English missionary parents. He trained as an anthropologist at the University of Cambridge, where he developed the dream of looking for evidence of ancient humans in Africa. Mary Douglas Leakey was born in England and studied archaeology, specializing in stone tools. After their marriage in 1936, Mary and Louis left England for Africa, establishing their home in Kenya.

In 1959, Mary discovered the first traces of a very ancient apelike animal at a site in Olduvai Gorge in northern Tanzania. Louis and Mary pieced together the fossilized fragments, recreating the nearly complete skull of a 1.8-million-year-old bipedal apelike creature now known as *Australopithecus boisei*. This animal had a brain capacity of approximately 500 cubic centimeters. At the time, Louis thought this apelike creature was the "missing link" between apelike creatures and humans because of the nearby discovery of very primitive paleoliths (stone tools) dated between 1 and 2.5 million years ago.Then in 1971, the skull of 1.8-million-year-old *Homo habilis* was pieced together by Mary and Louis. It was discovered in the same strata as *A. boisei*. *Homo habilis* had a brain capacity of approximately 600 cubic centimeters and appeared to be more closely related to modern humans than *A. boisei*. Richard Leakey characterized two very important *Homo* skulls: one of a 1.9-million-year-old *Homo habilis*, with a brain capacity of only 510 cubic centimeters, and a second of 1.8-million-year-old *Homo rudolfensis*, with a brain capacity of 775 cubic centimeters. These and other discoveries suggest that the paleoliths were produced by one of the *Homo* populations and not by any of the *Australopithecus* populations. Turkana boy's fossil remains, characterized by Richard and Maeve, suggest that this 1.5-million-year-old *Homo erectus* was about 4.5 feet tall and would have grown to about 5.5 feet. He had a brain capacity of about 880 cubic centimeters.

In 1975, Mary Leakey discovered the traces of humanlike footprints in hardened volcanic ash at Laetoli, near Tanzania's Olduvai Gorge. These footprints have been dated at 3.6 million years by the potassium-argon method. Since no *H. habilis* fossils this old have been discovered, the footprints must be of an *Australopithecus*, possibly related to *Australopithecus afarensis*, whose fossil remains have been discovered in the area and in much of East Africa. Although these animals lived between 3.8 and 2.7 million years ago, they were fully erect, and their footprints appear very human. Maeve Leakey discovered the fossil remains of 4.1-million-year-old *Australopithecus anamensis*. Her discovery of this very apelike creature has increased the span of time in which bipedal apelike creatures evolved.

The discoveries made by the Leakey family helped to establish the fact that a number of different biped species of *Australopithecus* and different species of *Homo* were living together in Africa 1.8 million years before the present. Locomotion on two legs was the first human trait to develop, at least 3.6 million years ago, but it developed first in a number of nonhuman animals, various species of *Australopithecus*. The crude stone tool culture first characterized by Louis and Mary, as well as the proximity of *Homo habilis* fossils suggests that *H. habilis* or closely related species such as *H. rudolfensis* were the first animals to be both bipeds and toolmakers. The Leakey discoveries indicate that some early human population closely related to *H. habilis* or *H. rudolfensis* was the ancestor of *H. erectus*, although Maeve Leakey's discovery of a new genus, *Kenyanthropus platyops*, announced in early 2001, suggests that the lineage of human ancestry in the middle Pliocene is more complex than previously thought. The Leakeys' discoveries also established that Africa, over a period of four million years, was the birthplace of numerous species of both *Australopithecus* and *Homo*.

—Jaime Stanley Colomé

The Leakey family (left to right, Richard, Mary, and Louis) have been a major force in the discovery of hominid ancestors in Africa. (Win Parks, National Geographic Society)

Periods and Extinctions

Era	*Period*	*Date (millions of years ago)*	*Newly dominant fossils*	*Extinctions*	*Most Likely Causes*
Cenozoic	Quaternary	2-present	Recent mammals	One lesser extinction at the T-Q boundary.	
	Tertiary	65-2	Diversified small and large mammals	Two lesser extinctions: one each at around 30 million years and around 10 million years before the present. Mass extinction that eliminated around 75 percent of all species. All dinosaurs except for birds, many land reptiles, all marine reptiles (plesiosaurs and ichthyosaurs), and all flying reptiles (terosaurs) went extinct.	Separation of North and South American land masses from European and African land masses. This altered oceanic currents and atmospheric streams, which produced glaciers. Glacier formation caused the sea level to drop around 200 feet. Volcanic activity may also have contributed to glacier formation. Deep water may have been anoxic because of poor circulation. A huge meteor impact may have contributed to the mass extinction.
Mesozoic	Cretaceous	145-65	Diversified dinosaurs, flowering plants	Three lesser extinctions: one at the J-K boundary and one each at around 110 million years and around 90 million years before the present.	

	Jurassic	205-145	Diversified early dinosaurs, first birds, small early mammals	Lesser extinction at around 138 million years before the present. Seed-ferns all went extinct. Mass extinction that eliminated about 80 percent of all species.	Breakup of Pangaea initiated. Newly forming continents in the northern hemisphere, equatorial continent, and South Pole continent. This altered oceanic currents and atmospheric streams. The temperature was increasing during the T-J transition, yet sea levels fell slightly (around 50 feet), suggesting some glacier formation. Volcanic activity may have contributed to glacier formation. Deep water may have been anoxic because of poor circulation.
	Triassic	250-205	Early dinosaurs, diversified reptiles: mammal-like reptiles, marine reptiles; cycads, diversified ginkgoes	Mass extinction that eliminated around 95 percent of all species. All trilobites, all armored fishes, and all reptilelike amphibians went extinct.	Formation of Pangaea completed. A massive continent from the Northern hemisphere to the South Pole. Water level dropped around 300 feet suggesting huge glacier formation at the poles. Extensive volcanism lowered the temperature, as did altered water currents and atmospheric streams. Volcanism produced huge amounts of toxic sulfur dioxide and acid rain as well as carbon dioxide. Deep water may have been anoxic because of poor circulation.
Paleozoic	Permian	290-250	Diversified reptiles, decline of reptilelike amphibians	One lesser extinction occurred at the C-P boundary.	

Continued

Periods and Extinctions—continued

Era	*Period*	*Date (millions of years ago)*	*Newly dominant fossils*	*Extinctions*	*Most Likely Causes*
	Carboniferous	360-290	Diversified sharks, bony fishes; early reptiles, reptilelike amphibians; seedless ferns, seed ferns, ginkgoes, pine forests	At least one lesser extinction occurred. Mass extinction that eliminated around 80 percent of all species. Most armored fishes and most jawless fishes went extinct.	Movement of northern continents toward Gondwana at the South Pole. Glaciers formed, and sea level dropped around 100 feet due to altered oceanic currents and atmospheric streams. Volcanic activity may have contributed to glacier formation. Deep water may have been anoxic because of poor circulation.
	Devonian	400-360	Diversified armored jawless and bony fishes; amphibians; insects; seedless, spore-forming tree ferns	At least two lesser extinctions and six minor extinctions occurred.	
	Silurian	440-400	Armored jawless fishes, first bony fishes, first fishes with jaws (placoderms and sharklike fishes); simple land plants	At least one lesser extinction occurred. Mass extinction that eliminated around 85 percent of all species. Most Burgess shale organisms went extinct. Trilobites survived, but just barely.	Fusion of some northern continents with each other at the equator. Movement of Gondwana toward the South Pole. Massive glaciers formed and sea level dropped 150 feet. Glaciers were caused by altered oceanic currents and atmospheric streams. Volcanic activity may have contributed to glacier formation. Deep water may have been anoxic because of poor circulation.

	Ordovician	500-440	Diversified arthropods, first jawless fishes, primitive chordates, filter feeders, mollusks	At least two lesser extinctions occurred.	
	Cambrian	540-500	Burgess shale fossils: early arthropods, animals with mineralized shells like the brachiopods, animals with notochords	At least five lesser extinctions occurred in which different groups were affected to different degrees.	Unknown causes.
Proterozoic	Precambrian	600-540	Ediacaran fossils: sponges, jellyfish, segmented wormlike animals, colonial filter feeders	Lesser extinction that eliminated up to 50 percent of all species near the end of the Precambrian.	Unknown causes.
Archaeozoic		1000-600 3800-1000	Microscopic animals, algae Bacteria		

and the organisms encased in it are often referred to as fossils. Ethanol or isopropyl alcohol dropped on copal makes its surface sticky but has no effect on amber. Copal is usually less than 2 million years old, whereas the oldest ambers are about 150 million years old.

The hard parts (skin, cellulose walls, wood, and exoskeletons) of organisms are generally preserved in copal and amber, although some tissues are replaced by minerals such as pyrite (FeS_2). The pyrite turns portions or all of the fossil black. Completely blackened fossils retain little of the original organism. The fossils in copal and amber have given paleontologists a picture of life during different ancient (Jurassic and Cretaceous) and recent (Tertiary and Quaternary) periods.

Radioisotopes Used to Date Fossils

The radioisotope often used to date very old fossils is potassium-40 (^{40}K), which decays into argon-40 (^{40}Ar) by the conversion of a proton into a neutron. It takes 1,300 million years for one half of a ^{40}K sample to decay into ^{40}Ar. By using the half-life for $^{40}K(T_{1/2}$ = 1300 million years) and measurements of ^{40}K and ^{40}Ar in volcanic rock, the volcanic rock can be dated. If, for example, a sample of volcanic rock contains equal amounts of ^{40}K and ^{40}Ar, then the volcanic rock would be 1,300 million years old. Fossils are dated by determining the age of volcanic rock below and above the fossils. The age of the fossils would be between the ages determined for the volcanic rock.

Carbon-14 (^{14}C) and carbon-12 (^{12}C) measurements are used to date fossils less than thirty thousand years old. ^{14}C decays into ^{12}C by losing two neutrons. The half-life for this decay is 5,700 years. Generally, in living organisms the ratio of radioactive ^{14}C to nonradioactive ^{12}C remains constant because fresh ^{14}C replaces the lost ^{14}C. When an organism dies, however, ^{14}C no longer replaces the ^{14}C lost, and so the ratio of ^{14}C to ^{12}C decreases in the surviving tissue. The smaller the ratio of ^{14}C to ^{12}C, the older the sample is. A fossil may be dated by directly measuring the age of the fossil, by determining the age of organic material closely associated with the fossil, or by determining the age of organic material both below and above the fossil. The errors become quite large for dates greater than forty thousand years.

Mass Extinctions

The five mass extinctions during the last five hundred million years have been very important in the evolution of life because they eliminated nearly all of the most highly adapted species that existed before each extinction. This allowed many of the surviving, more generalized species to evolve into highly specialized species that filled vacated and new environments. The species that arose after each mass extinction were very different from those they replaced.

In most cases, mass extinctions were caused by the plate tectonics that fused and fragmented continents. Colliding continents created shallow seas and mountains. Fragmenting continents initially created shallow seas. In some cases, these shallow seas developed into deep oceans. The fusion and the fragmentation of continents drastically changed oceanic currents and weather patterns, which often lowered temperatures both in the ocean and on land. The movement of plates to and from the equator and poles also affected the world's environments. Extensive volcanic activity occurred both when small continents collided and fused with each other and when massive continents fragmented and the volcanic debris blown into the upper atmosphere absorbed and reflected light, resulting in a cooling of the earth. Large decreases in temperature, changes in rainfall, and environmental loss were deleterious for highly adapted species.

Huge comets, asteroids, or meteoroids colliding with the earth may have played a minor role in any of the mass extinctions. The mass extinction that marked the end of the Cretaceous period about sixty-five million years before the present, which eliminated more than 75 percent of all species and all of the dinosaurs except the birds, may have been helped along by a meteoroid about ten miles across. Although this impact spewed millions of tons of earth into the atmosphere, it is not known whether the debris was sufficiently fine to remain in the atmosphere long enough to drastically alter the temperature and weather. Many biologists favor the idea that plate tectonics, not a meteoroid, ended the Cretaceous period. During the late Cretaceous period, the supercontinent Pangaea was fragmenting into northern and southern continents. In addition, these continents themselves were fragmenting from north to south, and an ocean was forming between them, slowly becoming the Atlantic Ocean.

At least nineteen lesser extinctions and five minor extinctions (Devonian and Devonian-Carboniferous transition) occurred during the last 600 million years. In some cases, the lesser extinctions eliminated up to 50 percent of all species. This allowed new species to evolve into the environments vacated.

Geological Periods and Dominant Fossils

The preceding table, titled Periods and Extinctions, characterizes each of the geological periods by listing some of the newly dominant fossils (organisms) that appeared during each period. The timing of the five major and nineteen lesser extinctions is indicated, along with the most likely cause of the extinctions.

Dating the different layers in sedimentary rock, some many hundreds of feet thick, establishes the great age of the fossils in the layers. The fossils in the different layers of sediment clearly illustrate the gradual and in many cases the rapid disappearance of most early forms of life as well as the repeated appearance of totally new forms of life. Numerous extinctions induced by the evolving earth eliminated countless species and allowed countless other species to evolve. Geology (plate tectonics, dating of strata, and paleontology) and evolution have produced a complex picture of the evolving earth and life.

Bibliography

Dingus, Lowell, and Timothy Rowe. *The Mistaken Extinction: Dinosaur Evolution and the Origin of Birds*. New York: W. H. Freeman, 1998. For all its information, this book is easy to read. It contains a comprehensive discussion of dinosaur fossils from the Jurassic and Cretaceous periods and how they relate to fossil and modern birds. The many photographs and outstanding figures and drawings make this an outstanding reference book.

Gould, Stephen Jay. *Wonderful Life: The Burgess Shale and the Nature of History*. New York: W. W. Norton, 1989. A very readable book, containing extensive discussion of the Cambrian period fossils found in the Burgess Shale of Canada. The book contains numerous informative photos and interpretive drawings of the fossils.

Hallam, Anthony, and P. B. Wignall. *Mass Extinctions and Their Aftermath*. New York: Oxford University Press, 1997. An extensive discussion of mass extinctions and what caused them.

Johanson, Donald C., and Blake Edgar. *From Lucy to Language*. New York: Simon & Schuster, 1996. This is a picture book of ape and human fossils. Concise analyses and discussions place these fossils into a temporary evolutionary framework. Clearly explains the contributions made by the most famous paleontologists of the twentieth century. Beautiful and informative photographs on every page.

Leakey, Richard, and Roger Lewin. *Origins Reconsidered: In Search of What Makes Us Human*. New York: Doubleday, 1992. Richard Leakey reconsiders the evolutionary relationship between the fossilized *Australopithecus* species and *Homo* species that have been discovered during the twentieth century, with special attention to *A. boisei* (*Zinganthropus boisei*), *A. afarensis* (Lucy), *H. habilis*, *H. erectus* (Turkana Boy), *H. erectus neandertal*, and *H. sapiens sapiens*. The remains of *A. boisei, H. habilis*, and *H. erectus* (Turkana Boy) were discovered by members of the Leakey family.

Vickers-Rich, Patricia, and Thomas Hewitt Rich. *Wildlife of Gondwana*. Bloomington: Indiana University Press, 1999. Although Laurasia and Gondwana formed from the fragmentation of Pangaea during the Triassic period, Gondwana rocks range from the Carboniferous to the Jurassic. This paleontology book correlates plate tectonics and the accompanying environmental changes with extinctions and the appearance of new life forms. The book contains many useful diagrams, beautiful pictures of fossils, and photos of animals and plants now living in Australia.

PANDAS

Type of animal science: Classification
Fields of study: Anatomy, conservation biology, physiology, reproduction science, wildlife ecology

The giant panda, with its distinctive black and white coat, is one of the most easily recognized animals in the world. It is extremely specialized for a bamboo diet. Despite efforts by many conservationists, the panda is highly endangered.

Principal Terms

CARNIVORE: animal dependent on an animal diet
DELAYED IMPLANTATION: an extended period after fertilization when an embryo stops developing, and before it attaches to the uterine wall and resumes embryonic development
HERBIVORE: animal dependent on a plant diet
RADIAL SESAMOID: forefoot wrist bone

Giant pandas are members of the bear family, and resemble other bears in size and shape. In contrast, the red panda, which lives in the same habitat as the giant panda, is closely related to and resembles the raccoon. The black-and-white giant panda coat is recognizable to people all over the world. Its legs, ears, eye patches, and a band across the shoulders are black, while the rest of the coat is white. Pandas have large jaws and broad teeth, with an increased number of cusps that help them chew tough bamboo stalks. The wide jaw contributes to the large, round shape of the panda's head. The black eye patches create an illusion of very large eyes. These features, along with short legs, give the panda a cute, infantlike appearance to humans, which contributes to their enormous popularity. Another remarkable feature is the "thumb." Pandas have the same five digits of other bears, plus a sixth digit, an opposable thumb, which is actually a modified wrist bone (sesamoid). The thumb allows them to grasp bamboo with considerable dexterity.

Diet and Reproduction

Giant pandas are the most nearly herbivorous of the bears. Ninety-nine percent of their diet consists of bamboo. They also eat other plants and meat that they can scavenge, and will eat a variety of foods in captivity. However, pandas live in areas once covered by vast bamboo forests, and their jaws, teeth, paws, and behavior are all adapted to eating bamboo. Nonetheless, they have a short, simple digestive tract similar to those of other bears, a sign of their carnivorous ancestry, which is not well-adapted to digesting the leaves and fiber of bamboo. Accordingly, pandas can only digest 21 percent of the bamboo that they consume, whereas ruminants such as cows digest up to 60 percent of the plant material that they eat. Because of this inefficiency, pandas consume 12 to 15 percent of their body weight in bamboo each day, and must spend twelve to fourteen hours each day eating.

Pandas mate in the spring between March and May, with cubs born in late summer. The total gestational period varies from 87 to 165 days. Cubs are born very small, between three and five ounces. Combined with hormonal data, these characteristics suggest that pandas have a delayed implantation. That is, after fertilization, the embryo remains free-floating in the uterus for several months before attaching to the uterine wall. After attachment, pregnancy is only about forty days, resulting in small newborns. Delayed implantation also occurs in some other bear species. Pandas have between one and three cubs at a time. However, they usually raise only one cub, which the mother nurtures intensively for several months.

The panda's distinctive black-and-white coloration makes it one of the most recognized wild animals. (Corbis)

Status and Distribution

The giant panda is an endangered species, with fewer than 1,500 individuals remaining. Panda habitat once covered an area of roughly 450,000 square miles in southeastern China, ranging from central China, to Hong Kong, into Burma and Vietnam. Today, they are found within only a 5,400-square-mile area. Even within this area, they are separated into many subpopulations, which prevents interbreeding. Within their range, pandas live at elevations above human settlements (four to eight thousand feet) to the upper edges of bamboo forest (ten to eleven thousand feet). The continuing expansion of human farms and villages has forced them from the lower elevations, which further contributes to the fragmentation of their populations. Small subpopulations are at a high risk for inbreeding, which reduces the genetic variability and individual fitness, placing panda survival in doubt.

Because of the giant panda's endangered status and charismatic traits, extensive efforts are being made to prevent its extinction. It is considered a national treasure in China, and killing one is punishable by death. Western conservationists, including the World Wildlife Fund, which uses the panda as its symbol, are also aiding the preservation efforts. Captive panda breeding, mostly in China, has been a focus of these efforts. Unfortunately, breeding programs have never produced enough cubs to introduce into the wild, or even to sustain the captive populations. Still, many scientists and conservationists around the world are working to ensure a future for the giant panda.

Panda Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Carnivora
Family: Ursidae (bears)
Genus and species: Ailuropoda melanoleuca (giant panda)
Geographical location: China
Habitat: Bamboo forests
Gestational period: Probably a three-month embryonic diapause, followed by a forty-day gestation
Life span: Twenty to twenty-five years; known record, thirty years
Special anatomy: Coloration is white with black splotches; opposable "thumb"

PARROTS

Types of animal science: Anatomy, classification, reproduction
Fields of study: Anatomy, ornithology, zoology

Parrot species include macaws, cockatoos, true parrots, parakeets, and lories. They are kept as pets for their beautiful coloring and ability to learn to talk.

Principal Terms

PLUMAGE: the feathers of birds

ZYGODACTYL: having two toes pointing backward and two toes pointing forward

The hundreds of parrot species are vivid-colored members of the bird family Psittacidae. They belong to five classes: macaws, cockatoos, true parrots, parakeets, and lories. In parrot plumage, reds and greens often predominate, but blue, purple, yellow, and black also appear.

Parrots inhabit warm South and Central America, southern North America, Africa, Madagascar, Indonesia, and southern and Southeast Asia. They live in lowland tropical or subtropical and mountain forests. Parrot sizes range from three-inch New Guinea pigmy parrots to South American macaws, over three feet long.

Macaws, the largest parrots, have long, pointy tails. Cockatoos of Australia and Indonesia are white, with colored crests and other touches of yellow, red, or pink. True parrots are smaller, square-tailed, and have many green feathers. Parakeets, smaller than most true parrots, have long, pointy tails. Lories have red or orange bills, in-

Parrots and their relatives are distinguished by their curving beaks, which they use to help them climb. (Adobe) stead of gray bills like true parrots. In most species, males and females look similar, but males are more brightly colored.

Physical Characteristics of Parrots

The most noticeable features of parrots, beyond color, are their down-curved, hooked bills, thick, muscular tongues, and short legs. The bills have strong grasping ability that helps parrots to climb well. Parrot feet are zygodactyl, meaning that the two outer toes of the foot point backward and grip in the opposite direction to the two forward-pointing inner toes. Because of this, parrots walk awkwardly. However, zygodactyly makes them excellent climbers.

Parrots eat seeds, fruits, and nuts. Australian lories also eat pollen and nectar. The thick, muscular tongues of most parrots manipulate nuts and seeds, breaking them open as needed. Longer lorie tongues have brushlike tips for eating pollen and nectar. Most parrots find their food in trees, using feet and bills to navigate search areas.

The Lives of Parrots

Parrots are social birds that often live in flocks. Their loud voices are harsh and used in constant communication. Parrot breeding seasons depend on the geographic location of their habitat and the food they eat. Species living outside the tropics, where food supply changes seasonally, have yearly mating seasons. Those in tropical regions breed at irregular intervals when food is available.

Most parrots pair for life. Males attract mates by hopping, bowing, wagging tails, and flapping wings. After mating, females lay two to eight small white eggs. A mated pair does not part after breeding. They eat together and groom each other year round. Most parrots nest in holes in trees, termite mounds, and rock or ground tunnels. Others lay eggs in large grass or twig nests. Females incubate eggs for eighteen to thirty-five days, while males supply mates with food. Parrots are born blind and dependent on their parents. Young leave the nest after 1 month in smaller species and after 3.5 months in larger species. Some parrots live for sixty to eighty years.

Parrot Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata (have backbone)
Class: Aves
Order: Psittaciformes
Family: Psittacidae, with subfamilies Nestorinae (keas, one genus, 5 species); Psittrichasinae (vulturine parrots); Kakatoeinae (cockatoos, five genera, 14 species); Micropsittinae (pygmy parrots, one genus, 4 species); Trichoglossinae (lories, two tribes, fourteen genera, 21 species); Strigopinae (owl parrots); Psittacinae (true parrots, five tribes, fifty-four genera, 126 species)

Geographical location: South and Central America, southern North America, Africa, Madagascar, Indonesia, and southern and Southeast Asia

Habitat: Lowland tropical or subtropical and mountain forests

Gestational period: Eggs hatch in seventeen to thirty-five days

Life span: Forty to eighty years, in captivity

Special anatomy: Down-curved bills, muscular tongues, zygodactyly

Some Representative Parrot Species

African gray parrots (*Psittacus erithracus*) of Central and Western Africa grow to one-foot lengths and one-pound weights. They have gray bodies, black wingtips, and red tail feathers. They eat fruit, seeds, nuts, and berries, nesting in holes in trees. Females lay about four eggs and incubate them for a month, while males feed them. Chicks are fed by both parents. They fly in 2.5 months and parents feed them for 5 more months. These birds form flocks of up to thirty-six individuals. In captivity they live for up to eighty years.

Princess parrots (*Polytelis alexandrae*) live in the scrub land of central and western Australia. They nest in eucalyptus tree holes and eat acacia buds, seeds, berries, and fruit. They are high-altitude fliers, who travel widely seeking food. Their flocks contain up to twenty-four birds. Full-grown, they are fifteen inches long including the tail, and weigh around four ounces. Back, belly, and wing plumage is olive green and yellow; tail feathers are violet; throats are pink; bills are red-orange; and heads are light blue. Breeding occurs between September and December. Females lay four to six eggs and incubate them for three weeks. Young can fly at three months old. An endangered species, they are protected by law.

Indonesian salmon-crested cockatoos (*Cacatua moluccensis*) have plentiful, pink-tinted white plumage. Atop their heads are crests of salmon-red feathers, raised to show desire to mate. They eat berries, seeds, nuts, fruits, and insects. Breeding season is in November, and after mating they pair for life. Nests are in tree hollows. Females lay four to seven white eggs. Both birds incubate them for a month. After hatching, young remain in the nest for three months, and then live on their own. Salmon-crested cockatoos live for sixty years in captivity.

Wild parrots are pests. For example, farmers see cockatoos as nuisances because they eat crops. An interesting side note is that parrots are very ingenious. This is due to their great intelligence, estimated to equal that of porpoises and primates.

Parrots are liked as pets, due to their attractive coloring and ability to learn to talk. The popularity of pet parrots has brought some species close to extinction. In most countries, laws regulate their capture, export, and import. However, the laws are difficult to enforce.

PARTHENOGENESIS

Type of animal science: Reproduction
Fields of study: Embryology, reproductive science

Parthenogenesis is a process of asexual reproduction found mostly in lower animals. The egg divides and develops normally in the absence of fertilization.

Principal Terms

ARTHROPOD: a highly diverse phylum of animals that contains the crustaceans, insects, and spiders

DIPLOID: a cell containing two sets of chromosomes, usually one derived from the father and one derived from the mother; the normal condition of all cells except reproductive ones

HAPLOID: a cell (egg or sperm normally) containing one set of chromosomes, half the number found in nonreproductive cells

MEIOSIS: a special process of cell division consisting of two nuclear divisions in rapid succession, resulting in four haploid cells

OVUM: the female sex cell, or egg; usually undergoes meiosis following fertilization by a sperm

The term parthenogenesis comes from the Greek, meaning "to create from a virgin." Hence, it is sometimes popularly referred to as virgin birth. Parthenogenesis is a form of reproduction in which an ovum develops into a new individual without having been fertilized by a sperm. It is akin to other forms of asexual reproduction in that the offspring inherits all genetic information and traits from a single parent. The offspring is, therefore, genetically identical to the mother, and may be considered to be (in the broader sense of the word) a clone. The offspring may or may not look identical to the mother, since environment plays a large role in outward appearance. In fact, offspring may be male as well as female in those species where gender is determined by factors other than genetics alone, or by genetic factors different from those that occur in humans.

Natural Parthenogenesis

Parthenogenesis as a mode of reproduction is common in the animal kingdom up through the arthropods. In some, such as the aphid, parthenogenesis is the primary method of reproduction. Aphid eggs laid in the fall survive the winter and hatch as wingless females. These aphids mature in two weeks and reproduce parthenogenetically, giving live birth to daughters only, who in turn give live birth to the next generation of daughters. This cycle of parthenogenesis repeats itself through the spring and summer months until finally, in the fall, the next to last generation gives live birth to both females and males. These mate with each other and, rather than giving live birth, produce eggs that will hatch the following spring to start the cycle of parthenogenesis once again.

Other insects, such as honeybees and most species of ants, use both parthenogenesis and sexual reproduction side by side. In these species, unfertilized eggs give rise to haploid male drones, whereas fertilized eggs lead to diploid female workers and queens. The only insect known to be completely female (no males have ever been reported) is the white-fringed weevil. Since no males exist for fertilization, all reproduction is by parthenogenesis alone.

Ernest Everett Just

Born: August 14, 1883; Charleston, South Carolina
Died: October 27, 1941; Washington, D.C.
Fields of study: Cell biology, developmental biology, embryology, invertebrate biology, marine biology, reproduction science
Contribution: A pioneer in the fields of marine biology, cell biology, and fertilization, Ernest E. Just challenged many of the leading biological theories of his day. He significantly increased our understanding of the process of artificial parthenogenesis and the physiology of cell development.

Following graduation from Dartmouth College (1907) with a degree in zoology and special honors in botany and history, Ernest Just was offered a teaching position at Howard University. An excellent teacher with clear leadership skills, he was appointed head of the new Zoology Department in 1912. At Howard he also served as a professor in the Department of Physiology at the Medical School. He was awarded the first National Association for the Advancement of Colored People (NAACP) Spingarn Medal for exceptional contributions, in 1915, and received his doctorate in experimental embryology from the University of Chicago in 1916.

In 1909, Just was invited by Dr. Frank Lillie to spend his summer doing research at the Marine Biological Laboratory at Woods Hole, Massachusetts. His research there over the next twenty years, and the fifty papers which he published, led to international acclaim in several scientific fields. His work included the subjects of fertilization, experimental parthenogenesis, hydration and dehydration in cells, cell division, and the effects of magnetic fields and ultraviolet rays on chromosome number in animals and in altering the organization of the egg with respect to polarity. He successfully challenged Jacques Loeb's theory of artificial parthenogenesis, pushing the understanding of the process well ahead. Much of his early work is reported in his book, *Basic Methods for Experiments on Eggs of Marine Organisms* (1939), and in *General Cytology* (1924), which he coauthored with several of the other prominent biologists of the day, including Frank R. Lillie, T. H. Morgan, M. H. Jacobs, and E. G. Conklin.

A gifted, versatile, and productive researcher, Dr. Just was often referred to as a scientist's scientist. Even so, he experienced much of the racism of this period in history, and found the walls of prejudice and discrimination in America too high to climb. It was for that reason that he chose to move his research to Europe, and spent most of his time after 1933 working in Germany, France, and Italy.

Ernest Everett Just was a leading researcher, prior to World War II, in the fields of cell biology and parthenogenesis. (Associated Publishers, Inc.)

While he was living in France, his masterpiece, *The Biology of the Cell Surface* (1939), was published in Philadelphia. This important book summarized his life's work on small marine animals, and provided new knowledge for people interested in biological research. Unfortunately, Germany invaded France in 1940, and Dr. Just was imprisoned by the Germans. His health had begun to fail before his imprisonment, and it worsened during this time. After he was released, he returned to the United States, but was too ill to continue his research. He died of cancer a year after his return.

Dr. Ernest Everett Just was recognized in 1997 by a U.S. Postal Service commemorative stamp (Black Heritage Stamp Series) for his contributions to biology.

—*Kerry L. Cheesman*

Parthenogenesis has also been reported in aquatic organisms, such as rotifers, marine nematodes, and some mollusks. It rarely occurs in higher orders of animals, except in certain birds. A good example of avian parthenogenesis is the turkey, where it appears to be fairly common. The work of M. W. Olsen and others in the 1960's and 1970's established the fact that parthenogenesis is fairly common in most fowl, including chickens, and usually occurs in eggs that are incubated for a few days in the absence of fertilization. Thus, there may be economic implications associated with parthenogenesis in these birds.

Two processes collectively referred to as abortive parthenogenesis are known to occur in the animal kingdom. In gynogenesis, a sperm enters the egg in the normal way, but the egg begins to develop without including the nucleus (genes) of the sperm. In androgenesis, the nucleus of the egg fails to begin development following fertilization, and the genes of the sperm take over the role of directing early development. Neither of these is considered a normal reproductive process.

Most naturally occurring parthenogenesis is associated with a modification of the meiotic process that restores the diploid condition to the egg. Little evidence exists concerning the stimuli needed or the process required to produce haploid individuals from haploid eggs (as in bees and ants).

Artificial Parthenogenesis

The phenomenon of natural parthenogenesis was discovered in the eighteenth century by Charles Bonnet. In 1900, Jacques Loeb (and T. H. Morgan, in a separate study) accomplished the first clear case of artificial parthenogenesis when he pricked unfertilized sea urchin eggs with a needle and found that normal embryonic development ensued. Through further studies he claimed that both butyric acid and hypertonic seawater (water with an excess of salt in it) were necessary to stimulate parthenogenesis.

Several years later, E. E. Just demonstrated that Loeb's understanding of what he had done was in error, and showed that hypertonic seawater alone could stimulate parthenogenesis. He also demonstrated that the larvae produced looked no different than those produced from eggs that had been normally fertilized by sperm in the ocean. Through this and other experiments on sea urchins, Just advanced the knowledge of the cellular events of parthenogenesis tremendously.

Since then other investigators have been able to stimulate parthenogenetic development in silk moths, starfishes, marine worms, and various amphibians by pricking them, shaking them, changing the temperature, or washing them in acids, alkalis, salt solutions, or other fluids. In turkeys and chickens, factors such as temperature, viruses, additives in feed, and even the age of the hen have all been shown to increase the incidence of artificial parthenogenesis.

In mammals, there is no good evidence that complete development can occur by stimulated parthenogenesis, although a few reports have appeared over the years. For instance, in 1936, Gregory Pincus induced parthenogenesis in rabbit eggs through temperature change and chemical agents, but development was not complete. Abortive or incomplete parthenogenesis does appear to be a normal, or at least common, occurrence in some species of mammals, although the reason for such developmental quirks remains unclear. No reliable reports of human parthenogenesis experiments have been published.

PELICANS

Type of animal science: Classification
Fields of study: Anatomy, ornithology, physiology, population biology, wildlife ecology

Pelicans, unmistakable due to their large size, long bills, and enormous throat pouches, have existed for forty million years.

Principal Terms

BROOD: to cover the young with the wings
CREST: tuft of feathers on the head
MANDIBLE: the upper or lower portion of the bird's bill
THERMALS: rising currents of warm air
TOTIPALMATE: having all four toes fully webbed

Pelicans are large water birds that live on seacoasts or in warm inland water habitats. There are seven generally recognized species. The coastal brown pelican lives from North Carolina to the Gulf of Mexico and the Caribbean, and from British Columbia to Chile, as well as the Galápagos Islands. The American white pelican inhabits inland habitats in the western, central, and southeastern United States, Mexico, and Canada. The remaining species live in Australia, Europe, Asia, and Africa.

Physical Characteristics of Pelicans

Pelicans rank among the largest of living birds, ranging in size from four to six feet in length, and weighing from four to sixteen pounds. The brown pelican is smallest, and the large eastern great white pelican has a wingspan of up to ten feet. They have short legs and broad, fully webbed feet, which act as powerful paddles in the water, and cause them to walk with an awkward waddle on land.

The pelican is famous for its huge, featherless throat pouch that is attached to the lower mandible. The pouch stretches as it fills with water when the bird is fishing, and can hold nearly three gallons. The pouch also functions as an evaporative cooling mechanism. The pelican opens it mouth and flutters its pouch, which keeps air flowing over the moist surface.

Plumage color varies among species and according to age. Pelicans can be predominantly white, black, brown, or gray, with markings on the head, wingtips, underfeathers, or tail. The legs and feet are orange, brown, or black, and the bill and pouch are reddish, orange, or black. During the breeding season, these body parts change color, and many pelicans develop a yellow patch on the chest, a distinctive crest, and a bright ring around the eyes. The American white pelican also grows a noticeable horny knob on its beak.

Feeding and Other Behaviors

Pelicans feed on many species of saltwater and freshwater fish, from tiny anchovies to fish weighing over a pound. Small crayfish, salamanders, frogs, and snakes are also consumed. The pelican thrusts its head and neck underwater and uses its pouch as a dip net to scoop up its prey. It drains out the water, then tilts its head back and swallows the fish whole. Many pelicans are social fishers, swimming in a circle to close in on the school, then all thrusting and dipping at once. Brown pelicans are solitary feeders, utilizing a spectacular plunge dive from about twenty feet above the water, with neck outstretched and bill pointed down. They hit the water hard, stunning the fish and trapping them in the pouch. Air sacs beneath

Pelicans have large, featherless pouches under their beaks that are used for scooping fish out of the water and for evaporative cooling. (PhotoDisc)

ship, the male uses various behaviors such as bowing, stretching, and pouch displaying to attract a female. Both engage in nesting, the male often gathering sticks and bringing them to the female to incorporate into the nest. Nests are built on the ground or in trees. One to three eggs are laid, and take thirty days to hatch. The chicks are born featherless, and the parents brood them, protecting them from the elements until their feathers come in. Unless the food supply is abundant, only the strongest chick survives. Young chicks eat the parent's regurgitated food. Older chicks feed by sticking their

the pelican's skin cushion its dive and help it to surface quickly.

Pelicans are graceful fliers. They take off against the wind, beating their wings and pumping their feet simultaneously, hopping until they are airborne. They fly at a relatively slow speed, with their necks retracted and their heavy bills tucked in and resting on the breast, and often glide on thermals to conserve energy. Pelicans regularly fly in flocks in a V-formation, flapping their wings in unison. They often travel a great distance in search of food.

Pelicans sleep standing or sitting on their bellies, with the head twisted back and the beak tucked into its feathers. Self-care activities include muscle exercises such as body shaking, wing flapping, tail wagging, leg stretching, bill throwing, and yawning. Pelicans groom themselves by splash bathing, preening with their beaks, and by rubbing their heads over the body to distribute waterproofing oil to their feathers.

Reproduction

Pelicans are warm weather birds, migrating in large flocks to nest in huge colonies. During court-

Pelican Facts

Geographical location: North and South America, eastern Europe, Asia, Africa, Australia
Habitat: Coastal areas or inland lakes and rivers
Gestational period: Incubation lasts thirty days
Life span: Eight to twenty years
Special anatomy: Webbed feet; long, pointed bill with retractable throat pouch; air sacs under the skin; large wingspan

heads in the parent's pouch and throat. By twelve weeks of age, the chicks can fly and begin to hunt for themselves. By one year they have their full plumage. They begin reproduction at three to four years of age.

Endangerment

Pesticides, oil spills, habitat destruction, entanglement in fishing lines, and human disturbance have affected pelican populations in various parts of the world. In 1970, the U.S. Fish and Wildlife Service listed the brown pelican as an endangered species due to the heavy usage of dichloro-diphenyl-trichloroethane (DDT) and endrin. When pelicans ate DDT-contaminated fish, they produced thin-shelled eggs that crushed during incubation. Endrin was toxic. Populations improved after the pesticides were banned, but the birds are still endangered. The spot-billed pelican of Asia and the Dalmatian pelican of Europe and China also face difficulties.

PENGUINS

Type of animal science: Classification
Fields of study: Anatomy, ornithology, physiology, population biology

Penguins, highly specialized for their flightless aquatic existence, have origins dating back sixty million years. Their unique lifestyle and behavior have long fascinated observers.

Principal Terms

CRÈCHE: penguin chicks grouped together for warmth and safety
KRILL: small, shrimplike sea creatures
MOLT: to lose feathers and grow new ones
ROOKERY: a nesting penguin colony

Penguins are flightless marine birds that dwell only in the southern hemisphere. They do not inhabit the Arctic, where polar bears live. There are seventeen generally recognized species of penguins. Six species, the Adelie, gentoo, chinstrap, rockhopper, king, and emperor penguins, live in the cold environments of the Antarctic region. The rest live in subantarctic and temperate regions. The macaroni, fiordland, Snares, erect-crested, yellow-eyed, fairy, and royal penguins live off the coasts of New Zealand and Australia and nearby islands. The Magellanic and Humboldt penguins live off the coast of South America. The African penguin lives off the southern coast of Africa, and the Galápagos penguin is native to the Galápagos Islands. Penguins spend much of their lives in the ocean, coming to shore mainly to breed.

Physical Characteristics

All penguins are black with white undersides, and are commonly described as wearing tuxedos. This color pattern acts as camouflage when the penguin is swimming, protecting it from predators. From underneath, the white belly blends with the bright water surface, and from above, the black back is indistinguishable from the dark water. Penguin species can be grouped according to common characteristics. Banded penguins have black and white stripe patterns on their chests and heads. The crested penguins all have bright yellow or orange plumes on their heads. Brushtail penguins have long stiff tail feathers. The king and emperor penguins have bright yellow and orange chest and head patches, and the yellow-eyed penguin has a yellow crown. The fairy penguin's feathers are bluish.

The emperor penguin is the largest, at nearly four feet tall and seventy-five pounds. The small fairy penguin is sixteen inches tall and about three pounds. All have solid, heavy bones that help them dive deeply into the water. They have streamlined bodies that move smoothly through the water as they pump their strong, flipperlike wings and steer using their webbed feet and tails as rudders. Penguins can hold their breath for many minutes at a time, and they frequently leap out of the water, porpoiselike, to take in more air.

On land, penguins walk with an awkward sideways waddle. Because their short legs are set back on their bodies, they stand erect and must hold out their flippers for balance. Penguins often toboggan themselves by flopping on their bellies and pushing with their flippers and feet.

Penguin feathers are tiny and stiff, overlapping to form a waterproof coat. An underneath layer of down helps to trap warm air and protect the penguin from the cold water and wind. Penguins of the Antarctic region have an insulating layer of blubber. Those in temperate climates often have to cool themselves down by ruffling their feathers and holding out their flippers. They can control the flow of blood to their unfeathered areas, such as the feet and under their flippers, which helps regulate their body temperature. Penguins preen their feathers regularly, to spread waterproofing oil from a gland near the tail.

Feeding Behavior and Enemies

Penguins are carnivores. They eat many types of small sea creatures, such as fish, squid, and krill. After locating a school they snatch quickly with their sharp beaks. The tongue and upper palate are covered with stiff spines that grip the slippery food and assist in moving it toward the throat. Penguins make several catches per dive, swallowing the prey whole along with some seawater. Their specialized salt glands above each eye help them drain the extra salt they ingest.

Penguins usually enter and exit the water in large groups, to protect themselves from predators who often lurk near the shore. Their main enemies are sea lions, leopard seals, and killer whales. On land, adult penguins are safe. Petrels, skuas, gulls, and sheathbills hunt babies and eggs.

Reproduction

Most penguins follow an annual breeding cycle that begins in the spring, but timing varies according to species and climatic conditions. The Galápagos penguin will breed any month that the water temperature is right, and sometimes twice a year. Emperors begin their cycle in autumn, so there is a good food supply when their chicks hatch in spring. King penguins only reproduce twice every three years, because they follow a fifteen-month cycle.

Some penguins nest on the shore and others travel many miles inland to reach their rookeries, and they return to the same ones each year. Penguins are social, and one rookery may have thousands of penguins in closely spaced nests. They often squabble over nesting materials, mates, and territory. Nests are built of grass or stones on the ground, in rock crevices, or in burrows. The male engages in an ecstatic display to attract a female, pointing his beak, flapping his flippers, and squawking. Penguins usually mate for life, and in subsequent years the pair will greet each other affectionately. Two eggs are laid, and the parents take turns incubating for a few weeks at a time while the other leaves to feed. The incubating parent does not eat, and often loses a great deal of weight. Each penguin has a brood patch, an area of bare skin on its

Penguin Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Subphylum: Vertebrata
Class: Aves
Order: Sphenisciformes (penguins)
Family: Spheniscidae
Genus and species: Six genera and twenty-five species, including *Eudyptes chrysocome* (rockhopper penguin), *E. pachyrhychus* (fiordland penguin), *E. robustus* (Snares penguin), *E. sclateri* (erect-crested penguin), *E. chrysolophus* (macaroni penguin), *E. schlegeli* (royal penguin); *Spheniscus magellanicus* (Magellanic penguin), *S. humboldti* (Humboldt penguin), *S. mendiculus* (Galápagos penguin), *S. demersus* (African penguin); *Pygoscelis adeliae* (Adelie penguin), *P. antarctica* (chinstrap penguin), *P. papua* (gentoo penguin); *Aptenodytes patagonicus* (king penguin), *A. forsteri* (emperor penguin); *Megadyptes antipodes* (yellow-eyed penguin); *Eudyptula minor* (fairy penguin)

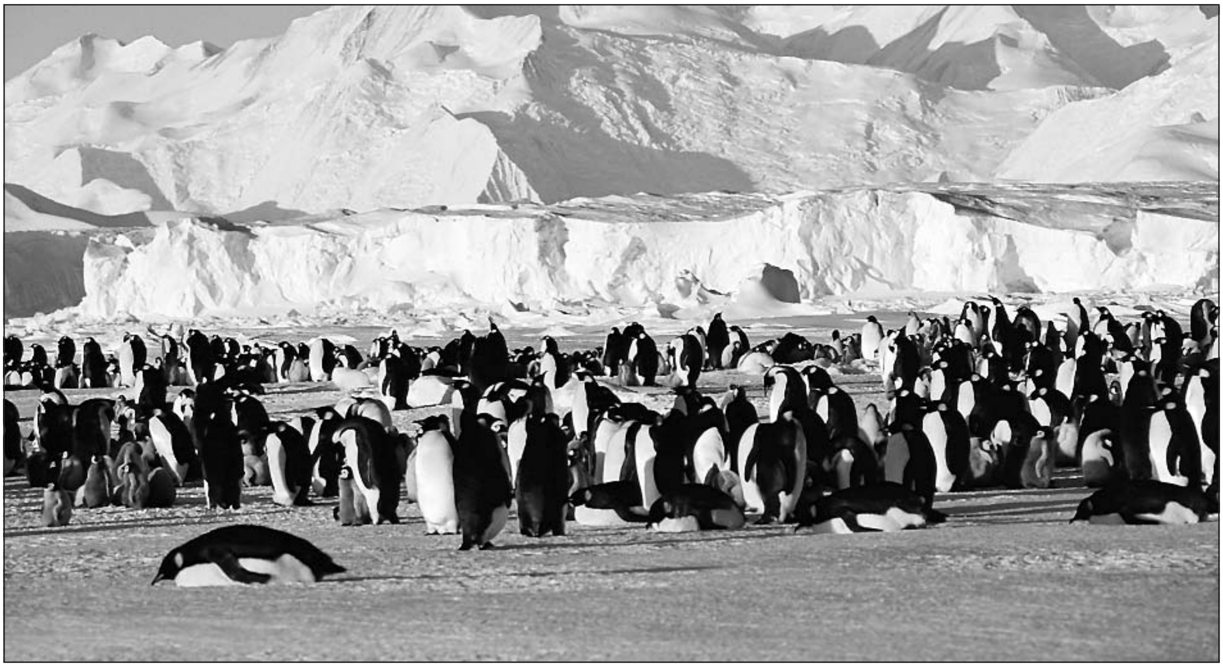
Geographical location: Along the coasts of Antarctica, Australia, New Zealand, South Africa, Chile, Peru, Argentina, and the Galápagos Islands

Habitat: Oceans and coasts in both cold and temperate latitudes

Gestational period: Incubation varies by species from thirty-three to sixty-four days

Life span: Twenty to thirty years

Special anatomy: Aerodynamic body shape; flippers; webbed feet; short, stiff, overlapped feathers; spiked tongue



The penguin's black-and-white coloration serves as camouflage, with the white underbelly making the swimming penguin difficult to locate from underneath while its black back blends into the water when seen from the top. (Digital Stock)

lower belly, that allows for better heat transfer to the eggs. Incubation varies from five weeks for the small fairy penguin to nine weeks for the emperor.

The king and emperor penguins are exceptions to the nesting rule. They lay only one egg, which they cradle on their feet instead of building a nest. They cover it with a flap of skin to keep it warm. Kings take turns incubating, while with emperors, only the male incubates.

Chicks are born down-covered, except for emperor chicks, which are naked. The parents brood them while they are young and feed them regurgitated food. When the chicks get too large for brooding, they huddle in crèches while the parents leave to hunt for food. When the chicks are grown and go off on their own, the parents molt. They cannot go into the water without their full coats of feathers, so they fast during this two- to four-week period.

pH MAINTENANCE

Type of animal science: Physiology
Field of study: Biochemistry

The maintenance of pH, which means "potential of hydrogen," is the regulation of acidity in the body fluids of animals; pH is the measure of acidity. Conditions that are too acidic or are not acidic enough will alter proteins such as enzymes and render them less effective. It is, therefore, vital that living organisms maintain proper acidity in body fluids.

Principal Terms

ACIDOSIS: a body fluid pH of less than 7.4 at 37 degrees Celsius

ALKALOSIS: a body fluid pH greater than 7.4 at 37 degrees Celsius, the opposite of acidosis

ANAEROBIC METABOLISM: metabolism in the absence of oxygen that leads to the production of lactic acid, a strong acid

PARTIAL PRESSURE: the pressure exerted by a specific gas in a mixture of gases such as the atmosphere; it is analogous to concentration

PH: the negative logarithm of the hydrogen ion concentration, with higher hydrogen ion concentrations indicating lower pH; the pH scale goes from 0 to 14, with a pH of 7 being neutral, values below 7 indicating acidity, and values above 7 indicating alkalinity

STRONG ACID: an acid that dissociates almost completely into its component ions; hydrochloric acid, for example, dissociates almost completely into hydrogen ions and chloride ions

WEAK ACID: an acid that does not dissociate to a great extent; carbonic acid, for example, dissociates to produce some ions, but most of the molecules remain in their original forms

The maintenance of pH is a collection of processes that regulate the hydrogen ion concentration of body fluids. The total body fluids account for about 60 percent of body mass. The body fluids are divided into several compartments. The largest volume of body fluid is in the intracellular compartment, and this consists of about 40 percent of body mass. The extracellular fluid consists of interstitial fluid (about 15 percent of body mass) and several specialized compartments. The largest of the specialized compartments is the vascular space, or blood volume. About half of the blood volume is in blood cells that belong to the intracellular volume. The other half is plasma, which makes up about 5 percent of the body mass. There are several other small extracellular spaces, such as the cerebrospinal fluid and the aqueous and vitreous humors of the eyes, that comprise smaller percentages of the extracellular volume. Each of these compartments is regulated in order to maintain normal pH. The pH levels of the different compartments can be very different. In mammals, the extracellular pH as measured in the plasma is generally 7.4. The specialized fluids within the extracellular compartment can differ. For example, the cerebrospinal fluid has a pH of 7.32. Intracellular pH can vary from cell type to cell type but tends to be lower than extracellular pH. For example, skeletal muscle has an intracellular pH of 6.89, while red blood cells have a pH of 7.20.

pH Maintenance

The first line of defense in the maintenance of pH is through the use of chemical buffers. Buffers are chemicals that resist pH change by absorbing hydrogen ions from acidic solutions or contributing hydrogen ions to alkaline solutions. They are made by producing a mixture of a weak acid and the salt of a weak acid. An example of a buffer is given by the bicarbonate buffer system. The components are H_2CO_3 (weak acid) and $NaHCO_3$ (salt of the weak acid). When a strong acid such as HCl is added to a solution containing this buffer pair, the H^+ released from the highly dissociated HCl combines with HCO_3^-; that is completely dissociated from the $NaHCO_3$ to form weakly dissociated H_2CO_3. This prevents the large pH drop that would otherwise occur because the H_2CO_3 is a weak acid. This buffer system is primarily extracellular. The body fluids also contain intracellular buffer systems which can resist pH changes when acids are introduced.

Acids can be introduced in several ways. Exercise and oxygen deprivation cause a buildup of lactic acid as a result of anaerobic metabolism. Metabolism of sulfur-containing amino acids causes the production of sulfuric acid, another strong acid. Both aerobic and anaerobic metabolism cause the buildup of carbon dioxide, which combines with water to form carbonic acid; even though this is a weak acid, the large accumulation of carbon dioxide can lower pH.

Acids produced by any of these means are buffered by one of the buffer systems in the body. In addition to the bicarbonate ($NaHCO_3$) buffer system described above, there are two intracellular buffers that participate in pH maintenance. In the phosphate buffer system, monosodium phosphate (H_2NaPO_4), a weak acid, dissociates to produce H^+ and $HNaPO_4^-$. The H^+ is exchanged for Na^+ by the kidneys or buffered on protein, leaving the salt disodium phosphate (HNa_2PO_4). This salt dissociates into Na^+ and $HNaPO_4^-$. The $HNaPO_4^-$ can then absorb H^+ ions which have dissociated from strong acids to form H_2NaPO_4, which is weakly dissociated. The phosphate buffer system is the least important of the buffer systems because there is so little phosphate in the body. The most important buffer system in the body is protein. Some of the individual amino acids in proteins can act as weak acids and accept H^+ ions; the amino acid histidine is the most significant of these under the temperature and pH conditions of the body. Protein buffering is primarily an intracellular phenomenon, as the protein concentration in extracellular fluid is relatively low. The intracellular protein buffer makes up about three quarters of the total body buffering capacity.

Acid-Base Disturbances

The most important extracellular buffer is the bicarbonate buffer system discussed above. This system is aided directly by a second line of defense against pH disturbances. This is called physiological buffering. Physiological buffering refers to the fact that the supply of the most important components of the bicarbonate buffer system, carbon dioxide and bicarbonate, can be controlled. The organs responsible for this control are the lungs (carbon dioxide) and kidneys (bicarbonate). For example, during exercise, the buildup of lactic acid consumes bicarbonate (HCO_3^-) and lowers pH. This is called a metabolic acidosis. The low pH stimulates the rate of breathing, which in turn results in increased elimination of carbon dioxide by the lungs. This lowers the partial pressure (concentration) of carbon dioxide in the blood, reducing the amount of carbonic acid (H_2CO_3) that can dissociate to form H^+. The reduction of carbon dioxide is called a respiratory alkalosis. This respiratory alkalosis compensates for the metabolic acidosis caused by the depletion of bicarbonate. The kidneys provide the final correction for the initial metabolic acidosis. These organs accomplish this in two ways: reabsorption of bicarbonate, and secretion of H^+ into the urine in exchange for Na^+. When bicarbonate concentration in the extracellular fluid is reduced by a metabolic acidosis, the hormone aldosterone, produced by the adrenal glands, stimulates the secretion of H^+ and reabsorption of bicarbonate. This raises both the pH and bicarbonate concentration back to normal. The increased pH relaxes stimulation of breathing, allowing breathing rate to slow and the partial pressure of carbon dioxide to return to normal.

The above is an example of one of the four basic types of acid-base disturbance: metabolic acidosis (bicarbonate concentration reduced), metabolic alkalosis (bicarbonate concentration increased), respiratory acidosis (an increase in the partial pressure of carbon dioxide), and respiratory alkalosis (a decrease in the partial pressure of carbon dioxide). As before, metabolic acidosis is compensated for by respiratory alkalosis. This is part of a general pattern in which one condition is compensated for by the opposite condition. Another example would be a respiratory acidosis, lowering the pH and stimulating bicarbonate retention and H^+ excretion in the kidneys to produce a compensatory metabolic alkalosis.

Body Temperature and Ion Exchange

Temperature also affects pH. This is usually of no consequence to warm-blooded animals such as mammals and birds, which have a constant body temperature. It is, however, of great consequence to cold-blooded animals such as fish, amphibians, and reptiles, in which body temperatures vary with the environmental temperature. There is a decrease in pH by about 0.015 for each degree increase in temperature. This means that the pH at 5 degrees Celsius is 7.88, or 0.48 pH units higher than at mammalian body temperature (pH 7.40 at 37 degrees Celsius). This does not mean that cold-blooded animals do not regulate pH. While the regulation differs from that of warm-blooded animals in that pH varies, it is still regulated in the sense that it varies in a very predictable manner. By controlling partial pressures of carbon dioxide and bicarbonate ion concentrations in much the same way that mammals do, cold-blooded vertebrates maintain their body fluid pH at a constant 0.6 to 0.8 pH units higher than the pH of pure water at the same temperature. It is, thus, the relative alkalinity that is regulated, rather than the pH.

While the kidneys of mammals are intimately involved in pH maintenance, the situation in lower vertebrates can be much different. Most fish use ion exchange transport systems in their gills to regulate pH. Specialized cells in the exterior lining of the gill surfaces transport sodium ions (Na^+) from the water bathing the animals into the blood in exchange for H^+. Similarly, chloride ions (Cl^-) are transported into the animal in exchange for HCO_3^-. When fish become acidotic, they increase Na^+/H^+ exchange and decrease Cl^-/HCO_3^- exchange. This results in a net elimination of H^+ and a net conservation of HCO_3^- to elevate the pH of the body fluids. While the kidneys of fish do participate in pH maintenance, they seem to play only a minor role, usually about 5 percent of the total regulatory effort. The kidneys of amphibians also appear to play a minor role in pH maintenance. The major regulatory organs in these animals are the skin and urinary bladder. Aquatic salamander larvae increase Na^+/H^+ exchange and decrease Cl^-/HCO_3^- exchange across their skin to regulate internal pH. Toads, which are primarily terrestrial and thus seldom in contact with water, appear to use their urinary bladders for pH regulatory ion exchanges. Relatively little is known about the role of the reptilian kidney in pH maintenance. The alligator kidney plays a major role in acid elimination. The urinary bladder of turtles also participates in pH regulation in much the same manner as the urinary bladder of the toad. The bird kidney plays a major role in pH maintenance, and its urine pH values are similar to the pH values of mammalian urine.

Studying pH Maintenance

The regulation of pH is usually studied by measuring the pH and the partial pressure of carbon dioxide of the blood. This measurement of the regulation of extracellular pH is a reflection of the overall acid-base status of the individual being studied. The first requirement is to be able to sample blood from an undisturbed, resting subject. This usually means an indwelling arterial cannula, through which blood from an artery can be sampled. The blood is then injected into a chamber in a blood-gas analyzer containing a glass pH electrode that measures the pH of the plasma. Additional blood is injected into another chamber that contains oxygen and carbon dioxide electrodes that measure the partial pressures of these two gases. Bicarbonate concentration can be calculated from the mathematical relationship among pH, the partial pressure of carbon dioxide, and the bicarbonate concentration when the former two are known. When making these kinds of measurements, it is important to measure the pH and partial pressure of the blood at the same temperature as the animal. Thermostated electrodes are used for this. The calculation used to estimate bicarbonate concentration requires the use of two constants which are also temperature-dependent. It is important to use the constants that are appropriate to the temperature of the animal and the measurement conditions.

Alternatively, bicarbonate concentration can be approximated by measuring the total amount of carbon dioxide (the sum of the carbon dioxide, carbonic acid, bicarbonate, and carbonate concentrations). Under physiological conditions, more than 99 percent of the carbon dioxide is in the form of HCO_3^-. When strong concentrated acid (HCl) is added to a measured volume of blood or plasma, all the carbonic acid, bicarbonate, and carbonate are released as carbon dioxide. This carbon dioxide can then be measured with a carbon dioxide electrode. The resulting total carbon dioxide, minus the concentration of carbon dioxide measured before adding the HCl, is very close to being equal to the concentration of bicarbonate.

While there are a number of indirect methods for measuring intracellular pH, the best results are achieved directly with micro pH electrodes which can be used to impale single cells. These techniques must be done on isolated tissues or anesthetized, restrained animals, whose acid-base status does not, in the least, resemble that of resting, undisturbed animals. The techniques are useful for studying pH maintenance at the cellular level and useful extrapolations can be made to the whole animal.

The usual approach to the study of pH maintenance is to induce a disturbance in the pH of an experimental animal and then to follow changes in the pH, partial pressure of CO_2, and the concentration of HCO_3^- in the blood. Breathing rates and volumes of air exchanged by the lungs can be measured to determine the contribution of the lungs to pH maintenance. For example, increasing the rate of breathing will increase the rate of elimination of carbon dioxide and lower the partial pressure of this gas in the blood. Urine collection can be done to assess the contribution of the kidneys to pH maintenance, and in aquatic animals that do not rely heavily on their kidneys for pH maintenance, changes in the composition of the water in which the animals are situated can be used to assess the contribution of the gills (fish) or skin (amphibians) to pH maintenance.

Examples of experimental manipulations that can produce pH disturbances in animals include infusion of acids and bases into the blood to produce metabolic acidosis and alkalosis respectively. Alternatively, animals can be exercised to elevate lactic acid in their blood to produce a metabolic acidosis. Respiratory acidosis and alkalosis can be induced by artificially altering breathing rates. Alternatively, elevation of the partial pressure of carbon dioxide in the air or water of an experimental animal will produce a respiratory acidosis.

pH Maintenance and Homeostasis

Maintenance of pH is part of the overall phenomenon of homeostasis or constancy of the internal environment in a changing external environment. The primary reason for maintaining consistent acid-base balance is the need to keep constant the conformation (shape) of proteins. Proteins are very sensitive to changes in pH, and the usual consequence of such changes is a change in the shapes of proteins. Protein conformation is critically important to proper protein function.

All enzymes (proteins that cause necessary biochemical reactions to occur) have very specific shapes that must be maintained in order for them to function properly. Changes in pH cause alterations in those shapes and compromise the effectiveness of the enzymes. Many other proteins require certain conformational states. Cell membranes contain proteins that determine which chemicals can enter and leave the cell's interior. These proteins are called carriers if they actively transport specific substances into or out of the cell interior. Alternatively, membrane proteins can act as specific channels that allow passive movement of only specific molecules or ions across the membrane. Both carriers and channels are sensitive to pH-induced conformational changes. There are other membrane-bound proteins called receptors that respond best to hormones and other chemical messengers when the pH is maintained at the norm. Proteins in the immune system, such as antibodies, also require proper pH in order to function optimally.

Cold-blooded animals do not regulate their pH to a specific point, but instead regulate the difference between their pH and the pH of pure water at the same temperature. This relative alkalinity ensures constant protein conformation in the same way that constant pH at constant temperature ensures constant protein conformation in warm-blooded animals, because the weak acid nature of proteins causes them to be partially dissociated from H^+ in the pH and temperature range experienced by animals. The conformation of protein is determined, to a large extent, by the net electrical charge (distribution of + and – charges over the protein). The net charge is influenced by the degree of dissociation of the protein and H^+. As discussed above, the dissociation in protein that is important to pH maintenance is the dissociation of H^+ from histidine. As long as the dissociated fraction of histidine remains constant, the protein conformation will remain constant. As long as the relative alkalinity is maintained, the fractional dissociation of histidine remains constant and thus protein conformation does not change. In reality, the regulation of mammalian pH at 7.4 (at 37 degrees Celsius) is one specific example of this general rule. The relative alkalinity of mammalian blood at 37 degrees is the same as the relative alkalinity of fish blood at 5 degrees or of reptile blood at 42 degrees.

Bibliography

Berne, R. M., and M. N. Levey. *Principles of Physiology*. 3d ed. St. Louis: C. V. Mosby, 2000. An introductory-level text on systemic physiology that presents the physiology of the lungs and kidneys in a straightforward, nonmathematical way. There is also a section on acid-base balance that will be useful to the beginning student. The major emphasis of the book is regulation.

Davenport, Horace W. *The ABC of Acid-Base Chemistry*. 6th ed. Chicago: University of Chicago Press, 1974. Although the title refers to chemistry, the subject matter is the chemistry of body fluids pertaining to pH regulation. This is an excellent quantitative approach to the understanding of pH maintenance in detail. It is the introductory text of choice for the student wishing to explore further the intricacies of acid-base balance.

Heisler, N., ed. *Acid-Base Regulation in Animals*. Amsterdam: Elsevier, 1986. This is a very detailed survey of acid-base balance in all groups of animals (as opposed to treatments dealing with mammalian-human species). It is extremely comprehensive and contains the most complete bibliographic information available on acid-base balance. It is appropriate for the advanced student.

Jacquez, John A. *Respiratory Physiology*. New York: McGraw-Hill, 1979. This is an advanced text on respiratory physiology. It is included here to provide a detailed reference to respiratory physiology topics which are central to acid-base balance. Of particular interest to the reader is the treatment of control of breathing rate by neural and chemical means.

Keyes, Jack L. *Fluid, Electrolyte, and Acid-Base Regulation*. Boston: Jones and Bartlett, 1999. An intermediate-level text dealing with pH maintenance and with an emphasis on medical aspects of fluid and acid-base balance and imbalance. There is a very clear explanation of the processes of ion-ion transport, which is useful in understanding the role of ion exchange in pH maintenance. Presents clinical case histories in a clear, understandable manner.

Lowenstein, Jerome. *Acid and Basics: A Guide to Understanding Acid-Base Disorders*. New York: Oxford University Press, 1993. A guide aimed at medical students and young physicians, but provides a good, basic guide to the concepts for anyone with a background in chemistry and physiology.

Stewart, P. A. *How to Understand Acid-Base: A Quantitative Acid-Base Primer for Biology and Medicine*. New York: Elsevier, 1981. An advanced text that derives the basis of acid-base balance in terms of ion balance in general. This is a controversial book that looks at pH maintenance from a very different perspective. In this treatment, H+ transport is considered not to exist and all changes in pH result from changes in the distribution of so-called strong ions such as sodium, potassium, calcium, magnesium, and chloride.

Valtin, Heinz. *Renal Function: Mechanisms Preserving Fluid and Solute Balance in Health*. 3d ed. Boston: Little, Brown, 1995. This book is primarily about the function of the kidneys. It gives one of the clearest presentations of their role in pH maintenance available. The section on pH maintenance in general will also be useful to the intermediate reader.

PHEROMONES

Type of animal science: Physiology
Fields of study: Ecology, ethology, evolutionary science, invertebrate biology

Pheromones are chemicals or mixtures of chemicals that are used as messages between members of a species. They are integral parts of the social communication within most species. They may prove to be of great value in pest control and in enhancing agricultural production.

Principal Terms

ALLELOCHEMIC: a general term for a chemical used as a messenger between members of different species; allomones and kairomones are allelochemics, but hormones and pheromones are not

ALLOMONE: a chemical messenger that passes information between members of different species, resulting in an advantage to the sender

KAIROMONE: a chemical messenger that passes information between members of different species, resulting in an advantage to the receiver

PRIMER PHEROMONE: a chemical that generates an often subtle physiological response in another member of the same species; a behavioral response may follow

SEMIOCHEMICAL: a chemical messenger that carries information between individual organisms of the same species or of different species; pheromones and allelochemics are semiochemicals, but hormones are not

VOLATILES: chemical compounds that are vapor or gas at environmental temperatures or that readily release many of their molecules to the vapor phase

Pheromones are chemical signals. Originally defined to include only signals between individuals of the same animal species, the term has been generalized to designate any chemical or chemical mixture that, when released by one member of any species, affects the physiology and/or behavior of another member of the same species. "Pheromone" is one of a set of terms developed to express the chemical interactions in ecological communities, and it can best be understood in the context of that set of terms.

In this context, pheromones are semiochemicals that carry information between members of a single species. To do so, the pheromone must be released into the atmosphere or placed on some structure in the organism's environment. It is thus made available to other members of the species for interpretation and response. It is also available to members of other species, however, so it is a potential allelochemic.

For example, klipspringer antelope mark vegetation in their environment with a chemical secreted from a special gland. Other klipspringer investigate the marks to gather information on the marking individual. Ticks that parasitize the klipspringer, however, are also attracted to the chemical marks and thus increase their chance of attaching to a host when the mark is renewed or when another klipspringer investigates it. The tick is using the pheromone as a kairomone. Pheromones can act as allomones as well, though the interaction is sometimes less direct. Bolas spiders produce the sex-attractant pheromone of a female moth and use it to lure male moths to a trap. The spider uses the moth pheromone as an allomone.

To appreciate fully the complexity of the interactions under consideration, it is important to remember that a pheromone may also be acting as a kairomone, allomone, or hormone. There are two general types of pheromone: those that elicit an immediate and predictable behavioral response, called releaser or signal pheromones, and those that bring about a less obvious physiological response, called primer pheromones (because they prime the system for a possible behavioral response). Pheromones are also categorized according to the messages they carry. There are trail, marker, aggregation, attractant, repellant, arrestant (deterrent), stimulant, alarm, and other pheromones. Their functions are suggested by the terms used to name them.

Pheromone Composition and Function

The chemical compounds that act as pheromones are numerous and diverse. Most are lipids or chemical relatives of the lipids, including many steroids. Even a single pheromonal message may require a number of different compounds, each present in the proper proportion, so that the active pheromone is actually a mixture of chemical compounds.

Different physical and chemical characteristics are required for pheromones with different functions. Attractant pheromones must generally be volatile to permit atmospheric dispersal to their targets. Many female insects emit sex-attractant pheromones to advertise their readiness to mate. The more widely these can be dispersed, the more males the advertisement will reach. On the other hand, many marking pheromones need not be especially volatile because they are placed at stations which are checked periodically by the target individuals. The klipspringer marking pheromone is an example. Some pheromones are exchanged by direct contact, and these need not have any appreciable volatile component. Many mammals rub, lick, and otherwise contact one another in social contexts and exchange pheromones at these times.

Specificity also varies for pheromones with different functions. Sex attractants usually need to be very specific, directed only to members of the opposite sex and the same species. Alarm pheromones, on the other hand, need not be so specific. These pheromones simply alert other members of the same species to a disturbance. It is usually harmless, and sometimes even helpful, to alert members of other species as well. In keeping with this argument, related groups of ant species produce species-specific sex-attractant pheromones: Each female attracts only males of its own species. In contrast, alarm pheromones of any species in the group will stimulate defensive reactions in individuals in many of the species.

Pheromonal systems are not organized in any standard way in different species. Many mites and ticks also have nonspecific alarm pheromones. Surprisingly, some groups also have nonspecific sex-attractant pheromones. In these cases, the specificity necessary for reproductive efficiency is generated by species-specific mating stimulant pheromones. These pheromones are produced by a female after males have been attracted to her. They stimulate mating behavior, but only in males of the same species. Thus the required specificity is achieved by a different mechanism. This is only one of many examples of the diversity of pheromonal schemes among organisms.

Pheromone Sources and Receptors

The sources of pheromones are also diverse. Some pheromones are produced by specialized glands; many insect species have glands specialized for the production of pheromones. One example is the harvester ant's alarm pheromone, which is produced in the mandibular gland at the base of the jaws. Other pheromones seem to be byproducts of other bodily functions. The lipids of mammalian skin are probably primarily important in waterproofing and in maintaining the outer layer of the skin, but many also function as pheromones.

The reproductive tract is an important source of pheromones in many species. These usually act as sex-attractant or sex-stimulant pheromones or as signal pheromones that give information on the sexual state of the emitter. The urine and feces of many species also contain pheromones which are used to mark territory boundaries and to transmit other information about the marking individual. Many pheromones seem to be produced not by the sending organism alone but by microorganisms living on the skin or in the glands or cavities of the sender's body. These microbes convert products of their host into the actual signal molecules, or pheromones, used by the host.

The receptors for pheromones are also of many different types, and the chemical receptors for taste and smell are often involved. In vertebrates, the vomeronasal organ (Jacobson's organ) seems to be an important receptor for many pheromones. It is a pouch off the mouth or nasal passages, and it contains receptors similar to those for smell. It is nonfunctional in humans, but it functions in more primitive mammals and seems to be of great importance to snakes and other reptiles. Insects and other invertebrates have many specialized structures for receiving pheromonal messages. Perhaps the best-known example is the feathery antennae of many male moths, which are receptors for the female moth's sex-attractant pheromone. Some pheromones seem to be absorbed through the skin or internal body linings and to bring about their effects by attaching to some unknown internal receptor.

Pheromones are widespread in nature, occurring in most, if not all, species. Most are poorly understood. The best-known are those found in insects, partly because of their potential use in the control of pest populations and partly because the relative simplicity of insect behavior allowed for rapid progress in the identification of pheromones and their actions. Despite these advantages, much remains to be learned even about insect pheromones. Mammalian pheromones are not as well known, although they may also be of economic importance. The more complex behavior of mammals makes the study of their responses to pheromones much more difficult.

Behavioral and Chemical Research

Both behavioral and chemical techniques are required in order to study pheromones and other semiochemicals. The observation of behavior, either in nature or in captivity, often suggests pheromonal functions. These hypothesized functions are then tested by presenting the pheromone to a potentially responsive organism and observing the response. Situations may be arranged which demand the subject's response to a particular pheromone under otherwise natural conditions. Alternatively, the organisms may be observed in enclosures to help control the experimental context. The presentation of the hypothetical pheromone may be in the form of another organism of the same species or some structure to which the presumed pheromone has been applied. The observed response (or lack of response) gives information on the status of the presented chemical as a pheromone in that behavioral context.

While the pheromonal function of secretions from a gland or other source can be determined from these behavioral tests, the tests can give information on specific chemical compounds only if the compounds can be isolated and identified. The isolation and identification of pheromonal compounds are challenging because of the great complexity of the secretions in which they are found and the exceptionally small amounts that are required to elicit a response. Many separation and identification techniques are used. One of the most powerful is a combination of gas chromatography and mass spectrometry.

Gas chromatography is used to separate and sometimes to identify chemicals that are volatile or can be made volatile. The unknown chemical is mixed with an inert gas, called the mobile phase of the gas chromatography system. This mixture is passed through a tube containing a solid, called the stationary phase. The inert gas does not interact with the solid; however, many of the compounds mixed with it do, each to an extent determined by the characteristics of the compound and the characteristics of the stationary phase. Some members of the mixture will interact very strongly with the solid and so move slowly through the tube, whereas others may not interact with the solid at all and so pass through rapidly. Other members of the mixture interact at intermediate strengths and so spend intermediate amounts of

Image Not Available

time in the tube. The different compounds are recorded and collected separately as they exit from the tube.

For identification, the compounds are often passed on to a mass spectrometer. In mass spectrometry the compound is broken up into electrically charged particles. The particles are then separated according to their mass-to-charge ratio, and the relative number of particles of each mass-to-charge ratio is recorded and plotted. The original compound can usually be identified by the pattern produced under the specific conditions used. After separation and identification, the individual chemicals may be subjected to behavioral studies.

Uses for Pheromones

Pheromones and other semiochemicals are of interest simply from the standpoint of understanding communication between living things. In addition, they have the potential to provide effective, safe agents for pest control. The possibilities include sex-attractant pheromones to draw pest insects of a particular species to a trap (or to confuse the males and keep them from finding females) and repellant pheromones to drive a species of insect away from a valuable crop species. One reason for the enthusiasm generated by pheromones in this role is their specificity. Whereas insecticides generally kill valuable insects as well as pests, pheromones will often be specific for one or a few species.

These chemicals were presented as a panacea for insect and other pest problems in the 1970's, but most actual attempts to control pest populations failed. Many people in the field have suggested that lack of understanding of a particular pest and its ecological context was the most common cause of failure. They maintain that pest-control applications must be made with extensive knowledge and careful consideration of pest characteristics and the ecological system. In this context, pheromones have become a part of integrated pest management (IPM) strategies, in which they are used along with the pest's parasites and predators, resistant crop varieties, insecticides, and other weapons to control pests. In this role, pheromones have shown great promise.

Some consideration has been given to the control of mammalian pests with pheromones, though this field is not as well developed as that of insect control. Pheromonal control of mammalian reproduction has received considerable attention for other reasons: Domestic mammals are of great economic importance, and many wild mammalian species are endangered to the point that captive breeding has been attempted. The manipulation of reproductive pheromones may be used to enhance reproductive potentials in both cases. The complexity of mammalian behavioral and reproductive systems, however, and the subtle changes brought about by mammalian pheromones present a particular challenge. As with insect pest control, the key to progress is a complete understanding of the entire system being manipulated.

Pheromones and other semiochemicals are of great potential economic importance as substitutes for or adjuncts to toxic pesticides in pest management. Mammalian reproductive pheromones are being explored as tools to enhance reproductive efficiency in domestic and endangered mammals. A complete understanding of the complex roles of pheromones in each of the systems being managed is necessary for success in all these endeavors.

Mayer, Marion S., and John R. McLaughlin. *Handbook of Insect Pheromones and Sex Attractants*. Boca Raton, Fla.: CRC Press, 1991. Encyclopedic coverage of the chemical composition of insect mating pheromones, written from the perspective of agricultural pest control.

Mitchell, Everett R., ed. *Management of Insect Pests With Semiochemicals: Concepts and Practice*. New York: Plenum, 1981. Addressed to pest management professionals, but much is accessible to nonspecialists. Contains forty articles on insect pest-control efforts and experiments. Boll weevil, gypsy moth, spruce budworm, bark beetles, southern pine beetles, and other pests are considered. Population monitoring, mass trapping, and mating disruption are the management techniques featured. Articles are generally good, and many references are given after each article. Cumulative index.

Mittler, Thomas E., Frank J. Radovsky, and Vincent H. Resh, eds. *Annual Review of Entomology*. Vol. 46. Palo Alto, Calif.: Annual Reviews, 2000. Written for entomologists, but most articles are accessible to nonspecialists. Each article lists many references, and each volume is well indexed.

Nordlund, Donald A., Richard L. Jones, and W. Joe Lewis, eds. *Semiochemicals: Their Role in Pest Control*. New York: John Wiley & Sons, 1981. Addressed to scientists, but accessible to nonspecialists. Fourteen review articles cover history, terminology, allelochemics, pheromones, chemistry, and evolution. Each chapter lists references. Well indexed.

Vandenbergh, John G., ed. *Pheromones and Reproduction in Mammals*. New York: Academic Press, 1983. Written for both the general reader and the specialist. Nine articles review mammalian pheromones, including mother-young interaction, regulation of puberty and the ovarian cycle, pregnancy block, effect of pheromones on hormones, detection of pheromones, and use of pheromones to control reproduction in domestic animals. References after each chapter. Good index.

Wilson, Edward O. "Pheromones." *Scientific American* 206 (May, 1963): 100-114. An early summary article on the concept of pheromones. Pheromones of the fire ant are given most consideration, but human, mouse, cockroach, gypsy moth, and other pheromones are considered. Explores differences in volatility, longevity, and specificity among pheromones. Excellent.

PHYLOGENY

Type of animal science: Evolution
Fields of study: Anthropology, archaeology, evolutionary science, population biology, systematics (taxonomy), zoology

Phylogeny is the study of the evolutionary history of an animal or of groups of animals. It is the methodology that traces the lines of descent among living things and tries to classify them in some systematic order based on ancestry.

Principal Terms

DEOXYRIBONUCLEIC ACID (DNA): the genetic material of most living organisms
EVOLUTION: the process by which the variety of plant and animal life has developed over time from the most primitive to the most complex life-forms
KINGDOM: the highest category into which organisms are classified; there are now believed to be five kingdoms
MOLECULE: the smallest part of a chemical compound
PHYLUM: a group that consists of several closely related classes
SPECIES: a group of organisms that can produce offspring with each other

Phylogeny traces the history of life on earth through the study of how animals and plants have developed over time and how they are related to one another. It is similar to taxonomy, the science of classifying organisms based on their structure and functions. Taxonomists create family trees of living and extinct species in order to discover the origins and lines of descent of various forms of life. Very few family trees are complete to their fossil origins, however, because of gaps in the fossil record. The first system of classification was devised by the eighteenth century Swedish scientist Carolus Linnaeus. Linnaeus classified life-forms based on their appearance; the more they resembled each other in size, shape, and form, he believed, the more closely they were related.

The theory of evolution developed by nineteenth century naturalist Charles Darwin was based on accumulated changes over time through natural selection and led to a new way of looking at the history of life and to the development of phylogeny as a method of classification. The new system classified the living world by similarities in ancestry rather than appearance. Life histories of species were derived from the study of comparative anatomy (the search for common features in different species), embryology (the study of the development of life from the egg to birth), and biochemistry (the study of invisible chemical characteristics of cells that link species that can look very dissimilar). Modern technology allows scientists to measure differences in deoxyribonucleic acid (DNA) molecules among species. DNA carries the genetic material of an organism and plays a central role in heredity. The degree of difference between two species helps scientists determine how much modern species have changed from their ancestors and to estimate when important events in evolution occurred. If a sufficient fossil record exists, biochemists can determine the timing of a major change that led to the development of a new characteristic such as a longer neck in giraffes or a different size eyeball in a bat.

Classifying Earth's Species

Studies of evolutionary change suggest that anywhere from three million to twenty million species now exist, with millions more having become extinct. The earth began about 5 billion years ago, and it has been occupied by living organisms for about 3.5 billion years. For about 2.5 billion years, the planet was populated only by single-celled bacteria. The earliest forms of life evolved by chance during a long period of chemical reactions. Random encounters between chemicals in the seas and the atmosphere produced amino acids and proteins. Small drops of proteins, made up of carbon, hydrogen, oxygen, nitrogen, and sulfur, somehow bound together and became organisms; that is, they began to reproduce themselves, which is the quality that makes them life-forms.

Every living thing is given a two-part Latin name under a system of binomial nomenclature. This name is usually based on an evolutionary, phylogenetic relationship. The first part of the name indicates the organism's genus; the second part identifies the specific species. For example, *Acer saccharum, Acer nigrum*, and *Acer rubrum* are all kinds of maple trees. They share the genus *Acer*, and their species names mean sugar, black, and red, respectively. No rules govern species names, though frequently they refer to a prominent feature such as color or characteristic, such as in the case of *Homo sapiens*, the Latin name for human beings, which literally means "the thinking one."

Of the five kingdoms of life-forms, one (containing the bacteria) is made up of prokaryotes; the other four are eukaryotes. Prokaryotes do not have cell nuclei; eukaryotes do. In prokaryotes, cells are smaller and simpler in structure, and the DNA is not organized into chromosomes. Chromosomes, the threadlike structures found in the cell nucleus of all eukaryotes, determine the characteristics of individual organisms, with offspring receiving an equal number of chromosomes from each parent. In bacteria, however, reproduction takes place by a simple division of the parent into two masses that eventually separate. Bacteria do not share chromosomes with other members of the species; in other words, reproduction is asexual.

The Nonanimal Kingdoms

All bacteria belong to the kingdom Prokaryotae. They are in terms of total numbers the most successful form of life in the universe. Some bacteria, which are germs, can cause disease, while some bacteria, such as antibiotics, can be used to cure disease. Bacterium-like fossils that were found in rocks from an Australian gold mine are about 3.5 billion years old. Bacteria are found in every climate and habitat, and are the first to invade and populate new habitats. Seventeen phyla of bacteria are known to exist, and none can be seen without a microscope.

The four other kingdoms of living things and the common names given to their most important phyla are Protoctista (algae, protozoa, slime molds), Fungi (mushrooms, molds, lichens), Animalia (sponges, jellyfish, flatworms, ribbon worms, rotifers, spiny-headed worms, parasitic nematodes, horsehair worms, mollusks, priapulid worms, spoon worms, earthworms, tongue worms, velvet worms, insects, beard worms, starfish, arrowworms, and chordates), and Plantae (mosses, ferns, and pine-bearing and flowering plants). Phyla are based on similarities in evolutionary development. Life-forms are divided into ninety-two phyla: There are seventeen phyla in the kingdom Prokaryotae; twenty-seven in Protoctista; five in Fungi; thirty-three in Animalia, and ten in Plantae. Each phylum is divided into classes, then orders, families, genera (the singular form is genus), and finally, species. The last two divisions are based on the most recent evolutionary differences. Some phyla have only a few genera and species, while others, such as those in Animalia, have millions. A species consists of a group of similar individual organisms that can breed and reproduce offspring. A genus contains similar species, but members of a genus cannot reproduce; only members of a species can.

Protoctista (also called Protista) means the "very first to establish." It is the kingdom made up of living forms that are neither animals, plants, nor fungi. It includes red, green, and brown algae, seaweeds, water and slime molds, and most protozoa (single-celled life-forms including amoebas). The twenty-seven phyla in this kingdom are found mostly in water habitats such as rivers, freshwater lakes, and oceans.

The kingdom Fungi (from a Greek word meaning "sponge") may have descended from the kingdom Protoctista. The oldest fossil Fungi are about 300 million years old. There are more than one hundred thousand identified species, including bread molds, yeasts, and mushrooms. Thousands more species are believed to exist but have yet to be identified.

The Animal Kingdom

All plants, from mosses to giant redwoods, belong to the kingdom Plantae (from a Latin word for "plant"), and most animals belong to the kingdom Animalia. This kingdom contains all multicellular, heterotrophic, diploid organisms that develop from an egg and sperm. A heterotrophic animal takes food into the body and digests it, or breaks it down, into energy for use. A diploid organism has two sets of chromosomes, one derived from the female parent and the other from the male. The characteristic that defines all Animalia, however, is that they develop from a blastula, a hollow ball of cells found in animal embryos (the earliest stage of development, when the egg just begins to divide) but not in plants. The blastula forms a layer around a central open space or cavity in the embryo.

Animalia (from a Latin word meaning "soul" or "breath") is the kingdom with the largest number of life-forms, from Placozoa, a phylum with a single species usually found growing on aquarium walls, to the phylum Arthropoda (from a Greek word meaning "jointed foot") that contains more than a half million identified species, including spiders, scorpions, beetles, shrimp, lobsters, crayfish, crabs, flies, centipedes, millipedes, butterflies, moths, and all other species of insects. Seventeen of the thirty-three phyla in Animalia are various kinds of worms found in the shallow and deep water of lakes, rivers, and oceans and in the ground. One worm phyla, Pentastoma, consists of more than seventy species that live exclusively in the tongues, lungs, nostrils, and nasal sinuses of dogs, foxes, goats, horses, snakes, lizards, and crocodiles. Another phyla, Platyhelminthes, consists of worms that live in bat dung and other equally unusual environments. Only two of the phyla, Arthropoda and Chordata (animals with nerve cords), live entirely on land. Among the phyla, Arthropoda has the largest number of identified species, more than a million, and possibly millions more not yet identified. Most of the species of Animalia that have ever lived are now extinct. Thirty-two of the thirty-three phyla are invertebrates, which means they lack backbones.

The History of Life-Forms

The phylogenetic method of classifying life, using animals as an example, begins with the earliest fossil records available. The earliest members of the Animalia kingdom evolved from members of the Protoctista kingdom about 565 million years ago. Exactly when and which members were the first is subject to debate; however, the first large, multicellular fossils date to this time. About 530 million years ago, there was a gigantic explosion of life-forms, including all kinds of clams, snails, arthropods, crabs, and trilobites. After a few tens of millions more years came echinoderms (starfish and sea urchins) and eventually chordates, out of which emerged fish and mammals.

The periods of explosive growth and massive extinction of life-forms are believed to have been caused by some major environmental changes, the exact nature and cause of which have not been determined. Scientists believe an explosion of new life could have been caused by an increase in atmospheric oxygen, which would allow life-forms to live out of water, and a mass extinction could have been the result of gigantic dust clouds, large enough to darken the sun's light for millions of years, stirred up by huge meteors crashing into earth. Such a critical darkening of the earth is believed to have taken place about sixty-five million years ago, plunging temperatures to near freezing and killing off thousands of species including all the dinosaurs.

The Phylum Chordata

Despite the tremendous losses resulting from the extinction of as much as 95 percent of the existing species, life-forms continued to survive and evolve. The most successful of the new forms emerged from the ancestors of the phylum Chordata (from a Latin word for "cord"). This phylum includes all mammals, birds, amphibians, reptiles, and species with backbones (vertebrates). More than forty-five thousand species of chordates exist. Three key features are used to classify members of the phylum. A member must have a single nerve cord along its back. In mammals, this cord has developed into the spinal cord and brain. It must also have a notochord, a bony rod located between the nerve cord and the digestive tract, which supports the body and the muscles and is found in the embryo and the adult. The last requirement is that members have gill slits in the throat at some stage of development, whether in the embryo stage as is true with land animals or throughout their entire life as in fish. Gill slits show that land animals developed from sea creatures.

The phylum Chordata includes two superclasses, Pisces (fish) and Tetrapoda (four-limbed forms). There are two classes of living Pisces, Chondrichthyes (boneless creatures), which includes sharks, skates, and rays, and Osteichthyes (bony fish), a class that contains about twenty-five thousand species. The earliest fish fossils are about 500 million years old. There are four classes in Tetrapoda: Amphibia, Reptilia, Aves, and Mammalia.

The class Amphibia contains about two thousand species of frogs, toads, and salamanders. Members of this class evolved about 370 million years ago and were the first vertebrates to live on land. Amphibia must lay their eggs in water and must live close to water, or their soft skin will dry out and cause their deaths.

The class Reptilia has more than five thousand species. It includes turtles, lizards, snakes, and crocodiles. Reptiles develop from an egg, live on land, and have dry, scaly skin. The largest reptiles, the dinosaurs, died out more than sixty million years ago. Reptiles are cold-blooded, which means they cannot control the temperature of their blood, they breathe air through lungs, and they are not required to lay their eggs in water. They probably evolved out of an amphibian species between 300 million and 320 million years ago.

The class Aves contains nine thousand species of living birds, with thousands more extinct. Aves evolved from dinosaur species perhaps 200 million years ago. Unlike reptiles, Aves class members have the ability to regulate their internal temperature. They have feathers rather than scales, but they lack teeth.

The fourth class is Mammalia, which has more than forty-five hundred living species, including human beings. Mammals are classed into Metatheria (marsupials) and Eutheria (placentals). Metatheria, such as kangaroos, have external pouches in which their young are born live. Eutheria have vaginas through which the fully developed young pass during birth. Most mammals are members of Eutheria. This includes the orders of Insectivora (hedgehogs, shrews, and moles), Primates (lemurs, monkeys, apes, and human beings), Carnivora (dogs, cats, and bears), and Pinnipedea (seals and sea lions.)

The Benefits of Classification

Life on earth includes millions of different types of organisms. Phylogeny is one method of making sense out of so many different life-forms. It provides a system that links organisms together on the basis of their evolutionary history of development. By grouping vast numbers of forms into related groups, phylogenetics helps bring some order to what seems like chaos. Attempts to classify life-forms have always been controversial, and there still is much disagreement in the scientific community over various types of classification. However, phylogeny is the most widely agreed upon system.

Developments in techniques used to analyze molecules and DNA in the 1980's have shed light on the evolutionary development of species and have demonstrated new links among living plants and animals. The information gleaned using these techniques can also be used to trace the ancestry of modern species back to the earliest fossil evidence available from 575 million years ago. Molecular comparisons have shown that the development of species from spores and eggs into embryos and adult stages is very similar across a wide range of phyla.

These techniques produce data that consist of long sequences of the four nucleic acids that make up the information contained in DNA. The patterns formed by the acids are very similar among related organisms. The more closely related the sequence of nucleic acids, the more closely the species are related. Closely related species differ only very slightly in the way their DNA is structured. The more species differ in their DNA structure, the more distant they are in evolutionary terms. By measuring and comparing the differences in a gene that controls basically the same function in various species, scientists can construct an evolutionary tree. Species can be placed on the tree at the points where they begin to diverge from other genus members. In this way, examinations of the phylogenetic development of organisms can be used to create a tree of life showing the close relationships among all organisms. The tree also shows that all forms of life are related because they originally came from the same source in some ancient pool where the right chemicals just happened to bump into one another, mix, and begin to produce offspring.

Bibliography

Copeland, Herbert F. *The Classification of Lower Organisms*. Palo Alto, Calif.: Pacific Books, 1956. The classic work by a biologist given credit for developing the current system of classification. It has many drawings of microscopic life-forms, and though old, is still useful because of the tremendous effort made by the author to revise the phylogenetic history of many species.

Gould, Stephen Jay. *Wonderful Life: The Burgess Shale and the Nature of History*. London: Vintage, 2000. A history of life on earth, that pays particular attention to the role of catastrophe in evolution. Tells how a major disaster destroyed 95 percent of life-forms some 65 million years ago. An interesting discussion of the problems of classification is included in this work by one of the best science writers and naturalists in the field. Contains an index and a useful bibliography.

Margulis, Lynn, and Karlene V. Schwartz. *Five Kingdoms: An Illustrated Guide to the Phyla of Life on Earth*. 3d ed. New York: W. H. Freeman, 1999. A very good source for the history of life. It contains a picture or drawing of each phylum of plants and animals in the five kingdoms. The illustrations and descriptions are clear and easy to understand. The discussion of each phylum includes an evolutionary history of its development and phylogeny. Includes a bibliography for each kingdom and phylum.

Romer, A. S. *The Vertebrate Story*. Chicago: University of Chicago Press, 1971. The best, most detailed evolutionary history of a subphylum of the phylum Chordata, out of which *Homo sapiens* (humans) developed. Good illustrations, a well-constructed family tree, and a good history of the classification debate.

Wilson, Edward O. *The Diversity of Life*. New York: W. W. Norton, 1992. A highly regarded zoologist discusses the history of life on earth and the many forms of life that have developed. Well-written with many drawings and charts that display the richness of animal and plant life. Describes how plants and animals evolved and discusses the current threat from environmental pollution to the future of living things. Contains a detailed index.

PHYSIOLOGY

Types of animal science: Anatomy, fields of study, physiology
Fields of study: Anatomy, developmental biology, embryology, evolutionary science, physiology, zoology

Physiology is a fundamental branch of biology, predating all disciplines except perhaps anatomy. Physiologists study the functions of living organisms. These functions are studied at many levels of organization: the molecular level, the cellular level, the tissue-organ level, and even the organismic (whole animal) level. The goal is to explain living functions in quantifiable terms that obey the laws of chemistry and physics.

Principal Terms

ARTERY: a blood vessel that carries blood from the heart to the body tissues

CAPILLARY: a small vessel that connects arteries to veins; this is where respiratory gases, nutrients, and wastes are exchanged between blood and tissues

GLOMERULUS: a specialized capillary in the kidneys that filters blood

NEPHRON: a tubular structure in the kidneys that extracts filtrate, and reabsorbs nutrients and other valuable substances and secretes wastes

NEURON: an individual nerve cell; nerves are made up of many neurons bundled together

VEIN: a blood vessel that returns blood to the heart

How animal bodies work is the subject of physiology. Early Greek philosophers such as Aristotle used deductive reasoning (the use of observations, logic, and intuition) to explain function. William Harvey (1578-1657) is generally considered the father of modern physiology, as he was among the first and most successful in employing inductive reasoning (experimentation) to explain body function. Inductive reasoning uses the scientific method to study unsolved problems. This approach starts with a hypothesis. Experiments are designed to test the hypothesis. Data are collected using quantified measurements; physiologists never simply say heart rate increased in response to the experimental treatment. The result is always expressed in quantified terms; for example, one might say that heart rate increased from thirty to forty-five beats per minute. Once the data are collected, they are analyzed and interpreted in terms of the original hypothesis. The interpretation usually leads to new hypotheses which are then tested with new experiments.

The Study of Systems

Classically, physiology has been divided into several organ systems. These include the neuromuscular system, the cardiovascular system, the pulmonary system (lungs), the renal system (kidneys), the digestive system, and the endocrine system. This nomenclature is based on mammalian systems and has had to be modified to include such alternative systems as gills (branchial system) in aquatic animals.

Physiology has been characterized as a synthetic science because it involves a synthesis of biology, chemistry, mathematics, and physics to describe body functions. The objective is to explain a given physiological function in terms which obey the laws of chemistry and physics. This often involves model building. A physiological model is a construct of hypotheses, which can be qualitative or quantitative. Harvey proposed a model in which the blood circulates from the heart to arteries, and then to capillaries which connect to veins to return the blood to the heart. He then did experiments to prove this. Quantitative or mathematical models are used to describe many functions using mathematical constructs and equations.

Physiology is studied at the molecular, cellular, tissue, organ, system, and organismic levels. There are several branches of physiology. Mammalian, fish, and insect physiologists restrict their studies to a certain group. General physiology seeks to describe functions that are common to all life forms, such as cell membrane function. Comparative physiology seeks to examine how different groups of animals accomplish similar goals while living in completely different circumstances, for example, in aquatic environments exchanging oxygen and carbon dioxide with water versus living on land and exchanging these respiratory gases with air.

Comparative studies are important for several reasons. First, the acquisition of each new piece of specific knowledge raises questions about its broader applicability. Once it is known that land animals need oxygen in air to breathe, the question arises: If a fish spends its entire life under water, why does it not drown? The answer is that it uses gills to extract oxygen efficiently from water (with a notoriously scarce oxygen supply) and to excrete carbon dioxide. Comparative physiology also helps to better understand evolution. The evolution of the vertebrate cardiovascular system from fish with two-chambered hearts, to amphibians and most reptiles with three-chambered hearts, to birds and mammals with four-chambered hearts, has attracted much interest in how the circulation of oxygen-rich blood is kept separate from oxygen-poor blood. Finally, comparative physiology can be used to study simple physiological systems in primitive animals such as invertebrates to help explain more complex systems in more advanced animals such as mammals.

Gaining Knowledge Through Experimentation

Our knowledge of how information is carried by neurons (the individual fibers of nerves) began with studies of squid neurons. Squid have giant neurons; they are so large that physiologists were able to insert electrodes inside them to discover the electrical events that produce nervous impulses and thus information transfer. Beyond this, the neurons are so large that it is possible to remove their contents and substitute artificial solutions to see how this alters neural impulse production. This is how it was discovered that the ions sodium and potassium are responsible for neural impulses. This research started in the 1920's, and developing technology has shown that mammalian neural function operates essentially the same way as squid neural function. Another example of such use of comparative physiology has led to the understanding of kidney function. In the early twentieth century, it was observed that kidney tubules in amphibians such as frogs and salamanders are large enough to allow samples of nephric tubular fluid to be removed and analyzed. Such studies led to the discovery that the initial event in urine formation is filtration of blood plasma in glomerular capillaries and that the final urine composition results from selective reabsorption and filtration of water and solutes in nephrons.

Physiology is a very interesting field that can prepare one for careers in teaching at all levels, basic research, or commercial research and development.

PIGS AND HOGS

Type of animal science: Classification
Fields of study: Anatomy, zoology

Pigs are social animals of the genus Sus, *living in family groups led by an older female and her offspring. The male likes to be alone except during the breeding season. The female will have between six and twelve babies at a time.*

Principal Terms

BARROW: a castrated male pig that has not produced any secondary sexual characteristics
BOAR: male pig
GILT: a young female pig that has not produced a litter
HOG: the general name applied to a pig over three months old
PORK: the meat of the pig used for food
SHOAT: an immature pig of either sex that weighs between 35 and 160 pounds
SOW: female pig that has produced a litter of babies
SWINE: the general name applied to the domesticated pig

Pigs are estimated to have evolved about 38 million years ago in central Europe, and about 25 million years ago to have become established in Africa and Asia. Pigs became domesticated in China about 5000 B.C.E. The reason for the delay in agricultural domestication is believed to be that pigs were unwilling to adapt to a nomadic lifestyle, as dogs, sheep, and goats did. The domesticated pig is thought to have descended from two different lines of wild hogs. It is believed that the East Indian pig (*Sus vittatus*) has had major influence on the swine of China and the surrounding region. The European wild boar has probably had major influence on the rest of the various breeds of pigs in the world.

The domestic pig is a compact, solid-looking animal with a large head, short, fast-moving legs, a rough coat, and a small tail. The color of a pig can vary greatly, from white or black to brownish-red, and any combination thereof, including spotted, solid colored, and banded. Some may reach a height of only twelve inches at the shoulder, others may reach all the way to four feet. The weight

Pig Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Theria
Order: Artiodactyla
Family: Suidae
Subfamily: Suinae
Genus: Sus
Geographical location: There are no true wild pigs in the Western Hemisphere, but there are feral hogs, except in Antarctica; the javelina, native to North and South America, is not a true pig; wild pigs are found in Southeast Asia and Eurasia
Habitat: Wide range, from swamps and rain forests to dry lands and mountains
Gestational period: A little less than four months (111-115 days)
Life span: Domestic pigs generally have a life span of from six to ten years, with an occasional occurrence of over twenty years
Special anatomy: Pigs have an excellent sense of smell and exceptional hearing, but their eyesight is weak

Image Not Available

of a pig also can vary, with some weighing only about 60 pounds, where others can go over 900. The average meat pig falls in the range from 225 to 300 pounds.

Humans use pigs in many different ways. From the point of view of the percentage of the carcass used, the pig is the most utilized of all domesticated animals. The hair is used for brushes because it is very strong, yet flexible. The hide is used for numerous products, from shoes to purses; in general it is lightweight and durable. The blood and offal are used for fertilizers, soaps, and medical supplies. Domestic pigs have been used by mankind for centuries as a main supplier of dietary protein.

Types of Pigs

Pigs are cloven-hoofed ungulates, and are closely related to the hippopotamus. As mentioned, the domestic pig (*Sus scrofa*) is now found worldwide. They are omnivorous, eating almost anything. However, pigs generally prefer to eat soft tissue plants, especially roots and tubers, which they dig up with their noses. They will also eat leaves, seeds, bugs, and anything that is found on the ground, including bird eggs, baby birds, snakes, and carrion.

There are hundreds of different breeds of pigs in the world. Most of the breeds that the various departments of agriculture recognize as major contributors to current swine production come from the United States or Europe. The pigs can be identified as being either meat, lard, or bacon types. Lard types have lost a great deal in numbers over the past fifty years, and have been bred into a style more like meat. The pig population in the world is large, and is approaching almost one billion in number, with China having the largest number, 250 million. Russia and the United States are tied in second place with about 60 million each. Brazil would be fourth with 35 million.

The largest consumer of pork per capita is Denmark (105 pounds annually), followed by Hungary, Germany, Austria, Luxembourg-Belgium, and the United States. In the United States, the state of

Iowa leads in production of hogs, followed by Illinois, Missouri, Indiana, and Minnesota.

Pigs are very smart domesticated animals. Their abilities are thought of as being greater than those of the domestic dog. Indeed, pigs make fine pets, as is evidenced by the pot-bellied pig of Southeast Asia.

PLACENTAL MAMMALS

Types of animal science: Development, reproduction
Fields of study: Anatomy, biochemistry, cell biology, embryology, physiology, reproductive science

Placental reproduction is the most common form of mammalian reproduction. All mammals except the marsupials (such as the kangaroo and opossum) and the monotremes (platypus and echidna) form placentas.

Principal Terms

CHORION: the outer cellular layer of the embryo sac of reptiles, birds, and mammals; the term was coined by Aristotle

EMBRYO: a young animal that is developing from a fertilized or activated ovum and that is contained within egg membranes or within the maternal body

ENDOMETRIUM: an inner, thin layer of cells overlying the muscle layer of the uterus

FETUS: a mammalian embryo from the stage of its development where its main adult features can be recognized, until birth

MATERNAL: referring to the female parent

OVUM: an unfertilized egg cell

UTERUS: in female mammals, the organ in which the embryo develops

VIVIPAROUS: producing young that are active upon birth (often referred to as live birth); the embryo is nurtured within the uterus

Monotremes are oviparous, or egg-laying mammals. Marsupials are ovoviviparous, meaning that the egg is large and has a yolk adequate to nourish the embryo during its early development, but it remains unattached to the wall of the uterus. Gestation in marsupials is necessarily short, therefore, and the young are born in an immature, fetal stage. They make their way to the mother's pouch and continue to grow, nourished by the mother's milk. All other mammals, termed placental, are viviparous. The small egg, lacking food substance, becomes attached to the uterine wall, and the developing embryo is nourished by the mother's blood passing through a placenta. This process allows longer gestation, and as a result the young are born in a more advanced (precocial) state of development.

The placental mammals form a diverse and successful group that includes the insectivores (such as shrews, hedgehogs, and moles), bats, sloths, anteaters, armadillos, primates (to which humans belong), rodents, rabbits, whales, dolphins and porpoises, carnivores (such as cats, dogs, and bears), seals, aardvarks, elephants, hyraxes, manatees, uneven-toed mammals (such as tapirs, horses, and rhinoceroses), and even-toed (cloven-hoofed) mammals such as pigs, camels, deer, sheep, cattle, and goats.

Placenta Structure

The term "placenta" comes from the Latin meaning "flat cake," and is used to describe the flat structure (in most animals) which attaches the developing embryo and fetus to the wall of the uterus. The term was first used in 1559 C.E., although knowledge of the placenta, at least in humans, goes far back into antiquity. Reference to it may be found in many ancient texts and drawings, including the Old Testament books of the Bible. Early Egyptians considered the placenta to be the seat of the external soul.

The placenta is the organ responsible for the transmission of materials between mother and fetus prior to birth—the only bridge between them. In many species, it has important endocrine functions, producing hormones necessary for development of the fetus or for maintenance of the pregnant state. It is essentially a product of both the developing ovum and the mother. The placenta is commonly referred to as the afterbirth, extruded from the mother's uterus at the end of the birth process.

When the ovum is released by the ovary and fertilized by sperm, it eventually comes to rest in the hollow cavity of the uterine horn (one of two chambers) or the uterus (single chamber). While it moves toward that area it begins to divide, forming a ball of cells known as a morula. As development continues, the ball becomes hollow, and it is then referred to as a blastocyst. Within this hollow blastocyst a few cells protrude into the cavity, forming a knob. These are the only cells that will eventually develop into the embryo and fetus. The rest of the cells are responsible for forming the supportive structures, including the chorion, the placenta, and the umbilical cord (which attaches the embryo to the placenta).

Among the eutherian (placental) mammals, a variety of placental configurations occurs. In many species the entire chorionic sac becomes connected to the uterine wall, and transfer of materials between the maternal and fetal compartments occurs over the whole surface. In other species, a much more specialized system develops. Here parts of the chorion (a membrane equivalent to the one that lines the shell of reptile and bird eggs) become highly specialized, establishing an intimate relationship with the uterine tissues. Thus, transfer of materials occurs only in one select region of the chorion, referred to as the placenta. It is these tissues, with their flattened, cakelike appearance, from which the name derives.

The most important feature of the placenta is the close contact between the fetal blood vessels in the placenta and the maternal blood vessels in the uterine wall. While it is a common misconception that the fetal and maternal blood mix or flow together, this is not a correct picture. What actually occurs is that the two blood systems come close to each other, at which point materials that can diffuse out of one vessel may diffuse into another. Thus, transfer of materials from mother to fetus, and vice versa, can occur. The closer the two blood pools come to each other, the better it is for transfer. Nutritional, respiratory, and excretory products are transferred.

Placenta Types

In the epithelio-chorial placenta, as found in the hoofed mammals (such as Artiodactyla and Perissodactyla), whales, and lemurs, the wall of the uterus retains its surface epithelium. The minimum separation of bloods is four cells thick (two epithelial cell layers and the endothelium of the blood vessels). Thus, it is vital to have a very large surface area to allow for adequate movement of materials. While this is a large improvement over the marsupial system, it is nonetheless 250 times less efficient at salt transfer than the placenta used by humans.

The separation between mother and fetus is reduced in carnivores and sloths. Here the chorion invades the uterine epithelium and comes in direct contact with the epithelium of the maternal blood vessels, allowing a more uniform transfer of materials. The most advanced form, showing minimal separation, is the hemo-chorial placenta, found in humans, rodents, bats, and most insectivores. Here the maternal blood vessel walls are chemically broken down and the invading chorion is now in direct contact with the maternal blood stream. Because this is so much more efficient for materials exchange, the size of the interacting surfaces can be much reduced.

In addition to the exchange of materials, the placenta plays an important role in immunology, and without the placenta, the mother's body would reject the developing embryo like any other foreign body. It is this tolerance of the embryo that separates the placental mammals from the marsupials, and allows for gestation periods to be extended. Fetuses in placental mammals receive antibodies from their mothers, thus enhancing their early immunity to disease.

The epithelio-chorial placenta, being only in contact with the uterine wall and not being invasive, is readily shed by the uterus when the fetus is born. There is no damage to the maternal tissue. The more invasive types of placenta, including the hemo-chorial type, can only be lost by separation through the uterine tissues. Thus, birth in species with hemo-chorial placentas is of necessity associated with some degree of maternal bleeding. In fact, in many hemo-chorial placentas, the blastocyst actually digests (chemically) the endometrial lining of the uterus and comes to lie completely within it. The endometrium then heals over the blastocyst, which then grows, fully surrounded by endometrium. The true placenta forms on the deep pocket of the endometrium in which the blastocyst lies. When the fetus is expelled from the uterus (that is, at birth), it ruptures the now very thin layer of stretched endometrium that covers the chorion. The placenta separates from the uterus as a result of rupture of the uterine blood vessels and tissues when the uterus contracts down after expulsion of the fetus. Bleeding between uterus and placenta produces a clot which eventually seals off the broken blood vessels and forms the basis for endometrial repair.

Most mammalian placentas, regardless of type, have some type of endocrine (hormonal) function. While the specific hormones may vary from species to species, two in particular are found in most placental mammals. Chorionic gonadotropin is a hormone secreted by the placenta which acts upon the ovary to increase progesterone synthesis. Progesterone, in return, is responsible for maintenance of pregnancy during the early phases. Placental lactogen, another hormone secreted by most placentas, acts on the mother to stimulate mammary gland development. This occurs throughout gestation, so that the mammary glands are ready for suckling by the time the offspring is born.

Gestation Periods

The length of gestation varies tremendously among placental mammals. In elephants the gestation period is as long as twenty-two months. However, size alone is not the determining factor. The giant among all mammals, the blue whale, has a gestation period of only eleven months, not appreciably longer than the human (nine to ten months).

Many bats and other mammals have a delayed implantation, in which the fertilized ovum remains dormant or its development is retarded at first, thus considerably extending the gestation period and delaying birth until the optimal season of warm weather or abundant food is present. Often a placenta is not found during this period of delay, with arrest of development occurring in the blastula stage. Thus, the gestation period of the fisher, a small North American carnivore with delayed implantation, is forty-eight to fifty-one weeks, or about the same as that of the blue whale. Gestation varies from twenty-two to forty-five days in squirrels, twenty to forty days in rats and mice, two to seven months in porcupines, six months in bears, and fourteen to fifteen months in giraffes.

Gestation length is ultimately constrained by the size of skull which will fit through the maternal pelvis. Where agility, speed, or long distances of travel put a premium on the mother's athleticism, gestation length is often shortened, and the birth weight of the offspring will be low.

Animals having long gestation periods, or whose young mature slowly and are suckled for a long period of time, generally do not breed as often as others. Many species of mice breed repeatedly throughout the spring, summer, and fall, having a gestation period of about twenty days, and being mature and ready to breed by twenty-one days of age. Many others, such as bears, coyotes, and weasels, breed only once a year. Environmental conditions, and the adaptability of various species to these conditions, play a large role in breeding cycles. It is clearly advantageous for young to be born during the season of least severe weather and to be weaned when food is most abundant. Many tropical mammals breed and give birth throughout the year, whereas in temperate or cold climates young are usually born in the spring or summer.

Similar factors also influence the number of young born in each litter among different species. Their rate of growth until weaned, mortality rates, adult activity cycles, and other factors no doubt help determine the litter size as well. Many rodents have three to six young per litter; a few species of mice can have as many as eighteen. Seals, whales, and most species of bats and primates bear only a single young at one time.

PLANT AND ANIMAL INTERACTIONS

Type of animal science: Ecology
Fields of study: Physiology, zoology

Interactions between plants and animals in natural environments often revolve around either food acquisition or pollination and seed dispersal. By studying such processes, scientists have discovered strategies to increase agricultural production and to duplicate naturally produced pesticides.

Principal Terms

CELLULAR RESPIRATION: the release of energy in organisms at the cell level, primarily through the use of oxygen

CHLOROPHYLL: one of several forms of photoactive green pigments in plant cells that is necessary for photosynthesis to occur

COEVOLUTION: a mutualistic relationship between two different organisms in which, as a result of natural selection, the organisms become interdependent

CROSS-POLLINATION: the transfer of pollen grains and their enclosed sperm cells from the male portion of a flower to a female portion of another flower within the same species

FOOD CHAIN: a diagram illustrating the movement of food materials from green plants (producers) through various levels of animals (consumers) within natural environments

NATURAL SELECTION: the survival of variant types of organisms as a result of adaptability to environmental stresses

PISTIL: a female portion of a flower that produces unfertilized egg cells

STAMEN: a male portion of a flower that produces pollen grains and their enclosed sperm cells

Ecology represents the organized body of knowledge that deals with the interrelationships between living organisms and their nonliving environments. Increasingly, the realm of ecology involves a systematic analysis of plant-animal interactions through the considerations of nutrient flow in food chains and food webs, exchange of such important gases as oxygen and carbon dioxide between plants and animals, and strategies of mutual survival between plant and animal species through the processes of pollination and seed dispersal.

Ecologists study both abiotic and biotic features of such plant and animal interactions. The abiotic aspects of any environment consist of nonliving, physical variables, such as temperature and moisture, that determine where species can survive and reproduce. The biotic (living) environment includes all other plants, animals, and microorganisms with which a particular species interacts. Certainly, two examples of plant and animal interactions involve the continual processes of photosynthesis and cellular respiration. Green plants are often classified as ecological producers and have the unique ability to carry out both these important chemical reactions. Animals, for the most part, can act only as consumers, taking the products of photosynthesis and chemically releasing them at the cellular level to produce energy for all life activities.

Plant-Animal Mutualism

One topic that has captured the attention of ecologists involves the phenomenon of mutualism, in which two different species of organisms beneficially reside together in close association, usually revolving around nutritional needs. One such example demonstrating a plant and animal association is a certain species of small aquatic flatworm that absorbs microscopic green plants called algae into its tissues. The benefit to the animal is one of added food supply; the adaptation to this alga has been so complete that the flatworm does not actively feed as an adult. The algae, in turn, receive adequate supplies of nitrogen and carbon dioxide and are literally transported throughout tidal flats in marine habitats as the flatworm migrates, thus exposing the algae favorably to increased sunlight. A similar example of mutualism has been reported by ecologists studying various types of reef-building corals, which are actually marine, colonial animals that grow single-celled green algae called zooxanthellae within their bodies. The coral organisms use the nutrients produced by these algae as additional energy supplies, enabling them to build more easily the massive coral reefs associated with tropical waters. In 1987, William B. Rudman reported a similar situation while researching the formation of such coral reefs in East African coastal waters. He discovered a type of sea slug called a nudibranch that absorbs green algae into its transparent digestive tract, producing an excellent camouflage as it moves about on the coral reefs in search of prey. In turn, the algae growing within both the coral and sea slugs receive important gases from these organisms for their own life necessities.

An example of plant-animal mutualism that has been documented as a classic example of coevolution involves the yucca plant and a species of small, white moth common throughout the southwestern United States. The concept of coevolution builds upon Charles Darwin's theories of natural selection, reported in 1859, and describes situations in which two decidedly different organisms have evolved into a close ecological relationship characterized by compatible structures in both. Thus, coevolution is a mutualistic relationship between two different species that, as a result of natural selection, have become intimately interdependent. The yucca plant and yucca moth reflect such a relationship. The female moth collects pollen grains bearing sperm cells from the stamens of one flower on the plant and transports these pollen loads to the pistil of another flower, thereby ensuring cross-pollination and fertilization. During this process, the moth will lay her own fertilized eggs in the flower's undeveloped seed pods. The developing moth larvae have a secure residence for growth and a steady food supply. These larvae will rarely consume all the developing plant seeds; thus, both species (plant and animal) benefit.

Defensive Mutualism

Although these examples demonstrate the evolution of structures and secretions that reflect mutual associations between plants and animals, other interactions are not so self-supportive. Plant-eating animals, called herbivores, have always been able to consume large quantities of green plants with little fear of reprisal. Yet, some types of carnivorous plants have evolved that capture and digest small insects and crustaceans as nutritional supplements to their normal photosynthetic activities. Many of these plants grow abundantly in marshlike environments, such as bogs and swamps, where many insects congregate to reproduce. Such well-known plants as the Venus's-flytrap, sundews, butterworts, and pitcher plants have modified stems and leaves to capture and consume insects and spiders rich in protein. On a smaller scale, in freshwater ponds and lakes, a submerged green plant commonly known as the bladderwort partially satisfies its protein requirements by snaring and digesting small crustaceans, such as the water flea, within its modified leaves.

A form of ecological interaction commonly classified as mimicry can be found worldwide in diverse environments. In such situations, an animal or plant has evolved structures or behavior patterns that allow it to mimic either its surroundings or another organism as a defensive or offensive strategy. Certain types of insects, such as leafhoppers, walking sticks, praying mantids, and katydids (a type of grasshopper), often duplicate plant structures in environments ranging from the tropical rain forests to the northern coniferous forests of the United States. Such exact mimicry of their plant hosts affords these insects protection from their predators as well as camouflage that enables them to capture their own prey readily. In other examples of mimicry, some insects will absorb unpalatable plant substances in their larval stages and retain these chemicals in their adult forms, making them undesirable to birds as food sources. The monarch butterfly demonstrates this type of interaction with the milkweed plant. The viceroy butterfly has evolved colorations and markings similar to those of the monarch, thereby ensuring its own survival against bird predators. Certain species of ambush bugs and crab spiders have evolved coloration patterns that allow them to hide within flower heads of such common plants as goldenrod, enabling them to grasp more securely the bees and flies that visit these flowers.

Nonsymbiotic Mutualism

Many ecologists have been studying the phenomenon known as nonsymbiotic mutualism: different plants and animals that have coevolved morphological structures and behavior patterns by which they benefit each other without necessarily living together physically. This type of mutualism can be demonstrated in the often unusual and bizarre shapes, patterns, and colorations that more advanced flowering plants have developed to attract various insects, birds, and small mammals for pollination and seed dispersal purposes. Pollination essentially is the transfer of pollen grains (and their enclosed sperm cells) from the male portion of a flower to the egg cells within the female portion of a flower. Pollination can be accomplished by the wind, by heavy dew or rains, or by animals, and it results in the plant's sexual production of seeds that represent the next generation of new embryo plants. Accessory structures, called fruits, often form around seeds and are usually tasty and brightly marked to attract animals for seed dispersal. Although the fruits themselves become biological bribes for animals to consume, often the seeds within these fruits are not easily digested and thus pass through the animals' digestive tracts unharmed, sometimes great distances from the original plant. Other types of seed dispersal mechanisms involve the evolution of hooks, barbs, and sticky substances on seeds that enable them to be easily transported by animals' fur, feet, feathers, or beaks to new regions for possible plant colonization. Such strategies of dispersal reduce competition between the parent plant and its new seedlings for moisture, living space, and nutritional requirements.

The evolution of flowering plants and their resulting use of animals in pollination and seed dispersal probably began in dense, tropical rain forests, where pollination by the wind would be cumbersome. Because insects are the most abundant form of animal life in rain forests, strategies based upon insect transport of pollen probably originated there. Because structural specialization increases the possibility that a flower's pollen will be transferred to a plant of the same species, many plants have evolved a vast array of scents, colors, and nutritional products to attract many insects, some birds, and a few mammals. Not only does pollen include the plant's sperm cells, but it is also rich in food for these animals. Another source of animal nutrition is a substance called nectar, a sugar-rich fluid often produced in specialized structures called nectaries within the flower itself or on adjacent stems and leaves. Assorted waxes and oils are also produced by plants to ensure plant-animal interactions. As species of bees, flies, wasps, butterflies, and hawkmoths are attracted to flower heads for these nutritional rewards, they unwittingly become agents of pollination by transferring pollen from male portions of flowers (stamens) to the appropriate female portions (pistils). Some flowers have evolved distinctive, unpleasant odors reminiscent of rotting flesh or feces, thereby attracting carrion beetles and flesh flies in search of places to reproduce and deposit their own fertilized eggs. As these animals consummate their own relationships, they often become agents of pollination for the plant itself. Some tropical plants such as orchids even mimic a

Image Not Available

female bee, wasp, or beetle, so that its male counterpart will attempt to mate with it, thereby ensuring precise pollination.

Among the bird species, probably the hummingbirds are the best examples of plant pollinators. Various types of flowers with bright, red colors, tubular shapes, and strong, sweet odors have evolved in tropical and temperate regions to take advantage of the hummingbirds' long beaks and tongues as an aid to pollination.

Because most mammals, such as small rodents and bats, do not detect colors as well as bees and butterflies do, flowers that use them as pollinators do not rely upon color cues in their petals but instead focus upon the production of strong, fermenting or fruitlike odors and abundant pollen rich in protein to attract them. In certain environments, bats and mice that are primarily nocturnal have replaced day-flying insects and birds in these important interactions between plants and animals.

Experiments with Plant-Animal Interaction

Contemporary ecologists have gone beyond the purely descriptive observations of plant-animal interactions (initially within the realm of natural history) and have designed controlled experiments that are crucial to the development of such basic concepts as coevolution. For example, the use of radioactive isotopes and the marking of pollen with dye and fluorescent material in field settings have allowed ecologists to demonstrate precise distances and patterns of pollen dispersal. Ecologists and insect physiologists have cooperatively studied how certain insects, such as bees, are sensitive to ultraviolet light. When some flowers are viewed under ultraviolet light, distinct floral patterns become evident to guide these insects to nectar pollen sources. Through basic research, Carolyn Dickerman reported in 1986 that animal color preferences vary throughout the season. Insect pollinators, who must feed every day, will adapt to these changes by shifting their foraging behavior. Research in the field has demonstrated that some species of flowers, such as the scarlet gilia, will produce differently colored flowers to accommodate shifts in pollinator species. Early in the growing season, this plant will produce long, red, tubular-shaped flowers to attract hummingbirds. As the hummingbirds migrate, the flowers will later become lighter in hue and be pollinated primarily by nocturnal hawkmoths.

In the laboratory, ecologists and biochemists have cooperatively analyzed the chemical composition of plant secretions and products. The chemical analysis of nectar indicates great variation in composition, correlating with the type of pollinator. Flowers pollinated by beetles generally have high amino acid content. The nectar associated with hummingbird-pollinated flowers is rich in sugar. Pollen also varies widely in chemical composition within plant species. Oils and waxes are major chemical products in the pollen of plants visited primarily by bees and flies. For bat-pollinated flowers, the protein content is quite high.

Research has also successfully analyzed how certain plants have been able to develop toxins as chemical defenses against animals. These protective devices include such poisons as nicotine and rotenone that help prevent insect and small mammal attacks. A more remarkable group of protective compounds recently isolated from some plants are known as juvocimines. These chemicals actually mimic juvenile insect hormones. Insect larvae feeding on leaves containing juvocimines are prevented from undergoing their normal development into functional, breeding adults. Thus, a specific insect population that could cause extensive plant damage is locally reduced.

Ecological interactions between plants and animals are diverse and varied. These plant-animal interactions can be viewed as absolute necessities for developing food chains and food webs and for maintaining the global balances of such important gases as oxygen and carbon dioxide. The interactions can also be very precise, limited, and crucial for determining species survival or extinction. By analyzing varied plant-animal interactions, from the microscopic level to the global perspective, one can more fully appreciate all the ecological relationships that exist on the earth.

The Ecology of Interaction

The ecological importance of plant-animal interactions cannot be stressed enough. Modern-day agriculture owes its existence to the activities of such insect pollinators as honeybees in regard to the production of domestic fruits, vegetables, and honey. It is becoming increasingly evident to many ecologists and forestry scientists how important certain bird species, such as blue jays and cedar waxwings, are in natural reforestation of burned and blighted areas through their seed dispersal strategies. The plant horticulture and floral industries also are developing an appreciation of specific plant-animal interactions that produce more viable natural strains of flowers and ornamental shrubbery. The study of natural chemical defenses produced by some plants against animal invasions is most promising. The renewed interest in earlier efforts to extract such plant products as nicotine, rotenone, pyrethrum, and caffeine may produce natural compounds that can be effective insecticides without the long-term, environmental hazards associated with such human-made pesticides as malathion, chlordane, and dichlorodiphenyl-trichloroethane (DDT).

Finally, humankind is realizing that it is important to understand and protect certain plant-animal interactions associated with the tropical regions of the earth; otherwise, the global balance of oxygen and carbon dioxide could be seriously disrupted. Also, these tropical areas represent the last natural environments for the continuation of important plant species that produce secretions and products that have favorable medicinal qualities for humans and domestic livestock. By maintaining these populations and understanding how certain animals interact with them, humans can be guaranteed a viable supply of beneficial plant species whose medicinal values can be duplicated within the laboratory.

Bibliography

Abrahamson, Warren G., ed. *Plant-Animal Interactions*. New York: McGraw-Hill, 1989. Covers herbivore-plant interactions, carnivorous plant ecology and evolution, pollination and population dispersal agents, plant communities as habitats for animals, interactions in agroecosystems, and coevolution.

Barth, Frederick G. *Insects and Flowers: The Biology of a Partnership*. Princeton, N.J.: Princeton University Press, 1991. This beautifully illustrated book, rich in both color photographs and electron micrographs, describes all aspects of flower-insect interactions. Includes bibliography and index. The writing style is appropriate for both general readers and introductory-level biology students.

Dickerman, Carolyn. "Pollination: Strategies for Survival." *Ward's Natural Science Bulletin*, Summer, 1986, 1-4. This article traces the coevolution of flowering plants with their animal pollinators, especially the beetles, butterflies, and hawkmoths. An excellent introduction to both strategies of pollination and seed dispersal. The author also outlines some current research techniques and includes a simplified biological key that focuses upon flower structures that will help determine which animals pollinate them.

Howe, Henry F., and Lynne C. Westley. *Ecological Relationships of Plants and Animals*. New York: Oxford University Press, 1990. Offers introductory students in botany, zoology, and ecology a comprehensive summary of both field and experimental studies on the ecology and evolution of plant and animal interactions. Excellent black-and-white photographs, illustrations, charts, and tables are found throughout. This textbook is written with clarity but is not only for the casual reader.

John, D. M., S. J. Hawkins, and J. H. Price, eds. *Plant-Animal Interactions in the Marine Benthos*. Oxford, England: Clarendon Press, 1992. The proceedings of a symposium on shallow-water marine plant-animal interactions.

Lanner, Ronald M. *Made for Each Other: A Symbiosis of Birds and Pines*. New York: Oxford University Press, 1996. Based on the author's research into the mutualism between Clark's nutcracker and several species of western white pines with wingless seeds. Accessible to the lay reader.

Meeuse, Bastian, and Sean Morris. *The Sex Life of Flowers*. New York: Facts on File, 1984. This well-written text includes beautiful photographs and illustrations, and it appeals to readers with varied scientific backgrounds. It describes the evolution of the flower as an organ of sexual reproduction and portrays selected animal adaptations in structure and behavior to accommodate pollination and seed dispersal. Includes a chapter-by-chapter listing of further reading sources. The photographs and writing are based upon the Public Broadcasting Service series entitled "Sexual Encounters of the Floral Kind."

Norstag, Knut, and Andrew J. Meyerriecks. *Biology*. 2d ed. Columbus, Ohio: Charles E. Merrill, 1985. A textbook written with exceptional clarity and organization. Discusses ecology and coevolution of plants and animals. Includes a glossary and index. Excellent photographs and diagrams. This is a college-level textbook but is also suitable for advanced high school students.

Rudman, William B. "Solar-Powered Animals." *Natural History* 96 (October, 1987): 50-53. A well-written article for all readers interested in plant-animal interactions, especially focusing upon mutualism involving marine corals, sea slugs, and their green algae allies. The undersea photography is excellent.

PLATYPUSES

Type of animal science: Classification
Fields of study: Conservation biology, embryology, reproduction science, wildlife ecology, zoology

The platypus is one of only three egg-laying mammals and is the only member of its family, Ornithorhynchidae. Its evolution in the relative isolation of Australia has led to such unique characteristics that the first specimen collected was believed to be a hoax.

Principal Terms

DORSAL: at or near the back

ELECTRORECEPTORS: sensors in the bill of the platypus that detect the weak electric field given off by animals; the electroreceptors help the platypus locate prey in murky water

METAZOA: organisms which are multicellular

MONOTREME: an animal that has a single, common, outer body opening for the excretory and reproductive systems; includes platypuses and echidnas

NOTOCHORD: longitudinal, flexible rod located between the gut and nerve cord

When the first platypus pelt arrived at London's Natural History Museum in the late 1790's, it was thought to be a fake made from bits of animals sewn together. This unusual mammal has a leathery bill, webbed feet, and fur, and it is one of only three mammals that lay eggs. Its body length is about eighteen inches, and its broad, flat tail is about seven inches long. The reclusive platypus spends most of its time in streams, rivers, and some lakes, foraging for food in the evening and sleeping during the day in burrows dug into the river banks.

Platypus Life

The unusual anatomical features of the platypus provide perfect adaptations for its life in water. The webbed feet are efficient paddles for swimming through the water. Claws on the feet help the platypus to dig burrows. Dense, waterproof fur covers the entire body except the feet and bill. The eyes and ear holes of the animal lie in folds that close when the animal is submerged, and the nostrils are located toward the end of the beak and also close under water. The bill is highly sensitive to touch, and is equipped with electrosensors that detect weak electrical fields produced by prey. Thus, the platypus can locate and capture prey in murky river bottoms without relying on vision, hearing, or smell.

Bottom-dwelling invertebrates, especially crustaceans, aquatic insects, and insect larvae, compose the majority of the platypus diet. Behind the bill are located two internal cheek pouches containing horny ridges that substitute for teeth, which are lost early in the life of the platypus. The pouches are used to store food while it is being chewed and sorted by the animal.

A male platypus has a spur on each rear ankle that is connected to a venom gland in the thigh. The spur is used against attackers, but also against competing males during the mating season. The venom is not fatal to humans, but can cause a great deal of pain. This feature makes the platypus one of very few mammals that are venomous.

From Egg to Adult

Courtship and mating occur in the water. After initial approaches by the female, the male chases and grasps her by the tail and inseminates her. After mating, a female will lay two to three eggs

Platypus Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebra
Class: Mammalia
Subclass: Prototheria
Order: Monotremata
Family: Ornithorhynchidae
Genus and species: Ornithorhynchus anatinus
Geographical location: Eastern Australia, Tasmania, Kangaroo Island in southern Australia
Habitat: Streams, rivers, and some lakes; must have permanent water and banks suitable for burrows
Gestational period: Seven to fourteen days
Life span: Ten or more years in the wild; seventeen years and longer in captivity
Special anatomy: Rubbery beak equipped with electrosensors used to detect prey; webbed feet; females have slits in abdominal walls from which milk expresses during lactation; males have spurs on rear feet used primarily to inject venom into rivals during mating season; reproductive and excretory tracts have one common opening to the exterior of the body

and incubate them in a special nesting burrow, which may extend one hundred feet away from the water. The female blocks the entry to the nesting burrow with soil plugs to protect the eggs and young from predators and flooding. She removes and replaces the plug each time she leaves to forage for food. When the eggs hatch, in seven to fourteen days, the young are about one inch long and totally dependent on the mother. Platypuses do not have nipples, but milk is produced in the mammary glands and expressed through openings in the abdominal wall. The young suck the milk directly from the fur. At about five months of age, the young emerge from the nesting burrow and begin learning to search for prey themselves. A typical platypus in the wild will live about ten years.

Bibliography

Brown, Malcolm W. "If a Platypus Had a Dream, What Would It Mean?" In *The Science Times Book of Mammals*, edited by Nicholas Wade. New York: Lyons Press, 1999. This highly readable article discusses scientific studies of brain activity during sleeping in platypuses, and how the study results have shed light on the evolution of monotremes.

Macdonald, David, ed. *The Encyclopedia of Mammals*. 2d ed. New York: Facts on File, 1995. This lavishly illustrated compendium of mammals gives detailed, accessible information on hundreds of wild mammals, organized by phylogenetic order. Of particular interest are the introductory chapter on mammals, and the chapter on monotremes, including the platypus.

National Geographic Society. *National Geographic Book of Mammals*. Washington, D.C.: Author, 1998. This excellent book for children and adults alike features detailed essays and marvelous photographs of over five hundred animals in their wild habitats.

Serena, Melody. "Duck-Billed Platypus: Australia's Urban Oddity." *National Geographic* 197, no. 4 (April, 2000): 118-129. Article chronicles the movement of platypuses to urban areas near Melbourne and the research study that tracks them; includes superb photographs.

Whitfield, Philip, ed. *The Simon and Schuster Encyclopedia of Animals*. New York: Simon & Schuster, 1998. This book, a who's who of the world's creatures, gives concise information on the platypus and other monotremes early in the work; its organization helps the reader compare animals across groups.

POISONOUS ANIMALS

Types of animal science: Classification, ecology, geography, physiology
Fields of study: Anatomy, biochemistry, ecology, invertebrate biology, zoology

Poisons disrupt life processes or kill. Animal poisons are venoms, delivered by biting, stinging, or body contact. Poisonous species occur throughout the animal kingdom, and include snakes, insects, spiders, other arachnids, mammals, lizards, and fish.

Principal Terms

ANAPHYLAXIS: hypersensitivity to a foreign substance, such as a venom, that causes discomfort and can even kill

ARACHNID: an arthropod having eight legs; a spider

ARTHROPOD: an organism with a horny, segmented external covering and jointed limbs

HEMOTOXIN: a substance that causes blood vessel damage and hemorrhage

NEUROTOXIN: a substance that damages the nervous system, most often nerves that control breathing and heart action

VENOM: a poison made by an animal

Substances that cause disease symptoms, injure tissues, or disrupt life processes on entering the body are poisons. When ingested in large quantities, most poisons kill. Poisons may be contacted from minerals, in vegetable foods, or in animal attack. Any poison of animal origin is a venom. Venoms are delivered by biting, stinging, or other body contacts. These animal poisons are used to capture prey or in self-defense. Often, it seems that ability to make venom arose in animals that were too small, too slow, or too weak to otherwise maintain an ecological niche. The mechanism for development of the ability to make venom is not clear.

The most familiar poisonous animals are snakes, insects, spiders, and some other arachnids. Poisonous species, however, occur throughout the animal kingdom, including a few mammals and lizards, and some fish. The severity of venom effects depends on its chemical nature, the nature of the contact mechanisms, the amount of venom delivered, and victim size. For example, all spiders are poisonous. However, their venom is usually dispensed in small amounts that do not affect humans. Hence, few spiders kill humans, though they kill prey and use venom in self-defense very effectively.

Chemically, venoms vary greatly. Snake venoms are mixtures of enzymes and toxins. Study of their effects led to the identification of hemotoxins, which cause blood vessel damage and hemorrhage; neurotoxins, which paralyze nerves controlling heart action and respiration; and clotting agents, which excessively promote or prevent blood clotting. Cobras, coral snakes, and arachnids all have neurotoxic venoms.

Poisonous Lizards, Arachnids, and Insects

The poisonous lizards are useful to explore first, because only two species are known: Gila monsters and beaded lizards (both holoderms). They inhabit the southwestern deserts of the United States and Mexico. They do not strike like snakes; rather, they bite, hold on, and chew to poison. Holoderm bites kill prey, but rarely kill humans. Beaded lizards grow to three feet long and Gila monsters grow to two feet long.

Most poisonous arthropods are spiders and scorpions. Both use venom to subdue and/or kill prey. As stated earlier, few spiders endanger humans because their venom is weak and is not injected in large quantities, but some species have very potent venom and harm or even kill humans. Best known of these are black widow spiders. Though rarely lethal to humans, black widow bites cause cramps and paralysis.

There are approximately six hundred scorpion species, of sizes between one and ten inches. All have tail-end stingers. Large, tropical scorpions can kill humans, while American scorpions are smaller and less dangerous. Scorpions are more dangerous than spiders because they crawl into shoes and other places where their habitat overlaps that of humans.

Many insects, such as caterpillars, bees, wasps, hornets, and ants, use venom in self-defense or to paralyze prey to feed themselves or offspring. Caterpillars use poison spines for protection. Bees, wasps, hornets, and ants use stingers for the same purpose. The venom of insects also kills many organisms that seek to prey on them. Humans, however, are rarely killed by insect bites. Such bites are usually mildly to severely painful for a period from a few minutes to several days. However, severe anaphylaxis occurs in some cases, followed by death.

Bee Stings

Most American honeybees came from Europe. They were brought to North America by early colonists to make honey for human consumption. Due to hive escapees, honeybees are now found wild throughout the country. Familiar worker honeybees are often seen collecting nectar and pollen from flowers.

When alarmed, worker bees sting. This is unfortunate for them, as their barbed stingers stay in the skin of victims, and in pulling away after stinging, essential bee body tissue is ripped away. This causes the bee to die quickly. Workers also defend hives in this way, committing suicide to protect the hive. Bee stings often disable or kill predators who seek to eat the bees or their honey.

Honeybees are so widespread that most people are stung at least once during their lives. Some individuals are severely allergic to bee stings, and occasionally the severe anaphylactic shock kills. Sensitive individuals should carry sting kits. A kit includes epinephrine and antihistamine, a tourniquet, and alcohol swabs. A stinger works its way deep into the skin and can cause infection. Thus, it should scraped off after a sting.

Poisonous Snakes

Poisonous snakes are colubrids, elapids, or vipers, depending on their anatomic characteristics. All have paired, hollow fangs in the front upper jaw. The fangs fold back against the upper palate when not used, and when a snake strikes they swing forward to inject a venom that attacks the victim's blood and tissues. The heads of poisonous snakes are scale-covered and triangular. Such snakes are found worldwide and among them are pit vipers, named for the pits on each side of the head that contain heat receptors. The pits detect warm-blooded prey, mostly rodents, in the dark. Pit vipers include rattlesnakes, moccasins, copperheads, fer-de-lance, and bushmasters.

The population and species of American and European poisonous snakes differ. In North America, twenty such snake types occur: elapid coral snakes and copperheads, sixteen rattler types, and cottonmouths (all vipers). Vipers are found everywhere but Alaska. Rattlers have the widest habitat, as shown by their abundance in the snake-rich Great Plains, Mississippi Valley, and southern Appalachia. In contrast, copperheads and cottonmouths are abundant in Appalachia and the Mississippi valley, respectively. Mexican poisonous snakes are divided into two ranges, the northern from the U.S.-Mexican border to Mexico City, and the southern, south of Mexico City. In the north, snakes are mostly rattlers, as in the contiguous United States. Coral snakes and pit vipers are plentiful in the south. Most perilous are the five- to eight-foot fer-de-lance, whose venom kills many humans. In South America, all vipers but rattlers are tropical. Bushmasters, the largest South American vipers, and elapid coral snakes are nocturnal and rarely endanger humans. Tropical rattlers and lance-headed vipers, somewhat less nocturnal, kill many. Europe has few snakes, due to its cool climates and scarce suitable habitats. Its few vipers range almost to the Arctic Circle. Eastern Mediterranean regions hold most of the European vipers.

There are many poisonous snakes in Africa and Asia. North Africa, mostly desert, has few snakes. Central Africa's diverse poisonous snakes are colubrid, elapid, and viper types. Elapids include dangerous black mambas, twelve to fourteen feet long, and smaller cobras, which also occur in South Africa. Among diverse vipers, the most perilous are Gaboon vipers and puff adders. The Middle East, mostly desert, has few poisonous snakes. Southeast Asia has the most poisonous snakes in the world—elapids, colubrids, and vipers. This is due to snake habitats that range from semiarid areas to rain forests. The huge human population explains why this area has the world's highest incidence of snakebite and related death, due to vipers, cobras, elapids, and sea snakes. Vipers bite most often, but elapids cause a larger portion of deaths. The Far East snake population is complex and its snakebite incidence is also high. Its important poisonous snakes are pit vipers.

Australia and New Guinea have large numbers of poisonous snakes. Australia has 65 percent of the world's snakes, while New Guinea has 25 percent. Also, sea snakes occur offshore and in some rivers and lakes. However, these countries have few snakebite deaths, due to the small size and nocturnal nature of most of indigenous snakes.

Sea Snakes

The name sea snake identifies members of about fifty species of poisonous water snakes, living in tropical oceans from the Persian Gulf to the southwest Pacific. They are very abundant in the Indian Ocean and Australian coastal waters. Sea snakes are five to nine feet long, depending on species. They have strong, flat, paddlelike tails used in swimming. Most species have nostrils atop the head. Sea snakes have lungs, not gills, and must surface for air. However, they remain underwater for several hours and can dive down twenty to thirty feet.

Most species live in warm, shallow waters, especially river mouths, bays, and swamps. Most rarely leave the water, so they lack the enlarged abdominal scales that terrestrial snakes use to move along the ground. A few types have abdominal scales like terrestrial snakes because they spend part of the time crawling in marshes. The eggs of sea snakes hatch internally and young are born alive. Sea snakes eat fish, especially eels, prawns, and fish eggs. They paralyze prey with their venom. They usually bite humans only if stepped on in shallow water or when removed from nets.

Poisonous Fish and Amphibians

Venomous fish are dangerous to those who enter the oceans, especially fisherman who take them from their nets. The geographical distribution of these fish is like that of all other fish. The highest population density is in warm temperate or tropical waters. Numbers and varieties of poisonous fish decrease with proximity to the North and South Poles and they are most abundant in Indo-Pacific and West Indian waters.

A well-known group of poisonous fishes is the stingrays (dasyatids). They inhabit warm, shallow, sandy-to-muddy ocean waters. Dasyatids lurk almost completely buried, awaiting prey that they sting to death with barbed, venomous teeth in their tails. The tail poison is made in glands at the bases of the teeth. Small, freshwater dasyatids are found in South American rivers, such as the Amazon, hundreds of miles from the river mouths. Stingrays near Australia grow to fifteen-foot lengths. Emphasizing wide distribution of stingrays and their danger to humans is their mention in Aristotle's third century B.C.E. writings, and the death of John Smith in 1608, killed by a stingray while exploring Chesapeake Bay.

Also well known are the venomous Scorpaenidae fish family, many members of which cause very painful stings. Zebra fish and stonefish are good examples. Both, like all scorpaenids, have sharp spines supporting dorsal fins. The spines, used in self-defense, have venom glands. The most deadly fish venom is that of the stonefish, which, when stepped on, can kill humans.

Poisonous animals which endanger by contact are exemplified by zebra fish and stonefish, just mentioned, and by poisonous frogs or toads. Most such frogs and toads, such as poison dart frogs, live in Africa and South America. They secrete poisons through the skin. Contact with the poisons causes effects which range from severe irritation to death in humans. The poisons frighten away or kill most predators that attempt eat them. The ecological function of poisonous animals is seen as helping to keep down the population of insects, rodents, arachnids, and small fishes. They thus contribute to maintaining the balance of nature. Poisonous land animals, such as scorpions and many poisonous snakes, are often nocturnal and add another dimension to pest control by nighttime predation.

Grice, Gordon D. *The Red Hourglass: Lives of the Predators*. New York: Delacorte, 1998. A fascinating book which describes predatory and poisonous animals, their characteristics, and their lives.

POLAR BEARS

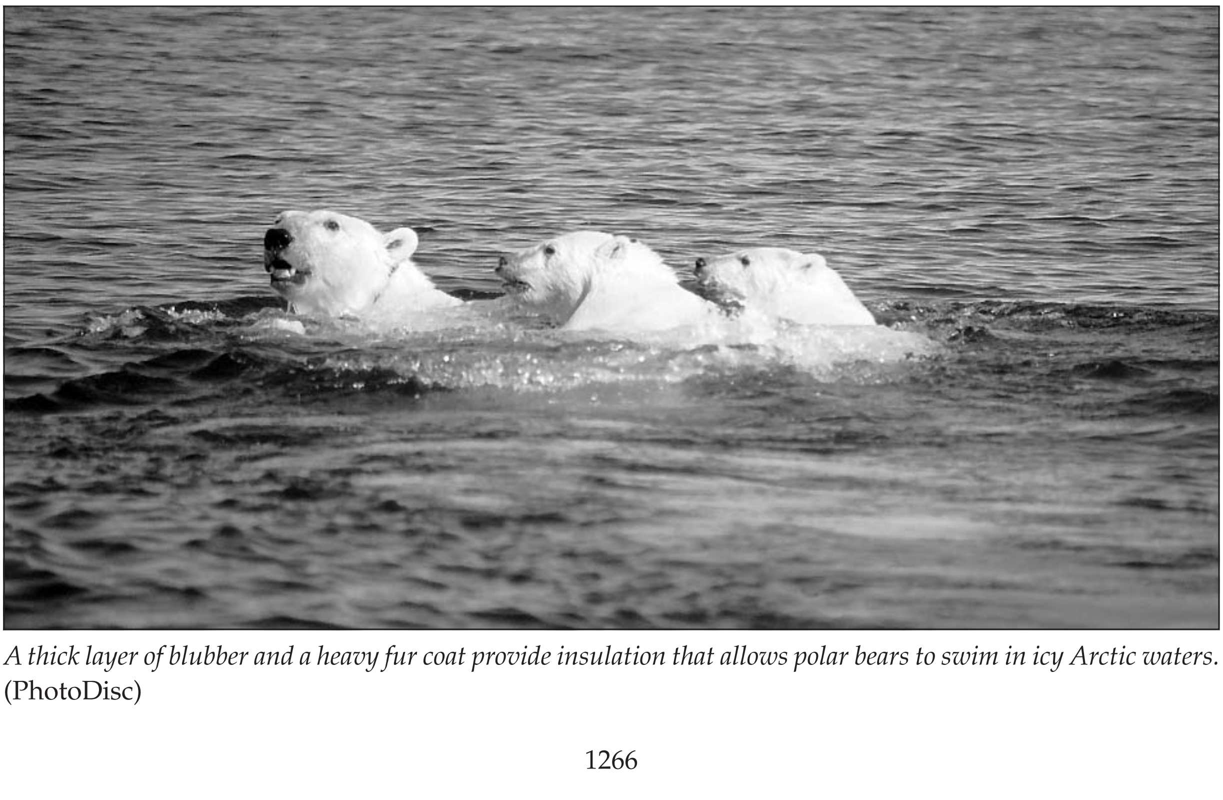
Type of animal science: Classification
Fields of study: Anatomy, conservation biology, evolutionary science, wildlife ecology, zoology

The polar bear lives in one of the harshest environments on earth: the Arctic. Yet it succeeds through a combination of hunting skill and the ability to store and conserve energy in the form of fat.

Principal Terms

BLUBBER: thick layer of fat under the skin
CARNIVOROUS: eating meat
GEOGRAPHICALLY ISOLATED: living in different habitats
PLANTIGRADE: walking on the entire foot, not just the toes
TERRESTRIAL: living on land

Protected from cold by a thick fur coat and a layer of blubber, the polar bear hunts seals in open areas in the Arctic sea ice. A strong swimmer, the polar bear uses its large front paws as paddles. Its white fur blends in with the ice and snow as it stalks or still-hunts seals. Ringed seals are the polar bear's primary food, but it also consumes bearded seals, and occasionally walruses, belugas, narwhals, musk oxen, and carrion (dead terrestrial and marine mammals). Although largely carnivorous, when on land the polar bear may eat grasses, kelp, berries, and lichens. Males and nonpregnant females do not make dens or hibernate, but spend the winter hunting on the sea ice.



A thick layer of blubber and a heavy fur coat provide insulation that allows polar bears to swim in icy Arctic waters. (PhotoDisc)

The polar bear evolved from the terrestrial brown bear about 100,000 to 200,000 years ago. In captivity, polar bears and brown bears have interbred and produced fertile offspring. This shows a high degree of genetic relatedness. In nature, however, these two species are geographically isolated from one another and would rarely meet.

Swimming in icy water among the ice floes of the Arctic, quietly stalking a resting seal, then killing it with a crushing blow of its forepaw, the polar bear is an impressive example of an animal's ability to adapt to and live in one of the harshest environments on earth.

Physical Characteristics of Polar Bears

Male polar bears are up to five feet high at the shoulder while on all fours and up to ten feet long. When standing on its hind legs, a male can be eleven feet tall. Adult males are generally much bigger than females: 1,100 to 1,770 pounds for males, 330 to 770 pounds for females. Like other bears, polar bears are plantigrade.

Mating takes place in late March to late May. This is the only time that the male is with the female. Other than family groups of females with their cubs, polar bears are solitary. Pregnant females dig snow or earth dens in which they will give birth to one to three cubs in late November to early January. The mother's milk is very rich, with an average fat content of 33 percent. The cubs, which weigh 1 to 1.5 pounds at birth, grow quickly and weigh 22 to 33 pounds when they emerge from the den with their mother in late February to early May. Polar bear cubs usually leave their mother at 2.5 years of age, at which time the mother is ready to breed again. Therefore, the female usually gives birth every third year.

Conservation

By the 1960's, polar bear populations were in serious decline due to sport hunting. In 1967, the five "polar bear nations" (the United States, Canada, Denmark, Norway, and the Soviet Union) limited hunting to the Inuit (Eskimo) people. By 2001, polar bears had recovered, and there were twenty thousand to forty thousand in the world.

A 1999 study by longtime polar bear biologist Ian Stirling and his colleagues shows that polar bears at Hudson Bay are 10 percent thinner and have 10 percent fewer cubs than they did twenty years ago. In 1999, the ice on Hudson Bay melted three weeks earlier than it did twenty-five years earlier. Polar bears must wait for ice to form each

Polar Bear Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Eutheria
Order: Carnivora
Suborder: Fissipedia
Family: Ursidae
Subfamily: Ursinae
Genus and species: Ursus maritimus

Geographical location: Northern marine areas of Alaska, Canada, Greenland, Norway's Svalbard Archipelago, and Russia

Habitat: The sea ice and adjacent land areas of the circumpolar Arctic

Gestational period: About eight months

Life span: Up to thirty-two years in the wild, over forty years in captivity

Special anatomy: Fur, hide, and blubber providing effective insulation from the extreme arctic cold; white fur providing camouflage against the backdrop of ice and snow and greatly aiding in stalking seals; large paws used for paddling in water and which act like snowshoes on thin ice; pads of the feet covered with small, soft papillae that improve traction on ice; small ears and tail to reduce heat loss and a large body mass to conserve heat fall to hunt ringed seals, their main food source. Hudson Bay polar bears fast six to eight months each year and then hunt seals intensively during the ice season. The three-week reduction of hunting time has not yet resulted in significant decline of the polar bear population, but is expected to do so if the climate trend continues.

POLLUTION EFFECTS

Types of animal science: Ecology, geography, physiology, scientific methods
Fields of study: Conservation biology, ecology, environmental science, pathology, physiology

Pollutants in soil, water, and atmosphere have created enormous problems for the living world. Destroyed habitats and polluted food sources and drinking water for animals have caused deformations in animal growth, development, and reproduction, as well as a shortening of life span, all of which contribute to an accelerated decrease in biodiversity and the extinction of more species. Realization of the severity of pollution is the first step toward seeking a long-term remedy.

Principal Terms

ACID RAIN: the burning of primarily fossil fuels leads to an excessive release of nitrogen oxides or sulfur dioxide, which in turn combines with water to form nitric or sulfuric acid; when acids dissolve into rainfall, it is called acid rain

CHEMICAL POLLUTANTS: harmful chemicals manufactured and released to the environment; normally referring to those that contaminate ecosystems

CHLOROFLUOROCARBONS (CFCs): a group of very stable compounds used widely since their development in 1928 for refrigeration, coolants, aerosol spray propellants, and other purposes; once risen into the stratosphere, they cause ozone depletion

GREENHOUSE EFFECT: the process by which certain gases, such as carbon dioxide and methane, trap sunlight energy in the atmosphere as heat, resulting in global warming as more gases are released to the atmosphere by human activities

OZONE LAYER: the ozone-enriched layer of the upper atmosphere that filters out some of the sun's ultraviolet radiation, which causes skin and other types of cancer
